Anatomical studies of neonatal and postnatal brains to evaluate maturational progression are now possible using diffusion tensor magnetic resonance imaging (DTMRI). A number of studies have assessed the growth status of white matter tracts from gestational ages to early childhood (Huang et al 2006, Huang et al 2009, Lodygensky et al 2010, Huang and Vasung 2014) (see Fig. 17.34). Those babies born premature and with very low birth weight have been shown to have changed cortical thickness, which is still present in late teenage years (Bjuland et al 2013), and white matter injury, including periventricular leukomalacia (Ment and Sould 2012, Molnar and Rutherford 2013). It is not clear whether such changes are a consequence of preterm delivery, of perinatal brain injury or of fetal inflammatory response syndrome.

## MENINGES

The meningeal layers originate from paraxial mesenchyme in the trunk and caudal regions of the head and from neural crest in regions rostral to the mesencephalon (the prechordal plate has also been suggested as making a contribution). Those skull bones that are formed from neural crest, i.e. the base of the skull rostral to the sella turcica, and the frontal, parietal and squamous temporal bones, overlie meninges that are also formed from crest cells

The meninges may be divided in development into the pachymeninx (dura mater) and leptomeninges (arachnoid mater, subarachnoid space with arachnoid cells and fibres, and pia mater). All meningeal layers are derived from loose mesenchyme that surrounds the developing neural tube, termed meninx primitiva, or primary meninx. (For a detailed account of the development of the meninges in the human, consult O'Rahilly and Müller (1986).)

The first indication of pia mater, containing a plexus of blood vessels that forms on the neural surface, is seen at stage 11 (24 days), around the caudalmost part of the medulla; this extends to the mesencephalic level by stage 12 . The pial basement membrane is formed from interaction between the neural crest and the end feet of the radial glial cells. Removal of the meninges halts tangential migration of cells within the
marginal zone (Siegenthaler and Pleasure 2011). Should the meningeal layer be incomplete, neural tissue may herniate in a cobblestone manner, as is seen in type II lissencephaly (Sun and Hevner 2014). Mesenchymal cells projecting from the rostral end of the notochord, and those in the region of the prechordal plate, extend rostrally into the mesencephalic flexure and form the earliest cells of the tentorium cerebelli; at the beginning of its development, the medial part of the tentorium is predominantly leptomeningeal. By stage 17 (41 days), dura mater can be seen in the basal areas where the future chondrocranium is also developing. The precursors of the venous sinuses lie within the pachymeninx at stage 19 ( 48 days), and by stage 20, cell populations in the region of the future falx cerebri are proliferating, although the dorsal regions of the brain are not yet covered with putative meninges.

By stage 23 ( 57 days), the dura is almost complete over the rhombencephalon and mesencephalon but is only present laterally around the prosencephalon. Subarachnoid spaces and most of the cisternae are present from this time, after the arachnoid mater becomes separated from the primitive dura mater by the accumulation of cerebrospinal fluid (which now has a net movement out of the ventricular system). The medial part of the tentorium is becoming thinner. A dural component of the tentorium is seen from stage 19. The earlier medial portion disappears, leaving an incomplete partition that separates a subarachnoid area containing the telencephalon and diencephalon from one containing the cerebellum and rhombencephalon.

There is a very close relationship, during development, between the mesenchyme from which the cranial dura mater is formed and that which is either chondrified and ossified, or ossified directly, to form the skull. These layers are only clearly differentiated as the venous sinuses develop. The relationship between the developing skull and the underlying dura mater continues during postnatal life while the bones of the calvaria are still growing.

The growth of the cranial vault is initiated from ossification centres within the desmocranial mesenchyme. A wave of osteodifferentiation moves radially outwards from these centres, stopping when adjacent bones meet at regions where sutures are induced to form. Once sutures are formed, a second phase of development occurs, in which growth of the cranial bones takes place at the sutural margins. This growth forms most of the skull (Ch. 36). A number of hypotheses have been generated to explain the process of sutural morphogenesis. It has been suggested that the dura mater contains fibre tracts that extend from fixed positions in the cranial base to sites of dural reflection underlying each of the cranial sutures, and that the tensional forces so generated dictate the position of the sutures and locally inhibit precocious ossification. Other hypotheses support the concept of local factors in the calvaria that regulate suture morphogenesis. Following removal of the entire calvaria, the skull regenerates and sutures and bones develop in anatomically correct positions, suggesting that the dura can dictate suture position, at least in regeneration of the neonatal calvaria. In transplants of sutures in which the fetal dura mater was left intact, a continuous fibrous suture remained between developing vault bones, whereas bony fusion occurred in transplants in which the fetal dura mater was removed (Opperman et al 1993).

The presence of fetal dura is not required for initial suture morphogenesis, which appears to be controlled by mesenchymal cell proliferation and fibrous extracellular matrix synthesis induced by the overlapping of the advancing osteo-inductive fronts of the calvarial bones. It is thought that, following overlap of the bone fronts, a signal is transferred to the underlying dura, which induces changes in localized regions beneath the sutures. Once a suture has formed, it serves as a primary site for cranial bone growth; constant interaction with the dura is required to avoid ossiferous obliteration.

## VASCULAR SUPPLY

## ARTERIES

## Cranial arteries

The cranial extensions of the dorsal aortae that supply the head receive blood entirely through the third aortic arches. The internal carotid artery is formed progressively from the third arch artery (which contributes its proximal part) (see Fig 36.9) and a further forward continuation that differentiates, at the time of regression of the first and second aortic arches, from the capillary plexus extending to the walls of the forebrain and midbrain. At its anterior extremity, this primitive internal carotid artery divides into cranial and caudal divisions. The former terminates as the primitive olfactory artery and supplies the developing regions
implied (see Fig. 36.8). The latter sweeps caudally to reach the ventral aspect of the midbrain; its terminal branches are the primitive mesencephalic arteries. Simultaneously, bilateral longitudinal channels differentiate along the ventral surface of the hindbrain from a plexus fed by intersegmental and transitory presegmental branches of the dorsal aorta and its forward continuation. The most important of the presegmental branches is closely related to the fifth nerve, the primitive trigeminal artery. Otic and hypoglossal presegmental arteries occur and may persist. The longitudinal channels later connect cranially with the caudal divisions of the internal carotid arteries (each of which gives rise to an anterior choroidal artery supplying branches to the diencephalon, including the telae choroideae and midbrain), and caudally with the vertebral arteries through the first cervical intersegmental arteries. Fusion of the longitudinal channels results in the formation of the basilar artery, while the caudal division of the internal carotid artery becomes the posterior communicating artery and the stem of the posterior cerebral artery. The remainder of the posterior cerebral artery develops comparatively late, probably from the stem of the posterior choroidal artery, which is annexed by the caudally expanding cerebral hemisphere, its distal portion becoming a choroidal branch of the posterior cerebral artery. The posterior choroidal artery supplies the tela choroidea at the future temporal end of the choroidal fissure; its rami advance through the tela to become confluent with branches of the anterior choroidal artery. The cranial division of the internal carotid artery gives rise to anterior choroidal, middle cerebral and anterior cerebral arteries. The stem of the primitive olfactory artery remains as a small medial striate branch of the anterior cerebral artery. The cerebellar arteries, of which the superior is the first to differentiate, emerge from the capillary plexus on the wall of the rhombencephalon.

The source of the blood supply to the territory of the trigeminal nerve varies at different stages in development. When the first and second aortic arch arteries begin to regress, the supply to the corresponding arches is derived from a transient ventral pharyngeal artery, which grows from the aortic sac. It terminates by dividing into mandibular and maxillary branches.

## Leptomeningeal arteries

At stage 20-23 (7-8weeks), further expansion of the cerebral hemispheres produces the completion of the circle of Willis; the anterior communicating arteries develop by 8 weeks' gestation. An anular network of leptomeningeal arteries, originating mainly from each middle cerebral artery, passes over each developing cerebral hemisphere. Caudally, similar meningeal branches arise from the vertebral and basilar arteries and embrace the cerebellum and brainstem. The further development of the telencephalon somewhat obscures this early pattern over the cerebrum.

The meningeal arteries so formed have been classified into three groups: namely, paramedian, short circumferential and long circumferential arteries. They can be described both supratentorially and infratentorially, and all give off fine side branches and end as penetrating arteries. Of the supratentorial vessels, the paramedian arteries have a short course prior to penetrating the cerebral neuropil (e.g. branches of the anterior cerebral artery); the short circumferential arteries have a slightly longer course before becoming penetrating arteries (e.g. the striate artery); and the long circumferential arteries reach the dorsal surface of the hemispheres. Infratentorial meningeal arteries are very variable. The paramedian arteries, after arising from the basilar or vertebral arteries, penetrate the brainstem directly. The short circumferential arteries end at the lateral surface of the brain before penetration and the long circumferential arteries later form the range of cerebellar arteries. These vessels, arranged as a series of loops over the brain, arise from the circle of Willis and brainstem vessels on the base of the brain.

At 16 weeks' gestation, the anterior, middle and posterior cerebral arteries that contribute to the formation of the circle of Willis are well established. The leptomeningeal arteries arising from them display a simple pattern with little tortuosity and very few branches. With the increasing age of the fetus and acquisition of the gyral pattern on the surface of the brain, their tortuosity, diameter and number of branches all increase. The branching pattern is completed by 28 weeks' gestation and the number of branches does not increase further. Numerous anastomoses (varying in size from 200 to $760 \mu \mathrm{~m}$ ) occur between the meningeal arteries in the depths of the developing sulci, nearly always in the cortical boundary zones of the three main cerebral arteries supplying each hemisphere. The number, diameter and location of these anastomoses change as fetal growth progresses, reflecting the regression and simplification of the complex embryonic cerebral vascular system. The boundary zones between the cerebral arteries may be the sites of inadequate perfusion in the premature infant.

## Vascularization of the brain

The brain becomes vascularized by angiogenesis (angiotrophic vasculogenesis) rather than by direct invasion by angioblasts. Blood vessels form by sprouting from vessels in the pial plexus that surrounds the neural tube from an early stage. These sprouts form branches that elongate at the junction between the ventricular and marginal zones; the branches project laterally within the inter-rhombomeric boundaries and longitudinally adjacent to the median floorplate. Subsequently, additional sprouts penetrate the inter-rhombomeric regions on the walls and floor of the hindbrain. Branches from the latter elongate towards and join the branches in the inter-rhombomeric junctions, forming primary vascular channels between rhombomeres and longitudinally on each side of the median floorplate. Later additional sprouts invade the hindbrain within the rhombomeres, anastomosing in all directions.

The leptomeningeal perforating branches pass into the brain parenchyma as cortical, medullary and striate branches (Fig. 17.35). The cortical vessels supply the cortex via short branches, which may form precapillary anastomoses, whereas the medullary branches supply the white matter. The latter converge towards the ventricle but rarely reach it; they often follow a tortuous course as they pass around bundles of nerves. The striate branches, which penetrate into the brain through the anterior perforated substance, supply the basal nuclei and internal capsule via a sinuous course; they are larger than the medullary branches and the longest of them reach close to the ventricle. The periventricular region and basal nuclei are also supplied by branches from the tela choroidea, which develops from the early pial plexus but becomes medially and deeply placed as the telencephalon enlarges.

The cortical and medullary branches irrigate a series of corticosubcortical cone-shaped areas, each centred around a sulcus containing an artery. They supply a peripheral portion of the cerebrum and are grouped as ventriculopetal arteries. In contrast, striate branches arborize close to the ventricle and supply a more central portion of the cerebrum; together with branches from the tela choroidea, they give rise to ventriculofugal arteries, which supply the ventricular zone (germinal matrix of the brain) and send branches towards the cortex. The ventriculopetal and ventriculofugal arteries run towards each other but they do not make any connections or anastomoses; the ventriculopetal arteries form networks of small arterioles (see Fig. 17.35). The ventriculopetal vessels supply relatively more mature regions of the brain compared to the ventriculofugal vessels, which are subject to constant remodelling and do not develop tunicae mediae until ventricular zone proliferation is completed. The boundary zone between these two systems (an outer centripetal and inner centrifugal) has practical implications related to the location of ischaemic lesions (periventricular leukomalacia, PVL) in the white matter of premature infant brains. Although it was believed that the distribution of ischaemic lesions in PVL coincided with the demarcation zone between the centrifugal and centripetal vascular arterial systems, this is now not thought to provide the complete answer. A number of major interacting factors contribute to the pathology seen in PVL: the incomplete state of development of the vasculature in the ventricular zone, the maturation-dependent impairment of cerebral blood flow regulation in premature infants, the vulnerability of oligodendroblasts in the periventricular region (which are particularly affected by swings in cerebral ischaemia and reperfusion) and prenatal systemic infection and inflammation (Volpe 2001, Volpe et al 2011).

The same pattern of centripetal and centrifugal arteries develops around the fourth ventricle. The ventriculofugal circulation is more extensive in the cerebellum than in the telencephalon. The arteries arise from the various cerebellar arteries and course, with the cerebellar peduncles, directly to the centre of the cerebellum, bypassing the cortex. The ventriculopetal arteries are derived from the meningeal vessels over the cerebellar surface, and most terminate in the white matter.

At 24 weeks' gestation, the blood supply to the basal nuclei and internal capsule is relatively well developed, via a prominent Heubner's artery (arteria recurrens anterior), a branch of the anterior cerebral artery. In contrast, the cortex and the white matter regions are rather poorly vascularized at this stage. The distribution of arteries and veins on the lateral aspect of the cerebral hemispheres is affected by the formation of the lateral fissure and development of cerebral sulci and gyri. Between 12 and 20 weeks' gestation, the middle cerebral artery and its branches are relatively straight, branching in an open-fan pattern. At the end of 20 weeks, the arteries become more curved as the opercula begin to appear and submerge the insular cortex. The area supplied by the middle cerebral artery becomes dominant when compared to the territories supplied by the anterior and posterior cerebral arteries. Early arterial anastomoses appear around 16 weeks' gestation and increase in size with advancing age. The sites of anastomoses between the middle and anterior cerebral arteries move from the convexity of the brain

Fig. 17.35 Development of cerebral blood vessels. A, The brain is surrounded by a system of leptomeningeal arteries from afferent trunks at its base. Intracerebral arteries arise from this system and converge (ventriculopetally) towards the ventricle (the inner circle in this diagram). B, A few deep, penetrating vessels supply the brain close to the ventricle and send ventriculofugal arteries towards the ventriculopetal vessels without making anastomoses. C, The arrangement of ventriculopetal and ventriculofugal vessels around a cerebral hemisphere. D, The similar arrangement of vessels around the cerebellum. $\mathbf{E}$, Changes in the arterial pattern of the human cerebrum between 24 and 34 weeks' gestation. F, Arterial supply to the basal nuclei at 30 weeks' gestation. (A-D, With permission from Van den Bergh R, Van der Eecken H 1968 Anatomy and embryology of cerebral circulation. Prog Brain Res 30: 1-25; E-F, With permission from the BMJ Publishing Group from Hambleton G, Wigglesworth J S 1976 Origin of intraventricular haemorrhage in the preterm infant. Arch Dis Child 51: 651-659.)
towards the superior sagittal sinus. Anastomotic connections between the middle and posterior cerebral arteries shift towards the basal aspect of the brain.

By 32-34 weeks, marked involution of the ventricular zone (germinal matrix) has occurred and the cortex acquires its complex gyral pattern and an increased vascular supply. Ventricular zone capillaries are gradually remodelled to blend with the capillaries of the caudate nucleus. Heubner's artery eventually supplies only a small area at the medial aspect of the head of the caudate nucleus. In the cortex, there is progressive elaboration of cortical blood vessels (see Fig. 17.35), and towards the end of the third trimester, the balance of cerebral circulation shifts from one that is central and basal nuclei-orientated, to one that predominantly serves the cortex and white matter. These changes in the pattern of cerebral circulation are of major significance in the pathogenesis and distribution of hypoxic/ischaemic lesions in the developing human brain. In a premature brain, the majority of ischaemic lesions occur in the boundary zone between the centripetal and centrifugal arteries, i.e. in the periventricular white matter, whereas, in a full-term infant, the cortical boundary zones and watershed areas between different arterial blood supplies are similar to those in adults, and so, presumably, are the risks of ischaemic lesion.

## Vessels of the ventricular zone (germinal matrix)

The germinal matrix (ventricular zone) is the end zone or border zone between the cerebral arteries and the collection zone of the deep cerebral veins. The germinal matrix is probably particularly prone to
ischaemic injury in the immature infant because of its unusual vascular architecture. The subependymal veins (septal, choroidal, thalamostriate and posterior terminal) flow towards the interventricular foramen. There is a sudden change of flow at the level of the foramen, and the veins recurve at an acute angle to form the paired internal cerebral veins. The capillary channels in the germinal matrix open at right angles directly into the veins, and it has been postulated that these small vessels may be points of vascular rupture and the site of subependymal haemorrhage.

The capillary bed in the ventricular zone is supplied mainly by Heubner's artery and terminal branches of the lateral striate arteries from the middle cerebral artery. The highly cellular structure of the ventricular zone is a temporary feature, and the vascular supply to this area displays some primitive features; it has the capacity to remodel when the ventricular zone cells migrate and the remaining cells differentiate as ependyma towards the end of gestation.

Vessel density is relatively low in the ventricular zone, suggesting that this area may normally have a relatively low blood flow. Immature vessels, without a complex basal lamina or glial sheet, have been described at up to 26 weeks' gestation in the zone; the endothelium of these vessels is apparently thinner than in the cortical vessels. In infants of less than 30 weeks' gestation, the vessels in the ventricular zone contain no smooth muscle, collagen or elastic fibres. Collagen and smooth muscle are seen in other regions after 30 weeks but are not detected in the remains of the germinal matrix. The lack of these components could make the vessels in this zone vulnerable to changes in
intraluminal pressure, and the lack of smooth muscle would preclude them from participating in autoregulatory processes. Cerebral vessels in premature infants lack elastic fibres and have a disproportionately small number of reticulin fibres. Comparison of the cortical and ventricular zone blood vessels shows that, in infants of between 25 and 32 weeks' gestation, the walls of vessels in the germinal matrix consist commonly of 1-2 endothelial cells with an occasional pericyte, and the capillary lumina are larger than those of the vessels in the cortex. In more mature infants, the basal lamina surrounding germinal matrix vessels is thicker and more irregular when compared to cortical vessels and it is deficient in fibronectin. The periventricular germinal matrix is the site of origin of intraventricular haemorrhage in the premature neonate. Rich vascularity and immaturity of the vessels within the matrix predispose to haemorrhage. Immaturity of the germinal matrix vasculature is indicated by circular cross-sectional shape of the vessels compared with a flattened shape in the cerebral cortex (Ballabh 2010).

Glial fibrillary acidic protein-positive cells have been detected around blood vessels in the germinal matrix from 23 weeks' gestation. Glial cells may contribute to changes in the nature of endothelial intercellular junctions in brain capillaries.

## Blood-brain barrier

Barriers between the blood supply and neural tissue, neurovascular units, function during development. Astrocytes are not required to induce the blood-brain barrier. Pericytes are required for endothelialastrocyte barrier formation during development, and disruption of pericyte-endothelial cell interaction may lead to barrier dysfunction. The ventricular zone operates a brain-cerebrospinal fluid barrier during development but not once the ventricular zone has ceased as a dividing layer and the cells have differentiated to form ependyma. The choroid plexuses, sites of a blood-cerebrospinal fluid barrier, function during development, controlling paracellular transport to the cerebrospinal fluid (Neuwelt et al 2011).

## VEINS

## Cerebral veins

From 16 weeks onwards, cerebral veins can be identified. The superior, middle, inferior, anterior and posterior cerebral veins appear more tortuous than meningeal arteries. Veins draining the cortex, white matter and deeper structures are recognized in the mid trimester. Subcortical veins drain the deep white matter, deep cortical and subcortical superficial tissue; they terminate together with cortical veins, which drain the cortex, in the meningeal veins. The deep white matter and central nuclei are drained by longer veins that meet and join subependymal veins from the ventricular zone. Anastomoses between various groups of cortical veins can be recognized by 16 weeks' gestation. The inferior anastomotic vein (of Labbé), an anastomosis between the middle cerebral and inferior cerebral veins, becomes recognizable at 20 weeks, but the superior anastomotic vein (of Trolard), connecting the superior and middle cerebral veins, does not appear before the end of 30 weeks.

Rapid cortical development is correlated with the regression of the middle cerebral vein and its tributaries, and development of ascending and descending cortical veins and intraparenchymal (medullary) arteries and veins.

Cerebral venous drainage in a full-term baby is essentially composed of two principal venous arrays, the superficial veins and the deep Galenic venous system; anastomoses between these two systems persist into adult life.

## Veins of the head

The earliest vessels form a transitory primordial hindbrain channel, which drains into the precardinal vein. This is soon replaced by the primary head vein, which runs caudally from the medial side of the trigeminal ganglion, lateral to the facial and vestibulocochlear nerves and otocyst, and then medial to the vagus nerve, to become continuous with the precardinal vein. An anastomosis to other, more lateral, venous channels developing over the hindbrain ultimately brings the primary head vein lateral to the vagus nerve. The cranial part of the precardinal vein forms the internal jugular vein.

The primary capillary plexus of the head is separated into three fairly distinct strata by the differentiation of the skull and meninges. The superficial vessels drain the skin and underlying soft parts, and eventually discharge in large part into the external jugular system, although they retain some connections with the deeper veins through so-called emissary veins. The next layer of vessels is the venous plexus of the dura

Fig. 17.36 Successive stages in the development of the veins of the head and neck. A, At approximately 8 mm crown-rump length. B, At approximately 24 mm crown-rump length.
mater, from which the dural venous sinuses differentiate; vessels from the plexus converge on each side into anterior, middle and posterior dural stems (Fig. 17.36). The anterior stem drains the prosencephalon and mesencephalon, and enters the primary head vein rostral to the trigeminal ganglion. The middle stem drains the metencephalon and empties into the primary head vein caudal to the trigeminal ganglion. The posterior stem drains the myelencephalon into the start of the precardinal vein. The deepest capillary stratum is the pial plexus, from which the veins of the brain differentiate. It drains at the dorsolateral aspect of the neural tube into the adjacent dural venous plexus. The primary head vein also receives, at its cranial end, the primitive maxillary vein, which drains the maxillary prominence and region of the optic vesicle.

The vessels of the dural plexus undergo profound changes, largely accommodating the growth of the cartilaginous otic capsule of the membranous labyrinth and the expansion of the cerebral hemispheres. As the otic capsule grows, the primary head vein is gradually reduced and a new channel, joining anterior, middle and posterior dural stems, appears dorsal to the cranial nerve ganglia and the capsule. The adult sigmoid sinus is formed where this channel joins the middle and posterior stems, together with the posterior dural stem itself (see Fig. 17.36B).

A curtain of capillary veins, the sagittal plexus, forms between the growing cerebral hemispheres and along the dorsal margins of the anterior and middle plexuses, in the position of the future falx cerebri. Rostrodorsally, this plexus forms the superior sagittal sinus. It is continuous behind with the anastomosis between the anterior and middle dural stems, which forms most of the transverse sinus. Ventrally, the sagittal plexus differentiates into the inferior sagittal and straight sinuses and the great cerebral vein; it commonly drains into the left transverse sinus.

The vessels along the ventrolateral edge of the developing cerebral hemisphere form the transitory tentorial sinus, which drains the convex surface of the cerebral hemisphere and basal ganglia, and the ventral aspect of the diencephalon, into the transverse sinus. With expansions of the cerebral hemispheres and, in particular, the emergence of the temporal lobe, the tentorial sinus becomes elongated and attenuated, eventually disappearing; its territory is drained by enlarging anastomoses of pial vessels that become the basal veins, radicles of the great cerebral vein.

The anterior dural stem disappears and the caudal part of the primary head vein dwindles; it is represented in the adult by the inferior petrosal
sinus. The cranial part of the primary head vein, medial to the trigeminal ganglion, persists and still receives the stem of the primitive maxillary vein. The latter has now lost most of its tributaries to the anterior facial vein, and its stem becomes the main trunk of the primitive supraorbital vein, which will form the superior ophthalmic vein of the adult. The main venous drainage of the orbit and its contents is now carried via the augmented middle dural stem, the pro-otic sinus, into the transverse sinus and, at a later stage, into the cavernous sinus. The cavernous sinus is formed from a secondary plexus derived from the primary head vein and lying between the otic and basioccipital cartilages. The plexus forms the inferior petrosal sinus, which drains through the primordial hindbrain channel into the internal jugular vein. The superior petrosal sinus arises later from a ventral metencephalic tributary of the pro-otic sinus and it communicates secondarily with the cavernous sinus. The pro-otic sinus, meanwhile, has developed a new and more caudally situated stem, the petrosquamosal sinus, which drains into the sigmoid sinus. With progressive ossification of the skull, the pro-otic sinus becomes diploic in position.

The development of the venous drainage and portal system of the hypophysis cerebri is closely associated with that of the venous sinuses.

# Ventricular system and subarachnoid space 

## CHAPTER 18

The cerebral ventricular system consists of a series of interconnecting spaces and channels within the brain (Figs 18.1 and 18.2), which are derived from the central lumen of the embryonic neural tube and the cerebral vesicles to which it gives rise (Ch. 17). Each cerebral hemisphere contains a large lateral ventricle that communicates near its rostral end with the third ventricle via the interventricular foramen (foramen of Monro). The third ventricle is a midline, slit-like cavity lying between the right and left thalamus and hypothalamus. Caudally, the third ventricle is continuous with the cerebral aqueduct, a narrow tube that passes the length of the midbrain, and which is continuous in turn with the fourth ventricle, a wide cavity lying between the brainstem and cerebellum. The fourth ventricle communicates with the subarachnoid space of the cisterna magna through the foramen of Magendie, and with the cerebellopontine angles through the foramina of Luschka; caudally it is continuous with the vestigial central canal of the spinal cord.

The ventricular system contains cerebrospinal fluid (CSF), which is mostly secreted by the choroid plexuses located within the lateral, third and fourth ventricles.

## TOPOGRAPHY AND RELATIONS OF THE VENTRICULAR SYSTEM

## LATERAL VENTRICLE

Viewed from its lateral aspect, the lateral ventricle has a roughly C-shaped profile (see Figs 18.1-18.2; Fig. 18.3). The shape is a consequence of the developmental expansion of the frontal, parietal and occipital regions of the hemisphere, which displaces the temporal lobe inferiorly and anteriorly. Both the caudate nucleus and the fornix, which lie in the wall of the ventricle, have adopted a similar morphology, so that the tail of the caudate nucleus encircles the thalamus in a C shape, and the fornix traces the outline of the ventricle forwards to the interventricular foramen.

The lateral ventricle is customarily divided into a body and anterior (frontal), posterior (occipital) and inferior (temporal) horns (Rhoton 2002).

The anterior horn lies within the frontal lobe. The posterior aspect of the genu and the rostrum of the corpus callosum bound it anteriorly, and its roof is formed by the anterior part of the body of the corpus callosum. The anterior horns of the two ventricles are separated by the septum pellucidum. The coronal profile of the anterior horn is roughly that of a flattened triangle in which the rounded head of the caudate nucleus forms the lateral wall and floor (Figs 18.4-18.5). The anterior horn extends back as far as the interventricular foramen.

Cavum septum pellucidum (CSP) describes a septum pellucidum that has a separation between its two leaflets (septal laminae). The cavity contains cerebrospinal fluid that filters from the ventricles through the septal laminae. The most common type of cavum septum pellucidum is non-communicating, i.e. it is not connected to the ventricular system. Cavum septum pellucidum is present in $100 \%$ of fetuses below 36 weeks' gestation. Its prevalence at 36,38 and 40 weeks is $69 \%$, $54 \%$ and $36 \%$ respectively, decreasing to $10 \%$ in children under 1 year, $5-6 \%$ at $2-5$ years, $2.7 \%$ at $6-9$ years and $2.3 \%$ at $10-14$ years (Farruggia 1981, Mott et al 1992, Nakano et al 1981).

The body of the lateral ventricle lies within the frontal and parietal lobes, and extends from the interventricular foramen to the splenium of the corpus callosum. The bodies of the lateral ventricles are separated by the septum pellucidum, which contains the columns of the fornices in its lower edge. The lateral wall of the body of the ventricle is formed by the caudate nucleus superiorly and the thalamus inferiorly. The boundary between the thalamus and caudate nucleus is marked by a groove that is occupied by a fascicle of nerve fibres, the stria terminalis, and by the superior thalamostriate vein (see Fig. 18.4). The inferior limit of the body of the ventricle and its medial wall are formed by the body of the fornix (Fig. 18.6). The fornix is separated from the thalamus by the choroidal fissure. The choroid plexus occludes the choroidal fissure and covers part of the thalamus and fornix (Nagata 1988) (Fig 18.7). The body of the lateral ventricle widens posteriorly to become

Fig. 18.1 The ventricular system. A, Anterior view. B, Left lateral view.

Fig. 18.2 The ventricular system. Three-dimensional computer-reformatted volumetric T2-weighted magnetic resonance images display the ventricles in lateral (A, D), superior (B, E) and anterior (C, F) views. A-C, Orientation of the ventricular system within the head, seen through the partially transparent skin surface. D-F, Magnified display of the isolated ventricles in the same orientation. See also Videos 18.1 and 18.2, and 28.1-28.3 for an interactive rotation. (With permission from Rios JC, Galper MW, Naidich TP, Ventricles and intracranial subarachnoid spaces. In: Naidich TP, Castillo M, Cha S, Smirniotopoulos JG (eds), Imaging of the Brain. 2013, Saunders, Elsevier.)
continuous with the posterior and inferior horns at the collateral trigone or atrium.

The posterior horn curves posteromedially into the occipital lobe. It is usually diamond-shaped or square in outline, and the two sides are often asymmetrical. Fibres of the tapetum of the corpus callosum separate the ventricle from the optic radiation, and form the roof and lateral wall of the posterior horn. Fibres of the splenium of the corpus callosum (forceps major) pass medially as they sweep back into the occipital lobe, and produce a rounded elevation in the upper medial wall of the posterior horn. Lower down, a second elevation, the calcar avis, corresponds to the deeply infolded cortex of the anterior part of the calcarine sulcus.

The inferior horn is the largest compartment of the lateral ventricle and extends forwards into the temporal lobe. It curves round the posterior aspect of the thalamus (pulvinar), passes downwards and posterolaterally and then curves anteriorly to end within 2.5 cm of the temporal pole, near the uncus. Its position relative to the surface of the hemisphere usually corresponds to the superior temporal sulcus. The roof of the inferior horn is formed mainly by the tapetum of the corpus callosum, but also by the tail of the caudate nucleus and the stria terminalis, which extend forwards in the roof to terminate in the amygdala at the anterior end of the ventricle. The floor of the inferior horn consists of the hippocampus medially and the collateral eminence, formed by the infolding of the collateral sulcus, laterally. The inferior part of the choroid fissure lies between the fimbria (a distinct bundle of efferent fibres that leaves the hippocampus) and the stria terminalis in the roof of the inferior horn (Fig. 18.8). The temporal extension of the choroid plexus fills this fissure and covers the outer surface of the hippocampus.

Fig. 18.3 A T1-weighted sagittal MRI, showing the C-shaped profile of the lateral ventricle.

## THIRD VENTRICLE

The third ventricle is a midline, slit-like cavity, which is derived from the primitive forebrain vesicle (see Figs 18.1, 18.6, 15.6; Figs 18.918.10) (Rhoton 2002). The upper part of the lateral wall of the ventricle is formed by the medial surface of the anterior two-thirds of the thalamus, and the lower part is formed by the hypothalamus anteriorly and the subthalamus posteriorly. An indistinct hypothalamic sulcus extends horizontally on the ventricular wall between the interventricular foramen and the cerebral aqueduct, and marks the boundary between the thalamus and hypothalamus. Dorsally, the lateral wall is limited by a ridge covering the stria medullaris thalami. The lateral walls of the third ventricle are commonly joined by an interthalamic adhesion, or massa intermedia, a band of grey matter that extends from one thalamus to the other. An interthalamic adhesion is almost always found in humans, more often in women, in whom it is larger by an average of 53\% (Orly 2005).

Anteriorly, the third ventricle extends to the lamina terminalis (see Fig. 18.10). This thin structure stretches from the optic chiasma to the rostrum of the corpus callosum and represents the rostral boundary of the embryonic neural tube. The lamina terminalis forms the roof of a small virtual cavity, the cistern of the lamina terminalis, which lies immediately below the ventricle and is an extension of the interpeduncular cistern. This is clinically important because it contains the anterior communicating artery; aneurysm development and rupture at this site may cause intraventricular haemorrhage through the thin membrane of the lamina terminalis. Above the lamina terminalis, the anterior wall of the third ventricle is formed by the diverging columns of the fornices and the transversely orientated anterior commissure, which crosses the midline. The narrow interventricular foramen is located immediately posterior to the column of the fornix and separates the fornix from the anterior nucleus of the thalamus.

Fig. 18.5 A coronal T2-weighted MRI scan, at the level of the anterior horn of the lateral ventricle.

Fig. 18.4 A horizontal section of the cerebrum dissected to remove the roofs of the lateral ventricles.

Fig. 18.6 The lateral and third ventricles, coronal section.

Fig. 18.7 An endoscopic view into the right lateral ventricle. The thalamostriate vein (white arrow) runs along the lateral wall and converges with the anterior septal vein (short black arrow) before converging and entering the foramen of Monro as the internal cerebral vein. The superior choroidal vein (long black arrow) is also seen coursing through the choroid plexus. (With permission from Winn HR, editor. Youmans Neurological Surgery. 6th edition. 2011 Philadelphia, W. B. Saunders, Elsevier.)

A small, angular, optic recess occurs inconsistently at the base of the lamina terminalis, just dorsal to and extending into the optic chiasma. Behind it, the anterior part of the floor of the third ventricle is formed mainly by hypothalamic structures. The thin infundibular recess lies immediately behind the optic chiasma and extends into the pituitary stalk. Behind this recess, the tuber cinereum and the mammillary bodies form the floor of the ventricle (see Fig. 18.10; Fig. 18.11).

The roof of the third ventricle is a thin ependymal layer that extends from its lateral walls to the choroid plexus, which spans the choroidal fissure. The body of the fornix lies above the roof (see Fig. 18.6).

The posterior boundary of the ventricle is marked by a suprapineal recess, the habenular commissure, a pineal (epiphysial) recess, which extends into the pineal stalk, and by the posterior commissure. Below the posterior commissure the ventricle is continuous with the cerebral aqueduct of the midbrain (see Fig. 18.10).

The third ventricle is larger in infants with trisomy 21 compared with controls (Schimmel et al 2006).

## CEREBRAL AQUEDUCT

The cerebral aqueduct is a small tube, roughly circular in transverse section and $1-2 \mathrm{~mm}$ in diameter. The length of the aqueduct in children, as measured at necropsy, is shown in Table 18.1. In children, the mean cross-sectional area of the aqueduct is $0.5 \mathrm{~mm}^{2}$, and the narrowest cross-sectional area compatible with normal ventricular size is $0.1 \mathrm{~mm}^{2}$ (Emery and Staschak 1972).

The aqueduct extends throughout the dorsal quarter of the midbrain in the midline and is surrounded by the periaqueductal (central) grey matter (see Figs 18.10, 21.17). Rostrally, it commences immediately below the posterior commissure, where it is continuous with the caudal aspect of the third ventricle. Caudally, it is continuous with the lumen of the fourth ventricle at the junction of the midbrain and pons. The superior and inferior colliculi are dorsal to the aqueduct and the midbrain tegmentum is ventral. Primary aqueductal stenosis is a feature of von Recklinghausen's disease in children (Spadaro et al 1986); this is not the only cause and population studies suggest that genetic factors may play a more important role in hydrocephalus than previously accepted (Munch et al 2012).

## FOURTH VENTRICLE

The fourth ventricle lies between the brainstem and the cerebellum (see Figs 18.1, 18.9-18.10, 21.5; Fig. 18.12) (Rhoton 2000). Rostrally, it is continuous with the cerebral aqueduct, and caudally with the central canal of the spinal cord. In sagittal section, the fourth ventricle has a characteristic triangular profile, and the apex of its tented roof protrudes into the inferior aspect of the cerebellum. The ventricle is at its widest at the level of the pontomedullary junction, where a lateral recess on both sides extends to the lateral border of the brainstem. At this point the lateral apertures of the fourth ventricle (foramina of Luschka) open into the subarachnoid space at the cerebellopontine angle, behind the upper roots of the glossopharyngeal nerves.

The floor of the fourth ventricle is a shallow diamond-shaped, or rhomboidal, depression (rhomboid fossa) on the dorsal surfaces of the pons and the rostral half of the medulla (see Fig. 18.2). It consists largely of grey matter and contains important cranial nerve nuclei (VXII). The precise location of some nuclei is discernible from surface features. The superior part of the ventricular floor is triangular in shape and is limited laterally by the superior cerebellar peduncles as they converge towards the cerebral aqueduct. The inferior part of the ventricular floor is also triangular in shape and is bounded caudally by the gracile and cuneate tubercles, which contain the dorsal column nuclei, and, more rostrally, by the diverging inferior cerebellar peduncles. A longitudinal median sulcus divides the floor of the fourth ventricle.

Fig. 18.9 A sagittal T2-weighted MRI scan of the head.

Fig. 18.10 The third and fourth ventricles, sagittal hemisection of the brain.

Each half is itself divided, by an often indistinct sulcus limitans, into a medial region known as the medial eminence and a lateral region known as the vestibular area. The vestibular nuclei lie beneath the vestibular area. In the superior part, the medial eminence is represented by the facial colliculus, a small elevation produced by an underlying loop of efferent fibres from the facial nucleus, which covers the abducens nucleus. Between the facial colliculus and the vestibular area the sulcus limitans widens into a small depression, the superior fovea. In its upper part, the sulcus limitans constitutes the lateral limit of the floor of the fourth ventricle. Here, a small region of bluish-grey pigmentation denotes the presence of the subjacent locus coeruleus. Caudal to the facial colliculus, at the level of the lateral recess of the ventricle, a variable group of nerve fibre fascicles, known as the striae medullaris, runs transversely across the ventricular floor and passes into the median sulcus. In the inferior part, the medial eminence is represented by the hypoglossal triangle (trigone), which lies over the hypoglossal nucleus. Laterally, the sulcus limitans widens to produce an indistinct inferior fovea. Caudal to the inferior fovea, between the hypoglossal triangle
and the vestibular area, is the vagal triangle (trigone), which covers the dorsal motor nucleus of the vagus. A narrow translucent ridge, the funiculus separans, which is separated from the gracile tubercle by the small area postrema, crosses below the vagal triangle.

The roof of the fourth ventricle is formed by the superior and inferior medullary veli. The thin superior medullary velum stretches across the ventricle between the converging superior cerebellar peduncles (see Fig. 18.12) and is continuous with the cerebellar white matter. Dorsally, it is covered by the lingula of the superior vermis. The inferior medullary velum is more complex and is mostly composed of a thin sheet, devoid of neural tissue, formed by ventricular ependyma and the pia mater of the tela choroidea. Just inferior to the nodule of the cerebellum, a median aperture, the foramen of Magendie, opens the roof of the fourth ventricle into the cisterna magna.

The aperture forms when a membranous structure (Blake's pouch) perforates into the fourth ventricle at the ninth week of fetal development; persistence of this membrane results in cystic obstruction of the median outlet from the fourth ventricle (Paladini et al 2012).

## CIRCUMVENTRICULAR ORGANS

The walls of the ventricular system are lined with ependymal cells that cover a subependymal layer of glia. At certain midline sites in the ventricular walls, collectively referred to as circumventricular organs, the blood-brain barrier is absent and specialized ependymal cells called

Fig. 18.11 An endoscopic view of the floor of the third ventricle. The ideal spot for fenestration is in the midline, midway between the dorsum sellae (short black arrow) and the basilar artery (short white arrow). The paired mammillary bodies (long black arrow) and the infundibular recess (long white arrow) are also seen. (With permission from Winn HR. Youmans Neurological Surgery. 6th edition. 2011 Philadelphia, W. B. Saunders, Elsevier.)
tanycytes are present (Horsburg and Massoud 2013) (Fig. 18.13). The functions of ependyma and tanycytes may include secretion into the CSF; transport of neurochemicals from subjacent neurones, glia or vessels to the CSF; transport of neurochemicals from the CSF to the same subjacent structures; and chemoreception (Rodriguez et al 2005). Adult mammalian neurogenesis occurs in discrete neurogenic niches that are best characterized in the ependymal and subependymal glial cell layers in the subgranular zone of the dentate gyrus and in the subventricular zone; the existence of adult human neurogenic niches is controversial.

The circumventricular organs include the vascular organ (organum vasculosum), subfornical organ, neurohypophysis, median eminence, subcommissural organ, pineal gland and area postrema (see Fig. 18.13).

The vascular organ lies in the lamina terminalis between the optic chiasma and the anterior commissure. Its external zone contains a richly fenestrated vascular plexus that covers glia and a network of nerve fibres. The ependymal cells of the vascular organ, like those of other circumventricular organs, are flattened and have few cilia. The major inputs appear to come from the subfornical organ, locus coeruleus and a number of hypothalamic nuclei. The vascular organ projects to the median preoptic and supraoptic nuclei. It is involved in the regulation of fluid balance and may also have neuroendocrine functions.

The subfornical organ lies at the level of the interventricular foramen. It contains many neurones, glial cells and a dense fenestrated capillary

Table 18.1 The length of the cerebral aqueduct, as measured at necropsy in children

| Crown-rump <br> length $(\mathbf{c m})$ | Length of <br> aqueduct $(\mathbf{m m})$ | Apparent equivalent <br> age of children | Mean range |
| :--- | :--- | :---: | :--- |
| 35 | 12.8 | $9.5-15.0$ | Birth to 6 weeks |
| 45 | 15.5 | $13.0-17.6$ | $3-9$ months |
| 55 | 17.4 | $15.2-18.8$ | $1-4$ years |
| 65 | 18.2 | $16.6-19.4$ | $5-7$ years |
| 75 | 18.8 | $17.6-20.0$ | $\geq 8$ years |

(With permission from Emery JL, Staschak MC. The size and form of the cerebral aqueduct in children. Brain 1972; 95:591-598.)

Fig. 18.12 The floor of the fourth ventricle, dorsal aspect of the brainstem.

Fig. 18.13 The locations of the circumventricular organs, median sagittal section of the brain.
plexus, and is covered by flattened ependyma. It is believed to have widespread hypothalamic interconnections and to function in the regulation of fluid balance and thirst.

The neurohypophysis (posterior pituitary) is the site of termination of neurosecretory projections from the supraoptic and paraventricular nuclei of the hypothalamus. Neurones in these nuclei release vasopressin and oxytocin respectively into the capillary bed of the neurohypophysis, where the hormones gain access to the general circulation.

The median eminence contains the terminations of axons of hypothalamic neurosecretory cells. Peptides released from these axons control the hormonal secretions of the anterior pituitary via the pituitary portal system of vessels.

The subcommissural organ lies ventral to and below the posterior commissure, near the inferior wall of the pineal recess.

The pineal gland is a small structure, approximately 8 mm in diameter, situated rostrodorsal to the superior colliculus and behind the stria medullaris.

The area postrema is a bilaterally paired structure, located at the caudal limit of the floor of the fourth ventricle. It is an important chemoreceptive area that triggers vomiting in response to the presence of emetic substances in the blood. The area postrema, along with the nucleus of the solitary tract and the dorsal motor nucleus of the vagus, makes up the so-called dorsal vagal complex, which is the major termination site of vagal afferent nerve fibres.

## CHOROID PLEXUS AND CEREBROSPINAL FLUID

## CHOROID PLEXUS

The vascular pia mater in the roofs of the third and fourth ventricles, and in the medial wall of the lateral ventricle along the line of the choroid fissure, is closely apposed to the ependymal lining of the ventricles, without any intervening brain tissue. It forms the tela choroidea, which gives rise to the highly vascularized choroid plexuses from which CSF is secreted into the lateral, third and fourth ventricles (see Figs 18.4, $18.6,18.8$ ). The body or stroma of the choroid plexus consists of many capillaries, separated from the ventricles by the pia mater and choroid ependymal cells (Strazielle 2000).

In the lateral ventricle, the choroid plexus extends anteriorly as far as the interventricular foramen, through which it is continuous across the third ventricle with the plexus of the opposite lateral ventricle. From the interventricular foramen, the plexus passes posteriorly, in contact with the thalamus, curving round its posterior aspect to enter the inferior horn of the ventricle and reach the hippocampus. Throughout the body of the ventricle, the choroid fissure lies between the fornix superiorly and the thalamus inferiorly (see Fig. 18.6).

From above, the tela choroidea is triangular with a rounded apex between the interventricular foramina, often indented by the anterior
columns of the fornices. Its lateral edges are irregular and contain choroid vascular fringes. At the posterior basal angles of the tela, these fringes continue and curve on into the inferior horn of the ventricle. When the tela is removed, a transverse slit (the transverse fissure) is left between the splenium and the junction of the ventricular roof with the tectum. The transverse fissure contains the roots of the choroid plexus of the third ventricle and of the lateral ventricles.

The choroid plexus of the third ventricle is attached to the tela choroidea, which is, in effect, the thin roof of the third ventricle as it develops during fetal life. In coronal sections of the cerebral hemispheres, it can be seen that the choroid plexus of the third and lateral ventricles are continuous.

The choroid plexus of the fourth ventricle is similar in structure to that of the lateral and third ventricles. The roof of the inferior part of the fourth ventricle develops as a thin sheet in which the pia mater is in direct contact with the ependymal lining of the ventricle. This thin sheet, the tela choroidea of the fourth ventricle, lies between the cerebellum and the inferior part of the roof of the ventricle. The choroid plexus of the fourth ventricle is T-shaped, with vertical and horizontal limbs, but the precise form varies widely from a single vertical limb to an elongated ' T ' that extends out through the foramina of Luschka into the cerebellopontine angle. The vertical (longitudinal) limb is double, flanks the midline and is adherent to the roof of the ventricle. The limbs fuse at the superior margin of the median aperture (foramen of Magendie) and are often prolonged on to the ventral aspect of the cerebellar vermis. The horizontal limbs of the plexus project into the lateral recesses of the ventricle. Small tufts of plexus may pass through the lateral apertures (foramina of Luschka) and emerge, still covered by ependyma, in the subarachnoid space of the cerebellopontine angle. The mean thickness of the choroid plexus in the fourth ventricle in children is 2.5 mm (Madhukar et al 2012).

The blood supply of the choroid plexus in the tela choroidea of the lateral and third ventricles is usually via a single vessel from the anterior choroidal branch of the internal carotid artery and several choroidal branches of the posterior cerebral artery; the two sets of vessels anastomose to some extent. Capillaries drain into a rich venous plexus served by a single choroidal vein. The blood supply of the fourth ventricular choroid plexus is from the inferior cerebellar arteries.

Physiological calcification of the choroid plexus and pineal gland are the most frequently described intracranial calcifications incidentally discovered during head computed tomography (CT) examinations (Doyle and Anderson 2006).

## CEREBROSPINAL FLUID

CSF is a clear, colourless liquid. Normal CSF contains small amounts of protein and differs from blood in its electrolyte content. It is not simply an ultrafiltrate of blood but is actively secreted by the choroid plexuses in the lateral, third and fourth ventricles.

The choroid plexus epithelium constitutes a blood-CSF barrier. Choroid plexus epithelial cells (see Figs 3.17, 3.18) have the characteristics of transport and secretory cells; their apical surfaces have microvilli, and their basal surfaces exhibit interdigitations and folding. Tight junctions (occluding junctions, zonulae adherentes) at the apical ends of the cells are permeable to small molecules. Fenestrated capillaries lie just beneath the epithelial cells in the stroma of the choroid plexus. The ependymal lining of the ventricles and the extracellular fluid from the brain parenchyma are additional sources of CSF, but how much each source contributes to CSF production is unclear.

## SUBARACHNOID SPACE AND CIRCULATION OF CEREBROSPINAL FLUID

## SUBARACHNOID SPACE

The subarachnoid space lies between the arachnoid and the pia mater (Videos 18.1 and 18.2). It is continuous with the lumen of the fourth ventricle via the median aperture (foramen of Magendie) and the paired lateral apertures (foramina of Luschka). The subarachnoid space contains CSF, the larger arteries and veins that traverse the surface of the brain, and the intracranial or intravertebral portions respectively of the cranial and spinal nerves.

Trabeculae, in the form of sheets or fine filiform structures, each containing a core of collagen, cross the subarachnoid space from the deep layers of the arachnoid mater to the pia mater (Fig. 18.14). The trabeculae are attached to the large blood vessels within the subarachnoid space and may form compartments, particularly in the perivascular

The ependymal cells on the dorsal aspect of the cerebral aqueduct are tall, columnar and ciliated, with granular basophilic cytoplasm; they may be involved in the secretion of materials into the CSF from adjoining axonal terminals or capillaries.

It is part of the epithalamus and consists of internal lobules of pinealocytes and sparse neurones covered by a pial capsule. It secretes melatonin, which appears to be involved in the inhibition of puberty in children and in the regulation of the sleep-wake cycle in both children and adults.

Fig. 18.16 The supratentorial subarachnoid cisterns. FIESTA MR images colour-coded to provide a visual approximation to the borders of the individually named supratentorial cisterns. These images are arrayed so that each row depicts a single cistern, in the axial plane (column 1), coronal plane (column 2) and sagittal plane (column 3). This montage is intended to indicate the general location for each cistern within the sea of multiple confluent CSF spaces around the brain. A-C, Paired Sylvian cisterns. D-F, Paired carotid cisterns. G-I, Midline chiasmatic cistern. J-L, Midline cistern of the lamina terminalis. M-O, Midline pericallosal cistern. P-R, Paired olfactory cisterns. S-U, Midline perimesencephalic cistern. V-X, Cistern of the velum interpositum. The perimesencephalic cistern is often considered in four portions (S-U): midventral interpeduncular fossa (red), paired anterolateral crural cisterns (green), paired posterolateral ambient cisterns (blue), and mid-dorsal quadrigeminal plate (vein of Galen) cistern (yellow). (With permission from Rios JC, Galper MW, Naidich TP. Ventricles and intracranial subarachnoid spaces. In: Naidich TP, Castillo M, Cha S, Smirniotopoulos JG (eds), Imaging of the Brain. Chapter 13, 245-271. 2013, Elsevier, Saunders.)

Fig. 18.17 Infratentorial subarachnoid cisterns. FIESTA MR images colour-coded to provide a visual approximation to the borders of the individually named infratentorial cisterns. These images are arrayed so that each row depicts a single cistern, in axial plane (column 1), coronal plane (column 2) and sagittal plane (column 3) images. This montage is intended to indicate the general location for each cistern within the sea of multiple confluent CSF spaces around the brain. A-C, Midline quadrigeminal plate (vein of Galen) cistern (yellow). D-F, Midline prepontine cistern. G-I, Midline premedullary cistern. J-L, Midline superior vermian cistern. M-O, Midline cisterna magna. P-R, Paired cerebellopontine angle cisterns. S-U, Paired cerebellomedullary cisterns. (With permission from Rios JC, Galper MW, Naidich TP. Ventricles and intracranial subarachnoid spaces. In: Naidich TP, Castillo M, Cha S, Smirniotopoulos JG (eds), Imaging of the Brain. Chapter 13, 245-271. 2013, Elsevier, Saunders.)

Fig. 18.14 The relationships between the dura mater, the leptomeninges and the blood vessels that enter and leave the cerebral cortex. The subarachnoid space is divided by trabeculae.

Fig. 18.15 The principal subarachnoid cisterns, sagittal section.
regions, thereby possibly facilitating directional flow of CSF through the space. A thin layer of leptomeninges, often only one cell thick, coats the trabeculae, vessels and nerves that cross the subarachnoid space; it fuses with the arachnoid mater at the margins of the exit foramina in the skull and vertebral column.

Arachnoid and pia mater are in close apposition over the convexities of the brain, such as the cortical gyri, whereas concavities are followed by the pia but spanned by the arachnoid. This arrangement produces a subarachnoid space of greatly variable depth that is location-dependent. The more expansive spaces form subarachnoid cisterns (Figs 18.1518.17), which are continuous with the general subarachnoid space and crossed by long, filamentous trabeculae (Inoue et al 2009).

The largest cistern, the cisterna magna (cerebellomedullary cistern) is formed where the arachnoid bridges the interval between the medulla oblongata and the inferior surface of the cerebellum. The cistern is continuous above with the lumen of the fourth ventricle through its median aperture, the foramen of Magendie, and below with the spinal subarachnoid space. It contains the vertebral arteries and the origins of
the posterior inferior cerebellar arteries, the glossopharyngeal, vagus, accessory and hypoglossal nerves, and the choroid plexus.

On either side, the paired cerebellopontine cisterns (angle cisterns or cerebellopontine angle cisterns) are situated in the lateral angle between the cerebellum and the pons. They are traversed by the trigeminal, facial and vestibulocochlear nerves, the anterior inferior cerebellar arteries and the superior petrosal veins.

The prepontine cistern (pontine cistern) is an extensive space ventral to the pons, which is continuous below with the spinal subarachnoid space, behind and laterally with the cerebellopontine cisterns, and rostrally with the interpeduncular cistern. The basilar artery runs through the pontine cistern into the interpeduncular cistern, which also contains the origins of the anterior inferior cerebellar and superior cerebellar arteries, and the abducens nerves.

The quadrigeminal cistern (superior cistern, vein of Galen cistern, peripineal cistern) lies posterior to the brainstem and third ventricle, and occupies the interval between the splenium of the corpus callosum and the superior cerebellar surface. The great cerebral vein (formed by the union of the basal veins of Rosenthal and the internal cerebral veins) traverses this cistern and the pineal gland protrudes into it. It also contains the P3 segments of the posterior cerebral arteries and portions of the medial and lateral posterior choroidal arteries.

The paired ambient cisterns are extensions of the quadrigeminal cistern. On each side, they lie between the parahippocampal and dentate gyri of the temporal lobes laterally and the lateral surface of the midbrain behind the cerebral peduncles medially; they therefore extend laterally and anteriorly around the midbrain on either side to the interpeduncular cistern (basal cistern) (see Figs 18.16, 21.3). They are divided into supra- and infratentorial compartments and contain the basal vein of Rosenthal, the P2 segment of the posterior cerebral artery, the superior cerebellar artery and the trochlear nerves.

The average width of the ambient cistern in children is greatest at $1-3$ years $(2.8 \pm 0.6 \mathrm{~mm})$ and lowest at $4-10$ years $(2.4 \pm 0.6 \mathrm{~mm})$; it is reported to be larger anteriorly in boys (Skadorwa et al 2010).

The paired crural cisterns lie between the posterior borders of the unci and the cerebral peduncles on each side and contain the P1 segment of the posterior cerebral artery and the postoptic part of the anterior choroidal artery. The midline interpeduncular cistern (basal cistern) lies between the two cerebral peduncles, bordered superiorly and inferiorly by the diencephalic and mesencephalic leaves respectively of Liliequist's membrane. It contains the basilar artery, the origins of the posterior cerebral and thalamoperforating arteries, the proximal portion of the anterior pontomesencephalic vein and the proximal portions of the oculomotor nerves. Anteriorly, the interpeduncular cistern extends to the optic chiasma.

The paired cisterns of the lateral fossa (Sylvian cistern) are formed on either side by the arachnoid as it bridges the lateral sulcus between
the frontal, parietal and temporal opercula and contain the middle cerebral artery and veins.

Several smaller cisterns have been described. They include the chiasmatic cistern (suprasellar cistern), which is related to the optic chiasma, and the cistern of the lamina terminalis and the supracallosal cistern, all of which are extensions of the interpeduncular cistern and contain the anterior cerebral arteries. The subarachnoid space extends through the optic foramina into the orbits, where it is bounded by the sheath of the optic nerve. The latter is formed by fusion of the arachnoid mater and dura mater, and surrounds the orbital portion of each optic nerve as far as the back of the globe, where the dura fuses with the sclera of the eyeball. For further reading, see Rios et al (2013).

## CIRCULATION OF CEREBROSPINAL FLUID

The total volume of CSF in the adult ranges from 140 to 270 ml . The volume of the ventricles is about 25 ml . CSF is produced at a rate of $0.2-0.7 \mathrm{ml}$ per minute ( $600-700 \mathrm{ml}$ per day), which means that the entire CSF volume is replaced approximately 4 times per day

In children, CSF production, as measured by output through external ventricular drainage, increases during infancy, reaching 64\% of the output of a 15 -year-old child by 2 years of age. There is a logarithmic increase in CSF output with age and body weight (Yasuda et al 2002).

Mixing of CSF from different sources within the subarachnoid space is probably assisted by cilia on the ependymal cells lining the ventricles and by arterial pulsations.

## Arachnoid villi and granulations

Arachnoid villi and granulations (Pacchionian bodies) are focal pouches of arachnoid mater and subarachnoid space that protrude through the walls of the dural venous sinuses, very often close to points where veins enter the sinuses. They are found in the superior sagittal, transverse, superior petrosal and straight sinuses in decreasing frequency and are most prominent along the margins of the great longitudinal fissure, commonly in the lateral lacunae of the superior sagittal sinus.

At the base of each arachnoid granulation, a thin neck of arachnoid mater projects through an aperture in the dural covering of a venous sinus and then expands to form a core of collagenous trabeculae and interwoven channels (Fig. 18.18). An apical cap of arachnoid cells, some $150 \mu \mathrm{~m}$ thick, surmounts the core and is attached to the endothelium of the sinus over an area some $300 \mu \mathrm{~m}$ in diameter. The rest of the core of the granulation is separated from the endothelium by a fibrous dural cupula. Channels extend through the cap to reach the subendothelial regions of the granulation. Meningiomas, the most common benign intracranial tumours, arise from arachnoid cap cells.

Dural depressions in the venous wall containing microscopic clusters of arachnoidal cells penetrating between the dural fibres are seen in the twenty-sixth fetal week. At 35 weeks they develop into arachnoid villi, which are simple protrusions through the dura. At full term, the number and complexity of the villi increase. It is generally believed that the fetal and early infantile villi do not fully penetrate the dural wall of the cranial venous sinus. With maturation they grow in size, number and structural complexity, achieve penetration through the wall of the venous sinus, and are thereafter referred to as arachnoid granulations Granulations are visible to the naked eye in the parieto-occipital region of the superior sagittal sinus by the age of 18 months. In the elderly, the arachnoid membrane thickens and the arachnoid granulations degenerate and often calcify.

The function of arachnoid granulations is incompletely understood

## Hydrocephalus

Obstruction of the circulation of CSF leads to accumulation of fluid within the ventricular system (hydrocephalus; Fig. 18.19). Within the brain, critical points at which obstruction may occur correspond to the narrow foramina and passages of the ventricular system. Thus, obstruc tion of the interventricular foramen causes enlargement of the lateral ventricles; obstruction of the cerebral aqueduct leads to enlargement of both the lateral ventricles and the third ventricle; and obstruction or congenital absence of the apertures of the fourth ventricle leads to enlargement of the entire ventricular system. Membranes in the subarachnoidal cisterns can cause extraventricular obstruction to CSF flow. Hydrocephalus in the presence of intact communications between the ventricular and subarachnoid spaces, 'communicating hydrocephalus', is most often associated with defective absorption of CSF

Fig. 18.18 An arachnoid granulation. (Modified with permission from Springer-Verlag, Principles of Pediatric Neurosurgery, Vol 4: Morphology of CSF drainage pathways in man. Raimondi (ed), Kida and Weller 1994.)

## PIA MATER

The pia mater is a delicate membrane that closely invests the surface of the brain and spinal cord, from which it is separated by a microscopic subpial space. It follows the contours of the brain into concavities and the depths of fissures and sulci (see Fig. 18.14). In the spinal canal, it contributes to the formation of the dentate ligaments and the filum terminale (Adeeb et al 2013).

Pia mater is formed from a layer of leptomeningeal cells, often only 1-2 cells thick, in which the cells are joined by desmosomes and gap junctions but few, if any, tight junctions. The cells are continuous with the coating of the subarachnoid trabeculae and separated from the basal lamina of the glia limitans by bundles of collagen, fibroblast-like cells and microscopic vessels that lie in the subpial space (Mercier et al 2002) (see Fig. 18.14).

It was long thought that the subarachnoid space was connected directly with the perivascular spaces (Virchow-Robin spaces) that surround blood vessels in the brain. However, it is now recognized that the pia mater is reflected from the surface of the brain on to the surface of blood vessels in the subarachnoid space, which means that the subarachnoid space is separated by a layer of pia from the subpial and perivascular spaces of the brain (see Fig. 18.14). The pia mater appears to form a regulatory interface between the subarachnoid space and the brain, across which small molecules may diffuse between the interstitial space and the CSF through the perivascular space. This may allow movement of metabolites and could play a role in blood-brain barrier function (Zhang et al 1990).

During development the pia mater becomes apposed to the ependyma in the roof of the telencephalon and fourth ventricle to form the tela choroidea. It shares a common embryological origin and structural similarity with the arachnoid mater.

Fig. 18.19 Axial CT images post contrast showing acute hydrocephalus (from posterior fossa meningioma). Note the transudation of fluid into the juxtaventricular white matter secondary to acute hydrocephalus.

Magnetic resonance imaging with fluid movement-sensitive sequences performed on normal subjects has shown CSF flow to be pulsating and bidirectional between the compartments of the ventricular system, probably with a net flow in a direction towards the fourth ventricle (Yamada 2008). The flow of CSF changes at the age of 2 years from an infantile to a mature pattern. The infantile pattern is characterized by flow directed into the ventricular system, and the mature pattern by flow directed out of the ventricles (Bateman and Brown 2012). The route of CSF through the subarachnoid space is even more complex and less understood, and it is debated whether CSF moves mainly over the cerebral convexities or mainly at the cranial base. It is known that CSF is absorbed into the superior sagittal sinus, but also that this site is insufficient to account for all CSF absorption and that this absorption system may only start to operate when CSF pressure is increased. Therefore one or more additional routes of absorption must exist but their precise location, function and mutual contributions to CSF absorption have yet to be clarified (Pollay 2010). Absorption through pial and subarachnoid vessels, across the ependymal ventricular surfaces and pial surfaces and via extracranial lymphatics may all be involved (Zakharov 2004).

It has long been thought that arachnoid villi and arachnoid granulations constitute the major pathway for the absorption of CSF from the subarachnoid space into the blood, and there are observations both to support and to question this. Their relative paucity in the fetal and early postnatal period strongly suggests the importance of other absorption routes. The degenerative changes in arachnoid granulations in old age could be the substrate for the condition of 'normal pressure hydrocephalus' and for decreased CSF absorption, which could play an important role in degenerative brain diseases of the elderly.

An alternative, and not necessarily mutually exclusive, view of arachnoid granulations is that they are involved in dissipating the pressure wave that occurs in the subarachnoid space during arterial systole (caused by the pulsation of the arterial vessels within the space). Since the dural venous sinuses lie within thick, non-compliant dural coverings, pressure changes within them functionally represent the extracranial venous compartment; systolic dilation of the arachnoid granulations would therefore dissipate intracranial pressure changes into the extracranial venous system.

## Vascular supply and drainage of the brain

The brain is a highly vascular organ, its profuse blood supply characterized by a densely branching arterial network (Kaplan and Ford 1966). It has a high metabolic rate that reflects the energy requirements of constant neural activity. It receives about $15 \%$ of the cardiac output and utilizes $25 \%$ of the total oxygen consumption of the body. The brain is supplied by two internal carotid arteries and two vertebral arteries that form a complex anastomosis (circulus arteriosus, circle of Willis) on the base of the brain. Vessels diverge from this anastomosis to supply the various cerebral regions. In general, the internal carotid arteries and the vessels arising from them supply the forebrain, with the exception of the occipital lobe of the cerebral hemisphere, and the vertebral arteries and their branches supply the occipital lobe, the brainstem and the cerebellum. Venous blood from the brain drains into sinuses within the dura mater. Acute interruption of the blood supply to the brain for more than a few minutes causes permanent neurological damage. Such ischaemic strokes, along with intracranial haemorrhage, are major contemporary sources of morbidity and mortality.

## ARTERIES OF THE BRAIN

The arterial supply of the brain is derived from the internal carotid and vertebral arteries, which lie, together with their proximal branches, within the subarachnoid space at the base of the brain.

## INTERNAL CAROTID ARTERY

The internal carotid arteries (Fig. 19.1) and their major branches (the internal carotid system or 'anterior' circulation) supply blood to the majority of the forebrain. Some parts of the occipital and temporal
lobes are supplied by branches of the vertebrobasilar system (see Fig. 19.5).

The internal carotid artery arises from the bifurcation of the common carotid artery, ascends in the neck and enters the carotid canal of the temporal bone. Its subsequent course is said to have petrous, cavernous and intracranial parts.

## Petrous part

The petrous part of the internal carotid artery ascends in the carotid canal, curves anteromedially and then superomedially above the cartilage that fills the foramen lacerum, and enters the cranial cavity. It lies at first anterior to the cochlea and tympanic cavity, and is separated from the latter and the pharyngotympanic tube by a thin, bony lamella that is cribriform in the young and partly absorbed in old age. Further anteriorly, it is separated from the trigeminal ganglion by the thin roof of the carotid canal, although this is often deficient. The artery is surrounded by a venous plexus and by the carotid autonomic plexus, derived from the internal carotid branch of the superior cervical ganglion. The petrous part of the artery gives rise to two branches. The caroticotympanic artery is a small, occasionally double, vessel that enters the tympanic cavity by a foramen in the carotid canal and anastomoses with the anterior tympanic branch of the maxillary artery and the stylomastoid artery. The pterygoid artery is inconsistent; when present, it enters the pterygoid canal with the nerve of the same name, and anastomoses with a (recurrent) branch of the greater palatine artery.

## Cavernous part

The cavernous part of the internal carotid artery ascends to the posterior clinoid process. It turns anteriorly to the side of the body of the sphenoid within the cavernous sinus and then curves superiorly and medial

Fig. 19.1 Internal carotid arteriograms. A, Lateral projection. B, Towne's projection.
to the anterior clinoid process, to emerge through the dural roof of the sinus. The oculomotor, trochlear, ophthalmic and abducens nerves are lateral to it within the cavernous sinus. The abducens nerve is closely related to the lateral wall of the internal carotid artery, whilst the oculomotor and trochlear nerves are situated in the lateral wall of the cavernous sinus (see Figs 28.9, 28.10). This explains the higher risk of abducens nerve injury secondary to pathology such as aneurysms of the cavernous part of the carotid artery. Occasionally, the caroticoclinoid ligament between the anterior and middle clinoid processes becomes ossified, forming a bony ring (caroticoclinoid foramen) around the artery (Ray and Gupta 2006).

The cavernous part of the artery gives off a number of small vessels. Branches supply the trigeminal ganglion, the walls of the cavernous and inferior petrosal sinuses, and the nerves contained therein. A minute meningeal branch passes over the lesser wing of the sphenoid to supply the dura mater and bone in the anterior cranial fossa, and also anastomoses with a meningeal branch of the posterior ethmoidal artery. Numerous small hypophysial branches supply the neurohypophysis, and are of particular importance because they form the pituitary portal system (see Fig. 23.11).

## Intracranial part

After piercing the dura mater, the internal carotid artery turns back below the optic nerve to run between it and the oculomotor nerve. It reaches the anterior perforated substance at the medial end of the lateral fissure and terminates by dividing into the anterior and middle cerebral arteries (Fig. 19.2).

Several preterminal vessels leave the cerebral portion of the internal carotid. The ophthalmic artery arises from the anterior part of the internal carotid as it leaves the cavernous sinus, often at the point of piercing the dura, and enters the orbit through the optic canal. The posterior communicating artery (Fig. 19.3) runs back from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral artery (a terminal branch of the basilar artery), thereby contributing to the circulus arteriosus around the interpeduncular fossa. The posterior communicating artery is usually very small. However, sometimes it is so large that the posterior cerebral artery is supplied via the
posterior communicating artery rather than from the basilar artery ('fetal posterior communicating artery'); it is often larger on one side only. Small branches from its posterior half pierce the posterior perforated substance together with branches from the posterior cerebral artery. Collectively they supply the medial thalamic surface and the walls of the third ventricle. The anterior choroidal artery leaves the internal carotid just distal to its posterior communicating branch and passes back above the medial part of the uncus. It crosses the optic tract to reach and supply the crus cerebri of the midbrain, then turns laterally, recrosses the optic tract, and gains the lateral side of the lateral geniculate body, which it supplies with several branches. It finally enters the inferior horn of the lateral ventricle via the choroidal fissure and ends in the choroid plexus. This small, but important, vessel also contributes to the blood supply of the globus pallidus, caudate nucleus, amygdala, hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, optic radiation, optic tract, hippocampus and the fimbria of the fornix.

The combination of the petrous, cavernous and intracranial parts of the internal carotid artery is called the 'carotid siphon' because of its sigmoid course (see Fig. 19.1). However, in infants, the parasellar region of the internal carotid artery does not form a siphon but takes a relatively straight course (Weninger and Muller 1999). The cranial and sympathetic nerves therefore have different topographical relationships with the artery in the infant compared with that found in older children and adults.

## Anterior cerebral artery

The anterior cerebral artery is the smaller of the two terminal branches of the internal carotid (see Fig. 19.3).

Surgical nomenclature divides the vessel into three parts: $\mathrm{A}_{1}$ - from the termination of the internal carotid artery to the junction with the anterior communicating artery; $\mathrm{A}_{2}$ - from the junction with the anterior communicating artery to the origin of the callosomarginal artery; and $\mathrm{A}_{3}$ - distal to the origin of the callosomarginal artery; this segment is also known as the pericallosal artery.

Fig. 19.2 The arteries on the base of the brain. The anterior part of the left temporal lobe has been removed to display the initial course of the middle cerebral artery within the lateral fissure.

Fig. 19.3 The circulus arteriosus on the base of the brain showing the distribution of central (perforating or ganglionic) branches.

Fig. 19.4 The major arteries supplying the medial $(\mathbf{A})$ and lateral $(\mathbf{B})$ aspects of the brain.

The anterior cerebral artery starts at the medial end of the stem of the lateral fissure. It passes anteromedially above the optic nerve to the great longitudinal fissure where it connects with its fellow by a short transverse anterior communicating artery. The anterior communicating artery is about 4 mm in length and may be double. It gives off numerous anteromedial central branches that supply the optic chiasma, lamina terminalis, hypothalamus, para-olfactory areas, anterior columns of the fornix and the cingulate gyrus (Fig. 19.4A).

The two anterior cerebral arteries travel together in the great longitudinal fissure. They pass around the curve of the genu of the corpus callosum and then along its upper surface to its posterior end, where they anastomose with posterior cerebral arteries. They give off cortical and central branches.

The cortical branches of the anterior cerebral artery are named according to their distribution. Two or three orbital branches ramify on the orbital surface of the frontal lobe and supply the olfactory cortex,

Fig. 19.5 The arteries supplying the left cerebral hemispheres. A, Lateral surface. B, Medial surface.
gyrus rectus and medial orbital gyrus. Frontal branches supply the corpus callosum, cingulate gyrus, medial frontal gyrus and paracentral lobule. Parietal branches supply the precuneus, while the frontal and parietal branches both send twigs over the superomedial border of the hemisphere to supply a strip of territory on the superolateral surface (Figs 19.4B, 19.5). Cortical branches of the anterior cerebral artery, therefore, supply the areas of the motor and somatosensory cortices that represent the lower limb.

Central branches of the anterior cerebral artery arise from its proximal portion and enter the anterior perforated substance (see Fig. 19.3) and lamina terminalis. Collectively, they supply the rostrum of the corpus callosum, the septum pellucidum, the anterior part of the putamen, the head of the caudate nucleus and adjacent parts of the internal capsule. Immediately proximal or distal to its junction with the anterior communicating artery, the anterior cerebral artery gives rise to the medial striate artery, which supplies the anterior part of the head of the caudate nucleus and adjacent regions of the putamen and internal capsule.

## Middle cerebral artery

The middle cerebral artery is the larger terminal branch of the internal carotid.

Surgical nomenclature divides the vessel into four parts: $\mathrm{M}_{1}$ - from the termination of the internal carotid artery to the bi-/trifurcation, this segment also being known as the sphenoidal; $M_{2}$ - the segment running in the lateral (Sylvian) fissure, also known as the insular; $\mathrm{M}_{3}$ - coming out of the lateral fissure, also known as the opercular; and $\mathrm{M}_{4}$ - cortical portions.

The middle cerebral artery runs at first in the lateral fissure, then posterosuperiorly on the insula, and divides into branches distributed to the insula and the adjacent lateral cerebral surface (see Figs 19.319.5). Like the anterior cerebral artery, it has cortical and central branches.

Cortical branches send orbital vessels to the inferior frontal gyrus and the lateral orbital surface of the frontal lobe. Frontal branches supply the precentral, middle and inferior frontal gyri. Two parietal branches are distributed to the postcentral gyrus, the lower part of the superior parietal lobule and the whole inferior parietal lobule. Two or three temporal branches supply the lateral surface of the temporal lobe. Cortical branches of the middle cerebral artery therefore supply the motor and somatosensory cortices that represent the whole of the body (other than the lower limb), the auditory area and the insula.

Small central branches of the middle cerebral artery, the lateral striate or lenticulostriate arteries, arise at its origin and enter the anterior perforated substance together with the medial striate artery. Lateral striate arteries ascend in the external capsule over the lower lateral aspect of the lentiform complex, then turn medially, traverse the lentiform complex and the internal capsule and extend as far as the caudate nucleus.

## VERTEBRAL ARTERY

The vertebral arteries and their major branches (sometimes referred to as the 'vertebrobasilar system') essentially supply blood to the upper spinal cord, the brainstem and cerebellum, and a significant but variable part of the posterior cerebral hemispheres (Fig. 19.6; see Fig. 19.5).

The vertebral arteries are derived from the subclavian arteries (p. 457). They ascend through the neck in the foramina transversaria of the upper six cervical vertebrae and enter the cranial cavity through the foramen magnum, close to the anterolateral aspect of the medulla (see Fig. 19.2). They converge medially as they ascend the medulla and unite to form the midline basilar artery at approximately the level of the junction between the medulla and pons.

One or two meningeal branches arise from the vertebral artery near the foramen magnum and ramify between the bone and dura mater in the posterior cranial fossa. They supply bone, diploë and the falx cerebelli.

A small anterior spinal artery arises near the end of the vertebral artery, and descends anterior to the medulla oblongata to unite with its fellow from the opposite side at mid-medullary level. The single trunk then descends on the ventral midline of the spinal cord, and is reinforced sequentially by small spinal rami from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, which all enter the vertebral canal via intervertebral foramina. Branches from the anterior spinal arteries and the beginning of their common trunk are distributed to the medulla oblongata.

The largest branch of the vertebral artery is the posterior inferior cerebellar artery (see Fig. 19.6A). It arises near the lower end of the olive and then ascends behind the roots of the glossopharyngeal and vagus nerves to reach the inferior border of the pons. Here it curves and descends along the inferolateral border of the fourth ventricle before it turns laterally into the cerebellar vallecula between the hemispheres, and divides into medial and lateral branches. The medial branch runs back between the cerebellar hemisphere and inferior vermis, and supplies both. The lateral branch supplies the inferior cerebellar surface as far as its lateral border and anastomoses with the anterior inferior and superior cerebellar arteries (from the basilar artery). The trunk of the posterior inferior cerebellar artery supplies the medulla oblongata dorsal to the olivary nucleus and lateral to the hypoglossal nucleus and its emerging nerve roots. It also supplies the choroid plexus of the fourth ventricle and sends a branch lateral to the cerebellar tonsil to supply the dentate nucleus. The posterior inferior cerebellar artery is sometimes absent.

A posterior spinal artery usually arises from the posterior inferior cerebellar artery, but may originate directly from the vertebral artery near the medulla oblongata. It passes posteriorly and descends as two branches, which lie anterior and posterior to the dorsal roots of the spinal nerves. These are reinforced by spinal twigs from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, all of which reach the vertebral canal by the intervertebral foramina, and sustain the posterior spinal arteries to the lower spinal levels.

Fig. 19.6 Vertebral arteriograms. A, Lateral projection. B, Towne's projection.

Minute medullary arteries arise from the vertebral artery and its branches, and are distributed widely to the medulla oblongata.

## BASILAR ARTERY

The basilar artery is a large median vessel formed by the union of the vertebral arteries at the junction of the medulla and pons (see Figs 19.2-19.3, 19.6). It lies in the pontine cistern, and follows a shallow median groove on the ventral pontine surface, extending to the upper border of the pons. It ends by dividing into two posterior cerebral arteries at a variable level behind the dorsum sellae, usually in the interpeduncular cistern.

Numerous small pontine branches arise from the front and sides of the basilar artery along its course and supply the pons. The long and slender labyrinthine (internal auditory) artery has a variable origin. It usually arises from the anterior inferior cerebellar artery, but variations in its origin include the lower part of the basilar artery, the superior cerebellar artery or, occasionally, the posterior inferior cerebellar artery. The labyrinthine artery accompanies the facial and vestibulocochlear nerves into the internal acoustic meatus and is distributed to the internal ear.

The anterior inferior cerebellar artery (see Fig. 19.2) is given off from the lower part of the basilar artery and runs posterolaterally, usually ventral to the abducens, facial and vestibulocochlear nerves. It commonly exhibits a loop into the internal acoustic meatus below the nerves, and when this occurs, the labyrinthine artery may arise from the loop. The anterior inferior cerebellar artery supplies the inferior cerebellar surface anterolaterally and anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches supply the inferolateral parts of the pons and occasionally also supply the upper medulla oblongata.

The superior cerebellar artery (see Figs 19.3, 19.6) arises near the distal portion of the basilar artery, immediately before the formation of the posterior cerebral arteries. It passes laterally below the oculomotor nerve, which separates it from the posterior cerebral artery, and curves round the cerebral peduncle below the trochlear nerve to gain the superior cerebellar surface. Here it divides into branches that ramify in the pia mater and supply this aspect of the cerebellum, and also anastomose with branches of the inferior cerebellar arteries. The superior cerebellar artery supplies the pons, pineal body, superior medullary velum and tela choroidea of the third ventricle.

## Posterior cerebral artery

The paired posterior cerebral arteries are the terminal branches of the basilar artery (see Figs 19.2-19.4). Surgical nomenclature divides the vessel into three parts: $P_{1}$ - from the basilar bifurcation to the junction with the posterior communicating artery; $\mathrm{P}_{2}$ - from the junction with the posterior communicating artery to the portion in the perimesencephalic cistern; and $P_{3}$ - the portion that runs in the calcarine fissure.

The posterior cerebral artery is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve and, lateral to the midbrain, by the trochlear nerve. It passes laterally, parallel with the superior cerebellar artery, and receives the posterior communicating artery. It then winds round the cerebral peduncle and reaches the tentorial cerebral surface, where it supplies the temporal and occipital lobes. Like the anterior and middle cerebral arteries, the posterior cerebral artery has cortical and central branches.

The cortical branches of the posterior cerebral artery are named according to their distribution. Temporal branches, usually two, are distributed to the uncus and parahippocampal, medial occipitotemporal and lateral occipitotemporal gyri. Occipital branches supply the cuneus, lingual gyrus and posterolateral surface of the occipital lobe. Parieto-occipital branches supply the cuneus and precuneus. The posterior cerebral artery supplies the visual areas of the cerebral cortex and other structures in the visual pathway.

The central branches supply subcortical structures. Several small posteromedial central branches arise from the beginning of the posterior cerebral artery (see Fig. 19.3) and, together with similar branches from the posterior communicating artery, pierce the posterior perforated substance to supply the anterior thalamus, subthalamus, lateral wall of the third ventricle and globus pallidus. One or more posterior choroidal branches pass over the lateral geniculate body and supply it before entering the posterior part of the inferior horn of the lateral ventricle via the lower part of the choroidal fissure. Branches also curl round the posterior end of the thalamus and pass through the transverse fissure, or go to the choroid plexus of the third ventricle, or traverse the upper choroidal fissure. Collectively these branches supply the choroid plexuses of the third and lateral ventricles and the fornix. Small posterolateral central branches arise from the posterior cerebral artery beyond the cerebral peduncle, and supply the peduncle and the posterior thalamus, superior and inferior colliculi, pineal gland and medial geniculate body.

## CIRCULUS ARTERIOSUS

The circulus arteriosus (circle of Willis) is a large arterial anastomosis that unites the internal carotid and vertebrobasilar systems (see Figs 19.3, 19.6B). It lies in the subarachnoid space within the basal cisterns that surround the optic chiasma and infundibulum. The anterior cerebral arteries are derived from the internal carotid arteries and are linked by a small, but functionally important, anterior communicating artery. Posteriorly, the two posterior cerebral arteries, formed by the division of the basilar artery, are joined to the ipsilateral internal carotid artery by a posterior communicating artery.

There is considerable individual variation in the pattern and calibre of vessels that make up the circulus arteriosus (Puchades-Orts et al 1976). Although a complete circular channel almost always exists, one vessel is usually sufficiently narrowed to reduce its role as a collateral route and the circle is rarely functionally complete. Cerebral and communicating arteries individually may all be absent, variably hypoplastic, double or even triple. The haemodynamics of the circle are influenced by variations in the calibre of communicating arteries and in the segments of the anterior and posterior cerebral arteries that lie between their origins and their junctions with the corresponding communicating arteries. The greatest variation in calibre between individuals occurs in the posterior communicating artery, which is normally very small, so that only limited flow is possible between the anterior and posterior circulations. Commonly, the diameter of the precommunicating part of the posterior cerebral artery is larger than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the vertebrobasilar system. However, sometimes the diameter of the pre-communicating part of the posterior cerebral artery is smaller than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the internal carotids via the posterior communicating arteries. Since the primary purpose of the vascular circle is to provide anastomotic channels if one vessel is occluded, it is important to note that a normal-sized posterior communicating artery cannot usually fulfil this role. Agenesis or hypoplasia of the initial segment of the anterior cerebral artery is more frequent than anomalies in the anterior communicating artery and contribute to defective circulation in about one-third of individuals.

## CENTRAL OR PERFORATING ARTERIES

Numerous small central (perforating or ganglionic) arteries arise from the circulus arteriosus or from vessels near it (see Fig. 19.3). Many of these enter the brain through the anterior and posterior perforated substances. Central branches supply nearby structures on or near the base of the brain together with the interior of the cerebral hemisphere, including the internal capsule, basal ganglia and thalamus. These branches form four principal groups. The anteromedial group arises from the anterior cerebral and anterior communicating arteries, and passes through the medial part of the anterior perforated substance. These arteries supply the optic chiasma, lamina terminalis, anterior, preoptic and supraoptic areas of the hypothalamus, septum pellucidum, para-olfactory areas, anterior columns of the fornix, cingulate gyrus, rostrum of the corpus callosum and the anterior part of the putamen and the head of the caudate nucleus. The posteromedial group comes from the entire length of the posterior communicating artery and from the proximal portion of the posterior cerebral artery. Anteriorly, these arteries supply the hypothalamus and pituitary gland, and the anterior and medial parts of the thalamus via thalamoperforating arteries. Caudally, branches of the posteromedial group supply the mammillary bodies, subthalamus, the lateral wall of the third ventricle, including the medial thalamus, and the globus pallidus. The anterolateral group is mostly comprised of branches from the proximal part of the middle cerebral artery that are also known as striate, lateral striate or lenticulostriate arteries. They enter the brain through the anterior perforated substance and supply the posterior striatum, lateral globus pallidus and the anterior limb, genu and posterior limb of the internal capsule. The medial striate artery, derived from the middle or anterior cerebral arteries, supplies the rostral part of the caudate nucleus and putamen, and the anterior limb and genu of the internal capsule. The posterolateral group is derived from the posterior cerebral artery distal to its junction with the posterior communicating artery, and supplies the cerebral peduncle, colliculi, pineal gland and, via thalamogeniculate branches, the posterior thalamus and medial geniculate body.

## REGIONAL ARTERIES OF THE BRAIN

## Brainstem

The medulla oblongata is supplied by branches of the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries, entering along the ventral (anterior) median fissure and the posterior median sulcus. Vessels that supply the central substance enter along the rootlets of the glossopharyngeal, vagus and hypoglossal nerves. There is an additional supply via a pial plexus from the same main arteries. The choroid plexus of the fourth ventricle is supplied by the posterior inferior cerebellar arteries. The pons is supplied by the basilar artery and the anterior inferior and superior cerebellar arteries. Direct branches from the basilar artery enter the pons along the basilar sulcus. Other vessels enter along the trigeminal, abducens, facial and vestibulocochlear nerves and from the pial plexus. The midbrain is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels entering on their medial and lateral sides. The medial vessels enter the medial side of the crus and also supply the superomedial part of the tegmentum, including the oculomotor nucleus. Lateral vessels supply the lateral part of the crus and the tegmentum. The colliculi are supplied by three vessels on each side from the posterior cerebral and superior cerebellar arteries. An additional supply to the crura, and the colliculi and their peduncles, comes from the posterolateral group of central branches of the posterior cerebral artery.

## Cerebellum

The cerebellum is supplied by the posterior inferior, anterior inferior and superior cerebellar arteries. The cerebellar arteries form superficial anastomoses on the cortical surface. Anastomoses between deeper, subcortical, branches have been postulated (Duvernoy et al 1983).

## Optic chiasma, tract and radiation

The blood supply to the optic chiasma, tract and radiation is of considerable clinical importance. The chiasma is supplied in part by the anterior cerebral arteries but its median zone depends upon rami from the internal carotid arteries reaching it via the stalk of the hypophysis. The anterior choroidal and posterior communicating arteries supply the optic tract, and the optic radiation receives blood through deep branches of the middle and posterior cerebral arteries.

## Diencephalon

The thalamus is supplied chiefly by branches of the posterior communicating, posterior cerebral and basilar arteries (Plets et al 1970). A contribution from the anterior choroidal artery is often noted but this has been disputed. The medial branch of the posterior choroidal artery supplies the posterior commissure, habenular region, pineal gland and medial parts of the thalamus, including the pulvinar. Small central branches, which arise from the circulus arteriosus and its associated vessels, supply the hypothalamus. The pituitary gland is supplied by hypophysial arteries derived from the internal carotid artery, and the anterior cerebral and anterior communicating arteries supply the lamina terminalis.

The choroid plexuses of the third and lateral ventricles are supplied by branches of the internal carotid and posterior cerebral arteries.

## Basal ganglia

The majority of the arterial supply to the basal ganglia comes from the striate arteries, which are branches from the roots of the anterior and middle cerebral arteries. They enter the brain through the anterior perforated substance and also supply the internal capsule. The caudate nucleus receives blood additionally from the anterior and posterior choroidal arteries. The posteroinferior part of the lentiform complex is supplied by the thalamostriate branches of the posterior cerebral artery. The anterior choroidal artery, a preterminal branch of the internal carotid artery, contributes to the blood supply of both segments of the globus pallidus and the caudate nucleus. Famously, the ligation of this vessel during a neurosurgical procedure on a patient suffering from Parkinson's disease led to alleviation of the parkinsonian symptoms, presumably as a consequence of infarction of the globus pallidus. This chance observation led to the initiation of pallidal surgery (pallidotomy) for this condition (see also p. 371).

## Internal capsule

The internal capsule is supplied by central, or perforating, arteries that arise from the circulus arteriosus and its associated vessels. These include the lateral and medial striate arteries that come from the middle and anterior cerebral arteries and also supply the basal ganglia. The lateral striate arteries supply the anterior limb, genu and much of the posterior limb of the internal capsule and are commonly involved in ischaemic and haemorrhagic stroke. One of the larger striate branches of the middle cerebral artery is known as 'Charcot's artery of cerebral haemorrhage'. The medial striate artery, a branch of the proximal part of either the middle or anterior cerebral artery, supplies the anterior limb and genu of the internal capsule and the basal ganglia. The anterior choroidal artery also contributes to the supply of the ventral part of the posterior limb and the retrolenticular part of the internal capsule.

## Cerebral cortex

The entire blood supply of the cerebral cortex comes from cortical branches of the anterior, middle and posterior cerebral arteries (see Figs 19.4-19.5; Duvernoy et al 1981). In general, long branches traverse the cortex and penetrate the subjacent white matter for 3 or 4 cm without communicating. Short branches are confined to the cerebral cortex and form a compact network in the middle zone of the grey matter, whereas the outer and inner zones are sparingly supplied. Although adjacent vessels anastomose on the surface of the brain, they become end arteries as soon as they enter it. In general, superficial anastomoses only occur between microscopic branches of the cerebral arteries, and there is little evidence that they can provide an effective alternative circulation after the occlusion of larger vessels.

The lateral surface of the hemisphere is mainly supplied by the middle cerebral artery. This includes the territories of the motor and somatosensory cortices, which represent the whole of the body, apart from the lower limb, and also the auditory cortex and language areas. The anterior cerebral artery supplies a strip next to the superomedial border of the hemisphere, as far back as the parieto-occipital sulcus. The occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) are supplied by the posterior cerebral artery.

Medial and inferior surfaces of the hemisphere are supplied by the anterior, middle and posterior cerebral arteries. The area supplied by the anterior cerebral artery is the largest; it extends almost to the parietooccipital sulcus and includes the medial part of the orbital surface. The rest of the orbital surface and the temporal pole are supplied by the middle cerebral artery, and the remaining medial and inferior surfaces are supplied by the posterior cerebral artery.

Near the occipital pole, the junctional zone between the territories of the middle and posterior cerebral arteries corresponds to the visual (striate) cortex, which receives information from the macula. When the posterior cerebral artery is occluded, a phenomenon known as 'macular sparing' may occur, in which vision with the central part of the retina is preserved. Collateral circulation of blood from branches of the middle cerebral artery into those of the posterior cerebral artery may account for this phenomenon. In addition, in some individuals, the middle cerebral artery may itself supply the macular area.

## CEREBRAL BLOOD FLOW

The brain is devoid of either glucose stores or a means of storing oxygen and is, therefore, dependent minute by minute on an adequate blood supply. It has a high metabolic rate in comparison to other organs, which reflects the metabolic demands of constant neural activity. The blood supply of grey matter is more copious than that of white matter.

Cerebral blood flow in the human brain is approximately $50 \mathrm{ml} \mathrm{g}^{-1} \mathrm{~min}^{-1}$. Global cerebral blood flow is autoregulated, i.e. it remains constant in normal individuals despite variations in mean arterial blood pressure over a range of $8.7-18.7 \mathrm{kPa}(65-140 \mathrm{mmHg})$. If the blood pressure falls below this range, cerebral blood flow decreases. Alternatively, if the pressure rises above this range, cerebral blood flow may increase. Arterial and arteriolar intraluminal pressure directly control contraction of intramural muscle; e.g. an increase in arterial pressure causes arterial constriction, and blood flow remains constant.

Although autoregulation normally ensures that global cerebral blood flow remains constant, regional blood flow varies in response to the level of neural activity and, thus, to local metabolic demand. This has been demonstrated for many brain areas including the motor and sensory cortical regions, areas involved in convulsive activity and even
cortical areas involved in complex thought processes. The principal local factors affecting regional blood flow are the local hydrogen ion $\left(\mathrm{H}^{+}\right)$or carbon dioxide concentrations, which cause arterial dilation both by a direct action on the endothelium and through indirect mediators, such as nitric oxide.

Not all substances circulating in arterial blood have access to the brain parenchyma. Particulate matter, such as bacteria, is excluded. In general, lipophilic molecules and small molecules, such as oxygen and carbon dioxide, can cross the blood-brain barrier but hydrophilic ones (excluding glucose) cannot. The cellular basis for the blood-brain barrier is discussed on page 50.

Ischaemic stroke Stroke refers to the clinical syndrome of a rapidly developing focal neurological deficit that is not due to seizure activity. If the cause is lack of, or reduced, blood supply to a portion of the brain, then the term ischaemic stroke (Fig. 19.7) is used, as opposed

Fig. 19.7 A, A frontal projection of a selective catheter angiogram of the left internal carotid artery, showing a focal narrowing at the termination of the left internal carotid artery and the origin of the left middle cerebral artery. B, A coronal T2-weighted image of the brain at the level of the basal ganglia. There is an abnormal high signal in the left putamen and adjacent white matter, consistent with infarction. It is likely that the infarction was due to occlusion of small perforating vessels originating in the area of the stenosis and supplying the basal ganglia.

It is difficult to make truly quantifiable measurements of regional cerebral blood flow, particularly in young children, but this has been attempted using, for example, 133Xe single-photon emission computed tomography (SPECT). These studies have shown that regional cerebral blood flow to the cortex in newborns tends to be considerably lower than that in adults; there is a continuing increase through infancy and by the age of 5-6 years the cortical flow is at least $50 \%$ higher than in adults (Chiron et al 1992). After that age, the cortical blood flow decreases and adult levels are attained at between 15 and 19 years. It should be appreciated that cerebral blood flow, in its strictest sense of microvascular perfusion, cannot be measured by less invasive methods such as ultrasonography. That said, it is possible, using these techniques, to estimate blood velocity and/or macroscopic bulk flow in large vessels such as the internal carotid artery or middle cerebral artery, and to demonstrate a significant increase in blood flow to the brain with increasing gestational age in premature and term babies.
to haemorrhagic stroke, e.g. subarachnoid haemorrhage. The lack of blood flow can be due to pathology in the vessel lumen, such as thrombosis or embolus (common); pathology outside the blood vessel, such as occlusion from the mass effect of a tumour or haematoma (rare); or pathology of the vessel wall, such as inflammatory or infective arteritides (rare). The symptoms and signs of ischaemic stroke depend on the location and extent of the arterial infarction (Bogousslavsky and Caplan 2002). In certain locations, even a small-volume stroke can have devastating effects. For example, the internal capsule and most of the adjacent basal ganglia are supplied by small perforating arteries, which are a common site for ischaemic stroke. Corticonuclear and corticospinal motor pathways and third-order thalamocortical sensory fibres all pass through the internal capsule, so that it is effectively the only route connecting the cerebral cortex with other regions of the neuraxis. The neurological deficits that result from stroke in the internal capsule, therefore, may include contralateral spastic hemiparesis, contralateral hemisensory loss and psychological deficits.

It is possible for a major vessel, such as the internal carotid artery in the neck, to become occluded and for the individual to remain asymptomatic, providing an appropriate flow of blood can be recruited to supply the affected brain region from other sources (collateral supply). The primary role of the circulus arteriosus is to allow for this eventuality by redirecting blood from other sources, such as the contralateral internal carotid and vertebrobasilar system in the example given above. If the circulus arteriosus is complete, two or even three of the four major arteries supplying the brain can occlude without producing an ischaemic stroke. Unfortunately, the circulus arteriosus is rarely haemodynamically complete; ischaemic stroke is, therefore, often caused because the collateral supply is inadequate. For example, an individual in whom neither anterior nor posterior communicating arteries are patent will suffer an ischaemic stroke if there is occlusion of one internal carotid artery because the proximal anterior and middle cerebral arteries cannot receive collateral flow from the incomplete circulus arteriosus. Some collateral flow may be available from anastomoses between distal branches of the external carotid artery (e.g. middle meningeal artery) but invariably this is not sufficient to supply the whole hemisphere.

Somewhat paradoxically, the more distally the occlusion occurs in the cerebral vasculature, the more likely it is to cause an ischaemic stroke (although the volume of infarcted tissue will be less). This is because the major capacity to form collateralization is proximal, mainly at the circulus arteriosus. For example, an embolus formed in the proximal internal carotid artery may travel to the $\mathrm{M}_{1}$ portion of the ipsilateral middle cerebral artery and occlude the vessel. There is very little scope for collateralization at this site and an ischaemic stroke is unavoidable, unless the embolus can be cleared and flow restored in good time.

Watershed areas Regions of the brain lying at the extreme edges of the major cerebral arterial territories are called watershed areas; they are the first to be deprived of sufficient blood flow in the event of cerebral hypoperfusion. Ischaemic infarcts of the cortex and adjacent subcortical white matter in the border zones between these territories are known as watershed, boundary-zone or border-zone infarcts. There is some evidence that a second arterial border zone, the internal arterial border zone, exists within the white matter of the centrum semiovale and corona radiata (between the lenticulostriate perforators and the deep penetrating branches of the distal middle cerebral artery).

Cerebral aneurysms Aneurysms are balloon-like swellings that occur on arteries as a result of defects in the vessel wall. They are most commonly found on the vessels of the circulus arteriosus, particularly at or near the junctions of vessels. Aneurysms on the internal carotid artery near its termination may compress the lateral aspect of the optic chiasma and compromise axons derived from the temporal side of the ipsilateral retina, which causes a defect in the nasal visual field. Aneurysms in the vicinity of the oculomotor nerve, e.g. on the posterior communicating artery, superior cerebellar artery or the tip of the basilar artery, can cause damage to the oculomotor nerve by compression (Fig. 19.8, Video 19.1).

Subarachnoid haemorrhage Bleeding into the subarachnoid compartment, subarachnoid haemorrhage, is the most common pathology that involves the subarachnoid space (Sengupta and McAllister 1986). There are many causes: in adults, the most common is rupture of an aneurysm of the intracranial vessels that run within the subarachnoid space. A person who has had a subarachnoid haemorrhage usually complains of a headache of very sudden onset that is frequently described as being their 'worst ever headache' or 'like being hit on the head with a hammer'. When this is suspected, the first investigation is

Fig. 19.8 An intra-arterial digital subtraction angiogram of the right internal carotid artery in a patient with a complete right oculomotor nerve palsy, lateral projection.

Fig. 19.9 An axial CT image (without intravenous contrast agent) at the level of the posterior clinoids. There is abnormally high attenuation in the basal cisterns and subarachnoid space of the interhemispheric fissure, indicating an acute subarachnoid haemorrhage, subsequently shown to be due to a ruptured aneurysm on the anterior communicating artery.
an X-ray CT examination, which has a very high sensitivity for detecting fresh haemorrhage. Blood will be seen in the basal cisterns and entering the depths of the cortical sulci, i.e. delineating the anatomy of the subarachnoid space, a presentation that permits an accurate diagnosis (Fig. 19.9). In marked contrast, the spread of blood in a subdural haemorrhage is limited by the arachnoid mater on its deep surface, and the blood therefore remains on the surface of the brain.

Arteriovenous malformations Arteriovenous malformations (AVMs) of the brain are developmental abnormalities of the blood vessels supplying the brain and are thought to occur in 1-2/10,000 people. In the normal brain, blood flows from a cerebral artery into a capillary system and then into a draining vein(s). When an AVM is present, arterial blood passes into a tangle (nidus) of abnormal blood vessels that allows passage into the venous system without passing through normal capillaries (Fig. 19.10). As a result, there is often rapid, high-volume blood flow through the nidus, which, coupled with abnormal vessel walls, leads to a high risk of rupture. The resulting
haemorrhage from a cerebral AVM is associated with high mortality/ morbidity, and recurrent haemorrhages are common in survivors. Not all brain AVMs present with rupture but they may cause headaches, seizures or focal neurological deficits and some brain AVMs are discovered incidentally. There are several treatment options for brain AVMs, including surgical resection, endovascular obliteration and stereotactic radiosurgery. In some circumstances, conservative management is appropriate.

## VEINS OF THE BRAIN

The venous drainage of the brain occurs through a complex system of deep and superficial veins (Andeweg 1996) devoid of valves and with thin walls that lack muscular tissue. They pierce the arachnoid mater and the inner layer of the dura mater to open into the dural venous sinuses.

## VEINS OF THE POSTERIOR FOSSA

The veins of the brainstem form a superficial venous plexus deep to the arteries.

Veins of the medulla oblongata drain into the veins of the spinal cord or the adjacent dural venous sinuses, or into variable radicular veins that accompany the last four cranial nerves to either the inferior petrosal or occipital sinuses, or to the superior bulb of the jugular vein. Anterior and posterior median medullary veins may run along the ventral (anterior) median fissure and posterior median sulcus, to become continuous with the spinal veins in corresponding positions. Pontine veins, which may include a median vein and a lateral vein on each side, drain into the basal vein, cerebellar veins, the petrosal or transverse sinuses or the venous plexus of the foramen ovale. Veins of the midbrain join the great cerebral vein (of Galen) or the basal vein.

The veins of the cerebellum drain mainly into sinuses adjacent to them or, from the superior surface, into the great cerebral vein. The cerebellar veins course on the cerebellar surface, and consist of superior and inferior groups. Superior cerebellar veins either run anteromedially across the superior vermis to the straight sinus or great cerebral vein, or they run laterally to the transverse and superior petrosal sinuses. Inferior cerebellar veins include a small median vessel that runs backwards on the inferior vermis to enter the straight or sigmoid sinus. Laterally coursing vessels join the inferior petrosal and occipital sinuses.

## VEINS OF THE CEREBRAL HEMISPHERE

Superficial and deep cerebral veins drain the surfaces and the interior of the cerebral hemisphere respectively (Figs 19.11-19.14). The superficial veins may be divided into three groups, namely: superior, middle and inferior. Between 8 and 12 superior cerebral veins drain the superolateral and medial surfaces of each hemisphere. They mainly follow the sulci, although some pass across gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface, and then open into the superior sagittal sinus. Superior cerebral veins in the anterior part of the hemisphere join the sinus almost at right angles. The larger posterior veins are directed obliquely forwards, against the direction of flow in the sinus, an arrangement that may resist their collapse when intracranial pressure is raised.

The superficial middle cerebral vein drains most of the lateral surface of the hemisphere, and follows the lateral fissure to end in the cavernous sinus. A superior anastomotic vein runs posterosuperiorly between

Fig. 19.13 The internal (deep) cerebral veins, viewed from above after removal of the central portion of the corpus callosum.
the superficial middle cerebral vein and the superior sagittal sinus, thus connecting the superior sagittal and cavernous sinuses. An inferior anastomotic vein courses over the temporal lobe and connects the superficial middle cerebral vein to the transverse sinus. The deep middle cerebral vein drains the insular region and joins the anterior cerebral and striate veins to form a basal vein. Regions drained by the anterior cerebral and striate veins correspond approximately to those supplied
by the anterior cerebral artery and the central branches that enter the anterior perforated substance. The basal veins pass back alongside the interpeduncular fossa and midbrain, receive tributaries from this vicinity and join the great cerebral vein.

Inferior cerebral veins on the orbital surface of the frontal lobe join the superior cerebral veins and thus drain to the superior sagittal sinus. Those on the temporal lobe anastomose with basal veins and middle cerebral veins, and drain to the cavernous, superior petrosal and transverse sinuses.

The basal vein begins at the anterior perforated substance by the union of a small anterior cerebral vein, which accompanies the anterior cerebral artery; a deep middle cerebral vein, which receives tributaries from the insula and neighbouring gyri, and runs in the lateral cerebral fissure; and striate veins, which emerge from the anterior perforated substance. The basal vein passes back round the cerebral peduncle to the great cerebral vein and receives tributaries from the interpeduncular fossa, inferior horn of the lateral ventricle, parahippocampal gyrus and midbrain.

The internal cerebral vein drains the deep parts of the hemisphere and the choroid plexuses of the third and lateral ventricles. It is formed near the interventricular foramen, behind the column of the fornix, primarily by union of the thalamostriate and choroidal veins, although numerous smaller veins from surrounding structures also converge here. The thalamostriate vein runs anteriorly, between the caudate nucleus and thalamus, and receives many tributaries from both. The choroidal vein runs a convoluted course along the whole choroid plexus, and receives veins from the hippocampus, fornix, corpus callosum and adjacent structures. After their formation, the two internal cerebral veins travel back parallel to one another beneath the splenium of the corpus callosum, where they unite to form the great cerebral vein. The great cerebral vein is a short median vessel that curves sharply up around the splenium of the corpus callosum and opens into the anterior end of the straight sinus after receiving the right and left basal veins.

Intracranial venosinus thrombosis One of the most potentially serious pathologies affecting the intracranial venous system is venosinus thrombosis (Fig. 19.15). In this condition, blood clots within the dural sinuses and/or intracranial veins, and the resulting obstruction of venous drainage may produce life-threatening complications.

In many cases, the cause of the venosinus thrombosis is not found; trauma involving the dural sinuses and infections in the vicinity of the sinuses (e.g. mastoiditis) present significant risk. Conditions that increase the coagulability of the blood, such as the oral contraceptive pill, pregnancy, dehydration and inborn abnormalities of the coagulation pathways, are also risk factors.

Individuals with intracranial venosinus thrombosis at its most severe present moribund, in coma or with major seizure activity; in these situations the prognosis is poor. The clot within the dural sinuses and/or cortical veins obstructs the drainage of venous blood from the brain and causes venous hypertension. As the pressure in the venous system approaches the arterial pressure, the blood flow perfusing the affected parts of the brain decreases. If it dips below a critical level, the brain tissue will become ischaemic and may die (venous infarction). As the arterial supply to the brain is still present, the infarcted areas of the brain frequently undergo major haemorrhage and this is often the factor that kills the patient.

Clinicians distinguish between thrombosis that affects the 'superficial' and 'deep' venous systems, although they may occur together (see Fig. 19.11). Superficial thrombosis usually occurs in the superior sagittal sinus (with or without involvement of the cortical veins), whilst deep intracranial thrombotic disease usually affects the great cerebral vein and the straight sinus. The parts of the cerebral hemispheres affected are different in the two situations: superficial thrombosis affects the cerebral hemispheres (particularly the white matter) and deep thrombosis affects the thalami and basal ganglia. However, one common feature is the tendency for bilateral involvement because all of the main draining venous channels are in the midline and accept venous drainage from both hemispheres.

If the extent of the intracranial venosinus thrombosis is less severe, or if alternative venous drainage has been accommodated by reasonable collateral channels, the patient may have more modest symptoms such as headaches or visual disturbance. Those symptoms are due to raised intracranial pressure and, if untreated, may become chronic.

Fig. 19.15 Venosinus thrombosis. Images from a magnetic resonance study in an adult patient with a 6-day history of headache and increasingly severe seizures. A, The sagittal T1-weighted image shows abnormal high signal along the course of the superior sagittal sinus (arrows). B, The axial T2-weighted image also shows high signal in the enlarged superior sagittal sinus (arrow). This pattern of abnormal signal indicates extensive subacute thrombus in the sinus. There are abnormal high signal changes in the left paracentral lobule (arrowheads), indicating venous infarction. This was shown to be bilateral and haemorrhagic on other images.

## Spinal cord: internal organization

The spinal cord provides innervation for the trunk and limbs via spinal nerves and their peripheral ramifications. It receives primary afferent fibres from peripheral receptors located in widespread somatic and visceral structures, and sends motor axons to skeletal muscle. It also contains the cell bodies of all the preganglionic neurones responsible for the sympathetic innervation of cardiac and smooth muscle and secretory glands, and for the parasympathetic innervation of smooth muscle in the distal part of the hindgut, the pelvic viscera and the erectile tissues of the external genitalia. Many bodily functions are regulated at an unconscious level by intraspinal reflex connections between afferent and efferent neurones. Profuse ascending and descending pathways link the spinal cord with the brain, allowing higher centres to monitor and perceive external and internal stimuli and to modulate and control spinal efferent activity.

## EXTERNAL FEATURES AND RELATIONS

The topographical anatomy of the spinal cord and its external features and relations are described in more detail in Chapter 45. In brief, the cord lies within the vertebral canal. It is continuous rostrally with the medulla oblongata, just below the level of the foramen magnum and it terminates caudally as the conus medullaris, which is continuous with the filum terminale and is anchored to the dorsum of the coccyx. The cord is ensheathed by spinal meninges that are continuous with the cranial meninges through the foramen magnum. Although it is approximately circular in cross-section, the diameter of the spinal cord varies according to level; it bears two enlargements, cervical and lumbar.

The spinal cord is essentially a segmental structure, giving rise to 31 bilaterally paired spinal nerves. These attach to the cord as a linear series of smaller dorsal and ventral nerve rootlets. Dorsal rootlets contain afferent nerve fibres and ventral rootlets contain efferent fibres (see Fig. 16.2). Groups of adjacent rootlets coalesce to form dorsal or ventral nerve roots that cross the subarachnoid space and unite to form functionally mixed spinal nerves as they pass through the intervertebral foramina. The dorsal roots bear dorsal root ganglia that contain the cell bodies of primary afferent neurones.

## INTERNAL ORGANIZATION

In transverse section, the spinal cord is incompletely divided into symmetrical halves by a dorsal (posterior) median septum and a ventral (anterior) median fissure (sulcus) (Fig. 20.1). It consists of an outer layer of white matter and an inner core of grey matter; their relative sizes and configuration vary according to level. The amount of grey matter reflects the number of neuronal cell bodies present; it is proportionately largest in the cervical and lumbar enlargements, which contain the neurones that innervate the limbs. The absolute amount of white matter is greatest at cervical levels and decreases progressively at lower levels because descending tracts shed fibres as they descend and ascending tracts accumulate fibres as they ascend.

A diminutive central canal, lined by columnar, ciliated epithelium (ependyma) and containing cerebrospinal fluid (CSF), extends the whole length of the spinal cord, lying in the centre of the spinal grey matter. Rostrally, the central canal extends into the caudal half of the medulla oblongata and then opens into the fourth ventricle.

## SPINAL GREY MATTER

In transverse section, the spinal grey matter is often described as being 'butterfly-shaped' or resembling the letter 'H' (see Fig. 20.1). It consists

Fig. 20.1 Transverse sections through the spinal cord at representative levels. Approximately $\times 5$. (Figure enhanced by B Crossman.)

Fig. 20.2 A transverse section of a spinal cord at a mid-lumbar level. Groups of the larger motor neurones in the ventral grey column are prominent. Stained with cresyl fast violet.
of four linked cellular masses: the right and left dorsal horns, which project dorsolaterally, and the right and left ventral horns which project ventrolaterally towards the surface. The grey matter that immediately surrounds the central canal and unites the two sides constitutes the dorsal and ventral grey commissures. The dorsal horn is the site of termination of the primary afferent fibres that enter the cord via the dorsal roots of spinal nerves. The tip of the dorsal horn is separated from the dorsolateral surface of the cord by a thin fasciculus or tract (of Lissauer), in which primary afferent fibres ascend and descend for a short distance before terminating in the subjacent grey matter. The ventral horn contains efferent neurones whose axons leave the spinal cord in ventral nerve roots. A small intermediate, or lateral, horn is present at thoracic and upper lumbar levels; it contains the cell bodies of preganglionic sympathetic neurones.

Spinal grey matter (Fig. 20.2) is a complex mixture of neuronal cell bodies, their processes and synaptic connections, neuroglia and blood vessels. Neurones in the grey matter are multipolar. They vary in size and features such as the length and the arrangement of their axons and dendrites. Neurones may be intrasegmental, i.e. contained within a single segment, or intersegmental, i.e. their ramifications spread through several segments.

## Neuronal cell groups of the spinal cord

The grey matter of the spinal cord may be divided, on the basis of cytoarchitecture, into 10 zones, known as Rexed's laminae, which are numbered sequentially from dorsal to ventral. The laminae are defined on the basis of neuronal size, shape, cytological features and density. Some of these lamina are equated with cell groupings of particular functional types (Fig. 20.3) (Rexed 1952).

Laminae I-IV correspond to the dorsal part of the dorsal horn, and are the main site of termination of cutaneous primary afferent terminals and their collaterals. Many complex polysynaptic reflex paths (ipsilateral, contralateral, intrasegmental and intersegmental) start from this region, as also do many long ascending tract fibres, which pass to higher levels. Lamina I (lamina marginalis) is a very thin layer with an ill-defined boundary at the dorsolateral tip of the dorsal horn. It has a reticular appearance, reflecting its content of intermingling bundles of coarse and fine nerve fibres. It contains small, intermediate and large neuronal somata, many of which are fusiform in shape. The much larger lamina II consists of densely packed small neurones, responsible for its dark appearance in Nissl-stained sections. With myelin stains, lamina II is characteristically distinguished from adjacent laminae by

A

Fig. 20.3 Rexed's laminae shown in the cervical cord (A) and in the thoracic cord (B). Abbreviations: CC, central canal; IL, intermediolateral; IM, intermediomedial; T, posterior thoracic nucleus. (A, Redrawn with permission from Crossman AR, Neary D 2010 Neuroanatomy, 4th edn. Edinburgh: Churchill Livingstone; B, Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)
the almost total lack of myelinated fibres. Lamina II corresponds approximately to the substantia gelatinosa. Lamina III consists of somata that are mostly larger, more variable and less closely packed than those in lamina II. It also contains many myelinated fibres. The ill-defined nucleus proprius of the dorsal horn corresponds to some of the cell constituents of laminae III and IV. Lamina IV is a thick, loosely packed, heterogeneous zone permeated by fibres. Its neuronal somata vary considerably in size and shape, from small and round, through intermediate and triangular, to very large and stellate (Schoenen and Faull 1990).

Laminae V and VI lie at the base of the dorsal horn. They receive most of the terminals of proprioceptive primary afferents, profuse corticospinal projections from the motor and sensory cortex, and input from subcortical levels, suggesting their involvement in the regulation of movement. Lamina V is a thick layer, divisible into a lateral third and medial two-thirds. Both have a mixed cell population but the former contains many prominent well-staining somata interlaced by numerous bundles of transverse, dorsoventral and longitudinal fibres. Lamina VI is most prominent in the limb enlargements. It has a densely staining medial third of small, densely packed neurones and a lateral two-thirds containing larger, more loosely packed, triangular or stellate somata.

Lamina VII occupies the region just ventral to lamina VI and extending across the spinal grey matter on each side. This region is known as the intermediate zone and within the thoracic cord includes the lateral horn. The size of lamina VII varies at different spinal levels. In the cervical and lumbar enlargements, lamina VII extends laterally and ventrally
throughout the ventral horn containing cell groups of lamina IX neurones embedded within it. In the thoracic region, lamina VII occupies the intermediate zone and the dorsal part of the ventral horn only. Three important nuclear groups are contained within lamina VII: the posterior thoracic nucleus (nucleus thoracicus posterior, Clarke's column), which extends throughout the thoracic and upper lumbar segments and gives rise to the dorsal spinocerebellar tract; the intermediolateral nucleus, which is located between T1 and L2 and gives rise
to the preganglionic sympathetic fibres; and the intermediomedial nucleus, which extends the full length of the cord and may be involved in the control of visceral motor neurones (Fig. 20.4).

Lamina VIII spans the base of the ventral horn in the thoracic region but is restricted to the medial aspect of the ventral horn in the cervical and lumbar enlargements. Its neurones display a heterogeneous mixture of sizes and shapes from small to moderately large. Lamina VIII is a mass of propriospinal interneurones. It receives terminals from the

Fig. 20.4 The groups of nerve cells in the grey columns of the spinal cord. The relative positions of these columnar groups and their extent through spinal segments are indicated. (Modified with permission of Simon \& Schuster from Correlative Anatomy of the Nervous System by E Crosby, T Humphrey, E Lauer. Copyright © 1962 Macmillan Publishing Company.)
adjacent laminae, many commissural fibres from the contralateral lamina VIII, and descending connections from the interstitiospinal, reticulospinal and vestibulospinal tracts and the medial longitudinal fasciculus. The axons from these interneurones influence $\alpha$ motor neurone activity bilaterally, perhaps directly but more probably by excitation of small $\gamma$ motor neurones supplying efferent fibres to muscle spindles.

Lamina IX consists of several distinct groups of somatic motor neurones located throughout the ventral horn. In the thoracic cord, these nuclear groups are embedded within lamina VIII, whereas in the cervical and lumbar enlargements, the lamina IX cell groups are embedded within both lamina VII and lamina VIII. Lamina IX is a complex array of cells consisting of $\alpha$ and $\gamma$ motor neurones and many interneurones. The large $\alpha$ motor neurones supply motor end-plates of extrafusal muscle fibres in striated muscle. Recording techniques have demonstrated tonic and phasic $\alpha$ motor neurones. The former have a lower rate of firing and lower conduction velocity, and tend to innervate type S muscle units. The latter have higher conduction velocity and tend to supply fast twitch (type FR, FF) muscle units. The smaller $\gamma$ motor neurones give rise to small-diameter efferent axons (fusimotor fibres), which innervate the intrafusal muscle fibres in muscle spindles. There are several functionally distinct types of $\gamma$ motor neurone. The 'static' and 'dynamic' responses of muscle spindles have separate controls mediated by static and dynamic fusimotor fibres, which are distributed variously to nuclear chain and nuclear bag fibres (Boyd and Gladden 1985).

Lamina X surrounds the central canal and consists of the dorsal and ventral grey commissures.

## Dorsal horn

The dorsal horn is a major zone of termination of primary afferent fibres, which enter the spinal cord through the dorsal roots of spinal nerves. Dorsal root fibres contain numerous molecules, which are either known, or suspected, to fulfil a neurotransmitter or neuromodulator role. These include glutamic acid, substance P, calcitonin gene-related peptide (CGRP), bombesin, vasoactive intestinal polypeptide (VIP), cholecystokinin (CСK), somatostatin, dynorphin and angiotensin II. Dorsal root afferents carry exteroceptive, proprioceptive and interoceptive information. Laminae I-IV are the main cutaneous receptive areas; lamina $V$ receives fine afferents from the skin, muscle and viscera; and lamina VI receives proprioceptive and some cutaneous afferents. Most, if not all, primary afferent fibres divide into ascending and descending branches on entering the cord. These then travel for variable distances in the tract of Lissauer, near the surface of the cord, and send collaterals into the subjacent grey matter.

The lamina marginalis (lamina I) is a thin lamina of neurones at the dorsolateral tip of the dorsal horn, deep to the tract of Lissauer. Beneath it lies the substantia gelatinosa (laminae II), which is present at all levels, and consists mostly of small neurones, together with some larger neurones. The substantia gelatinosa receives afferents via the dorsal roots, and its neurones give rise to fibres that form the contralateral spinothalamic tract. The large propriospinal neurones of the nucleus proprius lie ventral to the substantia gelatinosa within lamina III and lamina IV; they link segments for the mediation of intraspinal coordination (see Fig. 20.2).

The posterior thoracic nucleus lies at the base of the dorsal horn within lamina VII. At most levels, it is near the dorsal white funiculus and may project into it. It can usually be identified from the eighth cervical to the third or fourth lumbar segments. Neurones of the posterior thoracic nucleus vary in size but most are large, especially in the lower thoracic and lumbar segments. Some send axons into the dorsal spinocerebellar tracts and others are interneurones.

## Pain pathways

Fifty years ago, a paper was published that not only had a profound effect on thinking about sensory processing and perception at the time but also continues to influence research in the field of pain perception The authors described a mechanism by which nociceptive input from the skin was modulated ('gated') by local circuits within the dorsal horn and by descending inputs from the brain; the theory was known as the gate control theory (GCT; Melzack and Wall 1965). Interneurones in the substantia gelatinosa, SG cells, were cast in the role of the metaphorical gate, modulating patterns of afferent input to noci-responsive projection neurones (T cells, tract cells), found mainly in lamina I of the dorsal horn, and responsible for onward transmission of noxious messages to the brain. According to the GCT, increased activity in the collaterals of large-calibre innocuous afferents excited SG cells, which
in turn inhibited the T cells, i.e. the gate was closed. Activity in smallcalibre nociceptive afferents had the opposite effect of inhibiting the SG interneurones and opening the gate (Fig. 20.5). Since all primary afferents are excitatory, the model implied that inhibition of the SG cells was the product of interneuronal circuitry, although the participating cells had yet to be identified.

More is now known about the dorsal horn circuitry that generates the gate. Interneurones in laminae I-IV are morphologically, topographically and neurochemically heterogeneous: islet, central, radial and vertical cells have been identified in experimental animal studies. Islet cells are predominantly GABAergic (transmitting or secreting $\gamma$-aminobutyric acid); a subset co-express glycine and are presumed to be exclusively inhibitory. Radial and vertical cells are predominantly glutamatergic and presumed to be excitatory, and central cells include both inhibitory and excitatory subsets. The input from C nociceptors is concentrated in lamina I and lamina II; recent evidence has refocused attention on the concept of labelled lines (each sensory modality is processed via a fixed path from skin to brain) for noxious heat, cold, noxious mechanical stimulation and pruritogens, at least at the level of the primary afferent input. The main elements in the circuitry by which noxious and innocuous primary afferent inputs are thought to influence projection neurones within the dorsal horn of the spinal cord are shown in Figure 20.6. (For further reading, see Ma (2010), Moayedi and Davis (2013), Todd and Koerber (2013), Zhang et al (2013), Braz et al (2014), Mendell (2014).)

Onward transmission in the lateral spinothalamic tract is likely to evoke the perception of pain at supraspinal levels, although the activity of spinothalamic tract neurones may be modified by descending pain modulatory systems. In the brainstem, the regions inducing such effects correspond to a number of midbrain and rhombencephalic nuclei, which, with their connections, constitute an endogenous analgesic

Fig. 20.6 Routes by which noxious and innocuous primary afferent inputs may engage projection neurones in lamina I. Note that the excitatory activation circuits have a ventral-to-dorsal organization. Nociceptive C and $A \delta$ fibres (purple) activate vertical cells $(\mathrm{V})$ of the outer part of lamina II (IIo) directly and these, in turn, excite neurokinin 1 (NK1)-expressing projection neurones of lamina I (green axon). Nociceptive C fibres also activate central cells (C) of lamina II (III); the C cells contact, and probably excite, V cells in lamina llo. The projection neurones in lamina I also receive direct nociceptive $C$ and $A \delta$ input. Non-nociceptive $A \beta$ fibres (blue) project to deeper laminae (III-IV), where they establish monosynaptic connections with local excitatory interneurones (E), which directly activate V cells. The majority of the inhibitory neurones (I) in lamina II are islet cells (l-i). These dorsally directed circuits are the route through which both noxious and innocuous primary afferent input can engage the projection neurones of lamina I. The excitatory circuits in the superficial dorsal horn are subject to profound inhibitory controls (red). The majority of the inhibitory neurones (I) in lamina II are islet cells (I-i) and these can be directly engaged by input from low-threshold, mechanoreceptive C fibres (blue). The islet cells in turn establish monosynaptic inhibitory connections with both vertical cells of lamina Ilo and NK1 receptor-expressing projection neurones of lamina I. Lowthreshold $A \delta$ (D-hair; blue) and $A \beta$ fibres also directly engage inhibitory interneurones in laminae Ili-IV. The latter in turn exert inhibitory control of a variety of excitatory interneurones, including vertical $(\mathrm{V})$ and central (C) cells. The $A \beta$-to-inhibitory cell circuit presumably underlies the circuit through which the 'gate' of the gate control theory may be closed. (Redrawn with permission from Braz J, Solorzano C, Wang X, et al 2014 Transmitting pain and itch messages: a contemporary view of the spinal cord circuits that generate gate control, Neuron 82:522-536.)

Fig. 20.5 The basic arrangement of the sensory 'gate' mechanism in the dorsal laminae of the grey matter of the spinal cord. (Redrawn with permission from Melzack R, Wall PD. Pain mechanisms: a new theory. Science 150:971-979. Copyright 1965 American Association for the Advancement of Science.)
system. In the midbrain, these regions are the periaqueductal grey matter, dorsal raphe nucleus and part of the cuneiform nucleus. Neurones in these sites contain 5-HT (5-hydroxytryptamine, serotonin), GABA, substance P, CCK, neurotensin, enkephalin and dynorphin. The periaqueductal grey matter receives afferents from the frontal somatosensory and cingulate neocortex, the amygdala, numerous local reticular nuclei and the hypothalamus. Afferents from the latter are separate bundles, which carry histamine, luteinizing hormone-releasing hormone (LHRH), vasopressin, oxytocin, adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone ( $\gamma$-MSH), endorphin and angiotensin II. Some fibres descend from the periaqueductal grey matter to rhombencephalic centres, while others pass directly to the spinal cord.

In the rhombencephalon, the nucleus raphe magnus and the medial reticular column constitute an important multineuromediator centre. Neurones in these sites contain 5-HT, substance P, CCK, thyrotrophinreleasing hormone (TRH), enkephalin and dynorphin; some neurones contain two or even three neuromediators. Descending corticospinal fibres pass to the nucleus of the spinal tract of the trigeminal nerve and its continuation, the substantia gelatinosa. The latter extends throughout the length of the cord and contains populations of neurones that express many different neuromediators, e.g. GABA, substance P, neurotensin, enkephalin and dynorphin. There is abundant physiological and pharmacological evidence that all of these regions are intimately concerned with the control of nociceptive (and probably other modality) inputs.

Stimulation of forebrain sites, including the periventricular grey matter, the ventral posterolateral nucleus of the thalamus, and the primary sensory (S1) and posterior parietal cortices, inhibit spinothalamic tract cells. In contrast, some spinothalamic tract cells are excited by stimulation of the medullary reticular formation and the primary motor cortex (the latter effect probably being mediated by the corticospinal tract).

Modern neuroimaging and molecular, genetic and behavioural studies confirm that the experience of pain involves a complex network of responsive brain regions. The somatosensory cortices (S1 and S2) and the insula are thought to encode the sensory features of pain, whereas the prefrontal cortex and components of the limbic system (anterior cingulate cortex, amygdala, ventral tegmental area and nucleus accumbens) mediate the affective and contextual aspects of pain. Mechanisms underlying 'deep' visceral, muscular, neuropathic and persistent, chronic pain remain even less clear than those mediating cutaneous pain (Devor 2013). Patients with chronic pain may have anatomical alterations within the regions involved in the cognitive and emotional modulation of pain, e.g. the dorsolateral and medial prefrontal cortex, anterior cingulate gyrus and insula (Bushnell et al 2013, Denk et al 2014) and dysregulation of the descending pain modulation systems (Ossipov et al 2014).

## Lateral horn

The lateral horn is a small lateral projection of grey matter located between the dorsal and ventral horns in lamina VII. It is present from the eighth cervical or first thoracic segment to the second or third lumbar segment. It contains the cell bodies of preganglionic sympathetic neurones. These develop in the embryonic cord dorsolateral to the central canal and migrate laterally, forming the intermediolateral cell columns. Their axons travel via ventral spinal roots and white rami communicantes to the sympathetic trunk. A similar cell group is found in the second to fourth sacral segments but, unlike the thoracolumbar lateral cell column, it does not form a visible lateral projection. It is the source of the sacral outflow of parasympathetic preganglionic nerve fibres.

## Ventral horn

Lamina IX neurones in the ventral horn vary in size. The largest cell bodies, which may exceed $25 \mu \mathrm{~m}$ in diameter, are those of $\alpha$ motor neurones, the axons of which emerge in ventral roots to innervate extrafusal fibres in striated skeletal muscles. Large numbers of smaller neurones, 15-25 $\mu \mathrm{m}$ in diameter, are also present. Some of these are $\gamma$ motor neurones, which innervate intrafusal fibres of muscle spindles, and the rest are interneurones. Motor neurones utilize acetylcholine as their neurotransmitter.

The basic building block of the motor neurones in lamina IX is represented by a longitudinally disposed group of neurones, which innervate a given muscle, and in which the $\alpha$ and $\gamma$ motor neurones are intermixed. The various groups innervating different muscles are aggre-

Fig. 20.7 The approximate location of motor neurone groups at the C8 segmental level of the spinal cord.
gated into two major longitudinal columns: medial and lateral. In transverse section these form the medial and lateral cell groups in the ventral horn (Fig. 20.7). The motor neurones of lamina IX are somatotopically organized. The basic arrangement is that medial cell groups innervate the axial musculature, and lateral cell groups innervate the limbs.

The medial nuclear group is divisible into a posteromedial and anteromedial group. This group innervates the muscles attached to the axial skeleton. The medial nuclear group extends throughout the length of the spinal cord. Its neurones innervate epaxial muscle groups (which extend the head and vertebral column) and hypaxial muscle groups (which flex the head and vertebral column). Epaxial muscles include the erector spinae group, while hypaxial muscles include prevertebral muscles of the neck, intercostal and anterior abdominal wall muscles. The epaxial muscles are innervated by branches of the dorsal primary rami of the spinal nerves, and the hypaxial muscles by branches of the ventral primary rami. In the medial column, motor neurones supplying epaxial muscles are sited ventral to those supplying hypaxial muscles.

The lateral nuclear group innervates the rest of the body musculature. In the thoracic region, it is small and innervates the lateral trunk muscles, including the intercostal muscles. In the cervical and lumbar enlargements, the lateral nuclear group is enlarged and a number of subgroups may be distinguished, including the anterolateral (ventrolateral), posterolateral (dorsolateral), central and retroposterolateral (retrodorsolateral) groups.

In the cervical and lumbar enlargements, the lateral nuclear group innervates muscles of the upper and lower limbs, respectively. These neurones are somatotopically organized. Passing round the cervical ventral horn clockwise from ventromedial to dorsolateral, $\alpha$ motor neurones successively innervate muscles of the trunk, shoulder girdle, upper arm and lower arm (see Fig. 20.4). The proximal muscles of the limb are supplied from motor cell groups located more rostrally in the enlargement than those supplying the distal muscles, e.g. motor neurones in C 8 and T 1 innervate the intrinsic muscles of the hand, and motor neurones in C5 and C6 innervate shoulder muscles. There is a similar overall arrangement in the lumbosacral cord for motor neurones innervating the muscles in the lower limb (Fig. 20.8).

The spinal nucleus of the accessory nerve (SAN) contains motor neurones that innervate sternocleidomastoid and trapezius. Described as a curvilinear band of motor neurones extending within the ventral horn from C1/2 to C5/6 (Orhan et al 2009; Saylam et al 2009) in line rostrally with the nucleus ambiguus, the spinal nucleus of the accessory nerve is unusual in that it not only lies between the most medial column in the ventral horn (innervating axial muscles) and the lateral column (innervating upper limb muscles) (Routal and Pal 2000) but also its rootlets exit the spinal cord just dorsal to the ligamentum denticulatum (Jenny et al 1988). They subsequently combine to form the intraspinal portion of the accessory nerve, which ascends the vertebral canal to enter the posterior cranial fossa via the foramen magnum. The supranuclear innervation of the spinal nucleus of the accessory nerve is uncertain. The bulk of current evidence favours bilateral hemispheric innervation of motor neurones in the rostral spinal nucleus of the accessory nerve (innervating sternocleidomastoid), although opinion varies as to the extent of the ipsilateral input, but predominantly contralateral supranuclear control of the neurones in the caudal spinal nucleus of the accessory nerve (innervating the upper and middle fibres of trapezius). This pattern is analogous to the supranuclear innervation of the facial nerve motor nucleus.

Fig. 20.8 The segmental arrangement of motor neurones innervating muscles of the lower limb. Obt. ext. = obturator externus; Tib. ant. = tibialis anterior; Tib. post. = tibialis posterior; Ten. fas. latae = tensor fasciae latae; Glut. med. and min. = gluteus medius and minimus; Ext. hall. I. = extensor hallucis longus; Fib. tert. = fibularis tertius; Fib. brevis = fibularis brevis; Fib. longus = fibularis longus; Lat. hip. rot. = lateral hip rotators; Gastrocn. = gastrocnemius; Soleus and plant. = soleus and plantaris; Gluteus max. = gluteus maximus; Flex. hall. I. and b. = flexors hallucis longus and brevis; Flex. dig. I. and b. = flexors digitorum longus and brevis.

The nucleus of Onuf, which is thought to innervate the perineal striated muscles, is an anterolateral group of lamina IX cells in the first and second sacral segments. The centrally situated phrenic nucleus, containing the motor neurones that innervate the diaphragm, lies in the third to seventh cervical segments. The lumbosacral nucleus is also centrally located and its axons have an unknown distribution.

The main afferent connections to motor neurones are: direct monosynaptic connections from proprioceptive dorsal root afferents in the same or nearby segments; connections from axonal collaterals of dorsal horn and other interneurones; direct monosynaptic connections from the vestibulospinal and corticospinal tracts.

## SPINAL WHITE MATTER

The spinal white matter surrounds the central core of grey matter. The white matter consists primarily of longitudinally running nerve fibres. Fibres subserving related functions, or those with common origins or destinations, are generally grouped together anatomically to form tracts (fasciculi), which may be ascending, descending and propriospinal. Ascending tracts consist either of primary afferent fibres, which enter the cord via the dorsal roots of spinal nerves, or fibres derived from intrinsic spinal neurones, which carry afferent impulses to supraspinal levels. Descending tracts contain fibres that descend from the cerebral cortex or brainstem nuclei to control the activity of spinal neurones. Propriospinal tracts contain the axons of neurones that are localized entirely to the spinal cord; they contain both ascending and descending components, collectively mediating intersegmental coordination

The spinal white matter is conventionally described as being arranged into three large, bilaterally paired masses, the dorsal, lateral and ventral funiculi, each of which contains a number of specific tracts (see Fig. 20.1; Fig. 20.9). The dorsal (posterior) funiculus lies between the dorsal horn and the posterior median septum. The lateral funiculus lies between the dorsal root entry zone and the site where the ventral roots emerge. The ventral (anterior) funiculus lies between the ventral median fissure and the site where the ventral roots emerge. Narrow dorsal and ventral white commissures run between the two halves of the cord.

Fibres in the spinal white matter vary in calibre. Many are small and lightly myelinated or unmyelinated. Most regions contain a wide spectrum of fibre diameters, from $1 \mu \mathrm{~m}$ or less to $10 \mu \mathrm{~m}$. Some tracts typically contain only small fibres, e.g. the dorsolateral tract, fasciculus gracilis and central part of the lateral funiculus. The fasciculus cuneatus, ventral funiculus and peripheral zone of the lateral funiculus all contain many large-diameter fibres.

Whilst the ascending and descending tracts are, to a large extent, discrete and regularly located, significant overlap between adjacent tracts does occur. Their general disposition is shown in Figure 20.9 (Parent and Carpenter 1996).

## Ascending pathways

## Dorsal columns

The dorsal funiculus consists of two large ascending tracts, the fasciculus gracilis and fasciculus cuneatus (Fig. 20.10), which are also known as the dorsal columns. They are separated by a posterointermediate septum. The dorsal columns contain a high proportion of myelinated fibres carrying proprioceptive (position sense and kinaesthesia), exteroceptive (touch-pressure) and vibratory sensation to higher levels. These fibres come from several sources: long primary afferent fibres, which enter the cord in the dorsal roots of spinal nerves and ascend to the dorsal column nuclei in the medulla oblongata; shorter primary afferent fibres projecting to neurones of the posterior thoracic nucleus and other spinal neurones; and axons from secondary neurones of the spinal cord ascending to the dorsal column nuclei. The dorsal columns also contain axons of propriospinal neurones.

The fasciculus gracilis begins at the caudal end of the spinal cord. It contains long ascending branches of primary afferents, which enter the cord through ipsilateral dorsal spinal roots and ascending axons of secondary neurones in laminae IV-VI of the ipsilateral dorsal horn. As the fibres ascend, they are joined by axons of successive dorsal roots. Fibres entering in coccygeal and lower sacral regions are shifted medially by successive additions of fibres entering at higher levels.

The fasciculus gracilis lies medial to the fasciculus cuneatus in the upper spinal cord (see Fig. 20.9). At upper cervical levels, the fasciculus gracilis contains a larger proportion of afferents from cutaneous receptors than from deep proprioceptors because many of the latter leave the fasciculus at lower segments to synapse in the posterior thoracic nucleus. Indeed, proprioception from the lower limb mostly reaches the thalamus by relaying in the posterior thoracic nucleus and then again in nucleus Z . Axons of the fasciculus gracilis, from both primary and secondary neurones, terminate in the nucleus gracilis of the dorsal medulla.

The fasciculus cuneatus (see Fig. 20.9) begins at mid-thoracic level and lies lateral to the fasciculus gracilis. It is composed mostly of primary afferent fibres of the upper thoracic and cervical dorsal roots. At upper cervical levels, it contains a large population of afferents from both deep and cutaneous receptors of the upper limb. In addition, some of its axons arise from secondary neurones in laminae IV-VI of the ipsilateral dorsal horn. Many axons (both primary and secondary) that ascend in the fasciculus cuneatus terminate in the nucleus cuneatus of the dorsal medulla. Some also end in the lateral (external or accessory) cuneate nucleus; neurones in this nucleus project to the cerebellum via the cuneocerebellar pathway.

Many ascending fibres of the fasciculus gracilis and fasciculus cuneatus terminate by synapsing on neurones of the dorsal column nuclei (nucleus gracilis and nucleus cuneatus, respectively) in the medulla oblongata. (The connections of the dorsal column nuclei are described further with the medulla oblongata; Ch. 21.) Axons arising from neurones in the dorsal column nuclei arch ventromedially round the central grey matter of the medulla as internal arcuate fibres (see Fig. 21.7) and decussate in the great sensory decussation to form the medial lemniscus. They ascend to the ventral posterolateral nucleus of the thalamus, from where neurones project to the somatosensory cortex in the postcentral gyrus of the parietal lobe (areas 1, 2 and 3). Some neurones of the dorsal column nuclei form posterior external arcuate fibres that enter the cerebellum.

The high degree of somatotopic organization that is present in the dorsal columns is preserved as the pathways ascend through the dorsal column nuclei and thalamus to reach the primary somatosensory cortex. In the dorsal column nuclei, the lower limb is represented in the nucleus gracilis, the upper limb in the nucleus cuneatus, and the trunk in an intermediate position between them. Fibres are also segregated by modality in the dorsal columns; fibres from hair receptors are most superficial, while those from tactile and vibratory receptors lie in deeper layers.

A

Fig. 20.9 The approximate positions of nerve fibre tracts in the spinal cord at mid-cervical (A) and lumbar (B) levels.

## Spinocerebellar tracts

The dorsal (posterior) and ventral (anterior) spinocerebellar tracts occupy the periphery of the lateral aspect of the spinal white matter (see Fig. 20.9; Fig. 20.11) and carry proprioceptive and cutaneous information to the cerebellum for the coordination of movement. Both tracts contain large-diameter myelinated fibres but there are more in the dorsal tract. Finer-calibre fibres are associated with the ventral tract.

The dorsal spinocerebellar tract lies lateral to the lateral corticospinal tract. It begins at about the level of the second or third lumbar segment and enlarges as it ascends. Axons of the tract originate ipsilaterally from the larger neurones of the posterior thoracic nucleus, in lamina VII throughout spinal segments T1-L2. The posterior thoracic nucleus receives input from collaterals of long ascending primary afferents of the dorsal columns and terminals of shorter ascending primary afferents of the dorsal columns. Many of these afferent fibres ascend from segments caudal to L2. In the medulla, the dorsal spinocerebellar tract passes through the restiform body and thence the inferior cerebellar peduncle to terminate ipsilaterally in the rostral and caudal parts of the cerebellar vermis.

The ventral spinocerebellar tract lies immediately ventral to the dorsal tract. The cells of origin are in laminae V-VII of the lumbosacral cord and the tract carries information from the lower limb. Most of the axons forming the tract decussate but some remain ipsilateral. The tract begins in the upper lumbar region and ascends through the medulla
oblongata to reach the upper pontine level, from where it descends in the dorsal part of the superior cerebellar peduncle to terminate, mainly contralaterally, in the anterior cerebellar vermis.

The rostral spinocerebellar tract originates from cell groups of the intermediate zone and horn of the contralateral cervical enlargement and is considered to be the upper limb and upper trunk equivalent of the ventral spinocerebellar tract.

Experimental tracing studies in animals have demonstrated a cervicospinocerebellar tract arising from a central cervical nucleus in the upper cervical spinal cord (C1-C4); the central cervical nucleus, possibly Cajal's nucleus intermedius, receives primary afferents from the vestibular labyrinth and muscle afferents from the deep muscles of the neck. A similar pathway may exist in humans where the nucleus intermedius of Cajal receives fibres from only the upper two cervical roots (Marani and Schoen 2005).

The dorsal and ventral spinocerebellar tracts are organized such that fibres from lower spinal segments are most superficial. Both tracts convey proprioceptive and exteroceptive information, but they are functionally different. Neurones of the posterior thoracic nucleus are excited monosynaptically by Ia and Ib primary afferent fibres (from muscle spindles and tendon organs, respectively) and also by group II muscle afferents, and cutaneous touch and pressure afferents. The proprioceptive impulses often arise from a single muscle or from synergistic muscles acting at a common joint. Thus, the dorsal spinocerebellar tract transmits modality-specific and space-specific information that is used

Fig. 20.10 The dorsal columns. Primary afferent fibres from different levels and their associated second- and third-order neurones are depicted in different colours.
in the fine coordination of individual limb muscles. On the other hand, the cells of the ventral tract are activated monosynaptically by Ib afferents and transmit information from large receptive fields that include different segments of a limb. The ventral tract lacks subdivisions for different modalities and transmits information for the coordinated movement and posture of the entire lower limb.

Fig. 20.11 The spinocerebellar tracts. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)

Since the posterior thoracic nucleus diminishes rostrally (see Fig. 20.4) and does not extend above the lowest cervical segment, it follows that the dorsal spinocerebellar tract carries information from the trunk and lower limb. Proprioceptive and exteroceptive information from the upper limb travel in primary afferent fibres of the fasciculus cuneatus. These fibres end somatotopically in the accessory (external or lateral)
cuneate nucleus and the adjoining part of the cuneate nucleus situated in the medulla oblongata. Cells of these nuclei give rise to the posterior external arcuate fibres that form the cuneocerebellar tract (see Fig. 20.11), which enters the cerebellum via the ipsilateral inferior cerebellar peduncle. The cells in the accessory cuneate nucleus and the lateral part of the cuneate nucleus are considered to be homologous to the cells in the posterior thoracic nucleus. The cuneocerebellar tract is, therefore, functionally allied to the dorsal spinocerebellar tract, and is its upperlimb equivalent.

Axons of all the spinocerebellar tracts and the cuneocerebellar tract form part of the 'mossy-fibre system'. They end in the cerebellar cortex in a highly organized, somatotopical and functional pattern.

## Spinothalamic tracts

The spinothalamic tracts (see Fig. 20.9) consist of second-order neurones that convey pain, temperature, coarse (non-discriminative) touch and pressure information to the somatosensory region of the thalamus. The cells of origin lie in various laminae of all segments of the spinal cord. Fibres decussate in the ventral white commissure to reach the contralateral spinothalamic tracts; pain and temperature fibres do so promptly, within about one segment of their origin, whilst fibres carrying other modalities may ascend for several segments before crossing. Spinothalamic fibres mostly ascend in the white matter ventrolateral to the ventral horn, partly intermingled with ascending spinoreticular fibres and descending reticulospinal fibres. Some authorities describe two spinothalamic tracts (lateral and ventral) with more or less distinct anatomical locations and functions. However, physiological studies in animals support the notion that these tracts may be best considered as a structural and functional continuum.

The lateral spinothalamic tract (Fig. 20.12) is sited in the lateral funiculus, lying medial to the ventral spinocerebellar tract. Clinical evidence indicates that it subserves pain and temperature sensations. The ventral spinothalamic tract (Fig. 20.13) lies in the ventral funiculus medial to the point of exit of the ventral spinal nerve roots and dorsal to the vestibulospinal tract, which it overlaps. On the basis of clinical evidence, it subserves coarse tactile and pressure modalities.

A dorsolateral spinothalamic tract has been described in animals. The axons arise mainly from neurones in lamina I, and cross to ascend in the contralateral dorsolateral funiculus. These neurones respond maximally to noxious, mechanical and thermal cutaneous stimuli. Examples of clinical pain relief following dorsolateral cordotomy suggest that a similar projection exists in humans.

On reaching the lower brainstem, spinothalamic tract axons separate. Axons in the ventral tract join the medial lemniscus. Axons in the lateral tract continue as the spinal lemniscus.

There is clear somatotopic organization of the fibres in the spinothalamic tracts throughout their extent. Fibres crossing at any cord level join the deep aspect of those that have already crossed, which means that both tracts are segmentally laminated (Fig. 20.14). Somatotopy is maintained throughout the medulla oblongata and pons. In the midbrain, fibres in the spinal lemniscus conveying pain and temperature sensation from the lower limb extend dorsally, while those from the trunk and upper limb are more ventrally placed. Both lemnisci ascend to end in the thalamus. The major spinothalamic projections in humans are to the ventral posterolateral nucleus, and also to the centrolateral intralaminar nucleus.

## Neurones of the spinothalamic tracts

The specific localization of spinothalamic tract cell bodies is poorly documented in humans. In animals, about one-third are localized to the upper three cervical segments. About $20 \%$ are located in lower cervical segments, $20 \%$ in the thoracic region (mostly in segments T1-3), $20 \%$ in the lumbar region and $10 \%$ in the sacrococcygeal cord. Cells are located in laminae I and IV-VIII, the greatest concentration being in laminae VI and VII. Cell bodies giving rise to spinothalamic tract axons are predominantly contralateral, although a relatively small number ( $10 \%$ ), mostly in the upper three cervical segments, are ipsilateral.

Neurones of the spinothalamic tracts have varied receptive fields. Specificity of separate types of afferents, as it exists in the dorsal column nuclei, is absent in the spinothalamic nuclei. Convergence of different functional types of afferent fibres on to an individual tract cell is a common feature in the cord. On the basis of laminar site, functional properties, and specific thalamic termination of their axons, spinothalamic tract neurones may be divided into three separate groups. These are the apical cells of the dorsal grey column (lamina I), deep dorsal column cells (laminae IV-VI), and cells in the ventral grey column (laminae VII and VIII). There are species differences and the description below is derived from studies in non-human primates.

Fig. 20.12 The lateral spinothalamic tract. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)

Lamina I cells project to the thalamus. They respond maximally to noxious or thermal cutaneous stimulation and consist mainly of highthreshold but also some wide-dynamic-range units (responding to various different intensities of stimulus). Their receptive fields are usually small, representing a part of a digit or a small area of skin involving several digits. Lamina I spinothalamic tract neurones receive

Fig. 20.13 The ventral (anterior) spinothalamic tract. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)
input from A $\delta$ and C fibres, and some respond to convergent input from deep somatic and visceral receptors. Spinothalamic tract cells in the thoracic cord display marked viscerosomatic convergence. Hence pain from cardiac disease such as angina or a myocardial infarction is commonly felt as a tightness around the chest wall (referred pain). This is very similar to the pain that may be felt after an infarct of the spinal

Fig. 20.14 The general plan of the segmental organization of fibres in the dorsal funiculus, the lateral corticospinal tract and the spinothalamic tracts. The probable cross-sectional areas of these tracts are schematically enlarged. This general plan applies to all segmentally organized tracts, whether ascending, descending, ipsilateral or contralateral.
cord (Combarros et al 2002). Lamina I spinothalamic tract neurones project preferentially to the ventral posterolateral nucleus of the thalamus, with limited projections to the centrolateral intralaminar and mediodorsal thalamic nuclei.

The population of deep dorsal column (laminae IV-VI) spinothalamic neurones of the lumbar cord contains units of the wide-dynamicrange (60\%), high-threshold (30\%) and low-threshold (10\%) types. They can accurately code both innocuous and noxious cutaneous stimuli. Some cells also respond to input from deep somatic and visceral receptors. In the lumbar cord, their receptive fields are small or medium-sized; they are larger than the area of the foot but smaller than the entire leg. In the thoracic cord, the fields of these laminar cells are larger and often include the entire upper limb plus part of the chest. Many of the deep dorsal grey column spinothalamic tract neurones in the thoracic segments receive convergent input from sympathetic afferent fibres.

Laminae IV-VI spinothalamic tract units project either to the ventral posterolateral nucleus or to the centrolateral intralaminar nucleus of the thalamus, and sometimes to both. Units projecting to the ventral posterolateral nucleus receive input from all classes $(A \beta, A \delta$ and $C)$ of cutaneous fibres.

Ventral grey column (laminae VII and VIII) spinothalamic tract cells respond mainly to deep somatic (muscle and joint) stimuli but also to innocuous and/or noxious cutaneous stimuli. In the thoracic regions of the spinal cord, they also receive convergent input from visceral sources. The majority of laminae VII and VIII spinothalamic tract neurones have large, complex receptive fields (often bilateral), which encompass widespread areas of the body. Cells of this group, which project exclusively to the medial thalamus, receive input from $A \beta, A \delta$ and C classes of afferent fibres, and many respond to convergent input from receptors of deep structures. This population of neurones contains wide-dynamic-range (25\%), high-threshold (63\%) and low-threshold $(12 \%)$ units. Most of the spinothalamic tract cells in the ventral grey column project to the intralaminar nuclei of the thalamus. The wide-dynamic-range type of neurones are particularly effective for discriminating between different intensities of painful stimulation.

## Spinoreticular pathway

Spinoreticular fibres are intermingled with those of the spinothalamic tracts and ascend in the ventrolateral quadrant of the spinal cord

Fig. 20.15 The reticular tracts. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)
(Fig. 20.15). Evidence from animal studies suggests that cells of origin occur at all levels of the spinal cord, particularly in the upper cervical segments. Most neurones are in lamina VII, some are in lamina VIII, and others are in the dorsal horn, especially lamina V. Most axons in the lumbar and cervical enlargements cross the midline, but there is a large uncrossed component in cervical regions. Most axons are myelinated. The pattern of anterograde degeneration, in both human postmortem studies and in experimental animals following anterolateral cordotomy, indicates the existence of spinoreticular projections to many nuclei of the medial pontomedullary reticular formation. There is also a projection to the lateral reticular nucleus (a precerebellar relay nucleus). These projections do not appear to be somatotopically organized. Spinoreticular neurones respond to inputs from the skin or deep tissues. Innocuous cutaneous stimuli may inhibit or excite a particular cell, whereas noxious stimuli are often excitatory. A spino-reticulo-thalamo-cortical pathway has been proposed as an important route
serving pain perception. Like other ascending pathways, the tract cells are influenced by descending control. For example, electrical stimulation of the periaqueductal grey matter inhibits the responses of certain spinoreticular cells to input from cardiopulmonary afferents. Stimulation of the reticular formation also alters the activity of spinoreticular neurones.

## Spinocervicothalamic pathway

The lateral cervical nucleus is small in humans. It lies in the lateral funiculus, ventrolateral to the dorsal horn in the upper two cervical segments. In some human cord specimens, the nucleus is not distinctly defined and is possibly incorporated into the dorsal horn. It receives axons from the spinocervical tract, which ascends in the dorsolateral funiculus. The tract cells are found in laminae III-V at all levels of the spinal cord, ipsilateral to the nucleus. Most neurones of the nucleus project to the contralateral thalamus via the medial lemniscus, and some project to the contralateral midbrain. Specific thalamic targets include the ventral posterolateral nucleus and part of the posterior complex. Spinocervical tract neurones respond to hair movement, pressure, pinch and thermal stimuli and to high-threshold muscle input; many also respond to noxious stimuli. Like tract cells of other ascending pathways, they are under tonic descending inhibitory control.

## Spinomesencephalic pathway

The spinomesencephalic pathway consists of a number of tracts ascending from the spinal cord to various regions of the midbrain. It includes the spinotectal tract projecting to the superior colliculus, neurones synapsing in the periaqueductal grey matter, and other spinal cord projections that terminate in the parabrachial nucleus, the pretectal nuclei and the nucleus of Darkschewitsch. Cells of origin are located throughout the length of the spinal cord, particularly in the cervical segments and the lumbosacral enlargement, mostly in lamina I, but they are also present in laminae IV-VIII, where they are concentrated in lamina V. Most are contralateral, but a prominent ipsilateral group is also found at upper cervical levels. Spinomesencephalic fibres are mostly myelinated and ascend in the white matter of the ventrolateral quadrant of the spinal cord, in association with the spinothalamic and spinoreticular tracts.

Spinomesencephalic neurones are of low-threshold, wide-dynamicrange or high-threshold classes. Their receptive fields may be small, or very complex and encompass large surface areas of the body. Many spinomesencephalic cells are nociceptive and are likely to be involved in the motivational-affective component of pain. Electrical stimulation of their site of termination in the periaqueductal grey matter results in severe pain in humans. Furthermore, the cells of the deeper layers of the superior colliculus, where spinotectal fibres synapse, are activated by noxious stimuli.

## Spino-olivary tract

The spino-olivary tract is described in animals as arising from neurones in the deeper laminae of grey matter. Axons forming the tract cross and then ascend superficially at the junction of the ventral and lateral white funiculi, to end in the dorsal and medial accessory olivary nuclei. The tract carries information from muscle and tendon proprioceptors, and also from cutaneous receptors. A functionally similar route, the dorsal spino-olivary tract, ascends in the dorsal white funiculi, and relays in the dorsal column nuclei to the contralateral inferior olivary nucleus. Information on these tracts in primates is scant, but postmortem evidence following cordotomies in humans has revealed degenerating axonal terminals in the inferior olivary nucleus.

## Descending tracts

Descending pathways to the spinal cord originate primarily from the cerebral cortex and from numerous sites within the brainstem (see Fig. 20.15; Figs 20.16-20.17). They are concerned with the control of movement, muscle tone and posture, the modulation of spinal reflex mechanisms and the modulation of transmission of afferent information to higher levels. They also mediate control over spinal autonomic neurones (Kuypers 1981).

## Corticospinal and corticonuclear tracts

Corticospinal and corticonuclear fibres arise from neurones in the cerebral cortex. They project, in a somatotopically organized fashion, to neurones that are mostly located in the contralateral spinal cord or brainstem respectively (see Fig. 20.16). The majority of corticospinal and corticonuclear fibres arise from cells situated in the primary motor cortex (area 4) and the premotor cortex (area 6). A small contribution

Fig. 20.16 The corticospinal tracts. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)
comes from cells in the postcentral gyrus (somatosensory cortex; areas 3, 1 and 2) and the adjacent parietal cortex (area 5). In the monkey, $30 \%$ of corticospinal fibres arise from area $4,30 \%$ from area 6 , and $40 \%$ from the parietal regions. The cells of origin of corticospinal and corticonuclear fibres vary in size according to their cortical origins and

Fig. 20.17 A simplified scheme of some of the major descending pathways of the spinal cord, including their overlapping zones of termination in the grey matter. Within the grey matter the dotted lines show the laminar pattern, while within the white matter they are an approximate guide to the topography of the tracts.
are clustered into groups or strips. The largest neurones (giant pyramidal neurones, Betz cells) are located in the primary motor cortex of the precentral gyrus.

Corticospinal and corticonuclear fibres descend through the subcortical white matter to enter the genu and posterior limb of the internal capsule. They then pass through the ventral part of the midbrain in the crus cerebri. As they continue caudally through the pons, they are separated from its ventral surface and fragmented into fascicles by transversely running pontocerebellar fibres. Corticonuclear fibres leave to terminate in association with the cranial nerve motor nuclei of the midbrain, pons and medulla. In the medulla oblongata, the residual corticospinal fibres form a discrete bundle, the pyramid, which is visible as a prominent longitudinal column on the ventral surface of the medulla (see Fig. 21.4); the corticospinal tract is, therefore, also referred to as the pyramidal tract. Each pyramid contains about a million axons of varying diameter. The majority are myelinated. Most have a diameter of $1-4 \mu \mathrm{~m}$; approximately $10 \%$ have diameters of $5-10 \mu \mathrm{~m}$; and a very few have diameters of $11-22 \mu \mathrm{~m}$. The largest-diameter axons arise from the giant pyramidal neurones.

Just rostral to the level of the spinomedullary junction, $75-90 \%$ of the corticospinal fibres in the pyramid cross the median plane in the motor decussation (decussation of the pyramids) and continue caudally as the lateral corticospinal tract. The rest of the fibres continue uncrossed as the ventral corticospinal tract. The lateral corticospinal tract (see Fig. 20.16) descends in the lateral funiculus throughout most of the length of the spinal cord until about the fourth sacral segment. It occupies an oval area, ventrolateral to the dorsal horn and medial to the dorsal spinocerebellar tract (see Fig. 20.9). In the lumbar and sacral regions, where the dorsal spinocerebellar tract is absent, the lateral corticospinal tract reaches the dorsolateral surface of the cord. The lateral corticospinal tract is somatotopically organized such that axons destined for spinal segments innervating the upper limbs are located more medially than those destined for cord segments innervating the lower limbs (see Fig. 20.14). As it descends, its fibres terminate in progressively lower spinal segments, which means that the tract diminishes in size. The lateral corticospinal tract also contains some uncrossed corticospinal fibres.

The smaller ventral corticospinal tract (see Fig. 20.16) descends in the ventral funiculus. It lies close to the ventral median fissure, and is separated from it by the sulcomarginal fasciculus (see Fig. 20.9). The ventral corticospinal tract diminishes as it descends and usually disappears completely at mid-thoracic cord levels. It may either be absent or,
very rarely, contain almost all the corticospinal fibres. Near their termination, most fibres of the tract cross the median plane in the ventral white commissure to synapse on contralateral neurones. The vast majority of corticospinal fibres, irrespective of the tract in which they descend, therefore terminate in the spinal cord on the side contralateral to their cortical origin.

Knowledge of the detailed termination of corticospinal fibres is based largely on animal studies, but is supplemented by data from postmortem studies on human brains using anterograde degeneration methods. Most corticospinal fibres are believed to terminate contralaterally on interneurones in the lateral parts of laminae IV-VI and both lateral and medial parts of lamina VII; some are also distributed to lamina VIII bilaterally. Terminals are also associated with contralateral motor neuronal cell groups in lamina IX, in the dorsolateral group and the lateral parts of both central and ventrolateral groups (see Fig. 20.17).

Corticospinal fibres from the frontal cortex, including motor and premotor areas 4 and 6, terminate mostly on interneurones in laminae V-VIII, with the densest concentration ending in the lateral part of lamina VI. They influence $\alpha$ and $\gamma$ motor neurones of lamina IX, via these interneurones. As the widespread dendrites of multipolar neurones in lamina IX penetrate lamina VII, direct monosynaptic axodendritic contacts also occur on large $\alpha$ motor neurones. Direct termination on motor neurones is most abundant in the spinal enlargements.

Experimental evidence shows that precentral corticospinal axons influence the activities of both $\alpha$ and $\gamma$ motor neurones, facilitating flexor muscles and inhibiting extensors, which are the opposite effects to those mediated by lateral vestibulospinal fibres. Evidence from animal studies shows that direct projections from the precentral cortical areas to spinal motor neurones are concerned with highly fractionated, precision movements of the limbs. Accordingly, in primates, precentral corticospinal fibres are mainly distributed to motor neurones supplying the distal limb muscles. Corticospinal projections may use glutamate or aspartate, often co-localized, as excitatory neurotransmitters.

Corticospinal fibres from parietal sources end mainly in the contralateral dorsal horn, in the lateral parts of laminae IV-VI and lamina VII. Phylogenetically these fibres represent the oldest part of the corticospinal system. Axons from the sensory cortex terminate chiefly in laminae IV and V. They are concerned with the supraspinal modulation of the transmission of afferent impulses to higher centres, including the motor cortex.

Experimental studies in primates indicate that isolated transection of corticospinal fibres at the level of the pyramid (pyramidotomy) results in flaccid paralysis or paresis of the contralateral limbs and loss of independent hand and finger movements. Destruction of corticospinal fibres at the level of the internal capsule, commonly caused by a cerebral vascular accident or 'stroke', results in a contralateral hemiplegia. The paralysis is initially flaccid but later becomes spastic, and is most marked in the distal muscles of the extremities, especially those concerned with individual movements of the fingers and hand. Associated signs on the paralysed side are: hyperactive deep tendon reflexes; increased tone; the loss of superficial abdominal and cremasteric reflexes; and the appearance of dorsiflexion of the toes (Babinski's sign) in response to stroking the sole of the foot. The latter is usually interpreted as pathognomonic of corticospinal damage, but it is not always present in patients with confirmed corticospinal lesions. Moreover, Babinski's sign is normally present in human infants up to about 2 years of age; its subsequent disappearance may reflect the completion of myelination of the corticospinal fibres and/or the establishment of direct cortical connections to lower motor neurones.

Some of the sequelae of stroke damage in the internal capsule, in particular hyperreflexia and hypertonia, are due to the involvement of other pathways in addition to the corticospinal tract. These include descending cortical fibres to brainstem nuclei, such as the vestibular and reticular nuclei, which also give rise to descending projections that influence motor neurone activity.

## Rubrospinal tract

The rubrospinal tract arises from neurones in the caudal magnocellular part of the red nucleus (an ovoid mass of cells situated centrally in the midbrain tegmentum; p. 324). This part of the nucleus contains some 150-200 large neurones, interspersed with smaller neurones.

The origin, localization, termination and functions of rubrospinal connections are poorly defined in humans, and the tract appears to be rudimentary. Rubrospinal fibres cross in the ventral tegmental decussation and descend in the lateral funiculus of the cord, where they lie ventral to, and intermingled with, fibres of the lateral corticospinal tract (see Fig. 20.9). In animals, the tract descends as far as lumbosacral levels, whereas in humans it appears to project only to the upper three
cervical cord segments. Rubrospinal fibres are distributed to the lateral parts of laminae V-VI and the dorsal part of lamina VII of the spinal grey matter. The terminal zones of the tract correspond to those of corticospinal fibres from the motor cortex. Animal studies demonstrate that the effects of rubrospinal fibres on $\alpha$ and $\gamma$ motor neurones are similar to those of corticospinal fibres.

## Tectospinal tract

The tectospinal tract arises from neurones in the intermediate and deep layers of the superior colliculus of the midbrain. It crosses ventral to the periaqueductal grey matter in the dorsal tegmental decussation and descends in the medial part of the ventral funiculus of the spinal cord (see Fig. 20.9). Fibres of the tract project only to the upper cervical cord segments, ending in laminae VI-VIII. They make polysynaptic connections with motor neurones serving muscles in the neck, facilitating those that innervate contralateral muscles and inhibiting those that innervate ipsilateral ones. In animals, unilateral electrical stimulation of the superior colliculus causes turning of the head to the contralateral side, an effect mainly mediated through the tectospinal tract.

## Vestibulospinal tracts

The vestibular nuclear complex lies in the lateral part of the floor of the fourth ventricle, at the level of the pontomedullary junction. It gives rise to the lateral and medial vestibulospinal tracts, which are functionally and topographically distinct (Fig. 20.18).

The lateral vestibulospinal tract arises from small and large neurones of the lateral vestibular nucleus (Deiters' nucleus). It descends ipsilaterally, initially in the periphery of the ventrolateral spinal white matter, but subsequently migrating into the medial part of the ventral funiculus at lower spinal levels. Fibres of this tract are somatotopically organized. Thus, fibres projecting to the cervical, thoracic and lumbosacral segments of the cord arise from neurones in the rostroventral, central and dorsocaudal parts, respectively, of the lateral vestibular nucleus. Lateral vestibulospinal fibres end ipsilaterally, mostly in the medial part of the ventral horn in lamina VIII and the medial part of lamina VII.

The medial vestibulospinal tract (see Fig. 20.18) arises mainly from neurones in the medial vestibular nucleus, but some are also located in the inferior and lateral vestibular nuclei. It descends in the medial longitudinal fasciculus into the ventral funiculus of the spinal cord, where it lies close to the midline in the so-called sulcomarginal fasciculus (see Fig. 20.9). Unlike the lateral tract, it contains both crossed and uncrossed fibres, and does not extend beyond the mid-thoracic cord level. Fibres of the medial tract project mainly to the cervical cord segments, ending in lamina VIII and the adjacent dorsal part of lamina VII.

The vestibular nuclei exert a strong excitatory influence upon the antigravity muscles by way of the medial and lateral vestibulospinal tracts. The antigravity muscles include the epaxial muscles of the vertebral column and the extensor muscles of the lower limbs.

## Reticulospinal tracts

The reticulospinal tracts pass from the brainstem reticular formation to the spinal cord. The pontine reticulospinal tract (see Fig. 20.15) originates from the pontine tegmentum. The medullary reticulospinal tract arises from the nucleus gigantocellularis, which lies dorsal to the inferior olivary complex. The terminals of reticulospinal fibres are distributed to lamina VIII, and the central and medial parts of lamina VII. The medullary reticulospinal terminals are more widely distributed, ending additionally in the lateral parts of laminae VI and VII, and also directly on motor neurones. Terminations of reticulospinal fibres that originate in the medulla are, in general, more dorsally placed than those that originate in the pons, although there is considerable overlap.

The course and location of the reticulospinal tracts are poorly defined in humans. Some anatomical texts classify the reticulospinal tracts into medial, ventral and ventrolateral tracts, but this is based mainly on studies in animals (see Fig. 20.9). Studies in humans have reported that the reticulospinal fibres in general do not form welldefined tracts but are scattered throughout the ventral and lateral columns (Nathan et al 1996).

Both $\alpha$ and $\gamma$ motor neurones are influenced by reticulospinal fibres, through polysynaptic and monosynaptic connections. The pontine reticulospinal tract appears to be tonically active and is excitatory to the antigravity muscles, including the epaxial muscles of the vertebral column and the extensor muscles of the lower limbs.

On the other hand, the medullary reticulospinal tract is inhibitory to antigravity muscles. The cells of origin of the medullary reticulospinal tract receive input from the corticospinal tract and the rubrospinal

Fig. 20.18 The vestibulospinal tracts. (Redrawn with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins.)
tract. The reticulospinal tracts normally function in a coordinated, balanced fashion to control muscle tone. However, if the descending control from higher centres is lost, such as occurs after a stroke in the internal capsule, then the natural excitability of the pontine reticulospinal tract, combined with the activity of the vestibulospinal tracts, causes the antigravity muscles to become hypertonic and hyperreflexic (spasticity) (Guyton and Hall 2006).

## Interstitiospinal tract

The interstitiospinal tract arises from neurones in the interstitial nucleus (of Cajal) and the immediate surrounding area, and descends via the medial longitudinal fasciculus into the ventral funiculus of the spinal cord. Its fibres project, mainly ipsilaterally, as far as lumbosacral levels, and are mostly distributed to the dorsal part of lamina VIII and the dorsally adjoining part of lamina VII. They establish some monosynaptic connections with motor neurones supplying neck muscles, but their main connections are disynaptic with motor neurones supplying limb muscles.

## Solitariospinal tract

The solitariospinal tract is a small group of mostly crossed fibres that arises from neurones in the ventrolateral part of the nucleus solitarius of the medulla. Descending in the ventral funiculus and ventral part of the lateral funiculus of the cord, these axons terminate on phrenic motor neurones supplying the diaphragm and thoracic motor neurones that innervate intercostal muscles. A pathway with somewhat similar course and terminations to that of the solitariospinal tract originates from the nucleus retroambiguus. Both pathways subserve respiratory activities by driving inspiratory muscles, and some descending axons from the nucleus retroambiguus facilitate expiratory motor neurones. There is clinical evidence that bilateral ventrolateral cordotomy at high cervical levels abolishes rhythmic ventilatory movements.

## Hypothalamospinal fibres

Hypothalamospinal fibres exist in animals. They arise from the paraventricular nucleus and other areas of the hypothalamus, and descend ipsilaterally, mainly in the dorsolateral region of the cord, to be distributed to sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. Fibres from the paraventricular nucleus show oxytocin and vasopressin immunoreactivity. They are also distributed to laminae I and X. Descending fibres from the dopaminergic cell group (A11) situated in the caudal hypothalamus innervate sympathetic preganglionic neurones and neurones in the dorsal horn. That similar pathways exist in humans may be inferred from ipsilateral sympathetic deficits (e.g. Horner's syndrome), which follow lesions of the hypothalamus, the lateral tegmental brainstem, or the lateral funiculus of the cord.

## Monoaminergic spinal pathways

Monoaminergic cell groups utilize dopamine, adrenaline (epinephrine), noradrenaline (norepinephrine) and 5-HT as neurotransmitters. They occur widely throughout the brainstem and in the hypothalamus. They project rostrally to many forebrain areas and caudally to the spinal cord, and appear to be concerned with the modulation of sensory transmission, and the control of autonomic and somatic motor neuronal activities.

The projections to the spinal cord arise from several sources. Coeruleospinal projections originate from noradrenergic cell groups A4 and A6 in the locus coeruleus complex in the pons and descend via the ventrolateral white matter to innervate all cord segments bilaterally. They end in the dorsal grey matter (laminae IV-VI) and the intermediate and ventral horns. They also project extensively to preganglionic parasympathetic neurones in the sacral cord. Descending noradrenergic fibres, which arise from the lateral tegmental cell groups A5 and A7 of the pons, travel in the dorsolateral white matter. They are distributed to laminae I-III, and particularly to the intermediate grey horn. Descending fibres from adrenergic cell groups C1 and C3 of the medulla oblongata have been traced into the ventral funiculus of the cord and are extensively distributed to the intermediolateral column. Dopaminergic fibres projecting to the spinal cord travel in the hypothalamospinal pathway.

The raphe nuclei pallidus (B1), obscurus (B2) and magnus (B3) in the brainstem give rise to two serotoninergic descending bundles. The lateral raphe spinal bundle, from B3 neurones, is concerned with the control of nociception. It descends close to the lateral corticospinal tract and ends in the dorsal horn (laminae I, II and V). The ventral bundle, composed mainly of axons from B1 neurones, travels in the medial part of the ventral white column and ends in the ventral horn (laminae VIII and IX). It facilitates extensor and flexor motor neurones. Some descending serotoninergic fibres project to sympathetic preganglionic neurones and are concerned with the central control of cardiovascular function.

## Propriospinal pathways

Propriospinal pathways (fasciculi proprii) consist of the ascending and descending fibres of intrinsic spinal neurones. They contact other neurones within the same segment and/or in more distant segments of the spinal cord and so subserve intrasegmental and intersegmental integration and coordination. The majority of spinal neurones are propriospinal neurones, most of which lie in laminae V-VIII. Propriospinal fibres are mainly concentrated around the margins of the grey matter (see Fig. 20.9), but are also dispersed diffusely in the white funiculi.

The propriospinal system plays important roles in spinal functions. Descending pathways end on specific subgroups of propriospinal neurones and these, in turn, relay to motor neurones and other spinal neurones. The system mediates all those automatic functions that
continue after transection of the spinal cord, e.g. sudomotor and vasomotor activities, and bowel and bladder functions.

Some propriospinal axons are very short and span only one segment, while others run the entire length of the cord. The shortest axons lie immediately adjacent to the grey matter and the longer ones are situated more peripherally. Propriospinal neurones can be categorized according to the length of their axons as long, intermediate or short neurones. Long propriospinal neurones distribute their axons throughout the length of the cord, mainly via the ventral and lateral funiculi; their cell bodies are in lamina VIII and the dorsally adjoining part of lamina VII. Axons from the long propriospinal neurones of the cervical cord descend bilaterally, whereas those from the corresponding lumbosacral neurones ascend mainly contralaterally. Most of the fibres are fine (less than $3 \mu \mathrm{~m}$ in diameter). Some are the first spinal tract axons to become myelinated. Intermediate propriospinal neurones occupy the central and medial parts of lamina VII and project mainly ipsilaterally. Short propriospinal neurones are found in the lateral parts of laminae V-VIII and their axons run ipsilaterally in the lateral funiculus.

Propriospinal fibres in the different parts of the white funiculi are distributed preferentially to specific regions of the spinal grey matter. In the spinal enlargements, the propriospinal fibres in the dorsolateral funiculus project to the dorsal and lateral parts of the intermediate zone, and also to spinal motor neurones that supply distal limb muscles, especially those of the hand and the foot. The propriospinal fibres in the ventral part of the ventrolateral funiculus are distributed to the central and medial parts of lamina VII and to motor neurones of proximal limb and girdle muscles. Other propriospinal fibres run in the medial part of the ventral funiculus and travel mainly to the ventromedial part of the intermediate zone, which characteristically contains long propriospinal neurones, and to motor neurones innervating axial and girdle muscles.

## The tract of Lissauer

The tract of Lissauer (dorsolateral tract) lies between the apex of the dorsal horn and the surface of the spinal cord, where it surrounds the incoming dorsal root fibres. It is present throughout the spinal cord and is most developed in the upper cervical regions.

The tract consists of fine myelinated and unmyelinated axons. Many are the branches of axons in the lateral bundles of the dorsal roots. These axons bifurcate into ascending and descending branches as they enter the cord. The branches travel in the tract of Lissauer for one or two segments and give off collaterals that end on and around neurones in the dorsal horn. The tract also contains propriospinal fibres, some being short axons of small substantia gelatinosa neurones, which re-enter the dorsal horn.

## SPINAL REFLEXES

The intrinsic connections of the spinal cord and brainstem subserve a number of reflexes by which the functions of peripheral structures are modulated in response to afferent information in a relatively automatic or autonomous fashion. The fundamental components of such reflex 'arcs' are an afferent and an efferent neurone, although in all but the simplest of reflexes, interneurones intervene between the afferent and efferent components, conferring increased versatility and complexity on reflex responses. Reflexes may be confined to a single cord level (intrasegmental) or involve several cord segments (intersegmental). Reflexes, by their very nature, are relatively fixed and stereotyped in form. Nevertheless, they are strongly influenced and modulated by descending connections. In the case of spinal reflexes, these descending controls come from both the brainstem and the cerebral cortex. Pathology of descending supraspinal pathways commonly causes abnormalities of spinal reflex activity, which are routinely tested for in neurological examination; reflexes may be absent (areflexia), diminished (hyporeflexia) or exaggerated (hyperreflexia). During development, descending control mechanisms suppress what may be regarded as 'primitive' spinal reflex responses, such as the extensor plantar reflex and the grasp reflex. When the higher control mechanisms become damaged, these reflexes are released and reappear as a sign of central nervous system pathology (e.g. the Babinski reflex).

## Muscle stretch reflex

The muscle stretch reflex (also known as the tendon reflex or deep tendon reflex) is the mechanism by which stretch applied to a muscle elicits its reflex contraction. It is essential for the maintenance of both muscle tone and an upright stance (via the innervation of the postural muscles of the neck, back and lower limbs). Anatomically it is the simplest of reflexes, since it is mediated solely by an afferent and an

Fig. 20.19 The pathway for the patellar tendon reflex and reciprocal inhibition (left) and autogenic inhibition (right). The inhibitory glycinergic interneurones are represented by the red open cell bodies. (Redrawn with permission from Haines D, Fundamental Neuroscience for Basic and Clinical Applications, 4th Edition, 2013, Saunders, Elsevier.)
efferent neurone, and it is therefore also known as a monosynaptic stretch reflex or a myotactic reflex. The afferent component arises from stretch receptors associated with intrafusal muscle fibres located within muscle spindles. The primary or anulospiral endings of these receptive cells give rise to primary afferent fibres that enter the spinal cord, where they make excitatory synaptic contact directly on to $\alpha$ motor neurones innervating the same muscle (Fig. 20.19). The $\alpha$ motor neurones of antagonistic muscles are simultaneously inhibited via collateral connections to inhibitory interneurones (reciprocal innervation).

## Gamma reflex

As well as $\alpha$ motor neurones innervating extrafusal muscle fibres, muscles also receive $\gamma$ motor neurones, which innervate intrafusal muscle fibres. Activation of $\gamma$ motor neurones increases the sensitivity of the intrafusal fibres to stretch; changes in $\gamma$ activity have a profound effect on the stretch reflex and on muscle tone. Like $\alpha$ motor neurones, $\gamma$ motor neurones are under the influence of descending pathways from the brainstem and cerebral cortex. Changes in muscle tone and in the activity of the stretch reflex are commonly found in disorders of the central nervous system as well as the peripheral nervous system.

## Flexor reflex and crossed extensor reflex

Painful stimulation of the limbs leads to flexion withdrawal, mediated by a polysynaptic reflex (Fig. 20.20) in which interneurones link the afferent and efferent neurones. Thus, activation of nociceptive primary afferents indirectly causes activation of limb flexor motor neurones. Collateralization of fibres to nearby spinal segments mediates flexion of a limb at several joints, depending on the intensity of the stimulus. Decussating connections to the contralateral side of the cord activate $\alpha$ motor neurones innervating corresponding extensor muscles, which produces a crossed extensor reflex (Fig. 20.21). In principle, virtually any cutaneous stimulus has the potential to induce a flexor reflex but, other than in the case of noxious stimuli, this response is normally inhibited by descending pathways. When descending influences are lost, even harmless cutaneous stimulation can elicit flexion of the limbs. The Babinski (extensor plantar) reflex, which is generally regarded as pathognomonic of damage to the corticospinal tract, is part of a flexion withdrawal of the lower limb in response to stimulation of the sole of the foot.

Fig. 20.20 The pathway for the flexor reflex. The inhibitory glycinergic interneurone is represented by the red open cell and the excitatory glutaminergic interneurone by the green closed cell. In addition to being involved in reflexes, this nociceptive input is also relayed to higher levels of the neuraxis via the anterolateral system (ascending black fibre). (With permission from Haines D, Fundamental Neuroscience for Basic and Clinical Applications, 4th Edition, 2013, Saunders, Elsevier.)

## SPINAL CORD LESIONS

Mechanical compression and secondary ischaemic damage to underlying nervous tissue cause surgically relevant spinal cord disease (myelopathy). The site and the level of damage to the cord determine the particular clinical syndrome, e.g. whether the lesion involves the upper or lower cervical, thoracic or lumbosacral spinal cord. At each of these levels, symptoms and signs are determined by direct destruction of segmental tissue, i.e. transversely distributed damage, and disconnection of suprasegmental ascending and descending tracts above and below the level of a lesion, i.e. longitudinally distributed damage (Fig. 20.22). For example, a lower cervical spinal cord lesion damages the segmental sensory and motor contributions to the nerve roots and brachial plexus, causing sensory loss, weakness and wasting of the muscles and loss of tendon reflexes in the upper limbs. Disruption of the ascending sensory pathways in the lateral and dorsal columns of the cervical spinal cord leads to loss of sensation to pain and temperature (lateral spinothalamic tracts) and touch and proprioception (dorsal columns) below the 'sensory level' corresponding to the segment of the spinal cord. Damage to the descending corticospinal tracts in the lateral columns of the spinal cord produces a spastic paraparesis, i.e. increased tone of the muscles, weakness that is of an upper motor neurone pattern (weakness of extensors more than flexors in the upper limbs; weakness of flexors more than extensors in the lower limbs), exaggerated tendon reflexes and abnormal superficial reflexes, e.g. extensor plantar responses

Fig. 20.21 The pathway for the crossed extensor reflex. Glycinergic interneurones (inhibitory) are represented by the open red cell bodies and glutaminergic interneurones (excitatory) by the closed green cells. (Redrawn with permission from Haines D, Fundamental Neuroscience for Basic and Clinical Applications, 4th Edition, 2013, Saunders, Elsevier.)
and absent abdominal reflexes. Descending pathways to the bladder are interrupted and this produces a 'neurogenic bladder'.

The same principles apply to lesions at other levels of the spinal cord and they are illustrated in Figure 20.22.

The time course of spinal cord disease is very important in suggesting the likely cause, as the rate of evolution of a disorder varies depending on the aetiology. Disorders with sudden or rapid onset are usually caused by trauma or by a vascular accident (i.e. stroke). When a condition develops over days it is often due to an inflammatory disorder such as multiple sclerosis. Neoplastic lesions such as a spinal cord meningioma often progress over months. Degenerative problems usually progress over months (such as amyotrophic lateral sclerosis or motor neurone disease) or even years (e.g. hereditary spastic paraparesis).

In the online supplementary data there are case histories that illustrate typical patterns of spinal cord disease (Boxes 20.1-20.5). A good knowledge of spinal cord anatomy is vital in making the correct diagnosis.

## Bonus e-book image

Fig. 20.5 The basic arrangement of the sensory 'gate' mechanism in the dorsal laminae of the grey matter of the spinal cord.

## Box 20.1 Case history 1: Complete transection of the spinal cord

A 29-year-old man fractured his cervical spine after a road traffic accident, leading to transection of the spinal cord at C5. When examined 6 months later, he had paralysis of all four limbs but shoulder abduction and elbow flexion were spared (i.e. all muscles innervated by nerve fibres arising below C5 were paralysed). Tone was increased in the limbs with brisk reflexes and extensor plantar responses (i.e. the weakness was upper motor neurone or pyramidal weakness). He had complete loss of sensation below C5 and a neurogenic bladder.

Box 20.2 Case history 2: Hemisection of the spinal cord giving rise to the Brown-Séquard syndrome

A 20-year-old woman presented with a 4-day history of gradually worsening right leg weakness, burning pain and loss of sensation in the left leg. On examination she had pyramidal pattern weakness of the right leg (i.e. hip and knee flexion and ankle dorsiflexion were mainly affected). Tone was increased in the right leg: there were brisk right leg reflexes and a right extensor plantar response (i.e. right pyramidal weakness). There was impaired proprioception in the right leg. The patient had reduced pinprick sensation affecting the left leg and side up to the umbilicus.

This case illustrates a Brown-Séquard syndrome resulting from hemisection of the cord caused by a right-sided cord lesion in the thoracic spine. Involvement of the pyramidal tract causes pyramidal weakness below the level of the lesion on the same side as the lesion (because the pyramidal tract crosses in the medulla). Involvement of the dorsal columns causes impaired proprioception below the level of the lesion on the same side as the lesion (because the fibres in the dorsal columns also cross in the medulla). Involvement of the spinothalamic tract causes loss of pinprick sensation below the lesion on the contralateral side (because the spinothalamic tract crosses the midline soon after entering the cord). The progression of symptoms over several days suggests an inflammatory problem. Magnetic resonance imaging of the cord showed a right-sided area of cord inflammation (myelitis) at T10. The patient had previously had an episode of inflammation affecting the optic nerve (optic neuritis) and the diagnosis was therefore one of multiple sclerosis.

## Box 20.3 Case history 3: Anterior cord syndrome

A 75-year-old man with diabetes and hypertension presented with sudden onset of weakness and sensory disturbance in both legs. When examined 6 months later, he had pyramidal weakness of both legs with increased tone, brisk reflexes and extensor plantar responses, and a complete loss of pinprick sensation below T10. Proprioception was normal.

The acute onset suggested a vascular problem. The diagnosis was one of an anterior spinal artery infarction. Proprioception was spared because the anterior spinal artery supplies only the anterior cord, whereas the posterior cord, including the dorsal columns, is supplied by the posterior spinal arteries, and so was spared.

## Box 20.4 Case history 4: Posterior cord syndrome

A 73-year-old man presented with a 6-month history of unsteadiness on walking. When examined, he had an unsteady gait, a tendency to fall when asked to stand still with his eyes closed (positive Romberg's test), and impaired proprioception in all four limbs. Spinothalamic sensation (pinprick sensation) was intact and his power was normal.

Investigations revealed signal change in the posterior cervical cord on magnetic resonance imaging and his vitamin $B_{12}$ levels were very low. A diagnosis of posterior cord syndrome secondary to $B_{12}$ deficiency was made. Posterior cord syndromes involve the dorsal columns, leading to impaired proprioception. Although not illustrated in this case, $\mathrm{B}_{12}$ deficiency sometimes affects the corticospinal tract, causing weakness in the limbs, and may also sometimes affect the peripheral nerves.

## Box 20.5 Case history 5: Central cord syndrome

A 20-year-old woman presented with a 4-month history of painless injuries to her hands. For example, after gardening she would sometimes come inside and notice later that there were rose thorns sticking into her hands. Examination showed reduced pinprick sensation (spinothalamic sensation) over the upper limbs.

Magnetic resonance imaging of her cervical spine showed a collection of fluid in the centre of the cervical spinal cord (syringomyelia). A diagnosis of central cord syndrome secondary to syringomyelia was made. As spinothalamic tract fibres cross over from the dorsal horn to run in the contralateral spinothalamic tract, they pass very close to the centre of the cord. Central cord syndromes thus initially damage the spinothalamic tracts, resulting in altered pain sensation at the level of the lesion. As the lesion expands to involve the ventral horns, patients may develop lower motor neurone weakness of the upper limbs. They may subsequently experience upper motor neurone problems in the legs if the lesion expands further to involve the corticospinal tracts.

A high cervical cord lesion causes spastic tetraplegia with hyperreflexia, extensor plantar responses (upper motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.

Lower cervical cord lesion
A lower cervical cord lesion causes weakness, wasting and fasciculation of muscles and areflexia of the upper limbs (lower motor neurone lesion). In addition, there is spastic paraparesis, hyperreflexia and extensor plantar responses (upper motor neurone lesion) in the lower limbs, incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.

A thoracic cord lesion causes a spastic paraparesis, hyperreflexia and extensor plantar responses (upper motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.
Fig. 20.22 Lesions of the spinal cord. Continued

Lumbar cord lesion
A lumbar cord lesion causes weakness, wasting and fasciculation of muscles, areflexia of the lower limbs (lower motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.

This is characterized by ipsilateral loss of proprioception and upper motor neurone signs (hemiplegia/monoplegia) plus contralateral loss of pain and temperature sensation.

## Brainstem

The brainstem consists of the medulla oblongata, pons and midbrain. It is situated in the posterior cranial fossa, and its ventral surface lies on the clivus. It contains numerous intrinsic neuronal cell bodies and their processes, some of which are the brainstem homologues of spinal cell groups. Some brainstem cell groups are the nuclei of cranial nerves and are concerned with the sensory, motor and autonomic innervation of the head and neck. Other autonomic (visceromotor) fibres that arise from the brainstem are distributed widely within the thorax and abdomen via branches of the vagus nerve. The brainstem also contains a complex and sometimes ill-defined network of neurones, known as the reticular formation (Haines 2013, Olszewski and Baxter 1954), which extends throughout its length, and is continuous caudally with its spinal counterpart. Some reticular nuclei are referred to as vital centres because they are concerned with regulation of cardiac and respiratory activities; other parts of the reticular formation are essential for cerebral cortical arousal and the maintenance of consciousness, or are involved in the regulation of muscle tone, posture and reflex activities. The brainstem is the site of origin and/or termination of numerous ascending and descending fibres and is traversed by many others. The anterolateral system (spinal lemniscus), medial lemniscus and the trigeminothalamic tracts all ascend through the brainstem to reach the thalamus. Prominent corticospinal projections descend through the brainstem and corticonuclear projections end within it.

Damage to the brainstem is often devastating and life-threatening (Posner et al 2007). This is because it is a structurally and functionally compact region, where even small lesions can destroy vital centres (cardiac and respiratory), disconnect forebrain motor areas from brainstem and spinal motor neurones, and sever incoming sensory fibres from higher centres of consciousness, perception and cognition. Irreversible cardiac and respiratory arrest follows complete destruction of the neural respiratory and cardiac centres in the medulla. Clinically, this is part of a complex event called brain death (cerebral death), a condition that includes cessation of brainstem function. Accurate diagnosis is essential because brainstem death may occur in patients whose respiratory and cardiac functions may be artificially maintained indefinitely on life support.

## THE BRAINSTEM IN A CLINICAL CONTEXT

The advent of computed tomography (CT) and magnetic resonance imaging (MRI) has revolutionized clinical medicine and forever altered how we look at the brainstem in an educational setting. This is especially the case when the goal is to teach neuroanatomical concepts in a manner most applicable to the way in which these concepts are viewed and used in the clinical environment.

The time-honoured approach to teaching brainstem neurobiology is in an anatomical orientation, where dorsal/posterior is 'up' in the image and ventral/anterior is 'down' (Figs 21.1-21.2). Location of internal structures and the arrangement of somatotopic maps follow accordingly. Learning neuroanatomy in this orientation is correct but may not be the most appropriate for the clinical setting. Moreover, there is no standard of laterality in brainstem images viewed anatomically; the observer's right may be either the right or the left side. These inconsistencies disappear when the brainstem is taught using a clinical orientation: the shape of the image (stained section or line drawing) matches that of the corresponding MRI or CT (see Figs 21.1-21.2); the orientation of all images, irrespective of their source (stained section, drawing, CT, MRI), is the same, i.e. the observer's right is the patient's left and the observer's left is the patient's right; and so the concept of laterality, which is enormously important in diagnosis, is reinforced for the student. When learned in a clinical orientation, somatotopically organized tracts and pathways map exactly on to their counterparts in a patient (see Fig. 21.1). In recognition of the inherent value of contextualizing neuroanatomical concepts within clinical reality, examples will be integrated into this chapter.

## OVERVIEW OF CRANIAL NERVES AND CRANIAL NERVE NUCLEI

The cranial nerves are the routes by which the brain receives information directly from, and controls the functions of, structures that are located mainly, although not exclusively, within the head and neck. All but 3 of the 12 pairs of cranial nerves are regarded as being attached to the brainstem, the exceptions being the olfactory, optic and accessory nerves.

The cranial nerves are individually named and numbered, using Roman numerals, in a rostro-caudal sequence, reflecting their order of attachment to the brain (Haines 2015) (see Table 16.1). The olfactory nerve (I) arises from the olfactory epithelium in the nasal cavity and terminates directly in cortical and subcortical areas of the frontal and temporal lobes; it is closely associated functionally with the limbic system and is described in that context. The axons of the optic nerve (II) pass into the optic chiasma, where medially positioned axons decussate; all of the axons emerge as the optic tract, which terminates in
the lateral geniculate nucleus of the thalamus (the visual pathways are discussed in Ch. 42). The oculomotor (III) and trochlear (IV) nerves arise in, and are attached to, the midbrain. The trigeminal nerve (V) attaches to the pons, medial to the middle cerebellar peduncle. The abducens (VI), facial (VII) and vestibulocochlear (VIII) nerves attach to the brainstem at, or close to, the pontomedullary junction. The glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves all attach to the medulla. The accessory nerve (XI) arises from cervical levels C1-C5/ C6, enters the cranium through the foramen magnum and then exits via the jugular foramen, together with the glossopharyngeal and vagus nerves.

Cranial nerves III-X and XII are associated with brainstem cell groupings referred to collectively as the cranial nerve nuclei (Fig. 21.3). The latter are either the origin of efferent cranial nerve fibres or the site of termination of cranial nerve or descending cerebral cortical afferents. They are considered to be organized into six discontinuous longitudinal cell columns corresponding to columns that may be identified in the embryo (see Fig. 16.1). Three columns are 'sensory' and three are 'motor' in function.

For well over a century，the accessory nerve has been described as having two roots：a cranial root composed of a variable number of small rootlets that emerge from the postolivary groove of the dorsolateral medulla，caudal to the rootlets of the vagus，and a spinal root composed of fibres derived from the cervical segments of the spinal cord．Accord－ ing to this description，the cranial rootlets carry axons of motor neu－ rones located in the caudal part of the nucleus ambiguus，and the spinal rootlets carry axons of motor neurones located in a nucleus in the ventral horn of the cervical spinal cord in line with the nucleus ambig－ uus（Ch．18）．The spinal root ascends the vertebral canal and enters the skull via the foramen magnum．The cranial and spinal roots join，either before or within the jugular foramen，and the bundle so formed then divides into internal and external branches on leaving the jugular foramen．The internal branch joins the vagus nerve and its fibres inner－ vate branchiomeric muscles via the pharyngeal and laryngeal branches of the vagus nerve．The external branch descends into the neck to inner－ vate sternocleidomastoid and the upper and middle fibres of trapezius． In recent years，this description has been challenged：the cranial root has been redesignated as anatomically and functionally part of the vagus nerve，and the spinal root has become，de facto，the accessory nerve．The issue is not simply one of contentious anatomical terminol－ ogy；rather，it reflects the need to clarify the relevant microsurgical
anatomy in order to minimize potential complications during surgery in the region．Paradoxically，meticulous cadaveric dissection studies， often undertaken stereomicroscopically，have failed to reach a consen－ sus，finding either no connections between rootlets arising from the dorsolateral medulla and the spinal root of the accessory nerve because the cranial root was absent，or significant variations in the arrangement and size of plexiform connections between the cranial rootlets and the spinal root．Plexiform interconnections between neighbouring cranial nerves are not uncommon and are certainly not confined to the acces－ sory and vagus nerves（Shoja et al 2014）；their functional significance is often uncertain．（For further reading，see Krammer et al（1987）， Lachman et al（2002），Ryan et al（2007），Wiles et al（2007），Benninger and McNeil（2010），Skinner（2011），Liu et al（2014），Tubbs et al（2014）．）

In addition to the interaction between fibres of the corticospinal and rubrospinal systems at the spinal level，there is yet another factor that relates to the functional characteristics described above．Experimental lesions in primates that target either of these tracts are usually stereo－ taxically placed，damaging very specific fibre populations．On the other hand，spontaneous lesions in humans invariably damage，in addition to corticospinal axons，other axon populations that directly，or indi－ rectly，influence spinal alpha motor neurones．This is also a major contributor to the differential results seen in primates versus humans．

The sensory nucleus of the trigeminal nerve, which extends throughout the length of the brainstem and into the cervical spinal cord, represents a general somatic afferent cell column (Haines 2013, Haines 2015, Olszewski 1950). Its principal afferents are carried in the trigeminal nerve. General visceral afferents carried by the facial, glossopharyngeal and vagus nerves end in the nucleus solitarius of the medulla. The special somatic afferent column corresponds to the vestibular and cochlear nuclei, which are located beneath the vestibular area of the floor of the fourth ventricle.

The general somatic efferent cell column consists of four nuclei that lie near the midline and give rise to motor fibres that run in nerves of the same name. From rostral to caudal, these are the oculomotor, trochlear and abducens nuclei, which innervate the extraocular muscles, and the hypoglossal nucleus, which innervates all but one of the muscles of the tongue. The general visceral efferent, or parasympathetic, cell column is made up of the Edinger-Westphal preganglionic nucleus of the midbrain, the salivatory nuclei of the pons, and the vagal nucleus of the medulla. Cells in the special visceral efferent column innervate muscles derived from the branchial arches and lie in the trigeminal motor nucleus, the facial nucleus and the nucleus ambiguus.

## MEDULLA OBLONGATA

## EXTERNAL FEATURES AND RELATIONS

The medulla oblongata extends from just above the first pair of cervical spinal nerves to the lower border of the pons (Haines 2013). It is approximately 3 cm in length and 2 cm in diameter at its widest. The ventral surface of the medulla is separated from the basilar part of the occipital bone and apex of the dens by the meninges and occipito-axial ligaments. Caudally, the dorsal surface of the medulla is adjacent to the cisterna magna, a subarachnoid cistern between the cerebellar hemispheres.

The ventral and dorsal surfaces of the medulla (Figs 21.4-21.5) possess a longitudinal median fissure and sulcus, respectively, which are continuous with their spinal counterparts. Caudally, the ventral (anterior) median fissure is interrupted by the obliquely crossing fascicles of the motor decussation (pyramidal decussation). Rostrally, it ends at the pontine border in a diminutive depression, the foramen caecum. A prominent elongated ridge, the pyramid, which contains descending corticospinal axons, lies immediately lateral to the ventral median fissure. The lateral margin of the pyramid is indicated by a shallow ventrolateral sulcus. A linear series of rootlets forming the hypoglossal nerve emerge from this sulcus in line with the ventral spinal nerve roots. The abducens nerve emerges at the caudal border of the pons generally in line with the rootlets of the hypoglossal nerve. Caudally, most fibres of the pyramid taper, decussate and enter the lateral funiculus of the spinal cord. Lateral to the pyramid and the ventrolateral sulcus is an oval prominence, the olive (see Fig. 21.4), which contains the inferior olivary nuclear complex. The posterolateral sulcus is lateral to the olive; the glossopharyngeal and vagus nerves join the brainstem along the line of this sulcus, in line with the dorsal spinal nerve roots.

The spinal central canal extends into the caudal half of the medulla, migrating progressively more dorsally until it opens out into the lumen of the fourth ventricle at the obex. This divides the medulla into a closed part, which contains the central canal, and an open part, which contains the caudal half of the fourth ventricle (see Fig. 21.5).

In the closed part of the medulla, a shallow dorsal intermediate sulcus, on either side of the dorsal median sulcus, is continuous with its cervical spinal counterpart and indicates the location of the dorsal (posterior) columns (fasciculi gracilis and cuneatus). The ascending fasciculi are parallel to each other, but in the caudal medulla they diverge slightly to end in elongated swellings, the gracile and cuneate tubercles, produced by the subjacent nuclei gracilis and cuneatus respectively (see Fig. 21.5; Figs 21.6-21.7). Most fibres in the fasciculi synapse with neurones in their respective nuclei. The latter project to the contralateral thalamus, which, in turn, projects to the primary somaesthetic cortex (see Fig. 20.10). The restiform body lies dorsolaterally in the medulla, forming a rounded ridge between the caudal part of the fourth ventricle and the glossopharyngeal and vagal rootlets on each side. It contains a wide variety of fibres (dorsal spinocerebellar, cuneocerebellar, olivocerebellar, reticulocerebellar, and other cerebellar afferents) (see Fig. 21.9). The restiform bodies on the two sides diverge and incline to enter the cerebellar hemispheres as the major component of the inferior cerebellar peduncles. They are crossed at this point by the striae medullares, which run medial to lateral on the ventricular floor (see Fig. 21.5). Usually, each inferior cerebellar peduncle also contains a

Fig. 21.4 The ventral aspect of the brainstem. Key: 1, infundibulum; 2, tuber cinereum; 3, mammillary body; 4, basilar pons; 5 , abducens nerve; 6, foramen caecum; 7, olive; 8, glossopharyngeal nerve; 9, vagus nerve; 10 , rootlets of hypoglossal nerve; 11, accessory nerve; 12, olfactory tract; 13 , optic nerve; 14, optic chiasma; 15, optic tract; 16, oculomotor nerve; 17, uncus; 18, trochlear nerve; 19, trigeminal nerve; 20, facial nerve; 21, vestibulocochlear nerve; 22, flocculus; 23, pyramid; 24, motor decussation (decussation of pyramids).
small contribution from the juxtarestiform body (long Purkinje cell axons and efferents from the fastigial nuclei that traverse the vestibular nuclei; see Fig. 21.12). The inferior cerebellar peduncles form the anterior and rostral boundaries of the lateral recesses of the fourth ventricle; these are continuous with the subarachnoid space through the lateral apertures of the fourth ventricle (foramina of Luschka). A tuft of choroid plexus, continuous with that of the fourth ventricle, protrudes from the foramina on either side.

## INTERNAL ORGANIZATION

## Transverse section of the medulla at the level of the motor (pyramidal) decussation

A transverse section of the lower medulla oblongata (see Fig. 21.6) intersects the dorsal, lateral and ventral funiculi, which are continuous with their counterparts in the spinal cord. The ventral funiculi are separated from the central grey matter by corticospinal fibres, which cross in the motor (pyramidal) decussation to reach the contralateral lateral funiculi (see Fig. 21.16). The decussation displaces the central grey matter and central canal dorsally (Haines 2015). Continuity between the ventral grey column and central grey matter, which is maintained throughout the spinal cord, is lost. The column subdivides into the supraspinal nucleus (continuous above with that of the hypoglossal nerve), which is the efferent source of the first cervical nerve, and the nucleus of the accessory nerve, which is in line rostrally with the nucleus ambiguus.

Fig. 21.5 The dorsal aspect of the brainstem. The floor of the fourth ventricle has been exposed by cutting the cerebellar peduncles and removing the cerebellum. (With permission from Neuroanatomy by FA Mettler (1948) 2nd edn; St Louis: The CV Mosby Company.)

Fig. 21.6 A transverse section through the medulla oblongata at the level of the motor decussation. Figures 21.6-21.8, 21.10-21.12 and 21.15-21.16 are all prepared using a stain for myelinated nerve fibres (blue).

Fig. 21.7 A transverse section through the medulla oblongata at the level of the sensory decussation.

The dorsal grey column is also modified at this level as the nucleus gracilis appears in the ventral part of the fasciculus gracilis. The nucleus gracilis begins caudal to the nucleus cuneatus; the latter invades the fasciculus cuneatus from its ventral aspect in similar fashion.

The spinal nucleus and tract of the trigeminal nerve are visible ventrolateral to the dorsal columns and are continuous with the substantia gelatinosa and tract of Lissauer of the spinal cord.

## Transverse section of the medulla at the level of the sensory decussation of the dorsal column-medial lemniscus system

The medullary white matter is rearranged above the level of the motor decussation (see Fig. 21.7). The pyramids form two large ventral bundles flanking the ventral median fissure on the ventral surface of the medulla; they contain corticospinal fibres of ipsilateral origin.

The nucleus gracilis is prominent on the dorsal medullary aspect, with diminishing numbers of fibres of the fasciculus gracilis located on its margins. The nucleus cuneatus is well developed. Both nuclei retain continuity with the central grey matter at this level but this is lost more rostrally. First-order afferent fibres contained within the fasciculi gracilis and cuneatus synapse on neurones in their respective nuclei (Millar and Basbaum 1975). Second-order axons emerge from the nuclei as internal arcuate fibres, at first curving ventrolaterally around the central grey matter and then ventromedially between the spinal tract of the trigeminal nerve and the central grey matter. The fibres decussate in the midline, as the sensory decussation, and thereafter form the medial lemniscus, which ascends to the thalamus (Haines 2012). The decussation of these internal arcuate fibres is located dorsal to the pyramids and ventral to the central grey matter, which is therefore more dorsally displaced than in the previous section.

The medial lemniscus ascends from the sensory decussation as a flattened tract near the median raphe. The pyramidal tract lies ventrally, and the medial longitudinal fasciculus and the tectospinal tract lie dorsally. Decussating internal arcuate fibres are rearranged as they cross, so that those derived from the nucleus gracilis lie ventral to those from the nucleus cuneatus. Above this level, the medial lemniscus is further rearranged so that gracile fibres migrate laterally, while cuneate fibres migrate medially. At pontine levels, the medial lemniscus is somatotopically organized with $\mathrm{C} 1-\mathrm{S} 4$ spinal segments represented sequentially from medial to lateral (Nieuwenhuys et al 2008).

The spinal nucleus of the trigeminal nerve is separated from the central grey matter by internal arcuate fibres, and from the lateral medullary surface by the spinal tract of the trigeminal nerve and by some dorsal spinocerebellar tract fibres. The latter progressively incline dor-
sally to enter the restiform body and then the inferior cerebellar peduncle at a higher level.

## Transverse section of the medulla at the caudal end of the fourth ventricle

A transverse section at the caudal end of the fourth ventricle (Fig. 21.8) shows some new features together with most of those already described. The total area of grey matter is increased by the presence of the large inferior olivary nuclear complex and the nuclei of the vestibulocochlear, glossopharyngeal and vagus nerves.

A smooth, oval elevation, the olivary eminence, or olive, lies between the ventrolateral and dorsolateral sulci of the medulla. It is formed by the underlying inferior olivary complex and lies lateral to the pyramid, separated from it by the ventrolateral sulcus and emerging hypoglossal nerve fibres. The roots of the facial nerve emerge between its rostral end and the lower pontine border, in the cerebellopontine angle. The arcuate nuclei are curved, interrupted bands, located on the pyramids, and are said to be displaced pontine nuclei. Arcuatocerebellar fibres and those of the striae medullares are derived from them. They project mainly to the contralateral cerebellum through the inferior cerebellar peduncle (Fig. 21.9).

The inferior olivary complex (dorsal accessory, medial accessory, principal nuclei) is an irregularly crenated mass of grey matter with a medially directed hilum, through which numerous fibres enter and leave the nucleus (Nieuwenhuys et al 2008). It has prominent connections with the cerebellum and is described more fully in Chapter 22.

The central grey matter at this level constitutes the ventricular floor. It contains (sequentially from medial to lateral): the hypoglossal nucleus, dorsal motor nucleus of the vagus, nucleus solitarius, and the caudal ends of the inferior and medial vestibular nuclei.

The tractus and nucleus solitarius extend throughout the length of the medulla. The tract is composed of general visceral afferents from the vagus and glossopharyngeal nerves. The nucleus and its central connections with the reticular formation subserve the reflex control of cardiovascular, respiratory and cardiac functions (Ciriello 1983). The rostral portion of the nucleus solitarius (the gustatory nucleus) receives taste fibres from cranial nerves VII, IX and X. These same cranial nerves send general visceral sensation to the caudal portion of the nucleus solitarius (the cardiorespiratory nucleus).

The medial longitudinal fasciculus is a small compact tract near the midline, ventral to the hypoglossal nucleus. It contains fibre bundles including medial vestibulospinal tract fibres. At this medullary level, it is displaced dorsally by the pyramidal and lemniscal decussations. It ascends in the pons and midbrain, maintaining its relationship to the

Fig. 21.9 Some of the afferent components of the restiform body. The efferent components have been omitted.
central grey matter and midline, and is therefore near the somatic efferent nuclear column. Fibres from a variety of sources course for variable distances in this tract.

The spinocerebellar, spinotectal, vestibulospinal and rubrospinal tracts and the anterolateral system (spinal lemniscal) all lie in the ventrolateral area of the medulla at this level (Nathan and Smith 1982). These tracts are limited dorsally by the spinal tract and nucleus of the trigeminal nerve, and ventrally by the pyramid.

Numerous islets of grey matter are scattered centrally in the ventrolateral medulla, an area intersected by nerve fibres that run in all
directions. This is the reticular formation, which exists throughout the medulla and extends into the pontine tegmentum and midbrain (Olszewski and Baxter 1954).

## Corticospinal (pyramidal) tract

Each pyramid contains descending corticospinal fibres, derived from the ipsilateral cerebral cortex, which have traversed the internal capsule, midbrain and pons (see Fig. 20.16). Some $75-90 \%$ of the axons in the medullary pyramid cross the midline internal to the ventral median fissure as the motor (pyramidal) decussation. In the rostral part of the decussation, fibres cross ventromedially, whereas more caudally they pass dorsally, crossing ventral to the central grey matter. The decussation is orderly: fibres to cervical levels cross in its rostral part, whereas fibres to lumbosacral levels cross in its caudal portion. Fibres continue to pass dorsolaterally as they descend, to reach the contralateral lateral funiculus, where they form the crossed lateral corticospinal tract. A modest number of uncrossed corticospinal fibres descend in the ipsilateral ventral funiculus, as the ventral corticospinal tract, and a smaller uncrossed component joins the lateral corticospinal tracts (see Fig. 20.16). These small, uncrossed fascicles have no significant clinical relevance. The corticospinal tracts display somatotopy at almost all levels. In the pyramids the arrangement is like that at higher brainstem levels in that the lower extremity is represented laterally and the upper extremity is represented medially (Haines 2013, Nieuwenhuys et al 2008). Similar somatotopy is ascribed to the lateral corticospinal tracts within the spinal cord.

## Dorsal column nuclei

The nuclei gracilis and cuneatus, the dorsal column nuclei, are part of the pathway, commonly called the dorsal column-medial lemniscus system, that is the major route for discriminative aspects of tactile and proprioceptive sensation (Haines 2015, Millar and Basbaum 1975, Nieuwenhuys et al 2008). The upper regions of both nuclei are reticular and contain small and large multipolar neurones with long dendrites. The lower regions contain clusters of large, round neurones with short and profusely branching dendrites. Upper and lower zones differ in their connections but both receive terminals from the dorsal spinal roots at all levels. Dorsal funicular fibres from neurones in the spinal grey matter are components of the postsynaptic dorsal column system and terminate only in the superior, reticular zone. Variable ordering and overlap of terminals, on the basis of spinal root levels, occur in both zones. The lower extremity is represented medially, the trunk ventrally and the digits dorsally. There is modal specificity, i.e. lower levels respond to low-threshold cutaneous stimuli, and upper reticular levels to inputs from fibres serving receptors in the skin, joints and muscles. The nucleus cuneatus is divided into several parts. Its middle zone contains a large pars rotunda, in which rostrocaudally elongated, medium-sized neurones are clustered between bundles of densely
myelinated fibres. The reticular poles of its rostral and caudal zones contain scattered, but evenly distributed, neurones of various sizes. The pars triangularis is smaller and laterally placed.

There is a somatotopic pattern of termination of cutaneous inputs from the upper limb on the cell clusters of the pars rotunda. Terminations are diffuse in the reticular poles.

The nucleus gracilis and nucleus cuneatus serve as relays between the spinal cord and higher levels. Primary spinal afferents synapse with multipolar neurones in the nuclei that form the major nuclear efferent projection. The nuclei also contain interneurones, many of which are inhibitory. Descending afferents from the somatosensory cortex reach the nuclei through the corticonuclear tracts, and appear to be restricted to the upper, reticular zones. These afferents both inhibit and enhance activity and are believed to be involved in sensory modulation. The reticular zones also receive connections from the reticular formation.

Neurones of the dorsal column nuclei receive terminals of long, uncrossed, primary afferent fibres of the fasciculi gracilis and cuneatus, which carry information concerning deformation of skin, movement of hairs, joint movement and vibration. Unit recording of the neurones in the dorsal column nuclei shows that their tactile receptive fields (i.e. the skin area in which a response can be elicited) vary in size, although they are especially small for the digits and the face and lips. Some fields have excitatory centres and inhibitory surrounds, which means that stimulation just outside its excitatory field inhibits the neurone. Neurones in the nuclei are spatially organized into a somatotopic map of the periphery (in accord with the similar localization in the dorsal columns). In general, specificity is high. Many cells receive input from one or a few specific receptor types, e.g. hair, type I and II slowly adapting receptors and Pacinian corpuscles, and some cells respond to Ia muscle spindle input. However, some neurones receive convergent input from tactile pressure and hair follicle receptors.

A variety of control mechanisms can modulate the transmission of impulses through the dorsal column-medial lemniscus pathway. Concomitant activity in adjacent dorsal column fibres may result in presynaptic inhibition by depolarization of the presynaptic terminals of one of them. Stimulation of the sensory-motor cortex also modulates the transmission of impulses by both pre- and postsynaptic inhibitory mechanisms, and sometimes by facilitation. These descending influences are mediated by the corticospinal tract. Modulation of transmission by inhibition also results from stimulation of the reticular formation, raphe nuclei and other sites.

The accessory cuneate nucleus, dorsolateral to the cuneate nucleus, is part of the spinocerebellar system of precerebellar relay nuclei (see Fig. 21.9). It contains large neurones like those in the posterior thoracic nucleus (Clarke's column) and receives the lateral fibres of the fasciculus cuneatus, which carry proprioceptive impulses from the upper limb that enter the cervical spinal cord rostral to the thoracic nucleus. The accessory cuneate neurones give rise to the posterior external arcuate
(cuneocerebellar) fibres that enter the cerebellum by the ipsilateral inferior cerebellar peduncle. A group of neurones, nucleus Z , identified in animals between the upper pole of the nucleus gracilis and the inferior vestibular nucleus, is said to be present in the human medulla. Its input is probably from the dorsal spinocerebellar tract, which carries proprioceptive information from the ipsilateral lower limb, and it projects through internal arcuate fibres to the contralateral medial lemniscus.

## Sensory nucleus of the trigeminal nerve

The sensory nucleus of the trigeminal nerve is a large cell group that receives the primary afferents of the trigeminal nerve. It extends caudally into the cervical spinal cord and rostrally into the midbrain; its principal divisions are the spinal trigeminal, principal sensory and mesencephalic nuclei (see Figs 21.10-21.12) (Nieuwenhuys et al 2008; Olszewski 1950).

On entering the pons, the fibres of the sensory root of the trigeminal nerve run dorsomedially towards the principal sensory nucleus, which is situated at this level. Before reaching the nucleus, approximately $50 \%$ of the fibres divide into ascending and descending branches; the others ascend or descend without division. The descending fibres, of which $90 \%$ are less than $4 \mu \mathrm{~m}$ in diameter, form the spinal tract of the trigeminal nerve, which embraces the spinal nucleus of the trigeminal nerve and reaches the upper cervical spinal cord (see Figs 21.6-21.8; Fig. 21.10). There is a precise somatotopic organization within the tract (see Fig. 21.1). Fibres from the ophthalmic division of the trigeminal nerve lie ventrally, those from the mandibular division lie dorsally, and those from the maxillary division lie between. The tract is completed on its dorsal rim by fibres from the sensory roots of the facial, glossopharyngeal and vagus nerves. All of these fibres synapse in the pars caudalis of the spinal nucleus of the trigeminal nerve.

The detailed anatomy of the spinal tract of the trigeminal nerve excited early clinical interest because it was recognized that dissociated sensory loss could occur in the trigeminal area. For example, in Wallenberg's syndrome (lateral medullary syndrome), occlusion of the posterior inferior cerebellar artery (a branch of the vertebral artery) leads to loss of pain and thermal sense on the ipsilateral half of the face with retention of common sensation (Haines 2013). Neurosurgery in this region, as early as the 1890 s, attempted to alleviate paroxysmal trigeminal neuralgia. The introduction of medullary tractotomy confirmed that dissociated thermoanalgesia of the face was associated with destruction of the tract.

There are conflicting opinions on the pattern of termination of the fibres in the spinal nucleus. It has long been held that fibres are organized rostrocaudally within the tract. According to this view, ophthalmic fibres are ventral and descend to the lower limit of the first cervical spinal segment, and maxillary fibres are central and do not extend below the medulla oblongata, whilst mandibular fibres are dorsal and do not

Fig. 21.10 A transverse section through the superior half of the medulla oblongata at the level of the inferior olivary nucleus.
extend much below the mid-medullary level. The results of section of the spinal tract in cases of severe trigeminal neuralgia support this distribution. It was found that a section 4 mm below the obex rendered the ophthalmic and maxillary areas analgesic, but tactile sensibility, apart from the abolition of 'tickle', was much less affected. To include the mandibular area it was necessary to section at the level of the obex.

More recently, it has been proposed that fibres are arranged dorsoventrally within the spinal tract. There appear to be sound anatomicophysiological and clinical reasons for believing that all divisions terminate throughout the whole nucleus, although the ophthalmic division may not project fibres as far caudally as the maxillary and mandibular divisions. Fibres from the posterior face (adjacent to C2) terminate in the lower (caudal) part, whilst those from the upper lip, mouth and nasal tip terminate at a higher level. This can give rise to a segmental (cross-divisional) sensory loss in syringobulbia. Tractotomy of the spinal tract, if carried out at a lower level, can spare the perioral region, a finding that would accord with the 'onion-skin' pattern of loss of pain sensation. However, in clinical practice, the progression of anaesthesia on the face is commonly 'divisional' rather than strictly 'onion-skin' in distribution.

Fibres of the glossopharyngeal, vagus and facial nerves subserving common sensation (general somatic afferent) enter the dorsal region of the spinal tract of the trigeminal nerve and synapse with cells in the caudal part of the spinal nucleus. Consequently, operative section of the dorsal part of the spinal tract results in analgesia that extends to the mucosa of the tonsillar sinus, the posterior third of the tongue and adjoining parts of the pharyngeal wall (supplied by the glossopharyngeal nerve), and the cutaneous areas of the ear. Other afferents that reach the spinal nucleus are from the dorsal roots of the upper cervical nerves and from the sensory-motor cortex.

The spinal nucleus of the trigeminal nerve consists of three parts: the pars oralis (which adjoins the principal sensory nucleus); the pars interpolaris; and the pars caudalis (which is continuous with the dorsal horn of the spinal cord). The pars caudalis is different from the other parts because it has a structure analogous to that of the dorsal horn of the spinal cord, with a similar arrangement of cell laminae (subnuclei zonalis, gelatinosus and magnocellularis), and is involved in trigeminal pain perception. Cutaneous nociceptive afferents and small-diameter muscle afferents terminate in layers I, II, V and VI of the pars caudalis (see Fig. 21.1). Low-threshold mechanosensitive afferents of $A \beta$ neurones terminate in layers III and IV of the pars caudalis and in the rostral (interpolaris, oralis, principal sensory) nuclei.

Many of the neurones in the pars caudalis that respond to cutaneous or tooth-pulp stimulation are also excited by stimulation of jaw or tongue muscles. This indicates that convergence of superficial and deep afferent inputs via wide-dynamic-range or nociceptive-specific neurones occurs in this nucleus. Similar convergence of superficial and deep inputs occurs in the rostral nuclei and may account for the poor localization of trigeminal pain, and for the spread of pain, which often makes diagnosis difficult.

There are distinct subtypes of cells in lamina II. Afferents from 'higher centres' arborize within it, as do axons from nociceptive and low-threshold afferents. Descending influences from these higher centres include fibres from the periaqueductal grey matter and from the nucleus raphe magnus and associated reticular formation.

The nucleus raphe magnus projects directly to the pars caudalis, probably via enkephalin, noradrenaline (norepinephrine) and 5-HT (5-hydroxytryptamine, serotonin)-containing terminals. These fibres directly, or indirectly through local interneurones, influence pain perception. Stimulation of periaqueductal grey matter or nucleus raphe magnus inhibits the jaw-opening reflex to nociception, and may induce primary afferent depolarization in tooth-pulp afferents and other nociceptive facial afferents. Neurones in the pars caudalis can be suppressed by stimuli applied outside their receptive field, particularly by noxious stimuli. The pars caudalis is an important site for relay of nociceptive input and functions as part of the pain 'gate control'. However, rostral nuclei may also have a nociceptive role. Tooth-pulp afferents via wide-dynamic-range and nociceptive-specific neurones may terminate in rostral nuclei, which all project to the subnucleus caudalis.

Most fibres arising in the trigeminal sensory nuclei cross the midline and ascend as trigeminothalamic fibres (trigeminal lemniscus). They end in the contralateral ventral posteromedial thalamic nucleus, from which third-order neurones project to the cortical postcentral gyrus (areas 3, 1, 2). However, some trigeminal nuclear efferents ascend to the ipsilateral ventral posteromedial nucleus.

Fibres from the pars caudalis, especially from laminae I, V and VI, also project to the rostral trigeminal nuclei, cerebellum, periaqueductal grey of the midbrain, parabrachial area of the pons, the brainstem reticular formation and the spinal cord. Fibres from lamina I project to the subnucleus medius of the medial thalamus.

## Vagal nucleus

The vagal nucleus (the dorsal motor nucleus of the vagus) lies slightly dorsolateral to the hypoglossal nucleus, from which it is separated by the nucleus intercalatus. It extends caudally to the first cervical spinal segment and rostrally to the open part of the medulla under the vagal trigone in the floor of the fourth ventricle (see Fig. 21.8).

The vagal nucleus is a general visceral efferent nucleus and is the largest parasympathetic nucleus in the brainstem. Most (80\%) of its neurones give rise to the preganglionic parasympathetic fibres of the vagus nerve. The remainder are interneurones or project centrally. The vagal nucleus innervates the non-striated (smooth, cardiac) muscle of the viscera of the thorax (heart, bronchi, lungs and oesophagus) and abdomen (stomach, liver, pancreas, spleen, small intestine and proximal part of the colon), and glandular epithelium. Neurones within the nucleus are heterogeneous and can be classified into nine subnuclei, which are regionally grouped into rostral, intermediate and caudal divisions. Topographic maps of visceral representation in animals suggest that the heart and lungs are represented in the caudal and lateral part of the nucleus, the stomach and pancreas in intermediate regions, and the remaining abdominal organs in the rostral and medial part of the nucleus.

There is a sparse sensory afferent supply, which arises in the nodose ganglion and projects directly to the nucleus and possibly beyond into the nucleus tractus solitarius.

## Hypoglossal nucleus

The prominent hypoglossal nucleus lies near the midline in the dorsal medullary grey matter. It is approximately 2 cm long. Its rostral part lies beneath the hypoglossal trigone in the floor of the fourth ventricle (see Fig. 21.5) and its caudal part extends into the closed part of the medulla.

The hypoglossal nucleus consists of large motor neurones interspersed with myelinated fibres. It is organized into dorsal and ventral nuclear tiers, each divisible into medial and lateral subnuclei. There is a musculotopic organization of motor neurones within the nuclei that corresponds to the structural and functional divisions of tongue musculature. Thus, motor neurones innervating tongue retrusor muscles are located in dorsal/dorsolateral subnuclei, whereas motor neurones innervating the main tongue protrusor muscle are located in ventral/ ventromedial regions of the nucleus. Although relatively little is known about the organization of motor neurones innervating the intrinsic muscles of the tongue, experimental evidence suggests that motor neurones of the medial division of the hypoglossal nucleus innervate tongue muscles that are orientated in planes transverse to the long axis of the tongue (transverse and vertical intrinsics and genioglossus), whereas motor neurones of the lateral division innervate tongue muscles that are orientated parallel to this axis (styloglossus, hyoglossus, superior and inferior longitudinal).

Hypoglossal fibres emerge ventrally from their nucleus, traverse the reticular formation lateral to the medial lemniscus, pass medial to the inferior olivary nuclei, and curve laterally to emerge as a linear series of 10-15 rootlets in the ventrolateral sulcus between the pyramid and olivary eminence (see Fig. 21.8).

The hypoglossal nucleus receives corticonuclear fibres from the precentral gyrus and adjacent areas of predominately the contralateral hemisphere. They synapse either on motor neurones of the nucleus directly or on interneurones. Evidence indicates that the most medial hypoglossal subnuclei may receive projections from both hemispheres. The nucleus may connect with the cerebellum via adjacent perihypoglossal nuclei, and perhaps also with the medullary reticular formation, the trigeminal sensory nuclei and the nucleus solitarius.

## Inferior olivary nucleus

The olivary nuclear complex consists of a large principal olivary nucleus and smaller medial accessory and dorsal accessory olivary nuclei (see Figs 21.8, 21.10). They are also precerebellar nuclei, a group that includes the pontine, arcuate, vestibular, reticulocerebellar and spinocerebellar nuclei, all of which receive afferents from specific sources and project to the cerebellum. The inferior olivary nucleus contains small neurones, most of which form the olivocerebellar tract, which emerges primarily from the hilum to run medially and intersect the medial lemniscus (see Fig. 21.8). Its fibres cross the midline and sweep either dorsal to, or through, the opposite olivary nuclei. They intersect the lateral spinothalamic and rubrospinal tracts and the spinal nucleus of the trigeminal nerve, and enter the contralateral restiform body (and eventually the inferior cerebellar peduncle), where they constitute its major component. Fibres from the contralateral inferior olivary complex terminate on Purkinje cells in the cerebellum as climbing fibres; there is a one-to-one relationship between Purkinje cells and neurones in the complex (Nieuwenhuys et al 2008). Afferent connections to the inferior olivary nuclei are both ascending and descending. Ascending fibres,

Several smaller groups of cells lie near the hypoglossal nucleus (perihypoglossal nuclei), but none is known for certainty to be connected with the hypoglossal nerve or nucleus. They include the nucleus intercalatus, sublingual nucleus, nucleus prepositus hypoglossi and nucleus paramedianus dorsalis (reticularis). Gustatory and visceral connections are attributed to the nucleus intercalatus.
mainly crossed, arrive from all spinal levels in the spino-olivary tracts and via the dorsal columns. Descending ipsilateral fibres come from the cerebral cortex, cerebellar nuclei, thalamus, red nucleus and central grey of the midbrain. In part, the two latter projections make up the central tegmental tract.

## Nucleus solitarius

The nucleus solitarius (solitary nucleus, nucleus of the solitary tract) lies lateral or ventrolateral to the vagal nucleus (see Fig. 21.8). A neuronal group ventrolateral to the nucleus solitarius has been termed the nucleus parasolitarius. The nucleus solitarius is intimately related to, and receives fibres from, the tractus solitarius, which carries afferent fibres from the facial, glossopharyngeal and vagus nerves (Ciriello 1983, Haines 2013, Hamilton and Norgren 1984). These fibres enter the tract in descending order and convey gustatory information from the lingual and palatal mucosa. They may also convey visceral impulses from the pharynx (glossopharyngeal and vagus) and from the oesophagus and abdominal alimentary canal (vagus). There is some overlap in this vertical representation.

The nucleus solitarius is thought to project to the sensory thalamus and thence to the cerebral cortex (Hamilton and Norgren 1984). It may also project to the upper levels of the spinal cord through a solitariospinal tract. Secondary gustatory axons cross the midline. Many subsequently ascend the brainstem in association with the medial lemniscus and synapse on the most medial neurones of the ventral posteromedial thalamic nucleus (in a region sometimes termed the accessory arcuate nucleus). Axons from the ventral posteromedial nucleus radiate through the internal capsule to the anteroinferior area of the sensory-motor cortex and the insula. It is thought that other ascending paths end in a number of the hypothalamic nuclei, and so mediate the route by which gustatory information may reach the limbic system and allow appropriate autonomic reactions to be made.

## Nucleus ambiguus

The nucleus ambiguus is a group of large motor neurones, situated deep in the medullary reticular formation (see Fig. 21.10). It extends rostrally as far as the upper end of the vagal nucleus, while caudally it is in line with, but is not continuous with, the nucleus of the accessory nerve. Fibres emerging from it pass dorsomedially, then curve laterally. Rostral fibres join the glossopharyngeal nerve. Caudal fibres join the vagus and are distributed to the pharyngeal constrictors, intrinsic laryngeal muscles and striated muscles of the palate and upper oesophagus.

The nucleus ambiguus receives corticonuclear fibres bilaterally with a contralateral preponderance and is connected to many brainstem centres. At its upper end, a small retrofacial nucleus intervenes between it and the facial nucleus. Although the nucleus ambiguus is generally regarded as a special visceral efferent nucleus, it is also a reputed source of general visceral efferent fibres to the vagus.

## Swallowing and gag reflexes

Swallowing is initiated when food or liquid stimulates sensory nerves in the oropharynx and is usually regarded as programmed motor behaviour rather than a reflex. The patterning and timing of striated muscle contraction that occur in the pharynx, larynx and oesophagus during swallowing are generated in the brainstem in a network of neural circuits. The afferent limb is the glossopharyngeal nerve: information is relayed via the nucleus solitarius to the nucleus ambiguus, which contains the motor neurones innervating the muscles of the palate, pharynx and larynx. If stimulation of the oropharynx occurs other than during swallowing, a gag reflex may be initiated. There is a reflex contraction of the muscles of the pharynx, soft palate and fauces that, if extreme, may result in retching and vomiting.

## Cough and sneeze reflexes

The cough reflex is normally initiated by irritation of tracheal or laryngeal mucosae: there is evidence of both mechanosensing and chemosensing cough receptors (McGarvey 2014). Coughing involves a sequence of coordinated events that produce the profound change in breathing pattern needed to expel an irritant from the lower airway. Rapid inspiration is followed by an expiratory effort against a closed glottis, the rapid generation of intrapulmonary pressure and the sudden opening of the glottis and contraction of intercostal and abdominal wall muscles, collectively producing a high-velocity flow of expired air that sweeps irritant material up towards the pharynx in a forceful exhalation (cough). Laryngeal branches of the vagus nerve carrying general visceral afferent information (with cell bodies in the inferior vagal ganglion) terminate in the nucleus of the solitary tract. Second-order neurones project to medullary respiratory centres (including a putative cough centre) and to the nucleus ambiguus, recruiting motor neurones innervating pharyngeal, laryngeal, diaphragmatic, intercostal and abdominal muscles.

Stimulation of nasal mucosa by physical or chemical irritants initiates a sneezing reflex. Afferent impulses travel via the ethmoidal and maxillary nerves to the spinal nucleus of the trigeminal nerve. Interneurones project to the nucleus ambiguus and a putative 'sneezing centre' in the rostral dorsolateral medulla (Seijo-Martínez et al 2006). Recruitment of a critical number of inspiratory and expiratory neurones initiates a sneeze, which involves eye closing and deep inspiration, followed by explosive exhalation as described above. If the oropharyngeal isthmus is closed by the action of palatoglossus, the air flow is diverted through the nasal cavity; otherwise the stream of expelled air flows through both oral and nasal cavities.

## PONS

## EXTERNAL FEATURES AND RELATIONS

The pons lies rostral to the medulla and caudal to the midbrain (see Fig. 21.4). On the ventral surface of the brainstem, the transition between medulla and pons is clearly demarcated by a transverse sulcus. Laterally, in a region known as the cerebellopontine angle, the facial, vestibulocochlear and glossopharyngeal nerves emerge. The ventral surface of the pons is separated from the clivus (basisphenoid and dorsum sellae) by the pontine cistern (cisterna pontis) (see Fig. 18.15). It is markedly convex transversely but less so vertically, and abuts the petrous part of the temporal bone laterally up to the internal acoustic meatus. The surface of the basilar pons has a shallow median sulcus, in which the basilar artery runs, bounded bilaterally by prominences formed partly by descending corticospinal fibres. Bundles of transverse fibres, bridging the midline and originating from nuclei in the basal pons (nuclei pontis, pontine nuclei), converge on each side into the large middle cerebellar peduncle and project to the cerebellum (Brodal and Bjaalie 1992, Haines 2013, Nieuwenhuys et al 2008). The trigeminal nerve emerges near the mid-pontine level; the basilar pons is inferior to this exit and the middle cerebellar peduncle superior and caudal to it. It has a small superomedial motor root (portio minor) and a large inferolateral sensory root (portio major).

The dorsal surface of the pons is hidden by the cerebellum, which covers the rostral half of the rhomboid fossa, into which the cerebral aqueduct empties. The roof of the fossa is formed by a thin sheet of tissue, the superior medullary velum, which is overlain by the lingula of the cerebellar vermis. The velum is attached on each side to the superior cerebellar peduncles and is enclosed by pia mater above and ependyma below (see Fig. 21.5). The trochlear nerves decussate in the rostral aspect of the velum.

## INTERNAL ORGANIZATION

## Transverse sections of the pons

Transverse sections (Figs 21.11-21.12) reveal that the pons consists of a tegmental part, which is a continuation of the medulla (excluding the pyramids), and a basilar part. The latter contains bundles of longitudinal descending fibres, some of which continue into the pyramids, while others end in the many pontine or medullary nuclei. It also contains numerous transverse fibres and pontine nuclei.

## Basilar pons

The basilar pons is similar in structure at all levels. The longitudinal fibres of the corticopontine, corticonuclear and corticospinal tracts descend from the crus cerebri of the midbrain and enter the pons compactly. They rapidly disperse into fascicles, which are separated by the pontine nuclei and transverse pontine fibres. Corticospinal fibres run uninterrupted through the pons to the medullary pyramids, where they again converge into compact tracts. Corticonuclear fibres terminate in contralateral (and some ipsilateral) nuclei of cranial nerves and other nuclei in the pontine tegmentum. Clinical evidence supports the view that the neurones of the facial nucleus, and, in particular, those serving the muscles of the upper face, receive bilateral cortical control. The lower half of the face is controlled predominately by the contralateral cortex.

The pontine nuclei (see Fig. 21.11) include all the neurones (in humans, some 20 million) that are scattered throughout the basilar pons. They are probably all glutamatergic, and most project to the contralateral cerebellar cortex, with collaterals to the cerebellar nuclei. Efferent axons from the pontine nuclei constitute the transverse pontine (pontocerebellar) fibres, which decussate and continue as the major

The medial accessory olivary nucleus is a curved grey lamina, concave laterally, between the medial lemniscus and pyramid and the ventromedial aspect of the principal olivary nucleus. The dorsal accessory olivary nucleus is a similar lamina, dorsomedial to the principal olivary nucleus. Both accessory nuclei are connected with the cerebellum. These nuclei are phylogenetically older than the principal olivary nucleus, and are connected with the paleocerebellum. In all connections, cerebral, spinal and cerebellar, the olivary nuclei display specific topographical organization (Ch. 22).

Termination of special visceral afferents (taste) within the nucleus shows a viscerotopic pattern, predominantly in the rostral region (the gustatory nucleus). Experimental evidence suggests that fibres from the anterior two-thirds of the tongue and the roof of the oral cavity (which travel via the chorda tympani and greater petrosal branches of the facial nerve) terminate in the extreme rostral part of the solitary complex. Those from the circumvallate and foliate papillae of the posterior third of the tongue, tonsils, palate and pharynx (which travel via the lingual branch of the glossopharyngeal nerve) are distributed throughout the rostrocaudal extent of the nucleus, predominately rostral to the obex. Gustatory afferents from the larynx and epiglottis (which travel via the superior laryngeal branch of the vagus) have a more caudal and lateral distribution. The nucleus solitarius may also receive fibres from the spinal cord, cerebral cortex and cerebellum.

Medial and commissural subnuclei in the caudal part of the nucleus appear to be the primary site of termination for gastrointestinal afferents; this is the cardiorespiratory nucleus. Ventral and interstitial subnuclei probably receive tracheal, laryngeal and pulmonary afferents and play an important role in respiratory control and possibly rhythm generation. The carotid sinus and aortic body nerves terminate in the dorsal and dorsolateral region of the nucleus solitarius, which may be involved in cardiovascular regulation.

The nucleus ambiguus contains several cellular subgroups, and some topographical representation of the muscles innervated has been established. Individual laryngeal muscles are innervated by relatively discrete groups of cells in more caudal zones. Neurones that innervate the pharynx lie in the intermediate area, and neurones that innervate the oesophagus and soft palate are rostral.

Fig. 21.11 A transverse section through the pons at the level of the facial colliculus.

Fig. 21.12 A transverse section of the pons at the level of the principal sensory and motor nuclei of the trigeminal nerve.
constituent of the contralateral middle cerebellar peduncle. All pontocerebellar fibres end as mossy fibres in the cerebellar cortex, and a degree of somatotopy is maintained in these connections.

Corticopontine fibres, from the frontal, temporal, parietal and occipital cortices, end on neurones in the pontine nuclei. Frontopontine fibres end rostral to the level of the trigeminal nerve, and connect with pontine neurones that project to the contralateral cerebellum in the more rostral transverse pontine fibres. Corticopontine fibres arise mainly from neurones in layer V of the premotor, somatosensory, posterior parietal, extrastriate visual and cingulate neocortices. Projections from prefrontal, temporal and striate cortices are sparse. The terminal fields, although divergent, form topographically segmented patterns resembling overlapping columns, slabs or lamellae within the pons.

Subcortical projections to the pontine nuclei include those from the superior colliculus to the dorsolateral pons, and the medial mammillary nucleus to the rostromedial pons and pretectal nuclei. The lateral geniculate nucleus, dorsal column nuclei, trigeminal nuclei, hypothalamus and cerebellar nuclei also project to restricted neurones of the
pons. Functionally related subcortical and cerebrocortical afferents converge, e.g. those from the somatosensory cortex and dorsal column nuclei. There is also non-specific input from the reticular formation, raphe nuclei, locus coeruleus and periaqueductal grey matter.

## Pontine tegmentum

The pontine tegmentum varies in cytoarchitecture at different levels (Haines 2015, Nieuwenhuys et al 2008, Olszewski and Baxter 1954). However, a consistent feature is that all cranial nerves associated with the pons have their nuclei (motor or sensory) within the tegmentum, although their axons may traverse the basilar pons. The pedunculopontine nucleus, as its name implies, lies in the caudal part of the tegmentum of the midbrain and extends into the rostral part of the dorsolateral tegmentum of the pons; it is described below.

A transverse section through the lower pontine tegmentum transects the facial colliculus in the floor of the fourth ventricle (see Fig. 21.11;

Fig. 21.13 A transverse section of the pons, viewed from the rostral aspect, showing the central course of fibres of the facial nerve.

Fig. 21.13). This colliculus contains the nucleus of the abducens nerve and the fibres of the internal genu of the facial nerve. More deeply placed are the facial nuclei, the nearby vestibular and cochlear nuclei, and other isolated neuronal groups. The vestibular nuclei are laterally placed in the rhomboid fossa of the fourth ventricle, subjacent to the vestibular area, which spans the rostral medulla and caudal pons (see Figs 21.3, 21.5).

The striae medullares of the fourth ventricle (see Fig. 21.10) are an aberrant cerebropontocerebellar connection, in which the arcuatocerebellar fibres are involved. Axons from arcuate nuclei spread round the medulla, above and below the olivary eminence, where they are superficially visible as the circumolivary fasciculus. All these fibres, collectively known as the external arcuate fibres, enter the restiform body (see Fig. 21.9). Some fibres from arcuate nuclei pass dorsally through the medulla near its midline (as arcuatocerebellar fibres), decussate near the floor of the fourth ventricle, then turn laterally under the ependyma and enter the cerebellum through the inferior peduncle via the restiform body.

In addition to the tracts already noted at lower levels, the lower pontine tegmentum contains the trapezoid body, lateral lemniscus and emerging fibres of the abducens and facial nerves. The medial lemniscus is ventral, its transverse outline now a flat oval. It extends laterally from the median raphe (see Figs $21.11,21.12$ ) and is laterally related to the anterolateral system and trigeminal lemniscus. The fibres of the latter originate from neurones of the contralateral spinal trigeminal nucleus, serving pain and thermal sensibility in facial, nasal and oral cavities and the conjunctiva. Here these fibres form a transverse band that is composed, in lateral order from the midline, of the medial lemniscus, trigeminal lemnisci, the anterolateral system and the lateral lemniscus.

The trapezoid body contains cochlear fibres, mainly from the ventral cochlear and trapezoid nuclei. They ascend transversely in the ventral tegmentum, pass either through or ventral to the medial lemniscal fibres, and decussate with the contralateral fibres in the median raphe. Below the emerging facial axons, the trapezoid fibres turn rostral to enter the lateral lemniscus. As the lateral lemniscus ascends, it lies near the dorsolateral surface of the brainstem. Rostrally, its fibres enter the inferior colliculus and medial geniculate body. The ascending auditory pathway is described in detail on page 655.

The medial longitudinal fasciculus is paramedian, ventral to the fourth ventricle, near the midline and adjacent to motor nuclei of cranial nerves III, IV, VI and XII. It is the main intersegmental tract in the brainstem, particularly for interactions between nuclei of cranial nerves innervating the extraocular muscles and the vestibular system. In the lower pons it receives fibres from vestibular, and perhaps dorsal trapezoid, nuclei. Its greater part is formed by vestibular contributions.

A transverse section at an upper pontine tegmental level contains trigeminal elements (see Fig. 21.12), but otherwise shows little notable alteration from a section through a lower pontine tegmental level. Its dorsolateral parts are invaded by the superior cerebellar peduncles. The small nucleus of the lateral lemniscus, a relay in the auditory pathway, lies medial to its tract in the upper pons and receives some lemniscal terminals. Some of its efferent fibres enter the medial longitudinal fasciculus, while others return to the lemniscus.

The medial lemniscus (see Figs $21.11,21.12$ ) retains its position in the ventral pontine tegmentum, where it lies a little lateral to the median raphe, and is joined medially by fibres from the principal sensory nucleus of the trigeminal nerve. The trigeminal lemniscus, anterolateral system, and the lateral lemniscus and its nucleus all lie dorsolaterally.

## Cochlear nuclei

Fibres of the cochlear division of the vestibulocochlear nerve partially encircle the restiform body laterally and end in the dorsal and ventral cochlear nuclei. The dorsal (posterior) cochlear nucleus forms a bulge, the auditory tubercle, on the posterior surface of the restiform body, and is continuous medially with the vestibular area in the rhomboid fossa. The ventral (anterior) cochlear nucleus is ventrolateral to the dorsal cochlear nucleus, and lies between the cochlear and vestibular fibres of the vestibulocochlear nerve.

Cochlear nerve fibres, which are derived from neuronal somata in the spiral ganglion, bifurcate on entering the brainstem and terminate in both dorsal and ventral cochlear nuclei (see Fig. 38.20). The ventral cochlear nucleus has a complex cytoarchitecture.

It contains many neuronal types with distinct dendritic field characteristics. Marked topographical order has been demonstrated in cochlear nerve terminals within the nucleus. Different parts of the spiral ganglion and differing stimulation frequencies are related to neurones that are serially arrayed anteroinferiorly in the ventral nucleus. All cochlear nerve fibres enter the nucleus. There are approximately 25,000 axons in the human cochlear nerve, and they project on to a much larger number of neurones in the cochlear nucleus. The number of cochlear fibres in the lateral lemniscus greatly exceeds that in the cochlear nerve. A minor fraction of the cochlear neurones receive terminals from the nerve, though each fibre may connect with several neurones. Terminals are limited to the anteroinferior region of the ventral nucleus, where the neurones are probably mostly local interneurones.

The dorsal (posterior) cochlear nucleus is generally continuous with the ventral nucleus, from which it is separated only by a thin stratum of nerve cell bodies and fibres. Giant cells predominate, and their dendritic fields are aligned with the incoming auditory fibres.

Though the cellular origins are not precisely known, axons of most neuronal types in the cochlear nuclei leave to end at pontine levels in the superior olivary, trapezoid and lateral lemniscal nuclei (see Fig. 21.12). They leave the cochlear nuclei by three routes. The largest group of axons lies ventrally and decussates as the trapezoid body, level with the pontomedullary junction (see Figs 21.11, 21.12). Most of these axons ascend slightly, decussate and relay in the contralateral nuclei. A few do not cross, and synapse in the ipsilateral superior olivary nuclei. From both nuclei, the next-order axons ascend in the corresponding lateral lemniscus. Occasional decussating fibres traverse the contralateral superior olive and enter the lateral lemniscus to relay in lemniscal nuclei.

Some axons from ventral cochlear neurones pass dorsally, superficial to descending trigeminal spinal fibres, cerebellar fibres in the restiform body and axons of the dorsal cochlear nucleus. This bundle of ventral cochlear fibres is smaller than that of the trapezoid decussation. It swerves ventromedially across the midline, ventral to the medial longitudinal fasciculus, as the intermediate acoustic striae. Its further path is uncertain, but it most likely ascends in the contralateral lateral lemniscus.

The most dorsally placed axons issue from the dorsal cochlear nucleus. They curve dorsomedially round the restiform body towards the midline as the dorsal acoustic striae, ventral to the striae medullares. They incline ventromedially and cross the midline to ascend in the contralateral lateral lemniscus, probably relaying in its nuclei.

The nuclei of the lateral lemniscus consist of small groups of neurones (counts of 18,000-24,000 have been recorded in humans) that lie among the fibres of the lateral lemniscus. Dorsal, ventral and intermediate groups probably receive afferent axons from both cochlear nuclei. Their efferents enter the midbrain along the lateral lemniscus and terminate in the inferior colliculi.

Some efferent axons travel in the cochlear nerves to the spiral organ; these comprise the olivocochlear tract (bundle of Rasmussen). Though few in number, they are involved in hearing, perhaps by modulating sensory transduction through reflexes via cochlear nuclei. The neurones of origin are located at the hilus and along the lateral border of the lateral superior olivary nucleus and lateral edge of the ventral trapezoid nucleus. Fibres from both sides proceed to both cochleae.

## Vestibular nuclei

The vestibular complex consists of the medial (Schwalbe), lateral (Deiters' nucleus), superior (Bechterew) and inferior vestibular nuclei

The superior olivary complex is sited in the tegmentum of the caudal pons, lateral in the reticular formation at the level of the pontomedullary junction. This complex includes several named nuclei and nameless smaller groups. In humans, the lateral superior olivary nucleus is made up of some six small cellular clusters. The medial (accessory) superior olivary nucleus is large and compact. Cells in the immediate vicinity of these nuclei give rise to the olivocochlear tract. The trapezoid nucleus is medial and the retro-olivary group, also a potential source of cochlear efferents, is dorsal. Some internuclear connections have been described. The medial superior olivary nucleus receives impulses from both spiral organs, and may be involved in sound source localization. The superior olivary complexes and the trapezoid nuclei are relay stations in the ascending auditory projection. These intricate connections have not been definitively established in humans.

The medial nuclei of the trapezoid body are small in humans. They have a ventral component, which consists of large neurones scattered among the trapezoid fascicles, and a more compact dorsal nucleus, medial to the superior olivary complex. This nucleus lies at the level of the exiting abducens nerve roots, anterior to the central tegmental tract. It is likely that the human trapezoid nuclei function in the auditory relay pathway. Some trapezoid axons may enter the medial longitudinal fasciculus, and ascend to end in trigeminal, facial, oculomotor, trochlear and abducens nuclei, where they mediate reflexes involving tensor tympani, stapedius and oculogyric muscles, respectively.
(Haines 2013). The medial vestibular nucleus is the largest. It broadens, and then narrows as it ascends from the upper olivary level into the lower pons, where it is located lateral and superior to visceromotor nuclei of cranial nerves IX and X. It is crossed by the striae medullares, running nearer the floor, and is continuous with the nucleus intercalatus below. The inferior vestibular nucleus (which is the smallest) lies between the medial vestibular nucleus and restiform body, from the level of the upper end of the nucleus gracilis to the pontomedullary junction. It is traversed by descending fibres of the vestibular nerve, from the cerebellum, and the vestibulospinal tract. The lateral vestibular nucleus lies just above the inferior nucleus and is ventrolateral to the upper part of the medial nucleus. It ascends almost to the level of the abducens nucleus and its rostral end is continuous with the caudal end of the superior nucleus. The lateral vestibular nucleus is composed of large multipolar neurones, which are the main source of lateral vestibulospinal tract fibres. The superior vestibular nucleus is small and lies above the medial and lateral nuclei. It extends higher into the pons than other subdivisions, and occupies the upper part of the vestibular area.

Through its connections, the vestibular system influences movements of the eyes and head, and of the muscles of the trunk and limbs, in order to maintain equilibrium (Nieuwenhuys et al 2008). The vestibular nuclei receive fibres from the vestibular part of the vestibulocochlear nerve, cerebellum, brainstem reticular formation and spinal cord. They send axons to the cerebellum, medial longitudinal fasciculus, spinal cord and lateral lemniscus. Evidence suggests that the vestibular apparatus is spatially represented in the nuclei. Vestibular fibres of the vestibulocochlear nerve enter the medulla between the restiform body and the spinal tract of the trigeminal nerve, and approach the vestibular area, where they bifurcate into descending and ascending branches. The former descend medial to the restiform body and end in medial, lateral and inferior vestibular nuclei; the latter enter the superior and medial nuclei. A few vestibular fibres enter the cerebellum directly through the juxtarestiform body (the medial part of the inferior cerebellar peduncle), and end in the fastigial nucleus, flocculonodular lobe and uvula.

The vestibular nuclei project extensively to the cerebellum and also receive axons from the cerebellar cortex and the fastigial nuclei. Vestibulocerebellar fibres (primary and secondary) travel via the juxtarestiform body mainly to the flocculus and nodule. Cerebellovestibular fibres pass to the nuclei, also via the juxtarestiform body. They arise mainly in the flocculus and nodule (posterior lobe), but some fibres are derived from the anterior lobe and fastigial nucleus. The vestibular nuclear complex projects to the pontine reticular nuclei and to motor nuclei of the oculogyric muscles in the medial longitudinal fasciculus. The complex also projects to the spinal cord via medial and lateral vestibulospinal tracts, the former one part of the medial longitudinal fasciculus (see Fig. 20.18).

Information from the vestibular nuclei also reaches the cerebral cortex by way of the thalamus (probably via posterior parts of the ventroposterior complex and the medial pulvinar). The primary vestibular cortical area is located in the parietal lobe at the junction between the intraparietal and the postcentral sulci, which is adjacent to that portion of the postcentral gyrus where the head is represented. There may be an additional representation of the vestibular system in the superior temporal gyrus near the auditory cortex.

## Abducens nucleus

The abducens nucleus is a group of approximately 6500 neurones, occupying a paramedian position in the central grey matter, in line with the trochlear, oculomotor and hypoglossal nuclei, with which it forms a somatic motor column (see Fig. 21.3). It lies laterally adjacent to the medial longitudinal fasciculus, which is the means by which vestibular, cochlear and other cranial nerve nuclei, especially the oculomotor, connect with the abducens. The abducens nucleus contains large motor neurones and small multipolar interneurones, which are intermixed, although the latter are most heavily concentrated in its lateral and ventral aspects. Axons of abducens interneurones cross the midline at the level of the nucleus and ascend in the medial longitudinal fasciculus to all three medial rectus subnuclei of the oculomotor nucleus

Efferent abducens motor axons pass ventrally through the reticular formation, trapezoid body and medial lemniscus, and traverse the ventral pons to emerge at its inferior border (see Fig. 21.13); they innervate the lateral rectus muscle.

The abducens nucleus receives afferent connections from corticonuclear fibres (which are principally contralateral, some of the fibres being aberrant corticospinal fibres that descend from the midbrain to this level in the medial lemniscus); the medial longitudinal fasciculus (by which it is connected to oculomotor, trochlear and vestibular nuclei);
the tectobulbar tract (from the deep layers of the superior colliculus); the paramedian pontine reticular formation (which lies rostral and caudal to the nucleus); the nucleus prepositus hypoglossi; and the contralateral medullary reticular formation.

## Facial nucleus

The facial (motor) nucleus lies in the caudal pontine reticular formation, posterior to the dorsal trapezoid nucleus and ventromedial to the spinal tract and nucleus of the trigeminal nerve (Haines 2013, Nieuwenhuys et al 2008). Groups of facial neurones form columns, which innervate individual muscles or which correspond to branches of the facial nerve. Neurones innervating muscles in the scalp and upper face are dorsal, and those supplying the lower facial musculature are ventral.

Efferent fibres of the large motor neurones of the facial nucleus form the motor root of the facial nerve. The motor nucleus is part of the pharyngeal efferent column, but it lies much more deeply in the pons than might be expected and its axons have an unusual course (see Fig. 21.13). At first they incline dorsomedially towards the fourth ventricle, caudal to the abducens nucleus, and ascend medial to it, near the medial longitudinal fasciculus. They then curve round the rostral pole of the abducens nucleus and descend ventrolaterally through the reticular formation. Finally, they pass between their own nucleus medially and the spinal nucleus of the trigeminal nerve laterally. They emerge between the olive and restiform body at the cerebellopontine angle.

The facial nucleus receives corticonuclear fibres for volitional control. Neurones that innervate muscles in the scalp and upper face receive bilateral corticonuclear fibres, while those supplying lower facial musculature receive a predominately contralateral innervation. Clinically, upper and lower motor neurone lesions of the facial nerve can be differentiated because the former results in paralysis that is confined to the contralateral lower face (supranuclear facial palsy), whilst the latter results in a complete ipsilateral paralysis (Bell's palsy).

The facial nucleus also receives ipsilateral afferents from the nucleus solitarius and from the sensory nucleus of the trigeminal nerve, establishing important reflex connections.

Some efferent fibres of the facial nerve originate from visceromotor neurones in the superior salivatory nucleus, which is in the reticular formation dorsolateral to the facial nucleus. These preganglionic parasympathetic neurones belong to the general visceral efferent column. They send fibres into the sensory root of the facial nerve, a part of the intermediate nerve. These fibres travel via the chorda tympani to the submandibular ganglion and via the greater petrosal nerve and the nerve of the pterygoid canal to reach the pterygopalatine ganglion.

## Corneal and blink reflexes

Touching the cornea of one eye elicits reflex closure of both eyes via the corneal reflex. The afferent limb of the pathway involves mainly nasociliary branches of the ophthalmic division of the trigeminal nerve, with cell bodies in the trigeminal ganglion and central processes synapsing on second-order neurones in the ipsilateral spinal tract and chief sensory nuclei of the trigeminal nerve. These neurones drive a polysynaptic chain of interneurones in the lateral reticular formation in the pons and medulla, which, in turn, activate neurones innervating the palpebral components of orbicularis oculi in both ipsilateral and contralateral facial motor nuclei; the stimulated muscles contract to produce a bilateral blink. The sweep of the eyelids carries lacrimal secretions across the eye, helping to remove any irritating particles.

Shining a bright light into one eye elicits a similar reflex closure of both eyes via the blink reflex; the afferent limb of this reflex involves stimulation of the retina and optic pathway.

## Trigeminal sensory nucleus

On entering the pons, the fibres of the sensory root of the trigeminal nerve run dorsomedially towards the principal sensory nucleus (see Fig. 21.12). About $50 \%$ of the fibres divide into ascending and descending branches; the others ascend or descend without division. The descending fibres form the spinal tract of the trigeminal nerve, which terminates in the medially adjacent spinal nucleus of the trigeminal nerve.

Some ascending trigeminal fibres, many of them heavily myelinated, synapse around the small neurones in the principal sensory nucleus (see Fig. 21.12), which lies lateral to the motor nucleus and medial to the middle cerebellar peduncle, and is continuous inferiorly with the spinal nucleus of the trigeminal nerve. The principal nucleus is considered to be mainly concerned with tactile stimuli.

Other ascending fibres enter the mesencephalic nucleus (Fig. 21.14). This column of cells contains the only primary sensory unipolar neurones with somata in the CNS rather than in a sensory ganglion. The

peripheral processes of these neurones may convey proprioceptive impulses from the masticatory muscles, and possibly also from the teeth and the facial and oculogyric muscles. The nucleus is the relay for the 'jaw jerk', the only significant supraspinal monosynaptic reflex, elicited by lightly tapping the relaxed open jaw in a downward direction. Nerve fibres that ascend to the mesencephalic nucleus may give collaterals to the motor nucleus of the trigeminal nerve and to the cerebellum.

## Jaw jerk reflex

Rapid stretching of the muscles that close the jaw (masseter, temporalis, medial pterygoid) activates muscle spindle afferents, which travel via the mandibular division of the trigeminal nerve to the brain stem. The cell bodies of these primary afferent neurones are located in the mesencephalic trigeminal nucleus. Collaterals project monosynaptically to the motor nucleus of the trigeminal nerve in the pons. Motor axons arising in the nucleus travel via the mandibular nerve to innervate the muscles that act on the temporomandibular joint and close the jaw (Chapter 32).

Most fibres that arise in the trigeminal sensory nuclei cross the midline and ascend in the trigeminal lemniscus. They end in the contralateral ventral posteromedial thalamic nucleus, from which thirdorder neurones project to the postcentral gyrus (areas 3, 1, 2). Some trigeminal nuclear efferents ascend to the ventral posteromedial nucleus of the thalamus.

## Trigeminal motor nucleus

The motor nucleus of the trigeminal nerve is ovoid in outline and lies in the upper pontine tegmentum, under the lateral part of the floor of the fourth ventricle (see Fig. 21.3). It lies medial to the principal sensory nucleus, and is separated from it by fibres of the trigeminal nerve. It forms the rostral part of the pharyngeal (special visceral) efferent column.

The motor nucleus contains characteristic large multipolar neurones interspersed with smaller multipolar cells. The neurones are organized into a number of relatively discrete subnuclei, the axons from which innervate individual muscles. It receives fibres from both corticonuclear tracts. These fibres leave the tracts at the nuclear level or higher in the pons (aberrant corticospinal fibres), and may end on motor neurones or interneurones. The motor nucleus receives afferents from the sensory nuclei of the trigeminal nerve, possibly including some from the mesencephalic nucleus, which form monosynaptic reflex arcs for proprioceptive control of the masticatory muscles. It also receives afferents from the reticular formation, red nucleus and tectum, the medial longitudinal fasciculus and possibly from the locus coeruleus. Collectively, these represent pathways by which salivary secretion and mastication may be coordinated.

## Tensor tympani and stapedius reflex

Loud sound elicits reflex contraction of tensor tympani and stapedius, which attenuates movement of the tympanic membrane and middle ear ossicles. Afferent impulses travel in the cochlear nerve to the cochlear nuclei in the brainstem. Efferent fibres to tensor tympani arise in the motor nucleus of the trigeminal nerve and travel in the mandibular division of the nerve. Efferent fibres to stapedius originate in the facial nucleus and travel in the facial nerve.

## Salivatory nuclei

The salivatory nuclei are near the upper pole of the vagal nucleus, just above the pontomedullary junction and near the inferior pole of the facial nucleus. They are divided into superior and inferior salivatory nuclei, which send preganglionic parasympathetic fibres into the facial and glossopharyngeal nerves, respectively, for the control of the salivary and lacrimal glands.

## MIDBRAIN

## EXTERNAL FEATURES AND RELATIONS

The midbrain traverses the tentorial notch and connects the pons and cerebellum with the diencephalon. It is the shortest brainstem segment, not more than 2 cm in length, and much of it lies in the posterior cranial fossa (Haines 2013, Nieuwenhuys et al 2008). Lateral to it are the parahippocampal gyri, which hide its sides when the inferior surface of the brain is examined. For descriptive purposes, the midbrain may be divided into a tectum containing the pretectal area and corpora quadrigemina, and a basis pedunculi consisting of the substantia nigra and the crus cerebri (see Fig. 21.2). The former contains pigmented cells and the latter clinically important descending tracts. The midbrain tegmentum is the central midbrain area between the tectum and the substantia nigra; the cerebral aqueduct is located at the interface of tectum and tegmentum within the periaqueductal grey (Haines 2013). The cerebral peduncle may be regarded as the midbrain located below the tectum (the tegmentum plus basis pedunculi).

The crura cerebri are superficially corrugated and emerge from the cerebral hemispheres. They converge as they descend, forming the

Fig. 21.15 A transverse section of the midbrain at the level of the inferior colliculi.
caudolateral boundaries of the interpeduncular fossa, and eventually enter the basilar pons (Figs 21.15-21.16). At the level of the tentorial incisure, the basilar artery divides in the interpeduncular fossa into the right and left $P_{1}$ segments of the posterior cerebral arteries. The superior cerebellar arteries branch from the basilar artery immediately before this bifurcation. The posterior cerebral and superior cerebellar arteries both run laterally around the ventral surface of the crus, the former passing above the tentorium cerebelli, the latter passing below. The oculomotor and trochlear nerves lie between these two arteries. The roots of the oculomotor nerve emerge from the medial aspect of the crus via the oculomotor sulcus. The posterior communicating artery joins the posterior cerebral artery on the medial surface of the peduncle in the interpeduncular fossa. The numerous small openings in the interpeduncular fossa constitute the posterior perforated substance, which is pierced by central branches of the posterior cerebral arteries. The optic tract is located at the point where the crus emerges from the cerebral hemispheres.

The superior and inferior colliculi are two paired eminences on the dorsal surface of the midbrain (see Fig. 21.5). They lie rostral to the superior medullary velum, inferior to the pineal gland and caudal to the posterior commissure. Below the splenium of the corpus callosum, they are inferior and medial to the pulvinar of the thalamus. The superior and inferior colliculi are separated by a cruciform sulcus. The upper limit of the sulcus expands into a depression for the pineal gland, and a median frenulum veli is prolonged from its caudal end down over the superior medullary velum. The trochlear nerve emerges lateral to the frenulum and caudal to the inferior colliculus, passes ventrally over the lateral aspects of the cerebral peduncles and traverses the interpeduncular cistern to the petrosal end of the cavernous sinus. The superior colliculi, larger than the inferior, are centres for visual reflex responses. The inferior colliculi are a part of the ascending auditory pathway.

A brachium passes ventrolaterally from the lateral aspect of each colliculus (see Fig. 21.5). The brachium of the superior colliculus (superior quadrigeminal brachium) passes below the pulvinar, partly overlapping the medial geniculate body, and conveys fibres from the retina to the superior colliculus. The brachium of the inferior colliculus (inferior quadrigeminal brachium) ascends ventrally and conveys fibres from the lateral lemniscus and inferior colliculus to the medial geniculate body.

## INTERNAL ORGANIZATION

## Transverse sections of the midbrain

In transverse section, the cerebral peduncles are seen to be composed of dorsal and ventral regions separated by the substantia nigra (see Figs 21.15-21.16). On each side, the dorsal region is the tegmentum and the ventral part is the crus cerebri. The tegmenti are continuous across the midline but the crura are separated.

## Crus cerebri

The crus cerebri is approximately semilunar in section, being convex externally and concave internally. It contains corticonuclear, corticospinal and corticopontine fibres. Corticonuclear fibres terminate at various brainstem levels, many in association with the cranial nerve nuclei. Corticospinal fibres pass uninterrupted through the brainstem to enter the medullary pyramid and, thereafter, form the corticospinal tracts of the spinal cord (see Fig. 20.17). Corticonuclear and corticospinal fibres occupy about the middle two-thirds of the crus cerebri. Corticopontine fibres arise in the cerebral cortex and form two groups, both of which end in the pontine nuclei. Frontopontine fibres from the frontal lobe, principally areas 6 and 4 , traverse the internal capsule and then occupy the medial fourth of the ipsilateral crus cerebri. Temporopontine fibres, which originate largely from the posterior region of the temporal lobe, traverse the internal capsule and then run in the lateral part of the ipsilateral crus. Parietopontine and occipitopontine fibres are also described in the crus, lying medial to the temporopontine fibres; collectively, these fibres occupy about the lateral third of the crus. There are few fibres from the primary sensory cortex in corticopontine projections.

## Substantia nigra

The substantia nigra is a large nucleus that extends through the entire length of the midbrain, located between the crus cerebri ventrolaterally and ascending lemniscal fibres dorsomedially (see Figs 21.15-21.16). Its medial part is traversed by oculomotor axons passing to their point

Fig. 21.16 A transverse section of the midbrain at the level of the superior colliculi.

of exit in the interpeduncular fossa. The substantia nigra is divided into a larger part consisting of a dorsal pars compacta and a ventral pars reticularis and a smaller pars lateralis.

The pars compacta consists of darkly pigmented neurones, which contain neuromelanin granules. Their arrangement is irregular and they partially penetrate the subjacent pars reticularis. Pigmentation increases with age, is most abundant in primates, maximal in humans, and present even in albinos. The pigmented neurones synthesize dopamine as their neurotransmitter and correspond to the dopaminergic cell group A9 (Fig. 21.17). They project predominately to the caudate nucleus and putamen in a topographically organized fashion, but also project to the globus pallidus and subthalamic nucleus. Together with the retrorubral nucleus (A8), they comprise most of the dopaminergic neurone population of the midbrain and are the source of the mesostriatal dopamine system that projects to the striatum. The pars compacta of each side is continuous with its contralateral counterpart through the ventral tegmental dopamine group A10, which is sometimes known as the paranigral nucleus. This is the source of the
mesolimbic dopamine system, which supplies the ventral striatum, neighbouring parts of the dorsal striatum, and the prefrontal and anterior cingulate cortices. The dopaminergic neurones of the pars compacta (A9) and adjacent ventral tegmental area (A10) also contain cholecystokinin (CCK) or somatostatin.

The pars reticularis extends rostrally as far as the subthalamic region. It consists of clusters of large multipolar neurones, many of which intermingle with fibres of the crus cerebri. It is considered to be a homologue of the internal (medial) segment of the globus pallidus, which it resembles in terms of cell type and connectivity. It contains neurones that are very similar to those of the globus pallidus; their disc-like dendritic trees, like those of the pallidum, are orientated at right angles to afferents from the striatum, probably making en passant contacts. Most pars reticularis neurones are GABAergic and also contain high levels of iron. They project rostrally to the ventral anterior and dorsomedial thalamic nuclei and the deep (polysensory) layers of the superior colliculus, and caudally to the pedunculopontine nucleus and brainstem reticular formation, from where impulses are relayed to spinal ventral horn neurones. The connection from the striatum to the superior colliculus, via the pars reticularis, is thought to function in the control of gaze in a manner analogous to the pathway that initiates general body movement via the pallidum, thalamus and supplementary motor cortex. The uncontrolled or fixed-gaze disturbances of advanced Parkinson's disease, progressive supranuclear palsy and Huntington's disease tend to support this.

There are reciprocal connections between the substantia nigra and the basal ganglia, and these are discussed in Chapter 24. Briefly, topographically organized striatonigral axons, some of which may be collaterals of striatopallidal axons, originate from the caudate nucleus and putamen and project to the pars reticularis. They utilize GABA and substance $P$ or encephalin, and are distributed differentially in the pars reticularis in that enkephalinergic axons terminate in the medial part, whereas substance P axons terminate throughout. The head of the caudate nucleus projects to the rostral third of the substantia nigra, while the putamen projects to all parts. The fibres end in axodendritic synapses. A small number of GABAergic pallidonigral fibres from the external (lateral) segment of the globus pallidus end mostly in the pars reticularis. The subthalamic nucleus sends an important glutamatergic projection to the pars reticularis and to the globus pallidus. Some corticonigral fibres appear to exist, passing from precentral and postcentral gyri to neurones in the pars reticularis: this is predominantly a glutamatergic projection.

The pars lateralis projects to the ipsilateral superior colliculus, and may be involved in the control of saccadic eye movements.

Two other dopaminergic cell groups are found in the ventral tegmentum: cell group A10 in the rostromedial region, which corresponds to the ventral tegmental area (of Tsai), and cell group A8 in the dorsolateral reticular area, which forms the nucleus parabrachialis pigmentosus
(Nieuwenhuys 1985). The whole ventral tegmental system of dopaminergic neurones acts as an integrative centre for adaptive behaviour. It projects via a number of pathways, mainly through ascending fibres in the ipsilateral medial forebrain bundle. These pathways are a mesodiencephalic system, which terminates in thalamic and hypothalamic nuclei; a mesostriatal projection to the caudate nucleus and putamen; a mesolimbic pathway to the nucleus accumbens, olfactory tubercle, lateral septum, interstitial nucleus of the stria terminalis, amygdala and entorhinal cortex; and mesocortical fibres that project to most cortical areas, particularly the prefrontal, orbitofrontal and cingulate cortices.

## Mesencephalic tegmentum

The mesencephalic tegmentum (see Fig. 21.2) is continuous caudally with the pontine tegmentum. At inferior collicular levels, grey matter is restricted to collections of neurones forming the reticular formation and the central (periaqueductal) grey surrounding the cerebral aqueduct. The trochlear nucleus lies in the latter region, near the midline, in a position corresponding to the abducens and hypoglossal nuclei at more caudal levels. It extends through the lower half of the midbrain, just caudal to the oculomotor nucleus and immediately dorsal to the medial longitudinal fasciculus.

The mesencephalic nucleus of the trigeminal nerve occupies a lateral position in the central grey matter. It ascends from the principal sensory nucleus of the trigeminal nerve in the pons to the level of the superior colliculus in the midbrain. Its large ovoid neurones are unipolar, like those in peripheral sensory ganglia. They are arranged in many small groups that extend as curved laminae on the lateral margins of the periaqueductal grey matter; neurones are most numerous caudally.

Apart from these nuclei, the mesencephalic tegmentum contains many other scattered neurones, most of which are included in the reticular formation.

The white matter of the mesencephalic tegmentum contains the majority of the tracts present in the pontine tegmentum. The decussation of the superior cerebellar peduncles is particularly prominent. Numerous fibres that enter the mesencephalic tegmentum arise from the cerebellar nuclei, pass ventromedially, and decussate at the level of the inferior colliculus (see Fig. 21.15). Thereafter, these ascending fibres laterally encapsulate and penetrate the red nucleus, in which some fibres, or their collaterals, terminate (see Fig. 21.16). However, the majority of these fibres ascend to terminate in the nucleus ventralis lateralis of the thalamus. A relatively small number of uncrossed fibres are believed to end in the periaqueductal grey matter and reticular formation, the interstitial nucleus and the nucleus of the posterior commissure. Descending crossed fibres from the decussation of the superior cerebellar peduncle also end in the pontine nuclei, the medullary reticular formation, the nuclei of the inferior olivary complex and, possibly, some cranial nerve motor nuclei.

The medial longitudinal fasciculus adjoins the somatic efferent cell column, dorsal to the decussating superior cerebellar peduncles (see Fig. 21.15). The medial, trigeminal, lateral and spinal lemnisci (anterolateral system) form a curved band dorsomedial to the substantia nigra. Fibres in the medial, trigeminal and spinal lemnisci continue a rostral course to synapse with neurones in the lateral (VPL) and medial (VPM) parts of the ventral posterior thalamic nucleus. Some fibres of the lateral lemniscus end in the nucleus of the inferior colliculus, or send collaterals to it. The remaining lateral lemniscal fibres join with fibres originating in the inferior colliculus and enter the brachium of the inferior colliculus, which carries them to the medial geniculate body.

At the level of the superior colliculus, the tegmentum contains the red nucleus, which extends rostrally into the subthalamic region. The ventromedial central grey matter around the cerebral aqueduct also contains the elongated oculomotor nucleus, which is adjacent to the medial longitudinal fasciculus, and caudally reaches the trochlear nucleus. The oculomotor nucleus is divisible into neuronal groups that are correlated with the motor distribution of the oculomotor nerve. A group of parasympathetic neurones that control the activity of smooth muscle within the eyeball, the Edinger-Westphal preganglionic nucleus, lies dorsal to the oculomotor nucleus. The Edinger-Westphal complex, based on its connections, consists of an Edinger-Westphal preganglionic nucleus projecting only to the ciliary ganglion, and an EdingerWestphal centrally projecting nucleus that has a variety of targets in the central nervous system but does not target the ciliary ganglion (Kozicz et al 2011).

## Red nucleus

The red nucleus is a pink, ovoid mass, approximately 5 mm in diameter and lying dorsomedial to the substantia nigra (see Fig. 21.16). The tint
appears only in fresh material and is caused by a ferric iron pigment in its multipolar neurones. The latter are of varying size, and their relative proportions and arrangement vary between species. In primates the more caudal magnocellular part is decreased, and there is a reciprocal increase in the size of the more rostral parvocellular part. Small multipolar neurones occur in all parts of the nucleus. In humans, the larger neurones of the magnocellular part have been estimated to be as few as 200 in number. The magnocellular element is considered phylogenetically old, which accords with the parvocellular predominance in primates. Rostrally, the red nucleus is poorly demarcated, and it blends into the reticular formation and caudal pole of the interstitial nucleus. It is traversed and surrounded by fascicles of nerve fibres, including many from the oculomotor nucleus.

The principal afferent connections of the red nucleus are corticorubral and cerebellorubral fibres. Uncrossed corticorubral fibres originate from primary somatomotor and somatosensory areas. In animals, the red nucleus receives fibres from the contralateral nucleus interpositus (which corresponds to the human globose and emboliform nuclei) and dentate nucleus, via the superior cerebellar peduncle. It has bilateral, and probably reciprocal, connections with the superior colliculi. In humans, the rubrospinal tract is small and originates from the magnocellular part of the red nucleus. These fibres decussate in the ventral tegmental decussation, ventral to the tectospinal decussation, and ventromedial to the red nucleus. On reaching the grey matter ventral to the inferior cerebellar peduncle, the tract turns caudally to descend adjacent to the lateral lemniscus. It continues descending ventral to the spinal tract of the trigeminal nerve and nucleus throughout the medulla, and enters the upper part of the cervical cord intermingled with fibres of the lateral corticospinal tract (Nathan and Smith 1982). Some efferent axons form a rubrobulbar tract to motor nuclei of the trigeminal, facial, oculomotor, trochlear and abducens nerves. Few fibres reach the cervical cord.

The largest group of efferents from the red nucleus in humans is a descending component of the ipsilateral, central tegmental tract. Initially, this tract lies ventrolateral to the medial longitudinal fasciculus and dorsolateral to both the red nucleus and the decussation of the superior cerebellar peduncles (see Figs 21.10-21.12, 21.15). Most of its fibres arise from the parvocellular part of the red nucleus and pass to the ipsilateral inferior olivary complex in the medulla. Some tract fibres terminate in the brainstem reticular nuclei. Ascending and descending axons from the brainstem reticular formation also run in the central tegmental tract. These axons include dorsal and ventral ascending noradrenergic bundles, a ventral ascending serotoninergic bundle, and some fibres of dorsal and ventral ascending cholinergic bundles.

As mentioned elsewhere, lesions of the corticospinal system in humans result in permanent paresis or paralysis. In monkeys, although initially complete, the paralysis disappears and good recovery ensues. The explanation for this interprimate variability in recovery from corticospinal lesions appears to lie in the differential capacity of the rubrospinal system to compensate for loss of corticospinal drive. Monkeys never fully recover from combined lesions of both the corticospinal and rubrospinal tracts, which suggests that the two systems are functionally interrelated in the control of movement. Both encode force, velocity and direction parameters, but the rubrospinal system primarily directs activity both during the terminal phase of a movement and preceding a movement. There is, thus, overlap of activity in the two systems for all parameters during movements of limbs and even of individual digits. The corticospinal system is most active during the learning of new movements, whereas the rubrospinal system is most active during the execution of learned automated movements.

The rubro-olivary projection, which travels in the central tegmental tract, connects the red nucleus indirectly to the contralateral cerebellum via olivocerebellar fibres. The cerebellum is thought to play a role in motor learning, and so the rubro-olivary system could switch the control of movements from the corticospinal to the rubrospinal system for programmed automation. The relative absence of a rubrospinal system in humans could explain the poor recovery of motor function after stroke.

## Oculomotor nucleus

The nuclear complex from which the oculomotor nerve arises consists of several groups of large motor neurones (collectively, the oculomotor nucleus; see Fig. 21.16) and smaller preganglionic parasympathetic neurones (the Edinger-Westphal preganglionic nucleus). The motor neurone groups of the oculomotor nucleus innervate, in dorsoventral order, the ipsilateral inferior rectus, inferior oblique and medial rectus. A medially placed column of cells innervates the contralateral superior rectus; the axons from this subnucleus decussate in its caudal part.

The medial rectus subnucleus consists of three anatomically distinct subpopulations. The ventral portion, which contains the largest number of motor neurones, occupies the rostral two-thirds; a subpopulation of smaller motor neurones lies dorsally throughout the rostral two-thirds of the nucleus and innervates the small orbital fibres of the medial rectus; and another subpopulation lies dorsolaterally in the caudal twothirds of the nucleus.

A median subnucleus of large neurones, the caudal central nucleus, lies at the caudal pole of the oculomotor nucleus adjacent to the superior rectus and medial rectus subnuclei. In non-human primates, approximately $30 \%$ of the motor neurones in this subnucleus innervate levator palpebrae superioris bilaterally, which is unique for paired skeletal muscles.

The Edinger-Westphal preganglionic nucleus, composed of small, multipolar, parasympathetic neurones, lies dorsal to the main oculomotor nucleus. Its neurones give rise to axons that travel in the oculomotor nerve and synapse with postganglionic neurones in the ciliary ganglion (Kozicz et al 2011).

Fascicles of axons from these subnuclei course forwards in the midbrain and emerge as the oculomotor nerve in the interpeduncular fossa. The fascicles are most probably arranged from medial to lateral subserving the pupil, inferior rectus, medial rectus, levator palpebrae superioris and superior rectus, and inferior oblique. The human oculomotor nerve contains approximately 15,000 axons.

Afferent inputs to the oculomotor nuclear complex include fibres from the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come, either directly or indirectly, from the nuclei of the posterior commissure, the interstitial nucleus of Cajal, the frontal eye fields, the superior colliculus, the dentate nucleus and other cortical areas. The medial longitudinal fasciculus carries connections from the trochlear, abducens and vestibular nuclei; the medial and lateral vestibular nuclei project to the medial rectus subnucleus.

Afferent inputs to the Edinger-Westphal preganglionic nucleus come primarily from the pretectal nuclei bilaterally, mediating the pupillary light reflex, and from the visual cortex, mediating accommodation.

## Trochlear nucleus

The trochlear nucleus lies in the ventromedial periaqueductal grey immediately adjacent to the medial longitudinal fasciculus at the level of the inferior colliculus (see Figs 21.3, 21.15). It is in line with the ventromedial part of the oculomotor nucleus, in the position of the somatic efferent column. The trochlear nucleus is caudal to the oculomotor nucleus and distinguished by the smaller size of its neurones. The afferent inputs to the trochlear nucleus are similar to those described for the oculomotor nucleus. Trochlear efferent fibres pass laterodorsally round the central grey matter, descending caudally medial to the mesencephalic nucleus as they do so, to reach the upper end of the superior medullary velum, where they decussate and emerge lateral to the frenulum and caudal to the inferior colliculus. A few fibres may remain ipsilateral.

## Medial longitudinal fasciculus

The medial longitudinal fasciculus (see Figs 21.12, 21.15) is a heavily myelinated composite tract, lying adjacent to the midline, ventral to the periaqueductal and periventricular grey matter. It ascends to the interstitial nucleus of Cajal, which lies in the lateral wall of the third ventricle, just above the cerebral aqueduct. The fasciculus retains its position relative to the central grey matter through the midbrain, pons and upper medulla, but is displaced ventrally by the motor (pyramidal) decussation containing corticospinal fibres.

The medial longitudinal fasciculus interconnects the oculomotor, trochlear, abducens, Edinger-Westphal preganglionic, vestibular, reticular and spinal accessory nuclei, coordinating conjugate eye movements and associated movements of the head and neck. Lesions cause internuclear ophthalmoplegia. All four vestibular nuclei contribute ascending fibres. Those from the superior nucleus remain uncrossed, while the others are partly crossed. Some fibres reach the interstitial and posterior commissural nuclei, and some decussate to the contralateral nuclei. Descending axons, from the medial vestibular nuclei and perhaps the lateral and inferior nuclei, partially decussate and descend in the fasciculus to form the medial vestibulospinal tract, which travels in the medial longitudinal fasciculus into the ventral funiculus of the spinal cord (see Ch. 20 and Fig. 20.18). Fibres join the fasciculus from the dorsal trapezoid, lateral lemniscal and posterior commissural nuclei, which means that both the cochlear and vestibular components of the vestibulocochlear nerve may influence movements of the eyes and head via the medial longitudinal fasciculus. Some vestibular fibres may ascend in the medial longitudinal fasciculus as far as the thalamus.

## Tectum

## Inferior colliculus

The inferior colliculus (see Fig. 21.15) is part of the ascending auditory pathway and is the principal site of termination of the lateral lemniscus. It has a central, ovoid, main nucleus, which is lateral to the periaqueductal grey matter. It is surrounded by a lamina of nerve fibres, many from the lateral lemniscus, which terminate in it. The central nucleus
has dorsomedial and ventrolateral zones, which are covered by a dorsal cortex. In humans, the cortex has four cytoarchitectonic layers: layer I contains small neurones with flattened radial dendritic fields; layer II, medium-sized neurones with ovoid dendritic fields aligned parallel with the collicular surface; layer III, medium-sized neurones with spherical dendritic fields; and layer IV, large neurones with variably shaped dendritic fields.

Most efferent fibres from the inferior colliculus travel via the inferior brachium to the ipsilateral medial geniculate nucleus. Lemniscal fibres relay only in the central nucleus, and some pass without relay to the medial geniculate nucleus. In humans, the ventral division of the medial geniculate nucleus receives a topographic projection from the central nucleus and the dorsal division receives a similar projection from the dorsal cortex. Some colliculogeniculate fibres do not relay in the geniculate nucleus but continue, with those that do, via the auditory radiation to the auditory cortex. A descending projection from the auditory cortex reaches the inferior colliculus via the medial geniculate nucleus. Some fibres may traverse this projection without relay. This descending path may produce effects at levels from the medial geniculate nucleus downwards, and it probably links with efferent cochlear fibres, through the superior olivary and cochlear nuclei.

## Superior colliculus

The superior colliculus is an obviously laminated structure. At successive depths from the external surface, it may be divided into seven layers termed zonal, superficial grey, optic, intermediate grey, deep grey, deep white and periventricular strata, composed alternately of neuronal somata or their processes. The zonal layer consists chiefly of myelinated and non-myelinated fibres from the occipital cortex (areas 17, 18 and 19), which arrive as the external corticotectal tract. It also contains a few small neurones, which are horizontally arrayed. The superficial grey layer (stratum cinereum) forms a crescentic lamina over the deeper layers and contains many small multipolar interneurones, on which cortical fibres synapse. The optic layer consists partly of fibres from the optic tract. As they terminate, they permeate the entire anteriorposterior extent of the superficial layers with numerous collateral branches. This arrangement provides a retinotopic map of the contralateral visual field, in which the fovea is represented anterolaterally. Retinal axons terminate in clusters from specific retinotectal neurones and as collaterals of retinogeniculate fibres. The layer also contains some large multipolar neurones. Efferent fibres to the retina are said to start in this layer.

The intermediate grey and white layers collectively constitute the main receptive zone. The main afferent input is the medial corticotectal path from layer $V$ neurones of the ipsilateral occipital cortex (area 18), and from other neocortical areas that are concerned with ocular following movements. Afferent fibres are also received from the contralateral spinal cord (via spinotectal fibres in the anterolateral system), the inferior colliculus, and the locus coeruleus and raphe nuclei (from noradrenergic and serotoninergic neurones). The deep grey and deep white layers adjacent to the periaqueductal grey matter are collectively called the parabigeminal nucleus. They contain neurones whose dendrites extend into the optic layer, and whose axons form many of the collicular efferents.

The superior colliculus receives afferents from many sources including the retina, spinal cord, inferior colliculus and occipital and temporal cortices. The first three of these pathways convey visual, tactile and probably thermal, pain and auditory impulses. Collicular efferents pass to the retina, lateral geniculate nucleus, pretectum, parabigeminal nucleus, the inferior, medial and lateral pulvinar, and to numerous sites in the brainstem and spinal cord. Fibres passing from the pulvinar are relayed to primary and secondary visual cortices and form an extrageniculate retinocortical pathway for visual orientation and attention.

The tectospinal and tectobulbar tracts start from neurones in the superior colliculi. They sweep ventrally around the central grey matter to decussate ventral to the oculomotor nuclei and medial longitudinal fasciculi as part of the dorsal tegmental decussation. The tectospinal tract descends ventral to the medial longitudinal fasciculus throughout the brainstem, diverges ventrolaterally at the level of the motor decussation, and moves medially into the ventral funiculus in association with the medial longitudinal fasciculus. Tectospinal fibres descend to cervical segments. The tectobulbar tract, mainly crossed, descends near the tectospinal tract, and ends in the pontine nuclei and motor nuclei of the cranial nerves, particularly those innervating the oculogyric muscles. It subserves reflex ocular movements. Other tectotegmental fibres reach various tegmental reticular nuclei in the ipsilateral mesencephalic and contralateral pontomedullary reticular formation (gigantocellular reticular, caudal pontine reticular, oral pontine reticular

The central nucleus contains indistinct laminae. Bands of cells with disc-shaped or stellate dendritic fields orthogonally span the fibre layers in which the terminals of lateral lemniscal fibres ramify. The neurones are sharply tuned to frequency, and the laminae may represent the structural basis of tonal discrimination. Experimental studies have found cells driven by low frequencies in the dorsal laminae, and others driven by high frequencies in the ventral laminae. Neurones are broadly frequency-tuned in the dorsal cortex and lateral nucleus.

Inferior collicular projections to the brainstem and spinal cord appear to traverse the superior colliculi before they descend. In this way they connect with the origins of the tectospinal and tectotegmental tracts. These projections are relatively small and probably mediate reflex turning of the head and eyes in response to sounds.

In experimental animals, lesions of either the inferior colliculus or its brachium produce defects in tonal discrimination, sound localization and auditory reflexes. The effects of such lesions are poorly documented in humans.
nuclei), and the substantia nigra and red nucleus. Tectopontine fibres, which probably descend with the tectospinal tract, terminate in dorsolateral pontine nuclei, with a relay to the cerebellum.

## Pretectal nucleus

The pretectal nuclei, of which the olivary pretectal nucleus is one, is a poorly defined mass of neurones at the junction of the mesencephalon and diencephalon. It extends from a position dorsolateral to the posterior commissure caudally towards the superior colliculus, with which it is partly continuous. It receives fibres from the visual cortex via the superior quadrigeminal brachium, from the retina via the lateral root of the optic tract, and from the superior colliculus. Its efferent fibres reach the Edinger-Westphal preganglionic nuclei bilaterally. Those that decussate pass ventral to the aqueduct or through the posterior commissure. In this way, the sphincter pupillae contract in both eyes in response to impulses from either eye. This bilateral light reflex may not be the sole activity of the pretectal nucleus. Some of its efferents project to the pulvinar and deep laminae of the superior colliculus, and provide another extrageniculate path to the cerebral cortex.

## BRAINSTEM RETICULAR FORMATION

The brainstem contains extensive fields of intermingled neuronal cell bodies and nerve fibres, which are collectively termed the reticular formation (Haines 2013, Nieuwenhuys et al 2008, Olszewski and Baxter 1954). The reticular regions are often regarded as phylogenetically ancient, representing a primitive nerve network on which more anatomically organized, functionally selective connections have developed during evolution.

Reticular regions tend to be ill-defined collections of neurones with diffuse connections. Their conduction paths are difficult to define, often complex and polysynaptic, and they have ascending and descending components that are crossed, uncrossed and sometimes bilateral. Their components subserve somatic and visceral functions. They also include some distinct and important cell groups, which are distinguished on the basis of their connections and neurotransmitter substances. These include dopaminergic and noradrenergic neurones (group A), serotoninergic (group B), adrenergic (group C) and cholinergic (group Ch) neurones (Dahlström and Fuxe 1964, Dahlström and Fuxe 1965, Nieuwenhuys 1985 , Siegel et al 1999).

Reticular neurones have long dendrites that spread along the long axis of the brainstem. The dendrites may spread into $50 \%$ of the crosssectional area of their half of the brainstem, and they are intersected by, and may synapse with, a complex of ascending and descending fibres. Many axons of reticular neurones ascend or descend, or bifurcate in both directions. They often travel far, perhaps through the whole brainstem and beyond.

Multitudes of afferent fibres converging on individual neurones, and the myriad destinations of efferent fibres provide the structural basis for considering the reticular formation to be 'polymodal', 'diffuse' or 'nonspecific' in function.

A contrasting dendritic form is also found, in which dendrites are short, sinuous or curved, and branch profusely at the perimeter of a nuclear group, defining a boundary between it and its environs. In different zones, the proportion of different sizes of neuronal somata varies. Some regions contain only small to intermediate multipolar cells ('parvocellular' regions). However, there are a few areas where these mingle with large multipolar neurones in 'gigantocellular' or 'magnocellular' nuclei.

In general terms, the reticular formation is a continuous core that traverses the whole brainstem, and is continuous below with the reticular intermediate spinal grey. It is divisible, on the basis of cytoarchitectonic, chemoarchitectonic and functional criteria, into three bilateral longitudinal columns: median; medial, containing mostly large reticular neurones; and lateral, containing mostly small to intermediate neurones (Fig. 21.18).

## MEDIAN COLUMN OF RETICULAR NUCLEI

The median column of reticular nuclei extends throughout the medulla, pons and midbrain and contains neurones that are largely aggregated in bilateral, vertical sheets, located immediately adjacent to the midline and occupying the paramedian zones. Collectively they are called the nuclei of the raphe, or raphe nuclei. Many neurones in raphe nuclei are serotoninergic and are grouped into nine clusters, B1-9 (see Fig. 21.17) (Dahlström and Fuxe 1964, Dahlström and Fuxe 1965, Nieuwenhuys 1985, Hornung 2003). The raphe pallidus nucleus (B1) and associated raphe obscurus nucleus (B2) lie in the upper two-thirds of the medulla and cross the pontomedullary junction. The raphe magnus nucleus, corresponding to many B3 neurones, minimally overlaps with B1 and

Fig. 21.18 The dorsal aspect of the brainstem showing the approximate location of nuclei of the reticular formation. Nuclei of the median and paramedian nuclear column, pink; medial column nuclei, purple; lateral column nuclei, blue.

A tecto-olivary projection, from deeper collicular laminae to the upper third of the medial accessory olivary nucleus, exists in primates. It is crossed and links with the posterior vermis.

In animals, central collicular stimulation produces contralateral head movement as well as movements involving the eyes, trunk and limbs, which implicates the superior colliculus in the integration of vision and body movement.

As an example, a bifurcating axon from a cell in the magnocellular medullary nucleus may project rostrally into the upper medulla, pons, midbrain tegmentum, subthalamus, hypothalamus, dorsal thalamus, septum, limbic system and neocortex, while its descending branch innervates the reticular core of the lower medulla and may reach the cervical spinal intermediate grey of laminae V and VI. Many reticular neurones have unidirectional, shorter axons that synapse with the radiating dendrites of numerous other neurones en route, and give off collaterals that synapse with cells in 'specific' brainstem nuclei or cortical formations, such as the cerebellum.

B2, and ascends into the caudal pons. Above it is the pontine raphe nucleus, which is formed by cell group B5. Also located in the pons is the central superior raphe nucleus, which contains parts of cell groups B6 and B8. The dorsal (rostral) raphe nucleus, approximating to cell group B7, extends through much of the midbrain. B4 and B9 are small cell groups located in the medulla and midbrain, respectively.

Axons originating from the serotoninergic raphe neurones ramify extensively throughout the CNS.

All raphe nuclei provide descending serotoninergic projections, which terminate in the brainstem and spinal cord. Brainstem connections are multiple and complex. For example, the dorsal raphe nucleus, in addition to sending a large number of fibres to the locus coeruleus, projects to the dorsal tegmental nucleus and most of the rhombencephalic reticular formation, together with the central superior, pontine raphe and raphe magnus nuclei.

Raphe-spinal serotoninergic axons originate mainly from neurones in the raphe magnus, pallidus and obscurus nuclei. They project as ventral, dorsal and intermediate spinal tracts in the ventral and lateral funiculi, and terminate respectively in the ventral horns and laminae I, II and $V$ of the dorsal horns of all segments, and in the thoracolumbar intermediolateral sympathetic and sacral parasympathetic preganglionic cell columns. The dorsal raphe spinal projections function as a pain control pathway that descends from a mesencephalic pain control centre located in the periaqueductal grey matter, dorsal raphe and cuneiform nuclei. The intermediate raphe-spinal projection is inhibitory and, in part, modulates central sympathetic control of cardiovascular function. The ventral raphe-spinal system excites ventral horn cells and could function to enhance motor responses to nociceptive stimuli.

Principally, the mesencephalic serotoninergic raphe system is reciprocally interconnected rostrally with the limbic system, septum, prefrontal cortex and hypothalamus. Efferents ascend and form a large ventral and a diminutive dorsal pathway.

Major afferents to the mesencephalic raphe nuclei include those from the interpeduncular nucleus, linking the limbic and serotoninergic systems; from the lateral habenular nucleus, linking the septum, preoptic hypothalamus and prefrontal cortex via the fasciculus retroflexus and the medial forebrain bundle; and from the pontine central grey matter.

The ascending raphe system probably functions to moderate forebrain activities, particularly limbic, septal and hypothalamic activities. A degree of region-specific connectivity suggests that it exerts precise, as well as tonal, control.

## MEDIAL COLUMN OF RETICULAR NUCLEI

The medial column of reticular nuclei is composed predominantly of neurones of medium size, although very large neurones are found in some regions, and most have processes orientated in the transverse plane. In the lower medulla the column is indistinct, and is perhaps represented by a thin lamina lateral to the raphe nuclei. However, in the upper medulla it expands into the medullary gigantocellular (magnocellular) nucleus, which lies ventrolateral to the hypoglossal nucleus, ventral to the vagal nuclei and dorsal to the inferior olivary complex. Ascending further, the column continues as the pontine gigantocellular (magnocellular) nucleus, which lies medially in the tegmentum. Its neurones suddenly diminish in size to form, in rostral order, the almost coextensive caudal and oral pontine tegmental reticular nuclei. It then expands into the cuneiform nucleus and subcuneiform nucleus, before fading away in the midbrain tegmentum (Haines 2013, Nieuwenhuys et al 2008).

Axons of medial reticular column neurones form a multisynaptic ascending and descending system within the column, and ultimately enter the spinal cord and diencephalon. Descending fibres form pontine (medial) reticulospinal and medullary (lateral) reticulospinal tracts. Pontine reticulospinal axons arise from neurones in the caudal and oral parts of the pontine reticular nucleus, descend largely uncrossed in the ventral spinal funiculus, and terminate in spinal cord laminae VII, VIII and IX. Medullary reticulospinal axons descend bilaterally with an ipsilateral preponderance to end in laminae VII, VIII, IX and X, and ipsilaterally to end in laminae IV, V and VI. The system modulates spinal motor function and segmental nociceptive input.

Afferent components to the medial reticular nuclear column include the spinoreticular projection and collaterals of centrally projecting spinal trigeminal, vestibular and cochlear fibres. Spinoreticular fibres, part of the anterolateral system, arise from neurones in the intermediate grey matter of the spinal cord. They decussate in the ventral white commissure, ascend in the ventrolateral funiculus, and terminate not only
at all levels of the medial column of reticular nuclei but also in the intralaminar nuclei of the thalamus.

## LATERAL COLUMN OF RETICULAR NUCLEI

The lateral column of reticular nuclei contains six nuclear groups. These are the parvocellular reticular area, superficial ventrolateral reticular area, lateral pontine tegmental noradrenergic cell groups A1, A2, A4-A7 (A3 is absent in primates), adrenergic cell groups C1-C3 and cholinergic cell groups Ch5-Ch6 (Nieuwenhuys 1985, Siegel et al 1999). Cell groups Ch1-Ch4 are located in the basal forebrain. The column descends through the lower two-thirds of the lateral pontine tegmentum and upper medulla, where it lies between the gigantocellular nucleus medially, and the sensory nuclei of the trigeminal nerve laterally. It continues caudally and expands to form most of the reticular formation lateral to the raphe nuclei. It abuts the superficial ventrolateral reticular area, nucleus solitarius, nucleus ambiguus and vagal nucleus, and there contains the adrenergic cell group C2 and the noradrenergic group A2.

The lateral paragigantocellular nucleus lies at the rostral pole of the diffuse superficial ventrolateral reticular area (at the level of the facial nucleus). The zone extends caudally as the nucleus retroambiguus and descends into the spinal cord. It contains noradrenergic cell groups A1, A2, A4 and A5, and the adrenergic cell group C1. The ventrolateral reticular area is involved in cardiovascular, respiratory, vasoreceptor and chemoreceptor reflexes, and in the modulation of nociception. The A2 or noradrenergic dorsal medullary cell group lies in the nucleus of the tractus solitarius, vagal nucleus and adjoining parvocellular reticular area. Adrenergic group C1 lies rostral to the A2 cell group. Noradrenergic cell group A4 extends into the lateral pontine tegmentum, along the subependymal surface of the superior cerebellar peduncle. Noradrenergic group A5 forms part of the paragigantocellular nucleus in the caudolateral pontine tegmentum. Noradrenergic cell group A5 and adrenergic cell group C1 probably function as centres of vasomotor control. The entire region is subdivided into functional areas on the basis of experiments in animals, in which vasoconstrictor, cardioaccelerator, depressor, inspiratory, expiratory and sudomotor responses have been elicited.

The lateral pontine tegmental reticular grey matter is related to the superior cerebellar peduncle and forms the medial and lateral parabrachial nuclei and the ventral Kölliker-Fuse nucleus, a pneumotaxic centre. The locus coeruleus (noradrenergic cell group A6), area subcoeruleus, noradrenergic cell group A7 and cholinergic group Ch5 in the pedunculopontine tegmental nucleus (nucleus tegmentalis pedunculopontinus) are all located in the lateral pontine and mesencephalic tegmental reticular zones. A4 is sometimes considered part of the coeruleus complex. The mesencephalic group Ch5 is continuous caudally with cell group Ch6 in the pontine central grey matter.

Cell group A6 (also parts of A4) contains all the noradrenergic cells in the central region of the locus coeruleus. Group A6 has ventral (nucleus subcoeruleus, A6sc), rostral and caudolateral extensions ( A 6 cg ), the latter merging with the A4 group. The locus coeruleus probably functions as an attention centre, focusing neural functions to prevailing needs. The noradrenergic A7 group occupies the rostroventral part of the pontine tegmentum and is continuous with groups A5 and A1 through the lateral rhombencephalic tegmentum. The A7, A5, A1 complex is also connected by noradrenergic cell clusters with group A2, caudally, and group A6, rostrally. The A5 and A7 groups lie mainly within the medial parabrachial and Kölliker-Fuse nuclei. Reticular neurones in the lateral pontine tegmental reticular area, like those of the ventrolateral zone, function to regulate respiratory, cardiovascular and gastrointestinal activity. Two micturition centres are located in the dorsomedial and ventrolateral parts of the lateral pontine tegmentum.

The connections of the lateral column reticular nuclei are complex. The short ascending and descending axons of the parvocellular reticular area constitute medullary reflex pathways, which connect all branchiomotor nuclei and the hypoglossal nucleus with central afferent cranial nerve complexes through a propriobulbar system. This area also receives descending afferents from the contralateral motor cortex via the corticotegmental tract, and from the contralateral red nucleus via the rubrospinal tract. The longitudinal catecholamine bundle passes through the parvocellular reticular formation.

The superficial ventrolateral reticular area receives its principal input from the nucleus solitarius, and subserves cardiovascular, baroreceptor, chemoreceptor and respiratory reflexes; it also receives some input from the spinal cord, insular cortex and amygdala. Reticulospinal fibres from this region terminate bilaterally on sympathetic preganglionic neurones

Although many of these fibres are diffusely distributed, some have more specific connections. For example, whereas the central superior raphe nucleus projects divergently to all areas of the cerebral cortex, different neurones in the dorsal raphe nucleus project specifically not only to circumscribed regions of the frontal, parietal and occipital cortices, but also to functionally related regions of the cerebellar cortex. Similarly, the caudate nucleus and putamen receive a preferential input from the dorsal raphe nucleus, whereas the hippocampus, septum and hypothalamus are innervated mainly by cells in the central superior mesencephalic raphe nucleus.

Both originate from neurones in the dorsal and central superior raphe nuclei. The raphe magnus nucleus also contributes to the dorsal ascending serotoninergic pathway, which is at first incorporated into the dorsal longitudinal fasciculus (of Schütz). A few fibres terminate in the central mesencephalic grey matter and posterior hypothalamus, but most continue into the medial forebrain bundle and merge with the axons of the ventral pathway, which are distributed to the same targets. The fibres of the ventral ascending serotoninergic pathway exit the ventral aspect of the mesencephalic raphe nuclei, and then course rostrally through the ventral tegmentum from where fibres pass to the ventral tegmental area, substantia nigra and interpeduncular nucleus. A large number of fibres then enter the fasciculus retroflexus (habenulointerpeduncular tract) and run rostrally to innervate the habenular nucleus, intralaminar, midline, anterior, ventral and lateral dorsal thalamic nuclei, and the lateral geniculate body. The ventral ascending
serotoninergic pathway enters the medial forebrain bundle in the lateral hypothalamic area and splits to pass medially and laterally. The fibres in the medial tract terminate in the mammillary body, dorsomedial, ventromedial, infundibular, anterior and lateral hypothalamic, medial and lateral preoptic and suprachiasmatic nuclei. Those in the lateral tract take the ansa peduncularis-ventral amygdalofugal path to the amygdala, striatum and neocortex. The medial forebrain bundle carries the remaining ventral ascending serotoninergic axons into the medullary stria, stria terminalis, fornix, diagonal band, external capsule, cingulate fasciculus and medial olfactory stria, to terminate in all the structures that these systems interconnect.

Three areas of the medial reticular zone receive particularly high densities of terminations. These are the combined caudal and rostral ends of the gigantocellular and central nuclei, respectively, and the caudal pontine reticular nucleus and the pontine tegmentum. Retinotectal and tectoreticular fibres relay visual information and the medial forebrain bundle transmits olfactory impulses.

Efferents from the medial column of reticular nuclei project through a multisynaptic pathway within the column to the thalamus. Areas of maximal termination of spinoreticular fibres also project directly to the intralaminar thalamic nuclei. The multisynaptic pathway is integrated into the lateral column of reticular nuclei with cholinergic neurones in the lateral pontine tegmentum. The intralaminar thalamic nuclei project directly to the striatum and neocortex.
in the thoracic spinal cord. Fibres from the pneumotaxic centre project to an inspiratory centre in the ventrolateral part of the nucleus solitarius, and a mixed expiratory-inspiratory centre in the superficial ventrolateral reticular area. Inspiratory neurones in both centres monosynaptically project to the phrenic and intercostal motor neurones. Axons of expiratory neurones terminate on lower motor neurones that innervate intercostal and abdominal musculature.

Reticulospinal fibres descend from the lateral pontine tegmentum. A mainly ipsilateral subcoeruleospinal pathway is distributed to all spinal segments of the cord through the lateral spinal funiculus. Crossed pontine reticulospinal fibres descend from the ventrolateral pontine tegmentum, decussate in the rostral pons and occupy the contralateral dorsolateral spinal funiculus. They terminate in laminae I, II, V and VI of all spinal segments of the cord. Fibres from the pneumotaxic centre innervate the phrenic nucleus and $\mathrm{T} 1-\mathrm{T} 3$ sympathetic preganglionic neurones bilaterally through this projection system.

Bilateral projections from the micturition centres travel in the lateral spinal funiculus. They terminate on preganglionic parasympathetic neurones in the sacral cord (which innervate the detrusor muscle in the urinary bladder), and on neurones in the nucleus of Onuf (which innervate the musculature of the pelvic floor and the anal and urethral sphincters).

Descending fibres of the A6 noradrenergic neurones of the locus coeruleus project into the longitudinal dorsal fasciculus (as the caudal limb of the dorsal periventricular pathway), and into the caudal limb of the dorsal noradrenergic bundle (as part of the longitudinal catecholamine bundle). In this way they innervate, mainly ipsilaterally, all other rhombencephalic reticular areas, principal and spinal nuclei of the trigeminal nerve, pontine nuclei, cochlear nuclei, nuclei of the lateral lemniscus, and bilaterally, all spinal preganglionic autonomic neurones and the ventral region of the dorsal horn in all segments of the spinal cord.

Most ascending fibres from the locus coeruleus pass in the dorsal noradrenergic (or tegmental) bundle; others run either in the rostral limb of the dorsal periventricular pathway or in the superior cerebellar peduncle. The latter fibres terminate on the cerebellar nuclei. The dorsal noradrenergic bundle is large and runs through the ventrolateral periaqueductal grey matter to join the medial forebrain bundle in the hypothalamus, from where fibres continue forwards to innervate all rostral areas of the brain. The pathway contains efferent and afferent axons that reciprocally connect the locus coeruleus with adjacent structures along its course, e.g. central mesencephalic grey matter, dorsal raphe nucleus, superior and inferior colliculi, interpeduncular nucleus, epithalamus, dorsal thalamus, habenular nuclei, amygdala, septum, olfactory bulb and anterior olfactory nucleus, the entire hippocampal formation and neocortex.

## Pedunculopontine nucleus

The pedunculopontine nucleus (nucleus tegmentalis pedunculopontinus; PPN) lies in the dorsolateral part of the pontomesencephalic tegmentum. Despite some terminological confusion, most authors agree
that the pedunculopontine nucleus is bounded laterally by the medial lemniscus, medially by the superior cerebellar peduncle and its decussation, dorsally by the pontine cuneiform and subcuneiform nuclei and ventrally by the pontine reticular formation. Rostrally, its ventral border contacts the dorsomedial aspect of the substantia nigra and it is separated from the subthalamic nucleus by the retrorubral field. Its most caudal pole is adjacent to the locus coeruleus (Pahapill and Lozano 2000).

The pedunculopontine nucleus has been subdivided into two territories based on their cytoarchitectonic and neurochemical characteristics: namely, a caudal pars compacta consisting mainly of cholinergic neurones, and a rostral pars dissipata consisting of approximately equal numbers of cholinergic and glutamatergic neurones scattered from the mid-mesencephalic to mid-pontine levels (Hamani et al 2007). The pedunculopontine nucleus is encircled by the mesencephalic locomotor region (MLR), a region that also includes the cuneiform and subcuneiform nuclei. Based on experimental studies in animals, where stimulation of the mesencephalic locomotor region elicits locomotion, the pedunculopontine nucleus has been implicated in the initiation and modulation of gait and other stereotyped movements. Functionally, the pedunculopontine nucleus is associated with the reticular activating system via its cholinergic and glutaminergic connections with intralaminar thalamic nuclei. However, its most important and complex connections are reciprocal pathways with the basal ganglia, especially the internal globus pallidus and the substantia nigra; these pathways are described in detail in Chapter 24.

## BRAINSTEM LESIONS

## GENERAL CONCEPTS

Brainstem lesions (Figs 21.19-21.20) may arise as a result of extrinsic compression of the brainstem by space-occupying tumours (e.g. meningioma, vestibular schwannoma, metastatic carcinoma) or may be caused by intrinsic disease (e.g. glioma, demyelination, stroke). The clinical syndrome is generally characterized by: ipsilateral cranial nerve deficits, and a contralateral hemiplegia (corticospinal involvement) and/or contralateral hemianaesthesia (anterolateral system, dorsal column-medial lemniscus). Brainstem lesions may also result in cerebellar signs (damage to cerebellar afferents or efferents) or in symptoms reflecting small defects (nystagmus, internuclear ophthalmoplegia) (Haines 2013, Posner et al 2007).

In cases of brainstem lesions, the cranial nerve deficit is the best localizing sign; it specifies the side of the lesion (cranial nerves receive input from and project to the ipsilateral side) and the level within the brainstem. Midbrain lesions (cranial nerves III, IV) cause ophthalmoplegia, pupillary dilation and ptosis (oculomotor nerve palsy), and impaired upward gaze (e.g. due to a pinealoma). Mid-pontine lesions (cranial nerve V ) may result in a loss of sensation on the face and in the oral cavity and weakness of the masticatory muscles. Tumours or

The superficial ventrolateral area is also the seat of the 'visceral alerting response'. Fibres from the hypothalamus, periaqueductal grey matter and midbrain tegmentum mediate increased respiratory activity, raised blood pressure, tachycardia, vasodilation in skeletal muscle and renal and gastrointestinal vasoconstriction. Ascending efferents from the superficial ventrolateral area synapse on neurones of the supraoptic and paraventricular hypothalamic nuclei. Excitation of these neurones causes release of vasopressin from the neurohypophysis. Medullary noradrenergic cell groups A1 and A2 also innervate (directly and indirectly) the median eminence, and control the release of growth hormone, luteinizing hormone and adrenocorticotrophic hormone.

The lateral pontine tegmentum, particularly the parabrachial region, is reciprocally connected to the insular cortex. It shares reciprocal projections with the amygdala through the ventral amygdalofugal pathway, medial forebrain bundle and central tegmental tract, and with hypothalamic, median preoptic and paraventricular nuclei, which preferentially project to the lateral parabrachial nucleus and the micturition centres. It also shares reciprocal bulbar projections, many from the pneumotaxic centre, with the nucleus solitarius and superficial ventrolateral reticular area.

Other axons that contribute to the longitudinal catecholamine bundle originate from cell groups C1, A1, A2, A5 and A7. The main projection is a descending one from cell groups C 1 and A5, which are sudomotor neural control centres and innervate preganglionic sympathetic neurones.

Fibres from the locus coeruleus that travel in the rostral limb of the dorsal periventricular pathway ascend in the ventromedial periaqueductal grey matter adjacent to the longitudinal dorsal fasciculus and terminate in the parvocellular part of the paraventricular nucleus in the hypothalamus.

The functions of the locus coeruleus and related tegmental noradrenergic cell groups are incompletely understood. The diversity of their rostral and caudal projections suggests a widespread role in central
processing. In animals, firing rates of locus coeruleus neurones peak during wakefulness and decrease during sleep - they cease almost completely during rapid eye movement (REM) sleep. During wakefulness, firing rates are augmented when novel stimuli are presented. The locus coeruleus may, therefore, function to control the level of attentiveness. Other functions that have been ascribed to the locus coeruleus include control of the wake-sleep cycle, regulation of blood flow, and maintenance of synaptic plasticity.

The A1, A2, A5 and A7 noradrenergic cell groups project rostrally, mainly through the central tegmental tract. Their axons constitute a major longitudinal catecholamine pathway that continues through the medial forebrain bundle and ends in the amygdala, lateral septal nucleus, bed nucleus of the stria terminalis, nucleus of the diagonal band and the hypothalamus. The ascending dorsal periventricular pathway contains a few non-coerulean noradrenergic fibres, which terminate in the periventricular region of the thalamus.

Projections arising in the rhombencephalon receive contributions from the diffusely organized dorsal medullary and lateral tegmental noradrenergic cell groups. These interconnect cranial nerve nuclei and other reticular cell groups, particularly those of the vagus, facial and trigeminal nerves, and the rhombencephalic raphe and parabrachial nuclei.

Precerebellar nuclei are those that send axons to the cerebellar cortex and nuclei. The three related to the reticular formation are the lateral and paramedian reticular nuclei, and the reticulotegmental nucleus; these are involved in the relay of spinal information into primarily the vermis and paravermal regions of the ipsilateral cerebellar hemisphere. They receive inputs from the contralateral primary motor and sensory neocortices, and the ipsilateral cerebellar and vestibular nuclei and spinal cord (the latter through the ascending spinoreticular pathway). This system augments the dorsal and ventral spinocerebellar, cuneocerebellar, accessory cuneocerebellar and trigeminocerebellar tracts.

A Cingulate herniation under falx, potential anterior cerebral artery damage
B Herniation into opposite hemisphere, potential decorticate posturing
C Transtentorial or central herniation, potential decerebrate posturing, somnolence
D Uncal/parahippocampal gyrus herniation, pupil signs, hemiparesis, somnolence, stupor
E Upward cerebellar herniation, increased intracranial pressure, hydrocephalus, impaired upward gaze F Tonsillar herniation, potential cardiac and respiratory arrest

Fig. 21.20 Space-occupying lesions (SOL).
lesions at the level of the pontomedullary junction (cranial nerves VI, VII, VIII) may produce weakness of the lateral rectus muscle, a loss of facial sensation, and deafness, vertigo or tinnitus. Medullary lesions (cranial nerves IX, X, XII and traversing fibres of XI) may cause a 'bulbar palsy': dysarthria, dysphagia and dysphonia, with wasting of the hemitongue, and deviation, weakness and wasting of sternocleidomastoid and trapezius. All are usually accompanied by signs or symptoms of long tract involvement (motor, sensory or both).

## Herniation syndromes

Damage to the brainstem resulting in characteristic deficits is a major element of what are called herniation syndromes. An increase in
intracranial pressure, signalled by headache, nausea and papilloedema in one compartment (tumour, haemorrhage, abscess, metabolic disorder), usually results in an extrusion of CNS structures from a location of higher pressure to an adjacent location of lower pressure: the brain herniates. All herniation syndromes, directly or indirectly, will compromise brainstem viability (Posner et al 2007, Haines 2015).

An expanding lesion in parietofrontal areas, a supratentorial position, may result in herniation of structures such as the cingulate gyrus underneath the edge of the falx cerebri (see Fig. 21.20A). This may initially be a 'silent' event (no signs or symptoms) or may present as lower-extremity weakness related to compression of the anterior cerebral artery (ipsilateral, contralateral or bilateral) and decreased levels of consciousness.

Hemisphere lesions may enlarge, impinge into the opposite side of the brain, and produce a characteristic series of deficits (see Fig. 21.20B). These include decrease in consciousness indicating damage to the thalamic relays of the reticular activating system, generally increased muscle tone, a change in respiratory patterns, and altered pupils and eye movements. These patients may become decorticate: lower extremities extended, upper extremities flexed.

As a cerebral mass compromises the available supratentorial space and the clinical picture deteriorates, the herniation traverses the tentorial notch as a transtentorial (or central) herniation (see Fig. 21.20C). These patients have a significant decrease in the level of consciousness (some may be stuporous or in coma); breathing patterns are irregular (tachypnoea, Cheyne-Stokes); and eye movements are compromised - pupils are dilated and may be fixed. A state of decortication may convert to decerebrate rigidity, when all extremities are extended.

Lesions located in the temporal lobe may expand medially, forcing the uncus and possibly the parahippocampal gyrus over the edge of the tentorium cerebelli with impingement on the midbrain (see Fig. 21.20D). This is uncal herniation and may present in two forms. First, the midbrain injury involves structures on the side of the herniation with predictable deficits: ipsilateral pupil dilation and ophthalmoplegia, contralateral weakness of upper and lower extremities, an altered level of consciousness and hyperactive reflexes. Second, the herniation may shift the midbrain to the side opposite the herniation (e.g. with herniation on the right, the midbrain shifts to the left). In this case the dilated pupil and third nerve ophthalmoplegia are on the right, and the crus cerebri damaged on the left results in a right hemiplegia; both motor deficits are on the right side. The corticospinal deficit, in this case, is a false localizing sign.

Pressure increase in the posterior fossa, an infratentorial location, may result in herniation upwards through the tentorial notch or downwards into the foramen magnum. Upward cerebellar herniation (see Fig. 21.20E) displaces the brainstem against the tentorium and into the notch with resultant symptoms of increased intracranial pressure, paralysis of upward gaze, motor deficits and altered consciousness. Extrusion of the cerebellar tonsils (see Fig. 21.20F) downwards into the foramen magnum may result in damage to medullary cardiac and respiratory centres, with resultant changes in heart and respiratory rates. Both of these syndromes may constitute a medical emergency, the former due to rapidly developing hydrocephalus, the latter due to compromise of cardiac and respiratory centres.

## Cerebellum

The cerebellum occupies the posterior cranial fossa, separated from the occipital lobes of the cerebral hemispheres by the tentorium cerebelli. It is the largest part of the hindbrain; in adults, the weight ratio of cerebellum to cerebrum is approximately $1: 10$, and in infants $1: 20$. The cerebellum lies dorsal to the pons and medulla, from which it is separated by the fourth ventricle. It is joined to the brainstem by three bilaterally paired cerebellar peduncles.

The basic internal organization of the cerebellum is of a superficial cortex overlying a core of white matter. The cortex is highly convoluted, forming lobes and lobules that are further subdivided into folia (leaflets), separated by intervening transverse fissures. Aggregations of neuronal cell bodies embedded within the white matter form the fastigial (medial), globose (posterior interposed), emboliform (anterior interposed) and dentate (lateral) nuclei, which are collectively known as the (deep) cerebellar nuclei.

The cerebellum may be subdivided into a number of modules, each consisting of a longitudinal cortical zone, a cerebellar or vestibular target nucleus, and a supporting olivocerebellar climbing fibre system. Apart from their connections, the longitudinal cortical zones are characterized by their immunohistochemical properties. The cerebellum receives input from peripheral receptors and from motor centres in the spinal cord and brainstem and from large parts of the cerebral cortex through two different afferent systems: mossy and climbing fibres. It is located as a side path to the main ascending sensory and descending motor systems, and it functions to coordinate movement. During movement, the cerebellum provides corrections that are the basis for precision and accuracy, and it is critically involved in motor learning and reflex modification. Cerebellar output is directed to the thalamus and from there to the cerebral cortex, and also to brainstem centres such as the red nucleus, vestibular nuclei and reticular nuclei, which themselves give rise to descending spinal pathways.

Ideas on the involvement of the cerebellum in motor functions were derived mainly from movement disorders seen in experimental studies, summarized by Luciani (1891) in his triad of atonia, astasia and asthenia, and in human patients with cerebellar lesions who displayed the well-known symptoms of gait disturbances, limb ataxia, dysmetria, atonia and eye movement disorders (Glickstein et al 2009). Latterly, the observation that lesions of the cerebellar hemisphere not only resulted in minor and transient motor symptoms but also induced a cerebellar cognitive/affective syndrome (Schmahmann 2004) prompted the suggestion that the human cerebellum is also concerned with non-motor functions. These conceptual developments went hand in hand with the use of more sensitive experimental methods to trace cerebellar connectivity, mainly in subhuman primates, and the application of modern imaging techniques to the human brain. Although it is now recognized that the cortex is more heterogeneous than previously supposed, and despite our extensive knowledge of the sphere of influence of the cerebellum and the microcircuitry of its cortex and nuclei, we still do not fully understand how it contributes to motor and non-motor systems. The observation by Thomas Willis (1681) that 'the Spirits inhabiting the Cerebel perform unperceivedly and silently their Work of Nature without our Knowledge or Care' remains true today.

## EXTERNAL FEATURES AND RELATIONS

The cerebellum consists of two large, laterally located hemispheres that are united by a midline vermis (Figs 22.1-22.3). Numerous sulci and fissures of varying depth subdivide it into lobes, lobules and folia (leaflets) (Figs 22.4-22.5). The primary fissure, the deepest fissure on a sagittal section, divides it into anterior and posterior lobes. Paramedian fissures, shallow in the anterior cerebellum but prominent more posteriorly, separate the vermis from the cerebellar hemispheres. Both the anterior and posterior vermis and hemisphere are subdivided into lobules that received their names in the eighteenth and

nineteenth centuries from their shape, their position or their likeness to anatomical structures in other body parts (Glickstein et al 2009). This classical nomenclature (see Fig. 22.4, right panel) was largely replaced in the early twentieth century by a nomenclature based on Bolk's (1906) comparative anatomical investigations (see Fig. 22.4, left panel).

Bolk distinguished the relatively independent 'folial chains' of the vermis and the hemispheres. In later studies, this relative independence was found to reflect the continuity or discontinuity of the cortex between the lobules within a folial chain, or between the folial chains of the vermis and the hemispheres. Bolk used the cerebellum of a small lemur for his initial description (see Fig. 22.5F-G) and summarized the configuration of the folial chains in a stick diagram (see Fig. 22.5H). His description proved to be applicable to the cerebella of all the mammals he studied, including the human cerebellum.

Larsell (Larsell and Jansen 1972) based his subdivision of the cerebellum on embryological studies of the emergence of the transverse fissures with time. Contrary to Bolk, who emphasized the continuity within the folial chains, Larsell attached great importance to the mediolateral continuity of the lobules of the vermis and the hemispheres, and distinguished 10 lobules in the cerebellum, indicated using Roman numerals I-X for the vermis and the prefix H for the hemisphere. The correspondence of Larsell's lobules with the classical nomenclature is shown in Figure 22.4.

Lobules (H)I-V constitute the anterior lobe. Lobule I, the lingula, is conjoined with the superior medullary velum. Lobules VI (declive) and

The lobules are labelled by numbers and the fissures between the lobules are listed. B, The cerebellum viewed from above. C, A median sagittal section of cerebellum. The lobules are numbered and listed. D, The cerebellum viewed from below. Key and abbreviations: Anterior lobe: 1, lingula; 2, central; 3, culmen, vermis. Posterior lobe: 4, declive; 5, folium; 6, tuber; 7, pyramis; 8, uvula; 9, nodule. Fissures: apm, ansoparamedian; hzl, horizontal; intb, intrabiventral; pcen, precentral; plat, posterolateral; preb, prebiventral; precul, preculminate; prim, primary; psup, posterior superior; sec, secondary. Hemisphere: 1a, wing of lingula; 2a, wing of central lobule; 3a, anterior quadrangular lobule; 4a, posterior quadrangular lobule; 5a, superior semilunar lobule; 6a, inferior semilunar lobule; 7 a , gracile lobule; 8 a , biventral lobule; 9 a , tonsil of cerebellum, 10a, flocculus.

Fig. 22.4 Cerebellar nomenclature. The left-hand panel illustrates the comparative anatomical nomenclature for the hemisphere and Larsell's numbering system for the lobules of the vermis (Larsell and Jansen 1972). The right-hand panel shows the classical nomenclature. The homology of these lobules is indicated using the same colour. Asterisks denote areas devoid of cortex in the centre of the folial rosettes of the ansiform lobule and the paraflocculus.

Fig. 22.5 A-D, Anterior, dorsal, posterior and ventral views of the human cerebellum. E, A sagittal section of the human cerebellum. F-G, Dorsal and ventral views of the cerebellum of Lemur albifrons, Bolk's (1906) prototype for his ground plan of the mammalian cerebellum. Two loops are present in the folial chain of the hemisphere: (1) as the ansiform lobule, (2) as the paraflocculus. The course of the folial chains of the vermis and hemisphere in A-D and F-G is indicated with red lines. H, Bolk's stick diagram of the folial chains of the vermis and hemisphere. Key and abbreviations: 1, 2, Ansiform and parafloccular loops of the folial chain of the hemisphere; Ce, central lobule; Cu, culmen; De, declive; FA, fastigium; F/T, folium and tuber; Icp, inferior cerebellar peduncle; Li, lingula; Mcp, middle cerebellar peduncle; Nod, nodulus; PFLD, dorsal paraflocculus; PFLV, ventral paraflocculus; Py, pyramis; Scp , superior cerebellar peduncle; SI, simplex (posterior quadrangular) lobule; Uv, uvula; Vma, anterior (superior) medullary velum; Vmp, posterior medullary velum.

HVI (posterior quadrangular lobule) are also known as Bolk's simplex lobule. Behind the primary fissure, the folium (lobule VIIA) and tuber vermis (VIIB) are separated by the deep paramedian fissure from the superior semilunar lobule (HVIIA), the inferior semilunar lobule and the gracile lobule (together corresponding to HVIIA). Superior and inferior semilunar lobules correspond to the crus I and II of Bolk's ansiform lobule. Their folia fan out from the deep horizontal fissure that represents the intercrural fissure. The gracile lobule corresponds to the rostral part of Bolk's paramedian lobule. Its caudal portion is
formed by the biventral lobule (HVIII), the hemisphere from the pyramis (VIII). Lobule VIII (the pyramis) is continuous with the biventral lobule (HVIII) laterally. The gracile lobule corresponds to the rostral part of Bolk's paramedian lobule; the biventral lobule corresponds to its caudal portion. The tonsil (HIX) corresponds to the dorsal paraflocculus in the monkey. In the human, the folial loop of the tonsil is directed medially, contrary to the situation in most mammals, where the paraflocculus arches laterally. The flocculus appears as a double folial rosette; its dorsal leaf is known as the accessory paraflocculus of

Fig. 22.6 Dissection of the left cerebellar hemisphere and its peduncles.

Henle, while its ventral leaf represents the true flocculus. The accessory paraflocculus corresponds to the ventral paraflocculus in the monkey. Both these lobules belong to the vestibulocerebellum. The cortex between the tonsil and the accessory paraflocculus is interrupted. Between lobule X (the nodulus) and the flocculus (HX) with the accessory paraflocculus, the cortex is absent and the tissue is stretched out as the inferior medullary velum.

Two magnetic resonance imaging (MRI) atlases of the cerebellum have been published to aid localization in functional MRI (fMRI) (Schmahmann et al 1999, Diedrichsen 2006). The authors use Larsell's numerals and retain Bolk's terms crus I and II, but discard Larsell's use of the prefix H for the lobules of the hemisphere. As a consequence, it is difficult to determine whether descriptions of lobules using these criteria refer to the vermis or to the hemisphere.

## CEREBELLAR PEDUNCLES

Three pairs of peduncles connect the cerebellum with the brainstem (Fig. 22.6; see also Fig. 21.19).

The middle cerebellar peduncle is the most lateral and by far the largest of the three. It passes obliquely from the basal pons to the cerebellum and contains the massive pontocerebellar mossy fibre pathway, which is composed almost entirely of fibres that arise from the contralateral basal pontine nuclei, with a small addition from nuclei in the pontine tegmentum.

The inferior cerebellar peduncle is located medial to the middle peduncle. It consists of an outer, compact fibre tract - the restiform body - and a medial, juxtarestiform body. The restiform body is a purely afferent system; it receives spinocerebellar fibres and the trigeminocerebellar, cuneocerebellar, reticulocerebellar and olivocerebellar tracts from the medulla oblongata (see Fig. 21.19). The juxtarestiform body is mainly an efferent system, made up almost entirely of efferent Purkinje cell axons destined for the vestibular nuclei and uncrossed fibres from the fastigial nucleus. It also contains primary afferent mossy fibres from the vestibular nerve and secondary afferent fibres from the vestibular nuclei. The crossed fibres from the fastigial nucleus pass dorsal to the superior cerebellar peduncle as the uncinate tract, and enter the brainstem at the border of the juxtarestiform and restiform bodies.

The superior cerebellar peduncle contains all of the efferent fibres from the dentate, emboliform and globose nuclei, and a small fascicle from the fastigial nucleus. Its fibres decussate in the caudal mesencephalon, and are destined to synapse in the contralateral red nucleus and thalamus. The ventral spinocerebellar tract reaches the upper part of the pontine tegmentum, looping around the entrance of the trigeminal nerve to join this peduncle and unite with the spinocerebellar fibres entering through the restiform body.

## INTERNAL ORGANIZATION

The vast majority of cerebellar neuronal cell bodies are located within the outer, highly convoluted cortical layer. Beneath the cortex, the cerebellar white matter forms an extensive central core, from which a
characteristic branching pattern of nerve fibres (arbor vitae) extends towards the cortical surface (see Fig. 22.2). The white matter consists of afferent and efferent fibres travelling to and from the cerebellar cortex. Fibres cross the midline in the white core of the cerebellum and the superior medullary velum, effectively constituting a cerebellar 'commissure'.

## CEREBELLAR CORTEX

Although the human cerebellum makes up approximately one-tenth of the entire brain by weight, the surface area of the cerebellar cortex, if unfolded, would be about half that of the cerebral cortex. The great majority of cerebellar neurones are small granule cells, so densely packed that the cerebellar cortex contains many more neurones than the cerebral cortex. Unlike the cerebral cortex, where a large number of diverse cell types are arranged differently in different regions, the cerebellar cortex contains a relatively small number of different cell types, which are interconnected in a highly stereotyped way.

The elements of the cerebellar cortex possess a precise geometric order, arrayed relative to the tangential, longitudinal and transverse planes in individual folia. Three layers are distinguished in the cerebellar cortex (Figs 22.7-22.8). A monolayer of large neurones with apical dendrites, first identified by Purkinje (Glickstein et al 2009), separates a layer of small granule cells from the superficial, cell-poor molecular layer. The Purkinje cell layer contains the large, pear-shaped somata of the Purkinje cells and the smaller somata of Bergmann glia. Clumps of granule cells and occasional Golgi cells penetrate between the Purkinje cell somata. The granular layer consists of the somata of granule cells and the initial segments of their axons; dendrites of granule cells; branching terminal axons of afferent mossy fibres; climbing fibres passing through the granular layer en route to the molecular layer; and the somata, basal dendrites and complex axonal ramifications of Golgi neurones.

The molecular layer contains a sparse population of neurones, dendritic arborizations, unmyelinated axons and radial fibres of neuroglial cells.

## Purkinje cells

Purkinje cells are the only output neurones of the cortex. They are arranged in a single layer between the molecular and granular layers, and have a specific geometry that is conserved in all vertebrate classes (Fig. 22.9).

Their dendritic trees are flattened and orientated perpendicular to the parallel fibres in a plane transverse to the long axes of the folia (see Figs 22.7-22.8; see also Figs 3.3, 3.6). Large primary dendrites arise from the outer pole of a Purkinje cell. The proximal dendritic branches are smooth and are contacted by climbing fibres. The distal branches carry a dense array of dendritic spines (spiny branchlets) that receive synapses from the terminals of parallel fibres. Inhibitory synapses are also received from basket and stellate cells, and from the recurrent collaterals of Purkinje cell axons that contact the shafts of the proximal dendrites. The total number of dendritic spines per Purkinje neurone is in the order of 180,000 . The axon of a Purkinje cell leaves the inner pole of the soma and crosses the granular layer to enter the subjacent white matter. The initial axon segment receives axo-axonal synaptic contacts from distal branches of basket cell axons. Beyond the initial segment, the axon enlarges, becomes myelinated and gives off collateral branches. The main axon ultimately terminates in one of the cerebellar or vestibular nuclei; recurrent axonal collaterals form a sagittally orientated plexus with terminations on neighbouring Purkinje cells and Golgi cells. Purkinje cells are inhibitory and use $\gamma$-aminobutyric acid (GABA) as their neurotransmitter.

## Cortical interneurones

The cerebellar cortical interneurones were described by Ramón y Cajal (1906) (see Fig. 22.8). They can be divided into the interneurones of the molecular layer, the stellate and basket cells, and the Golgi cells of the granular layer. All interneurones are inhibitory. Those of the molecular layer use GABA as their neurotransmitter. Most Golgi cells are glycinergic. Stellate cells are located in the upper molecular layer, their axons terminating on Purkinje cell dendrites. Basket cells occupy the deep molecular layer, their axons terminating on a series of Purkinje cells with baskets surrounding their somata, ending in a plume around their initial axon. The dendrites of these interneurones and their axons are oriented in the sagittal plane. Golgi cell dendrites are located in the

Fig. 22.7 The circuitry of the cerebellar cortex. Glutamatergic neurones are shown in dark grey, GABAergic neurones in red and glycinergic elements in blue. A, A transparent dorsal view of the cortex showing the orientation of its major elements. Dendrites of Purkinje, stellate and basket cells, the collateral plexus of Purkinje cells, the cell bodies of the Lugaro cells, and the climbing fibres and the axonal plexus of the Golgi cells are orientated in the sagittal plane. B, A transverse section. Parallel fibres and the axons of the Lugaro cells are the only elements with a transverse orientation.

granular and molecular layers. Their axonal plexus occupies the granular layer, where it terminates on the granule cell dendrites, and also has its greatest dimension in the sagittal plane (see Fig. 22.7). Golgi cells are innervated by collaterals of mossy fibres and Purkinje cell axons. The dendrites of interneurones in the molecular layer are contacted by the parallel fibres. Synaptic contacts between climbing fibres and the dendrites or cell bodies of cerebellar interneurones in the molecular or granular layers have not been observed. However, interneurones of the molecular layer can be activated by 'spillover' of glutamate from the climbing fibres (Galliano et al 2013, Szapiro and Barbour 2007). Golgi cells, therefore, provide feed-back inhibition to the granule cells. Interneurones of the molecular layer provide feed-forward inhibition to the Purkinje cells. Stellate cells (Mann-Metzer and Yarom 2000) and Golgi cells (Dugué et al 2009) are electrotonically coupled. The extent of this coupling is not known; it may be restricted to the sagittal compartments that are one of the main features of the connectivity of the cerebellum, discussed below.

Two other types of interneurone exist. Lugaro cells are cigar-shaped neurones located at the level of the Purkinje cells (Lainé and Axelrad 1996) (see Fig. 22.7). These glycinergic neurones innervate the stellate and basket cells, and provide a long, transversely orientated axon that terminates on Purkinje cells. They receive a strong input from an extracerebellar serotoninergic system. Monopolar brush cells are excitatory neurones, mainly found in vestibular-dominated regions of the cerebellum (Mugnaini et al 1997), where they are considered to be a 'booster' system for vestibular mossy fibre input. Mossy fibres terminate with extremely large synapses on the base (the 'brush') of these cells. Their axons terminate as mossy fibres on the granule cells.

## CEREBELLAR NUCLEI

The four cerebellar nuclei were first described by Stilling (1864) as comprising (from medial to lateral) the fastigial nucleus, the emboliform and globose nuclei, and the dentate nucleus (Fig. 22.10). The

Fig. 22.9 The general organization of the cerebellar cortex. A single folium has been sectioned vertically, both in its longitudinal axis (right side of diagram) and transversely.

Fig. 22.10 The human cerebellar nuclei. A-E, Transverse sections through the cerebellar nuclei, A being the most rostral level. The dentate nucleus can be subdivided into dorsomedial microgyric and ventrocaudal macrogyric parts. F, A Weigert-stained section through the dentate nucleus, showing its subdivision into micro- and macrogyric parts. (A-E Redrawn from Larsell O, Jansen J 1972 The comparative anatomy and histology of the cerebellum. III. The human cerebellum, cerebellar connections, and cerebellar cortex. Minneapolis, University of Minnesota Press. F, Reproduced with permission from Winkler C 1926 De bouw van het zenuwstelsel. Haarlem, de erven Bohn.)
emboliform and globose nuclei are also known as the anterior and posterior interposed nuclei. The nuclei form two interconnected groups: a rostrolateral group consisting of the emboliform and dentate nuclei, and a caudomedial group including the fastigial and globose nuclei.

A collection of small, cholinergic neurones extends from the flocculus to the nodulus in the roof of the fourth ventricle, invading the spaces between the nuclei. These cells are known as the basal interstitial nucleus (Langer 1985); their connections are not known.

The dentate nucleus is located most laterally and is by far the largest of the group. It has the shape of a crumpled purse; the main efferent pathway of the cerebellum, the brachium conjunctivum, emerges from its hilus. The convolutions of the dentate nucleus are narrow rostromedially and much wider ventrocaudally. Interestingly, these microand macrogyral characteristics of the human dentate were observed by Vicq-d'Azir, who coined its name in the eighteenth century (Glickstein et al 2009). Recently, rostromedial motor and ventrocaudal non-motor divisions have been distinguished in the human dentate nucleus using fMRI (Küper et al 2012). Their significance and the possible correspondence with the anatomical subdivisions of the dentate are considered below.

The cerebellar nuclei contain cells of all sizes. Glutamatergic relay neurones provide the main output of the nuclei. Small GABAergic neurones innervate the contralateral inferior olive. Both GABAergic and glycinergic interneurones have been identified (Uusisaari and Knöpfel
2011); as far as we know, all cell types receive an inhibitory input from Purkinje cells and an excitatory input from mossy and climbing fibre collaterals.

## CEREBELLAR CIRCUITRY

The main circuitry of the cerebellum was described by Ramón y Cajal in the late nineteenth century and published in his Histologie du système nerveux (1906). It involves two extracerebellar afferent systems (climbing fibres and mossy fibres), intrinsic cortical neurones, including Purkinje, granule, stellate and basket cells, and neurones in the cerebellar nuclei (see Figs 22.7-22.9). The widely diverging mossy fibre-parallel fibre system terminates on Purkinje cells (the only output neurones of the cortex projecting to the cerebellar and vestibular nuclei); a climbing fibre terminates on the proximal, smooth Purkinje cell dendrites; Golgi cells provide backward inhibition to granule cells; and stellate and basket cells provide forward inhibition to Purkinje cells.

Climbing fibres and most mossy fibres are excitatory and use glutamate as their neurotransmitter. All climbing fibres take their origin from the contralateral inferior olivary nucleus in the medulla oblongata. In the cerebellum, they split into several branches, each branch providing a climbing fibre to a single Purkinje cell. The branches of a single olivocerebellar fibre innervate one or more sagittally orientated strips

Fig. 22.11 The orientation and branching pattern of mossy and climbing fibres. Left-hand panels: mossy fibres are orientated transversely. They distribute bilaterally and emit collaterals at specific, symmetrical locations. These collaterals terminate as sagittally orientated aggregates of mossy fibre terminals. Right-hand panels: olivocerebellar fibres branch in the sagittal plane. Each branch provides a Purkinje cell with a single climbing fibre. These climbing fibres form narrow, longitudinally orientated strips that may correspond to the microzones; strips of Purkinje cells that share the same climbing fibre receptive fields. Abbreviations: Py, pyramis; Uv, uvula. (Reproduced with permission from Nieuwenhuys, R, Voogd J, van Huijzen 2008 The Human Nervous System. 4th Ed Springer Verlag.)
of Purkinje cells (Fig. 22.11). These strips probably correspond to 'microzones' consisting of a narrow strip of Purkinje cells innervated by climbing fibres sharing the same receptive field. Microzones, with their Purkinje cells, are considered to be the basic structural and functional unit of the cerebellar cortex (Andersson and Oscarsson 1978).

Mossy fibres take their origin from multiple sources in the spinal cord and brainstem. Their myelinated axons terminate on the claw-like dendrites of the granule cells and on Golgi cells. The granule cells give rise to an ascending axon that splits in the molecular layer into two parallel fibres that run for some distance in the direction of the long axis of the folia. Parallel fibres terminate on the spines of the spiny branches of the Purkinje cell dendritic tree and the dendrites of interneurones that they meet along their course (see Figs 22.7, 22.9). The length of the parallel fibres in the human cerebellar cortex is not known but the two branches probably do not exceed 10 mm . Like the climbing fibres, mossy fibres branch profusely in the cerebellar white matter (see Fig. 22.11). The parent fibres enter the cerebellum laterally and run a transverse course to decussate in the cerebellar commissure. During their course, they emit thin collaterals that enter the white matter of the lobules and terminate in multiple, longitudinally orientated and symmetrically distributed aggregates of mossy fibre terminals in the granular layer (Wu et al 1999).

The climbing fibre microzones and the subjacent mossy fibre aggregates have been found to share the same peripheral receptive fields in regions of the cerebellum receiving somatosensory information from the periphery (Ekerot and Larson 1980, Ekerot and Jörntell 2003). A similar topographical relationship between microzones and mossy fibre terminal aggregates exists in other parts of the cerebellar cortex; their common denominator remains unknown (Pijpers et al 2006). The significance of such a topographical relationship is difficult to understand because the parallel fibres would disperse a localized mossy fibre input over a wide, mediolateral region of the molecular layer. Different hypotheses to explain this topographical relationship have been proposed, some of the more recent ones involving the interneurones of the cerebellar cortex, but the matter remains undecided (Ekerot and Jörntell 2003, Barmack and Yakhnitsa 2011).

## THE MODULAR ORGANIZATION OF THE CEREBELLUM AND THE CORTICONUCLEAR AND OLIVOCEREBELLAR PROJECTIONS

The output of the cerebellum is organized as a series of parallel, sagittal modules (Voogd and Bigaré 1980, Voogd and Ruigrok 2012). Each module consists of one or more longitudinal Purkinje cell zones that project to one of the cerebellar or vestibular nuclei (Fig. 22.12A). Some of these Purkinje cell zones are restricted to certain lobules; others span the entire rostrocaudal length of the cerebellum. Climbing fibres from
a subdivision of the contralateral inferior olive terminate on the Purkinje cells of a particular zone and also send a collateral innervation to the corresponding deep cerebellar nucleus. This collateral innervation is reciprocated by the, mainly crossed, nucleo-olivary pathway that originates from the small GABAergic neurones of the cerebellar nuclei. Modules can be visualized because their Purkinje cell axons and their climbing fibre afferents collect in compartments in the cerebellar white matter. The borders between these compartments, i.e. between the modules, become visible when stained for acetylcholine esterase (AChE) (Fig. 22.12B). The modular organization of the cerebellum has been studied in most detail in rodents and carnivores, and has been confirmed in non-human primates. For the human cerebellum, evidence for its presence is mainly embryological.

The modular organization of the cerebellum appears very early during its development, long before the emergence of any of its transverse fissures. Purkinje cells, born in the ventricular matrix of the cerebellar anlage, migrate to the meningeal surface, where they form a series of mediolaterally arranged clusters (Korneliussen 1968, Kappel 1981). During the later increase of the cerebellar surface in the rostrocaudal dimension, reflecting the proliferation of millions of granule cells in the transient external matrix (the external granular layer) (see Fig. 22.15), the Purkinje cell clusters increase in length and thus are transformed into Purkinje cell zones. The Purkinje cells become located in a monolayer and the original borders between the clusters are no longer visible. This mode of development has been studied in different species and can also be recognized in the human fetal cerebellum. Purkinje cell clustering in the human does not differ from that in other species, with the exception of the immense size of the most lateral cluster, which is clearly related to the anlage of the dentate nucleus (Fig. 22.13). This cluster develops into the D2 zone, the most lateral Purkinje cell zone, responsible for the large size of the human cerebellar hemisphere.

Eight or nine of the modules can be recognized in the cerebellum of subhuman primates and lower mammals (see Fig. 22.14A). Purkinje cell zones differ in their climbing fibre afferents and their cerebellar or vestibular target nucleus. Moreover, Purkinje cells of the different zones differ in their immunohistochemical properties (Voogd and Ruigrok 2012). A Purkinje cell-specific antibody, known as 'zebrin 2', is distributed in a pattern of zebrin-positive and zebrin-negative Purkinje cell zones (Fig. 22.14D-E). This pattern has been shown to be congruent with the olivocerebellar and corticonuclear projection zones (Voogd et al 2003, Sugihara and Shinoda 2004). Many substances, such as the enzymes aldolase $\mathrm{C}, 5^{\prime}$ nucleotidase, protein kinase C and the metabotropic glutamate transporter 1A, co-localize with zebrin 2. Neurotransmission in different Purkinje cell zones may therefore differ: zebrin-positive Purkinje cells fire at a slower rate than the zebrinnegative cells (Zhou et al 2014).

In the following, the olivocerebellar climbing fibre and the efferent corticonuclear projections of the Purkinje cell zones will be described.

Fig. 22.12 A, A cerebellar module. Purkinje cell axons and climbing fibres are located in a white matter compartment, shown as a transparent structure in this diagram. B, An acetylcholinesterase-stained section through the anterior lobe: macaque monkey. The borders of the white matter compartments of the modules A-C are heavily stained. Abbreviations: m, midline.

Data are from experimental studies in the cat, the rat and subhuman primates (reviewed in Voogd and Ruigrok (2012)). The subdivision of the inferior olive, the sole source of the climbing fibres, is summarized in Figure 22.15.

The A zone is located next to the midline and extends over the entire vermis (see Fig. 22.14A). It is composed of several zebrin-positive and zebrin-negative subzones that may be present over limited segments of its extent. It projects to the fastigial and vestibular nuclei, and receives its climbing fibres from the caudal medial accessory olive. Whereas the A zone extends over the entire vermis, the X and B zones are restricted to the vermis of the anterior lobe, the simplex lobule (VI) and lobule VIII (the pyramis). The narrow X zone separates the A zone from the B zone, which occupies the lateral vermis of these lobules. The X zone projects to the interstitial cell groups, located between the fastigial and posterior interposed nuclei and receives climbing fibres from the intermediate region of the medial accessory olive. The B zone projects to Deiters' lateral vestibular nucleus and is innervated by climbing fibres from the caudal part of the dorsal accessory olive. The dorsal accessory olive, the B zone and the lateral vestibular nucleus are somatotopically organized. In the B zone, the hindlimb is represented laterally and the forelimb is represented medially (Andersson and Oscarsson 1978). In rodents, Purkinje cells of the X and B zones are zebrin-negative.

The hemisphere is composed of the C1-C3 and the D1, Y and D2 zones. Like the X and B zones, $\mathrm{C} 1, \mathrm{C} 3$ and the Y are restricted to the anterior lobe, the simplex lobule (HVI) and the paramedian lobule (HVIIB - the gracile lobule, and HVIII - the biventral lobule). Moreover, the Purkinje cells of these zones are zebrin-negative and thus appear as blank spaces in suitably immunostained histological sections of the

Fig. 22.13 A transverse section through the cerebellum of a 65 mm human fetus, showing the Purkinje cell clusters that will develop into the A, B, C1-C3 and D Purkinje cell zones. Note the large size of the D cluster. Abbreviations: EGL, external granular layer. (From the Schenk collection of the Dept. of Pathology of the Erasmus Medical Center Rotterdam.)
anterior and posterior cerebellum (see Fig. 22.14E). The C1, C3 and Y zones project to the anterior interposed nucleus and receive their climbing fibre input from the rostral dorsal accessory olive (DAOr) (Fig. 22.16). This subnucleus receives an input from peripheral receptors through dorsal column and trigeminal pathways. The climbing fibre projections of the rostral dorsal accessory olive to the C1, C3 and Y zones and the anterior interposed nucleus are somatotopically organized. In each of the zones, the hindlimb is represented rostrally in the anterior cerebellum and caudally in the posterior lobe; the forelimb and face occupy more central areas (Ekerot and Larson 1979) (see Fig. 22.16). This rostrocaudal distribution clearly differs from the mediolateral somatotopy in the vermal B zone. The somatotopical localization is an extremely detailed one, repeated in each of the zones. The $\mathrm{C} 1, \mathrm{C} 3$ and Y zones connect with motor centres in the brainstem and the cerebral cortex. The hemisphere of the anterior lobe and the simplex lobule, and the paramedian lobule (HVIIB - the gracile lobule, and HVIII - the biventral lobule) are considered as the motor regions of the cerebellum.

The C2, D1 and D2 zones extend beyond the anterior and posterior motor regions, where they interdigitate with the C1, C3 and Y zones, over most of the rostrocaudal length of the cerebellum. In rodents, these zones are zebrin-positive. The C2 zone projects to the posterior interposed nucleus and receives its climbing fibre input from the rostral medial accessory olive (see Fig. 22.18). A somatotopical organization is lacking in the C 2 zone. The D1 and D2 zones project to the caudal and rostral dentate and receive their climbing fibres from the ventral and dorsal laminae of the principal olive, respectively. The main connections of the C 2 and the D zones are with the cerebral cortex. The sections of the C2 and D2 zones located in the anterior and posterior motor regions of the cerebellar hemisphere are connected with motor, premotor and parietal cortical areas; these sections of the D 2 zone are somatotopically organized. Sections of the C 2 and the D zones located in the ansiform lobule (HVII) and the paraflocculus (the tonsil, HIX) subserve visuomotor and non-motor functions.

The modular organization of the vestibulocerebellum is fairly complex; multiple Purkinje cell zones, innervated by climbing fibres from subnuclei in the inferior olive, transmit optokinetic and vestibular information.

Each lobule of the cerebellum contains a particular set of Purkinje cell zones. Apart from the parallel fibres, which may cross several Purkinje cell zones or microzones in their course through the molecular layer, there is no cross-talk between the modules. Parallel fibres are, therefore, a key element in the integrative function of the cerebellum. The relative independence of the cerebellar modules is an important

Fig. 22.14 The connections of the Purkinje cell zones of the mammalian cerebellum. A, The flattened cerebellar cortex. B, Target nuclei of Purkinje cells. C, Sources of climbing fibres associated with Purkinje cells, shown in the flattened contralateral inferior olive (see Fig. 22.15) and indicated in the same colour. D, Zebrin-positive and zebrin-negative Purkinje cell bands. The zebrin-positive bands are numbered from 1 to 7 . A comparison with panel A shows that the A zone is a composite of zebrin-positive and zebrin-negative subzones; the $\mathrm{X}, \mathrm{B}, \mathrm{C} 1, \mathrm{C} 3$ and Y zones consist of zebrin-negative Purkinje cells. E, The zebrin-positive and zebrin-negative bands of the cerebellum of a rat. Abbreviations: A-D2, Purkinje cell zones A-D2; ANS, ansiform lobule; Beta, group beta; DAOc/r, caudal/rostral dorsal accessory olive; Dc, dorsal cap; Dmcc, dorsomedial cell column; Fast, fastigial nucleus; ICG, interstitial cell groups; M, midline, MAOc/int/r, caudal/intermediate/rostral medial accessory olive; PMD, paramedian lobule; POdL, dorsal lamina of the principal olive; POvL, ventral lamina of the inferior olive; PY, pyramis (lobule VIII); UV, uvula (lobule IX); VII, vermal lobule VII; VLO, ventrolateral outgrowth.
difference between the cerebellum and the cerebral cortex, where different functional areas are intimately interconnected.

## CONNECTIONS OF THE CEREBELLAR NUCLEI: RECIPROCAL ORGANIZATION OF THE CORTICO-OLIVARY SYSTEM

The connections of the cerebellar nuclei with the brainstem, the thalamus and the spinal cord determine the sphere of influence of the cerebellar modules. The A, X and B zones of the vermis project to the
fastigial nucleus, the interstitial cell groups and the lateral vestibular nucleus, respectively (see Fig. 22.14). In all mammals, the fastigial nucleus gives rise to the uncinate tract, which decussates in the cerebellar commissure, hooks around the brachium conjunctivum, and is distributed to the vestibular nuclei and the medullary and pontine reticular formation. A branch of the uncinate tract ascends to the ipsilateral midbrain and thalamus. Projections to the cerebral cortex are bilateral because the crossed ascending fibres of the uncinate fasciculus subsequently recross in the thalamus. Their projection to the cerebral cortex is incompletely known. The uncrossed, direct fastigiobulbar tract passes along the lateral margin of the fourth ventricle. It is distributed

Fig. 22.15 Transverse sections through the human inferior olive, section 1 being the most rostral. Lower panel: the flattened inferior olive showing the levels of sections 1-4 in the upper panel. Note the large size of the convoluted dorsal lamina of the principal olive (POdL), and the small ventral lamina (POvL). Other abbreviations: Beta, group beta; DAOc/r, caudal/rostral dorsal accessory olive; Dc, dorsal cap; Dmcc, dorsomedial cell column; MAOc/r, caudal/rostral medial accessory olive; VLO, ventrolateral outgrowth.
to the vestibular nuclei and the reticular formation in a symmetrical manner that mirrors that of the uncinate tract (Batton et al 1977). The direct fastigiobulbar tract is an inhibitory, glycinergic system (Bagnall et al 2009). Small GABAergic neurones give rise to a nucleoolivary pathway terminating in the contralateral caudal medial accessory olive.

The caudal pole of the fastigial nucleus receives its Purkinje cell afferents from lobule VII (folium and tuber vermis). This lobule is also known as the visual vermis because it is involved in the long-term adaptation of saccades and, possibly, in other eye movements. The projections of the oculomotor region of the fastigial nucleus (Fig. 22.17 ) are completely crossed. They terminate in the pontine paramedian reticular formation (the horizontal gaze centre), the superior colliculus, the rostral interstitial nucleus of the medial longitudinal fasciculus (the vertical gaze centre) and in the thalamic nuclei that may include the frontal and parietal eye fields as their targets (Noda et al 1990). The fastigial nucleus influences visceromotor systems via projections of the vestibular nuclei and connections with the catecholaminergic nuclei of the brainstem and the hypothalamus (Zhu et al 2006).

The projections of the interstitial cell groups located between the fastigial and posterior interposed nuclei, the target nucleus of the X module, have not been studied in primates. In lower mammals, these neurones provide collaterals to the superior colliculus, thalamus and spinal cord (Bentivoglio and Kuypers 1982).

The lateral vestibular nucleus (Deiters' nucleus) is the target nucleus of the lateral vermal B zone. This nucleus might better be considered as one of the cerebellar nuclei. It does not receive a primary input from the labyrinth and, contrary to the other vestibular nuclei, receives a collateral innervation from the climbing fibres innervating the B zone. It gives rise to the lateral vestibulospinal tract. Its nucleo-olivary pathway targets the caudal dorsal accessory olive.

The zones of the cerebellar vermis are in a position to affect neurotransmission in the vestibulospinal and reticulospinal systems, bilaterally controlling postural and vestibular reflexes of the axial and

Fig. 22.16 The connections of the emboliform (anterior interposed) nucleus. The entire system is somatotopically organized: this organization is more detailed than indicated in the diagram. Abbreviations: rostral DAO, rostral dorsal accessory olive.
proximal musculature, and in the oculomotor centres in the brainstem. The skeletomotor and oculomotor functions are located in specific segments of the vermis: skeletomotor functions in the anterior vermis and posterior lobule VIII (pyramis) (the X and B zones are restricted to these lobules), and oculomotor functions in lobule VII. Caudalmost, lobule X (nodulus) belongs to the vestibulocerebellum and is considered below. Other functions, such as vegetative regulation, are subserved by the vermis but have not been studied in detail.

The anterior interposed (emboliform) nucleus is the target of the C1, C3 and Y zones. The detailed somatotopical organization of these Purkinje cell zones is maintained in the anterior interposed nucleus, where Purkinje cells of different zones, but with the same climbing fibre input from a particular region of the body, project to a common set of neurones (see Fig. 22.16). Ascending axons from the anterior interposed nucleus enter the brachium conjunctivum. This tract decussates at the border of the pons and the mesencephalon. The ascending branch enters and surrounds the magnocellular red nucleus and proceeds to the thalamus, from where the anterior interposed nucleus is connected with the contralateral primary motor cortex. The descending branch of the brachium conjunctivum terminates in the nucleus reticularis tegmenti pontis (reticular tegmental nucleus of the pons). The entire system, including the magnocellular red nucleus and the primary motor cortex and their efferent tracts, is somatotopically organized. A nucleo-olivary pathway from the anterior interposed nucleus terminates in the rostral dorsal accessory olive.

The motor cortex and the magnocellular red nucleus give rise to the two main descending motor systems: the corticospinal (pyramidal) tract and the rubrospinal tract. Both of these tracts cross the midline, the former at the bulbospinal junction and the latter at its level of origin

Fig. 22.17 A transverse section through the cerebellum and medulla oblongata, showing the symmetrical distribution of the crossed and uncrossed connections of the fastigial nucleus. The inset depicts a sagittal section, showing the connections of the visual vermis (lobule VII) with the caudal pole of the fastigial nucleus and its efferent pathways in red. Abbreviations: Bc, brachium conjunctivum; PPRF, paramedian pontine reticular formation; riMLF, rostral interstitial nucleus of the medial longitudinal fasciculus.
in the midbrain. The corticospinal tract provides the magnocellular red nucleus with a collateral innervation. Both tracts influence distal movements of the limbs. During primate evolution, the corticospinal system increases in prominence at the cost of the rubrospinal system, which comes to occupy a subsidiary position in the human brain.

Climbing fibres innervating the $\mathrm{C} 1, \mathrm{C} 3$ and Y zones and the anterior interposed nucleus take their origin from the rostral dorsal accessory olive, which receives a somatotopically organized cutaneous input, mainly through the dorsal column and trigeminal nuclei, and contains a refined cutaneous map of the entire contralateral body surface (Gellman et al 1983). The corticospinal and rubrospinal tracts provide the dorsal column nuclei with a collateral innervation.

It should be emphasized that the concept of the cerebellum as a motor system is closely allied to the circuitry of the $\mathrm{C} 1, \mathrm{C} 3$ and Y zones, and to the anterior interposed nucleus and its output systems. The double decussation of the brachium conjunctivum and the rubrospinal and corticospinal tracts is responsible for the clinical observation that lesions of the cerebellum affect the ipsilateral half of the body. For most of the other modules with predominantly cerebral cortical connections, the functional relations are much less clear.

The connections of the posterior interposed (globose) and dentate nuclei are arranged according to the same plan. They ascend and decussate in the brachium conjunctivum, and terminate in a group of nuclei at the mesodiencephalic junction that includes the parvocellular red nucleus and the nucleus of Darkschewitsch in the central grey, and in the thalamic nuclei that project to motor, premotor, prefrontal and posterior parietal cortical areas and the frontal and parietal eye fields
(Fig. 22.18A). The nuclei at the mesodiencephalic junction give rise to the ipsilaterally descending tegmental tracts that terminate in the inferior olive, forming reciprocally organized loops; the function of these prominent recurrent loops has never been studied.

The posterior interposed (globose) nucleus projects to the nucleus of Darkschewitsch and, via the thalamus, to most, if not all, cortical areas (Fig. 22.18B). Reciprocal connections of the cerebral cortex to the nucleus of Darkschewitsch have been reported for most cortical areas. The nucleus of Darkschewitsch gives rise to a recurrent climbing fibre loop to the C 2 zone that consists of the medial tegmental tract and the rostral medial accessory olive. Motor and visual divisions can be distinguished in this system. The segments of the C2 zone located in the anterior and posterior motor regions of the cerebellum and the rostromedial posterior interposed nucleus receive input from the motor cortex. Visual and prefrontal input dominates in segments located in the ansiform lobule (HVII), the paraflocculus (HIX) and the flocculus (HX). The nucleo-olivary pathway from the posterior interposed nucleus innervates the contralateral rostral medial accessory olive.

The rostral and caudal dentate nucleus give rise to different pathways. Neurones of the caudal pole of the dentate nucleus are known to be activated by eye movements (van Kan et al 1993). The caudal dentate projects to a dorsomedial subnucleus of the parvocellular red nucleus, located medial to the fasciculus retroflexus (Fig. 22.18C). Its thalamocortical projections include the frontal and parietal eye fields, which are reciprocally connected with the dorsomedial subnucleus. The latter projects to the ventral lamina of the principal olive, which innervates the D1 zone. Although fairly prominent in lower mammals, the ventral lamina of the principal olive is represented by the narrow medial lamina of the human olive (see Fig. 22.15). This module, presumably, is much reduced in the human cerebellum. Crossed nucleo-olivary pathways from the rostral and caudal dentate terminate in the dorsal and ventral laminae of the principal olivary nucleus, respectively.

The rostral dentate includes the major part of the dentate nucleus. In monkeys, it has been divided into rostromedial motor and ventrocaudal non-motor portions (Strick et al 2009) (Fig. 22.18E). The motor division is somatotopically organized, with the hindlimb represented rostrally and the face more caudally; it receives projections from motor regions of the cerebellum. The caudal non-motor portion receives its corticonuclear projections from the ansiform lobule (HVII) and the paraflocculus (the tonsil, HIX). A similar subdivision of the dentate has been proposed in humans (Küper et al 2012); it seems likely that these divisions correspond with the rostromedial microgyric and ventrocaudal macrogyric regions of the human dentate (see Fig. 22.10).

The rostral dentate projects to the major, ventrolateral, portion of the parvocellular red nucleus. Its thalamocortical projections target the motor, premotor and posterior parietal cortices (Fig. 22.18D-E). Projections from the caudal dentate include the dorsal prefrontal cortex. Reciprocal connections between these cortical areas and the parvocellular red nucleus have been documented, mainly for the motor and premotor areas. These projections are somatotopically organized; they occupy the lateral portion of the parvocellular red nucleus. Prefrontal projections are located more medially. The parvocellular red nucleus connects with the dorsal lamina of the principal olivary nucleus through the central tegmental tract. Motor input is transmitted by the dorsal lamina to segments of the D2 zone located in the motor regions of the cerebellum; non-motor input is transmitted to the ansiform lobule (HVII) and the tonsil (HIX).

In humans, the D2 zone accounts for most of the cerebellar hemisphere. This is exemplified by its development (see Fig. 22.13) and by the size of the different components of its circuitry. In Figure 22.19, the first ever published lithograph of a section through the pontine tegmentum (Stilling 1846), the central tegmental tract can be recognized immediately as one of the largest fibre systems in the brainstem. Several explanations have been offered for the size of the dentate and its connections. They include the complexity of the cortical motor system, which is a major target of the dentate nucleus. (Multiple, interconnected premotor and posterior parietal areas involved in the preparation of movement converge on the primary motor cortex; the precise contribution of the cerebellum to these processes is not known.) Other possible explanations are the increased connectivity of the dentate with the prefrontal cortex subserving its non-motor functions (Stoodley and Schmahmann 2009), and an increase in the dentate-parietal projection, given that non-motor functions also involve the parietal cortex.

During evolution, the shapes of the dentate and the principal olivary nucleus change from compact nuclei to intricately folded sheets. This may indicate the presence of a detailed topical localization in the corticonuclear and climbing fibre afferent connections in the D2 zone, but almost nothing is known about its intrinsic organization.

Fig. 22.18 A, Cortical areas targeted by the cerebellothalamic pathways of the posterior interposed and dentate nuclei. The primary motor area (M1) with the primary sensory area (S1), the premotor cortex with the posterior parietal areas and the frontal and parietal eye fields constitute interconnected networks. ## AFFERENT MOSSY FIBRE CONNECTIONS OF THE CEREBELLUM

Mossy fibre systems take their origin from multiple sites in the spinal cord and the brainstem. The pontocerebellar pathway is the major mossy fibre system in primates. Although mossy fibre systems have rarely been traced with experimental methods in primates, fMRI has provided information on their organization in the human cerebellum.

Mossy fibre systems share several common features. Individual mossy fibres distribute bilaterally and give off collaterals at specific mediolateral positions that terminate in longitudinal aggregates of mossy fibre rosettes (see Fig. 22.11). Entire mossy fibre systems terminate as multiple, bilaterally distributed bands of mossy fibre terminals (Fig. 22.20A). These bands are not continuous, but are often restricted to either the apices or the bases of the folia. Exteroceptive components of mossy fibre systems terminate superficially, whereas proprioceptive systems terminate in the bases of the folia (Ekerot and Larson 1972)

Fig. 22.19 A lithograph of a transverse section through the pons, showing the localization of the central tegmental tract in the pontine tegmentum. Abbreviation: NRTP, nucleus reticularis tegmenti pontis. (Reproduced from Stilling B 1846 Untersuchungen über den Bau und die Verrichtungen des Gehirns. I. Über den Bau des Hirnknotens oder der Varolischen Brücke. Jena, Druck und Verlag von Friedrich Make.)
(Fig. 22.20B). The mossy fibre aggregates are not as distinct as the climbing fibre zones and often merge in the bases of the fissures. Mossy fibre aggregates of different systems interdigitate or overlap; precise information is lacking.

The termination of the spinocerebellar, reticulocerebellar, cuneocerebellar and trigeminocerebellar tracts is restricted to the anterior and posterior motor regions of the cerebellum, i.e. to the anterior lobe, the simplex lobule (VI and HVI), lobule VIII and the paramedian lobule (gracile HVIIB and biventral HVIII lobules). These lobules also receive primary and secondary vestibulocerebellar inputs and pontocerebellar mossy fibres relaying information from cortical motor areas. Many of these mossy fibre systems terminate according to a somatotopical pattern (Fig. 22.20C). A very similar somatotopical organization occurs in the C1, C3 and Y climbing fibre zones that are restricted to the hemisphere of the same lobules (see Fig. 22.16).

## Spinocerebellar, trigeminocerebellar, reticulocerebellar and vestibulocerebellar fibres

The spinal cord is connected to the cerebellum through the spinocerebellar and cuneocerebellar tracts, and through indirect mossy fibre pathways relayed by the lateral reticular nucleus in the medulla oblongata. These pathways are all excitatory in nature. Some of them give collaterals to the cerebellar nuclei before ending on cortical granule cells.

Fig. 22.20 A, The termination of spinocerebellar fibres as multiple sagittal bands in the anterior lobe of Tupaia glis. B, A sagittal section through the cerebellum showing the termination of exteroceptive mossy fibre systems in the apices of the lobules of the anterior lobe, the simplex lobule and lobule VIII (pyramis), and of proprioceptive systems in the bases of the fissures. C, The somatotopic organization of the termination of the exteroceptive components of the spinocerebellar, cuneocerebellar and trigeminocerebellar tracts in the hemisphere of the anterior lobe, the simplex lobule and the paramedian (biventral) lobule. D, The origin of the spinocerebellar, cuneocerebellar and reticulocerebellar tracts. Abbreviations: CE, external cuneate nucleus; CI , internal cuneate nucleus; DV, nucleus of the spinal tract of the trigeminal nerve; G , gracile nucleus; NRL, lateral reticular nucleus.

The dorsal spinocerebellar tract transmits information from the ipsilateral lower limb (Ch. 20). It contains proprioceptive fibres that arise from neurones in the posterior thoracic nucleus (Clarke's column) in the thoracic and upper lumbar spinal cord, and exteroceptive fibres from the thoracic and lumbar dorsal horns. It enters the cerebellum in the inferior cerebellar peduncle to terminate bilaterally in the vermis and hemisphere of the anterior and posterior lower limb regions.

The cuneocerebellar tract is considered as the upper limb equivalent of the dorsal spinocerebellar tract (Ch. 20). It takes its origin from the dorsal column nuclei, the exteroceptive component from the internal cuneate and gracile nuclei, and the proprioceptive component from the external cuneate nucleus. Both components terminate in the anterior and posterior upper limb regions: the proprioceptive component bilaterally in the bases of the fissures, and the exteroceptive component ipsilaterally in the apices of the lobules of the hemisphere. The exteroceptive component has been shown to terminate in multiple longitudinal zones congruent with the climbing fibre zones of this region; these zones share the same detailed somatotopical organization as the C1, C3 and the Y climbing fibre zones (Ekerot and Larson 1980).

The ventral spinocerebellar tract is a composite pathway. It informs the cerebellum about the state of activity of spinal reflex arcs related to the lower limb and lower trunk. Its fibres originate in the intermediate grey matter and the spinal border cells of the lumbar and sacral segments of the spinal cord, cross near their origin, and ascend close to the surface as far as the lower midbrain before looping around the entrance of the trigeminal nerve to join the superior cerebellar peduncle. Most of these fibres cross again in the cerebellar white matter.

The rostral spinocerebellar tract originates from cell groups of the intermediate zone and horn of the contralateral cervical enlargement. Although considered to be the upper limb and upper trunk equivalent of the ventral spinocerebellar tract, most of its fibres remain ipsilateral throughout their course. They enter the cerebellum through both the superior and the inferior cerebellar peduncles and terminate in the anterior and posterior vermis.

An upper (central) cervical spinocerebellar tract originates from a central cervical nucleus at high cervical levels (C1-C4). The tract terminates bilaterally in the bases of the fissures of the entire cerebellum, lacks a somatotopical organization and conveys labyrinthine information and proprioception from neck muscles (Matsushita and Tanami 1987).

Trigeminocerebellar mossy fibres stem from the ipsilateral principal sensory nucleus and the nucleus of the spinal tract of the trigeminal nerve, and terminate in the hemisphere in the anterior and posterior face regions (simplex lobule - HVI - and gracile lobule - HVIIB).

The distinct somatotopic organization of the anterior and posterior motor regions of the hemispheres is reflected in the termination of the exteroceptive components of the dorsal spinocerebellar, cuneocerebellar and trigeminocerebellar tracts. It is much less distinct for proprioceptive systems, such as the central cervical spinocerebellar tract.

Reticulocerebellar mossy fibres stem from the lateral and paramedian reticular nuclei of the medulla oblongata (Ch. 21). The lateral reticular nucleus supplies major collateral projections to the cerebellar nuclei. Spinoreticular fibres terminate in a somatotopical pattern within the ventral lateral reticular nucleus, which projects bilaterally, mainly to the vermis. Spinoreticular fibres from the cervical cord overlap with collaterals from the rubrospinal tract and a projection from the cerebral cortex, and all terminate in the dorsal part of the nucleus, which projects to forelimb regions of the ipsilateral hemisphere. The cerebellar cortical projection of the paramedian reticular nucleus is very similar to that of the ventral lateral reticular nucleus.

Primary vestibulocerebellar mossy fibres enter the cerebellum with the ascending branch of the vestibular nerve, pass through the superior vestibular nucleus and juxtarestiform body, and terminate, mainly ipsilaterally, in the granular layer of the nodule, caudal part of the uvula, ventral part of the anterior lobe and bases of the deep fissures of the vermis (Fig. 22.21A). Secondary vestibulocerebellar mossy fibres arise from the superior vestibular nucleus and the caudal portions of the medial and inferior vestibular nuclei, and terminate bilaterally, not only in the same regions that receive primary vestibulocerebellar fibres, but also in the flocculus and the adjacent ventral paraflocculus (the accessory paraflocculus of the human cerebellum), which lack a primary vestibulocerebellar projection (Fig. 22.21B). Some of the mossy fibres from the medial and inferior vestibular nuclei are cholinergic.

## CORTICOPONTOCEREBELLAR PROJECTION

The cerebral cortex is the largest single source of fibres that project to the pontine nuclei (Fig. 22.22). The fibres traverse the cerebral

Fig. 22.21 Vestibulocerebellar mossy fibre projections. A, Primary vestibulocerebellar projections from the bipolar neurones of the vestibular ganglion.
B, Secondary vestibulocerebellar projections from the vestibular nuclei. C, A sagittal section showing the distribution of both sets of afferents.
peduncle: those from the frontal lobe occupy the medial part of the peduncle; corticonuclear and corticospinal fibres occupy its central part; and fibres from the parietal, occipital and temporal lobes occupy its lateral part. The mediolateral sequence of the fibres in the cerebral peduncle is approximately maintained in their termination in the pontine nuclei. Prefronto-pontine fibres and the frontal eye fields project medially and rostrally; motor and premotor projections terminate centrally and caudally; and parietal, occipital and temporal fibres terminate in the lateral pontine nuclei (Schmahmann and Pandya 1997). Motor and premotor projections are somatotopically organized, such that the face is represented rostrally and the hindlimb caudally in the nuclei. In monkeys, the majority of the corticopontine fibres stem from motor, premotor and parietal areas. The prefrontal, general sensory and visual projections are relatively minor (Glickstein et al 1985). A prefrontal projection from the dorsal prefrontal cortex has been confirmed for humans (Beck 1950). Many corticopontine fibres are collaterals of axons that project to other targets in the brainstem and spinal cord (Ugolini and Kuypers 1986). The pontocerebellar projection is almost completely crossed. Fibres from the pontine nuclei access the cerebellum via the middle cerebellar peduncle and terminate throughout the entire cerebellar cortex, with the exception of lobule X (nodulus). Visual cortical mossy fibre input is found in the paraflocculus (tonsil, HIX). The pontocerebellar projection is still incompletely known; the relevant literature has been reviewed by Nieuwenhuys et al (2008) and by Voogd and Ruigrok (2012). Figure 22.22C is a simplified version of this projection (Glickstein et al 1985).

The nucleus reticularis tegmenti pontis (tegmental reticular nucleus of the pons) is located along the midline, dorsal to the pontine nuclei (see Fig. 22.22C). It gives rise to bilateral components of the middle cerebellar peduncle and receives a projection from the cerebellar nuclei
via the crossed descending branch of the superior cerebellar peduncle. The medial, visuomotor, division of the nucleus reticularis tegmenti pontis receives visuomotor afferents from the frontal eye fields, the contralateral superior colliculus (the tectopontine tract) and other visuomotor centres in the brainstem, and targets lobule VII, the visual vermis and the adjacent crus I, the flocculus and the adjacent ventral paraflocculus. The bilateral projection of its lateral, motor, portion overlaps with similar projections from the pontine nuclei. Mossy fibres from the nucleus reticularis tegmenti pontis provide the cerebellar nuclei with a collateral innervation complementary to that of the lateral reticular nucleus. An uncrossed component of the tectopontine tract terminates in the dorsolateral corner of the pontine nuclei, where it overlaps extrastriatal visual afferents.

## ‘OCULOMOTOR CEREBELLUM’

Traditionally, the flocculus and the nodulus are known as the 'vestibulocerebellum' because they maintain afferent and efferent connections with the vestibular system. They also belong to the functionally more comprehensive oculomotor division of the cerebellum, which includes lobule VII (visual vermis), the adjacent ansiform lobule, dorsal lobule IX (uvula), the ventral paraflocculus (the human accessory paraflocculus) and the dorsal paraflocculus (the human tonsil). The mossy fibre projection of the nucleus prepositus hypoglossi, a key element in the saccade-producing system (Ch. 41), outlines the entire oculomotor cerebellum, with the exception of the dorsal paraflocculus (Belknap and McCrea 1988) (Fig. 22.23B). The function of lobule X (nodulus) is not an exclusive oculomotor one because it also influences labyrinthine and postural reflexes and vegetative systems.

The oculomotor cerebellum is involved in long-term adaptation of saccades, ocular stabilization reflexes and smooth pursuit (reviewed in Voogd et al (2012)). The role of the flocculus and the adjacent ventral paraflocculus in long-term adaptation of the vestibulo-ocular reflex (VOR) has been extensively studied. It is one of the few instances where the function of the cerebellum is clearly understood.

## Vestibulo-ocular reflex

The VOR is an ancient reflex, being present in agnatha and fishes. It stabilizes the position of the retina in space, during movements of the head, by rotating the eyeball in the opposite direction. The VOR is an open reflex; there is no time for a feed-back connection that would compensate for inaccuracies in the execution of the reflex. This function is taken over by the long-term adaptation of the reflex by the flocculus. The circuitry of the flocculus, similar to the VOR, is organized on the coordinate system of the semicircular canals (Simpson and Graf 1981, van der Steen et al 1994). The VOR consists of different components. One component connects the lateral (horizontal) semicircular canal, via oculomotor neurones in the vestibular nuclei, with the oculogyric muscles that move the eyes in a plane co-linear with the plane of the lateral canal (Fig. 22.24). The anterior semicircular canal influences the ipsilateral superior oblique and the contralateral inferior oblique muscles that move the eye in the plane of this canal. (For further details, see Chs 38 and 41.)

Five Purkinje cell zones are present in the cortex of the flocculus and the adjacent ventral paraflocculus. Apart from the C 2 zone, located most medially, two pairs of zones occupy its lateral portion. Zones F1 and F3 connect with the oculomotor neurones in the vestibular nuclei, subserving the anterior canal VOR. The F2 and F4 zones connect with oculomotor neurones of the horizontal canal VOR. The flocculus and ventral paraflocculus receive vestibular mossy fibre input, relaying an efferent copy of the output of the vestibulo-oculomotor neurones. They also receive climbing fibre input, signalling retinal slip that occurs when the stabilization of the retina by the VOR is incomplete. Retinal slip is perceived by two groups of neurones in the mesencephalon. In the horizontal plane, it is relayed by the nucleus of the optic tract. This nucleus, located in the pretectum, receives fibres of the contralateral optic nerve via the optic tract and projects to the dorsal cap of the inferior olive, located dorsomedial to the caudal medial accessory olive (see Fig. 22.15). The dorsal cap provides the F2 and F4 zones with climbing fibres. Retinal slip in the plane of the anterior canal is conveyed by the lateral and medial nuclei of the accessory system, which belong to a group of nuclei located on the periphery of the rostral mesencephalon, receiving optic nerve fibres from an offshoot of the optic
nerve, known as the accessory optic tract. These nuclei project to the ventrolateral outgrowth of the inferior olive, located immediately rostral to the dorsal cap (see Fig. 22.15). The ventrolateral outgrowth innervates the F1 and F3 zones. Repeated simultaneous activation of the vestibular mossy fibre-parallel fibre input and the climbing fibres, relaying retinal slip, induces plastic changes in the Purkinje cell output that compensates for the retinal slip. Combinations of the horizontal and anterior canal systems ensure compensation of retinal slip in all possible planes. Knowledge of this system has been instrumental in the concept that climbing fibres are carriers of error signals, used in cerebellar learning (Marr 1969, Ito 1982).

## NEUROIMAGING AND THE FUNCTIONAL DIVISIONS OF THE CEREBELLUM

Mossy fibre projections have been studied in the human brain using fMRI. In the cerebellum, activity in climbing fibres and Purkinje cells is overwhelmed by the massive activity of the mossy fibres (Diedrichsen et al 2010), which means that the modular organization of the cerebellum therefore cannot be visualized with this method. The division of the human cerebellum into anterior and posterior motor and intermediate non-motor portions has been observed in numerous neuroimaging studies (reviewed by Stoodley and Schmahmann (2009)). The somatotopical localization in each hemisphere of the anterior lobe and the simplex and biventral lobules in the posterior lobe has been confirmed with fMRI (Grodd et al 2001, Buckner et al 2011, Yeo et al 2011). A systematic somatotopical gradient has been reported for the digits of the hand in the hemisphere of lobule V (Wiestler et al 2011).

The crura of the ansiform lobule (HVII) are activated during the execution of cognitive tasks. More recently, resting-state functional connectivity fMRI has been used to map topographical correlations between remote, functionally coupled regions in the cerebral cortex and the cerebellum. Several functional networks in the cerebral cortex have been identified with this method (Yeo et al 2011) (Fig. 22.25). However, it does not provide information on the anatomical connections or the excitatory or inhibitory nature of the constituent areas of each of these systems; connections between the cerebrum and the cerebellum could be indirect, e.g. through cortical association systems or brainstem nuclei other than the pontine nuclei. The networks are distributed in a mirrored fashion in the anterior and posterior cerebellum. The default mode network, a network of brain regions that are active when an individual is not focused on the outside world (Buckner et al 2008; Commentary 3.1), occupies a central position.

The diencephalon is part of the prosencephalon (forebrain), which develops from the foremost primary cerebral vesicle and differentiates into a caudal diencephalon and rostral telencephalon. The cerebral hemisphere develops from the side of the telencephalon, containing a lateral ventricle. The sites of evagination become the interventricular foramina, through which the two lateral ventricles and midline third ventricle communicate. The diencephalon corresponds largely to the structures that develop lateral to the third ventricle. The lateral walls of the diencephalon form the epithalamus most superiorly, the thalamus centrally, and the subthalamus and hypothalamus inferiorly.

## THALAMUS

The thalamus plays a crucial role in many brain functions, serving as a processing and distribution centre, relaying and regulating information from the outside world and the internal milieu to the cerebral cortex and vice versa. It is involved in multiple activities, including consciousness, sleep, memory and sensory and motor functions. Our increasing understanding of the role of the thalamus is providing insights into pathological disorders of the brain and is opening up the possibility of targeting its various constituent nuclei to treat a variety of disorders, including epilepsy, Parkinson's disease, pain and psychiatric disorders (Table 23.1; see Fig. 23.5) (For review, see Lozano and Lipsman 2013.)

Morphologically, the thalamus is a large ovoid nuclear mass, about 4 cm long, which borders the dorsal part of the third ventricle (Figs 23.1-23.2). Its narrow anterior pole lies close to the midline and forms the posterior boundary of the interventricular foramen. Posteriorly, an expansion, the pulvinar, extends beyond the third ventricle to overhang the superior colliculus (see Fig. 21.5). The brachium of the superior colliculus (superior quadrigeminal brachium) separates the pulvinar above from the medial geniculate body below. A small oval elevation, the lateral geniculate body, lies lateral to the medial geniculate.

The superior (dorsal) surface of the thalamus is covered by a thin layer of white matter, the stratum zonale. This curved surface is separated from the overlying body of the fornix by the choroid fissure with the tela choroidea within it. More laterally, it forms part of the floor of the lateral ventricle. The lateral border of the superior surface of the thalamus is marked by the stria terminalis and overlying thalamostriate vein, which separate the thalamus from the body of the caudate nucleus. Laterally, a slender sheet of white matter, the external medullary lamina, separates the main body of the thalamus from the reticular nucleus. Lateral to this, the thick posterior limb of the internal capsule lies between the thalamus and the lentiform complex.

The medial surface of the thalamus is the superior (dorsal) part of the lateral wall of the third ventricle. It is usually connected to the

Table 23.1 Thalamic deep brain stimulation targets

| Indication | Target | References |
| :--- | :--- | :--- |

Abbreviations: $C M$, centromedian nucleus of thalamus; PVG, periventricular grey; Vim, ventral intermediate nucleus of thalamus (nucleus ventrointermedius); VL, ventral lateral thalamic nucleus (nucleus ventrolateralis); Voa, nucleus ventro-oralis anterior; Vop, nucleus ventro-oralis posterior; VPI, ventral posterolateral nucleus; VPm, ventral posteromedial nucleus.
contralateral thalamus by an interthalamic adhesion (Fig. 18.10). The boundary with the hypothalamus is marked by a faint hypothalamic sulcus, which curves from the upper end of the cerebral aqueduct to the interventricular foramen. The thalamus is continuous with the midbrain tegmentum, the subthalamus and the hypothalamus.

Internally, the greater part of the thalamus is divided into anterior, medial and lateral nuclear groups by a vertical Y-shaped sheet of white matter, the internal medullary lamina (Figs 23.3-23.4; Table 23.2). In addition, intralaminar nuclei lie embedded within the internal medullary lamina and midline nuclei abut the lateral walls of the third ventricle. The reticular nucleus forms a shell-like lateral covering to the main nuclear mass, separated from it by an external medullary lamina of nerve fibres.

In general, thalamic nuclei both project to and receive fibres from the cerebral cortex (Jones 1985, Macchi and Jones 1997) (see Fig. 23.4). The whole cerebral cortex, including neocortex, paleocortex of the piriform lobe and archicortex of the hippocampal formation, is reciprocally connected with the thalamus. The thalamus is the major route by which subcortical neuronal activity influences the cerebral cortex, and the greatest input to most thalamic nuclei comes from the cerebral cortex.

The projection to the thalamus from the cortex is precisely reciprocal; each cortical area projects in a topographically organized manner to all sites in the thalamus from which it receives an input (see Table 23.2). Thalamocortical fibres terminate predominantly in layer IV of the cortex. Corticothalamic fibres that reciprocate 'specific' thalamocortical pathways arise from modified pyramidal cells of layer VI, whereas those reciprocating 'non-specific' inputs arise from typical pyramidal cells of layer V , and may in part be axon collaterals of other corticosubcortical pathways.

It is customary to consider thalamic nuclei as either 'specific' nuclei, which mediate finely organized and precisely transmitted sensory information to discrete cortical sensory areas, or as 'non-specific' nuclei, with less precisely defined functions.

The specific nuclei are further subdivided into relay nuclei and association nuclei. However, many nuclei classified as specific may also send non-specific projections to widespread cortical areas. Similarly, the division of thalamic nuclei into relay and association groups rests on the assumption that relay nuclei receive a major subcortical pathway, whereas association nuclei are reciprocally connected to cortical areas that are traditionally referred to as association areas and which receive their principal non-cortical input from other subcortical structures.

Fig. 23.1 A coronal T2-weighted magnetic resonance image at the level of the thalamus and third ventricle. (Courtesy of Professor Alan Jackson, Wolfson Molecular Imaging Centre, The University of Manchester, Manchester, UK.)

Fig. 23.2 The principal parts of the diencephalon and basal ganglia, coronal section.

Table 23.2 Main thalamic nuclei and their major afferent and efferent connections

| Group | Nucleus | Major subcortical connection | Major cortical connections | System |
| :---: | :---: | :---: | :---: | :---: |
| Anterior | Anterior | Mammillary bodies (MTT) | Cingulate and parahippocampal gyrus | Relay limbic |
| Medial | Dorsomedial | Amygdala, thalamic nuclei | Prefrontal cortex | Association |
| Lateral |  |  |  |  |
| Ventral | VA | GPi, SNr | Premotor cortex | Relay motor |
|  | VL | Ipsilateral GPi, contralateral cerebellum | Supplementary and primary motor cortex | Relay motor |
|  | VPI, VPm | STT to VPI, TTT to VPm, MLT to anterior surface | Somatosensory cortex, insula | Relay sensory |
|  | LGB | Optic tract | Visual cortex | Visual |
|  | MGB | Auditory pathway (inferior brachium) | Auditory cortex | Auditory |
| Dorsal | Pulvinar - LP | Superior colliculus | Parieto-occipitotemporal | Association |
|  | LD | Pretectum and superior colliculus | Cingulate, parahippocampus |  |
| Intralaminar | CM | GPi, cerebellum | Striatum, motor cortex |  |
| Reticular |  | Widespread connections | Widespread connections |  |

Abbreviations: CM, centromedian nucleus of thalamus; GPi, internal segment of globus pallidus; $L D$, lateral dorsal nucleus of thalamus; LGB, lateral geniculate body; LP, lateral posterior nucleus of thalamus; MGB, medial geniculate body; MLT, medial lemniscal tract; MTT, mammillothalamic tract; SNr, substantia nigra pars reticularis; STT, spinothalamic tract; TTT, trigeminothalamic tract; VA, ventral anterior nucleus; VL, ventral lateral nucleus; VPI, ventral posterolateral nucleus; VPm, ventral posteromedial nucleus.

There is little evidence of significant intrathalamic connectivity, but there are increasing indications of non-cortical afferent pathways linked to so-called association nuclei; the extensive connectivity between the reticular nucleus and other thalamic nuclei is a notable exception.

## ANTERIOR THALAMIC NUCLEI

The anterior group of nuclei lie between the arms of the Y-shaped internal medullary lamina, and underlie the anterior thalamic tubercle (see Figs 21.5, 23.4). Three subdivisions are recognized: the largest is the anteroventral nucleus, the others being the anteromedial and anterodorsal nuclei.

The anterior nuclei are the principal recipients of the mammillothalamic tract, which arises from the mammillary nuclei of the hypothalamus.

The mammillary nuclei receive fibres from the hippocampal formation via the fornix. The medial mammillary nucleus projects to the ipsilateral anteroventral and anteromedial thalamic nuclei, and the lateral mammillary nucleus projects bilaterally to the anterodorsal nuclei. The nuclei of the anterior group also receive a prominent cholinergic input from the basal forebrain and the brainstem.

The cortical targets of efferent fibres from the anterior nuclei of the thalamus lie largely on the medial surface of the hemisphere. They include the anterior limbic area (in front of and inferior to the corpus callosum), the cingulate gyrus and the parahippocampal gyrus (including the medial entorhinal cortex and the presubiculum and parasubiculum). There also appear to be minor connections between the anterior nuclei and the dorsolateral prefrontal and posterior areas of neocortex. The anterior thalamic nuclei are believed to be involved in the regulation of alertness and attention and in the acquisition of memory.

## MEDIAL THALAMIC NUCLEI

The single component of this thalamic region is the mediodorsal or dorsomedial nucleus, which is particularly large in humans. Laterally, it is limited by the internal medullary lamina and intralaminar nuclei. Medially, it abuts the midline parataenial and reuniens (medioventral) nuclei. It is divided into anteromedial magnocellular and posterolateral parvocellular parts.

The smaller magnocellular division receives olfactory input from the piriform and adjacent cortex, the ventral pallidum, and the amygdala.

The mediobasal amygdaloid nucleus projects to the dorsal part of the anteromedial magnocellular nucleus, and the lateral nuclei project to the more central and anteroventral regions. The anteromedial magnocellular nucleus projects to the anterior and medial prefrontal cortex, notably to the lateral posterior and central posterior olfactory areas on the orbital surface of the frontal lobe. In addition, fibres pass to the ventromedial cingulate cortex and some to the inferior parietal cortex and anterior insula. These cortical connections are reciprocal.

The larger, posterolateral parvocellular division connects reciprocally with the dorsolateral and dorsomedial prefrontal cortex, the anterior cingulate gyrus and the supplementary motor area. In addition, efferent fibres pass to the posterior parietal cortex.

The mediodorsal nucleus appears to be involved in a wide variety of higher functions. Damage may lead to a decrease in anxiety, tension, aggression or obsessive thinking. There may also be transient amnesia,

Fig. 23.3 The main nuclear aggregations of cell bodies in the diencephalon, coronal sections. A, At the level of the mammillary bodies. B, At the level of the tuber cinereum. Note the variations in cell size, shape and packing density, which characterize the nuclear masses of the thalamus, subthalamus and hypothalamus at these levels.
with confusion developing particularly over the passage of time. Much of the neuropsychology of medial nuclear damage reflects defects in functions similar to those performed by the prefrontal cortex, with which it is closely linked. The effects of ablation of the mediodorsal nuclei parallel, in part, the results of prefrontal lobotomy.

## LATERAL THALAMIC NUCLEI

The lateral nuclear complex, lying lateral to the internal medullary lamina, is the largest division of the thalamus. It is divided into dorsal and ventral tiers of nuclei. The lateral dorsal nucleus, lateral posterior nucleus and the pulvinar all lie dorsally. The lateral and medial geniculate nuclei lie inferior to the pulvinar near the posterior pole of the thalamus. The ventral-tier nuclei are the ventral anterior, ventral lateral and ventral posterior nuclei.

## Ventral anterior nucleus

The ventral anterior (VA) nuclear complex lies at the anterior pole of the ventral nuclear group. It is limited anteriorly by the reticular nucleus and posteriorly by the ventral lateral nucleus, and lies between the external and internal medullary laminae. It consists of a principal part
(VApc) and a magnocellular part (VAmc). The subcortical connections to this region are largely ipsilateral from the internal pallidum and the pars reticularis of the substantia nigra. The terminal fields from these origins do not overlap. Fibres from the globus pallidus end in the principal part of the ventral anterior nuclear complex. The substantia nigra projects to the magnocellular part of the ventral anterior nuclear complex. Corticothalamic fibres from the premotor cortex (area 6) terminate in the principal part and fibres from the frontal eye field (area 8) terminate in the magnocellular part. The ventral anterior thalamus does not appear to receive fibres directly from the motor cortex. The efferent projections from the ventral anterior nuclear complex are incompletely known. Some pass to intralaminar thalamic nuclei and others project to widespread regions of the frontal lobe and to the anterior parietal cortex. Their functions are unclear. The ventral anterior thalamus appears to play a central role in the transmission of the cortical 'recruiting response', a phenomenon in which stimulation of the thalamus can initiate long-lasting, high-voltage, repetitive negative electrical waves over much of the cerebral cortex.

## Ventral lateral nucleus

The ventral lateral (VL) nucleus consists of two major divisions with distinctly different connections and functions. The anterior division, or pars oralis (VLo), receives topographically organized fibres from the ipsilateral internal pallidum. The posterior division, or pars caudalis (VLc), receives topographically organized fibres from the contralateral deep cerebellar nuclei. Additional subcortical projections have been reported from the spinothalamic tract and the vestibular nuclei. Numerous cortical afferents to both the pars oralis and the pars caudalis originate from precentral motor cortical areas, including both area 4 and area 6 .

The pars oralis of the ventral lateral nucleus sends efferent fibres to the supplementary motor cortex on the medial surface of the hemisphere and to the lateral premotor cortex. The pars caudalis of the ventral lateral nucleus projects efferent fibres to the primary motor cortex, where they end in a topographically arranged fashion. The head region of area 4 receives fibres from the medial part of pars caudalis, and the leg region receives fibres from the lateral pars caudalis.

Approximately $70 \%$ of ventral lateral neurones are large relay neurones, and the other $30 \%$ are local circuit interneurones. Responses can be recorded in ventral lateral thalamic neurones during both passive and active movement of the contralateral body. The topography of its connections, and recordings made within the nucleus, suggest that the pars caudalis contains a body representation comparable to that in the ventral posterior nucleus. In patients with tremor, clusters of ventral lateral neurones fire in bursts that are synchronous with peripheral tremor: these cells have been designated as 'tremor cells'.

Stereotaxic surgery of the ventral lateral nucleus is sometimes used in the treatment of essential tremor (see Table 23.1; Fig. 23.5). In the past, thalamotomy was used extensively for the treatment of Parkinson's disease. The internal pallidum and the subthalamic nucleus are now the preferred neurosurgical targets for Parkinson's disease.

## Ventral posterior nucleus

The ventral posterior (VP) nucleus is the principal thalamic relay for the somatosensory pathways. It is thought to consist of two major divisions: the ventral posterolateral (VPl) and ventral posteromedial (VPm) nuclei. The ventral posterolateral nucleus receives the medial lemniscal and spinothalamic pathways, and the ventral posteromedial nucleus receives the trigeminothalamic pathway. Connections from the vestibular nuclei and lemniscal fibres terminate along the ventral surface of the ventral posterior nucleus.

There is a well-ordered topographic representation of the body in the ventral posterior nucleus. The ventral posterolateral nucleus is organized so that sacral segments are represented laterally and cervical segments medially. The latter abut the face area of representation (trigeminal territory) in the ventral posteromedial nucleus. Taste fibres synapse most anteriorly and ventromedially within the ventral posterolateral nucleus.

At a more detailed level, single body regions are represented as curved lamellae of neurones, parallel to the lateral border of the VP nucleus, such that there is a continuous overlapping progression of adjacent receptive fields from dorsolateral to ventromedial. Considerably less change in location of receptive field on the body is seen when passing anteroposteriorly through the nucleus. While not precisely dermatomal in nature, these curvilinear lamellae of cells probably derive from afferents related to a few adjacent spinal segments. There is

Fig. 23.5 Magnetic resonance images from four different patients with neurological or psychiatric disorders, showing the position of deep brainstimulating (DBS) electrodes. A, Bilateral anterior thalamic DBS for epilepsy. B, Left thalamic DBS for pain, with electrodes in the sensory relay nucleus (ventral caudal nucleus of the thalamus) laterally and the periventricular grey medially. C, DBS electrode in the ventral intermediate nucleus of the thalamus in a patient with essential tremor. D, Bilateral inferior thalamic peduncle DBS electrodes in a patient with obsessive-compulsive disorder.

Fig. 23.4 The main nuclear masses of the thalamus (viewed from the lateral aspect in the lower illustration), colour-coded to indicate the areas of cerebral neocortex with which they are interconnected. The lack of colour in the centromedian, intralaminar and reticular nuclei and in areas of the frontal and temporal lobes is not related to the colour code. The reticular nucleus lies lateral to the main mass of the thalamus. Only the anterior pole of the reticular nucleus is shown, its posterior extent being depicted by the heavy interrupted line.
considerable distortion of the body map within the nucleus, reflecting the differences in the density of peripheral innervation that occur in different body regions, e.g. many more neurones respond to stimulation of the hand than of the trunk. Within a single lamella, neurones in the anterodorsal part of the nucleus respond to deep stimuli, including movement of joints, tendon stretch, and manipulation of muscles. Most ventrally, neurones once again respond to deep stimuli, particularly tapping. Intervening cells within a single lamella respond only to cutaneous stimuli. This organization has been confirmed by recordings made in the human ventral posterior nucleus.

The ventral posterior nucleus projects to the primary somatic sensory cortex (SI) of the postcentral gyrus and to the second somatic sensory area (SII) in the parietal operculum. The posterior part of the ventral posteromedial nucleus projects to the insular cortex. Within the primary sensory cortex, the central cutaneous core of the ventral posterior nucleus projects solely to area 3 b ; dorsal and ventral to this, a narrow band of cells projects to both area 3 b and area 1 . The most dorsal and ventral deep stimulus receptive cells project to areas 3a and 2. The whole nucleus projects to the second somatic sensory area.

## Medial geniculate nucleus

The medial geniculate nucleus, which is a part of the auditory pathway, is located within the medial geniculate body, a rounded elevation situated posteriorly on the ventrolateral surface of the thalamus, and separated from the pulvinar by the superior quadrigeminal brachium. It receives fibres travelling in the inferior quadrigeminal brachium. Three major subnuclei - medial, ventral and dorsal - are recognized within it. The inferior brachium separates the medial (magnocellular) nucleus, which consists of sparse, deeply staining neurones, from the lateral nucleus, which is made up of medium-sized, densely packed and darkly staining cells. The dorsal nucleus overlies the ventral nucleus and expands posteriorly; it is, therefore, sometimes known as the posterior nucleus of the medial geniculate. It contains small- to medium-sized,
pale-staining cells, which are less densely packed than those of the lateral nucleus. The ventral nucleus receives fibres from the central nucleus of the ipsilateral inferior colliculus via the inferior quadrigeminal brachium and also from the contralateral inferior colliculus. The nucleus contains a complete tonotopic representation. Low-pitched sounds are represented laterally, and progressively higher-pitched sounds are encountered as the nucleus is traversed from lateral to medial. The dorsal nucleus receives afferents from the pericentral nucleus of the inferior colliculus and from other brainstem nuclei of the auditory pathway. A tonotopic representation has not been described in this subdivision and cells within the dorsal nucleus respond to a broad range of frequencies. The magnocellular medial nucleus receives fibres from the inferior colliculus and from the deep layers of the superior colliculus. Neurones within the magnocellular subdivision may respond to modalities other than sound. However, many cells respond to auditory stimuli, usually to a wider range of frequencies than neurones in the ventral nucleus. Many units show evidence of binaural interaction, with the leading effect arising from stimuli in the contralateral cochlea. The ventral nucleus projects primarily to the primary auditory cortex. The dorsal nucleus projects to auditory areas surrounding the primary auditory cortex. The magnocellular division projects diffusely to auditory areas of the cortex and to adjacent insular and opercular fields.

## Lateral geniculate nucleus

The lateral geniculate body, which is part of the visual pathway, is a small, ovoid, ventral projection from the posterior thalamus (see Figs $21.5,23.4$ ). The superior quadrigeminal brachium enters the posteromedial part of the lateral geniculate body dorsally, lying between the medial geniculate body and the pulvinar.

The lateral geniculate nucleus is an inverted, somewhat flattened, U-shaped nucleus and is laminated (Fig. 23.6A). Its internal organization is usually described on the basis of six laminae, although seven or

Single lemniscal axons have an extended anteroposterior terminal zone within the nucleus. Rods of cells running the length of the anteroposterior, dorsoventrally orientated, lamellae respond with closely similar receptive field properties and locations, derived from a small bundle of lemniscal afferents. It appears, therefore, that each lamella contains the complete representation of a single body part, e.g. a finger. Lamellae consist of multiple narrow rods of neurones, orientated anteroposteriorly, each of which receives input from the same small region of the body that is represented within the lamella, and from the same type of receptors. These thalamic 'rods' form the basis for both place- and modality-specific input to columns of cells in the somatic sensory cortex. Spinothalamic tract afferents to the ventral posterolateral nucleus terminate throughout the nucleus. The neurones from which these axons originate appear to be mainly of the 'wide-dynamicrange' class, responding to both low-threshold mechanoreceptors and high-threshold nociceptors; a smaller proportion of neurones respond exclusively to high-threshold nociceptors. Some neurones respond to temperature changes. There is evidence that spinothalamic tract neurones carrying nociceptive and thermal information terminate in a distinct nuclear area, identified as the posterior part of the ventral medial nucleus (VMpo).

(A, Photograph by Kevin Fitzpatrick, London.)
eight may be present. The laminae are numbered 1-6, from the innermost ventral to the outermost dorsal (Fig. 23.6BC). Laminae 1 and 2 consist of large cells, the magnocellular layers, whereas layers 4-6 have smaller neurones, the parvocellular laminae. The apparent gaps between laminae are called the interlaminar zones. Most ventrally, an additional superficial, or S, lamina is recognized.

The lateral geniculate nucleus receives a major afferent input from the retina. The contralateral nasal hemiretina projects to laminae 1, 4 and 6 , whereas the ipsilateral temporal hemiretina projects to laminae 2,3 and 5 . The parvocellular laminae receive axons predominantly of X-type retinal ganglion cells, i.e. more slowly conducting cells with sustained responses to visual stimuli. The faster-conducting, rapidly adapting Y-type retinal ganglion cells project mainly to the magnocellular laminae 1 and 2, and give off axonal branches to the superior colliculus. A third type of retinal ganglion cell, the W cells, which have large receptive fields and slow responses, project to both the superior colliculus and the lateral geniculate nucleus, where they terminate particularly in the interlaminar zones and in the $S$ lamina.

The lateral geniculate nucleus is organized in a visuotopic manner and it contains a precise map of the contralateral visual field. The vertical meridian is represented posteriorly, the peripheral anteriorly, the upper field laterally, and the lower field medially. Similar precise, point-to-point representation is also found in the projection of the lateral geniculate nucleus to the visual cortex. Radially arranged inverted pyramids of neurones in all laminae respond to a single small area of the contralateral visual field and project to a circumscribed area of cortex. The termination of geniculocortical axons in the visual cortex is considered in detail elsewhere.

The efferent fibres of the lateral geniculate nucleus pass principally to the primary visual cortex (area 17) in the banks of the calcarine sulcus. It is possible that additional small projections pass to extrastriate visual areas in the occipital lobe, possibly arising primarily in the interlaminar zones. For further reading on processing in the lateral geniculate nucleus, see Casagrande and Ichida (2011).

## Lateral dorsal nucleus

The lateral dorsal nucleus is the most anterior of the dorsal tier of lateral nuclei. Its anterior pole lies within a splitting of the internal medullary lamina, and posteriorly it merges with the lateral posterior nucleus. Subcortical afferents to the lateral dorsal nucleus are from the pretectum and superior colliculus. It is connected with the cingulate, retrosplenial and posterior parahippocampal cortices, the presubiculum of the hippocampal formation, and the parietal cortex.

## Lateral posterior nucleus

The lateral posterior nucleus, which lies dorsal to the ventral posterior nucleus, receives its subcortical afferents from the superior colliculus. It is reciprocally connected with the superior parietal lobe. Additional connections have been reported with the inferior parietal, cingulate and medial parahippocampal cortex.

## Pulvinar

The pulvinar corresponds to the posterior expansion of the thalamus, which overhangs the superior colliculus (see Fig. 21.5). It has three major subdivisions, which are the medial, lateral and inferior pulvinar nuclei. The medial pulvinar nucleus is dorsomedial and consists of compact, evenly spaced neurones. The inferior pulvinar nucleus lies laterally and inferiorly, and is traversed by bundles of axons in the mediolateral plane, an arrangement that confers a fragmented appearance of horizontal cords or sheets of cells separated by fibre bundles. The inferior pulvinar nucleus lies most inferiorly and laterally, and is a more homogeneous collection of cells.

The subcortical afferents to the pulvinar are uncertain. Medial and lateral pulvinar nuclei may receive fibres from the superior colliculus. It has been suggested that the inferior pulvinar nucleus receives fibres both from the superior colliculus and directly from the retina, and that it contains a complete retinotopic representation.

The cortical targets of efferent fibres from the pulvinar are widespread. In essence, the medial pulvinar nucleus projects to association areas of the parietotemporal cortex, whereas lateral and inferior pulvinar nuclei project to visual areas in the occipital and posterior temporal lobes. Thus, the inferior pulvinar nucleus connects with the striate and extrastriate cortex in the occipital lobe, and with visual association areas in the posterior part of the temporal lobe. The lateral pulvinar nucleus connects with extrastriate areas of the occipital cortex, with

Aside from retinal afferents, the lateral geniculate nucleus receives a major corticothalamic projection, the axons of which ramify densely in the interlaminar zones. The major part of this projection arises from the primary visual cortex, Brodmann's area 17, but smaller projections from extrastriate visual areas pass to the magnocellular and S laminae. Other afferents include: fibres from the superficial layer of the superior colliculus (which terminate in the interlaminar zone between laminae 1 and 2 , and 2 and 3, and around lamina S); noradrenergic fibres from the locus coeruleus; serotoninergic afferents from the midbrain raphe nuclei; and cholinergic fibres from the pontine and mesencephalic reticular formation.
posterior parts of the temporal association cortex and with the parietal cortex. The medial pulvinar nucleus connects with the inferior parietal cortex, with the posterior cingulate gyrus and with the widespread areas of the temporal lobe, including the posterior parahippocampal gyrus and perirhinal and entorhinal cortex. It also has extensive connections with prefrontal and orbitofrontal cortices. Similarly, the lateral pulvinar nucleus may also connect with the rostromedial prefrontal cortex

Little is known of the functions of the pulvinar. The inferior pulvinar nucleus contains a complete retinotopic representation, and lateral and medial pulvinar nuclei also contain visually responsive cells. However, the latter nucleus, at least, is not purely visual - other modality responses can be recorded and some cells may be polysensory. Given the complexity of functions of the association areas to which they project, particularly in the temporal lobe (e.g. perception, cognition and memory), it is likely that the role of the pulvinar in modulating these functions is equally complex.

Anteriorly, the major subdivisions of the pulvinar blend into a poorly differentiated region, within which several nuclear components have been recognized, including the anterior or oral pulvinar, the suprageniculate limitans nucleus and the posterior nuclei. The connectivity of this complex is also not well understood. It is recognized that different components receive subcortical afferents from the spinothalamic tract and the superior and inferior colliculi. Cortical connections centre primarily on the insula and adjacent parts of the parietal operculum posteriorly. Stimulation of this region has been reported to elicit pain, and large lesions may alleviate painful conditions. Similarly, excision of its cortical target in the parietal operculum, or small infarcts in this cortical region, may result in hypoalgesia.

## INTRALAMINAR NUCLEI

The term intralaminar nuclei refers to collections of neurones within the internal medullary lamina of the thalamus (see Fig. 23.4). Two groups of nuclei are recognized. The anterior (rostral) group is subdivided into central medial, paracentral and central lateral nuclei. The posterior (caudal) intralaminar group consists of the centromedian and parafascicular nuclei. The designations central medial and centromedian are open to confusion; however, they are an accepted part of the terminology of thalamic nuclei in common usage. The centromedian nucleus is much larger, is considerably expanded in humans in comparison with other species, and is importantly related to the globus pallidus, deep cerebellar nuclei and motor cortex. Anteriorly, the internal medullary lamina separates the mediodorsal nucleus from the ventral lateral complex. It is occupied by the paracentral nucleus laterally, and the central medial nucleus ventromedially, as the two laminae converge towards the midline. A little more posteriorly, the central lateral nucleus appears dorsally in the lamina as the latter splits to enclose the lateral dorsal nucleus. More posteriorly, at the level of the ventral posterior nucleus, the lamina splits to enclose the ovoid centromedian nucleus. The smaller parafascicular nucleus lies more medially.

The anterior intralaminar nuclei, i.e. central medial, paracentral and central lateral, have reciprocal connections with widespread cortical areas. There is some evidence of areal preference: the central lateral nucleus projects mainly to parietal and temporal association areas; the paracentral nucleus to occipitotemporal and prefrontal cortex; and the central medial nucleus to orbitofrontal and prefrontal cortex and to the cortex on the medial surface. In contrast, the posterior nuclei, i.e. centromedian and parafascicular nuclei, have more restricted connections, principally with the motor, premotor and supplementary motor areas. Both anterior and posterior intralaminar nuclei also project to the striatum. Many cells throughout the anterior nuclei have branched axons, which pass to both the cortex and the striatum. Dual projections are less frequent in the posterior nuclei. The thalamostriate projection is topographically organized. The posterior intralaminar nuclei receive a major input from the internal pallidum. Additional afferents come from the pars reticularis of the substantia nigra, the deep cerebellar nuclei, the pedunculopontine nucleus of the midbrain, and possibly the spinothalamic tract. The anterior nuclei have widespread subcortical afferents. The central lateral nucleus receives afferents from the spinothalamic tract, and all component nuclei receive fibres from the brainstem reticular formation, the superior colliculus and several pretectal nuclei. Afferents to all intralaminar nuclei from the brainstem reticular formation include a prominent cholinergic pathway.

The precise functional role of the intralaminar nuclei is unclear. They appear to mediate cortical activation from the brainstem reticular formation and to play a part in sensory-motor integration. Damage to the
intralaminar nuclei may contribute to thalamic neglect, i.e. the unilateral neglect of stimuli originating from the contralateral body or extrapersonal space. This may arise particularly from unilateral damage to the centromedian-parafascicular complex. The latter has been targeted in humans for the neurosurgical control of pain and epilepsy. Bilateral injury to the posterior intralaminar nuclei leads to a kinetic mutism with apathy and loss of motivation. A second syndrome associated with damage involving the intralaminar nuclei is that of unilateral motor neglect, in which there is contralateral paucity of spontaneous movement and motor activity.

## MIDLINE NUCLEI

There is considerable divergence between different authors as to which elements of the medial diencephalon constitute the nuclei of the midline thalamic group. In the present account, the midline group of nuclei includes those medial thalamic structures ventral to the central medial nucleus, i.e. the rhomboid and reuniens nuclei, together with the parataenial nuclei more dorsolaterally.

The midline nuclei receive subcortical afferent fibres from the hypothalamus, the periaqueductal grey matter of the midbrain, the spinothalamic tract and the medullary and pontine reticular formation. They are the major thalamic target of ascending noradrenergic and serotoninergic axons from the locus coeruleus and raphe nuclei respectively, and they also receive a cholinergic input from the midbrain. Efferents from the midline nuclei pass to the hippocampal formation, the amygdala and the nucleus accumbens. Additional thalamocortical axons reach the cingulate, and possibly orbitofrontal, cortex. The dual cortical and basal nuclear relationship of these nuclei has often led to their being considered a part of the intralaminar system. The cortical projections are reciprocal. The relationships of the midline nuclei clearly identify them as part of the limbic system. There is some evidence that they may play a role in memory and arousal, and, pathologically, may be important in the regulation of seizure activity.

## RETICULAR NUCLEUS

The reticular nucleus is a curved lamella of large, deeply staining fusiform cells that wraps around the lateral margin of the thalamus, separated from it by the external medullary lamina. Anteriorly, it curves around the rostral pole of the thalamus to lie between it and the prethalamic nuclei, notably the bed nucleus of the stria terminalis. The nucleus is so named because it is criss-crossed by bundles of fibres that, as they pass between thalamus and cortex, produce a reticular appearance.
The nucleus is thought to receive collateral branches of corticothalamic, thalamocortical and probably thalamostriatal and pallidothalamic fibres as they traverse it. It receives an additional, probably cholinergic, afferent pathway from the nucleus cuneiformis of the midbrain. Broadly speaking, the afferents from the cortex and thalamus are topographically arranged. The reticular nucleus contains visual, somatic and auditory regions, each with a crude topographic representation of the sensorium concerned. Cells within these regions respond to visual, somatic or auditory stimuli with a latency, suggesting that these properties arise from activation by thalamocortical axon collaterals. Only in areas where representations abut do cells show modality convergence.

The efferent fibres from the reticular nucleus pass into the body of the thalamus and are GABAergic. The projections into the main thalamic nuclei broadly, but not entirely, reciprocate the thalamoreticular connections. There may also be projections to the contralateral dorsal thalamus. The reticular nucleus is believed to function in gating information relayed through the thalamus.

## HYPOTHALAMUS

The hypothalamus consists of only $4 \mathrm{~cm}^{3}$ of neural tissue, or $0.3 \%$ of the total brain. Nevertheless, it contains the integrative systems that, via the autonomic and endocrine effector systems, control fluid and electrolyte balance, food ingestion and energy balance, reproduction, thermoregulation, and immune and many emotional responses.

The hypothalamus extends from the lamina terminalis to a vertical plane posterior to the mammillary bodies, and from the hypothalamic sulcus to the base of the brain beneath the third ventricle. It lies beneath the thalamus (see Fig. 16.6) and anterior to the tegmental part of the subthalamus and the mesencephalic tegmentum. Laterally, it is

Fig. 23.7 The inferior aspect of the hypothalamus and surrounding structures. The cut end of the trochlear nerve on the left side has folded during processing. (Photograph by Kevin Fitzpatrick, London.)
bordered by the anterior part of the subthalamus, internal capsule and optic tract. Structures in the floor of the third ventricle reach the pial surface in the interpeduncular fossa. From anterior to posterior they are the optic chiasma, the tuber cinereum, the median eminence and the infundibular stalk, the mammillary bodies and the posterior perforated substance (Fig. 23.7). The latter lies in the interval between the diverging crura cerebri, and is pierced by small central branches of the posterior cerebral arteries. It contains the small interpeduncular nucleus, which receives terminals of the fasciculus retroflexus (habenulointerpeduncular tract) of both sides, and has other connections with the mesencephalic reticular formation and mammillary bodies.

The mammillary bodies are smooth, hemispherical, pea-sized eminences, lying side by side, anterior to the posterior perforated substance, each with nuclei enclosed in fascicles of fibres derived largely from the fornix. The tuber cinereum, between the mammillary bodies and the optic chiasma, is a convex mass of grey matter. From it, the median, conical, hollow infundibulum becomes continuous ventrally with the posterior lobe of the pituitary. Around the base of the infundibulum is the median eminence, which is demarcated by a shallow tuberoinfundibular sulcus.

Hypothalamic lesions have long been linked with widespread and bizarre endocrine syndromes and with metabolic, visceral, motor and emotional disturbances. The hypothalamus has major interactions with the neuroendocrine system and the autonomic nervous system, integrating responses to both internal and external afferent stimuli with the complex analysis of the world provided by the cerebral cortex.

The hypothalamus controls the endocrine system in a variety of ways: through magnocellular neurosecretory projections to the posterior pituitary; through parvocellular neurosecretory projections to the median eminence (these control the endocrine output of the anterior pituitary and thereby the peripheral endocrine organs); and via the autonomic nervous system (Nieuwenhuys 1985). The posterior pituitary neurohormones, vasopressin and oxytocin, are primarily involved in the control of osmotic homeostasis and various aspects of reproductive function, respectively. Through its effects on the anterior pituitary, the hypothalamus influences the thyroid gland (thyroid-stimulating hormone, TSH), suprarenal cortex (adrenocorticotrophic hormone, ACTH), gonads (luteinizing hormone, LH; follicle-stimulating hormone, FSH; prolactin), mammary gland (prolactin), and the processes of growth and metabolic homeostasis (growth hormone, GH).

The hypothalamus influences both parasympathetic and sympathetic divisions of the autonomic nervous system. In general, parasympathetic effects predominate when the anterior hypothalamus is stimulated; sympathetic effects depend more on the posterior hypothalamus.

Stimulation of the anterior hypothalamus and paraventricular nucleus can cause decreased blood pressure and decreased heart rate. Stimulation in the anterior hypothalamus induces sweating and vasodilation (and thus heat loss) via projections that pass through the medial forebrain bundle to autonomic centres in the brainstem
and spinal cord. Damage to the anterior hypothalamus, e.g. during surgery for suprasellar extensions of pituitary tumours, can result in an uncontrollable rise in body temperature. Projections to the ventromedial hypothalamus conjointly regulate food intake; damage to these structures during surgery for hypothalamic lesions (e.g. craniopharyngioma) can result in uncontrolled eating and consequent obesity. Stimulation in the posterior part of the hypothalamus induces sympathetic arousal, which produces vasoconstriction, piloerection, shivering and increased metabolic heat production. Circuitry mediating shivering is located in the dorsomedial posterior hypothalamus. However, this does not imply the existence of discrete parasympathetic and sympathetic 'centres'. Stimuli in many different parts of the hypothalamus can cause profound changes in heart rate, cardiac output, vasomotor tone, peripheral resistance, differential blood flow in organs and limbs, the frequency and depth of respiration, motility and secretion in the alimentary tract, erection and ejaculation.

## HYPOTHALAMIC NUCLEI

The hypothalamus contains a number of neuronal groups that have been classified on phylogenetic, developmental, cytoarchitectonic, synaptic and histochemical grounds into named nuclei, many of which are not very clearly delimited, especially in the adult. While the hypothalamus contains a few large myelinated tracts, many of the connections are diffuse and unmyelinated, and the precise paths of many afferent, efferent and intrinsic connections are uncertain.

The hypothalamus can be divided anteroposteriorly into chiasmatic (supraoptic), tuberal (infundibulotuberal) and posterior (mammillary) regions, and mediolaterally into periventricular, intermediate (medial) and lateral zones. Between the intermediate and lateral zones is a paramedian plane, which contains the prominent myelinated fibres of the column of the fornix, the mammillothalamic tract and the fasciculus retroflexus. For this reason, some authors group the periventricular and intermediate zones as a single medial zone. These divisions are artificial and functional systems cross them. The main nuclear groups and myelinated tracts are illustrated in Figures 23.8 and 23.9 and are summarized in Table 23.3.

The periventricular zone of the hypothalamus borders the third ventricle. In the anterior wall of the ventricle is the vascular organ of the lamina terminalis (OVLT, organum vasculosum), which is continuous dorsally with the median preoptic nucleus and subfornical organ. On each side in the chiasmatic region are part of the preoptic nucleus, the small, sexually dimorphic suprachiasmatic nucleus and periventricular neurones, which are medial to, and blend with, the paraventricular nucleus. In the tuberal region, the periventricular cell group expands around the base of the third ventricle to form the arcuate nucleus, which overlies the median eminence. In the posterior region, the narrow periventricular zone is continuous laterally with the posterior hypothalamic area and behind that with midbrain periaqueductal grey matter. The periventricular zone also contains a prominent periventricular fibre system.

## Suprachiasmatic nucleus

Although it contains only a few thousand neurones, the suprachiasmatic nucleus is a remarkable structure. Sometimes called the master circadian pacemaker in mammals, it appears to be the neural substrate for day-night cycles in motor activity, body temperature, plasma concentration of many hormones, renal secretion, sleeping and waking, and many other variables. Lesions of the suprachiasmatic region lead to a disordered sleep-wake cycle. (For further reading, see Mohawk and Takahashi (2011).)

The suprachiasmatic nucleus has two principal subdivisions: ventrolateral and dorsomedial. Retinal fibres terminate in the ventrolateral subdivision, characterized by neurones immunoreactive for vasoactive intestinal polypeptide (VIP). This appears to be a general input zone, which also receives afferents from the midbrain raphe and parts of the lateral geniculate nucleus of the thalamus. The dorsomedial subdivision has relatively sparse afferent innervation, and characteristically contains parvocellular neurones immunoreactive for arginine vasopressin (AVP). Neurones within the suprachiasmatic nuclei that receive direct retinal input do not respond to pattern, movement or colour. Instead, they operate as luminance detectors, responding to the onset and offset of light, and their firing rates vary in proportion to light intensity, thereby synchronizing to the light-dark cycle.

The suprachiasmatic nucleus receives glutamatergic afferents from retinal ganglion cells that entrain the rhythm to the light-dark cycle, but these are not essential for the production of the rhythm, which

persists in the blind. It contains many different neurotransmitters, including vasopressin, VIP, neuropeptide Y (NPY) and neurotensin. Axons from the suprachiasmatic nucleus pass to many other hypothalamic nuclei, including the paraventricular, ventromedial, dorsomedial and arcuate nuclei.

Neurones producing growth hormone-releasing hormone (GHRH) are largely restricted to the arcuate nucleus. Some extend dorsally into the periventricular nucleus and laterally into the retrochiasmatic area. Their fibres run through the periventricular region to the neurovascular zone of the median eminence. The neurones receive afferent information from glucose receptors in the ventromedial nucleus. Inputs from the hippocampal-amygdala-septal complex could explain the release of GH during stress. In humans, midline defects such as septo-optic dysplasia are associated with defective GH secretion. Dopamine has a stimulatory effect.

Neurones producing somatostatin (growth hormone releaseinhibiting hormone) are located in the periventricular nucleus. GHRH and somatostatin are secreted in intermittent (3-5-hour) reciprocal pulses but the origin of the pulses is unclear. A large pulse of GH is secreted at the onset of slow-wave sleep. Somatostatin also inhibits release of pituitary TSH.

Neurones producing gonadotrophin-releasing hormone (GnRH) and projecting to the median eminence are located in the periventricular and arcuate nuclei. Other GnRH neurones are found in the median preoptic area, but these appear to project to the vascular organ of the
lamina terminalis. LH and FSH are secreted by the adenohypophysis in circhoral (hourly) pulses, which are stimulated by GnRH, and are influenced by central monoamine and $\gamma$-aminobutyric acid (GABA), by oestrogen and progesterone acting indirectly through other neurones, by corticotrophin-releasing factor, and by endogenous opioids. Gonadotrophin-inhibitory hormone (GnIH) is produced by neurones located in the dorsomedial hypothalamic area that project to the median eminence. GnIH inhibits gonadotrophin synthesis and release by decreasing the activity of GnRH neurones and also by acting directly on pituitary gonadotropes.

Corticotrophin-releasing hormone (CRH) is located primarily in parvocellular periventricular neurones. They are profoundly stimulated by neurogenic (limbic input) and hypoglycaemic (ventromedial nucleus) stress, and are also controlled by negative feedback by cortisol.

Thyrotrophin-releasing hormone (TRH) neurones are rather more widely distributed in the periventricular, ventromedial and dorsomedial nuclei. TRH release is influenced by core temperature, sensed in the anterior hypothalamus, and by negative feedback of thyroid hormones. It stimulates release of pituitary TSH and also acts to excite cold-sensitive neurones in the preoptic area and to inhibit warm-sensitive ones.

Other tubero-infundibular arcuate neurones contain NPY and neurotensin. Arcuate neurones containing pro-opiomelanocortin peptides project to the periventricular nucleus rather than the median eminence.

The suprachiasmatic nucleus also influences the activity of upper spinal preganglionic sympathetic neurones. These neurones in turn project to superior cervical ganglion neurones, which project to the pineal gland. Circadian variation in this postganglionic sympathetic input causes parallel variation in pineal $N$-acetyltransferase activity and thus pineal melatonin production. The role of the pineal gland in humans is uncertain: pineal tumours can influence reproductive development, and administration of melatonin has been advocated to alleviate jet-lag.

Parvocellular neurosecretory neurones lie within the periventricular zone: in particular, in the medial parvocellular part of the paraventricular nucleus, and the arcuate nucleus. The arcuate nucleus is median in the post-infundibular part of the tuber cinereum; it extends forwards into the median eminence and almost encircles the infundibular base, but does not meet anteriorly, where the infundibulum adjoins the median part of the optic chiasma. Its numerous neurones are all small and round in coronal section, and oval or fusiform in sagittal section. No glial layer intervenes between the nucleus and the ependymal tanycytes lining the infundibular recess of the third ventricle. Circadian variation in the secretion of all anterior pituitary hormones suggests that projections from the suprachiasmatic nucleus must reach parvocellular neurosecretory neurones. Afferents from the limbic system probably mediate the widespread effects of stress, and 5-HT (5-hydroxytryptamine, serotonin) and noradrenaline (norepinephrine) from the brainstem influence the output of most anterior pituitary hormones. The axons of parvocellular neurones converge on the infundibulum, forming a tubero-infundibular tract, which ends on the capillary loops that form the hypophysial portal vessels.

Fig. 23.9 A horizontal section showing the major cell groups and tracts in and around the hypothalamus. Abbreviations: III, third ventricle; AHA, anterior hypothalamic area; Arc, arcuate nucleus; AV, anteroventral preoptic nucleus; BST, bed nucleus of stria terminalis; DBB, nucleus of diagonal band; DM, dorsomedial nucleus; LHA, lateral hypothalamic area; MeP, median preoptic nucleus; MM, mammillary body (mainly medial mammillary nucleus); MP, medial preoptic nucleus; Nac, nucleus accumbens; OVLT, vascular organ of the lamina terminalis; PAG, periaqueductal grey matter; PHA, posterior hypothalamic area; PM, posteromedial nucleus in the chiasmatic/tuberal region of the hypothalamus; PV, periventricular nucleus ( PVa , anterior part; PVp , posterior part; PVpo, preoptic part); PVH, paraventricular (hypothalamic) nucleus; SCh, suprachiasmatic nucleus; Se, septal cortex; SNc, substantia nigra pars compacta; SNr , substantia nigra pars reticularis; T, midbrain tegmentum; TM, tuberomammillary nucleus; VM, ventromedial nucleus. Fibre tracts: CP, cerebral peduncle; F, fornix; IC, internal capsule; MFB, medial forebrain bundle; MTT, mammillothalamic tract; OT, optic tract. (Modified with permission from Elsevier. Progress in Brain Research, vol 87, Swanson LW, Biochemical switching in hypothalamic circuits mediating responses to stress, pp. 181-200, 1991.)

Table 23.3 Main hypothalamic nuclei and their function

| Region |  | Nucleus | Hormone secreted | Function |
| :---: | :---: | :---: | :---: | :---: |
| Chiasmatic | Medial | Median preoptic | GnRH |  |
|  |  | Periventricular | GnRH, somatostatin, CRH, TRH |  |
|  |  | Suprachiasmatic |  | 'Master' clock |
|  | Intermediate | Supraoptic | Vasopressin |  |
|  |  | Paraventricular | Vasopressin, oxytocin |  |
| Tuberal | Medial | Dorsomedial | TRH, ANP |  |
|  |  | Ventromedial | TRH | Satiety centre |
|  |  | Arcuate | GHRH, dopamine | Secrete to portal system |
|  | Lateral | Lateral |  | Feeding centre |
| Posterior | Medial | Mammillary body |  | Memory |

Abbreviations: ANP, atrial natriuretic peptide; CRH, corticotrophin-releasing hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotrophin-releasing hormone; TRH, thyrotrophin-releasing hormone

In addition to these peptide-containing cells, dopamine neurones in the arcuate nucleus (A12 group) have terminals in the median eminence and infundibulum. Dopamine acts as the principal prolactin release-inhibiting hormone, and also inhibits secretion of TSH (likewise, TSH acts as a prolactin-releasing hormone). Noradrenergic terminals are found in the median eminence, where they may act largely in a paracrine manner.

The intermediate zone of the hypothalamus contains the bestdifferentiated nuclei. These are: the paraventricular and supraoptic nuclei; 'intermediate' nuclear groups, which show sexual dimorphism;
ventromedial and dorsomedial nuclei; the mammillary body; and tuberomammillary nuclei. Magnocellular neurosecretory neurones are found in the supraoptic nucleus and paraventricular nucleus, and as isolated clusters of cells between them.

## Supraoptic and paraventricular nuclei

The supraoptic nucleus, curved over the lateral part of the optic chiasma, contains a uniform population of large neurones. Behind the chiasma, a thin plate of cells in the floor of the brain forms the retrochiasmatic part.

Supraoptic neurones synthesize vasopressin and they all appear to project to the neurohypophysis. The magnocellular vasopressin neurones detect as little as $1 \%$ increase in the osmotic pressure of the blood and stimulate release of vasopressin from the posterior pituitary. A fall in blood volume or blood pressure of greater than 5-10\% stimulates the release of vasopressin and the urge to drink. These responses are mediated via volume receptors in the walls of the great veins and atria and baroreceptors in the carotid sinus, which all project via the vagus and glossopharyngeal nerves to the nucleus tractus solitarius and thence to the magnocellular nuclei. A biochemical defect in vasopressin production, or interruption of the supraopticohypophysial pathway (e.g. due to a head injury), can cause cranial diabetes insipidus.

The paraventricular nucleus extends from the hypothalamic sulcus downwards across the medial aspect of the column of the fornix, its ventrolateral angle reaching towards the supraoptic nucleus. Its neurones are more diverse. Magnocellular neurones, which project to the neurohypophysis, tend to lie laterally; parvocellular neurones, which project to the median eminence and infundibulum, lie more medially; and intermediate-sized neurones, which may project caudally, lie posteriorly. The axons of the paraventricular magnocellular neurones pass towards the supraoptic nucleus (paraventriculohypophysial tract), where they join axons of supraoptic neurones to form a supraopticohypophysial tract. This runs down the infundibulum, superficially, and into the neural lobe, where the axons are distended and branch repeatedly around the capillaries. Vasopressin and oxytocin are produced by separate neurones; vasopressin neurones tend to cluster in the ventrolateral part of the paraventricular nucleus and the oxytocin neurones lie around them.

The hypothalamus is essential for the control of pituitary oxytocin, gonadotrophin and prolactin secretion. The release of oxytocin from neurosecretory nerve terminals in the neurohypophysis induces contraction of the uterus and of the myoepithelial cells that surround the mammary gland alveoli. Two neuroendocrine reflexes are involved. Stretching of the cervix of the uterus during childbirth stimulates a multisynaptic afferent pathway that passes via the pelvic plexus, anterolateral column and brainstem to the magnocellular oxytocin neurones (the Ferguson reflex). This is a positive feedback mechanism, which is terminated by the birth of the child. The milk ejection reflex is evoked by suckling of the nipple, which activates intercostal nerves and, thereby, an afferent connection to the hypothalamus. The reflex can be both conditioned to a baby's cry and inhibited by stress.

At the tuberal level, the ventromedial nucleus is well defined by a surrounding neurone-poor zone but the dorsomedial nucleus above it is much less distinct. The ventromedial nucleus contains neurones receptive to plasma levels of glucose and other nutrients, and receives visceral somatic afferents via the nucleus tractus solitarius. The lateral hypothalamus receives olfactory afferents, which act as important food signals. Both areas receive extensive inputs from limbic structures. Stimulation and lesion experiments, together with human case studies, suggest that the ventromedial nuclei act together as a 'satiety centre'. Bilateral ventromedial nucleus damage promotes overeating (hyperphagia), and restricting food intake may provoke rage-like outbursts. The resultant obesity is usually coupled with hyposexuality (Fröhlich syndrome). Interestingly, in infants, ventromedial damage can lead to emaciation despite apparently normal feeding. Experimental lesions in the lateral hypothalamus promote hypophagia or aphagia, while stimulation can prolong feeding, supporting the concept of a lateral hypothalamic 'feeding centre'.

The ventromedial nucleus, lateral hypothalamic area and paraventricular nucleus also influence intermediate metabolism through the autonomic and endocrine systems. These appear to complement the effects on feeding behaviour. Thus, ventromedial stimulation facilitates glucagon release and increases glycogenolysis, gluconeogenesis and lipolysis, whereas lateral hypothalamic stimulation causes insulin release and the opposite metabolic effects. Lesions of the ventromedial nucleus also cause increased vagal and decreased sympathetic tone.

The medial mammillary nuclei, which form the bulk of the mammillary bodies, are very prominent. The distinct existence of a lateral mammillary nucleus is controversial, though a group of larger cells does occur along the lateral border of the medial mammillary nucleus. Lateral to this is the tuberomammillary nucleus, which gives rise to widespread axons that diffusely innervate the entire cerebral cortex, hypothalamus and brainstem.

The lateral zone of the hypothalamus forms a continuum that runs from the preoptic nucleus through the lateral hypothalamic area to the posterior hypothalamus. In the tuberal region, the lateral tuberal nuclei are large and well defined, and surrounded by fine fibres.

## CONNECTIONS OF THE HYPOTHALAMUS

The hypothalamus has reciprocal interaction with the rest of the body via two (possibly three) quite distinct routes: neural connections, the bloodstream and (probably) the cerebrospinal fluid.

Some hypothalamic neurones have specific receptors that sense the temperature, osmolarity, glucose, free fatty acid and hormone content of the blood. Neurosecretory neurones secrete neurohormones into the blood. These control the anterior pituitary and act on organs such as the kidney, breast, uterus and blood vessels. Some of the neural connections, especially those to the mammillary bodies, form discrete myelinated fascicles, but most are diffuse and unmyelinated, and their origin and termination are uncertain. Most pathways are multisynaptic and many of the synapses on hypothalamic neurones are derived from intrinsic interneurones.

Broadly, neural inputs to the hypothalamus are derived from the ascending visceral and somatic sensory systems, the visual and olfactory systems, and numerous tracts from the brainstem, thalamus, 'limbic' structures and neocortex. Efferent neural projections are reciprocal to most of these and, in particular, they impinge on and control the central origins of autonomic nerve fibres. The hypothalamus therefore exerts control via the autonomic and endocrine systems and through its connections to the telencephalon.

## Afferent connections

The hypothalamus receives visceral, gustatory and somatic sensory information from the spinal cord and brainstem. It receives largely polysynaptic projections from the nucleus tractus solitarius, probably directly and indirectly via the parabrachial nucleus and medullary noradrenergic cell groups (ventral noradrenergic bundle); collaterals of lemniscal somatic afferents (to the lateral hypothalamus); and projections from the dorsal longitudinal reticular formation. Many enter via the medial forebrain bundle (see Fig. 23.9) and periventricular fibre system. Others converge in the midbrain tegmentum, forming the mammillary peduncle to the mammillary body.

The major forebrain inputs to the hypothalamus are derived from structures in the limbic system, including the hippocampal formation, amygdala and septum, and from the piriform lobe and adjacent neocortex. These connections, which are reciprocal, form prominent fibre systems, i.e. the fornix, stria terminalis and ventral amygdalofugal tracts.

The hippocampal formation - in particular, the subiculum and CA1 - is reciprocally connected to the hypothalamus by the fornix, a complex tract that also contains commissural connections. As the fornix curves ventrally towards the anterior commissure, it is joined by fascicles from the cingulate gyrus, indusium griseum and the septal area. It divides around the anterior commissure into pre- and postcommissural parts. The precommissural fornix is distributed to the septum and preoptic hypothalamus, and the septum in turn sends numerous fibres to the hypothalamus. The postcommissural fornix passes ventrally and posteriorly through the hypothalamus to the medial mammillary nucleus. In its course it gives off many fibres to the medial and lateral hypothalamic nuclei.

The amygdala innervates most hypothalamic nuclei anterior to the mammillary bodies. Its corticomedial nucleus innervates preoptic and anterior hypothalamic areas and the ventromedial nucleus. The central nuclei project to the lateral hypothalamus. The fibres reach the hypothalamus by two routes. The short ventral amygdalofugal path passes medially over the optic tract, beneath the lentiform complex, to reach the hypothalamus. The long curved stria terminalis runs parallel to the fornix, separated from it by the lateral ventricle, passes through the bed nucleus of the stria terminalis, and is then distributed to the anterior hypothalamus via the medial forebrain bundle.

Olfactory afferents reach the hypothalamus largely via the nucleus accumbens and septal nuclei, and most terminate in the lateral hypotha-
lamus. Visual afferents leave the optic chiasma and pass dorsally into the suprachiasmatic nucleus. No auditory connections have been identified, though it is clear that such stimuli influence hypothalamic activity. However, many hypothalamic neurones respond best to complex sensory stimuli, suggesting that sensory information reaching the neocortex has converged and been processed by the amygdala, hippocampus and neocortex. Neocortical corticohypothalamic afferents to the hypothalamus are poorly defined, but probably arise from frontal and insular cortices. Some may relay in the mediodorsal thalamic nucleus and project into the hypothalamus via the periventricular route. Other direct corticohypothalamic fibres may end in lateral, dorsomedial, mammillary and posterior hypothalamic nuclei, but all these connections are questioned.

Like the rest of the forebrain, the hypothalamus also receives diffuse aminergic inputs from the locus coeruleus and raphe nuclei. In addition, it receives input from the ventral tegmental ascending cholinergic pathway: a noradrenergic input to dorsomedial, periventricular, paraventricular, supraoptic and lateral hypothalamic nuclei from the ventral tegmental noradrenergic bundle, and fibres from the mesolimbic dopaminergic system. Group A11 innervates the medial hypothalamic nuclei, and groups A13 and A14 supply the dorsal and rostral hypothalamic nuclei. Many of these fibres also run in the medial forebrain bundle.

The medial forebrain bundle is a loose grouping of fibre pathways that mostly run longitudinally through the lateral hypothalamus (see Fig. 23.9). It connects forebrain autonomic and limbic structures with the hypothalamus and brainstem, receiving and giving small fascicles throughout its course. It contains descending hypothalamic afferents from the septal area and orbitofrontal cortex, ascending afferents from the brainstem, and efferents from the hypothalamus.

## Efferent connections

Hypothalamic efferents include reciprocal paths to the limbic system, descending polysynaptic paths to autonomic and somatic motor neurones, and neural and neurovascular links with the pituitary.

Septal areas and the amygdaloid complex have reciprocal hypothalamic connections along the paths described above. The medial preoptic and anterior hypothalamic areas give short projections to nearby hypothalamic groups. The ventromedial nucleus has more extensive projections that pass via the medial forebrain bundle to the bed nucleus of the stria terminalis, nucleus basalis (basal nucleus of Meynert), central nucleus of the amygdala, and midbrain reticular formation. The posterior hypothalamus projects largely to the midbrain central grey matter. Some tuberal and posterior lateral hypothalamic neurones project directly to the entire neocortex and appear to be essential for maintaining cortical arousal, but the topography of these projections is unclear.

Hypothalamic neurones projecting to autonomic neurones are found in the paraventricular nucleus (oxytocin and vasopressin neurones), perifornical and dorsomedial nuclei (atrial natriuretic peptide neurones), lateral hypothalamic area ( $\alpha$-melanocyte-stimulating hormone; $\alpha-$ MSH neurones) and zona incerta (dopamine neurones). These fibres run through the medial forebrain bundle into the tegmentum, ventrolateral medulla and dorsal lateral funiculus of the spinal cord. In the brainstem, fibres innervate the parabrachial nucleus, nucleus ambiguus, nucleus of the solitary tract and dorsal motor nucleus of the vagus. In the spinal cord, they end on sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. Both oxytocin- and vasopressin-containing fibres can be traced to the most caudal spinal autonomic neurones.

The medial mammillary nucleus gives rise to a large ascending fibre bundle, which diverges into the mammillothalamic and mammillotegmental tracts (see Fig. 23.9). The mammillothalamic tract ascends through the lateral hypothalamus to reach the anterior thalamic nuclei, whence massive projections radiate to the cingulate gyrus. The mammillotegmental tract curves inferiorly into the midbrain ventral to the medial longitudinal fasciculus, and is distributed to tegmental reticular nuclei.

## PITUITARY GLAND

The pituitary gland, or hypophysis cerebri (Fig. 23.10; see Fig. 18.10), is a reddish-grey, ovoid body, about 12 mm in transverse and 8 mm in anteroposterior diameter, and with an average adult weight of 500 mg . It is continuous with the infundibulum, a hollow, conical, inferior process from the tuber cinereum of the hypothalamus. It lies within the pituitary fossa of the sphenoid bone, where it is covered superiorly by

Fig. 23.10 A median section through the hypophysis cerebri.
a circular diaphragma sellae of dura mater. The latter is pierced centrally by an aperture for the infundibulum and separates the anterior superior aspect of the pituitary from the optic chiasma. Inferiorly, the pituitary is separated from the floor of the fossa by a venous sinus that communicates with the circular sinus. The meninges blend with the pituitary capsule and are not separate layers.

The pituitary (Sam and Frohman 2008) has two major parts, the neurohypophysis and adenohypophysis, which differ in their origin, structure and function. The neurohypophysis is a diencephalic downgrowth connected with the hypothalamus. The adenohypophysis is an ectodermal derivative of the stomatodeum. Both include parts of the infundibulum (whereas the older terms 'anterior lobe' and 'posterior lobe' do not). The infundibulum has a central infundibular stem, which contains neural hypophysial connections and is continuous with the median eminence of the tuber cinereum. Thus, the term neurohypophysis includes the median eminence, infundibular stem and neural lobe or pars posterior. Surrounding the infundibular stem is the pars tuberalis, a component of the adenohypophysis. The main mass of the adenohypophysis may be divided into the pars anterior (pars distalis) and the pars intermedia, which are separated in fetal and early postnatal life by the hypophysial cleft, a vestige of Rathke's pouch, from which it develops.

The neurohypophysis includes the pars posterior (pars nervosa, posterior or neural lobe), infundibular stem and median eminence. The adenohypophysis includes the pars anterior (pars distalis or glandularis), pars intermedia and pars tuberalis.

## Neurohypophysis

In early fetal life, the neurohypophysis contains a cavity continuous with the third ventricle. Axons arising from groups of hypothalamic neurones (e.g. the magnocellular neurones of the supraoptic and paraventricular nuclei) terminate in the neurohypophysis. The long magnocellular axons pass to the main mass of the neurohypophysis. They form the neurosecretory hypothalamohypophysial tract and terminate near the sinusoids of the posterior lobe. Some smaller parvocellular neurones in the periventricular zone have shorter axons, and end in the median eminence and infundibular stem among the superior capillary beds of the venous portal circulation. These small neurones produce releasing and inhibitory hormones, which control the secretory activities of the adenohypophysis via its portal blood supply.

The neurohormones stored in the main part of the neurohypophysis are vasopressin (antidiuretic hormone; ADH), which controls reabsorption of water by renal tubules, and oxytocin, which promotes the contraction of uterine smooth muscle in childbirth and the ejection of milk from the breast during lactation (pituitary hormones are summarized in Table 23.4). Storage granules containing active hormone polypeptides bound to a transport glycoprotein, neurophysin, pass down axons from their site of synthesis in the neuronal somata (Fig. 23.11).

## Adenohypophysis

The adenohypophysis is highly vascular. It consists of epithelial cells of varying size and shape arranged in cords or irregular follicles, between which lie thin-walled vascular sinusoids supported by a delicate reticular connective tissue (Fig. 23.12). Most of the hormones synthesized by the adenohypophysis are trophic (see Table 23.4 for a summary of pituitary hormones). They include the peptides GH, involved in the control of body growth, and prolactin, which stimulates both growth of breast tissue and milk secretion. Glycoprotein trophic hormones are the large pro-opiomelanocortin precursor of ACTH , which controls the secretion of certain suprarenal cortical hormones; TSH; FSH, which stimulates growth and secretion of oestrogens in ovarian follicles and spermatogenesis (acting on testicular Sertoli cells); and LH, which induces progesterone secretion by the corpus luteum and testosterone synthesis by Leydig cells in the testis. Pro-opiomelanocortin is cleaved into a number of different molecules, including ACTH. Beta-lipotropin is released from the pituitary but its lipolytic function in humans is uncertain. Beta-endorphin is another cleavage product released from the pituitary.

Neurones that secrete the peptides and amines that control the anterior lobe are widely distributed within the hypothalamus. They are situated mainly in the medial zone, in the arcuate nucleus, medial parvocellular part of the paraventricular nucleus, and periventricular nucleus.

## Arteries and veins of the pituitary gland

The arteries of the pituitary arise from the internal carotid arteries via a single inferior and several superior hypophysial arteries on each side (Page 1982). The former come from the cavernous part of the internal carotid artery, the latter from its supraclinoid part and from the anterior and posterior cerebral arteries. The inferior hypophysial arteries divide into medial and lateral branches, which anastomose across the midline and form an arterial ring around the infundibulum. Fine branches from this circular anastomosis enter the neurohypophysis to supply its capillary bed. The superior hypophysial arteries supply the median eminence, upper infundibulum and, via the artery of the trabecula, the lower infundibulum. (The trabecula is a compact band of connective tissue and blood vessels lying within the pars distalis on either side of the midline; it forms a prominent fibrovascular tuft close to the junction of the central and lateral parts of the pars distalis; Xuereb et al (1954).) A confluent capillary net, extending through the neurohypophysis, is supplied by both sets of hypophysial vessels. Reversal of flow can occur in cerebral capillary beds lying between the two supplies.

The arteries of the median eminence and infundibulum end in characteristic sprays of capillaries, which are most complex in the upper infundibulum. In the median eminence, these form an external or 'mantle' plexus and an internal or 'deep' plexus. The external plexus, fed

Usually obliterated in childhood, remnants may persist in the form of cystic cavities, often present near the adenoneurohypophysial frontier, which sometimes invade the neural lobe. The human pars intermedia is rudimentary. It may be partially displaced into the neural lobe, and has been included in the anterior and posterior parts by different observers. Apart from this equivocation, which is of little significance, the pars anterior and pars posterior may be equated with the anterior and posterior lobes. When the associated infundibular parts continuous with these lobes are included, the names adenohypophysis and neurohypophysis become appropriate.

The thin, unmyelinated axons of the neurohypophysis are ensheathed by typical astrocytes in the infundibulum (see Fig. 23.12). Near the posterior lobe, astrocytes are replaced by pituicytes. These are dendritic neuroglial cells of variable appearance, often with long processes running parallel to adjacent axons; they constitute most of the nonexcitable tissue in the neurohypophysis. Typically, their cytoplasmic processes end on the walls of capillaries and sinusoids between nerve terminals. Axons also end in perivascular spaces; they lie close to the walls of sinusoids but remain separated from them by two basal laminae, one around the nerve endings and the other underlying the fenestrated endothelial cells. The spaces between the basal laminae are occupied by fine collagen fibrils.

The epithelial endocrine cells, which secrete the different adenohypophysial hormones, may be distinguished in part by their differing affinities for acidic and basic dyes. Cells staining strongly are described as chromophils, while those with low affinity for dyes are chromophobes. Acidophils stain strongly with acidic dyes, whereas basophils, which are more prevalent in the central part of the gland, stain strongly with basic dyes. Cells may also be classified according to the hormones they synthesize into somatotrophs (GH-secreting acidophils, the most numerous chromophil type); lactotrophs (prolactin-secreting acidophils, which are dominant in pregnancy and hypertrophy during lactation); gonadotrophs (FSH- and LH-secreting basophils); thyrotrophs (TH-secreting basophils); and corticotrophs (ACTH-secreting basophils). Chromophobes are thought to be quiescent or degranulated chromophils, or immature precursor cells, and constitute up to half of the cells of the adenohypophysis.

The pars intermedia contains follicles of chromophobe cells that surround cyst-like structures lined by epithelium and are filled, to varying degrees, with glycosylated colloidal material. Secretory products of this region may include cleavage products of pro-opiomelanocortin but their functional significance is uncertain. The pars tuberalis contains a large number of blood vessels, between which are cords or clusters of gonadotrophs and undifferentiated cells.

Table 23.4 Pituitary hormones

| Hormone | Cell type | Function / effector <br> site | Releasing <br> factor | Inhibitor |
| :--- | :--- | :--- | :--- | :--- |
| ACTH | Corticotrophs <br> (basophils) | Suprarenal cortex | CRH |  |
| TSH | Thyrotrophs <br> (basophils) | Thyroid gland | TRH | Somatostatin |
| LH, FSH | Gonadotrophs <br> (basophils) | Gonads | GnRH <br> (pulsatile) | GnIH |
| GH | Somatotrophs <br> (acidophils) | Body growth and <br> metabolism | GHRH | Somatostatin |
| Prolactin | Lactotrophs <br> (acidophils) | Mammary gland |  | Dopamine |
| Vasopressin <br> (ADH) | Magnocellular <br> hypothalamic neurons | Water absorption in <br> distal renal tubule <br> Oxytocin | Magnocellular <br> hypothalamic neurons <br> Smooth muscle and <br> ejection of breast milk |  |

Abbreviations: ACTH, adrenocorticotrophic hormone; ADH, antidiuretic hormone; CRH, corticotrophinreleasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormonereleasing hormone; GnIH, gonadotrophin-inhibitory hormone; GnRH, gonadotrophin-releasing hormone; LH, Iuteinizing hormone; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone.

A small collection of adenohypophysial tissue lies in the mucoperiosteum of the human nasopharyngeal roof. By 28 weeks in utero it is well vascularized and capable of secretion, receiving blood from the systemic vessels of the nasopharyngeal roof. At this stage, it is covered posteriorly by fibrous tissue. This is replaced in the second half of fetal life by venous sinuses, and a trans-sphenoidal portal venous system develops, bringing the nasopharyngeal tissue under the same hypothalamic control as the cranial adenohypophysial tissue. The peripheral vascularity of the pharyngeal hypophysis persists until about the fifth year. The organ is then reinvested by fibrous tissue and presumed to be controlled once more by factors present in systemic blood. Though it does not change in size after birth in males, in females it becomes smaller, returning to natal volume during the fifth decade, when once again it may be controlled via a trans-sphenoidal extension of the hypothalamohypophysial portal venous system. The human pharyngeal hypophysis may be a reserve of potential adenohypophysial tissue, which may be stimulated, particularly in females, to synthesize and secrete adenohypophysial hormones in middle age, when intracranial adenohypophysial tissue is beginning to fail.

Fig. 23.11 The main systems controlling the endocrine secretory activities of the pituitary gland.

Fig. 23.12 The pituitary gland (trichrome-stained). A, The endocrine cells of the adenohypophysis. Chromophils can be distinguished as acidophils (yellow) and basophils (pink). Chromophobes are pale-staining cells. A network of sinusoids is seen between clusters of secretory cells. B, The neurohypophysis (right), with nerve fibres and pituicytes. To the left is the pars intermedia (PI) with scattered, deeper-staining secretory cells and a cyst containing colloid (top left), representing the remnants of Rathke's pouch (RP).
by the superior hypophysial arteries, is continuous with the infundibular plexus and is drained by long portal vessels, which descend to the pars anterior. The internal plexus lies within and is supplied by the external plexus. It is continuous posteriorly with the infundibular capillary bed and, like the external plexus, is drained by long portal vessels. Short portal vessels run from the lower infundibulum to the pars anterior. Both types of portal vessel open into vascular sinusoids, which lie between the secretory cords in the adenohypophysis and provide most of its blood. There is no direct arterial supply. The portal system carries hormone-releasing factors, probably elaborated in parvocellular groups of hypothalamic neurones, and these control the secretory cycles of cells in the pars anterior. The pars intermedia appears to be avascular.

There are three possible routes for venous drainage of the neurohypophysis: to the adenohypophysis, via long and short portal vessels; into the dural venous sinuses, via the large inferior hypophysial veins; and to the hypothalamus, via capillaries passing to the median eminence. The venous drainage carries hypophysial hormones from the
gland to their targets and also facilitates feedback control of secretion. However, venous drainage of the adenohypophysis appears restricted: few vessels connect it directly to the systemic veins and so the routes by which blood leaves remain obscure.

## SUBTHALAMUS

The subthalamus is a complex region of nuclear groups and fibre tracts (see Fig. 24.12). The main nuclear groups are the subthalamic nucleus, the reticular nucleus, the zona incerta, the fields of Forel and the pregeniculate nucleus. The rostral poles of the red nucleus and substantia nigra also extend into this area.

The main subthalamic tracts are: the upper parts of the medial, spinal and trigeminal lemnisci and the solitariothalamic tract, all approaching their terminations in the thalamic nuclei; the dentatothalamic tract from the contralateral superior cerebellar peduncle
accompanied by ipsilateral rubrothalamic fibres; the fasciculus retroflexus; the fasciculus lenticularis; the fasciculus subthalamicus; the ansa lenticularis; fascicles from the prerubral field ( H field of Forel); the continuation of the fasciculus lenticularis (in the $\mathrm{H}_{2}$ field of Forel); and the fasciculus thalamicus (the $\mathrm{H}_{1}$ field of Forel).

## SUBTHALAMIC NUCLEUS

The subthalamic nucleus is structurally and functionally related to the basal ganglia and is therefore considered with them on page 369.

## ZONA INCERTA AND FIELDS OF FOREL

The zona incerta is an aggregation of small cells that lies between the ventral part of the external medullary lamina of the thalamus and the cerebral peduncle. It is linked to the reticular nucleus dorsolaterally. More medially there is a scattered group of cells in a matrix of fibres known as the H field of Forel (see Fig. 24.11). Field $\mathrm{H}_{1}$ of Forel consists of the thalamic fasciculus, which lies dorsal to the zona incerta. Field $\mathrm{H}_{2}$ of Forel contains the fasciculus lenticularis and lies ventrally, between the zona incerta and the subthalamic nucleus (see Figs 24.6, 24.12).

The zona incerta receives fibres from the sensorimotor cortex, the pregeniculate nucleus, the deep cerebellar nuclei, the trigeminal nuclear complex and the spinal cord. It projects to the spinal cord and the pretectal region. Its functions are unknown.

The neurones of the H field of Forel receive afferents from the spinal cord, the reticular formation of the brainstem and, possibly, the internal pallidum. They may project to the spinal cord. Like the zona incerta, their functions are unknown.

In addition to terminal parts of the lemniscal, dentatothalamic and rubrothalamic tracts, the subthalamus contains massive fibre tracts derived from the globus pallidus. The fasciculus lenticularis is the dorsal component of pallidofugal fibres that traverse the internal capsule. It turns medially near the medial aspect of the capsule, partly intermingled with the dorsal zone of the subthalamic nucleus and the ventral part of the zona incerta, where the fasciculus traverses the $\mathrm{H}_{2}$ field of Forel. Reaching the medial border of the zona incerta, the fasciculus intermingles with fibres of the ansa lenticularis, scattered elements of the prerubral nucleus, and dentatothalamic and rubrothalamic fibres. This merging of diverse pathways and associated cell groups is variously called the prerubral, tegmental or H field of Forel.

The ansa lenticularis has a complex origin from both parts of the globus pallidus and possibly other adjacent structures. It curves medially round the ventral border of the internal capsule, and continues dorsomedially to mingle with other fibres in the prerubral field. Some fibres in the fasciculus lenticularis and ansa lenticularis synapse in the subthalamic nucleus, prerubral field and zona incerta. The remainder continue laterally, with other fascicles, into the thalamic nuclei, particularly the ventral anterior, ventral lateral and centromedian nuclei.

The thalamic fasciculus extends from the prerubral field, and its territory is termed the $\mathrm{H}_{1}$ field of Forel. It lies dorsal to, and also partly traverses, the zona incerta, and is related dorsally to the ventral thalamic nuclei. It contains continuations of the fasciculus lenticularis and ansa lenticularis, and dentatothalamic, rubrothalamic and thalamostriate fibres.

The subthalamic fasciculus connects the subthalamic nucleus with the globus pallidus. It contains an abundant two-way array of fibres that traverse the internal capsule, interweaving with it at right angles.

## EPITHALAMUS

The epithalamus consists of the anterior and posterior paraventricular nuclei, the medial and lateral habenular nuclei, the stria medullaris thalami, posterior commissure and the pineal body.

## HABENULAR NUCLEI AND STRIA MEDULLARIS THALAMI

The habenular nuclei lie posteriorly at the dorsomedial aspect of the thalamus, immediately deep to the ependyma of the third ventricle, with the stria medullaris thalami above and laterally. The medial habenular nucleus is a densely packed, deeply staining mass of cholinergic neurones, whereas the lateral nucleus is more dispersed and palerstaining. The fasciculus retroflexus (habenulo-interpeduncular tract) emerges from the ventral margin of the nuclei and courses ventrally, skirts the inferior zone of the thalamic mediodorsal nucleus, and
traverses the superomedial region of the red nucleus to reach the interpeduncular nucleus. The habenular nuclear complex is limited laterally by a fibrous lamina, which enters the fasciculus retroflexus. Posteriorly, the nuclei of the two sides and the internal medullary laminae are linked across the midline by the habenular commissure. The tela choroidea of the third ventricle usually arises from the ependyma at the superolateral corner of the medial habenular nucleus.

Afferent fibres to the habenular nuclei travel in the stria medullaris from the prepiriform cortex bilaterally, the nucleus basalis (of Meynert) and the hypothalamus. Afferents from the internal pallidum ascend through the thalamus and may be collaterals of pallidothalamic axons. Additional inputs come from the pars compacta of the substantia nigra, the midbrain raphe nuclei and the lateral dorsal tegmental nucleus. The afferent pathways mostly end in the lateral habenular nucleus. The only identified afferent fibres to the medial habenular nucleus come from the septofimbrial nucleus.

The medial habenular nucleus sends efferent fibres to the interpeduncular nucleus of the midbrain. The lateral habenular nucleus sends fibres to the raphe nuclei and the adjacent reticular formation of the midbrain, the pars compacta of the substantia nigra and the ventral tegmental area, and to the hypothalamus and basal forebrain.

The main habenular outflow reaches the interpeduncular nucleus, mediodorsal thalamic nucleus, mesencephalic tectum and reticular formation, the largest component constituting the fasciculus retroflexus to the interpeduncular nucleus. The latter provides relays to the midbrain reticular formation, from which tectotegmentospinal tracts and dorsal longitudinal fasciculi connect with autonomic preganglionic neurones controlling salivation, gastric and intestinal secretory activity and motility, and motor nuclei for mastication and deglutition.

The stria medullaris crosses the superomedial thalamic aspect, skirts medial to the habenular trigone and sends many fibres into the ipsilateral habenula. Other fibres cross in the anterior pineal lamina and decussate, as the habenular commissure, to reach the contralateral habenula. Some fibres are really commissural and interconnect the amygdaloid complexes and hippocampal cortices. They are accompanied by crossed tectohabenular fibres. Serotonin-containing fibres from the ventral ascending tegmental serotoninergic bundle, which join the fasciculus retroflexus to reach the nuclei, may control neurones of the habenulopineal tract, and thus influence innervation of pinealocytes. Similarly, habenular nuclear afferents from the dorsal ascending tegmental noradrenergic bundle may influence pinealocytes.

Little is known of the physiological functions of the habenular nuclei. It has been suggested that they may be involved in the control of sleep mechanisms. Though the human habenula is relatively small, it is a focus of integration of diverse olfactory, visceral and somatic afferent paths. Lesions that include this area of the medial diencephalon indicate that it plays a role in the regulation of visceral and neuroendocrine functions. Ablation of the habenula causes extensive changes in metabolism and in endocrine and thermal regulation.

## POSTERIOR COMMISSURE

The posterior commissure, which is of unknown constitution in humans, is a small fasciculus that decussates in the inferior pineal lamina. Various small nuclei are associated with it. Among these are the interstitial nuclei of the posterior commissure, the nucleus of Darkschewitsch in the periaqueductal grey matter, and the interstitial nucleus of Cajal near the upper end of the oculomotor complex, closely linked with the medial longitudinal fasciculus. Fibres from all these nuclei and the fasciculus cross in the posterior commissure. It also contains fibres from thalamic and pretectal nuclei and the superior colliculi, together with fibres that connect the tectal and habenular nuclei. The destinations and functions of many of these fibres are obscure.

## PINEAL GLAND

The pineal gland or epiphysis cerebri (see Figs 18.10, 25.48B) is a small, reddish-grey organ, occupying a depression between the superior colliculi. It is inferior to the splenium of the corpus callosum, from which it is separated by the tela choroidea of the third ventricle and the contained cerebral veins. It is enveloped by the lower layer of the tela, which is reflected from the gland to the tectum. The pineal is about 8 mm long. Its base, directed anteriorly, is attached by a peduncle, which divides into inferior and superior laminae, separated by the pineal recess of the third ventricle, and containing the posterior and habenular commissures respectively. Aberrant commissural fibres may invade the gland but do not terminate near parenchymal cells.

Septa extend into the pineal gland from the surrounding pia mater. They divide the gland into lobules and carry blood vessels and fine unmyelinated sympathetic axons. The gland has a rich blood supply. The pineal arteries are branches of the medial posterior choroidal arteries, which are themselves branches of the posterior cerebral artery. Within the gland, branches of the arteries supply fenestrated capillaries whose endothelial cells rest on a tenuous and sometimes incomplete basal lamina. The capillaries drain into numerous pineal veins, which open into the internal cerebral veins and/or into the great cerebral vein.

Postganglionic adrenergic sympathetic axons (derived from neurones in the superior cervical ganglion) enter the dorsolateral aspect of the gland from the region of the tentorium cerebelli as the nervus conarii, which may be single or paired. The nerve lies deep to the endothelium of the wall of the straight sinus and is associated with blood vessels and parenchymal cells within the pineal.

The pineal gland contains cords and clusters of pinealocytes, associated with astrocyte-like neuroglia. Neuroglia are the main cellular component of the pineal stalk. Pinealocytes are highly modified neurones. They contain multiple synaptic ribbons, randomly distributed between adjacent cells, and are coupled by gap junctions. Two or more processes extend from each cell body and end in bulbous expansions near capillaries or, less frequently, on ependymal cells of the pineal recess. These terminal expansions contain rough endoplasmic reticulum, mitochondria and dense-cored vesicles that store melatonin. Melatonin, and its precursor 5-HT (serotonin), are synthesized from tryptophan by the pinealocytes, and secreted into the surrounding network of fenestrated capillaries.

The pineal is an endocrine gland of major regulatory importance (Macchi and Bruce 2004). It modifies the activity of the adenohypophysis, neurohypophysis, endocrine pancreas, parathyroids, suprarenal cortex, suprarenal medulla and gonads. Its effects are largely inhibitory. Indoleamine and polypeptide hormones secreted by pinealocytes are believed to reduce the synthesis and release of hormones by the pars anterior, either by direct action on its secretory cells or indirectly by inhibiting production of hypothalamic releasing factors. Pineal secretions may reach their target cells via the cerebrospinal fluid or the blood stream. Some pineal indoleamines, including melatonin and enzymes for their biosynthesis (e.g. $5-\mathrm{HT}, \mathrm{N}$-acetyltransferase), show circadian rhythms in concentration. The level rises during darkness, and falls during the day, when secretion may be inhibited by sympathetic activity. It is thought that the intrinsic rhythmicity of an endogenous circadian

Fig. 23.13 An axial CT image showing calcification of the pineal gland and choroid plexus.
oscillator in the suprachiasmatic nucleus of the hypothalamus governs cyclical pineal behaviour (see above).

From the second decade, calcareous deposits accumulate in pineal extracellular matrix, where they are deposited concentrically as corpora arenacea or 'brain sand' (Fig. 23.13). Pineal gland and choroid plexus calcifications are the most frequent sites of intracranial calcifications incidentally discovered among head computed tomography examinations; calcification can provide a useful indicator of a space-occupying lesion if the gland is significantly displaced from the midline.

## CHAPTER <br> 24

## Basal ganglia

The term basal ganglia is used to denote a number of subcortical nuclear masses that lie in the inferior part of the cerebral hemisphere, in close relationship with the internal capsule (Fig. 24.1; see Fig. 25.43). The traditional definition of the basal ganglia included the corpus striatum, claustrum and amygdaloid complex. The term has now been restricted to the corpus striatum and, according to some authorities, other nuclei in the diencephalon and midbrain (principally the subthalamic nucleus, substantia nigra, pedunculopontine nucleus) that collectively form a functional complex involved in the control of movement and motivational aspects of behaviour (Jankovic 2012). The function of the claustrum is unknown; the amygdala is more closely related to the limbic system and is, therefore, described in that context.

Disorders of the basal ganglia are principally characterized by abnormalities of movement, muscle tone and posture. There is a wide spectrum of clinical presentations ranging from poverty of movement and hypertonia at one extreme (typified by Parkinson's disease) to abnormal involuntary movements (dyskinesias) at the other. The underlying pathophysiological mechanisms that mediate these disorders have been much studied in recent years and are better understood than for any other type of complex neurological dysfunction (Penney and Young 1986, Jankovic 2012). This has led to the introduction of new rational

Fig. 24.1 Axial (A) and coronal (B) magnetic resonance images of the brain showing the basal ganglia, thalamus and internal capsule. (Courtesy of Alan Jackson.)
therapeutic strategies for both medical and neurosurgical treatments of movement disorders.

## CORPUS STRIATUM

The corpus striatum consists of the caudate nucleus, putamen and globus pallidus (Fig. 24.2). Because of their close proximity, the putamen and globus pallidus were once considered as an entity, the lentiform (lenticular) complex or nucleus. However, although the name has been retained in gross anatomical terminology and in some compound names (e.g. sublenticular, retrolenticular), the putamen and globus pallidus have quite different connections. Rather, it is now known that the putamen and caudate nucleus share a common chemocytoarchitecture and connections, and they are referred to jointly as the neostriatum, or simply the striatum.

The striatum is considered to be the principal 'input' structure of the basal ganglia since it receives the majority of afferents from other parts of the neuraxis. Its principal efferent connections are to the globus pallidus and pars reticularis of the substantia nigra. The globus pallidus and, more particularly, its medial segment, together with the pars reticularis of the substantia nigra, is regarded as the main 'output' structure because it is the source of basal ganglia efferent fibre projections, mostly directed to the thalamus.

## LENTIFORM COMPLEX

The lentiform complex (see Figs 16.7, 24.1; Fig. 24.3) lies deep to the insular cortex, with which it is roughly coextensive, although they are separated by a thin layer of white matter and by the claustrum. The latter splits the insular subcortical white matter to create the extreme

Fig. 24.2 Terminology and relationships of structures forming the basal ganglia.
and external capsules; the external capsule separates the claustrum from the putamen. The internal capsule separates the lentiform complex from the caudate nucleus.

The lentiform complex consists of the laterally placed putamen and the more medially placed globus pallidus (pallidum), which are separated by a thin layer of fibres, the external medullary lamina. The globus pallidus is itself divided into two segments, a lateral (external) segment and a medial (internal) segment, separated by an internal medullary lamina. The two segments have distinct afferent and efferent connections. Inferiorly, a little behind the fundus striati, the lentiform complex is grooved by the anterior commissure, which connects inferior parts of the temporal lobes and the anterior olfactory cortex of the two sides (see Fig. 24.6). The area above the commissure is referred to as the dorsal pallidum, and that below it as the ventral pallidum.

## STRIATUM

The striatum consists of the caudate nucleus, putamen and ventral striatum, which are all highly cellular and well vascularized. The vast bulk of the caudate nucleus and putamen are often referred to as the

Fig. 24.3 The anterior aspect of a coronal section through the left cerebral hemisphere.
dorsal striatum. A smaller inferomedial part of the rostral striatum is referred to as the ventral striatum, and includes the nucleus accumbens. The caudate and putamen are traversed by numerous small bundles of thinly myelinated, or unmyelinated, small-diameter axons, which are mostly striatal afferents and efferents. They radiate through the striatal tissue as though converging on, or radiating from, the globus pallidus. The bundles are occasionally referred to by the archaic term 'Wilson's pencils' and they account for the striated appearance of the corpus striatum.

## CAUDATE NUCLEUS

The caudate nucleus is a curved, tadpole-shaped mass. It has a large anterior head, which tapers to a body, and a down-curving tail (Fig. 24.4). The head is covered with ependyma and lies in the floor and lateral wall of the anterior horn of the lateral ventricle, in front of the interventricular foramen. The tapering body is in the floor of the body of the ventricle, and the narrow tail follows the curve of the inferior horn, and so lies in the ventricular roof, in the temporal lobe. Medially, the greater part of the caudate nucleus abuts the thalamus, along a junction that is marked by a groove, the sulcus terminalis. The sulcus contains the stria terminalis, lying deep to the ependyma (Fig. 24.5).

Fig. 24.4 The striatum within the left cerebral hemisphere. (With permission from Crossman AR, Neary D 2010 Neuroanatomy, 4th edn. Edinburgh: Churchill Livingstone.)

Fig. 24.5 An oblique section through the diencephalon and basal ganglia. Abbreviations: ICV, internal cerebral veins; $\mathrm{H}, \mathrm{H}_{1}, \mathrm{H}_{2}$, subthalamic fields of Forel.

Fig. 24.6 Coronal sections through the corpus striatum and anterior perforated substance. $\mathbf{A}$ is anterior to $\mathbf{B}$.

Fig. 24.7 The posterior aspect of a coronal section through the anterior horn of the lateral ventricles.

The sulcus terminalis is especially prominent anterosuperiorly (because of the large size of the head and body of the caudate nucleus relative to the tail), and here the stria terminalis is accompanied by the thalamostriate vein.

The corpus callosum lies above the head and body of the caudate nucleus. The two are separated laterally by the fronto-occipital fasciculus, and medially by the subcallosal fasciculus, which caps the nucleus (see Fig. 24.5; Fig. 24.6). The caudate nucleus is largely separated from the lentiform complex by the anterior limb of the internal capsule (see Figs 24.1, 24.6; Fig. 24.7). However, the inferior part of the head of the caudate becomes continuous with the most inferior part of the putamen immediately above the anterior perforated substance; this junctional region is sometimes known as the fundus striati (see Fig. 24.6). Variable bridges of cells connect the putamen to the caudate nucleus for most of its length. They are most prominent anteriorly, in the region of the fundus striati and the head and body of the caudate nucleus, where they penetrate the anterior limb of the internal capsule (see Fig. 24.7). In the temporal lobe, the anterior part of the tail of the caudate nucleus becomes continuous with the posteroinferior part of the putamen.

## VENTRAL STRIATUM

The ventral striatum consists of the nucleus accumbens and the olfactory tubercle. In front of the anterior commissure, much of the grey matter of the anterior perforated substance, and especially the olfactory tubercle, is indistinguishable from, and continuous with, the fundus striati, in terms of cellular composition, histochemistry and interconnections. The caudate nucleus is continuous medially with the
nucleus accumbens (see Fig. 24.6), which abuts the nuclei of the septum, close by the paraolfactory area, diagonal band of Broca and the fornix.

The nucleus accumbens receives a dopaminergic innervation from the midbrain ventral tegmental area (cell group A10). It is believed to represent the neural substrate for the rewarding effects of several classes of drugs of abuse and is, therefore, a major determinant of their addictive potential. The experimental observation that the locomotor activating effects of psychomotor stimulant drugs such as amphetamine and cocaine (which act presynaptically on dopaminergic neurones to enhance dopamine release or block its reuptake, respectively) are dependent on dopamine transmission in the nucleus accumbens, led to the hypothesis that the reinforcing or rewarding properties of these drugs are mediated by the mesolimbic dopamine system.

## STRIATAL CONNECTIVITY

Neurones of both dorsal and ventral striatum are mainly medium-sized multipolar cells. They have round, triangular or fusiform somata, mixed with a smaller number of large multipolar cells. The ratio of medium to large cells is at least $20: 1$. The large neurones have extensive spherical or ovoid dendritic trees up to $60 \mu \mathrm{~m}$ across. The medium-sized neurones also have spherical dendritic trees, approximately $20 \mu \mathrm{~m}$ across, which receive the synaptic terminals of many striatal afferents. The dendrites of both medium and large striatal cells may be either spiny or non-spiny. The most common neurone (approximately $75 \%$ of the total) is a medium-sized cell with spiny dendrites (so-called medium spiny neurones). These cells utilize $\gamma$-aminobutyric acid (GABA) as their transmitter and also express the genes coding for either enkephalin or substance $\mathrm{P} /$ dynorphin, depending on their efferent connections. Enkephalinergic neurones express D2 dopamine receptors. Substance $\mathrm{P} /$ dynorphin neurones express D1 receptors. These neurones are the major, and perhaps exclusive, source of striatal efferents to the pallidum and substantia nigra pars reticularis. The other medium-sized striatal neurones are aspiny, and are intrinsic cells that contain acetylcholinesterase (AChE), choline acetyltransferase (CAT) and somatostatin. Large neurones with spiny dendrites contain AChE and CAT; most, perhaps all, are intrinsic neurones. Aspiny large neurones are all intrinsic neurones.

Intrinsic synapses are probably largely asymmetric (type II), while those derived from external sources are symmetric (type I). The aminergic afferents from the substantia nigra, raphe and locus coeruleus all end as profusely branching axons with varicosities, which contain dense-core vesicles (the presumed store of amine transmitters). Many of these varicosities have no conventional synaptic membrane specializations, and may release transmitter in a way analogous to that found in peripheral postsynaptic sympathetic axons.

Neuroactive chemicals, whether intrinsic or derived from afferents, are not distributed uniformly in the striatum. For example, 5-HT (5-hydroxytryptamine, serotonin) and glutamic acid decarboxylase (GAD) concentrations are highest caudally, while substance P, acetylcholine (ACh) and dopamine are highest rostrally. However, there is a finer-grain neurochemical organization showing that the striatum consists of a mosaic of islands or striosomes (sometimes referred to as patches), each $0.5-1.5 \mathrm{~mm}$ across, packed into a background matrix. Striosomes contain substance P and enkephalin. During development,
the first dopamine terminals from the substantia nigra are found in striosomes. Although this exclusivity does not persist after birth, striosomes in the adult caudate nucleus still contain a higher concentration of dopamine than the matrix. The latter contains ACh and somatostatin, and is the target of thalamostriatal axons. Receptors for at least some neurotransmitters are also differentially distributed. For example, opiate receptors are found almost exclusively within striosomes, and muscarinic receptors predominantly so. Moreover, the distribution of neuroactive substances within the striosomes is not uniform. In humans, the striosome/matrix patchwork is more evident in the caudate than the putamen, the latter consisting predominantly of matrix.

All afferents to the striatum terminate in a mosaic manner. The size of a cluster of terminals is usually $100-200 \mu \mathrm{~m}$ across. Some afferent terminal clusters are not arranged in register with the clear striosome/ matrix distributions seen in nigrostriatal and thalamostriatal axons. In general, afferents from the neocortex end in striatal matrix and those from the allocortex end in striosomes. However, the distinction is not absolute: although afferents from the neocortex arise in layers V and VI, those from the superficial part of layer V end predominantly in striatal matrix, whereas those from deeper neocortex project to striosomes. Striatal cell bodies that are the sources of efferents also form clusters but, again, are not uniformly related to striosomes. For example, the cell bodies of some striatopallidal and striatonigral axons lie clustered within striosomes, but others lie outside them, still in clusters. The neurones and neuropil of the ventral striatum are essentially similar to those of the dorsal striatum, but the striosomal/matrix organization is less well defined and seems to consist predominantly of striosomes.

The major connections of the striatum are summarized in Figure 24.8. Although the connections of the dorsal and ventral divisions overlap, the generalization can be made that the dorsal striatum is predominantly connected with motor and associative areas of the cerebral cortex, whilst the ventral striatum is connected with the limbic system and orbitofrontal and temporal cortices. For both dorsal and ventral striatum, the pallidum and substantia nigra pars reticularis are key efferent structures. The fundamental arrangement is the same for both divisions. The cerebral cortex projects to the striatum, which in turn projects to the pallidum and substantia nigra pars reticularis. Efferents from the pallidum and substantia nigra pars reticularis influence the cerebral cortex (either the supplementary motor area or prefrontal and cingulate cortices via the thalamus) and the superior colliculus (see below).

The entire neocortex sends glutamatergic axons to the ipsilateral striatum. Previously, these axons were thought to be collaterals of cortical efferents to other regions, but it is now known that they arise exclusively from small pyramidal cells in layers V and VI. It has also been

Fig. 24.8 Connections of the striatum. The major afferent projections to the striatum are shown on the right and major efferent projections from the striatum on the left.
suggested that some of the cells of origin lie in the supragranular 'cortical association' layers II and III. The projection is organized topographically. The greater part of the input from the cerebral cortex to the dorsal striatum is derived from the frontal and parietal lobes, with that from the occipitotemporal cortex being relatively small. Thus, the orbitofrontal association cortex projects to the inferior part of the head of the caudate nucleus, which lies next to the ventral striatum. The dorsolateral frontal association cortex and frontal eye fields project to the rest of the head of the caudate nucleus, and much of the parietal lobe projects to the body of the nucleus. The somatosensory and motor cortices project predominantly to the putamen. Their terminals establish a somatotopic pattern, in which the lower body is represented laterally and the upper body is represented medially. The motor cortex is unique in also sending axons through the corpus callosum to the opposite putamen, where they end with the same spatial ordering. The occipital and temporal cortices project to the tail of the caudate nucleus and to the inferior putamen.

The striatum receives afferents from the polysensory intralaminar thalamus and these are more crudely organized spatially. The nucleus centralis lateralis, which receives a cerebellar input, projects to the anterior striatum (especially the caudate nucleus), while the centromedian nucleus, which receives input from both the cerebellum and internal (medial) globus pallidus, projects to the putamen.

The aminergic inputs to the caudate and putamen are derived from the substantia nigra pars compacta (dopaminergic group A9; see Fig. 21.17), the retrorubral nucleus (dopaminergic group A8), the dorsal raphe nucleus (serotoninergic group B7) and the locus coeruleus (noradrenergic group A6). The nigrostriatal input is sometimes referred to as the 'mesostriatal' dopamine pathway. It reaches the striatum by traversing the H fields (of Forel) in the subthalamus and running in the medial forebrain bundle. These aminergic inputs appear to modulate the responses of the striatum to cortical and thalamic afferent influences.

Efferents from the striatum pass to both segments of the globus pallidus and to the substantia nigra pars reticularis, where they end in a topically ordered fashion. Fibres ending in either the external or internal pallidum originate from different striatal cells (see Fig. 24.8). Those projecting to the external pallidum come from neurones that co-localize GABA and encephalin, and give rise to the so-called 'indirect pathway'. This name refers to the fact that these striatal neurones influence the activity of basal ganglia output neurones in the internal pallidum via the intermediary of the subthalamic nucleus. Other striatal neurones, which co-localize GABA and substance P /dynorphin, project directly to the internal pallidum and are, therefore, described as the 'direct pathway'.

The striatal projection to the pars reticularis of the substantia nigra also has both direct and indirect components, via the external pallidum and subthalamic nucleus (Figs 24.9-24.10). The axons of the direct striatonigral projection constitute the laterally placed 'comb' system, which is spatially quite distinct from the ascending dopaminergic nigrostriatal pathway. Striatonigral fibres end in a spatially ordered way in the pars reticularis.

The ventral striatum is the primary target of fibres from limbic cortices, including allocortex, and from limbic associated regions (see Fig. 24.9). Thus, the hippocampus (through the fornix) and orbitofrontal cortex (through the internal capsule) project to the nucleus accumbens, and the olfactory, entorhinal, anterior cingulate and temporal visual cortices project to both the nucleus accumbens and olfactory tubercle. The olfactory tubercle also receives afferents from the amygdala. The contiguity of the cortical areas that project to the ventral striatum and neighbouring dorsal striatum emphasizes the imprecise nature of the boundaries between these two divisions. All the cortical regions abut and overlap with neighbouring areas and they project to neighbouring parts of the dorsal striatum as well as to the ventral striatum. The fundus striati and ventromedial caudate nucleus abut the olfactory tubercle and nucleus accumbens (see Fig. 24.6) and receive connections from the orbitofrontal cortex and, to a lesser extent, from the lateral prefrontal and anterior cingulate cortices (which also project to the contiguous head of the caudate nucleus).

This continuity of the ventral and dorsal striata, as revealed by the arrangements of corticostriatal projections, is reinforced by consideration of the aminergic inputs to the ventral striatum. They are derived from the dorsal raphe (serotoninergic group B7), the locus coeruleus (noradrenergic group A6) and the ventral tegmental area (dopamine group A10), as well as the most medial part of the substantia nigra pars compacta (A9) (see Fig. 21.17). The dopamine projections constitute the so-called mesolimbic dopamine pathway, which also projects to the septal nuclei, hippocampus and amygdala, and prefrontal and cingulate cortices through the medial forebrain bundle. The lateromedial

Fig. 24.9 The principal output connections of the basal ganglia derived from dorsal (A) and ventral (B) divisions of the striatum. In each case, pathways established through the pallidum are distinguished from those passing through the substantia nigra pars reticularis. Abbreviations: DA, dopamine; NA, noradrenaline (norepinephrine); 5-HT, 5-hydroxytryptamine (serotonin).

Fig. 24.10 The principal connections of the basal ganglia with the diencephalon and brainstem.
continuity of cell groups A9 and 10 is thus reflected in the relative positions of their ascending fibres in the subthalamus and hypothalamus (the H fields and medial forebrain bundle, respectively), as well as in the lateromedial topography of the dorsal and ventral striata (see Fig. 24.6), which in turn have contiguous and overlapping sources of cortical afferents.

As with the dorsal striatum, efferents from the ventral striatum project to the pallidum (in this case, the ventral pallidum) and the substantia nigra pars reticularis (see Figs 24.9-24.10). In the latter case, the connection is both direct and indirect, via the subthalamic nucleus. The projections from the pars reticularis are as described for the dorsal system, but axons from the ventral pallidum reach
the thalamic mediodorsal nucleus (which projects to cingulate and prefrontal association cortex) and midline nuclei (which project to the hippocampus). Ventral pallidal axons also reach the habenular complex of the limbic system.

The brain areas beyond the basal ganglia, substantia nigra and subthalamic nucleus to which both ventral and dorsal systems appear to project are, therefore, the prefrontal association and cingulate cortices and the deep superior colliculus.

## GLOBUS PALLIDUS

The globus pallidus (pallidum) lies medial to the putamen and lateral to the internal capsule. It consists of external (lateral) and internal (medial) segments separated by an internal medullary lamina, which have substantially different connections. Both segments receive large numbers of fibres from the striatum and subthalamic nucleus. The external segment projects to the subthalamic nucleus as part of the 'indirect pathway'. The internal segment is considered to be a homologue of the pars reticularis of the substantia nigra, with which it shares similar cellular and connectional properties. Together, therefore, these structures constitute the main output of the basal ganglia to other levels of the neuraxis, principally to the thalamus and superior colliculus.

The cell density of the globus pallidus is less than one-twentieth that of the striatum. The morphology of the majority of cells is identical in the two segments. They are large multipolar GABAergic neurones that closely resemble those of the substantia nigra pars reticularis. The dendritic fields are discoid, with planes at right angles to incoming striatopallidal axons, each of which, therefore, potentially contacts many pallidal dendrites en passant. This arrangement, coupled with the diameters of the dendritic fields $(500 \mu \mathrm{~m})$, suggests that a precise topographical organization is unlikely within the pallidum.

Striatopallidal fibres are of two main types. They project to either the external or the internal pallidum. Those projecting to the external segment constitute the beginning of the so-called 'indirect pathway'. They utilize GABA as their primary transmitter and also contain enkephalin. Efferent axons from neurones in the external segment pass through the internal capsule in the subthalamic fasciculus and travel to the subthalamic nucleus (Fig. 24.11).

Striatopallidal axons destined for the internal pallidum constitute the so-called 'direct pathway'. Like the indirect projection, these utilize GABA as their primary transmitter but they also contain substance P and dynorphin. Efferent axons from the internal pallidum project through the ansa lenticularis and fasciculus lenticularis (see Fig. 24.11). The former runs round the anterior border of the internal capsule and the latter penetrates the capsule directly. Having traversed the internal
capsule, both pathways unite in the subthalamic region, where they follow a horizontal hairpin trajectory, and turn upwards to enter the thalamus as the thalamic fasciculus. The trajectory circumnavigates the zona incerta and creates the so-called ' H ' fields of Forel (see Figs 24.5, 24.11). Within the thalamus, pallidothalamic fibres end in the ventral anterior and ventral lateral nuclei and in the intralaminar centromedian nucleus. These in turn project excitatory (presumed glutamatergic) fibres primarily to the frontal cortex, including the primary and supplementary motor areas. The internal pallidum also projects fibres caudally to the pedunculopontine nucleus, as described below (see Fig. 24.10).

## SUBTHALAMIC NUCLEUS

The subthalamic nucleus is a biconvex, lens-shaped nucleus in the subthalamus of the diencephalon. It lies medial to the internal capsule, immediately rostral to the level at which the latter becomes continuous with the crus cerebri of the midbrain (see Figs 24.5, 24.3). Within the nucleus, small interneurones intermingle with large multipolar cells with dendrites that extend for about one-tenth the diameter of the nucleus. Dorsally, the nucleus is encapsulated by axons, many of which are derived from the subthalamic fasciculus; these carry a major GABAergic projection from the external segment of the globus pallidus as part of the indirect pathway. The nucleus also receives afferents from the cerebral cortex. It is unique in the intrinsic circuitry of the basal ganglia in that its cells are glutamatergic and project excitatory axons to both the globus pallidus and substantia nigra pars reticularis. Within the pallidum, subthalamic efferent fibres end predominantly in the internal segment but many also end in the external segment.

The subthalamic nucleus plays a central role in the normal function of the basal ganglia and in the pathophysiology of basal ganglia-related disorders. Destruction of the nucleus, which occurs rarely as a result of stroke, results in the appearance of violent, uncontrolled involuntary movements of the contralateral side of the body, known as ballism (hemiballismus). The subthalamic nucleus is crucially involved in the pathophysiology of Parkinson's disease and is a target for functional neurosurgical therapy of the condition. (For a detailed description of the anatomical structure and variability of the subthalamic nucleus seen using high-field magnetic resonance imaging (MRI) with histological validation, see Massey et al (2012) and Massey and Yousry (2010).)

## SUBSTANTIA NIGRA

The substantia nigra is a nuclear complex deep to the crus cerebri in each cerebral peduncle of the midbrain (see Fig. 21.16); its

Fig. 24.11 A coronal section of the brain showing the major connections of the basal ganglia with the diencephalon.
cytoarchitecture and connections are described in Chapter 21. Briefly, it consists of a pars compacta, a pars reticularis and a smaller pars lateralis. The pars compacta and pars lateralis correspond to the dopaminergic cell group A9. The pars compacta projects heavily to the caudate nucleus and putamen; lesser projections end in the globus pallidus and the subthalamic nucleus. The neurones of the pars reticularis and the internal pallidum collectively constitute the output neurones of the basal ganglia system. In Parkinson's disease, the levels of dopamine in the substantia nigra and striatum decrease dramatically as a result of the degeneration of pars compacta neurones and their terminals in the neostriatum.

## PEDUNCULOPONTINE NUCLEUS

The pedunculopontine nucleus (nucleus tegmentalis pedunculopontinus) lies in the dorsolateral part of the pontomesencephalic tegmentum. Anterograde tract-tracing studies in non-human primates and rodents have revealed multiple afferent and efferent connections between the pedunculopontine nucleus and the basal ganglia, cerebellum, substantia nigra, thalamus, cerebral cortex and spinal cord.

The pedunculopontine nucleus receives GABAergic efferent fibres from the globus pallidus and substantia nigra. In animal models of Parkinson's disease, these projections are overactive and the pedunculopontine nucleus is inhibited. Taken in conjunction with other experimental evidence, this suggests that the pedunculopontine nucleus is involved in the pathophysiology of disturbances of locomotion, gait and posture in Parkinson's disease (Mena-Segovia et al 2004). That said, the variation in nuclear connectivity between quadripedal and bipedal animals must be considered when evaluating evidence from any non-primate animal model (Alam et al 2011, Stein and Aziz 2012).)

## PATHOPHYSIOLOGY OF BASAL GANGLIA DISORDERS

The basal ganglia might be said to guide intention into action. As far as their role in movement control is concerned, they appear to promote and support patterns of behaviour that are appropriate in the prevailing circumstances and to inhibit unwanted or inappropriate movements. This is exemplified by disorders of the basal ganglia, which are characterized, depending on the underlying pathology, by an inability to initiate and execute wanted movements (as in Parkinson's disease) or an inability to prevent unwanted movements (as in Huntington's disease).

Parkinson's disease is the most common pathological condition affecting the basal ganglia. It is characterized by akinesia, muscular rigidity and tremor due to degeneration of the dopaminergic neurones of the substantia nigra pars compacta (which project to the striatum in the nigrostriatal pathway). As a consequence, dopamine terminals are lost in the striatum and dopamine levels are severely depleted. Dopamine receptors, which are located on medium spiny neurones and are the target of the nigrostriatal pathway, are spared.

Dopamine appears to have a dual action on medium spiny striatal neurones. It inhibits those of the indirect pathway and excites those of the direct pathway. Consequently, when dopamine is lost from the striatum, the indirect pathway becomes overactive and the direct pathway becomes underactive (Fig. 24.12). Overactivity of the striatal projection to the external pallidum results in inhibition of pallidosubthalamic neurones and, consequently, overactivity of the subthalamic nucleus. Subthalamic efferents mediate excessive excitatory drive to the internal globus pallidus and substantia nigra pars reticularis. This is exacerbated by underactivity of the GABAergic, inhibitory direct pathway. Overactivity of basal ganglia output then inhibits the motor thalamus and its excitatory thalamocortical connections. While this description is little more than a first approximation of the underlying pathophysiology, this model of the basis of parkinsonian symptoms has led to the introduction of new neurosurgical approaches to the treatment of Parkinson's disease, based upon lesioning and deep-brain stimulation of the internal globus pallidus and subthalamic nucleus (see below).

The current medical treatment for Parkinson's disease largely relies on levodopa ( $\mathrm{L}-\mathrm{DOPA}$; L-dihydroxyphenylalanine), the immediate metabolic precursor of dopamine, or on dopamine agonists. Whilst these usually provide good symptomatic relief for many years, eventually they lead to the development of side-effects, including dyskinesias. The involuntary movements that occur as a consequence of long-term

Bold lines indicate overactivity
Interrupted lines indicate underactivity
Fig. 24.12 The pathophysiology of Parkinson's disease (A) and dyskinesias (B). (Adapted with permission from Crossman AR, Neary D 2010 Neuroanatomy, 4th edition. Edinburgh: Churchill Livingstone.)
treatment of Parkinson's disease resemble those seen in Huntington's disease, tardive dyskinesia and ballism. Experimental evidence suggests that these may share a common neural mechanism (see Fig. 24.12). Thus, the indirect pathway becomes underactive, e.g. due to the effects of dopaminergic drugs in Parkinson's disease, or the degeneration of the striatopallidal projection to the external pallidum in Huntington's disease. This leads to physiological inhibition of the subthalamic nucleus by overactive pallidosubthalamic neurones. The involvement of the subthalamic nucleus explains why the dyskinetic movements of levodopa-induced dyskinesia and Huntington's disease resemble those of ballism produced by lesion of the subthalamic nucleus. Underactivity of the subthalamic nucleus removes the excitatory drive from internal pallidal neurones, which are known to be underactive in dyskinesias (Crossman 1990). Once again, this anatomical model of basal ganglia function is an oversimplification. Whilst it is true that underactivity of the internal globus pallidus is associated with dyskinesias, it is also known that lesions of the globus pallidus alleviate them. This so-called 'pallidotomy paradox' suggests that the dynamic aspects of pallidal and nigral efferent activity are important factors in the generation of dyskinesia (Marsden and Obeso 1994). A more recent 'rate model' of basal ganglia function hypothesizes that specific components oscillate in neuronal synchrony at different frequencies to select specific voluntary motor patterns (Little and Brown 2014). Both rodent electrophysiology and recording from deep-brain electrodes implanted in patients with Parkinson's disease suggest that neuronal activity suppression in the $8-30 \mathrm{~Hz}$ beta frequency band correlates with relief of parkinsonian akinesia and rigidity by both dopamine and subthalamic nucleus deepbrain stimulation.

There is evidence that dysfunction of the basal ganglia is also involved in other complex, less well understood, behavioural disorders. In animal experiments, lesions of the basal ganglia, especially of the caudate nucleus, induce uncontrollable hyperactivity (e.g. obstinate progression, incessant pacing and other constantly repeated behaviours). This and other evidence has led to the notion that the corpus striatum enables the individual to make motor choices and to avoid 'stimulus-bound' behaviour. Positron emission tomography (PET) studies in humans have shown that sufferers from obsessive-compulsive disorder (OCD), which is characterized by repeated ritualistic motor behaviour and intrusive thoughts, exhibit abnormal activity in the prefrontal cortex and caudate nuclei. There are similar suggestive observations in childhood attention deficit hyperactivity disorder (ADHD) and Gilles de la Tourette's syndrome. In this respect, it may be significant
that the basal ganglia, besides receiving connections from the frontal lobe and limbic cortices, also have an ascending influence on the prefrontal and cingulate cortices through the substantia nigra pars reticularis and dorsomedial and ventromedial thalamus in parallel, functionally segregated, corticostriatothalamic circuits subserving locomotor, oculomotor, cognitive and affective behaviour (Alexander et al 1986; see Fig. 24.9).

Before the advent of levodopa therapy, neurosurgery for Parkinson's disease was commonplace. The globus pallidus and thalamus were favoured targets for chemical or thermal lesions. Pallidotomy and thalamotomy often improved rigidity and tremor, but they produced little consistent beneficial effect on akinesia. With the arrival of levodopa therapy, which very effectively alleviates akinesia, the surgical treatment of Parkinson's disease underwent a progressive decline. It soon became clear, however, that long-term use of levodopa was associated with a number of side-effects such as dyskinesias, 'wearing-off' and the 'on-off' phenomenon. More recent advances in understanding the pathophysiology of movement disorders, and of Parkinson's disease in particular, have stimulated a renaissance in the use of neurosurgery to treat movement disorders.

Lesioning the subthalamic nucleus in experimental primates that had been made parkinsonian with the neurotoxin MPTP dramatically alleviated the parkinsonian symptoms, suggesting that that the subthalamic nucleus might be an appropriate clinical target (Pereira and Aziz 2006). While therapeutic surgical lesions of the subthalamic nucleus can alleviate tremor, rigidity and bradykinesia in patients with Parkinson's disease, the risk of side-effects is not trivial: the subthalamic nucleus is a small structure wrapped by fibres of passage and close to the hypothalamus and internal capsule.

In 1992, Laitinen et al reintroduced pallidotomy for the treatment of end-stage Parkinson's disease, but confined the lesions to the posteroventral part of the internal pallidum. These lesions were found to be extremely reliable in abolishing contralateral rigidity and drug-induced dyskinesias, with slightly less efficacy on tremor and bradykinesia (Laitinen et al 1992).

Implantation of deep-brain electrodes, through which highfrequency pulses generated by a pacemaker could inhibit cells in the vicinity, has been a concept since the early 1970s but did not become a widespread reality until the late 1980s, as a result of technological advances. The introduction of the technique of deep-brain stimulation (DBS), which avoids making permanent lesions, made bilateral surgery safer. There have been numerous reports of the effectiveness of both bilateral pallidal and subthalamic nucleus stimulation in Parkinson's disease (Rodriguez-Oroz et al 2012; Figs 24.13-24.14). Subthalamic nucleus stimulation is favoured by most for relieving akinesia and rigidity, with pallidal stimulation considered to ameliorate dyskinesias. Subthalamic stimulation is more effective than pallidal stimulation in allowing patients to reduce their anti-parkinsonian medication. Tremor is best relieved by stimulation of either the contralateral ventral intermediate thalamic nucleus or the zona incerta.

Another manifestation of basal ganglia dysfunction is dystonia, which is characterized by increased muscle tone and abnormal postures. Dystonia may occur as a consequence of levodopa treatment in Parkinson's disease or inherited disease (e.g. early-onset torsion, or Oppenheim's dystonia, an autosomal dominant disorder most commonly associated with a mutation in the DYT1 gene that encodes torsin A). Although the pathophysiological basis of dystonia is unclear (Hallett 2006), it is probably caused by underactivity of basal ganglia output. The observation that painful dystonic posturing of the limbs in parkinsonian patients responds dramatically to bilateral pallidal stimulation led to the development of bilateral pallidal stimulation for dystonia. Intriguingly, in dystonia the pallidal neurones are held to fire at rates below normal, and so it is open to question how this stimulation works. Moreover, while the effect of stimulation is immediate in the case of Parkinson's disease, in dystonia the improvement may take weeks to emerge, suggesting that the neural mechanism(s) underlying the therapeutic effect of stimulation for these conditions is/are different and implicating a role for neuroplasticity in dystonia.

An even more recent neurosurgical development in the therapy of Parkinson's disease has involved targeting the pedunculopontine nucleus, which both receives fibres from and sends fibres to basal ganglia and related nuclei. Recently, DBS of the pedunculopontine nucleus through implanted electrodes has been applied in drug-resistant akinetic parkinsonian patients (Fig. 24.15). Low-frequency stimulation alleviates postural instability and on-medication gait freezing and falling, symptoms that conventional medication and surgery fail to improve.

## Cerebral hemispheres

The cerebral hemispheres are the largest and most developed part of the human brain. They contain the primary motor and sensory cortices, the highest levels at which motor activities are controlled and to which general and special sensory systems project, and which provide the neural substrate for the conscious experience of sensory stimuli. Association areas are both modality-specific and multimodal, enabling complex analyses of the internal and external environment and of the relationship of the individual with the external world. The elements of the limbic system are particularly concerned with memory and the emotional aspects of behaviour, and provide an affective overtone to conscious experience as well as an interface with subcortical areas such as the hypothalamus, through which widespread physiological activities are integrated. Other cortical areas, primarily within the frontal region, are concerned with the highest aspects of cognitive function and contribute to personality, judgment, foresight and planning.

The external surface of each hemisphere is highly convoluted into a series of folds or gyri, separated by furrows or sulci (Fig. 25.1). The configuration of the main cerebral sulci and gyri provides the basis for dividing the hemispheres into frontal, parietal, occipital, temporal, insular and limbic lobes. The internal white matter contains association fibres limited to each hemisphere, commissural fibres linking corresponding areas of both hemispheres, and projection fibres connecting the cerebral cortex of each hemisphere with subcortical, brainstem and spinal cord nuclei. Some of these bundles (tracts, fasciculi) are relatively well defined macroscopically and microscopically, while others are less easy to identify. A detailed knowledge of the threedimensional anatomical interrelationships of white matter tracts is a requisite for the planning, intraoperative monitoring and execution of neurosurgical resective procedures, e.g. for tumour surgery, and epilepsy and deep brain stimulation procedures. Current understanding of these relationships owes much to the seminal work of Josef Klingler and his meticulous dissection of white matter tracts using formalinfixed, freeze-thawed brains (Agrawal et al 2011). Contemporary neurosurgical anatomical studies seek to define and delineate these fibre bundles, particularly in areas of complexity such as fibre crossing, by correlating anatomical findings obtained using Klingler's dissection techniques with the results obtained from diffusion-weighted magnetic resonance imaging, functional MRI (fMRI), intraoperative elec-
trostimulation and behavioural analyses (Alarcon et al 2014, Jin et al 2014). Some details of the anatomy of the gyri, sulci, association fibres and the amygdaloid nuclear complex are described online only (Figs 25.2; 25.9-25.13; 25.14; 25.17; 25.18; 25.20; 25.22; 25.27; 25.36; 25.37; 25.46-25.49).

## CEREBRAL HEMISPHERE SURFACES, SULCI AND GYRI <br> SULCI AND GYRI

Each hemisphere has superolateral, medial and inferior (basal) surfaces, separated by superomedial, inferolateral, medial orbital and medial occipital margins respectively.

The superolateral surface is convex and lies beneath the bones of the cranial vault; the frontal, parietal, temporal and occipital lobes correspond approximately in surface extent to the overlying bones from which they take their names. The frontal and parietal lobes are separated from the temporal lobe by the prominent lateral (Sylvian) fissure.

The inferior surface is divided by the anterior part of the lateral fissure into a small anterior orbital part and a larger posterior tentorial part. The orbital part is the concave orbital surface of the frontal lobe and rests on the floor of the anterior cranial fossa. The posterior part is formed by the basal aspects of the temporal and occipital lobes, and rests on the floor of the middle cranial fossa and the upper surface of the tentorium cerebelli, which separates it from the superior surface of the cerebellum. The medial surface is flat and vertical, separated from the opposite hemisphere by the longitudinal fissure and the falx cerebri. Anteriorly, the cerebral hemisphere terminates at the frontal and temporal poles, and posteriorly at the occipital pole.

The cerebral sulci delineate the brain gyri and are extensions of the subarachnoid space (Butler and Hodos 2005, Sarnat and Netsky 1981, Park et al 2007, Chi et al 1977, Nishikuni and Ribas 2013, Ono et al 1990, Catani and Thiebaut de Schotten 2012, Duvernoy 1991, Naidich et al 2013). When they are deep and anatomically constant, they are referred to as fissures. The main sulci have depths of $1-3 \mathrm{~cm}$, and their walls harbour small gyri that connect with each other (transverse gyri). Sulci that separate the transverse gyri vary in length and depth, and may become visible as incisures at the surface of the brain. The indentations

Fig. 25.3 A sagittal section of the brain, with the brainstem removed, showing the major gyri and sulci on the medial aspect of the left cerebral hemisphere. (Photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London; figure enhanced by B Crossman.)
caused by cortical arteries can have an appearance similar to that of the incisures. The sulci of the superolateral and inferior surfaces of the hemisphere are usually orientated towards the nearest ventricular cavity.

On the brain surface, the sulci can be long or short, interrupted or continuous. Sulci that are usually continuous include the lateral fissure and the callosal, calcarine, parieto-occipital, collateral and, generally, the central sulcus

On the superolateral surface of the hemisphere, the frontal and temporal regions are each composed of three horizontal gyri (superior, middle and inferior frontal and temporal gyri). The central area is composed of two slightly oblique gyri (pre- and postcentral gyri). The parietal region is comprised of two semicircular lobules (superior and inferior parietal lobules, the inferior being formed by the supramarginal and angular gyri) (see Fig. 25.1). The occipital region is composed of two or three less well-defined gyri (superior, middle and inferior occipital gyri). The insula, which lies deep in the floor of the lateral fissure, consists of 4-5 diagonal gyri (short and long insular gyri) (Fig. 25.2).

The orbital part of the inferior surface is covered by the orbital gyri and the basal aspect of the rectus gyri, and the tentorial part of the inferior surface is covered by the basal aspects of the inferior temporal, inferior occipital and lingual gyri, and the fusiform gyrus. The medial surface of the hemisphere is characterized by a very well defined C-shaped inner ring composed primarily of two continuous gyri (cingulate and parahippocampal gyri), surrounded by a much less well defined outer ring of gyri (medial aspects of rectus and superior frontal gyri, paracentral lobule, precuneus, cuneus, and medial aspect of lingual gyrus) (Fig. 25.3).

## MICROSTRUCTURE OF THE CORTEX

The microscopic structure of the cerebral cortex is an intricate complex of nerve cells and fibres, neuroglia and blood vessels. The neocortex essentially consists of three neuronal cell types. Pyramidal cells are the most abundant. Non-pyramidal cells, also called stellate or granule cells, are divided into spiny and non-spiny types. All types have been further subdivided on the basis of size and shape (Fig. 25.4; see Fig. 3.3).

## LAMINAR ORGANIZATION

The most obvious microscopic feature of a thin section of the neocortex stained to demonstrate cell bodies or fibres is its horizontal lamination. The extent to which this organization aids the understanding of cortical functional organization is debatable, but the use of cytoarchitectonic description to identify regions of cortex is common. Typical neocortex is described as having six layers, or laminae, lying parallel to the surface (Fig. 25.5). These are the molecular or plexiform layer; external granular lamina; external pyramidal lamina; internal granular lamina; internal pyramidal (ganglionic) lamina; and multiform (or fusiform/pleiomorphic) layer.

## NEOCORTICAL STRUCTURE

two types - granular and agranular - are regarded as virtually lacking certain laminae, and are referred to as heterotypical. Homotypical variants, in which all six laminae are found, are called frontal, parietal and polar, names that link them with specific cortical regions in a somewhat misleading manner (e.g. the frontal type also occurs in parietal and temporal lobes).

The agranular type is considered to have diminished, or absent, granular laminae (II and IV) but always contains scattered stellate somata. Large pyramidal neurones are found in the greatest densities in agranular cortex, which is typified by the numerous efferent projections of pyramidal cell axons. Although it is often equated with motor cortical areas such as the precentral gyrus (area 4), agranular cortex also occurs elsewhere, e.g. areas 6,8 and 44, and parts of the limbic system.

In the granular type of cortex the granular layers are maximally developed and contain densely packed stellate cells, among which small pyramidal neurones are dispersed. Laminae III and IV are poorly developed or unidentifiable. This type of cortex is particularly associated with afferent projections. However, it does receive efferent fibres, derived from the scattered pyramidal cells, although they are less numerous than elsewhere. Granular cortex occurs in the postcentral gyrus (somatosensory area), striate area (visual area) and superior temporal gyrus (acoustic area), and in small areas of the parahippocampal gyrus. Despite its very high density of stellate cells, especially in the striate area, it is almost the thinnest of the five main types. In the striate cortex, the external band of Baillarger (lamina IV) is well defined as the stria (white line) of Gennari

The other three types of cortex are intermediate forms. In the frontal type, large numbers of small- and medium-sized pyramidal neurones appear in laminae III and V, and granular layers (II and IV) are less prominent. The relative prominence of these major forms of neurone varies reciprocally wherever this form of cortex exists.

The parietal type of cortex contains pyramidal cells, which are mostly smaller in size than in the frontal type. In marked contrast, the granular laminae are wider and contain more of the stellate cells: this kind of cortex occupies large areas in the parietal and temporal lobes. The polar type is classically identified with small areas near the frontal and occipital poles, and is the thinnest form of cortex. All six laminae are represented, but the pyramidal layer (III) is reduced in thickness and not so extensively invaded by stellate cells as it is in the granular type of cortex. In both polar and granular types, the multiform layer (VI) is more highly organized than in other types.

It is customary to refer to some discrete cortical territories not only by their anatomical location in relation to gyri and sulci, but also in relation to their cytoarchitectonic characteristics (Brodmann's areas) (Fig. 25.7). Some of the areas so defined, e.g. the primary sensory and motor cortices, have clear relevance in terms of anatomical connections and functional significance, others less so.

## CORTICAL LAMINATION AND CORTICAL CONNECTIONS

The cortical laminae represent, to some extent, horizontal aggregations of neurones with common connections. This is most clearly seen in the lamination of cortical efferent (pyramidal) cells. The internal pyramidal lamina, layer V, gives rise to cortical projection fibres, most notably corticostriate, corticobulbar (including corticopontine) and corticospinal axons. In addition, a significant proportion of feedback

Four main types of sulci have been described: large primary sulci (e.g. central, precentral, postcentral and continuous sulci); short primary sulci (e.g. rhinal, olfactory, lateral and occipital sulci); short sulci composed of several branches (e.g. orbital and subparietal sulci); and short, free supplementary sulci (e.g. medial frontal and lunate sulci) (Ono et al 1990). Sulci often have side branches that may be unconnected or connected (with end-to-side, end-to-end or side-to-side connections that can also join two neighbouring parallel sulci).

Pyramidal cells have a flask-shaped or triangular cell body ranging from 10 to $80 \mu \mathrm{~m}$ in diameter. The soma gives rise to a single thick apical dendrite and multiple basal dendrites. The apical dendrite ascends towards the cortical surface, tapering and branching, to end in a spray of terminal twigs in the most superficial lamina, the molecular layer. From the basal surface of the cell body, dendrites spread more horizontally, for distances up to 1 mm for the largest pyramidal cells. Like the apical dendrite, the basal dendrites branch profusely along their length. All pyramidal cell dendrites are studded with a myriad of dendritic spines. These become more numerous as distance from the parent cell soma increases. A single slender axon arises from the axon hillock, which is usually situated centrally on the basal surface of the pyramidal neurone. Ultimately, in the vast majority of cases, if not in all, the axon leaves the cortical grey matter to enter the white matter. Pyramidal cells are thus, perhaps universally, projection neurones. They use an excitatory amino acid, either glutamate or aspartate, as their neurotransmitter.

Spiny stellate cells are the second most numerous cell type in the neocortex and, for the most part, occupy lamina IV. They have relatively small multipolar cell bodies, commonly 6 to $10 \mu \mathrm{~m}$ in diameter. Several primary dendrites, profusely covered in spines, radiate for variable distances from the cell body. Their axons ramify within the grey matter predominantly in the vertical plane. Spiny stellate cells probably use glutamate as their neurotransmitter.

The smallest group comprises the heterogeneous non-spiny or sparsely spinous stellate cells. All are interneurones, and their axons are confined to grey matter. In morphological terms, this is not a single class of cell but a multitude of different forms, including basket, chandelier, double bouquet, neurogliaform, bipolar/fusiform and horizontal cells. Various types may have horizontally, vertically or radially ramifying axons.

Neurones with mainly horizontally dispersed axons include basket and horizontal cells. Basket cells have a short, vertical axon, which rapidly divides into horizontal collaterals, and these end in large terminal sprays synapsing with the somata and proximal dendrites of pyramidal cells. The cell bodies of horizontal cells lie mainly at the superficial border of lamina II, occasionally deep in lamina I (the molecular or plexiform layer). They are small and fusiform, and their dendrites spread short distances in two opposite directions in lamina I. Their axons often stem from a dendrite, then divide into two branches, which travel away from each other for great distances in the same layer.

Neurones with an axonal arborization predominantly perpendicular to the pial surface include chandelier, double bouquet and bipolar/ fusiform cells. Chandelier cells have a variable morphology, although most are ovoid or fusiform and their dendrites arise from the upper and lower poles of the cell body. The axonal arborization, which emerges from the cell body or a proximal dendrite, is characteristic and identifies these neurones. A few cells in the more superficial laminae (II and IIIa) have descending axons, deeper cells (laminae IIIc and IV) have ascending axons, and intermediate neurones (IIIb) often have both. The axons ramify close to the parent cell body and terminate in numerous vertically orientated strings, which run alongside the axon hillocks of pyramidal cells, with which they synapse. Double bouquet (or bitufted) cells are found in laminae II and III and their axons traverse laminae II and V. Generally, these neurones have two or three main dendrites, which give rise to a superficial and deep dendritic tuft. A single axon arises usually from the oval or spindle-shaped cell soma and rapidly divides into an ascending and descending branch. These branches collateralize extensively, but the axonal arbor is confined to a perpendicularly extended, but horizontally confined, cylinder, $50-80 \mu \mathrm{~m}$ across. Bipolar cells are ovoid with a single ascending and a single descending dendrite, which arise from the upper and lower poles, respectively. These primary dendrites branch sparsely and their branches run vertically to produce a narrow dendritic tree, rarely more than $10 \mu \mathrm{~m}$ across, which may extend through most of the cortical thickness. Commonly, the axon originates from one of the primary dendrites, and rapidly branches to give a vertically elongated, horizontally confined axonal arbor, which closely parallels the dendritic tree in extent.

CHAPTER 25

Fig. 25.2 The basic organization of the main cerebral gyri.
A, Superolateral surface, left side. B, Medial and basal surfaces, right side. Red lines indicate constant gyri. The frontal and temporal regions each consist of three horizontal gyri; the central area consists of two slightly oblique gyri; the parietal region consists of two lobules (a quadrangular superior lobule and an inferior lobule consisting of two semicircular gyri); the occipital region consists of three irregular, less well defined, predominantly longitudinal gyri that converge towards the occipital pole; and the insula is composed of four or five diagonal gyri. Medially, the external lateral gyri and lobules extend along the superior and inferolateral borders of each hemisphere. Together, they constitute an outer medial ring that surrounds a well-defined, C-shaped inner ring composed of two continuous gyri. (With permission from Ribas GC, The cerebral sulci and gyri, Neurosurg Focus 2010 Feb;28(2):E2.)

The principal recognizable neuronal type is the neurogliaform or spiderweb cell. These small spherical cells, $10-12 \mu \mathrm{~m}$ in diameter, are found mainly in laminae II-IV, depending on cortical area. Seven to ten thin dendrites typically radiate out from the cell soma, some branching once or twice to form a spherical dendritic field of approximately $100-150 \mu \mathrm{~m}$ diameter. The slender axon arises from the cell body or a proximal dendrite. Almost immediately, it branches profusely within the vicinity of the dendritic field (and usually somewhat beyond), to give a spherical axonal arbor up to $350 \mu \mathrm{~m}$ in diameter.

The majority of non-spiny or sparsely spinous non-pyramidal cells probably use $\gamma$-aminobutyric acid (GABA) as their principal neurotransmitter. This is almost certainly the case for basket, chandelier, double bouquet, neurogliaform and bipolar cells. Some are also characterized by the coexistence of one or more neuropeptides, including neuropeptide Y, vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), somatostatin and substance P. Acetylcholine is present in a subpopulation of bipolar cells, which may additionally be GABAergic and contain VIP.

The molecular or plexiform layer is cell-sparse, containing only scattered horizontal cells and their processes enmeshed in a compacted mass of tangential, principally horizontal axons and dendrites. These are afferent fibres, which arise from outside the cortical area, together with intrinsic fibres from cortical interneurones, and the apical dendritic arbors of virtually all pyramidal neurones of the cerebral cortex. In histological sections stained to show myelin, layer I appears as a narrow horizontal band of fibres. The external granular lamina contains a varying density of small neuronal cell bodies, including both small pyramidal and non-pyramidal cells; the latter may predominate. Myelin fibre stains show mainly vertically arranged processes traversing the layer. The external pyramidal lamina contains pyramidal cells of varying sizes, together with scattered non-pyramidal neurones. The size of the pyramidal cells is smallest in the most superficial part of the layer and greatest in the deepest part. This lamina is frequently further subdivided into IIII, IIIb and IIIC, with IIIa most superficial and IIIc deepest. As in layer II, myelin stains reveal a mostly vertical organization of fibres. The internal granular lamina is usually the narrowest of the cellular laminae. It contains densely packed, small, round cell bodies of non-pyramidal cells, notably spiny stellate cells and some small pyramidal cells. Within the lamina, in myelin stained sections, a prominent band of horizontal fibres (outer band of Baillarger) is seen. The internal pyramidal (ganglionic) lamina typically contains the largest pyramidal cells in any cortical area, though actual sizes vary considerably from area to area. Scattered non-pyramidal cells are also present. In myelin stains, the lamina is traversed by ascending and descending vertical fibres, and also contains a prominent central band of horizontal fibres (inner band of Baillarger). The multiform (or fusiform/pleiomorphic) layer consists of neurones with a variety of shapes, including recognizable pyramidal, spindle, ovoid and many other shapes of somata. Typically, most cells are small to medium in size. This lamina blends gradually with the underlying white matter, and a clear demarcation of its deeper boundary is not always possible.

Fig. 25.4 A, Characteristic neocortical neurones. From left to right are shown Martinotti, neurogliaform, basket, horizontal, fusiform, stellate and pyramidal types of neurone. B, The most frequent types of neocortical neurone, showing typical connections with each other and with afferent fibres. The right and left afferent fibres are association or corticocortical connections; the central afferent is a specific sensory fibre. Neurones are shown in their characteristic lamina but many have somata in more than one layer.
corticocortical axons arise from cells in this layer, as do some corticothalamic fibres. Layer VI, the multiform lamina, is the major source of corticothalamic fibres. Supragranular pyramidal cells, predominantly layer III but also lamina II, give rise primarily to both association and commissural corticocortical pathways. Generally, short corticocortical fibres arise more superficially, and long corticocortical (both association and commissural) axons come from cells in the deeper parts of layer III. Major afferents to a cortical area tend to terminate in layers I, IV and VI. Quantitatively lesser projections end either in the intervening laminae II/III and V, or sparsely throughout the depth of the cortex. Numerically, the largest input to a cortical area tends to terminate mainly in layer IV. This pattern of termination is seen in the major thalamic input to visual and somatic sensory cortex. In general, nonthalamic subcortical afferents to the neocortex, which are shared by widespread areas, tend to terminate throughout all cortical layers, but the laminar pattern of their endings still varies considerably from area to area.

## COLUMNS AND MODULES

Experimental physiological and connectional studies have demonstrated an internal organization of the cortex, which is at right angles to the pial surface, with vertical columns or modules running through the depth of the cortex. The term 'column' refers to the observation that all cells encountered by a microelectrode penetrating and passing perpendicularly through the cortex respond to a single peripheral stimulus, a phenomenon first identified in the somatosensory cortex. In the visual cortex, narrow $(50 \mu \mathrm{~m})$ vertical strips of neurones respond to a bar stimulus of the same orientation (orientation columns), and wider strips $(500 \mu \mathrm{~m})$ respond preferentially to stimuli detected by one eye
(ocular dominance columns). Adjacent orientation columns aggregate within an ocular dominance column to form a hypercolumn, responding to all orientations of stimulus for both eyes for one point in the visual field. Similar functional columnar organization has been described in widespread areas of neocortex, including motor cortex and association areas.

## CEREBRAL LOBES

Each cerebral hemisphere is divided into six lobes: frontal, parietal, occipital, temporal, insular and limbic lobes. The surface features of the hemispheres exhibit considerable inter-individual variation in terms of the depth and size of their sulci and the resulting patterns of gyral separation (Ribas 2010). Connections between sulci are common; differing interpretations of these patterns of connectivity continue to contribute to inconsistencies in the literature, e.g. the use of different boundaries to demarcate the temporal, parietal and occipital lobes (Fig. 25.8).

In what follows, each lobe will be described in terms of its external sulci and gyri, internal cortical structure and connectivity. Unless otherwise indicated in the caption, the dissections in this chapter display features in left cerebral hemispheres.

## FRONTAL LOBE

The frontal lobe is the largest part of the cerebral hemisphere. It contains the primary motor area (MI) within the precentral gyrus, the supplementary motor area (SMA) anteriorly and medially, and the premotor areas anteriorly and laterally. While movement is thought to be initiated from within MI, the supplementary motor and premotor

## Frontal lobe internal structure and connectivity

## Primary motor cortex

The primary motor cortex (MI) corresponds to the precentral gyrus (area 4), and is the area of cortex with the lowest threshold for eliciting contralateral muscle contraction by electrical stimulation. It contains a detailed topographically organized map (motor homunculus) of the opposite body half, with the head represented most laterally, and the leg and foot represented on the medial surface of the hemisphere in the paracentral lobule (Fig. 25.15). A striking feature is the disproportionate representation of body parts in relation to their physical size: large areas represent the muscles of the face and hand, which are capable of finely controlled or fractionated movements.

The cortex of area 4 is agranular, and layers II and IV are difficult to identify. The most characteristic feature is the presence in lamina V of some extremely large pyramidal cell bodies, Betz cells, which may approach $80 \mu \mathrm{~m}$ in diameter. These neurones project their axons into the corticospinal and corticonuclear tracts.

The major thalamic connections of area 4 are with the ventral posterolateral nucleus, which in turn receives afferents from the deep cerebellar nuclei. The ventral posterolateral nucleus also contains a topographic representation of the contralateral body half, which is preserved in its point-to-point projection to area 4, where it terminates largely in lamina IV. Other thalamic connections of area 4 are with the centromedian and parafascicular nuclei. These appear to provide the only route through which output from the basal ganglia, routed via the thalamus, reaches the primary motor cortex, since the projection of the internal segment of the globus pallidus to the ventrolateral nucleus of the thalamus is confined to the anterior division, and there is no overlap with cerebellothalamic territory. The anterior part of the ventrolateral nucleus projects to the premotor and supplementary motor areas of cortex with no projection to area 4.

The ipsilateral somatosensory cortex (SI) projects in a topographically organized way to area 4 , and the connection is reciprocal. The projection to the motor cortex arises in areas 1 and 2 , with little or no contribution from area 3b. Fibres from SI terminate in layers II and III of area 4 , where they contact mainly pyramidal neurones. Evidence suggests that neurones activated monosynaptically by fibres from SI, as well as those activated polysynaptically, make contact with layer V pyramidal cells, including Betz cells, which give rise to corticospinal fibres. Movement-related neurones in the motor cortex that can be activated from SI tend to have a late onset of activity, mainly during the execution of movement. It has been suggested that this pathway plays a role primarily in making motor adjustments during a movement. Additional ipsilateral corticocortical fibres to area 4 from behind the central sulcus come from the second somatic sensory area (SII).

Neurones in area 4 are responsive to peripheral stimulation, and have receptive fields similar to those in the primary sensory cortex. Cells located posteriorly in the motor cortex have cutaneous receptive fields, whereas more anteriorly situated neurones respond to stimulation of deep tissues.

The motor cortex receives major frontal lobe association fibres from the premotor cortex and the supplementary motor area, and also fibres from the insula. It is probable that these pathways modulate motor cortical activity in relation to the preparation, guidance and temporal organization of movements. Area 4 sends fibres to, and receives fibres from, its contralateral counterpart, and also projects to the contralateral supplementary motor cortex.

Apart from its contribution to the corticospinal tract, the motor cortex has diverse subcortical projections. The connections to the striatum and pontine nuclei are heavy. It also projects to the subthalamic nucleus. The motor cortex sends projections to all nuclei in the brainstem, which are themselves the origin of descending pathways to the spinal cord: namely, the reticular formation, the red nucleus, the superior colliculus, the vestibular nuclei and the inferior olivary nucleus.

Fig. 25.9 The main sulci $(\mathbf{A})$ and gyri $(\mathbf{B})$ of the superolateral surface of the brain. Abbreviations: AG, angular gyrus; ASCR, anterior subcentral ramus of Sylvian fissure; CS, central sulcus; IFG, inferior frontal gyrus; IFS, inferior frontal sulcus; IOS, inferior occipital sulcus; IPS, intraparietal sulcus; ISJ, intermediary sulcus of Jensen; ITG, inferior temporal gyrus; ITS, inferior temporal sulcus; MFG, middle frontal gyrus; MFS, middle frontal sulcus; MOG, middle occipital gyrus; MTG, middle temporal gyrus; Op, opercular part of inferior frontal gyrus; Orb, orbital part of inferior frontal gyrus; PostCG, postcentral gyrus; PostCS, postcentral sulcus; PreCG, precentral gyrus; PreCS, precentral sulcus; PSCR, posterior subcentral ramus of Sylvian fissure; SFG, superior frontal gyrus; SFS, superior frontal sulcus; SMG, supramarginal gyrus; SOG, superior occipital gyrus; SOS, superior occipital sulcus; SPLob, superior parietal lobule; STG, superior temporal gyrus; STS, superior temporal sulcus; SyF, lateral or Sylvian fissure; Tr, triangular part of inferior frontal gyrus. (Adapted with permission from Ribas GC. The cerebral sulci and gyri. Neurosurg Focus 2010, 28(2):E2.)

The inferior connection corresponds to the subcentral gyrus, delineated anteriorly and posteriorly by the anterior and posterior subcentral rami of the lateral fissure. It can either be situated completely over the lateral fissure or be in part internal to the fissure, in this situation giving the false impression that the central sulcus is a branch of the lateral fissure. The superior connection corresponds to the paracentral lobule (of Ecker) disposed along the medial surface of the hemisphere inside the interhemispheric fissure, delineated anteriorly by the paracentral sulcus and posteriorly by the ascending and distal part (marginal ramus) of the cingulate sulcus. Broca described a middle connection between the pre- and postcentral gyri (pli de passage moyen of Broca) that may be present as a gyral bridge, usually hidden within the central sulcus; on the cortical surface, this corresponds to the classic, posteriorly convex, middle genu of the central sulcus. When this middle connection is sufficiently developed so that it reaches the brain surface, it interrupts the central sulcus (Régis et al 2005).

The localization of motor and sensory hand areas has been studied by correlating imaging cortical stimulation and postmortem cadaveric studies. The motor hand area has been localized by fMRI to a protrusion of the precentral gyrus that corresponded precisely to the middle genu of the central sulcus, at the distal end of the superior frontal sulcus (Yousry et al 1997, Ribas 2010) (Figs 25.11-25.12). Postmortem studies revealed that this protrusion was delimited by two anteriorly directed fissures that deepened towards the base of the protrusion. Hand sensory function has been localized to the postcentral component of the middle connection of the pre- and postcentral gyri (Boling and Olivier 2004, Boling et al 2008).

The precentral gyrus is delimited anteriorly by the precentral sulcus, itself divided into superior and inferior precentral sulci by the connection of the middle frontal gyrus with the precentral gyrus. Further connections of the superior, middle and inferior frontal gyri may divide the superior and the inferior precentral sulci into additional segments. The

Fig. 25.10 The main sulci $(\mathbf{A})$ and gyri $(\mathbf{B})$ of the medial and basal temporo-occipital surfaces of the right side of the brain. Abbreviations: AntCom, anterior commissure; Ant and PostOlfS, anterior and posterior paraolfactory sulcus; CaF, calcarine fissure; CaN, caudate nucleus; CaS, callosal sulcus; CC, corpus callosum; CiG, cingulate gyrus; CiPo, cingulate pole; CiS, cingulate sulcus; ColS, collateral sulcus; CS, central sulcus; Cu, cuneus; Fo, fornix; FuG, fusiform gyrus; GRe, gyrus rectus; IIIV, third ventricle; InfRosS, inferior rostral sulcus; Ist, isthmus of cingulate gyrus; ITG, inferior temporal gyrus; IVeFo, interventricular foramen of Monro; LatV, lateral ventricle; LiG, lingual gyrus; MaCiS, marginal ramus of the cingulate sulcus; MedFG, medial frontal gyrus; OTS, occipitotemporal sulcus; PaCLob, paracentral lobule; PaCS, paracentral sulcus; PaOIfG, paraolfactory gyri; PaTeG, paraterminal gyrus; PHG, parahippocampal gyri; POS, parieto-occipital sulcus; PreCS, precentral sulcus; PreCu, precuneus; RhiS, rhinal sulcus; RoCC, rostrum of the corpus callosum; SFG, superior frontal gyrus; Spl, splenium of corpus callosum; SubPS, subparietal sulcus; SupRosS, superior rostral sulcus; TePo, temporal pole; Tha, thalamus; Un, uncus. (Adapted with permission from Ribas GC. The cerebral sulci and gyri. Neurosurg Focus 2010, 28(2):E2.)
superior part of the precentral sulcus is very often interrupted superiorly by a connection between the superior frontal and precentral gyri, producing a more medial segment, the medial precentral sulcus, that corresponds to the sulcus precentralis medialis of Eberstaller. More dorsally, within the precentral region, the marginal precentral sulcus (sulcus precentralis marginalis of Cunningham) may merge with the superior precentral or central sulci. The inferior segment of the precentral sulcus always ends inside the opercular part of the inferior frontal gyrus, producing its characteristic U shape.

The superior frontal gyrus is continuous anteriorly and inferiorly with the rectus gyrus; it may also be connected to the orbital gyri and the middle frontal gyrus. Posteriorly, it is connected to the precentral gyrus by at least one fold, which most commonly lies medially along the interhemispheric fissure. Usually the superior longitudinal gyrus is subdivided into two longitudinal portions by a medial frontal sulcus; its medial portion is sometimes termed the medial frontal gyrus. The supplementary motor area is located along the most medial portion of the superior frontal gyrus, immediately facing the precentral gyrus; it varies between individuals and has poorly defined borders. The middle frontal gyrus is usually the largest of the frontal gyri, frequently connected superficially to the precentral gyrus by a prominent root that lies between the extremities of a marked interruption in the precentral sulcus. It harbours a complex of multiple shallow sulcal segments known collectively as the middle or intermediate frontal sulcus (Petrides
2012). Superiorly, the inferior frontal gyrus is crossed by various small branches of the interrupted inferior frontal sulcus; the triangular sulcus typically pierces the superior aspect of the triangular part. In the dominant hemisphere, the opercular and triangular parts of the inferior gyrus correspond to Broca's area, which is responsible for the production of spoken language (Fig. 25.13) (Quiñones-Hinojosa et al 2003). The most posterior aspect of the inferior frontal gyrus, identifiable by the connection of its opercular part with the precentral gyrus, corresponds to the ventral premotor cortical area; its bilateral stimulation causes speech arrest (Duffau 2011).

The superior frontal sulcus separates the superior and middle frontal gyri. It is very deep and is frequently continuous, ending posteriorly by encroaching on the precentral gyrus at the level of its omega region (corresponding to the motor cortical representation of the contralateral hand). The superior frontal sulcus therefore tends to point the way to the middle frontoparietal pli de passage, as well as to the middle genu of the precentral gyrus, where there is also a motor representation of the hand (Boling et al 1999)

The inferior frontal sulcus is always interrupted by the multiple connections running between the middle and inferior gyri and usually has three parts: orbital, triangular and opercular. The orbital part is the most prominent. The triangular part is usually more retracted, such that there is a small widening of the lateral fissure at its base corresponding to the anterior Sylvian point. It is characterized by horizontal and anterior

Fig. 25.11 The hand motor activation site corresponds to a knob-like cortical area of the contralateral precentral gyrus, which in MRI axial planes usually resembles an inverted omega shape (the area within the red circle) and may be identified by its relationship to the posterior end of the superior frontal sulcus. Abbreviations: PreCG, precentral gyrus; PreCS, precentral sulcus; SFS, superior frontal sulcus (non-continuous, interrupted). (Courtesy of Professor Edson Amaro Jr MD, Department of Radiology, University of São Paulo Medical School.)
ascending rami of the lateral fissure that consistently divide the lateral fissure into anterior and posterior branches. The opercular part is always U-shaped and harbours the inferior aspect of the precentral sulcus; it is continuous posteriorly with the basal aspect of the precentral gyrus over the anterior subcentral ramus of the lateral fissure (Fig. 25.14). The anterior basal portion of the opercular part is sometimes divided by another branch of the lateral fissure, the diagonal sulcus of Eberstaller.

Inferiorly, the orbital part continues with the lateral orbital gyrus, at times passing under a shallow sulcus known as the fronto-orbital sulcus. The basal apex of the triangular part is always superior to the lateral fissure; the base of the opercular part can be located either superiorly or within the fissure. Anteriorly, the inferior frontal gyrus terminates by merging with the anterior portion of the middle frontal gyrus. All of the frontal gyri are delineated anteriorly by the frontomarginal sulcus (frontomarginal sulcus of Wernicke), which lies superior and parallel to the supraciliary margin, separating the superolateral and orbital frontal surfaces. Posteriorly, the inferior frontal gyrus is connected to the precentral gyrus along the posterior aspect of its opercular part.

The olfactory sulcus lies longitudinally in a paramedian position on the frontobasal or orbital surface of each frontal lobe. It accommodates the olfactory tract and bulb. Posteriorly, the olfactory tract is divided into medial and lateral striae, which delineate the most anterior aspect of the anterior perforated substance (see Figs 25.20B, 25.32). The narrow gyrus rectus, medial to the olfactory sulcus, is considered to be the most anatomically constant of the cerebral gyri. The orbital gyri, lateral to the olfactory sulcus, account for the greatest proportion of the frontobasal surface. The anterior, posterior, medial and lateral orbital gyri are delineated by the lateral, medial and transverse orbital sulci and the cruciform sulcus of Rolando, which together form a characteristic H shape. The posterior orbital gyrus lies anterior to the anterior perforated substance and typically presents a configuration similar to a tricorn hat, a feature that may facilitate its identification in anatomical specimens where the H-shaped orbital sulcus is less obvious. The remaining orbital gyri are connected to the superior, middle and inferior frontal gyri along the frontal pole.

Fig. 25.12 A reconstruction of the short U-shaped (red) and long projection (green) tracts of the hand-knob motor region in the left hemisphere. A, Left lateral view. B, Top view. C, Posterior view. The connections of the hand region resemble a 'poppy flower' with a green stem and four red 'petals' (1, posterior; 2, inferior; 3, anterior; 4, superior). The posterior (1) and inferior (2) petals correspond to the frontoparietal U-tracts between the precentral (PrCG) and postcentral (PoCG) gyri (i.e. hand superior and hand middle, respectively). The anterior (3) and superior (4) petals correspond to the U-shaped connections between the precentral gyrus and the middle frontal gyrus (MFG), and the middle frontal gyrus and superior frontal (SFG) gyrus, respectively. The 'green stem' is formed by ascending thalamocortical projection fibres and descending projections to the putamen (corticostriatal), pons (corticopontine) and spinal cord (corticospinal tract). Fig. 25.13 Functional magnetic resonance images (fMRI) of the language cortical areas (left cerebral hemisphere) activated by rhyme tasks (A, red), semantic tasks ( $B$, blue) and fluency tasks ( $C$, green). Abbreviations: MFG, middle frontal gyrus; Op, opercular part of inferior frontal gyrus; Orb, orbital part of inferior frontal gyrus; SOG, superior occipital gyrus; STS, superior temporal sulcus; Tr , triangular part of inferior frontal gyrus. (Courtesy of Prof. Edson Amaro Jr MD, Department of Radiology, University of São Paulo Medical School.)

The paracentral lobule, bounded posteriorly by the marginal ramus and anteriorly by the paracentral sulcus (a branch of the cingulate sulcus), contains the distal part of the central sulcus and, inferior to it, the so-called paracentral fossa. Anterior to the paracentral lobule, the medial aspect of the superior frontal gyrus lies over the cingulate sulcus and the cingulate gyrus, merging inferiorly with the gyrus rectus. The latter is bounded superiorly by the superior rostral sulcus and accommodates the shallower inferior rostral sulcus along its surface. The cingulate gyrus systematically connects with the gyrus rectus around the posterior end of the superior rostral sulcus by a prominent U-shaped cortical fold known as the cingulate pole, which is located immediately anterior to the subcallosal gyri. Small supraorbital sulci lie within the medial surface of the frontal pole, superior to the superior rostral sulcus at the level of the genu of the corpus callosum.

Fig. 25.14 Components of the frontoparietal operculum. A, A cadaveric specimen. B, MRI. The triangular part of the inferior frontal gyrus usually contains a descending branch of the inferior frontal sulcus (IFS). Three U-shaped convolutions are formed by the opercular part of the inferior frontal gyrus, which always harbours the inferior part of the precentral sulcus (PreCS); the subcentral gyrus or Rolandic operculum (the inferior connection of the pre- and postcentral gyri enclosing the inferior part of the central sulcus (CS)); and the connection between the postcentral and supramarginal gyri that contains the inferior part of the postcentral sulcus (PostCS). The most distal component of the operculum is a C-shaped convolution that connects the supramarginal and superior temporal gyri, and encircles the posterior end of the lateral (Sylvian) fissure. The bases of the U-shaped convolutions and their related sulcal extremities may be either superior to the fissure, as indicated in this specimen, or inside the fissure. Other abbreviations: ASyP, anterior Sylvian point; IRP, inferior Rolandic point. ## Corticospinal tract

The corticospinal or pyramidal tract provides direct control by the cerebral cortex over motor centres of the spinal cord (Ch. 20). A homologous pathway to the brainstem, the corticonuclear projection, fulfils a similar function in relation to motor nuclei of the brainstem (Ch. 21).

The percentage of corticospinal fibres that arise from the primary motor cortex may be in the region of $20-30 \%$. They arise from pyramidal cells in layer V and give rise to the largest-diameter corticospinal axons. There is also a widespread origin from other parts of the frontal lobe, including the premotor cortex and the supplementary motor area. Many axons from the frontal cortex, notably the motor cortex, termi-
nate in the ventral horn of the spinal cord. In cord segments mediating dexterous hand and finger movements, they terminate in the lateral part of the ventral horn, in close relationship to motor neuronal groups. A small percentage establish direct monosynaptic connections with $\alpha$ motor neurones. Between 40 and $60 \%$ of pyramidal tract axons arise from parietal areas, including area 3 a , area 5 of the superior part of the parietal lobe, and SII in the parietal operculum. The majority of parietal fibres to the spinal cord terminate in the deeper layers of the dorsal horn.

Motor cortical neurones are active in relation to the force of contraction of agonist muscles; their relation to amplitude of movement is less

Fig. 25.8 Lobar boundaries and nomenclature. A, Lateral surface, left side. The central sulcus (1) separates the frontal (F) from the parietal (P) lobes. The Sylvian fissure (3) separates the frontal from the temporal (T) lobes. The demarcation of the temporal, parietal and occipital lobes according to two different systems is shown. In one system, a parietotemporal line is drawn from the lateral edge of the parieto-occipital sulcus (2) to the preoccipital notch (temporo-occipital incisure) (4). This line sets the arbitrary anterior border of the occipital lobe (O), separating it from the parietal and temporal lobes anterior to it. A second arbitrary temporo-occipital line (5) is drawn from the posterior descending ramus of the Sylvian fissure (3) to the middle of the parietotemporal line (6). This line sets the arbitrary parietotemporal boundary. B, Medial surface, right side. The central sulcus (1) usually curves onto the medial surface perpendicular to the marginal segment of the cingulate sulcus. A line drawn from the central sulcus to the cingulate sulcus establishes the frontoparietal border. The deep parieto-occipital sulcus (2) demarcates the parietal lobe from the occipital lobe. An arbitrary basal parietotemporal line (8) drawn from the inferior end of the parieto-occipital sulcus to the preoccipital notch establishes the temporal (T)/occipital (O) border. The limbic lobe ( L ) is delimited by the cingulate sulcus (9), the subparietal sulcus (10) and the collateral sulcus (11). The number 7 indicates the orbital surface. clear. Their activity precedes the onset of electromyographic activity by 50-100 milliseconds, suggesting a role for cortical activation in generating rather than monitoring movement.

## Premotor cortex

Brodmann's area 6 lies immediately in front of the primary motor cortex (Fig. 25.16). It extends on to the medial surface, where it becomes contiguous with area 24 in the cingulate gyrus, anterior and inferior to the paracentral lobule. A number of functional motor areas are contained within this cortical region. Lateral area 6, the area over most of the lateral surface of the hemisphere, corresponds to the premotor cortex.

The premotor cortex is divided into a dorsal and a ventral area (PMd and PMv respectively) on functional grounds, and on the basis of ipsilateral corticocortical association connections.

A

Fig. 25.15 A, The motor homunculus showing proportional somatotopical representation in the main motor area. B, The sensory homunculus showing proportional somatotopical representation in the somaesthetic cortex.

The major thalamic connections of the premotor cortex are with the anterior division of the ventrolateral nucleus and with the centromedian, parafascicular and centrolateral components of the intralaminar nuclei. Subcortical projections to the striatum and pontine nuclei are prominent, and this area also projects to the superior colliculus and the reticular formation. Both dorsal and ventral areas contribute to the corticospinal tract. Commissural connections are with the contralateral premotor, motor and superior parietal (area 5) cortex. Ipsilateral corticocortical connections with area 5 in the superior parietal cortex, and inferior parietal area 7 b , are common to both dorsal and ventral subdivisions of the premotor cortex, and both send a major projection to the primary motor cortex. The dorsal premotor area also receives fibres from the posterior superior temporal cortex and projects to the supplementary motor cortex. The frontal eye field (area 8) projects to the dorsal subdivision. Perhaps the greatest functionally significant difference in connectivity between the two premotor area subdivisions is that the dorsal premotor area receives fibres from the dorsolateral

Fig. 25.16 The lateral surface of the left cerebral hemisphere showing the frontal eye field (parts of areas 6, 8, 9), the motor speech (Broca's) area (areas 44, 45) and Wernicke's area. The perimeter of these areas is delineated by an interrupted line to indicate uncertainty as to their precise extent. Wernicke's area is variously depicted by different authorities as encompassing a large parietotemporal area that includes areas 39 and 40 . Areas 22 and 37 are considered by some to be respectively auditory and visuo-auditory areas associated with speech and language.
prefrontal cortex, whereas the ventral subdivision receives fibres from the ventrolateral prefrontal cortex. All of these association connections are likely to be, or are known to be, reciprocal.

Neuronal activity in the premotor cortex in relation to both preparation for movement and movement itself has been extensively studied experimentally. Direction selectivity for movement is a common feature of many premotor neurones. In behavioural tasks, neurones in the dorsal premotor cortex show anticipatory activity and task-related discharge as well as direction selectivity, but little or no stimulus-related changes. The dorsal premotor cortex is probably important in establishing a motor set or intention, contributing to motor preparation in relation to internally guided movement. In contrast, ventral premotor cortex is more related to the execution of externally (especially visually) guided movements in relation to a specific external stimulus.

## Frontal eye field

The frontal eye field corresponds to parts of Brodmann's areas 6, 8 and 9 (see Fig. 25.16). As its name implies, it is important in the control of eye movements. It receives its major thalamic projection from the parvocellular mediodorsal nucleus, with additional afferents from the medial pulvinar, the ventral anterior nucleus and the suprageniculatelimitans complex, and connects with the paracentral nucleus of the intralaminar group. The thalamocortical pathways to the frontal eye field form part of a pathway from the superior colliculus, the substantia nigra and the dentate nucleus of the cerebellum. The frontal eye field has extensive ipsilateral corticocortical connections, receiving fibres from several visual areas in the occipital, parietal and temporal lobes, including the medial temporal area (V5) and area 7a. There is also a projection from the superior temporal gyrus, which is auditory rather than visual in function. From within the frontal lobe, the frontal eye field receives fibres from the ventrolateral and dorsolateral prefrontal cortices. It projects to the dorsal and ventral premotor cortices and to the medial motor area, probably to the supplementary eye field adjacent to the supplementary motor area proper. It projects prominently to the superior colliculus, to the pontine gaze centre within the pontine reticular formation, and to other oculomotor related nuclei in the brainstem.

## Supplementary motor cortex

The supplementary motor area (SMA; MII) lies medial to area 6, and extends from the most superolateral part to the medial surface of the hemisphere. Area 24 in the cingulate gyrus adjacent to area 6 contains several motor areas, which are termed cingulate motor areas. An additional functional subdivision, the pre-supplementary motor area, lies anterior to the supplementary motor area on the medial surface of the cortex. In the present discussion, these additional medial motor areas are included with the supplementary motor cortex.

The supplementary motor area receives its major thalamic input from the anterior part of the ventral lateral nucleus, which in turn is the major recipient of fibres from the internal segment of the globus pallidus. Additional thalamic afferents are from the ventral anterior
nucleus, the intralaminar nuclei - notably the centrolateral and centromedial nuclei, and also from the mediodorsal nucleus. The connections with the thalamus are reciprocal. The supplementary motor cortex receives connections from widespread regions of the ipsilateral frontal lobe, including from the primary motor cortex, the dorsal premotor area, the dorsolateral and ventrolateral prefrontal, medial prefrontal and orbitofrontal cortex, and the frontal eye field. These connections are reciprocal but the major ipsilateral efferent pathway is to the motor cortex. Parietal lobe connections of the supplementary motor cortex are with the superior parietal area 5 and possibly inferior parietal area 7 b . Contralateral connections are with the supplementary motor area, and motor and premotor cortices of the contralateral hemisphere. Subcortical connections, other than with the thalamus, pass to the striatum, subthalamic nucleus and pontine nuclei, the brainstem reticular formation and the inferior olivary nucleus. The supplementary motor area makes a substantial contribution to the corticospinal tract, contributing as much as $40 \%$ of the fibres from the frontal lobe.

The supplementary motor area contains a representation of the body in which the leg is posterior and the face anterior, with the upper limb between them. Its role in the control of movement is primarily in complex tasks that require temporal organization of sequential movements and in the retrieval of motor memory.

Stimulation of the supplementary motor area in conscious patients has been reported to elicit the sensation of an urge to move, or of anticipation that a movement is about to occur. A region anterior to the supplementary motor area for face representation (areas 44, 45) is important in vocalization and speech production (see Fig. 25.16).

## Prefrontal cortex

The prefrontal cortex on the lateral surface of the hemisphere comprises predominantly Brodmann's areas 9, 46 and 45 (see Fig. 25.16). In non-human primates, two subdivisions of the lateral prefrontal cortex are recognized: a dorsal area equivalent to area 9, and perhaps including the superior part of area 46; and a ventral area, consisting of the inferior part of area 46 and area 45 . Areas 44 and 45 are particularly notable in humans since, in the dominant hemisphere, they constitute the motor speech area (Broca's area) within the opercular and triangular parts of the inferior frontal gyrus, immediately anterior to the most inferior aspect of the precentral gyrus. Both the dorsolateral and ventrolateral prefrontal areas receive their major thalamic afferents from the mediodorsal nucleus, and there are additional contributions from the medial pulvinar, from the ventral anterior nucleus and from the paracentral nucleus of the anterior intralaminar group. The dorsolateral area receives long association fibres from the posterior and middle superior temporal gyrus (including auditory association areas), from parietal area 7a, and from much of the middle temporal cortex. From within the frontal lobe it also receives projections from the frontal pole (area 10), and from the medial prefrontal cortex (area 32) on the medial surface of the hemisphere. It projects to the supplementary motor area, the dorsal premotor cortex and the frontal eye field. All these thalamic and corticocortical connections are reciprocal. Commissural connections are with the homologous area and with the contralateral inferior parietal cortex. The ventrolateral prefrontal area receives long association fibres from both area 7 a and area 7b of the parietal lobe, from auditory association areas of the temporal operculum, from the insula and from the anterior part of the lower bank of the superior temporal sulcus. From within the frontal lobe it receives fibres from the anterior orbitofrontal cortex and projects to the frontal eye field and the ventral premotor cortex. It connects with the contralateral homologous area via the corpus callosum. These connections are probably all reciprocal.

The cortex of the frontal pole (area 10) receives thalamic input from the mediodorsal nucleus, the medial pulvinar and the paracentral nucleus. It is reciprocally connected with the cortex of the temporal pole, the anterior orbitofrontal cortex and the dorsolateral prefrontal cortex. The orbitofrontal cortex connects with the mediodorsal, anteromedial, ventral anterior, medial pulvinar, paracentral and midline nuclei of the thalamus. Cortical association pathways come from the inferotemporal cortex, the anterior superior temporal gyrus and the temporal pole. Within the frontal lobe it has connections with the medial prefrontal cortex, the ventrolateral prefrontal cortex and medial motor areas. Commissural and other connections follow the general pattern for all neocortical areas.

The medial prefrontal cortex is connected with the mediodorsal, ventral anterior, anterior medial pulvinar, paracentral, midline and suprageniculate-limitans nuclei of the thalamus. It receives fibres from the anterior cortex of the superior temporal gyrus. Within the frontal lobe, it has connections with the orbitofrontal cortex, and the medial motor areas of the dorsolateral prefrontal cortex.

## PARIETAL LOBE

The parietal lobe lies posterior to the central sulcus on the superolateral and medial surfaces of the cerebral hemisphere (see Figs 25.1, $25.8-25.10$ ). This region is part of the complex language network (see below). Posterior to the supramarginal gyrus and again in the dominant hemisphere, the cortex of the angular gyrus is related to neuronal processing associated with reading and writing.

## Parietal lobe sulci and gyri

The parietal gyri are morphologically poorly defined and tortuous; some are termed lobules. Posteriorly, the parietal lobe is delineated on the medial aspect by the parieto-occipital sulcus and on the lateral aspect by an imaginary line running from the point where the parietooccipital sulcus emerges on to the superolateral border to the preoccipital notch (a small sulcus situated on the inferolateral border approximately 5 cm anterior to the occipital pole). The inferior boundary is the posterior ramus of the lateral fissure and its imaginary posterior prolongation.

The lateral aspect of the parietal lobe is divided into three areas by the postcentral and intraparietal sulci. The intraparietal sulcus lies predominantly longitudinally along the midportion of the parietal superolateral surface (see Fig. 25.1). It delineates the superior parietal lobule, continuous medially with the precuneus, and the inferior parietal lobule, made up of the supramarginal and angular gyri and a more posterior convolution continuous with the occipital lobe. The inferior aspect of the supramarginal gyrus within the inferior parietal lobule of the dominant hemisphere corresponds to Wernicke's area, which extends along the posterior aspect of the superior temporal gyrus.

The postcentral gyrus lies posterior to the precentral gyrus and is connected to it along the superior and inferior extremities of the central sulcus. It is usually narrower than the precentral gyrus. Both gyri are located obliquely on the superolateral surface of the hemisphere, just superior to the lateral fissure; their midportions correspond approximately to the anteroposterior centre of each cerebral hemisphere. The superior portions of the pre- and postcentral gyri, which constitute the paracentral lobule on the medial surface of the cerebral hemisphere, are topographically related to the ventricular atrium, situated posterior to the thalamus. The inferior portions of both gyri cover the posterior half of the insula and are topographically related to the body of the lateral ventricle, situated superior to the thalamus. The portion of the subcentral gyrus corresponding to the base of the postcentral gyrus consistently lies over the transverse gyri of Heschl, situated on the opercular surface of the temporal lobe (Wen et al 1999).

## Parietal lobe internal structure and connectivity

## Somatosensory cortex

The postcentral gyrus corresponds to the primary somatosensory cortex (SI; Brodmann's areas 3a, 3b, 1 and 2). Area 3a lies most anteriorly, apposing area 4 , the primary motor cortex of the frontal lobe; area 3b is buried in the posterior wall of the central sulcus; area 1 lies along the posterior lip of the central sulcus; and area 2 occupies the crown of the postcentral gyrus.

The primary somatosensory cortex contains within it a topographical map of the contralateral half of the body. The face, tongue and lips are represented inferiorly, the trunk and upper limb are represented on the superolateral aspect, and the lower limb on the medial aspect of the hemisphere, giving rise to the familiar 'homunculus' map (see Fig. 25.15).

The somatosensory properties of SI depend on its thalamic input from the ventral posterior nucleus of the thalamus, which in turn receives the medial lemniscal, spinothalamic and trigeminothalamic pathways. The nucleus is divided into a ventral posterolateral part, which receives information from the trunk and limbs, and a ventral posteromedial part, in which the head is represented. Within the ventral posterior nucleus, neurones in the central core respond to cutaneous stimuli and those in the most dorsal anterior and posterior parts, which arch as a 'shell' over this central core, respond to deep stimuli. This is reflected in the differential projections to SI: the cutaneous central core projects to 3b, the deep tissue-responsive neurones send fibres to areas 3 a and 2, and an intervening zone projects to area 1 . Within the ventral posterior nucleus, anteroposterior rods of cells respond with similar
modality and somatotopic properties. They appear to project to restricted focal patches in SI of approximately 0.5 mm width, which form narrow strips mediolaterally along SI. The laminar termination of thalamocortical axons from the ventral posterior nucleus is different in the separate cytoarchitectonic subdivisions of SI. In 3a and 3b, these axons terminate mainly in layer IV and the adjacent deep part of layer III, whereas in areas 1 and 2 they end in the deeper half of layer III, avoiding lamina IV. Additional thalamocortical fibres to SI arise from the intralaminar system, notably the centrolateral nucleus.

There is a complex internal connectivity within SI. An apparently stepwise hierarchical progression of information processing occurs from area 3b through area 1 to area 2 . Outside the postcentral gyrus, SI has ipsilateral corticocortical association connections with a second somatosensory area (SII); area 5 in the superior part of the parietal lobe; area 4 , the motor cortex, in the precentral gyrus; and the supplementary motor cortex in the medial part of area 6 of the frontal lobe.

SI has reciprocal commissural connections with its contralateral homologue, with the exception that the cortices containing the representation of the distal extremities are relatively devoid of such connections. Callosal fibres in SI arise mainly from the deep part of layer III and terminate in layers I-IV. Pyramidal cells contributing callosal projections receive monosynaptic thalamic and commissural connections.

SI has reciprocal subcortical connections with the thalamus and claustrum, and receives afferents from the nucleus basalis (basal nucleus of Meynert), the locus coeruleus and the midbrain raphe. It has other prominent subcortical projections. Corticostriatal fibres, arising in layer V, pass mainly to the putamen of the same side. Corticopontine and corticotectal fibres from SI arise in layer V. SI projects to the main pontine nuclei and to the nucleus reticularis tegmenti pontis (pontine tegmental reticular nucleus). In addition, axons arising in SI pass to the dorsal column nuclei and the spinal cord. Corticospinal pyramidal cells are found in layer V of SI. The topographical representation in the cortex is preserved in terms of the spinal segments to which different parts of the postcentral gyrus project. Thus, the arm representation projects to the cervical enlargement, the leg representation to the lumbosacral enlargement, and so on. Within the grey matter of the spinal cord, fibres from SI terminate in the dorsal horn, in Rexed's laminae 3-5; fibres from 3b and 1 end more dorsally, and those from area 2 more ventrally.

The second somatosensory area (SII) lies along the upper bank of the lateral fissure, posterior to the central sulcus. SII contains a somatotopic representation of the body, with the head and face most anteriorly, adjacent to SI, and the sacral regions most posteriorly. SII is reciprocally connected with the ventral posterior nucleus of the thalamus in a topographically organized fashion. Some thalamic neurones probably project to both SI and SII via axon collaterals. Other thalamic connections of SII are with the posterior group of nuclei and with the intralaminar central lateral nucleus. SII also projects to laminae IV-VII of the dorsal horn of the cervical and thoracic spinal cord, the dorsal column nuclei, the principal trigeminal nucleus, and the periaqueductal grey matter of the midbrain.

Within the cortex, SII is reciprocally connected with SI in a topographically organized manner and projects to the primary motor cortex. SII also projects in a topographically organized way to the lateral part of area 7 (area 7b) in the superior part of the parietal lobe, and makes connections with the posterior cingulate gyrus. Both right and left SII areas are interconnected across the corpus callosum, although distal limb representations are probably excluded. There are additional callosal projections to SI and area 7b.

Experimental studies show that neurones in SII respond particularly to transient cutaneous stimuli, e.g. brush strokes or tapping, which are characteristic of the responses of Pacinian corpuscles in the periphery. They show little response to maintained stimuli.

## Superior and inferior parietal lobules

Posterior to the postcentral gyrus, the superior part of the parietal lobe is composed of areas $5,7 \mathrm{a}$ and 7 b (see Fig. 25.7). Area 5 receives a dense feed-forward projection from all cytoarchitectonic areas of SI in a topographically organized manner. The thalamic afferents to this area come from the lateral posterior nucleus and from the central lateral nucleus of the intralaminar group. Ipsilateral corticocortical fibres from area 5 go to area 7 , the premotor and supplementary motor cortices, the posterior cingulate gyrus and the insular granular cortex. Commissural connections between area 5 on both sides tend to avoid the areas of representation of the distal limbs. The response properties of cells in area 5 are more complex than in SI, with larger receptive fields and evidence of submodality convergence. Area 5 contributes to the corticospinal tract.

The postcentral sulcus delineates the posterior boundary of the postcentral gyrus. It is frequently interrupted by connections with the superior and inferior parietal lobules. The inferior part of the postcentral sulcus always ends at a basal connection between the postcentral and the supramarginal gyri (Ribas 2010). The intraparietal sulcus, which originates from around the midpoint of the postcentral sulcus, is prominent on the superolateral surface of the parietal lobe, running parallel with the superior margin of the hemisphere. Anteriorly, the intraparietal sulcus is usually continuous with the inferior portion of the postcentral sulcus and posteriorly it passes into the occipital lobe as the intraoccipital sulcus (superior occipital sulcus), which continues more posteriorly into the transverse occipital sulcus. The intraparietal sulcus divides the superolateral parietal surface into superior and inferior parietal lobules; along its length, it typically gives rise to superior and inferior vertical sulcal branches. The superior vertical sulcal branch (transverse parietal sulcus of Brissaud) divides the superior parietal lobule. The inferior vertical sulcal branch (intermediate sulcus of Jensen; sulcus intermedius primus of Jensen) separates the supramarginal gyrus anteriorly from the angular gyrus posteriorly.

The supramarginal gyrus is always a very well defined curved gyrus. It surrounds the distal portion of the lateral fissure (its posterior ascending branch) and becomes continuous with the posterior portion of the superior temporal gyrus. Above the distal end of the lateral fissure, the supramarginal gyrus is connected anteriorly to the postcentral gyrus through a fold that runs underneath the inferior aspect of the postcentral sulcus. Posteriorly, it occasionally rounds the inferior extremity of the intermediate sulcus and connects to the angular gyrus. The angular gyrus is a curved gyrus, often poorly defined morphologically. It always surrounds one of the distal segments of the superior temporal sulcus, usually the middle one (angular sulcus), and its most inferior portion is continuous with the middle temporal gyrus. The configuration of the angular gyrus is defined by the distal branching of the superior temporal sulcus, which typically ends as three continuous or interrupted caudal branches.

The most superior distal branch of the superior temporal sulcus has an ascending course; it may either penetrate the supramarginal gyrus or coincide with the intermediate sulcus of Jensen separating the supramarginal and angular gyri. The second branch is usually more horizontal and enters the angular gyrus as the angular sulcus. The most inferior caudal branch of the superior temporal sulcus is less evident and less constant. It courses underneath a posterior fold that frequently connects the angular gyrus and the most lateral aspect of the occipital lobe, and is usually continuous with the anterior occipital sulcus, lying predominantly vertically along the anterior edge of the middle occipital gyrus. The bulge of the supramarginal and angular gyri is responsible for the cranial parietal tuberosity (bossa).

The superior parietal lobule has a quadrangular shape. It is delineated anteriorly by the superior aspect of the postcentral sulcus and laterally by the intraparietal sulcus; medially, it is continuous with the precuneus gyrus along the superomedial border (Fig. 25.17). Anteriorly, it is typically connected to the postcentral gyrus via a fold that transects the most superior portion of the postcentral sulcus and, occasionally, via a fold that interrupts the postcentral sulcus more inferiorly. Posteriorly, the superior parietal lobule continues to the superior occipital gyrus via the prominent parieto-occipital arcus.

On the medial surface of each hemisphere, the precuneus lies posterior to the paracentral lobule as a medial extension of the superior parietal lobule. The precuneus and the medial aspect of the postcentral gyrus correspond to the medial portion of the parietal lobe (see Figs $25.3,25.10 \mathrm{~B}$ ). The precuneus is quadrangular (quadrangular lobule of Foville), delineated anteriorly by the marginal branch of the cingulate sulcus, posteriorly by the parieto-occipital sulcus and inferiorly by multiple Y-shaped sulcal segments that constitute the subparietal sulcus. Inferior to the subparietal sulcus, the precuneus is connected to the isthmus of the cingulate gyrus, which is continuous with the parahippocampal gyrus.

The parieto-occipital sulcus separating the precuneus from the cuneus is deep and contains many small sulci and gyri. The precuneal limiting sulcus and the cuneal limiting sulcus delineate the inferior (posterior) limit of the precuneus and the superior (anterior) limit of the cuneus, respectively. They lie along the most superficial aspects of the superior and inferior margins of the parieto-occipital sulcus. Small cuneal gyri lie along its inner surfaces. The superior parietal lobule and the precuneus are also referred to as $P_{1}$ and the supramarginal and angular gyri are referred to as $P_{2}$ and $P_{c} 3$ or $P_{3}$ respectively.

Fig. 25.17 A superior view of the cerebral hemispheres. Abbreviations: AG, angular gyrus; CaS, calcarine sulcus; CS, central sulcus; IOG, inferior occipital gyrus; IPaLob, inferior parietal lobule; IPS, intraparietal sulcus; MOG, middle occipital gyrus; PaCLob, paracentral lobule; POArc, parieto-occipital arch; POS, parieto-occipital sulcus; PosCS, postcentral sulcus; PostCG, postcentral gyrus; PreCG, precentral gyrus; PreCu, precuneus; PreOccNo, pre-occipital notch; SFG, superior frontal gyrus; SMG, supramarginal gyrus; SOG, superior occipital gyrus; SPaLob, superior parietal lobule. (Adapted with permission from Ribas GC. The cerebral sulci and gyri. Neurosurg Focus 2010, 28(2):E2.)

In non-human primates, the inferior parietal lobule is area 7. In humans, this area is more superior; areas 39 and 40 intervene inferiorly. The counterparts for the latter areas in monkeys are unclear and little experimental evidence is available on their connections and functions. Their role in human cerebral processing is discussed below. In the monkey, area 7 b receives somatosensory inputs from area 5 and SII. Connections pass to the posterior cingulate gyrus (area 23), insula and temporal cortex. Area 7b is reciprocally connected with area 46 in the prefrontal cortex and the lateral part of the premotor cortex. Commissural connections of area 7 b are with the contralateral homologous area and with SII, the insular granular cortex and area 5. Thalamic connections are with the medial pulvinar nucleus and the intralaminar paracentral nucleus.

In monkeys, area 7 a is not related to the cortical pathways for somatosensory processing but instead forms part of a dorsal cortical pathway for spatial vision. The major ipsilateral corticocortical connections to area 7a are derived from visual areas in the occipital and temporal lobes. In the ipsilateral hemisphere, area 7 a has connections with the posterior cingulate cortex (area 24) and with areas 8 and 46 of the frontal lobe. Commissural connections are with its contralateral homologue. Area 7a is connected with the medial pulvinar and intralaminar paracentral nuclei of the thalamus. In experimental studies, neurones within area 7a are visually responsive; they relate largely to peripheral vision, respond to stimulus movement, and are modulated by eye movement.

## OCCIPITAL LOBE

On the superolateral cerebral surface, the occipital lobe is situated posterior to an imaginary line connecting the point of emergence of the parieto-occipital fissure on the superomedial border of the cerebral hemisphere with the preoccipital notch of Meynert (approximately 5 cm anterior to the occipital pole) (see Fig. 25.8). On the medial surface, the occipital lobe is limited anteriorly by the parieto-occipital sulcus and by its prolongation towards the tentorium cerebelli. Along the inferior cerebral surface, the base of the occipital lobe is continuous with the base of the temporal lobe. The superolateral surface of the occipital lobe lies mostly beneath the squamous part of the occipital bone; its medial surface faces the most posterior aspect of the falx cerebri, and the inferior surface lies over the tentorium cerebelli. The sulci and gyri of the occipital lobe, especially of its superolateral surface, exhibit a greater degree of anatomical variation than is seen in the other lobes: this is reflected in an often confusing literature where the same sulcus may be identified using different names, and two obviously different sulci may be called by the same name. The particular complexity of sulcal, and therefore gyral, variability in this part of the occipital lobe has been attributed to variations in regional cortical folding that are reflected in the diversity of sulcal origin, degree of segmentation, length, depth and intrasulcal geometry. Regarding the major named sulci, there appears to be reasonable consensus that the parieto-occipital, calcarine, paracalcarine, lingual, transverse occipital, inferior lateral occipital and anterior occipital sulci, together with the occipital parts of the collateral and lateral occipitotemporal sulci, are constant features of the surface of the occipital lobe, whereas the superior occipital, superior lateral occipital, inferior occipital, lunate and occipitopolar sulci are less constant. (For further details, consult Iaria and Petrides (2007), Iaria et al (2008), Alves et al (2012), Malikovic et al (2012).)

## $\triangle$ Occipital lobe sulci and gyri

There are two or three gyri (superior, middle and inferior, or $\mathrm{O} 1, \mathrm{O} 2$ and O3, respectively) on the superolateral cerebral surface of the occipital lobe (see Figs 25.9B, 25.17). They converge posteriorly to form the occipital pole. Commonly, only the superior and inferior gyri are present; the area corresponding to the middle occipital gyrus lies between the inferior extension of the intra-occipital (or superior occipital or transverse occipital) sulcus and the lateral (or inferior occipital) sulcus.

The fusiform or lateral temporo-occipital gyrus lies along the temporo-occipital transition. Its posterior or occipital part is bounded medially by the collateral sulcus and laterally by the occipitotemporal sulcus; hence it lies between the lingual gyrus medially and the inferior occipital gyrus laterally. The occipital part of the fusiform gyrus $\left(\mathrm{O}_{4}\right)$ lies over the tentorium cerebelli just posterior to the petrous part of the temporal bone. Topographically, it corresponds to the floor of the ventricular atrium; the temporal part of the gyrus lies underneath the temporal or inferior horn of the lateral ventricle.

The occipitotemporal sulcus rarely extends posteriorly as far as the occipital pole; both the collateral and occipitotemporal sulci frequently have secondary side branches and merge anteriorly. The inferior or basal aspect of the inferior occipital gyrus lies lateral to the fusiform gyrus and constitutes the most inferior portion of the lateral aspect of the occipital lobe. Along the inferolateral border of the hemisphere, the inferior temporal gyrus is continuous with the inferior occipital gyrus over the preoccipital notch, and the inferior occipital gyrus is continuous with the lingual gyrus along the occipital pole. Along the parietal and occipital aspects of the superomedial border of the hemisphere, the superior parietal lobule is continuous with the precuneus, and the superior occipital gyrus is continuous with the cuneus above the calcarine sulcus and with the lingual gyrus below the calcarine sulcus.

## Occipital lobe internal structure and connectivity

The occipital lobe is composed almost entirely of Brodmann's areas 17, 18 and 19. Area 17, the striate cortex, is the primary visual cortex (VI). A host of other distinct visual areas reside in the occipital and temporal cortex. Functional subdivisions V2, V3 (dorsal and ventral) and V3A lie within Brodmann's area 18. Other functional areas at the junction of the occipital cortex with the parietal or temporal lobes lie wholly or partly in area 19.

The primary visual cortex is mostly located on the medial aspect of the occipital lobe and is coextensive with the subcortical nerve fibre stria of Gennari in layer IV; hence its alternative name, the striate cortex.

It occupies the upper and lower lips and depths of the posterior part of the calcarine sulcus and extends into the cuneus and lingual gyrus.

The primary visual cortex receives afferent fibres from the lateral geniculate nucleus via the optic radiation (Fig. 25.19). The latter curves posteriorly and spreads through the white matter of the occipital lobe. Its fibres terminate in strict point-to-point fashion in the striate area. The cortex of each hemisphere receives impulses from two hemi-retinae, which represent the contralateral half of the binocular visual field. Superior and inferior retinal quadrants are connected with corresponding areas of the striate cortex. Thus, the superior retinal quadrants (representing the inferior half of the visual field) are connected with the visual cortex above the calcarine sulcus, and the inferior retinal quadrants (representing the upper half of the visual field) are connected with the visual cortex below the calcarine sulcus. The peripheral parts of the retinae activate the most anterior parts in the visual cortex. The macula impinges on a disproportionately large posterior part around the occipital pole.

The striate cortex is granular. Layer IV, bearing the stria of Gennari, is commonly divided into three sublayers. Passing from superficial to deep, these are IVA, IVB (which contains the stria) and IVC. The densely cellular IVC is further subdivided into a superficial IVC $\alpha$ and a deep IVC $\beta$. Layer IVB contains only sparse, mainly non-pyramidal neurones. The input to area 17 from the lateral geniculate nucleus terminates predominantly in layers IVA and IVC. Other thalamic afferents, from the inferior pulvinar nucleus and the intralaminar group, pass to layers I and VI. Geniculocortical fibres terminate in alternating bands. Axons from geniculate laminae that receive information from the ipsilateral eye (laminae 2,3 and 5) are segregated from those of laminae that receive input from the contralateral eye (laminae 1, 4 and 6). Neurones within layer IVC are monocular, i.e. they respond to stimulation of either the ipsilateral or contralateral eye, but not both. This horizontal segregation forms the anatomical basis of the ocular dominance column in that neurones encountered in a vertical strip from pia to white matter, although binocular outside layer IV, exhibit a preference for stimulation of one or other eye. The other major functional basis for visual cortical columnar organization is the orientation column. This describes the observation that an electrode passing through the depth of the cortex, at right angles to the plane from pia to white

Fig. 25.19 The superior aspect of a horizontal section through the left cerebral hemisphere.

The superior occipital gyrus is always well defined, and is continuous along the superomedial margin of the hemisphere with the cuneus. Superiorly, it is delimited by the depth of the parieto-occipital fissure on the superolateral hemispheric surface. It is continuous with the superior parietal lobule through the parieto-occipital arcus (corresponding to the first or superior parieto-occipital 'pli de passage' of Gratiolet). Laterally, the superior occipital gyrus may be delimited by either the intra-occipital, transverse occipital or superior occipital sulcus.

The inferior occipital gyrus lies horizontally along the inferolateral margin of the hemisphere, with its base lying over the tentorium cerebelli. Anteriorly, it is usually continuous with the inferior temporal gyrus; posteriorly, it extends medially around the occipital pole, becoming continuous with the lingual gyrus on the medial surface of the hemisphere. Superiorly, the inferior occipital gyrus is delimited by the lateral or inferior occipital sulcus.

The lateral occipital sulcus is a very evident horizontal sulcus. Anteriorly, it is frequently connected to the inferior temporal sulcus; inferiorly, it may be accompanied by a shorter accessory lateral occipital sulcus. Both of these sulci may be connected with a sulcal complex known as the anterior occipital sulcus, which, when present, lies along the anterior aspect of the middle occipital gyrus. The inferior occipital sulcus is sometimes described as a distinct and very small sulcus located near the inferior margin of the inferior occipital gyrus, but here the lateral and inferior occipital sulci are considered to be part of the same structure.

The intraparietal sulcus extends longitudinally and inferiorly into the occipital lobe, where it becomes the intra-occipital sulcus. The latter may occasionally descend to the occipital pole but it usually terminates on reaching the transverse occipital sulcus, dividing it into lateral and medial parts that penetrate the superior occipital gyrus (see Fig. 25.17). Since the lateral (inferior) occipital sulcus is always present and clearly divides the superolateral occipital surface into an inferior part, constituted by the inferior occipital gyrus, and a superior part, it has been suggested that the gyral pattern of the superior part depends mainly on the morphology of the lateral aspect of the transverse occipital sulcus. When this sulcal segment descends towards the occipital pole as an inferior extension of the intra-occipital sulcus, it divides the upper occipital convexity into superior and middle occipital gyri. The lunate sulcus, although conspicuous in monkeys and apes, is only sometimes identifiable in human brains, when it appears as a well-defined vertical and backward-curved sulcus anterior to the occipital pole.

Despite significant anatomical variation, the superolateral occipital convolutions are connected to the parietal and temporal convolutions by consistent cortical folds. According to the classic description by Gratiolet, four folds connect the parietal and temporal lobes with the occipital lobe: the superior parieto-occipital fold (parieto-occipital arcus) connects the superior parietal lobule with the superior occipital gyrus; the inferior parieto-occipital fold, a posterior extension of the angular gyrus, connects with the middle occipital gyrus and occasionally also with the superior occipital gyrus; the first temporo-occipital fold is the continuation of the middle temporal gyrus with the inferior occipital gyrus; and the second temporo-occipital fold is the continuation of the inferior temporal gyrus with the inferior occipital gyrus.

The medial surface of the occipital lobe shows less morphological variation than the superolateral surface. It is separated from the parietal lobe by the parieto-occipital sulcus and dominated by the calcarine sulcus. The dorsal part of this region, above the calcarine sulcus and posterior to the parieto-occipital fissure, is the cuneus. The ventral part of this region, lying below the calcarine sulcus and extending as far as the occipital extension of the collateral fissure, is the lingual gyrus (see Fig. 25.10B). The calcarine sulcus starts anteriorly underneath the splenium of the corpus callosum, delineating the inferior aspect of the isthmus of the cingulate gyrus, and runs posteriorly just above the inferomedial margin of the hemisphere. The parieto-occipital fissure emerges superiorly from the calcarine sulcus, separates the cuneus from the precuneus of the parietal lobe, and divides the calcarine sulcus into
an anterior and a posterior part. The parieto-occipital and calcarine sulci appear continuous on the surface, but when their borders are retracted it becomes obvious that they are separated by one or more small gyri. The anterior part of the calcarine sulcus is classified as a complete sulcus because its depth creates an elevation (calcar avis) in the medial wall of the occipital horn of the lateral ventricle. The posterior part of the calcarine sulcus is considered an axial sulcus, given that its axis runs along the visual cortex. Only the posterior part includes the primary visual cortical areas, which are located on its superior (cuneal) and inferior (lingual) surfaces. This part of the calcarine sulcus frequently harbours the cuneolingual gyrus that links both gyri.

At the level of the occipital pole, the calcarine sulcus usually branches in a T or Y shape as the retrocalcarine sulcus. The gyrus descendens of Ecker lies posterior to and along the retrocalcarine sulcus and is occasionally bounded posteriorly by the occipitopolar sulcus. The retrocalcarine sulcus and its variations are sometimes referred to as external calcarine sulci.

Given the anatomical constancy of the calcarine and parieto-occipital fissures on the medial occipital surface, the cuneus $\left(\mathrm{O}_{6}\right)$ is always a well-defined wedge-like convolution. The real anterior border of the cuneus is the cuneal limiting sulcus within the parieto-occipital fissure. Posteriorly, the cuneus rests over the posterior part of the calcarine sulcus and over the posterior aspect of the lingual gyrus. Superior to the posterior part of the calcarine sulcus, the cuneus harbours the paracalcarine or cuneal sulcus (the inferior sagittal sulcus of the cuneus of Retzius) and, further dorsally, the occipital paramedial sulcus (the paramesial sulcus of Elliot Smith or superior sagittal sulcus of Retzius).

The basal or inferior surface of the occipital lobe is continuous with the basal surface of the temporal lobe. It is formed, from medial to lateral, by the lingual, fusiform and inferior occipital gyri respectively (see Fig. 25.10B; Fig. 25.18). For details of the sulcal and gyral anatomy of the basal occipital-temporal lobe, see Chau et al (2014).

The lingual gyrus (medial temporo-occipital gyrus, $\mathrm{O}_{5}$ ) lies inferiorly along the entire length of the calcarine sulcus, forming the mediobasal portion of the occipital lobe. It is continuous anteriorly with the parahippocampal gyrus and its basal surface rests on the tentorium cerebelli. Posteriorly, it is frequently divided into a superior and inferior part by an intralingual sulcus, which may be a posteromedial ramus of the collateral sulcus.

matter, encounters neurones that all respond preferentially to either a stationary or a moving straight line of a given orientation within the visual field. Cells with simple, complex and hypercomplex receptive fields occur in area 17 . Simple cells respond optimally to lines in a narrowly defined position. Complex cells respond to a line anywhere within a receptive field, but with a specific orientation. Hypercomplex cells are similar to complex cells except that the length of the line or bar stimulus is also critical for an optimal response. There is a relationship between the complexity of response and the position of cells in relation to the cortical laminae. Simple cells are mainly in layer IV, and complex and hypercomplex cells predominate in either layers II and III or layers V and VI.

The second visual area (V2) occupies much of area 18 but is not coextensive with it. It contains a complete retinotopic representation of the visual hemifield, which is a mirror image of that in area 17, with the vertical meridian represented most posteriorly along the border between areas 17 and 18. The major ipsilateral corticocortical feedforward projection to V2 comes from V1. Feed-forward projections from V2 pass to several other visual areas (and are reciprocated by feedback connections), including the third visual area (V3) and its various subdivisions (V3/V3d; VP/V3v; V3a); the fourth visual area (V4); areas in the temporal and parietal association cortices; and the frontal eye field. Thalamic afferents to V2 come from the lateral geniculate nucleus, the inferior and lateral pulvinar nuclei and parts of the intralaminar group of nuclei. Additional subcortical afferents are as for cortical areas in general. Subcortical efferents arise predominantly in layers V and VI They pass to the thalamus, claustrum, superior colliculus, pretectum, brainstem reticular formation, striatum and pons. As for area 17, the callosal connections of V2 are restricted predominantly to the cortex, which contains the representation of the vertical meridian.

The third visual area (V3) is a narrow strip adjoining the anterior margin of V2, probably still within area 18 of Brodmann. V3 has been subdivided into dorsal (V3/V3d) and ventral (VP/V3v) regions on the basis of its afferents from area V1, myeloarchitecture, callosal and association connections, and receptive field properties. The dorsal subdivision receives from V1, whereas the ventral does not. Functionally, the dorsal part shows less wavelength selectivity, greater direction selectivity and smaller receptive fields than does the ventral subdivision. Both areas receive a feed-forward projection from V2 and are interconnected by association fibres. A further visual area, area V3a, lies anterior to the dorsal subdivision of V3. It receives afferent association connections from V1, V2, V3/V3d and VP/V3v, and has a complex and irregular topographic organization. All subdivisions project to diverse visual areas in the parietal, occipital and temporal cortices, including V4, and to the frontal eye fields.

The fourth visual area, V4, lies within area 19 anterior to the V3 complex. It receives a major ipsilateral feed-forward projection from V2. Colour selectivity as well as orientation selectivity may be transmitted to V4 and bilateral damage causes achromatopsia. V4 is more complex than a simple colour discrimination area because it is also involved in the discrimination of orientation, form and movement. It sends a feedforward projection to the inferior temporal cortex and receives a feedback projection. It also connects with other visual areas that lie more dorsally in the temporal lobe, and in the parietal lobe. Thalamocortical connections are with the lateral and inferior pulvinar and the intralaminar nuclei. Other subcortical connections conform to the general pattern for all cortical areas. Callosal connections are with the contralateral V4 and other occipital visual areas.

Visual processing in inferior temporal and temporoparietal cortices involves two parallel pathways (dorsal and ventral visual streams) that emanate from the occipital lobe and are specialized for action and perception respectively (Goodale and Milner 1992, Goodale et al 2005). The dorsal pathway, concerned primarily with visuospatial discrimination, projects from V1 and V2 to the superior temporal and surrounding parietotemporal areas, and ultimately to area 7a of the parietal cortex; it mediates the sensory-motor transformations required to enable visually guided actions directed at an object. The fourth visual area, V4, is a key relay station for the ventral stream of projections, which is related to the perceptual identification of objects. Its connections pass sequentially along the inferior temporal gyrus in a feedforward manner, from V4 to posterior, intermediate and then anterior, inferior temporal cortices. Ultimately, they feed into the temporal polar and medial temporal areas and so interface with the limbic system.

## TEMPORAL LOBE

The lateral surface of the temporal lobe is inferior to the lateral fissure and lies beneath the squamous portion of the temporal bone. The basal
surface lies over the floor of the middle cranial fossa posterior to the greater wing of the sphenoid bone. The opercular surface lies inside the lateral fissure (see Figs 25.1, 25.9). Along the superolateral surface of the hemisphere, the posterior limit of the temporal lobe is arbitrarily defined by imaginary lines that run from the superomedial part of the parieto-occipital sulcus to the preoccipital notch or incisure, and by a posterior prolongation of the lateral fissure. Functionally, the temporal lobe is bilaterally related with auditory functions and in the dominant hemisphere mostly with the comprehension of language. (For further reading on the microsurgical anatomy of the temporal lobe, see Kucukyuruk et al (2012).)

## Temporal lobe sulci and gyri

The lateral surface is composed of superior, middle and inferior temporal gyri (T1, T2 and T3 respectively), separated by the superior and inferior temporal sulci and all lying parallel to the lateral fissure (see Figs 25.1, 25.8). Anteriorly, the middle temporal gyrus is generally shorter; when this occurs, the superior and inferior gyri come together to form the temporal pole (see Fig. 25.9B; Fig. 25.20A).

## Temporal lobe internal structure and connectivity

The superior, middle and inferior temporal gyri correspond to Brodmann's areas 22,21 and 20 respectively, and the temporal pole corresponds to area 38 . The anterior transverse temporal gyrus and adjoining part of the superior temporal gyrus are auditory in function, and are considered to be Brodmann's area 42. The anterior gyrus is approximately area 41 .

The temporal operculum houses the primary auditory cortex, AI. This is coextensive with the granular area 41 in the transverse temporal gyri. Surrounding areas constitute auditory association cortex. The primary auditory cortex is reciprocally connected with all subdivisions of the medial geniculate nucleus, and may receive additional thalamocortical projections from the medial pulvinar. The geniculocortical fibres terminate densely in layer IV. AI contains a tonotopic representation of the cochlea in which high frequencies are represented posteriorly and low frequencies anteriorly. Single-cell responses are to single tones of a narrow frequency band. Cells in single vertical electrode penetrations share an optimum frequency response.

The auditory cortex interconnects with prefrontal cortex, though the projections from AI are small. In general, posterior parts of the operculum project to areas 8 and 9 . Central parts project to areas 8,9 and 46 . More anterior regions project to areas 9 and 46, to area 12 on the orbital surface of the hemisphere, and to the anterior cingulate gyrus on the medial surface. Contralateral corticocortical connections are with the same and adjacent regions in the other hemisphere. Onward connections of the auditory association pathway converge with those of the other sensory association pathways in cortical regions within the superior temporal sulcus.

The posterior cortical area of the dominant hemisphere, Wernicke's area, is intrinsically related to the auditory cortex. It is particularly responsible for the comprehension of language but its stimulation causes speech arrest. Wernicke's area is not well defined anatomically but occupies mainly the posterior aspect of the superior temporal gyrus and the basal aspect of the supramarginal gyrus. It may extend inferiorly along the middle temporal gyrus and anteriorly to within 3 cm of the temporal pole (Ojemann et al 1989).

Evidence suggests that area 21, the middle temporal cortex, is polysensory in humans, and that it connects with auditory, somatosensory and visual cortical association pathways. The auditory association areas of the superior temporal gyrus project in a complex ordered fashion to the middle temporal gyrus, as does the parietal cortex. The middle temporal gyrus connects with the frontal lobe: the most posterior parts project to posterior prefrontal cortex, areas 8 and 9, while intermediate regions connect more anteriorly with areas 19 and 46. Further forwards, the middle temporal region has connections with anterior prefrontal areas 10 and 46, and with anterior orbitofrontal areas 11 and 14. The most anterior middle temporal cortex is connected with the posterior orbitofrontal cortex, area 12, and with the medial surface of the frontal pole. Further forwards, this middle temporal region projects to the temporal pole and the entorhinal cortex. Thalamic connections are with the pulvinar nuclei and the intralaminar group. Other subcortical connections follow the general pattern for all cortical areas. Some projections (e.g. to the pons), particularly from anteriorly in the temporal lobe, are minimal. Physiological responses

Ipsilateral corticocortical fibres pass from area 17 to a variety of functional areas in areas 18 and 19 and in the parietal and temporal cortices. Fibres from area 17 pass to area 18 (which contains visual areas V2, V3 and V3a); area 19 (which contains V4); the posterior intraparietal and the parieto-occipital areas; and to parts of the posterior temporal lobe, the middle temporal area and the medial superior temporal area. Subcortical efferents of the striate cortex pass to the superior colliculus, pretectum and parts of the brainstem reticular formation. Projections to the striatum (notably the tail of the caudate nucleus) and to the pontine nuclei are sparse. Geniculo- and claustrocortical projections are reciprocated by prominent descending projections, which arise in layer VI.

The superior temporal sulcus is well defined and deep. Typically, it is interrupted and composed of up to four segments but it may be continuous (Ochiai et al 2004). It terminates within the inferior parietal lobule, posterior to the end of the lateral fissure, by trifurcating into an ascending sulcal segment and an inferior branch that runs towards the occipital lobe. The superior temporal gyrus always continues posteriorly to the supramarginal gyrus encircling the terminal portion of the lateral fissure. The middle temporal gyrus is always connected to the angular gyrus beneath the distal and horizontal portion of the superior temporal sulcus. The inferior temporal gyrus is continuous posteriorly with the inferior occipital gyrus over the preoccipital notch. The inferior temporal sulcus is usually discontinuous. Both superior and inferior temporal sulci start at the most anterior aspect of the temporal pole and end posterior to the arbitrary border of the temporal lobe; both of them have their depths directed towards the inferior or temporal horn of the lateral ventricle. Topographically, the depth of the posterior part of the superior temporal sulcus is particularly related to the ventricular atrium.

The basal surface of the temporal lobe is composed laterally by the inferior surface of the inferior temporal gyrus and medially by the anterior or temporal portion of the fusiform or lateral temporo-occipital gyrus; the gyri are separated by the temporo-occipital sulcus. Medially, the fusiform gyrus is delimited by the collateral sulcus (inferior longitudinal sulcus of Huschke), which separates it from the parahippocampal gyrus of the limbic lobe (see Fig. 25.18). Short and secondary sulci (fusiform sulci) are found within its surface. Although not extensive, the fusiform gyrus has an anterior or temporal part, $\mathrm{T}_{4}$ (between the inferior and parahippocampal gyri), and a posterior or occipital part, $\mathrm{O}_{4}$ (between the inferior occipital and lingual gyri). The anterior part of the fusiform gyrus is typically curved or pointed, resembling an arrow; its anterior border usually lies close to the level of the cerebral peduncle. The temporal portion of the fusiform gyrus lies over the posterior aspect of the floor of the middle fossa and the upper surface of the petrous part of the temporal bone. The occipital part of the fusiform gyrus lies underneath the ventricular atrium.

Anterior to the fusiform gyrus, the collateral sulcus may be continuous with the rhinal sulcus. Alternatively, and more frequently, these sulci are separated by the so-called temporolimbic passage. The rhinal sulcus separates the entorhinal cortex of the uncus medially from the neocortex of the temporal pole laterally.

The superior or opercular surface of the temporal lobe is formed by the superior surface of the superior temporal gyrus, which lies within the lateral fissure and is composed of multiple transverse gyri. One of these is the voluminous transverse gyrus. It originates around the midpoint of the superior temporal gyrus and is orientated diagonally towards the posterior vertex of the floor of the lateral fissure, with its longest axis orientated towards the ventricular atrium. This gyrus, which may be single or double, is Heschl's gyrus; it is bounded anteriorly by the first transverse sulcus and posteriorly by the more defined sulcus of Heschl, and divides the temporal opercular surface into an anterior, polar plane and a posterior, temporal plane. The sulcus acusticus, an infrequent, small superior extension of the superior temporal sulcus anterior to Heschl's gyrus, indicates the anterior aspect of Heschl's gyrus on the superolateral surface of the temporal lobe. If the transverse temporal sulcus, which lies posterior to Heschl's sulcus within the temporal plane, reaches the lateral surface of the superior temporal gyrus, it indicates the posterior aspect of Heschl's gyrus. The transverse gyrus of Heschl and the most posterior aspect of the superior temporal gyrus correspond to the primary auditory cortex.

The surface of the polar plane is composed of multiple transverse gyri directed obliquely towards the inferior part of the insular circular sulcus (inferior limiting sulcus) (Fig. 25.21A). The temporal plane is flat, perpendicular to the brain surface, and triangular in shape. Its internal vertex corresponds to the posterior vertex of the base of the lateral (Sylvian) fissure, at the point where the superior part of the insular circular sulcus (superior limiting sulcus) meets the inferior part of the insular circular sulcus (inferior limiting sulcus), lying immediately over the atrium. The temporal plane is usually larger in the dominant hemisphere, supposedly reflecting its association with language functions (Geschwind and Levitsky 1968). Topographically, the oblique polar plane covers the insular surface, Heschl's gyrus underlies the opercular surface of the postcentral gyrus, and the flat surface of the temporal plane underlies the opercular surface of the supramarginal gyrus.

Abbreviations: AntLimS, anterior limiting sulcus; Ap, insular apex; CInsS, central insular sulcus; CS, central sulcus; IFG, inferior frontal gyrus; InfLimS, inferior limiting sulcus; ITG, inferior temporal gyrus; LIG, long insular gyri; MedOrbG, medial orbital gyrus; MFG, middle frontal gyrus; MTG, middle temporal gyrus; PoPI, polar plane of the opercular temporal surface; PostOrbG, posterior orbital gyrus; SFG, superior frontal gyrus; ShIG, short insular gyri; STG, superior temporal gyrus; SupLimS, superior limiting sulcus of insula; SyF, lateral or Sylvian fissure; TrInsG, transverse insular gyrus. (Adapted with permission from Ribas GC. The cerebral sulci and gyri. Neurosurg Focus 2010, 28(2):E2.)
of cells in this middle temporal region show convergence of different sensory modalities, and many neurones respond to faces.

The inferior temporal cortex, area 20, is a higher visual association area. The posterior inferior temporal cortex receives major ipsilateral corticocortical fibres from occipitotemporal visual areas, notably V4. It contains a coarse retinotopic representation of the contralateral visual field, and sends a major feed-forward pathway to the anterior part of the inferior temporal cortex. The anterior inferior temporal cortex projects on to the temporal pole and to paralimbic areas on the medial surface of the temporal lobe. Additional ipsilateral association connections of the inferior temporal cortex are with the anterior middle temporal cortex, in the walls of the superior temporal gyrus, and with visual areas of the parietotemporal cortex. Frontal lobe connections are with area 46 in the dorsolateral prefrontal cortex (posterior inferior temporal) and with the orbitofrontal cortex (anterior inferior temporal). The posterior area also connects with the frontal eye field. Reciprocal thalamic connections are with the pulvinar nuclei; the posterior part is related mainly to the inferior and lateral nuclei, and the anterior part to the medial and adjacent lateral pulvinar. Intralaminar connections are with the paracentral and central medial nuclei. Other subcortical connections conform to the general pattern of all cortical regions. Callosal connections are between corresponding areas and the adjacent visual association areas of each hemisphere.

The cortex of the temporal pole receives feed-forward projections from widespread areas of temporal association cortex that are immediately posterior to it. The dorsal part receives predominantly auditory
input from the anterior part of the superior temporal gyrus. The inferior part receives visual input from the anterior area of the inferior temporal cortex. Other ipsilateral connections are with the anterior insular, the posterior and medial orbitofrontal, and the medial prefrontal cortices. The temporal pole projects onwards into limbic and paralimbic areas. Thalamic connections are mainly with the medial pulvinar nucleus and with intralaminar and midline nuclei. Other subcortical connections are as for the cortex in general, although some projections, such as that to the pontine nuclei, are very small. Physiological responses of cells in this and more medial temporal cortex correspond particularly to behavioural performance and to the recognition of high-level aspects of social stimuli.

The cortex of the medial temporal lobe includes major subdivisions of the limbic system, such as the hippocampus and entorhinal cortex. Areas of neocortex adjacent to these limbic regions are grouped together as medial temporal association cortex.

Nuclei of the amygdala project to, and receive fibres from, neocortical areas, predominantly of the temporal lobe, and possibly inferior parietal cortex. The density of these pathways increases towards the temporal pole.

## INSULAR LOBE

The insula forms the base of the Sylvian cistern and lies between the frontal and temporal lobes (see Fig. 25.21; Fig. 25.22).

Fig. 25.22 The temporal opercular surface, the insula and the temporal stem, right side. A, View from above: the right frontal and occipital lobes have been sectioned horizontally and their superior parts removed. B, The hippocampus (Hippoc) lying along the temporal horn. Other abbreviations: AntLimS, anterior limiting sulcus; Atr, atrium of lateral ventricle; BoFo, body of fornix; CaN, caudate nucleus; CI, claustrum; CS, central sulcus; Fi, fimbria; HeG, Heschl gyrus; IntCap, internal capsule; Ins, insula; Orb, orbital part of inferior frontal gyrus; PaCLob, paracentral lobule; PoPI, polar plane of the opercular temporal surface; Put, putamen; SupLimS, superior limiting sulcus of insula; TempSt, temporal stem; TePI, temporal plane; Tha, thalamus. (Adapted with permission from Ribas GC. The cerebral sulci and gyri. Neurosurg Focus 2010, 28(2):E2.)

## Insular lobe sulci and gyri

The insula has both lateral and anterior surfaces. The superior and inferior limiting sulci are morphologically true sulci that delineate the lateral insular surface from the frontoparietal operculum, the lateral insular surface and the temporal operculum (Türe et al 1999). The anterior limit of the insula is considerably deeper and morphologically characteristic of a true fissure or space and separates the anterior surface of the insula from the fronto-orbital operculum. The upper half of the fundus of the anterior limiting sulcus is separated from a true anterior recess of the lateral ventricle, anterior to the head of the caudate nucleus, by the fibres of the thin anterior limb of the internal capsule, whereas the fundus of the lower half continues to the ventral striatopallidal or anterior perforated substance region (Heimer 2003).

## Insular lobe internal structure and connectivity

Cytoarchitectonically, three zones are recognized within the insula Anteriorly, and extending caudally into the central insula, the cortex is agranular. It is surrounded by a belt of dysgranular cortex, in which laminae II and III can be recognized, and this in turn is surrounded by an outer zone of homotypical granular cortex that extends to the caudal limit of the insula.

Thalamic afferents to the insula come from subdivisions of the ventral posterior nucleus and of the medial geniculate body, from the oral and medial parts of the pulvinar, the suprageniculate/nucleus limitans complex, the mediodorsal nucleus and the nuclei of the intralaminar and midline groups. It appears that the anterior (agranular) cortex is connected predominantly with the mediodorsal and ventroposterior nuclei, while the posterior (granular) cortex is connected predominantly with the pulvinar and the ventral posterior nuclei. The other nuclear groups appear to connect with all areas.

Ipsilateral cortical connections of the insula are diverse. Somatosensory connections are with SI, SII and surrounding areas, and areas 5 and 7 b of the parietal lobe. The insular cortex also has connections with the orbitofrontal cortex. Several auditory regions in the temporal lobe interconnect with the posterior granular insula and the dysgranular cortex more anteriorly. Connections with visual areas are virtually absent. The anterior agranular cortex of the insula appears to have connections primarily with olfactory, limbic and paralimbic structures, including, most prominently, the amygdala.

The insula receives somatosensory, viscerosensory, homeostatic and nociceptive information from the entire body. (For a discussion of the role of the operculo-insular region in the processing of somatosensory inputs, see Mazzola et al (2012).)

## LIMBIC LOBE

Limbus means edge or border; the descriptive term limbic was first used in the sixteenth century (Morgane and Mokler 2006), but is more usually associated with Broca, who described the cingulate and parahippocampal gyri as the greater limbic lobe, and considered the different sulci that limited these two gyri as parts of a single sulcus that he called the limbic sulcus (Broca 1877). On phylogenetic grounds, Broca considered that these structures might be associated with olfaction and for many years the term rhinencephalon ('smell brain') was used synonymously with limbic lobe; the term is no longer used.

The limbic lobe contains the cortical structures on the most medial edge of the hemisphere and includes the cingulate, parahippocampal and dentate gyri, the cingulate isthmus, the subcallosal area (paraolfactory and paraterminal gyri), the collateral and rhinal sulci, the uncus and the hippocampal formation. (The Terminologia Anatomica restricts the hippocampal representation in the limbic lobe to the fimbria of the hippocampus; other authors include the hippocampal formation (e.g Chronister and Hardy 2006).)

## Limbic lobe sulci and gyri

Within the inner aspect of the medial surface of each cerebral hemisphere, the cingulate gyrus wraps around the corpus callosum and continues posteriorly and inferiorly to the parahippocampal gyrus (see Fig. 25.10B). Lying above the callosal sulcus and below the cingulate sulcus, the cingulate gyrus starts within the subcallosal area below the rostrum of the corpus callosum and ascends around the genu of the
corpus callosum, frequently connecting with the medial aspect of the superior frontal gyrus in its course. It is connected to the paracentral lobule as it lies over the body of the corpus callosum; more posteriorly, it is connected to the precuneus. Posterior to the splenium of the corpus callosum, it narrows to become the isthmus, and continues to the parahippocampal gyrus. Anteriorly and basally, the cingulate sulcus may be continuous with the anterior paraolfactory sulcus under the rostrum of the corpus callosum; when this occurs, the cingulate gyrus is continuous with the paraolfactory or subcallosal gyri. The cingulate sulcus may be double and parallel; the additional superior fold is the paracingulate sulcus.

Anteriorly, the parahippocampal gyrus folds back on itself medially to form the uncus, which is incorporated superiorly into the most lateral aspect of the frontobasal region via a well-defined neural peduncle anterior to the inferior horn of the lateral ventricle (see Figs 25.18 and 25.20B). Along its axial extension, the basal and medial surface of the parahippocampal gyrus curves laterally, forming a flat superior surface, the subiculum. The latter is slightly triangular with an anterior vertex; it corresponds to the floor of the lateral part of the transverse fissure. This portion of the transverse fissure harbours the so-called lateral wing of the ambient cistern. Laterally, the parahippocampal gyrus is contiguous with the fusiform gyrus underneath the depths of the collateral sulcus. Posteriorly, it is continuous with the lingual gyrus and the cingulate gyrus along its isthmus. Medially, it lies under the thalamus along the choroidal fissure. Superiorly, it is attached along the inferior aspect of the insular lobe via fibres that cover the inferior horn.

The indusium griseum is a thin layer of grey matter lying over the corpus callosum and covered by medial and lateral longitudinal striae running within the callosal sulcus beneath each cingulate gyrus. Anteriorly, the indusium griseum is connected to the paraterminal gyrus via the prehippocampal rudiment. Posteriorly, it circles the splenium of the corpus callosum and runs along the fasciolar gyrus on each side.

In the subcallosal area, the anterior and posterior paraolfactory gyri lie anterior to the paraterminal gyrus, separated by the anterior paraolfactory sulcus. Anteriorly, a consistent fold connects the most basal portion of the cingulate gyrus with the gyrus rectus, encircling the posterior end of the superior rostral sulcus, called the cingulate pole (Yasargil 1994). The paraterminal gyrus lies on the medial wall of the cerebral hemisphere posterior to the paraolfactory gyri, immediately facing the lamina terminalis, and delineated anteriorly by the short, vertical posterior olfactory sulcus. Inferiorly, the paraterminal gyrus extends along the diagonal band of Broca and the lateral olfactory stria.

The choroidal fissure extends between the entire fornix and thalamus, from the inferior choroidal point between the head and the body of the hippocampus to the interventricular foramen. Anterior to the inferior choroidal point (the point at which the anterior choroidal artery enters the temporal pole of the lateral ventricle (Tubbs et al 2010)), the anterior and mesial parts of the temporal lobe and the parahippocampal gyrus merge with the basal and lateral aspect of the frontal lobe through a neural peduncle that constitutes the so-called temporal stem (see below). Posterior to the inferior choroidal point, the choroidal fissure lies within the inferior horn between the fimbria of the fornix and the inferior aspect of the thalamus, along the parapeduncular space that harbours the ambient cistern. More posteriorly, the choroidal fissure within the atrium lies between the crura and the pulvinar, lateral to the quadrigeminal or pineal cistern. More superiorly and anteriorly, the choroidal fissure lies between the body of the fornix and the superior surface of the thalamus.

The collateral sulcus is a long, deep sulcus that extends along the basal temporal and occipital surface, with multiple side branches. Its temporal segment bulges into the ventricular floor as the collateral eminence, located lateral to the hippocampus. Its occipital segment corresponds to the collateral trigone that forms the triangular, flat surface of the ventricular atrium and posterior horn. The rhinal sulcus, which is not always readily identifiable, separates the uncus from the rest of the temporal pole. The subcallosal, cingulate, subparietal, anterior calcarine, collateral and rhinal sulci are frequently considered to form the limbic fissure.

## Uncus

The uncus is triangular. It has a medial vertex; its anteromedial surface faces the carotid cistern and its posteromedial surface faces and encircles the mesencephalic peduncle (see Fig. 25.18). The semilunar gyrus, a lateral extension of the lateral olfactory stria, and the ambient gyrus form two small prominences on its medial and anterior surface. Both gyri cover the amygdala and are separated by the semi-annular sulcus,

The anterior surface of the insula is covered by the fronto-orbital operculum (the posterior portion of the posterior orbital gyrus and the orbital part of the inferior frontal gyrus). Its lateral surface is covered superiorly by the frontoparietal operculum (triangular and opercular parts of the inferior frontal gyrus, subcentral gyrus, and anterior and basal part of the supramarginal gyrus) and inferiorly by the temporal operculum (polar plane of the superior temporal gyrus; see Fig. 25.14).

The lateral surface of the insula may be conceptualized as a pyramid with a triangular base; its anteroinferior vertex is the limen insulae and its summit is the insular apex. The limen insulae consists of a narrow strip of olfactory cortex that extends along the lateral aspect of the lateral olfactory stria, conjoining the insular cortex and anterior perforated substance. The surface of the insula is divided into anterior and posterior parts by a deep central sulcus that courses obliquely from the limen insulae towards the central sulcus of the cerebral hemisphere. The anterior part of the insular surface is composed of transverse, accessory and short insular gyri (anterior, middle and posterior short insular gyri), all arising from the region of the insular apex. The middle and posterior short insular gyri are separated by the precentral insular sulcus.

The transverse insular gyrus runs along the limen insulae, connecting the anterior insula with the posteromedial orbital lobule. The latter is the connection between the posterior portion of the medial orbital gyrus and the posterior orbital gyrus, and is located anterior to and along the lateral olfactory stria. The accessory gyrus extends from the anterior portion of the anterior short gyrus superiorly to the transverse insular gyrus, beneath the fronto-orbital operculum. Both gyri constitute the insular pole within the anterior aspect of the insula (Türe et al 1999, Türe et al 2000). The posterior part of the insula is located behind its central sulcus and is composed of anterior and posterior insular long gyri. Both of these gyri are separated by the postcentral insular sulcus; the anterior long gyrus is usually larger, and may be single and divided at its upper end.

The insular surface is delineated peripherally by the peri-insular sulcus (circular sulcus of Reil), which is interrupted by the transverse insular gyrus running across the limen insulae. Given the triangular shape of the insula, the peri-insular sulcus is usually divided into three parts, variously named either as the anterior, superior and inferior periinsular sulci (Türe et al 1999), or the anterior, superior and inferior limiting sulci of the insula (Rhoton 2003).
which harbours the anterior choroidal artery. Inferiorly, the free edge of the tentorium cerebelli is frequently associated with another depression. The most rostral and anterior aspects of the uncus correspond to the entorhinal cortex. The posterior half of the uncus contains the head of the hippocampus and is separated inferiorly from the parahippocampal gyrus by the uncal sulcus. The medial surface of the uncus faces the crural cistern. Its inferior surface is hidden inside the uncal sulcus, in which the posterior half of the uncus harbours the uncinate gyrus anteriorly and the uncal apex (intralimbic gyrus, hippocampus inversus) posteriorly, separated by the band of Giacomini. Collectively, these structures correspond to the extraventricular part of the head of the hippocampus. The band of Giacomini corresponds to the tail of the dentate gyrus, which vanishes on the medial aspect of the uncus. Along the cerebral base, the parahippocampal gyrus is delineated laterally by the collateral sulcus, separating it from the fusiform gyrus, and more anteriorly by the rhinal sulcus, which is occasionally continuous with the collateral sulcus.

## Hippocampus

The hippocampus (hippocampus proper, cornu ammonis, Ammon's horn) is a convex elevation, approximately 5 cm long, within the parahippocampal gyrus inside the inferior (temporal) horn of the lateral ventricle (Duvernoy 1998) (Figs 25.23-25.24). Macroscopically, it can be divided into a head, a body and a tail (see Fig. 25.22B). Anteriorly, the head is expanded and bears two or three shallow grooves (pes hippocampi). The surface of the hippocampus, the alveus, is covered by the ependyma inside the ventricular cavity.

The dentate gyrus consists of small cortical prominences that form a chain along the medial aspect of the hippocampus (Fig. 25.25). Along its medial margin, it is separated from the subiculum of the parahippocampal gyrus by the hippocampal sulcus, usually a shallow sulcus that terminates anteriorly within the uncus (see Fig. 25.23). More superiorly and medially, the dentate gyrus is separated from the fimbria of
the fornix by the fimbriodentate sulcus lying parallel to the hippocampal sulcus (Fig. 25.26).

The main outflow bundle of the hippocampus, the fornix, wraps round the thalamus, from which it is separated by the choroidal fissure and the choroid plexus (see Fig. 25.3). It has several named parts: fimbria, crus, body and column (pillar). The fibres of the alveus converge to form the fimbria along the medial portion of the floor of the inferior horn of the lateral ventricle. At a point beneath the splenium of the corpus callosum, the white matter of the fimbria separates from the hippocampus to become the crus of the ipsilateral fornix. The two crura pass upwards and forwards beneath the corpus callosum, mirroring its arch but with a tighter curve. They are joined via fibres that cross in the commissure of the fornix (hippocampal commissure). Beyond this point, the crura merge to become the body of the fornix, which continues anteriorly within the roof of the third ventricle, below the lower border of the septum pellucidum and near the midline (Figs 25.27-25.28). At the level of the interventricular foramen (foramen of Munro) and the anterior commissure, the most anterior segment of the body diverges from its contralateral counterpart, and passes in an anterior, lateral and inferior direction as the column (pillar) of the fornix to penetrate the hypothalamic parenchyma towards the ipsilateral mammillary body. As they separate from the underlying thalamus, the columns of the fornix form the anterior margins of the interventricular foramen.

## Limbic lobe internal structure and connectivity

## Cingulate and parahippocampal cortex

The cingulate gyrus may be divided rostrocaudally into several cytoarchitectonically discrete areas: prelimbic (area 32) and infralimbic (area 25) cortices, anterior cingulate cortex (areas 23, 24, 32 and 33)

Fig. 25.23 A series of coronal sections of the temporal lobe and inferior horn of the lateral ventricle illustrating the relationships between the components of the hippocampal formation.

Fig. 25.24 A dissection of the left cerebral hemisphere demonstrating components of the limbic system. The body of the corpus callosum has been divided sagittally; the left frontal, temporal and occipital lobes have been sectioned horizontally and their superior parts removed. The left lentiform complex and thalamus have been removed and the floor of the inferior horn of the lateral ventricle opened. (Dissection by AM Seal; photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London; figure enhanced by B Crossman.)

Fig. 25.27 The fornix and related structures, right side of the brain. A, Medial structures after the removal of the corpus callosum, disclosing neural structures related to limbic circuits. B, The ventral striatopallidal region (VeStrPa) inferior and anterior to the anterior commissure (AntCom). The septal region (Sept) lies anterior to the anterior commissure and posterior to the cingulate pole. The column of the fornix (Fo) runs posterior to the anterior commissure. Other abbreviations: CC, corpus callosum; CiG, cingulate gyrus; Cl , claustrum; Ge , genu of corpus callosum; Hypothal, hypothalamus; LamTer, lamina terminalis; MaBo, mammillary body; MaThTr, mammillothalamic tract; ON, optic nerve; Put, putamen; SeptPell, septum pellucidum; Ro, rostrum of corpus callosum; StTerm, stria terminalis; Tha, thalamus. (Dissection courtesy of Professor Guilherme Ribas.)
and part of the posterior cingulate or retrosplenial cortex (area 29) [C] (Commentary 3.1).

The cingulate gyrus contains specific motor areas and has extensive connections with neocortical areas of the frontal lobe and with somatosensory and visual association areas of the parietal, occipital and temporal lobes. The afferents to the cingulate gyrus are predominantly from neocortical areas on the lateral surface of the hemisphere. Within the cingulate cortex, most projections pass caudally, ultimately into the parahippocampal gyrus. Through this system, afferents from widespread areas of association cortex converge on the medial temporal lobe and hippocampal formation. There are parallel stepwise routes to these targets through cortical areas on the lateral surface. The anterior cingulate gyrus appears to be a component of a functional circuit that mediates pain perception and processing. The cingulate motor cortex subregion of the anterior cingulate gyrus is one of the first cortical brain regions activated in pain processing; its probable function is to mediate withdrawal actions and so minimize further injury. (For further reading, see Weston (2012).) The insula has strong functional connections with anterior and dorsal subregions of the anterior cingulate gyrus (areas 24 and 32),

The parahippocampal gyrus includes areas 27, 28 (entorhinal cortex), 35, 36, 48 and 49, and temporal cortical fields. It has complex interconnections with the cingulate cortex and with the hippocampal formation. In monkeys, the infralimbic cortex (area 25) has been shown to project to areas 24 a and 24 b . Area 25 also has reciprocal con-

Fig. 25.25 The basal aspect of the brain dissected to display the dentate gyrus, uncus and fimbria on the left.
nections with the entorhinal cortex. Projections between the paralimbic area 32 and the limbic cortex (anterior, retrosplenial and entorhinal cortex) are somewhat less prominent. Areas 24 and 29 are connected with the paralimbic posterior cingulate area 23 . In primates, the parahippocampal gyrus projects to virtually all association areas of the cortex; it also provides the major funnel through which polymodal sensory inputs converge on the hippocampus.

## Hippocampal cortex

The hippocampus is composed of trilaminar archicortex: a single layer of pyramidal cells sandwiched between plexiform layers. It is divided into three distinct fields: CA1, CA2 and CA3 (see Fig. 25.26; Fig. 25.29).

Field CA3 borders the hilus of the dentate gyrus at one end, and field CA2 at the other. Field CA3 pyramidal cells are the largest in the hippocampus and receive the mossy fibre input from dentate granule cells on their proximal dendrites. The whole pyramidal cell layer in this field is about 10 cells thick. The border between CA3 and CA2 is not well marked. The CA2 field has the most compact layer of pyramidal cells.

Fig. 25.26 The hippocampal formation showing the disposition of the various cell fields.

Fig. 25.28 Components of the limbic system (yellow). The medial aspect of the left cerebral hemisphere. The approximate locations of some Brodmann's areas are indicated.

Fig. 25.29 A coronal, thionin-stained section of the human hippocampal formation. Abbreviations: a, molecular layer of the dentate gyrus; b, granule cell layer of the dentate gyrus; c, plexiform layer of the dentate gyrus; CA1-3, fields of the hippocampus; d, stratum oriens layer of the hippocampus; DG, dentate gyrus; e, pyramidal cell layer of the hippocampus; EC, entorhinal cortex; f, stratum radiatum of the hippocampus; fim, fimbria; g, stratum lacunosum-moleculare of the hippocampus; PaS, parasubiculum; PRC, perirhinal cortex; PrS, presubiculum; S, subiculum. (Courtesy of D Amaral.)

It completely lacks a mossy fibre input from dentate granule cells and receives a major input from the supramammillary region of the hypothalamus. Field CA1 is usually described as the most complex of the hippocampal subdivisions and its appearance varies along its transverse and rostrocaudal axes. The CA1/CA2 border is not sharp, and at its other end CA1 overlaps the subiculum for some distance. Approximately $10 \%$ of neurones in this field are interneurones.

It is common to describe several strata within the layers of the hippocampus. Working from the ventricular aspect, these are the alveus (contains subicular and hippocampal pyramidal cell axons converging on the fimbria of the fornix); stratum oriens (mainly the basal dendrites of pyramidal cells and some interneurones); stratum pyramidalis; stratum lucidum (contains mossy fibres that make contact with the proximal dendrites of pyramidal cells in field CA3); stratum radiatum; and stratum lacunosum-moleculare. The stratum lucidum is not as prominent in humans as it is in other primates, and is not present in fields CA1 and CA2.

In the stratum radiatum and stratum oriens, CA3 and CA2 cells receive associational connections from other rostrocaudal levels of the hippocampus, as well as afferents from subcortical structures, such as the septal nuclei and supramammillary region. The projections from pyramidal cells of fields CA3 and CA2 to CA1, often called Schaffer collaterals, also terminate in the stratum radiatum and stratum oriens. The projections from the entorhinal cortex to the dentate gyrus (the perforant pathway) travel in the stratum lacunosum-moleculare, where they make synaptic contact en passant with the distal apical dendrites of hippocampal pyramidal cells.

The trilaminar cortex of the dentate gyrus is the least complex of the hippocampal fields (see Fig. 25.29). Its major cell type is the granule cell, found in the dense granule cell layer. Granule cells have unipolar dendrites that extend into the overlying molecular layer. The latter receives most of the afferent projections to the dentate gyrus, primarily from the entorhinal cortex (Fig. 25.30). The granule cell and molecular layers are sometimes referred to as the fascia dentata. The polymorphic layer, or hilus of the dentate gyrus, contains cells that give rise primarily to ipsilateral association fibres. They remain within the dentate gyrus and do not extend into other hippocampal fields.

## LIMBIC SYSTEM

The limbic system is an extended neural network that is concerned with emotional and motivational activity and other basic psychological functions such as memory and learning. The complex connectivity of its

Fig. 25.30 The neuronal organization and connections of the dentate gyrus, hippocampus (cornu ammonis), subiculum and parahippocampal gyrus.
components has always rendered it anatomically and functionally difficult to dissect. Although much of the earliest research was necessarily undertaken in non-human primates, cats and rodents, the use of noninvasive imaging, deep-brain stimulation and clinical behavioural studies is enabling detailed analyses of the human limbic system in both normal and pathological states.

Most descriptions of the limbic system include the structures within the limbic lobe; the amygdaloid nuclear complex; various nuclei of the hypothalamus, particularly those associated with the mammillary body; the septal nuclei; nucleus accumbens; cingulate cortex; major areas of the prefrontal cortex habenula; anterior thalamic nuclei; parts of the basal ganglia; ventral tegmental area; and limbic midbrain areas, including the periaqueductal grey (Morgane and Mokler 2006). The term 'limbic brain' encompasses all of these structures and their projections to forebrain, midbrain, lower brainstem and spinal cord limbic systems, principally via the fornix, stria terminalis, ventral amygdalofugal pathway and the mammillothalamic tract. The appropriateness of continuing to regard the limbic system as the sole theoretical framework for emotional functions has been questioned (Heimer and van Hoesen 2006, Heimer 2008). (Seminal studies by Papez (1937), Klüver and Bucy (1937) and Nauta (1958) document the development of ideas about the limbic system.)

## Hippocampal formation

The hippocampal formation includes the dentate gyrus, hippocampus proper, subicular complex (subiculum, presubiculum, parasubiculum) and entorhinal cortex (area 28). Passing medially from the collateral sulcus, the neocortex of the parahippocampal gyrus merges with the transitional juxtallocortex of the subiculum (see Fig. 25.23). The latter curves superomedially to the inferior surface of the dentate gyrus, then laterally to the laminae of the hippocampus. This curvature continues, first superiorly, then medially above the dentate gyrus, and ends pointing towards the centre of the superior surface of the dentate gyrus.

Glutamate and/or aspartate appears to be the major excitatory transmitter in three pathways in the hippocampal formation: namely, the perforant pathway, which arises in the entorhinal cortex and terminates primarily in the dentate gyrus; the mossy fibres, which run from the dentate granule cells to the pyramidal cells of the CA3 field; and in the Schaffer collaterals of CA3 pyramidal cells, which terminate on CA1 pyramidal cells. GABAergic neurones are found in the deep portions of the granule cell layer in the dentate gyrus (basket cells).

The highest concentration of GABA receptors is found in the molecular layer of the dentate gyrus. In the hippocampus proper, GABAergic cells are found mostly in the stratum oriens, but also in the pyramidal cell layer and stratum radiatum.

There are many peptide-containing neurones in the hippocampal formation. Granule cells in the dentate gyrus appear to contain the opioid peptide dynorphin, which is also present in mossy fibres running to the CA3 field. Enkephalin, or a related peptide, may be present in fibres arising in the entorhinal cortex. There is a dense plexus of somatostatin-immunoreactive fibres in the molecular layer of the dentate gyrus and also in the stratum lacunosum-moleculare of the hippocampus. The polymorphic layer of the dentate gyrus, stratum oriens of the hippocampus and the deep layers of the entorhinal cortex all contain somatostatin-immunoreactive neurones. VIPimmunoreactive neurones are plentiful in many hippocampal fields, especially in the superficial layers of the entorhinal cortex. Cells containing CCK immunoreactivity are found in the hilar region of the dentate gyrus, in all layers of the hippocampus, especially in the pyramidal cell layer, and also throughout the subicular complex and entorhinal cortex. There are also substantial plexuses of CCK-immunoreactive fibres in the stratum lacunosum-moleculare, subicular complex and entorhinal cortex. Hippocampal CCK-immunoreactive cells may give rise to extrinsic projections, e.g. to the lateral septum and medial mammillary nucleus, because CCK-immunoreactive fibres are found in the fimbria/fornix.

The medial septal complex and the supramammillary area of the posterior hypothalamus are the two major sources of subcortical afferents to the hippocampal formation. There are also projections from the amygdaloid complex and claustrum (to the subicular complex and entorhinal cortex), as well as monoaminergic projections from the ventral tegmental area, the mesencephalic raphe nuclei and the locus coeruleus. The noradrenergic and serotoninergic projections reach all hippocampal fields but are especially dense in the dentate gyrus. Neurones in the supramammillary area project to the hippocampal formation via the fornix and a ventral route; they terminate most heavily in the dentate gyrus and fields CA2 and CA3 of the cornu ammonis. All divisions of the anterior thalamic nuclear complex and associated lateral dorsal nucleus project to the hippocampal formation, predominantly to the subicular complex. Some midline thalamic nuclei, particularly the parataenial, central medial and reuniens nuclei, project especially to the entorhinal cortex.

## Subicular complex

The subicular complex is generally subdivided into subiculum, presubiculum and parasubiculum. The subiculum consists of a superficial molecular layer containing apical dendrites of subicular pyramidal cells, a pyramidal cell layer and a deep polymorphic layer. The presubiculum, lying medial to the subiculum, is distinguished by a densely packed superficial layer of pyramidal cells and forms the boundary between the subicular complex and the entorhinal cortex. The cell layers deep to the parasubiculum are indistinguishable from the deep layers of the entorhinal cortex.

The major subcortical projections of the hippocampal formation, to the septal nucleus, lateral and medial mammillary nuclei, nucleus accumbens, anterior thalamus and entorhinal cortex, all arise from pyramidal neurones of the subicular complex. The presubiculum, in particular, projects to the anterior thalamic nuclear complex (anteromedial, anteroventral and laterodorsal nuclei). The subicular complex receives numerous direct cortical inputs, e.g. from the temporal polar, perirhinal and dorsolateral cortices and the parahippocampal and superior temporal gyri.

## Entorhinal cortex

The entorhinal cortex is the most posterior part of the piriform cortex and is divided into medial and lateral areas (Brodmann's areas 28a and 28b). It extends rostrally to the anterior limit of the amygdala and caudally it overlaps a portion of the hippocampal fields. The lateral areas receive fibres from the olfactory bulb and the piriform and periamygdaloid cortices; more caudal regions do not generally receive primary olfactory inputs.

The entorhinal cortex is divisible into six layers and is quite distinct from other neocortical regions. Layer I is acellular and plexiform. Layer II is a narrow cellular layer, which consists of islands of large pyramidal and stellate cells. These cell islands are a distinguishing feature of the entorhinal cortex. They form small bumps on the surface of the brain that can be seen by the naked eye (verrucae hippocampi) and provide an indication of the boundaries of the entorhinal cortex. Layer III consists of medium-sized pyramidal cells. There is no internal granular layer (another classic feature of entorhinal cortex); in its place is an acellular region of dense fibres called the lamina dissecans, which is sometimes called layer IV. Layers III and V are apposed in regions where the lamina dissecans is absent. Layer V consists of large pyramidal cells five or six deep. Layer VI is only readily distinguishable from layer V close to the border with the perirhinal cortex. Its cells continue around the angular bundle (subcortical white matter deep to the subicular complex made up largely of perforant path axons) to lie beneath the pre- and parasubiculum.

The entorhinal cortex has reciprocal connections with the hippocampus and neocortical regions. It receives afferents from many areas, including the parahippocampal gyrus and dorsal bank of the superior temporal gyrus, and perirhinal (Brodmann's area 35), temporal polar, agranular insular, posterior orbitofrontal, dorsolateral prefrontal (Brodmann's areas 9, 10, 46), medial frontal (Brodmann's areas 25, 32), cingulate (Brodmann's areas 23, 24) and retrosplenial cortices. It projects to the perirhinal and temporal polar cortices and the caudal parahippocampal and cingulate gyri. Evidence from clinical and animal studies suggests that the entorhinal cortex plays an essential role within a frontotemporal cortical memory network (Takehara-Nishiuchi 2014).

## Septum

The septum is a midline and paramedian structure (see Fig. 24.6). Its upper portion corresponds largely to the bilateral laminae of fibres, sparse grey matter and neuroglia known as the septum pellucidum, which separates the lateral ventricles (see Fig. 25.28). Below this, the septal region is made up of four main nuclear groups: dorsal, ventral, medial and caudal. The dorsal group is essentially the dorsal septal nucleus, the ventral group consists of the lateral septal nucleus, the medial group contains the medial septal nucleus and the nucleus of the diagonal band of Broca, and the caudal group contains the fimbrial and triangular septal nuclei.

The major afferents to the region terminate primarily in the lateral septal nucleus. They include fibres carried in the fornix that arise from hippocampal fields CA3 and CA1 and the subiculum, and afferents arising from the preoptic area, anterior, paraventricular and ventromedial hypothalamic nuclei, and the lateral hypothalamic area. The lateral septum receives a rich monoaminergic innervation, including noradrenergic afferents from the locus coeruleus and medullary cell groups (A1, A2), serotoninergic afferents from the midbrain raphe nuclei, and dopaminergic afferents from the ventral tegmental area (A10).

Efferents from the lateral septum project to the medial and lateral preoptic areas, anterior hypothalamus, supramammillary and midbrain ventral tegmental area, via the medial forebrain bundle, and to the medial habenular nucleus and some midline thalamic nuclei via the stria medullaris thalami. The projections from the habenula via the fasciculus retroflexus to the interpeduncular nucleus and adjacent ventral tegmental area in the midbrain provide a route through which forebrain limbic structures influence midbrain nuclear groups.

Efferents from the medial septal and vertical limb nuclei of the diagonal band travel via the dorsal fornix, fimbria, supracallosal striae and a ventral route through the amygdaloid complex. While these projections reach all hippocampal fields, the most prominent terminations are in the dentate gyrus, field CA3, presubiculum, parasubiculum and entorhinal cortex. Many are GABAergic or cholinergic.

## Amygdala

The amygdala (amygdaloid nuclear complex) consists of lateral, central and basal nuclei lying in the dorsomedial temporal pole, anterior to the hippocampus, close to the tail of the caudate nucleus and partly deep to the gyrus semilunaris, gyrus ambiens and uncinate gyrus (Figs 25.31-25.32; see Fig. 25.28). Collectively, the nuclei form the ventral, superior and medial walls of the tip of the inferior horn of the lateral ventricle. The amygdala is partly continuous above with the inferomedial margin of the claustrum. Fibres of the external capsule and substriatal grey matter, including the cholinergic magnocellular nucleus basalis of Meynert, partially separate it from the putamen and globus pallidus. Laterally, the amygdala lies close to the optic tract.

Fig. 25.31 The uncinate fasciculus has been removed to expose the anterior commissure and the lateral fibres of the anterior commissure have been removed to expose the optic radiation. Abbreviations: AntCom, anterior commissure; AnsaPed, ansa peduncularis; CaN, caudate nucleus; CoRa, corona radiata; GloPa, globus pallidus; IntCap, internal capsule; OptRad, optic radiation; SupLongFasc, superior longitudinal fasciculus. (Courtesy of Richard Gonczalo Párraga. Adapted from: Párraga RG, Ribas GC, Welling LC, Alves RV, de Oliveira E. Microsurgical anatomy of the optic radiation and related fibres in 3-dimensional images. Neurosurgery 2012, 71[ONS Suppl 1]:ons160-ons172.)

Fig. 25.32 The inferior aspect of the brain. The brainstem has been removed and the right temporal pole has been displaced laterally to expose underlying structures. Abbreviations: APS, anterior perforated substance; EA, entorhinal area; GA, gyrus ambiens; GS, gyrus semilunaris; UG, uncinate gyrus.

The lateral nucleus has dorsomedial and ventrolateral subnuclei. The basal nucleus is commonly divided into dorsal magnocellular and intermediate parvicellular basal nuclei and a ventral band of darkly staining cells, the paralaminar basal nucleus, so called because it borders the white matter ventral to the amygdaloid complex. The accessory basal nucleus lies medial to the basal nuclear divisions and may be divided into dorsal, magnocellular and ventral, parvicellular parts. The lateral and basal nuclei are often referred to collectively as the basolateral area (nuclear group) of the amygdaloid complex. It has been suggested that the basolateral nuclear complex (lateral, basal, accessory basal) should be considered as a quasicortical structure because it shares several characteristics with the cortex. Although it lacks a laminar structure, it has direct, often reciprocal, connections with adjacent temporal and other areas of cortex, and it projects to the motor or premotor cortex. It receives a direct cholinergic and non-cholinergic input from the magnocellular corticopetal system in the basal forebrain, and has reciprocal connections with the mediodorsal thalamus. The distribution of small peptidergic neurones in the basolateral nuclear complex, e.g. those containing neuropeptide Y (NY), somatostatin (SOM) and CCK, are also similar in form and density to those found in the adjacent temporal lobe cortex. Projection neurones from this part of the amyg-
dala appear to utilize, at least in part, the excitatory amino acids glutamate or aspartate as a transmitter. Moreover, they project to the ventral striatum rather than to hypothalamic and brainstem sites. Thus, it may be appropriate to consider this part of the amygdaloid complex as a polymodal cortex-like area, separated from the cerebral cortex by fibres of the external capsule.

The central nucleus is present through the caudal half of the amygdaloid complex. It lies dorsomedial to the basal nucleus and is divided into medial and lateral parts. The medial part, which contains larger cells than the lateral part, resembles the adjacent putamen. The medial and central nuclei appear to have an extension across the basal forebrain, as well as within the stria terminalis, which merges with the bed nucleus of the stria terminalis. This extensive nuclear complex is sometimes referred to as the 'extended amygdala' (Fig. 25.33). It is formed by the centromedial amygdaloid complex (medial nucleus, medial and lateral parts of the central nucleus), the medial bed nucleus of the stria terminalis, and the cell columns that traverse the sublenticular substantia innominata, which lies between them. Developmental and cyto- and chemoarchitectonic studies suggest that the subnuclei of the bed nucleus of the stria terminalis are aligned along an anterior to posterior rather than a medial to lateral gradient (Crestani et al 2013). Portions of the medial nucleus accumbens may also be included in the extended amygdala.

A consistent feature of the intrinsic connections among amygdaloid nuclei is that they arise primarily in the lateral and basal nuclei, and terminate in the central and medial nuclei, suggesting a largely unidirectional flow of information. In brief, the lateral nucleus projects to all divisions of the basal nucleus, accessory basal nucleus, paralaminar and anterior cortical nuclei, and less heavily to the central nucleus; it receives few afferents from other nuclei. The magnocellular, parvicellular and intermediate parts of the basal nucleus project to the accessory basal, central (especially the medial part) and medial nuclei, as well as to the periamygdaloid cortex and the amygdalohippocampal area. The accessory basal nucleus projects densely to the central nucleus, especially its medial division, as well as to the medial and cortical nuclei. Its major intra-amygdaloid afferents arise from the lateral nucleus. The medial nucleus projects to the accessory basal, anterior cortical and central nuclei, as well as to the periamygdaloid cortex and amygdalohippocampal area, while afferents arise especially from the lateral nucleus. The intrinsic connections of the cortical nucleus are not well understood. The posterior part of the cortical nucleus projects to the medial nucleus but it has been difficult to differentiate this projection from that arising in the amygdalohippocampal area. The central nucleus projects to the anterior cortical nucleus and the various cortical transition zones. It forms an important focus for afferents from many of the amygdaloid nuclei, especially the basal and accessory basal nuclei, and it has major extrinsic connections.

The amygdaloid complex has particularly extensive and rich connections with many areas of the neocortex in unimodal and polymodal regions of the frontal, cingulate, insular and temporal neocortices. It receives numerous projections from the brainstem, including the peripeduncular and parabrachial nuclei. The amygdala receives a rich monoaminergic innervation. The noradrenergic projection arises primarily from the locus coeruleus, serotoninergic fibres arise from the dorsal and, to some extent the median, raphe nuclei, and the dopaminergic innervation arises primarily in the midbrain ventral tegmental area (A10). The basal and parvicellular accessory basal nuclei, the amygdalohippocampal area and nucleus of the lateral olfactory tract receive a very dense cholinergic innervation arising from the magnocellular nucleus basalis of Meynert.

## OLFACTORY PATHWAYS

The organization of the olfactory system reflects its phylogenetically ancient lineage. Afferent olfactory pathways proceed directly to the

Fig. 25.33 A coronal section through the basal forebrain and temporal pole, illustrating the relationship between the striatum, nucleus accumbens, globus pallidus, ventral pallidum, extended amygdala and magnocellular basal forebrain system.
olfactory cortex in the orbitofrontal region of prefrontal cortex, bypassing the thalamus; many of their terminal fields are primitive cortical areas that are considered to be parts of the limbic system, an arrangement that underscores the ability of odours to modulate emotional processing and behaviour (Gottfried 2006).

The olfactory nerves arise from olfactory receptor neurones in the olfactory mucosa. The axons collect into numerous small bundles ensheathed by a population of unique glia and surrounded by layers of meninges, and enter the anterior cranial fossa by passing through the foramina in the cribriform plate of the ethmoid bone. They attach to the inferior surface of the olfactory bulb, which is situated at the anterior end of the olfactory sulcus on the orbital surface of the frontal lobe, and terminate in the bulb.

## Olfactory bulb

The olfactory bulb is continuous posteriorly with the olfactory tract, through which the output of the bulb passes directly to the ipsilateral piriform cortex, amygdala and rostral entorhinal cortex. There is a clear laminar structure in the olfactory bulb (Fig. 25.34). From the surface inwards, the laminae are the olfactory nerve layer, glomerular layer, external plexiform layer, mitral cell layer, internal plexiform layer and granule cell layer. The olfactory nerve layer consists of the unmyelinated axons of the olfactory neurones. The continuous turnover of receptor cells means that axons in this layer are at different stages of growth, maturity or degeneration. The glomerular layer consists of a thin sheet of glomeruli where the incoming olfactory axons divide and synapse on terminal dendrites of secondary olfactory neurones, i.e. mitral, tufted and periglomerular cells. The external plexiform layer contains the principal and secondary dendrites of mitral and tufted cells. The mitral cell layer is a thin sheet composed of the cell bodies of mitral cells, each of which sends a single principal dendrite to a glomerulus, secondary dendrites to the external plexiform layer, and a single axon to the olfactory tract. It also contains a few granule cell bodies. The internal plexiform layer contains axons, recurrent and deep collaterals of mitral and tufted cells, and granule cell bodies. The granule cell layer contains the majority of the granule cells and their superficial and deep processes, together with numerous centripetal and centrifugal nerve fibres that pass through the layer.

Different odour molecules are represented by different patterns of spatial activity in the olfactory bulb (Shepherd 2006). The principal neurones in the olfactory bulb are the mitral and tufted cells; their axons form its output via the olfactory tract.

The granule cell layer of the bulb is extended into the olfactory tract as scattered medium-sized multipolar neurones that constitute the anterior olfactory nucleus. Many centripetal axons from mitral and tufted cells relay in, or give collaterals to, the anterior olfactory nucleus; the axons from the nucleus continue with the remaining direct fibres from the bulb into the olfactory striae.

Afferent inputs to the olfactory bulb arise from a variety of central sites. Neurones of the anterior olfactory nucleus and collaterals of pyramidal neurones in the olfactory cortex project to the granule cells of the olfactory bulb. Cholinergic neurones in the horizontal limb nucleus of the diagonal band of Broca, part of the basal forebrain cholinergic system, project to the granule cell layer and also to the glomerular layer. Other afferents to the granule cell layer and the glomeruli arise from the pontine locus coeruleus and the mesencephalic raphe nucleus.

Fig. 25.34 Organization of the olfactory bulb.

The amygdaloid nuclear complex has rich interconnections with allocortical, juxtallocortical and, especially, neocortical areas. It projects to widely dispersed neocortical fields, principally from the basal nucleus. The complex projects to virtually all levels of the visual cortex in both temporal and occipital lobes; the largest component of these projections arises from the magnocellular basal nucleus. It has been suggested that a direct pathway to the amygdala that bypasses the primary sensory cortices and relies on crude sensory input in the visual domain may represent a neural 'alarm' system for rapid alerting to sources of threat, without the need for conscious appraisal (Liddell et al 2005). The amygdala also reciprocates projections to the auditory cortex in the rostral half of the superior temporal gyrus. Projections to the polymodal sensory areas of the temporal lobe generally reciprocate the amygdalopetal projections. Efferents from the lateral and accessory basal nuclei are directed to the temporal pole, particularly the medial perirhinal area. The insular cortex is heavily innervated by the amygdaloid medial and anterior cortical nuclei. The orbital cortex and medial frontal cortical areas 24,25 and 32 , including parts of the anterior cingulate gyrus, receive a heavy projection, whereas areas $8,9,45$ and 46 of the dorsolateral prefrontal cortex, as well as the premotor cortex (area 6), are reported to receive a patchy innervation. The basal nucleus is an important source of these projections, which are augmented by contributions from the accessory basal (magnocellular and parvicellular divisions) and lateral nuclei.

In addition to direct projections from the olfactory bulb to the nucleus of the lateral olfactory tract, anterior cortical nucleus and the periamygdaloid cortex (piriform cortex), there are also associational connections between all parts of the primary olfactory cortex and these same superficial amygdaloid structures. The anterior temporal lobe provides the largest proportion of the cortical input to the amygdala, predominantly to the lateral nucleus. Rostral parts of the superior temporal gyrus, which may represent unimodal auditory association cortex, project to the lateral nucleus. There are also projections from polymodal sensory association cortices of the temporal lobe, including perirhinal cortex (areas 35 and 36), the caudal half of the parahippocampal gyrus, the dorsal bank of the superior temporal sulcus, and both the medial and lateral areas of the cortex of the temporal pole. The CA1 field of the hippocampus and adjacent subiculum, and possibly the entorhinal cortex, project to the amygdala, mainly to the parvicellular basal nucleus. The rostral insula projects heavily to the lateral, parvicellular basal and medial nuclei. The caudal insula, which is reciprocally connected with the second somatosensory cortex, also projects to the lateral nucleus, thus providing a route by which somatosensory information reaches the amygdala. The caudal orbital cortex projects to the basal, magnocellular accessory basal and lateral nuclei. The medial prefrontal cortex projects to the magnocellular divisions of the accessory and basal nuclei.

The central nucleus is the major relay for amygdaloid projections to the hypothalamus. Amygdaloid fibres reach the bed nucleus of the stria terminalis primarily via the stria terminalis, but also via the ventral amygdalofugal pathway. In general, central and basal nuclei project to the lateral bed nucleus, and medial and posterior cortical nuclei project to the medial bed nucleus. Anterior cortical and medial nuclei project largely to the medial preoptic area and anterior medial hypothalamus (including the paraventricular and supraoptic nuclei) and to the ven-
tromedial and premammillary nuclei. The amygdala projects to the rostrocaudal extent of the lateral hypothalamus. The majority of the fibres originate in the central nucleus and run principally in the ventral amygdalofugal pathway and medial forebrain bundle. There is a rich projection to the medial, magnocellular part of the mediodorsal nucleus of the thalamus, particularly from the lateral, basal and accessory basal nuclei and the periamygdaloid cortex. The central and medial nuclei project to the midline nuclei, especially the nucleus centralis and nucleus reuniens. The parvicellular division of the basal nucleus, magnocellular accessory basal nucleus (but not the magnocellular basal nucleus) and the central nucleus all project to basal forebrain cholinergic cell groups, notably the nucleus basalis of Meynert and the horizontal limb nucleus of the diagonal band. The striatum, and particularly the nucleus accumbens, receives prominent projections from the amygdaloid complex, predominantly from the basal and accessory basal nuclei. The ventral striatum sends many fibres to the ventral pallidum, which in its turn projects to the mediodorsal nucleus of the thalamus. The ventral striatopallidal system thus provides an additional route by which the amygdala can influence mediodorsal thalamic-prefrontal cortical processes. The lateral, magnocellular accessory basal and parvicellular basal nuclei contribute the largest proportion of efferents to the hippocampal formation. The main projection is from the lateral nucleus to the rostral entorhinal cortex, but many fibres also terminate in the hippocampus proper and the subiculum. There appears to be marked polarity in amygdalohippocampal connections in that the amygdala has a greater influence on hippocampal processes than vice versa. Amygdala-cortical functional connectivity underlies a range of cognitive and affective processes. The appropriate development of these functional connections has been correlated with the emotional behaviour of adults; extensive and specific changes in these connections emerge between childhood and adolescence (Gabard-Durnam et al 2014). Atypical functional connectivity patterns have been implicated in conditions including depression, schizophrenia and bipolar disorder.

The central nucleus is also the major relay for projections from the amygdala to the brainstem and receives many reciprocal projections. It projects to the periaqueductal grey matter, ventral tegmental area, substantia nigra pars compacta, peripeduncular nucleus, mesencephalic tegmental reticular formation, parabrachial nucleus, nucleus of the solitary tract and the dorsal motor nucleus of the vagus.

These cells are morphologically similar and most use an excitatory amino acid, probably glutamate or aspartate, as their neurotransmitter. The mitral cell spans the layers of the bulb and receives the sensory input superficially at its glomerular tuft. The axons of mitral and tufted cells appear to be parallel output pathways from the olfactory bulb. The main types of interneurones in the olfactory bulb are the periglomerular cells and granule cells. The majority of periglomerular cells are dopaminergic (cell group A15) but some are GABAergic; their axons are distributed laterally and terminate within extraglomerular regions. Granule cells are similar in size to periglomerular cells. Their most characteristic feature is the absence of an axon and they therefore resemble amacrine cells in the retina. Granule cells have two principal spine-bearing dendrites that pass radially in the bulb; they appear to be GABAergic. The granule cell is likely to be a powerful inhibitory influence on the output neurones of the olfactory bulb.

## Olfactory tract and anterior perforated substance

As the olfactory tract approaches the anterior perforated substance (ventral striatopallidal region), it flattens and splays out as the olfactory trigone. Fibres of the tract continue from the caudal angles of the trigone as diverging medial and lateral olfactory striae, which border the anterior perforated substance (see Figs 25.20B, 25.32). The lateral olfactory stria follows the anterolateral margin of the anterior perforated substance to the limen insulae, where it bends posteromedially to merge with an elevated region, the gyrus semilunaris, at the rostral margin of the uncus in the temporal lobe. The lateral olfactory gyrus forms a tenuous grey layer covering the lateral olfactory stria; it merges laterally with the gyrus ambiens, part of the limen insulae. Together, the lateral olfactory gyrus and gyrus ambiens form the prepiriform region of the cortex, which passes caudally into the entorhinal area of the parahippocampal gyrus. The prepiriform and periamygdaloid regions and the entorhinal area (area 28) together make up the piriform cortex, the largest cortical olfactory area. The medial olfactory stria passes medially along the rostral boundary of the anterior perforated substance towards the medial continuation of the diagonal band of Broca and together they curve up on the medial aspect of the hemisphere, anterior to the attachment of the lamina terminalis. The anterior perforated substance is continuous laterally with the peduncle of the temporal stem and the amygdaloid complex, and medially with the septal region.

The main targets of the lateral olfactory tract are the piriform cortex, amygdala and rostral entorhinal cortex (Gottfried 2006). Neurones in the piriform cortex project widely to targets that include the neocortex (especially the orbitofrontal cortex), agranular insula, thalamus (especially the medial dorsal thalamic nucleus), hypothalamus, amygdala and hippocampal formation.

## WHITE MATTER OF THE CEREBRAL HEMISPHERES

The use of diffusion tensor imaging (DTI) as a tool with which to explore gross fibre architecture non-invasively has enabled the virtual dissection and visualization of those tracts in the living human brain; the impact of this technology, e.g. in neurosurgery, has been dramatic (Fernández-Miranda et al 2008a, Martino et al 2011). The extensive tractography literature should be consulted not only for anatomical details that are beyond the scope of this book but also for critical analyses of the methodological issues that compromise interpretation of image reconstructions, particularly where fibres change direction abruptly or bundles cross or 'kiss' each other. While an undoubtedly powerful tool, DTI does not provide information about functional or synaptic connections.

The white matter of the cerebral hemispheres is composed of three categories of myelinated axons. Association fibres link different cortical
areas in the same hemisphere; commissural fibres link corresponding cortical areas in the two hemispheres; and projection fibres connect the cerebral cortex with the corpus striatum, diencephalon, brainstem and spinal cord.

## ASSOCIATION FIBRES

Association fibres may be either short or long. They serve to connect regions of grey matter reciprocally, establishing spatially defined networks that determine function. Short association fibres (arcuate or U-fibres) may be entirely intracortical, passing between the walls of a sulcus, or they may pass subcortically between adjacent gyri. They connect clusters of cortical areas subserving similar functions, e.g. in the frontal lobe, short intralobar tracts connect the supplementary motor area and presupplementary motor area with posterior Broca's region (frontal 'aslant' tract); posterior orbitofrontal cortex with the anterior polar region (fronto-orbitopolar tract); and the posterior precentral cortex with anterior prefrontal cortex (frontal superior longitudinal fasciculus) (Catani et al 2012).

Fasciculi (bundles, tracts) of long association fibres connect anatomically distant yet functionally highly integrated areas of the ipsilateral cortex. It is assumed that they enable rapid feed-forward propagation of sensory input to the cortical circuitry responsible for the performance of complex behavioural and cognitive functions. They include the superior, middle and inferior longitudinal fasciculi, inferior fronto-occipital fasciculus, uncinate fasciculus, cingulum and fornix (Martino and de Lucas 2014). Individual variability in both the three-dimensional topography and size of these tracts has been reported.

## Superior longitudinal fasciculus

The superior longitudinal fasciculus (SLF) is composed of three subsets of fibres: a frontoparietal or horizontal segment; a temporoparietal or vertical segment; and a temporofrontal segment or arcuate fasciculus (Catani et al 2005, Fernández-Miranda et al 2008a, Martino and Brogna 2011) (Figs 25.35-25.37; see Fig. 25.41).

## Inferior longitudinal fasciculus

The inferior longitudinal fasciculus connects the anterior aspect of the temporal lobe with the posterior aspect of the occipital lobe and runs predominantly within the depth of the fusiform gyrus (see Fig. 25.35). It consists of a direct and a more lateral indirect pathway. The direct pathway connects with the anterior portions of the temporal gyri, fusiform and parahippocampal gyri and with the amygdala and hippocampus (Catani and Thiebaut de Schotten 2008). The indirect, occipitotemporal pathway consists of short U-shaped bundles connecting adjacent gyri in the inferior temporal and occipital convexities. The function of the inferior longitudinal fasciculus has not been

Fig. 25.35 A diffusion tensor imaging tractography reconstruction of the association bundles of a left hemisphere. Key: 1, inferior fronto-occipital fasciculus; 2, inferior longitudinal fasciculus; 3, uncinate fasciculus; 4 , arcuate fasciculus; 5 , horizontal segment of the superior longitudinal fasciculus; 6, vertical segment of the superior longitudinal fasciculus. Neurosurgery 2012, 71[ONS Suppl 1]:ons160-ons172.)

Fig. 25.37 A diffusion tensor imaging reconstruction of the superior longitudinal fasciculus (SupLF). Abbreviations: FPSeg, frontoparietal or horizontal segment; TFSeg, temporal-frontal segment; TPSeg, temporoparietal or vertical segment. (Courtesy of Prof. Edson Amaro Jr MD, Department of Radiology, University of São Paulo Medical School.)

Frontoparietal fibres run deeply underneath the frontoparietal operculum, connecting the posterior aspect of the inferior frontal gyrus (Broca's area) with the inferior parietal lobule (supramarginal and angular gyri). This frontoparietal portion of the superior longitudinal fasciculus appears to consist of three components: SLF I connects the superior parietal lobule and the precuneus with the premotor and prefrontal cortex (areas 6, 8 and 9, and the supplementary motor area); SLF II runs above the superior limiting sulcus of the insula and connects the angular gyrus with the dorsal premotor and prefrontal areas; and SLF III connects the supramarginal gyrus with the ventral premotor and prefrontal cortex (Broca's area) and corresponds to the horizontal segment itself (Makris et al 2005).

Temporal-parietal fibres connect the posterior portions of the superior and middle temporal gyri (Wernicke's area) with the inferior parietal lobule (Catani et al 2005, Fernández-Miranda et al 2008a, Martino and Brogna 2011). The temporal-frontal segment connects more diffuse areas of the posterior aspect of the temporal lobe with the posterior aspect of the frontal lobe and corresponds to the arcuate fasciculus. This longer portion of the superior longitudinal fasciculus is anatomically more defined posteriorly where it arches around the distal aspect of the lateral fissure (Bernal and Altman 2010, Bernal and Ardila 2009, Glasser and Rilling 2008, Martino and Brogna 2011). The superior longitudinal fasciculus thus forms an indirect pathway that links Broca's area with Wernicke's area through the inferior parietal lobule and by a direct and deeper pathway corresponding to the arcuate fasciculus.
established: there is speculation that it is involved in activities such as semantic language processing, face recognition and visual perception.

## Inferior fronto-occipital fasciculus

The inferior fronto-occipital fasciculus runs mostly along the temporal lobe and connects the dorsolateral aspects of the frontal and occipital lobes (Forkel et al 2014, Sarubbo et al 2013) (see Figs 25.35-25.36) Two components of the inferior fronto-occipital fasciculus have been described in postmortem brains dissected using the Klingler fibre dissection technique. A superficial, dorsal part connects the frontal lobe, superior parietal lobule and the posterior portions of the superior and middle occipital gyri. A deep, ventral subpart connects the frontal lobe with the posterior portion of the inferior occipital gyrus and the posterior temporobasal area. Anteriorly, the fasciculus is intermingled with other association fasciculi and with the most anterior fibres of the external capsule, the latter consisting mainly of claustrocortical fibres. Inferiorly, the fibres of the inferior fronto-occipital fasciculus cross the anteroinferior portion of the external capsule and claustrum in order to join the temporal stem, underneath the anterior aspect of the inferior limiting sulcus of the insula and just behind the limen insulae and the uncinate fasciculus. While the uncinate fasciculus corresponds to the anterior one-third of the temporal stem, the inferior fronto-occipital fasciculus corresponds to its posterior two-thirds, reaching the level of the lateral geniculate body underneath the inferior limiting sulcus (Martino et al 2010a, Martino et al 2010b). Within the temporal lobe, the inferior fronto-occipital fasciculus joins the sagittal stratum covering the temporal horn and the atrium superiorly and laterally, running just superior to the optic radiation and inferior to the auditory radiation (Türe et al 2000). According to the findings of studies based on subcortical brain mapping by intraoperative electrostimulation, the superior longitudinal fasciculus is related to phonological aspects of language, whereas the inferior fronto-occipital fasciculus is more related to its semantic aspect (Duffau 2008).

## Uncinate fasciculus

The uncinate fasciculus is a hook-shaped bundle that connects the anteromedial temporal lobe (superior, middle and inferior temporal gyri, cortical nuclei of the amygdala) with the orbitofrontal region (medial and posterior orbital cortex, gyrus rectus and subcallosal area) see Figs 25.35-25.36). The ventromedial part originates in the mesial temporal lobe and is connected to the medial frontal areas. The dorsolateral part originates from the superior and middle temporal gyri and reaches the orbital gyri (Wang et al 2011). Its fibres constitute a welldefined tract along the temporal stem, where it occupies its anterior one-third, immediately posterior to the limen insulae and anterior to the inferior fronto-occipital fasciculus, underneath the most anterior aspect of the inferior limiting sulcus of the insula. Both the uncinate fasciculus and the inferior fronto-occipital fasciculus intermingle with the most ventral fibres of the extreme and external capsules (FernándezMiranda et al 2008b).

## Middle longitudinal fasciculus

The middle longitudinal fasciculus runs in the white matter within the superior temporal gyrus, connecting the angular gyrus (area 39) with the superior temporal gyrus (area 22) up to the temporal pole (area 38) (Makris and Pandya 2009) (Fig. 25.38). It lies medial and ventral to segment II of the superior longitudinal fasciculus and the arcuate fasciculus; lateral and superior to the inferior fronto-occipital fasciculus; and dorsal to the inferior longitudinal fasciculus. Posteriorly, it is close to the inferior longitudinal fasciculus in the sagittal stratum. Its function is unknown: initial speculation that it is essential for language function has not been supported by electrostimulation mapping in glioma patients during surgical resection (De Witt Hamer et al 2011).

## Cingulum

The cingulum lies within the depth of the cingulate and parahippocampal gyri, starting below the rostrum of the corpus callosum within the paraolfactory gyri. It contains fibres of different length; the longest run from the anterior temporal gyrus to the orbitofrontal cortex, while short U-shaped fibres connect the medial frontal, parietal, occipital and temporal lobes and different portions of the cingulate cortex. The cingulum receives fibres of the anterior thalamic nuclei, superior frontal gyrus, paracentral lobule and precuneus along its curved course, which enlarge it significantly. The cingulum ends within the presubiculum and entorhinal cortex of the parahippocampal gyrus.

## Fornix

The fornix is the largest single pathway linking the hippocampus with distal brain sites. It contains many different hippocampal connections: some appear to be exclusively efferent, e.g. from the hippocampus to the anterior thalamic nuclei (anterior medial, anterior ventral and anterior dorsal thalamic nuclei), mammillary bodies, ventral striatum and prefrontal cortex; some are reciprocal e.g. with the medial septum and nucleus reuniens; some are exclusively afferent to the hippocampus, e.g. from the supramammillary and raphe nuclei and the locus coeruleus (Aggleton et al 2010, Jang and Kwon 2013, Jang and Kwon 2014). As a midline white matter tract, the fornix is particularly susceptible to involvement by tumours that favour this route of spread, e.g. glioblastoma multiforme, and to rotational shearing injuries responsible for diffuse axonal injury (Thomas et al 2011). The topography of the fornix is described with the hippocampal formation (Fig. 25.39).

## Temporoparietal fibre intersection area

The temporoparietal fibre intersection area has been described as a critical neural crossroads involving millions of axons (Martino et al 2013). Located deep to the angular gyrus and the posterior portions of the supramarginal, superior, middle and inferior temporal gyri, the temporoparietal fibre intersection area is traversed by the superior

Fig. 25.38 A diffusion tensor imaging tractography reconstruction of the middle longitudinal fasciculus (1) and inferior longitudinal fasciculus (2). (With permission from Martino J, De Lucas EM. Subcortical anatomy of the lateral association fascicles of the brain: a review. Clin Anat 2014 May;27(4):563-9.)

Fig. 25.39 The location of the fornix and its divisions. The blue arrows show fornical connections that are solely efferent from the hippocampal formation, the green arrows show fornical connections that are solely afferent to the hippocampal formation, and the red arrows show reciprocal connections within the fornix. Abbreviations: AC, anterior commissure; ATN, anterior thalamic nuclei; Hypoth, hypothalamus; LC, locus coeruleus; LD, thalamic nucleus lateralis dorsalis; MB, mammillary bodies; MTT, mammillothalamic tract; NAcc, nucleus accumbens; RE, nucleus reuniens; SUM, supramammillary nucleus. (With permission from Aggleton JP, O'Mara SM, Vann SD et al, Hippocampal-anterior thalamic pathways for memory: uncovering a network of direct and indirect actions, Eur J Neurosci 2010 Jun;31(12):2292-307.)
longitudinal fasciculus (horizontal portion and arcuate fasciculus), middle longitudinal fasciculus, inferior longitudinal fasciculus, inferior fronto-occipital fasciculus, optic radiations and tapetum. Given the organizational complexity of the area, a lesion within the temporoparietal fibre intersection area is likely to produce disconnections involving more than one fasciculus.

## COMMISSURAL FIBRES

## Corpus callosum

The corpus callosum contains 150-200 million fibres and is the largest fibre pathway of the brain. It forms an anteroposterior midline arch approximately 10 cm long and divided into four portions for descriptive purposes, namely: rostrum, genu, trunk and splenium (see Fig. 25.3). The genu corresponds to the anterior wall of the frontal horn of the lateral ventricle; the rostrum corresponds to its floor.

The genu is the most anterior portion, and is located approximately 4 cm from the frontal poles. The ventral aspect of the genu curves posteroinferiorly in front of the septum pellucidum, then diminishes rapidly in thickness and is prolonged to the upper end of the lamina terminalis as the rostrum. Posterior to the genu, the trunk of the corpus callosum arches backwards, convex above, and ends posteriorly in the expanded splenium. This is the thickest part of the corpus callosum and is located approximately 6 cm from the occipital poles. Superiorly, the median region of the trunk of the corpus callosum forms the floor of the longitudinal fissure, supporting the anterior cerebral arteries and lying underneath the lower border of the falx cerebri, which may contact it behind. On each side, the trunk is overlapped by the cingulate gyrus, from which it is separated by the callosal sulcus. The inferior surface of the corpus callosum is concave in its long axis, and attached to the septum pellucidum along the trunk, genu and rostrum. It is fused with the crura of the fornix and with the commissure of the fornix underneath the splenium. The inferior surface of the splenium covers the pineal region.

The layers of the septum pellucidum are attached superiorly to the callosal trunk, anteriorly to the genu, and inferiorly to the rostrum (anteriorly) and the bodies of the fornices (posteriorly); the two layers correspond to the medial walls of the frontal horns and bodies of the lateral ventricles. Both layers of the septum pellucidum end at the level where the bodies of the fornices become crura and attach to the inferior surface of the splenium, thereby establishing the anatomical limit between the lateral ventricular body and the atrium within each hemisphere (Rhoton 2003).

The splenium of the corpus callosum overhangs the posterior ends of the thalami, the pineal gland and tectum, but is separated from them by several structures. On each side the crus of the fornix and gyrus
fasciolaris curve up to the splenium. The crus continues forwards on the inferior surface of the callosal trunk, but the gyrus fasciolaris skirts above the splenium, then rapidly diminishes into the indusium griseum.

A superior and an inferior layer of tela choroidea advance below the splenium through the transverse fissure, forming the velum interpositum cistern within the roof of the third ventricle and between the thalami, just below the bodies of the fornices; it contains the distal branches of the medial posterior choroidal arteries and the internal cerebral veins. The internal cerebral veins join together distally giving rise to the great cerebral vein (of Galen), which runs upwards around the posterior aspect of the splenium to join the straight sinus located along the junction between the falx and the tentorium cerebelli.

Axons of the corpus callosum radiate into the white matter core of each hemisphere, thereafter dispersing to the cerebral cortex. Commissural fibres forming the rostrum extend laterally, below the anterior horn of the lateral ventricle, connecting the orbital surfaces of the frontal lobes. Fibres in the genu curve forwards, as the forceps minor, to connect the lateral and medial surfaces of the frontal lobes (Fig. 25.40). Fibres of the trunk pass laterally, intersecting with the projection fibres of the corona radiata to connect wide neocortical areas of the hemispheres. Fibres of the trunk and splenium, which form the roof and lateral wall of the atrium and the lateral wall of the inferior horn of the lateral ventricle, constitute the tapetum, which runs underneath the optic radiation within the sagittal stratum. The remaining fibres of the splenium curve back into the occipital lobes as the forceps major.

Interhemispheric connections through the corpus callosum do not all represent a simple linking of loci in one hemisphere with the same loci in the other. In areas containing a clear representation of a contralateral sensorium (e.g. body surface, visual field), only those areas that are functionally related to midline representation are linked to the contralateral hemisphere. This is most clearly seen for the visual areas, where the cortex containing the representation of each midline retinal zone is linked to its counterpart on the contralateral side. A similar arrangement is seen in somatic areas, where the trunk representation is callosally linked, but the peripheral limb areas (hand and foot) are not. Connections that link the same, or similar, areas on each side are termed homotopic connections. The corpus callosum also interconnects heterogeneous cortical areas on the two sides (heterotopic connections). These may serve to connect functionally similar, but anatomically different, loci in the two hemispheres, and/or to connect functional areas in one hemisphere with regions that are specialized for a unilaterally confined function in the other.

## Anterior commissure

The anterior commissure is a compact bundle, about 4 mm in diameter, containing approximately 3.5 million myelinated axons (Peltier et al 2011). It runs within the basal forebrain and fans out laterally within the temporal lobe. It is believed to connect areas that include the olfactory bulb and anterior olfactory nucleus; the anterior perforated substance, olfactory tubercle and diagonal band of Broca; the prepiriform cortex; the entorhinal area and adjacent parts of the parahippocampal gyrus; part of the amygdaloid complex (especially the nucleus of the lateral olfactory stria); the bed nucleus of the stria terminalis and the nucleus accumbens; and the anterior regions of the middle and inferior temporal gyri.

The anterior commissure has the shape of a classic bicycle handlebar. It crosses the midline just ventral to the supraoptic recess of the third ventricle, immediately anterior to the major component of the column of the fornix that projects to the mammillary body, and posterior to the smaller components of the fornix that project to the septal nuclei (see Figs 25.27A, 25.28). At this point, the anterior commissure bulges inside the third ventricle, just underneath the interventricular foramen. The lamina terminalis is attached superiorly to the midline segment of the anterior commissure and inferiorly to the upper surface of the optic chiasma; the optic recess of the third ventricle is the cleft between the lamina terminalis and the midportion of the superior surface of the chiasma.

Each side of the anterior commissure is composed of a well-defined posterolateral bundle (the hemispheric part) and a smaller, anterior component (the olfactory part) (Déjérine 1895). The anterior component curves forwards and vertically through the anterior perforated substance towards each olfactory tubercle. The hemispheric component curves posterolaterally, passing through a deep groove on the anteroinferior aspect of the globus pallidus (see Fig. 25.31), and fanning out mostly to the anterior part of the temporal lobe, including the parahippocampal gyrus, but also reaching the occipital lobe posteriorly.

Fig. 25.40 The superior aspect of the corpus callosum revealed by partial removal of the cerebral hemispheres.

When passing under the inferior limiting sulcus of the insula, superior to the temporal horn of the lateral ventricle, the fibres of the anterior commissure join the temporal stem, merging with the fibres of the uncinate and inferior fronto-occipital fasciculi. They pass posteriorly as the sagittal stratum, together with the inferior fronto-occipital fasciculus and the fibres of the optic radiation, over the lateral aspect of the temporal horn and ventricular atrium. Within the temporal stem, the fibres of the anterior commissure are mostly medial to the uncinate fasciculus; both are inferior to the inferior fronto-occipital fasciculus. Within the sagittal stratum, they intermingle but run predominantly below the inferior fronto-occipital fasciculus, superior to the fibres of the optic radiation. The line between the anterior and posterior commissures, the AC-PC line, is a very important landmark in stereotactic atlases, used when localizing neuroanatomical targets for stereotactic neurosurgical procedures.

## Hippocampal commissure

The hippocampal commissure (commissure of the fornix) is a thin triangular sheet of fibres that lies between the crura of the fornices, connecting the hippocampi. It is situated underneath and attached to the splenium, overhanging the pineal region.

## Posterior commissure

The posterior commissure lies below the pineal recess of the third ventricle, crossing the midline along the caudal lamina of the pineal stalk, at the level of the upper aspect of the cerebral aqueduct. It contains both decussating and commissural fibres that connect diencephalic and mesencephalic nuclei: the interstitial and dorsal nuclei of the posterior commissure located within the periventricular grey matter; nucleus of Darkschewitsch of the periaqueductal grey matter; interstitial nucleus of Cajal located at the rostral end of the oculomotor nucleus and closely linked with the medial longitudinal fasciculus; and posterior thalamic, pretectal, tectal and habenular nuclei.

## Habenular commissure

The habenular commissure lies between the habenulae, small protuberances of the thalami located at the distal ends of the striae medullaris. It contains both decussating fibres (e.g. tectohabenular) and commissural fibres (connecting the habenular nuclei). The habenular nuclei receive olfactory inputs from the septal nuclei, and transmit them
mainly to the interpeduncular nucleus of the mesencephalon and to the rostral salivatory nucleus in the floor of the fourth ventricle to activate reflex salivation (Peltier et al 2011). The pineal gland is attached superiorly to the habenular commissure and inferiorly to the posterior commissure, and so the pineal recess of the third ventricle lies between these two commissures.

## PROJECTION FIBRES

Projection fibres connect the cerebral cortex with lower levels in the brain and spinal cord. They include large numbers of both corticofugal and corticopetal projections. Corticofugal projection fibres converge from all directions to form the dense subcortical white matter mass of the corona radiata (Figs 25.41-25.42). Large numbers of fibres pass to the corpus striatum and the thalamus, intersecting commissural fibres of the corpus callosum en route. The corona radiata is continuous with the internal capsule, which contains the majority of the cortical projection fibres.

## Internal capsule

The internal capsule has the shape of a V in horizontal section (axial images), with its vertex (genu) located medially between the head of the caudate nucleus and the thalamus. For descriptive purposes, the internal capsule is arbitrarily divided into five parts: anterior limb, located between the putamen and the head of the caudate nucleus; genu, approximating to its vertex; posterior limb, located between the putamen and the thalamus; retrolenticular or retrolentiform portion, located posterior to the putamen; and sublenticular (or sublentiform) portion, located inferior to the putamen (see Fig. 25.19; Figs 25.43-25.44).

Cortical efferent fibres of the internal capsule converge as they descend. Fibres derived from the frontal lobe tend to pass posteromedially, while temporal and occipital fibres pass anterolaterally. Many, but not all, corticofugal fibres pass into the crus cerebri of the ventral midbrain. Here, corticospinal and corticonuclear fibres are located in the middle half of the crus. Frontopontine fibres are located medially, whereas corticopontine fibres from temporal, parietal and occipital cortices are found laterally.

The anterior limb of the internal capsule contains frontopontine fibres, which arise from the cortex in the frontal lobe. They synapse with cells in the pontine nuclei. Axons of these cells enter the opposite cerebellar hemisphere through the middle cerebellar peduncle.

Ascending thalamocortical fibres
Descending cortical efferent fibres to thalamus, brainstem and spinal cord
Fig. 25.44 A horizontal section through the internal capsule illustrating its main fibre components.

Anterior thalamic radiations interconnect the medial and anterior thalamic nuclei and various hypothalamic nuclei and limbic structures with the frontal cortex. The genu of the internal capsule is usually regarded as containing corticobulbar fibres, which are mainly derived from area 4 and terminate mostly in the contralateral motor nuclei of cranial nerves. Anterior fibres of the superior thalamic radiation, between the thalamus and cortex, also extend into the genu. The posterior limb of the internal capsule includes the corticospinal or pyramidal tract. The fibres concerned with the upper limb are anterior, and the more posterior regions contain fibres representing the trunk and lower limbs.

The corticospinal tract fibres that arise within the precentral gyrus are disposed as a fan throughout the corona radiata and converge towards the internal capsule genu and posterior limb (see Figs 25.31, 25.41; Fig. 25.45). The corticospinal fibres' transition between the corona radiata and the internal capsule is defined medially by the superior aspect of the body of the caudate nucleus and the fibres of the splenium, collectively forming the lateral upper edge of the body of the lateral ventricle, and laterally by the superior aspect of the putamen and the superior insular sulcus. To join the internal capsule, as well as

Fig. 25.45 A diffusion tensor imaging reconstruction of the corticospinal tracts of the right (red) and left (green) cerebral hemispheres. (Courtesy of Prof. Edson Amaro Jr MD, Department of Radiology, University of São Paulo Medical School.)
converging, the corticospinal tract fibres undergo an internal rotation of approximately 90 degrees, since the main axes of the precentral gyrus and of the internal capsule genu and posterior limb are almost perpendicular. Throughout their convergence and rotation the fibres keep their somatotopical motor arrangement, originated according to the homuncular cortical representation, and end up having an anteriorcranial to a posterior-caudal disposal along the genu and the anterior portion of the internal capsule posterior limb. Radiologically and surgically, this important portion of the internal capsule can have its topography estimated from the position of the interventricular foramen (of Monro) that lies medially and adjacent to the internal capsule genu, which contains the corticonuclear bundle.

Other descending axons include frontopontine fibres, particularly from areas 4 and 6, and corticorubral fibres, which connect the frontal lobe to the red nucleus. Most of the posterior limb also contains fibres of the superior thalamic radiation (the somaesthetic radiation) ascending to the postcentral gyrus.

The retrolenticular part of the internal capsule contains parietopontine, occipitopontine and occipitotectal fibres. It also includes the posterior thalamic radiation and the optic radiation, and interconnections between the occipital and parietal lobes and caudal parts of the thalamus, especially the pulvinar.

The fibres of the optic radiation arise from the lateral geniculate body and the pulvinar, join the retrolenticular and the sublenticular parts of the internal capsule, run within the sagittal stratum over the inferior horn and ventricular atrium, and project posteriorly, passing superiorly and inferiorly to the posterior horn as part of the posterior thalamic peduncle to reach both the superior and inferior lips of the calcarine sulcus. Within the temporal lobe, the fibres of the optic radiation are located along the depths of the superior and middle temporal gyri about 2 cm from the brain surface, inferior to the vertical segment of the superior longitudinal fasciculus, and always superior to the inferior temporal sulcus. In coronal sections, the optic radiation appears predominantly flat anteriorly and comma-shaped posteriorly. Its fibres are divided into anterior, central and posterior bundles.

The sublenticular part of the internal capsule contains temporopontine and some parietopontine fibres, the auditory radiation from the medial geniculate body to the superior temporal and transverse temporal gyri (areas 41 and 42), and a few fibres that connect the thalamus with the temporal lobe and insula. Fibres of the auditory radiation sweep anterolaterally below and behind the lentiform complex to reach the cortex, and are superior to the inferior horn, the atrium and the optic radiation.

## OVERVIEW OF CORTICAL CONNECTIVITY

All neocortical areas have axonal connections with other cortical areas on the same side (association fibres) and the opposite side (commissural fibres), and with subcortical structures (projection fibres). The primary somatosensory, visual and auditory areas give rise to ipsilateral corticocortical connections to the association areas of the parietal, occipital and temporal lobes, respectively, which then progressively project towards the medial temporal limbic areas: notably, the parahippocampal gyrus, entorhinal cortex and hippocampus. Thus, the first (primary) somatic sensory area (SI) projects to the superior parietal cortex (Brodmann's area 5), which in turn projects to the inferior parietal cortex (area 7). From here, connections pass to cortex in the walls of the superior temporal sulcus, and so on to the posterior parahippocampal gyrus, and on into limbic cortex. Similarly, for the visual system, the primary visual cortex (area 17) projects to the parastriate cortex (area 18), which in turn projects to the peristriate region (area 19). Information then flows to inferotemporal cortex (area 20), to cortex in the walls of the superior temporal sulcus, then to medial temporal cortex in the posterior parahippocampal gyrus, and so to limbic areas. The auditory system shows a similar progression from primary auditory cortex to temporal association cortex, and so to the medial temporal lobe.

In addition to this stepwise outward progression from sensory areas through posterior association cortex, connections also occur at each stage with parts of the frontal cortex. Thus, taking the somatic sensory system as an example, primary somatic sensory cortex (SI) in the postcentral gyrus is reciprocally connected with the primary motor cortex (area 4) in the precentral gyrus. The next step in the outward progression, the superior parietal lobule (area 5), is interconnected with the premotor cortex (area 6), and this in turn is connected with area 7 in the inferior parietal lobule. This has reciprocal connections with prefrontal association cortex on the lateral surface of the hemisphere (areas 9 and 46), and temporal association areas, which connect with more anterior prefrontal association areas and, ultimately in the sequence, with orbitofrontal cortex. Similar stepwise links exist between areas on the visual and auditory association pathways in the occipitotemporal lobe and areas of the frontal association cortex. The connections between sensory and association areas are reciprocal.

All neocortical areas are connected with subcortical regions, although their density varies between areas. First among these are connections with the thalamus. All areas of the neocortex receive afferents from more than one thalamic nucleus, and all such connections are reciprocal. The vast majority of, if not all, cortical areas project to the striatum, tectum, pons and brainstem reticular formation. Additionally, all cortical areas are reciprocally connected with the claustrum; the frontal cortex connects with the anterior part and the occipital lobe with the posterior part.

All cortical areas receive topographically organized cholinergic projections from the basal forebrain, noradrenergic fibres from the locus coeruleus, serotoninergic fibres from the midbrain raphe nuclei, dopaminergic fibres from the ventral midbrain, and histaminergic fibres from the posterior hypothalamus.

Different cortical areas have widely different afferent and efferent connections. Some have connections that are unique, e.g. the corticospinal tract arises from pyramidal cells in a restricted area around the central sulcus.

Widely separated, but functionally interconnected, areas of cortex share common patterns of connections with subcortical nuclei, and within the neocortex. For example, contiguous zones of the striatum, thalamus, claustrum, cholinergic basal forebrain, superior colliculus and pontine nuclei connect with anatomically widely separated areas in the prefrontal and parietal cortex, which are themselves interconnected. In contrast, other functionally distinct cortical regions, e.g. areas in the temporal and parietal cortex, do not share such contiguity in their subcortical connections.

## THE TEMPORAL STEM AND THE SAGITTAL STRATUM

The term temporal stem is derived from the appearance of temporal lobe fibres on coronal sections of the brain (Horel 1978, Choi et al 2010). As these fibres converge towards the medial part of the temporal lobe along the inferior aspect of the inferior limiting sulcus of the insula, they resemble the stem of an inclined tree. The terms temporal stem and sagittal stratum are a means of conceptualizing the arrangement of fibre tracts within the temporal lobe. They are of significance
particularly in the interpretation of neuroimages and in temporal lobe microneurosurgery. Although there is debate as to their exact composition, in broad outline, the temporal stem lies anterior to the inferior horn and connects anteromedial temporal structures to the basolateral frontal portion of the hemisphere. The sagittal stratum corresponds to fibres running along the inferior limiting sulcus of the insula forming the roof and lateral walls of the inferior horn and ventricular atrium.

## CEREBRAL CENTRAL CORE

The cerebral central core, lying between the insula and the midline, contains all the white matter fibres and grey matter nuclei that connect the cerebral cortex with subcortical nuclei in the brainstem and spinal cord. It therefore includes the extreme, external and internal capsules; claustrum; putamen; globus pallidus; caudate nucleus; amygdala; diencephalon; substantia innominata; fornix; anterior commissure; mammillothalamic tract; fasciculus retroflexus; thalamic peduncles, including optic and auditory radiations; ansa peduncularis; thalamic fasciculus; and lenticular fasciculus. On either side, the central core is attached to the rest of the cerebral hemisphere by the cerebral isthmus, a bundle of white matter fibres located between the dorsolateral margin of the caudate nucleus and the full circumference of the circular sulcus of the insula. The rostral fibres of the corpus callosum are included in the frontal portion of the cerebral isthmus.

The extreme capsule lies beneath the superior and inferior limiting sulci of the insula (see Fig. 25.48A). It runs between the inferior frontal gyrus (Broca's area) and the superior temporal gyrus, extending into the inferior parietal lobule (Wernicke's area); its outer layer contains U-shaped fibres connecting individual insular gyri and the frontoparietal and temporal operculi. The extreme capsule has been described as distinguishable from adjacent fasciculi (uncinate fasciculus; external capsule; middle longitudinal fasciculus; arcuate bundle; components of the superior longitudinal fasciculus and inferior longitudinal fasciculus) (Makris and Pandya 2009); alternatively, it has been described as having a deeper portion that consists of fibres of the occipitofrontal and uncinate fasciculi (Wang et al 2011).

The claustrum (meaning enclosed or hidden space) is a fine lamina of grey matter beneath the extreme capsule, along the entire rostrocaudal extent of the striatum (Fernández-Miranda et al 2008b) (see Fig. 25.19). Its ventral portion is thinner and populated by small islands of grey matter within the white matter; its dorsal portion is thicker and better defined. Little is known about the connections and functional significance of the claustrum in the human brain; several hypotheses have been put forward (Mathur 2014, Smythies et al 2014). The external capsule lies beneath the claustrum and consists mainly of fibres originating within the claustrum; anteriorly, its fibres intermingle with those of the uncinate and inferior occipitofrontal fasciculi (FernándezMiranda et al 2008b).

## CEREBRAL ASYMMETRY

The two human cerebral hemispheres are not simply mirror images of each other. Much information on the lateralization of cerebral function has come from studying patients in whom the corpus callosum had been divided (commissurotomy) as a treatment for intractable epilepsy (Sperry 1974), and from those rare individuals who lack part, or all, of their corpus callosum. Commissurotomy produces the 'split-brain' syndrome, which has provided evidence supporting the notion that abilities or functions are predominantly associated with one or other hemisphere. Knowledge of the lateralization of function has been advanced significantly by functional brain imaging techniques, such as positron emission tomography (PET) and fMRI.

The left hemisphere usually prevails for verbal and linguistic functions, for mathematical skills and for analytical thinking. The right hemisphere is mostly non-verbal. It is more involved in spatial and holistic or 'Gestalt' thinking, in many aspects of musical appreciation and in some emotions. Memory also shows lateralization. Thus, verbal memory is primarily a left hemisphere function, while non-verbal memory is represented in the right hemisphere. These asymmetries are relative, not absolute, and vary in degree according to the function and individual concerned. Moreover, they apply primarily to right-handed men. Those men with left-hand preference, or mixed handedness, make up a heterogeneous group, which (as an approximation) shows reduced or anomalous lateralization, rather than a simple reversal of the situation in right-handers. For example, speech representation can occur in either or both hemispheres. Women show less functional asymmetry, on average, than men.

The most anterior fibres in the tree correspond to the upper extension of the posterior aspect of the anterior half of the uncus, and appear as a true neural peduncle located between the limen insulae and the inferior horn of the lateral ventricle (Figs 25.46-25.47). The external surface of this peduncle is the transverse insular gyrus along the limen insulae, connecting the insula to the posteromedial orbital lobule. This gyrus harbours, from anterior to posterior, the anterobasal aspect of the extreme capsule (subcortical insular white matter); the uncinate fasciculus (connecting mesial temporal structures with the fronto-orbital region); the inferior fronto-occipital fasciculus (runs immediately posterior to the uncinate fasciculus); the ventral amygdalofugal fibres of the ansa peduncularis; the anterior commissure; and, more medially, the superior extension of the amygdala towards the globus pallidus.

The ansa peduncularis sweeps around the cerebral peduncle and contains amygdaloseptal, amygdalohypothalamic and amygdalothalamic fibres (Gloor 1997, Peuskens et al 2004). The extracapsular thalamic peduncle lies immediately posterior and superior to the ansa peduncularis, carrying fibres from the amygdala and the cortex of the anterior temporal region to the medial thalamic nucleus and the hypothalamus. As its name implies, the extracapsular thalamic peduncle runs within the ventral striatopallidal region and not through the internal capsule. The ansa lenticularis runs posterior to the extracapsular thalamic peduncle. The amygdala extends posteriorly, partially covering the head of the hippocampus. The stria terminalis runs along the roof of the inferior horn medially to the tail of the caudate nucleus, towards the bed nucleus of the stria terminalis (Párraga et al 2012).

Fig. 25.46 A, The lower and upper portions of the frontal and temporal opercula respectively have been removed to reveal the relationships between opercular and insular structures. The central insular sulcus courses superficial to, and almost parallel with, the central sulcus. B, Sagittal section, dissected to show the relationship between the insula and the temporal horn. The temporal stem is between the lower circular sulcus of the insula and the roof of the temporal horn. Abbreviations: AccGyr, accessory gyrus; ALG, anterior long gyrus; AntLimSul, anterior limiting sulcus; ASG, anterior short gyrus; CentInsSul, central insular sulcus; CentSul, central sulcus; ChPlex, choroid plexus; HippoBody, body of hippocampus; HippoHead, head of hippocampus; InfLimSul, inferior limiting sulcus; LimenIns, limen insula; MSG, middle short gyrus; ParsOper, pars opercularis; ParsTri, pars triangularis; PLG, posterior long gyrus; PostcentGyr, postcentral gyrus; PrecentGyr, precentral gyrus; PSG, posterior short gyrus; TempStem, Temporal stem. (With permission from Wang F, Sun T, Li X, et al, Microsurgical and tractographic anatomical study of insular and transsylvian transinsular approach, Neurol Sci 2011 Oct;32(5):865-74.)

(Courtesy of Richard Gonczalo Párraga).

Anteriorly, the tail of the caudate nucleus merges with the amygdala, still within the roof of the inferior horn. A ventral extension of the centromedial amygdala, running along the basal forebrain and also towards the bed nucleus of the stria terminalis, has also been described. The amygdala is situated inside the anterior half of the uncus, which means that all these extensions of the amygdala and the fibres and cortex that lie over them have to be surgically severed in order to disconnect the anterior part of the temporal lobe; on that basis, these structures are therefore included within the anteromedial temporal peduncle.

The sagittal stratum lies beneath the subcortical white matter of the temporal lobe and the temporal extension of the superior longitudinal fasciculus; its fibres are organized in layers. From superior to inferior, the layers are the fibres of the inferior fronto-occipital fasciculus, which
ascend and vanish within the external capsule; the fibres of the anterior commissure, which group more anteriorly and medially; the posterior and inferior thalamic peduncles, which include the auditory and optic radiations; and the tapetum (Ludwig and Klingler 1956, Türe et al 2000). The tapetum lies under the optic radiation and is separated from the ventricular cavity only by the ependymal; it connects both posterior temporal areas (Catani et al 2012) (Fig. 25.48). The fibres in the anterior commissure leave the sagittal stratum and join the anterior and mesial temporal peduncle. The most anterior fibres in Meyer's loop reach the anterior temporal peduncle but stay lateral to it and do not group with its fibres. Any dorsal temporal surgical approach to the inferior horn or to the ventricular atrium will divide the sagittal stratum, including the fibres of the optic radiation, to some degree.

Fig. 25.48 A, A lateral view of the left hemisphere: the vertical segment of the superior longitudinal fasciculus (SupLongFasc) has been removed. The tapetum is exposed via a window in the sagittal stratum (SagStr). B, A medial view of the left hemisphere: the ependyma of the lateral ventricle has been removed. The tapetum lies underneath the optic radiation along the lateral wall of the atrium. Other abbreviations: AntCom, anterior commissure; CorpCall, corpus callosum; CoRa, corona radiata; ExtCap, external capsule; ExtrCap, extreme capsule; Hab, habenula; LoG, long gyri of insula; MaBo, mammillary body; OcN, oculomotor nerve; PiGl, pineal gland; PostComm, posterior commissure; StrMedTh, stria medullaris thalami; SubNucl, subthalamic nucleus; ThRad, thalamic radiation. (Courtesy of Richard Gonczalo Párraga. Adapted from: Párraga RG, Ribas GC, Welling LC, Alves RV, de Oliveira E. Microsurgical anatomy of the optic radiation and related fibres in 3-dimensional images. Neurosurgery 2012, 71[ONS Suppl 1]:ons160-ons172.)

Certain cerebral anatomical asymmetries are apparent at both the macroscopic and histological levels. One of the most notable is in the planum temporale, which is usually larger on the left than the right side. Subtle asymmetries in the superior temporal lobe have been demonstrated in terms of overall size and shape, sulcal pattern and cytoarchitecture, and at the neuronal level. It seems reasonable to assume that these differences underlie some of the functional asymmetry for language representation.

Asymmetries in areal size, cytoarchitecture or neurocytology occur elsewhere in the cerebral cortex as well as subcortically. For example, many brains have a wider right frontal pole and a wider left occipital pole. Brodmann's area 45 in the inferior frontal lobe, corresponding to Broca's area, contains a population of large pyramidal neurones that are found only on the left side. The cortical surface surrounding the central sulcus is larger in the left hemisphere, especially in the areas containing the primary somatosensory and motor maps of the arm, suggesting that one cerebral manifestation of hand preference is a larger amount of neural circuitry in the relevant parts of the cortex. Histological asymmetries are also found in areas that are not usually considered to be closely related either to language or to handedness. The left entorhinal cortex has significantly more neurones than the right.

## COGNITIVE FUNCTIONS

The cognitive or high cortical functions of perception, spatial analysis, learned skilled movement, language, memory, problem-solving (all executive functions) and emotion are organized within the cerebral hemispheres (Fig. 25.49). According to Mesulam, five well-defined networks are most relevant to clinical practice: a left-dominant perisylvian network for language; a right-dominant parietofrontal network for spatial cognition; an occipitotemporal network for face and object recognition; a limbic network for retentive memory; and a prefrontal network for attention and comportment (Mesulam 2011, Catani et al 2005).

The organization of cognitive functions is highly localized and involves the association areas of the neocortex and the limbic system. The parietal association areas are concerned with the perceptual recognition of objects by kinaesthetic and visual stimuli, and the visuospatial orientation of the body and its parts in space. Large focal lesions (particularly of the right cerebral hemisphere) and bilateral lesions (e.g. in Alzheimer's disease) lead to visual disorientation in space, with an inability to navigate the environment, locate objects, and dress in relationship to body parts. Acute focal lesions (especially of the right cerebral hemisphere) lead to neglect of the body and space in the opposite side of corporeal and visual space (neglect). Failure of recognition of objects by touch or vision represents tactile or visual agnosia. The parietal-temporal cortical connections are particularly important for visual object recognition and lesions lead to an inability to identify, copy or match objects (apperceptive visual agnosia).

The anterior superior parts of the parietal lobes and the related connections with the premotor areas, including the supplementary motor areas, are concerned in the execution of skilled movements through development and experience (praxis). Lesions of these areas lead to contralateral loss of skilled movements of the face, mouth and limbs (ideomotor apraxia).

The anterior temporal neocortex (middle and inferior temporal gyri) is concerned in ascribing meaning to perceptual stimuli. Bilateral lesions of these areas (e.g. in semantic dementia) lead to loss of recognition of words and percepts. Unilateral lesions in the left hemisphere particularly affect word meaning and naming (semantic or transcortical aphasia), whereas lesions of the right hemisphere lead primarily to loss
of recognition of visual percepts (associative visual agnosia) and faces (prosopagnosia), and objects can be copied or matched but not identified for meaning or name.

The premotor areas (frontal association cortex, parietal and temporal association cortex) combine to form the 'language area' in the cortex that surrounds the lateral fissure in the left dominant hemisphere (Ojemann et al 1989). Focal lesions of the language area lead to breakdown in verbal communication (aphasia) and loss of the ability to read (alexia), write (agraphia) and calculate (acalculia). The aphasic syndromes of Broca, conduction and Wernicke correspond to lesions within the frontal, parietal and temporal cortical areas, respectively. Lesions of the parietal cortex immediately posterior to the language area (angular gyrus) can lead to alexia, agraphia and acalculia, in the absence of aphasia.

The prefrontal association cortex and its connections with the limbic system, and in particular, with the amygdala, are essential for problem-solving behaviour (executive functions) and the affective motivational aspects of behaviour. Bilateral lesions of these areas (e.g. in frontotemporal dementia) lead to the 'frontal lobe syndrome', in which there is a radical change in personality, with loss of reason, judgement and insight, together with loss of personal and social feelings (sympathy and empathy). The restricted involvement of the orbital frontal areas and limbic connections leads to overactivity and disinhibition (pseudo-psychopathic behaviour). Spread of lesions into the dorsolateral surface of the prefrontal area leads to an inert, apathetic state (pseudo-depression). Unilateral focal lesions of the prefrontal areas are not usually associated with obvious cognitive or behavioural change.

The limbic allocortex and its connections comprising the Papez circuit (hippocampus, mammillary body, anterior nucleus of the thalamus and cingulate gyrus) are thought to be responsible for the laying down of autobiographical (episodic) memory. Medial diencephalic structures such as the nucleus reuniens and retrosplenial cortex may also have mnemonic functions independent of the hippocampus, suggesting that there may be parallel, disynaptic routes enabling prefrontal control of hippocampal activity (Aggleton 2014). Bilateral lesions (e.g. in Alzheimer's disease) or following alcoholic encephalopathy (Korsakoff psychosis) lead to the loss of the ability to learn new information (anterograde amnesia) or remember experiences in the relatively recent past (retrograde amnesia), although perceptual information about the world and language (semantic memory) is preserved because the temporal neocortical association areas are spared.

Patients with chronic epilepsy who have undergone surgical section of the corpus callosum in order to relieve their seizures portray few difficulties under normal circumstances. However, when these 'splitbrain' patients undergo psychological testing, the two halves of the brain appear to behave relatively autonomously, e.g. visual information directed to the right cerebral hemisphere alone does not evoke a verbal response, and consequently individuals cannot name objects or read words solely presented to the left visual field. A single lesion in the splenium of the corpus callosum interrupting white matter tracts running from the visual cortices of both hemispheres to the left angular gyrus, or lesions to the splenium and the left primary visual cortex, or lesions involving the splenium and the lateral geniculate nucleus, either by posterior cerebral artery territory infarct, tumours or demyelinating disease such as multiple sclerosis, lead to the posterior disconnection syndrome of 'alexia without agraphia'. Disconnection of visual processes in the right hemisphere from the verbal processes of the dominant left cerebral hemisphere means that the language zone is robbed of its visual inputs but remains intact, and so these individuals speak and write without difficulty but cannot understand written material (alexia).

# The resting human brain and the predictive potential of the default mode network 

## COMMENTARY <br> 3.1

Stefano Sandrone

Wilton Street, London, August 1858. Having completed the main text of Anatomy: Descriptive and Surgical, Henry Gray opened the preface to his book with the following sentence: 'This Work is intended to furnish the Student and Practitioner with an accurate view of the Anatomy of the Human Body, and more especially the application of this science to Practical Surgery.' At that time, the idea of generating a non-invasive view of the human brain and of using that view to predict imminent events within the brain was inconceivable. Today, view-based predictions are tangibly close to realization.

The development of neuroimaging techniques, such as computed axial tomography (CAT scanning), functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), has been one of the major biomedical achievements of the past hundred years. These techniques gave new impetus to medicine, neurology, psychiatry, psychology, philosophy and related fields by providing two unprecedented types of insight. On the one hand, by yielding structural images of brain anatomy, these techniques enabled the detection of pathological abnormalities, and hence constituted a major breakthrough in medical diagnosis. On the other hand, as well as providing functional insights, neuroimaging has shed ample light on philosophical questions that are intimately linked to 'who we are' and are as old as mankind.

While medicine was focused on diagnostic imaging and neuroscience in the designing of experimental paradigms that might isolate human emotion, thoughts, language, and consciousness, etc. (i.e. taskbased modes of investigation), ancillary fMRI recordings of the brain during resting state, namely a behavioural state characterized by quiet repose with the eyes either closed or open, with or without visual fixation (Raichle 2009), showed regular and low-frequency cerebral fluctuations indicating that the brain was active even when in a resting state
(Biswal et al 1995, Biswal 2012). It is true that a similar brain fluctuation had already been recorded in 1929 by means of the electroencephalogram (Berger 1929, Raichle and Snyder 2007), but at that time this activity was considered to be uninformative noise and not worthy of investigation.

At the beginning of the new millennium, the boundaries of this resting activity started to be defined. It was demonstrated that during resting state a spontaneously organized neural activity occurs in a unique constellation of brain regions. Defined as the default mode network (DMN), this constellation mainly involves the posterior cingulate cortex, the precuneus and regions of the ventromedial prefrontal cortex (Fig. 3.1.1) (Raichle et al 2001, Buckner 2012, Snyder and Raichle 2012). In the face of a certain degree of scepticism (Morcom and Fletcher 2007), research on this topic continued, producing inter-species, longitudinal, inter-individual and physiopathological studies.

DMN activity has subsequently also been detected in chimpanzees (Rilling et al 2007), monkeys (Kojima et al 2009, Mantini et al 2011) and rats (Lu et al 2012), findings that suggest that such activity could be a fundamental aspect of the mammalian brain. The same activity also manifests at several stages in the human life cycle, from its emergence in 2-day-old newborns (Gao et al 2009) to its disappearance in brain-dead patients (Boly et al 2009). DMN-related differences between individuals (Power et al 2010) and between healthy and pathological conditions have started to emerge (Sandrone 2012).

Remarkably, these differences and abnormalities not only constitute neuropathophysiological correlates of in fieri neurological and psychiatric diseases (Fox and Raichle 2007), but also offer informative and predictive markers about the pathology that is going to impact on the brain (Sandrone 2012). In fact, they often appear before the overt

Fig. 3.1.1 Modern descriptions of the default mode network. A, A surface projection of the default mode network is displayed from the Shulman et al. (1997) data. The regions in blue represent those regions more active during passive task states than a variety of active tasks. B, A near-complete topography of the default network can be accounted for by exploring regions functionally coupled to the posterior cingulate, dorsal medial prefrontal cortex (dMPFC) and hippocampal formation (HF+). However, detailed analysis of the coupling properties reveals that the default network is not a single, coherent system but rather is made up of multiple, functionally interacting subsystems. Other abbreviations: Ins, insula; IPL, inferior parietal lobule; LTC, lateral temporal cortex; pCC, posterior cingulate cortex; PFC, prefrontal cortex; Rsp, retrosplenial cortex; vMPFC, ventral medial prefrontal cortex. (With permission from Buckner RL 2012 The serendipitous discovery of the brain's default network. Neurolmage 62: 1137-1145; Elsevier.)
onset of pathological phenotypes: abnormal patterns of DMN activity and connectivity seem to anticipate future behavioural phenotypes and clinical impairment (Sandrone 2013). They can represent reliable non-invasive biomarkers for differential diagnosis and disease monitoring, providing us with novel views on the functional architecture of the human brain and opening up an intriguing medical field.

This predictive potential of DMN has been seen in a plethora of diseased conditions (Table 3.1.1). For example, clinicopathological phenotypes of dementia with Lewy bodies and Alzheimer's disease often overlap, making discrimination difficult; notably, DMN functional connectivity abnormalities can support early discrimination between them (Galvin et al 2011) and tracks clinical deterioration in Alzheimer patients (Damoiseaux et al 2012). Functional disruption of DMN in cognitively unimpaired patients with Parkinson's disease has been reported even in the absence of significant structural differences between patients and controls (Tessitore et al 2012, Sandrone and Catani 2013). Changes of resting-state functional connectivity predict the persistence of cognitive rehabilitation effects in patients with multiple sclerosis (Parisi et al 2014). The extent of DMN reduction depends on the clinical severity of the manifestations in disorders of consciousness (vegetative state versus minimally conscious state versus emerging from a minimally conscious state) (Fernández-Espejo et al 2012), and DMN connectivity may serve as an indicator of the extent of cortical disruption and predict reversible impairments in consciousness (Norton et al 2012). Specific differences in resting-state functional network connectivity might be candidate psychosis endophenotypes discriminating between schizophrenia and psychotic bipolar probands and unaffected relatives (Meda et al 2012). Moreover, whole-brain resting-state functional connectivity analyses can identify subjects with major depressive disorder from healthy controls, with the most discriminating connections located across or within the DMN (Zeng et al 2012). Failure to deactivate the DMN has been highlighted as a possible endophenotype of autism (Spencer et al 2012), and other reports also point towards the feasibility of a functional connectivity MRI diagnostic assay for autism with DMN regions playing a key role (Anderson et al 2011, but see also Lynch et al 2013). These promising resting biomarkers are of particular interest because they avoid performance-related confounding variables that are commonly present in patients with cognitive or sensorimotor defects (Zhang and Raichle 2010).

Observation of the resting brain as a predictor of clinical outcome and the use of DMN abnormalities as pathological markers and diagnostic and prognostic tools are great challenges for the coming years. Future research will undoubtedly shed light on the ability of DMN to discriminate single patients from single healthy controls with increasing sensitivity and high specificity. Systematic replication of DMN experi-
ments on larger samples is crucial to test and improve the accuracy rate of every prediction. Additionally, resting state acquisition is currently performed differently by different research groups, and greater experimental design homogeneity is needed. Methodological guidelines should accordingly be standardized to ensure comparability between all resting-state studies (Northoff et al 2010, Northoff et al 2011). Resting-state fMRI data coherencies still need to be further characterized and quantified across subjects and sessions (Damoiseaux et al 2006); technical optimization, experimental refinement and a balanced comparison between the differing methods are required (Cole et al 2010, Birn 2012, Lee et al 2013).

Further work is needed to clarify the anatomical and functional boundaries of the cerebellar contribution to intrinsic connectivity networks (Habas et al 2009, Krienen and Buckner 2009), given that most of the human cerebellum is linked to association networks including the executive control network and the DMN (Buckner 2013). An integrative exploration of the 'functional connectome' and the related aberrant intrinsic networks across diseases (Menon 2011, but see also Barkhof et al 2014 and Fox et al 2014), as well as detailed guidelines for research on clinical populations (Fox and Greicius 2010, Sandrone 2013), are needed to bridge the gap between basic research studies and their translational application. Basic research studies rely on homogeneous criteria, whereas clinical practice deals with heterogeneous conditions and comorbidity of diseases. Moreover, the ontological meaning of this resting activity still needs to be fully elucidated: so far, activations and deactivations of DMN brain regions have often been related to self-specific processes in both healthy (Gusnard et al 2001) and diseased subjects (Sheline et al 2009, Irish et al 2012).

DMN-based research will certainly enrich our understanding of brain function and will undoubtedly gravitate to the centre-stage of medical investigation. From an epistemological point of view, the predictive potential of DMN and resting state does not belong a priori to any academic domain, and its impact will necessarily be crossdisciplinary. As such, it will challenge the boundaries of medical sciences and neutralize the traditional demarcations between neurology and psychiatry.

We will witness an intriguing paradigm shift (Kuhn 1962). Although time-to-completion estimates would be foolhardy, research will generate a DMN-based 'functional taxonomy' of the human brain, in which clinical subpopulations and subtypes are identified on the basis of their resting cerebral activity (Sandrone 2013). In the challenging and neverresting search for a better understanding of the human brain and a cure for cerebral diseases, it will be a resting person inside a neuroimaging scanner who will push forward the medical field and revolutionize the way we deal with medical diagnosis and prognosis.

Table 3.1.1 The predictive potential of the DMN in disease

| Condition | Evidence | Reference |
| :---: | :---: | :---: |
| Ageing, amnestic mild cognitive impairment and Alzheimer's disease | Functional alteration patterns of DMN derived from simultaneous comparison of the three different groups | Cha et al 2013 Eur J Neurosci 37:1916-24 |
| Amnestic mild cognitive impairment | Disrupted functional brain connectome in amnestic mild cognitive impairment individuals at risk for Alzheimer's disease <br> Early onset of the functional/topological reorganization of the DMN | Wang et al 2013 Biol Psychiatry 73:472-81 Wang et al 2013 Radiology 268:501-14 |
| Alzheimer's disease and frontotemporal dementia | Behavioural variant frontotemporal dementia and Alzheimer's disease lead to divergent network connectivity patterns | Zhou et al 2010 Brain 133:1352-67; but see also Zhou and Seeley 2014 Biol Psychiatry 75:565-73 |
| Alzheimer's disease and dementia with Lewy bodies | Resting blood oxygen level-dependent (BOLD) fMRI differentiates Alzheimer disease from dementia with Lewy bodies | Galvin et al 2011 Neurology 76:1797-803 |
| Alzheimer's disease | DMN activity distinguishes Alzheimer's disease from healthy ageing Selective changes of resting-state networks in individuals at risk for Alzheimer's disease | Greicius et al 2004 Proc Natl Acad Sci U S A 101:4637-42 Sorg et al 2007 Proc Natl Acad Sci U S A 104:18760-5; Wang et al 2013 Biol Psychiatry 73:472-81; but see also Fjell et al 2013 J Neurosci 33:8237-42 and Jacobs et al 2013 Neurosci Biobehav Rev 37:753-65 |
|  | Resting-state functional connectivity in preclinical Alzheimer's disease | Sheline and Raichle 2013 Biol Psychiatry 74:340-7 |
|  | Functional connectivity tracks clinical deterioration in Alzheimer's disease | Damoiseaux et al 2012 Neurobiol Aging 33:828.e19-30 |
|  | Functional disruption of the DMN occurs early in the course of autosomal dominant Alzheimer's disease, beginning before clinically evident symptoms and worsening with increased impairment | Chhatwal et al 2013 Neurology 81:736-44 |
| Amyotrophic lateral sclerosis | Changes of resting-state brain networks in amyotrophic lateral sclerosis | Mohammadi et al 2009 Exp Neurol 217:147-53 |
|  | Divergent brain network connectivity and alteration of large-scale functional networks associated with cognition, even in the absence of overt dementia | Agosta et al 2013 Neurobiol Aging 34:419-27 |
|  | Independent component analysis and machine learning can support identification of the amyotrophic lateral sclerosis diseased brain | Welsh et al 2013 Front Hum Neurosci 7:251 |
| Autism spectrum disorder | Functional connectivity MRI classification/diagnostic assay for autism | Anderson et al 2011 Brain 134:3742-54 |
|  | Failure to deactivate the DMN as possible endophenotype of autism | Spencer et al 2012 Mol Autism 3:15 |
|  | Differential deactivation during mentalizing and classification of autism based on DMN connectivity | Murdaugh et al 2012 PLoS One 7:e50064 |
|  | Large-scale evaluation of the intrinsic brain architecture in autism | Di Martino et al 2014 Mol Psychiatry 19:659-67 |
| Bipolar disorder | Correlation of DMN activation with bipolarity index in young people with mood disorders | Ford et al 2013 J Affect Disord 150:1174-8; but see also Vargas et al 2013 J Affect Disord 150:727-35 |

Table 3.1.1 The predictive potential of the DMN in disease-cont'd

| Condition | Evidence | Reference |
| :---: | :---: | :---: |
| Disorder of consciousness | DMN connectivity is decreased in severely brain-damaged patients in proportion to their degree of consciousness impairment <br> DMN integrity correlates with the level of remaining consciousness in coma, vegetative state and minimally conscious state | Vanhaudenhuyse et al 2010 Brain 133:161-71; see also Norton et al 2012 Neurology 78:175-81 <br> Fernández-Espejo et al 2012 Ann Neurol 72:335-43; Guldenmund et al 2012 Arch Ital Biol 150:107-21 |
| Generalized anxiety disorder | Functional network dysfunction in anxiety and anxiety disorders | Andreescu et al 2014 Int J Geriatr Psychiatry 29:704-12; Sylvester et al 2012 Trends Neurosci 35:527-35 |
| Epilepsy | The decoupling of functional and structural connectivity may reflect the progress of long-term impairment in idiopathic generalized epilepsy Resting-state network disruption in temporal lobe epilepsy <br> DMN connectivity indicates episodic memory capacity in mesial temporal lobe epilepsy | Zhang et al 2011 Brain 134:2912-28 <br> Voets et al 2012 Brain 135:2350-7; Cataldi et al 2013 Epilepsia 54:2048-59 <br> McCormick et al 2013 Epilepsia 54:809-18 |
| Huntington's disease | DMN changes identified at preclinical level Reduced brain connectivity before and after disease onset | Wolf et al 2012 Exp Neurol 237:191-8 <br> Dumas et al 2013 Neuroimage: Clin 2:377-84; Werner et al 2014 Hum Brain Mapp 35:2582-93 |

# Head and neck: overview and surface anatomy 

This chapter contains an overview of the topographical anatomy of the head and neck described in detail in Chapters 27-42, and an account of the clinically relevant surface anatomy.

## SKIN AND FASCIA

## FACE AND SCALP

The superficial fascia of the scalp is firm, dense, fibroadipose, and closely adherent to the skin and to the underlying muscle, epicranius and the epicranial aponeurosis. Posteriorly, the fascia is continuous with the superficial fascia of the back of the neck, and laterally it is prolonged into the temporal region, where it is looser in texture. Three fascial layers (a subcutaneous fibroadipose tissue, a superficial musculoaponeurotic system (SMAS) and the parotid-masseteric fascia) are recognized on the face superficial to the plane of the facial nerve and its branches. On the lateral side of the head, above the zygomatic arch, the temporoparietal fascia lies in the same plane as, but does not blend with, the superficial musculo-aponeurotic system. It is superficial to the temporal fascia and blends superiorly with the epicranial aponeurosis. The parotid gland is surrounded by a fibrous capsule derived from the deep cervical fascia.

## NECK

The superficial cervical fascia is a zone of loose connective tissue between dermis and deep fascia, and is joined to both. It contains a variable amount of adipose tissue and platysma but is hardly demonstrable as a separate layer. The deep cervical fascia is conventionally subdivided into three sheets (superficial investing, middle and deep layers) that surround the muscles and viscera of the neck to varying degrees, and the carotid sheath, a condensation of deep fascia around the common and internal carotid arteries, internal jugular vein, vagus and ansa cervicalis. The fascial layers of the neck define a number of potential tissue 'spaces' above and below the hyoid bone (Ch. 31). In health, the tissues within these spaces are either closely applied to each other or are filled with relatively loose connective tissue. However, they offer potential routes by which unchecked infection may spread within the head and neck, and between the tissue spaces of the face and the mediastinum. They also offer convenient planes for dissection during surgery.

## BONES AND JOINTS

## SKULL AND MANDIBLE

The skull is composed of 28 separate bones, most of them paired (Ch. 27). It can be divided into the cranium, consisting of the calvaria (brain box) and basicranium, which together surround and protect the brain; a delicate facial skeleton composed mainly of thin-walled bones, some of which contain air-filled cavities that are known collectively as the paranasal sinuses; and the mandible. The cranial cavity contains the brain and the intracranial portions of the cranial nerves; the blood vessels that supply and drain the brain and the haemopoietic marrow of the overlying bones; the meninges (dura, arachnoid and pia mater); and the cerebrospinal fluid in the subarachnoid space. The cavity is incompletely divided by dural partitions, notably the falx cerebri, lying between the cerebral hemispheres, and the tentorium cerebelli, lying between the cerebellum and occipital lobes. Almost all of the venous blood from the brain and cranial bones drains via sinuses lying between the endosteal and meningeal layers of the dura mater into the internal jugular vein. Internally, the cranial base is divided into anterior, middle and posterior cranial fossae, which contain the frontal and temporal
lobes of the cerebral hemispheres and the cerebellum, respectively. Foramina in the bones of the skull base and facial skeleton transmit neurovascular bundles that may be compromised at these sites by pathology or trauma.

The bony orbits contain the eyeballs, oculogyric muscles and lacrimal glands with their associated neurovascular supplies (Chs 41 and 42). The temporal bones contain the inner, middle and external ears (Chs 37 and 38). The maxillae are the largest of the pneumatized bones of the midface; they contain the maxillary air sinuses and bear the upper teeth. The mandible bears the lower teeth and articulates with the temporal bones at the temporomandibular joints. The skull articulates with the first cervical vertebra (atlas); movements of the skull on the cervical vertebrae occur at the atlanto-occipital joints.

The skull provides attachments for many muscles, including all the craniofacial muscles, the oculogyric muscles, the muscles that act on the temporomandibular joint, the superior constrictor of the pharynx, the muscles of the soft palate, all but one of the extrinsic muscles of the tongue, the muscles of the suboccipital region, and the cranial attachments of trapezius and sternocleidomastoid.

## CERVICAL VERTEBRAE

There are seven cervical vertebrae. They are the smallest of the movable vertebrae and are characterized by a disproportionately large vertebral canal. All but the seventh are also characterized by a foramen in each transverse process, the foramen transversarium (these foramina may be absent or sometimes duplicated in the seventh cervical vertebra). The first (atlas), second (axis) and seventh (vertebra prominens) cervical vertebrae are atypical.

## HYOID BONE AND LARYNGEAL CARTILAGES

The hyoid bone lies in the midline at the front of the neck at the level of the third cervical vertebra. It is suspended from the styloid processes by the stylohyoid ligaments and gives attachment to the suprahyoid and infrahyoid groups of muscles. The skeletal framework of the larynx is formed by a series of cartilages interconnected by ligaments and fibrous membranes, and moved by a number of muscles (Ch. 35). The laryngeal cartilages are the single cricoid, thyroid and epiglottic cartilages, and the paired arytenoid, cuneiform, corniculate and tritiate cartilages.

## MUSCLES

The striated muscles of the head and neck produce the movements of the facial soft tissues that animate so many aspects of communication; the movements at the temporomandibular joint that occur during mastication and speech (Ch. 32); the conjugate movements of the eyeballs; and the coordinated movements that occur during activities such as swallowing, speaking and turning the head in response to visual and/or auditory stimuli. The 'extrinsic' muscles that run between the axial skeleton and upper limb act on the scapula and humerus (Ch. 48).

The superior tarsal muscle, sphincter and dilator pupillae and the ciliary muscle are composed of smooth muscle (Chs 41 and 42).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

The main arterial supply of the head and neck is derived from branches of the carotid and subclavian arteries (Figs 26.1-26.2). Branches of the

Fig. 26.2 An overview of the deep arteries of the head and neck.
internal carotid and vertebral arteries anastomose in the circle of Willis within the interpeduncular cistern on the ventral aspect of the brain (Ch. 19).

## Carotid system

The cervical portion of the common carotid artery is similar on both sides. Each lies within the carotid sheath of deep cervical fascia, together with the internal jugular vein and vagus nerve. In the lower part of the neck, the arteries are separated by a narrow gap that contains the trachea, and higher up they are separated by the thyroid gland, larynx and pharynx. At the level of the upper border of the thyroid cartilage (C4), the common carotid artery bifurcates into external and internal carotid arteries (see below). The external carotid artery passes upwards on either side of the neck, inclined at first slightly forwards and then backwards and a little laterally. It usually gives off the ascending pharyngeal, superior thyroid, lingual, facial, occipital and posterior auricular arteries, and then enters the parotid salivary gland where it divides into its terminal branches, the superficial temporal and maxillary arteries. The branches of the external carotid artery supply the face, scalp, tongue, upper and lower teeth and gingivae, palatine tonsil, paranasal sinuses and nasopharyngeal tube, external and middle ears, pharynx, larynx and superior pole of the thyroid gland. They also anastomose with branches of the internal carotid arteries on the scalp, forehead and face, in the orbit, nasopharynx and nasal cavity, and with branches of the subclavian artery in the pharynx, larynx and thyroid glands.

The internal carotid artery supplies most of the ipsilateral cerebral hemisphere, eye and accessory organs, the forehead and, in part, the external nose, nasal cavity and paranasal sinuses. It passes up the neck anterior to the transverse processes of the upper three cervical vertebrae and enters the cranial cavity via the carotid canal in the petrous part of the temporal bone. The artery has no branches in the neck and so is easily distinguishable from the external carotid artery, should the latter require ligation, e.g. to control haemorrhage from a penetrating injury to the neck.

## Subclavian artery

The subclavian arteries give off several branches that supply structures in the head and neck. The vertebral arteries supply the upper spinal cord, brainstem, cerebellum and occipital lobe of the cerebrum. They pass through the foramina transversaria of the first six cervical vertebrae, enter the cranial cavity through the foramen magnum and unite at the lower border of the pons to form the basilar artery (hence this system is often called the vertebrobasilar system). Branches from the thyrocervical trunk supply the inferior poles of the thyroid gland and the parathyroid glands, the larynx and the pharynx, and branches from the costocervical trunks supply deep cervical muscles.

## VEINS

The veins of the neck lie superficial or deep to the deep investing fascia. Superficial veins ultimately drain into either the external, anterior or posterior external jugular veins; they drain a much smaller volume of tissue than the deep veins. Deep veins tend to drain into either the internal jugular vein or the subclavian vein. The internal jugular vein drains blood from the skull, brain, superficial face and much of the neck. It descends in the neck within the carotid sheath and unites with the subclavian vein behind the sternal end of the clavicle to form the brachiocephalic vein (Figs 26.3-26.4). At its junction with the internal jugular vein, the left subclavian vein usually receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct.

## LYMPHATIC DRAINAGE

Lymph nodes in the head and neck are arranged in two horizontal rings and two vertical chains on either side of the neck (Fig. 26.5). The outer, superficial, ring consists of the occipital, preauricular (parotid), submandibular and submental nodes, and the inner, deep, ring is formed by clumps of mucosa-associated lymphoid tissue (MALT) located

Fig. 26.3 An overview of the superficial veins of the head and neck.

Fig. 26.4 An overview of the deep veins of the head and neck.
primarily in the nasopharynx and oropharynx (Waldeyer's ring). The vertical chain consists of superior and inferior groups of nodes related to the carotid sheath. All lymph vessels of the head and neck drain into the deep cervical nodes, either directly from the tissues or indirectly via nodes in outlying groups. Lymph is returned to the systemic venous circulation via either the right lymphatic duct or the thoracic duct.

## INNERVATION

## CRANIAL NERVES

There are 12 pairs of cranial nerves. They are individually named and numbered (using Roman numerals) in a rostrocaudal sequence (see Table 16.1). Some are functionally mixed, others are either purely motor or purely sensory, and some also carry pre- or postganglionic parasympathetic fibres that are secretomotor to the salivary and lacrimal glands or motor to the smooth muscle within the eyeball and orbit. Branches of the oculomotor, trochlear, trigeminal, abducens, facial, glossopharyngeal, vagus, accessory and hypoglossal nerves supply muscle groups within the eyeball, face, neck, pharynx, larynx and tongue. Branches of the trigeminal, glossopharyngeal and vagus nerves transmit general sensory information from the skin of the face and part of the scalp; the epithelium lining the oral and nasal cavities, the paranasal sinuses, middle ear, pharynx and larynx, and the dorsal surface of the tongue and the cornea; the intracranial meninges; and the periosteum and bones of the skull. Branches of the trigeminal nerve innervate the temporomandibular joint. The olfactory, optic, trigeminal, facial, vestibulocochlear and vagus nerves contain axons that transmit the special sensations of olfaction, vision, hearing, balance and taste. The olfactory nerve is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus (Ch. 25). The optic nerve terminates in the thalamus (Ch. 23). The other ten pairs of cranial nerves are attached to the brainstem or, in the case of the accessory nerve, to the upper cervical spinal cord; their component fibres arise from or terminate in named cranial nerve nuclei. The cranial nerves pass through named foramina in the skull, often with named vessels.

With one exception, all of the cranial nerves are confined to the head and neck. The exception is the vagus, which travels through the neck
and thorax, and enters the abdominal cavity by passing through the diaphragm with the oesophagus.

## Reflexes

A number of reflexes involving structures in the head and neck are mediated by sensory and motor branches of certain of the cranial nerves, coordinated via appropriate nuclei in the brainstem. They include swallowing, gagging, retching and vomiting, sneezing and coughing; lacrimation; jaw jerk; visual reflexes (pupillary light reflex and accommodation); and the corneal 'blink' reflex and the stapedial reflex. Reflexes that involve energetic exhalation, e.g. sneezing and coughing, also involve the recruitment of cervical and thoracic spinal neurones to mediate the coordinated contraction of intercostal and abdominal wall muscles that this activity requires.

## SPINAL NERVES

There are eight pairs of cervical spinal nerves (Fig. 26.6). Cutaneous branches of the dorsal rami of the second, third, fourth and fifth cervical nerves innervate the scalp and the skin over the back of the neck, and motor branches of all of the cervical dorsal rami supply cervical postvertebral muscles. All of the cervical ventral rami supply anterior and lateral groups of prevertebral muscles. The upper four cervical ventral rami form the cervical plexus, whose branches collectively innervate the infrahyoid strap muscles and the diaphragm, and the skin covering the lateral and anterior parts of the neck, and the angle of the mandible. The lower four cervical ventral rami, together with most of the first thoracic ventral ramus, form the brachial plexus.

## PARASYMPATHETIC NERVES

In the head and neck, the parasympathetic system innervates the salivary and lacrimal glands, the mucous glands of the oral and nasal cavities and paranasal sinuses, and the sphincter pupillae and ciliary muscles in the eyeball. Many thousands of preganglionic parasympathetic axons travel in the vagus from cell bodies in the dorsal motor nucleus of the vagus in the medulla. Although they travel through the

Fig. 26.5 An overview of the lymph nodes of the head and neck.
neck in the right and left vagi, they are destined for pulmonary, cardiac, oesophageal, gastric and intestinal targets; they synapse in minute ganglia in the walls of the viscera and do not innervate structures in the head and neck.

There are four pairs of parasympathetic ganglia in the head, named ciliary, pterygopalatine, otic and submandibular (Fig. 26.7).

## Ciliary ganglion

Preganglionic axons originate in the Edinger-Westphal preganglionic nucleus of the midbrain (Ch. 21). They travel via a branch of the oculomotor nerve (nerve to the inferior oblique) to the ciliary ganglion, where they synapse. Postganglionic fibres travel in the short ciliary nerves, which pierce the scleral coat of the eyeball and run forwards in the perichoroidal space to enter the ciliary muscle and sphincter pupillae. Their activation mediates accommodation of the eye to near objects and pupillary constriction.

## Submandibular ganglion

Preganglionic axons originate in the superior salivatory nucleus. They emerge from the brainstem in the nervus intermedius and leave the main facial nerve trunk in the middle ear to join the chorda tympani, which subsequently joins the lingual nerve. In this way, they reach the submandibular ganglion, where they synapse. Postganglionic fibres innervate the submandibular, sublingual and lingual salivary glands; some axons presumably re-enter the lingual nerve to access the lingual glands, while others pass directly along blood vessels to enter the submandibular and sublingual glands.

Some preganglionic fibres may synapse around cells in the hilum of the submandibular gland. Stimulation of the chorda tympani dilates the arterioles in both glands, as well as having a direct secretomotor effect.

## Pterygopalatine ganglion

Preganglionic axons travel in the greater petrosal branch of the facial nerve and the nerve of the pterygoid canal, and relay in the pterygopalatine ganglion. Postganglionic secretomotor axons innervate secretory acini and blood vessels in the palatine, pharyngeal and nasal mucosa via the palatine and nasal nerves, but whether they also innervate the lacrimal gland via the zygomatic and zygomaticotemporal branches of the maxillary nerve, as was once thought, is less certain. It is likely that postganglionic orbital branches, carrying a mixture of postganglionic parasympathetic and somatic sensory axons, pass through the inferior orbital fissure and innervate the lacrimal gland and ophthalmic artery directly. Some axons pass into the cranial cavity via the ethmoidal vessels to innervate the choroid; the pterygopalatine ganglion is believed to be the main source of parasympathetic input to the choroid.

## Otic ganglion

Preganglionic axons originate in the inferior salivatory nucleus and travel in the glossopharyngeal nerve and its tympanic branch. They traverse the tympanic plexus and lesser petrosal nerve, and pass through the foramen ovale to reach the otic ganglion, where they synapse. Postganglionic fibres pass by communicating branches to the

Fig. 26.6 An overview of the nerves forming the cervical and brachial plexuses. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
auriculotemporal nerve, which conveys them to the parotid gland. Stimulation of the lesser petrosal nerve produces vasodilator and secretomotor effects.

## SYMPATHETIC NERVES

In the neck, the sympathetic trunk lies behind and medial to the carotid sheath and anterior to the transverse processes of the cervical vertebrae and the prevertebral muscles. There are usually three cervical ganglia on each side - superior, middle and inferior (cervicothoracic); they may be connected by a solid trunk or by two or three fibrous strands. The ganglia receive preganglionic fibres from neurones whose cell bodies lie in the intermediolateral column of the upper thoracic spinal cord; there is no preganglionic output from the cervical spinal cord. Postganglionic fibres reach their target tissues in the head and neck via the cervical spinal nerves and perivascular nerve plexuses distributed along the carotid and vertebral arteries (see Fig. 26.7).

## SURFACE ANATOMY

## SURFACE ANATOMY OF THE HEAD

## Skeletal landmarks

The palpable bony landmarks of the head can be examined from the back, sides and front (Figs 26.8-26.9). The pericraniocervical line, which demarcates the head from the neck, runs from the midpoint of the chin anteriorly to the external occipital protuberance posteriorly.

## Calvaria

Most of the superficial aspect of the calvaria is covered by skin, subcutaneous tissue and thin muscles; many bony prominences and surfaces are therefore palpable through the hair and are visible in bald people.

Suture lines can be palpated as irregular ridges. The anterior fontanelle, at the junction of the coronal and sagittal sutures, may be palpated up to 18 months after birth. The mastoid process is palpable medial to the lobule of the pinna. Deep palpation immediately anteroinferior to the mastoid apex reveals the relatively indistinct resistance offered by the styloid process and associated soft tissues, and posteroinferior palpation reveals the firm mass of the transverse process of atlas (C1). The external occipital protuberance (inion) is a palpable bony protuberance located on the posterior midline of the occipital bone. The confluence of the dural venous sinuses sits mainly to the upper right side of the inion (Sheng et al 2012). The superior nuchal lines are palpable passing laterally from the inion. The asterion can be palpated as a slight depression $1-2 \mathrm{~cm}$ behind the pinna at a level approximately at the junction of the upper third and lower two-thirds of the pinna. It marks the junction of the occipitomastoid, parietomastoid and occipitoparietal sutures, and is commonly employed to define the location of transversesigmoid sinus junction (Day and Tschabitscher 1998), although it does not always do so (Sheng et al 2012).

## Mandible

The mental tubercles are palpable on the anterior chin, and the mandibular body, alveolar processes and teeth are palpable through the cheek. The lower border of the mandible can be traced to the angle at vertebral level C2. The mental foramen, which transmits the mental nerve and vessels, gradually migrates posteriorly after birth and through childhood (Balcioglu et al 2011). In adults, it lies an average of 2.5 cm from the midline face (Udhaya et al 2013), between the root apices of mandibular teeth 4 and 5 (range: teeth 3-6) (Fishel et al 1976, von Arx et al 2013, Udhaya et al 2013). Most foramina usually sit either level with or inferior to the tooth root apex (Fishel et al 1976), and accessory mental foramina, if present, are mainly situated posterior or inferior to the main foramen (Katakami et al 2008). The mandibular foramen sits on the medial surface of the ramus an average of 1.9 cm posterior to the third molar (Nicholson 1985); a 21 mm needle is therefore sufficient to reach the foramen for dental anaesthesia (Menke and Gowgiel 1979). The foramina almost always (Mbajiorgu and Ekanem 2000, Nicholson 1985) sit level with or below the occlusal plane, the remainder sitting above.

The mandibular ramus is largely covered by masseter and the parotid gland. Its posterior border is palpable through the parotid up to the neck of the mandibular condylar process, which lies anterior to the lower tragus/intertragal notch of the pinna. Movement of the condylar head at the temporomandibular joint is palpable anterior to the tragus during mouth opening/closing. The coronoid process is palpable anterior to the condylar process through the buccal mucosa.

## Face

The lateral aspect of the face, from above downwards, consists of the temporal region, cheek and lower jaw (Ch. 30). The temporal region lies in front of the external ear and above the zygomatic arch. It is demarcated superiorly and posteriorly by the palpable superior temporal line, anteriorly by the frontal process of the zygoma, and inferiorly by the zygomatic arch. The palpable zygomatic arch is formed by the zygomatic process of the temporal bone posteriorly and the temporal process of the zygomatic bone anteriorly, both of which articulate via the palpable zygomaticotemporal suture. The variable prominence of the 'cheekbone' (zygoma) is largely attributable to the shape of the body of the underlying zygomatic bone. The sharp posterior margin of the frontal process of the zygomatic bone can be palpated superiorly to its articulation with the zygomatic process of the frontal bone at the palpable zygomaticofrontal suture. From here, the superior temporal line can be palpated passing posteriorly in the line of a gentle curve. The lower temporal line terminates by curving downwards and forwards to end just above the root of the mastoid process as the supramastoid crest on the squamous part of the temporal bone. The suprameatal triangle overlies the lateral wall of the mastoid (tympanic) antrum and is demarcated superiorly by the palpable supramastoid crest (a palpable ridge of bone posterior to the upper pinna), anteroinferiorly by the posterosuperior margin of the external acoustic meatus, and posteriorly by a vertical line through the posterior border of the external acoustic meatus. The lateral/Sylvian fissure of the brain aligns with the anterior part of squamosal suture in a zone $2.5-4.0 \mathrm{~cm}$ anterior to the external acoustic meatus (Rahmah et al 2011). The pterion represents the junction of the frontal, sphenoid, parietal and temporal sutures within the temporal fossa. It is situated within a 1 cm diameter circle centred approximately 2.6 cm posterior and 1.3 cm superior to the posterolateral margin of the zygomaticofrontal suture (Ma et al 2012). Alternatively, the pterion is located approximately 4 cm above the midpoint of the zygomatic arch (Ukoha et al 2013). It usually marks the position

Fig. 26.7 An overview of the visceral efferent pathways in the head. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
of the anterior (frontal) branch of the middle meningeal artery, with the remainder of arteries sitting immediately posterior (Ma et al 2012) (Ch. 28). Knowledge of middle meningeal artery surface anatomy is important for accurate positioning of burr-holes to evacuate extradural haematomas. The posterior (parietal) arterial branch runs backwards and parallel with the upper border of the zygomatic arch and is usually exposed vertically above the mastoid process on a level horizontal with the upper margin of the orbit. The asterion is a craniometric point at the site of the posterolateral, or mastoid, fontanelle. It is found at the junction of the lambdoid, occipitomastoid and parietomastoid sutures. It has been used as a landmark in lateral approaches to the posterior fossa as it defines the superior limit of bone removal for the craniectomy. However, the asterion almost always sits over the junction between the transverse and sigmoid sinuses, or sometimes inferior to the sinus junction (Sheng et al 2012).

The forehead extends from the hair margin of the scalp to the eyebrows. The rounded frontal tuberosity may be felt approximately 3 cm above the midpoint of each supraorbital margin. The superciliary arch is usually palpable above the orbit and is better marked in the male than the female. The glabella, a small horizontal ridge, is easily palpable between the superciliary arches. Below the glabella, the nasal bones meet the frontal bone in a small depression, the nasion, at the root of the nose. With a little finger inserted into the nostril, the bony margins of the anterior nasal aperture can be felt; they are formed by the inferior border of the nasal bone, the sharp margins of the nasal notch, and the coapted nasal spines of the maxillae (Ch. 33).

The orbital opening is relatively quadrangular and its margins palpable (Ch. 41). The supraorbital margin is formed entirely by the frontal bone. The supraorbital foramen/notch can be palpated along the superomedial orbital margin and sits an average of 2.7 cm (range $1.8-4.3 \mathrm{~cm}$ ) from the midline face (Chrcanovic et al 2011). Foramen position can vary with gender, race, side and climatic origin (Chrcanovic et al 2011, Tomaszewska et al 2012). This notch/foramen transmits the supraorbital nerve and vessels, and pressure exerted here with the fingernail can be painful. An additional notch may be found more towards the bridge of the nose; it transmits the supratrochlear neurovascular bundle.

The lateral margin of the orbit consists of the frontal process of the zygomatic bone and the zygomatic process of the frontal bone. The
frontozygomatic suture between them may be palpated as a depression. Approximately 1 cm below this suture, a tubercle (Whitnall's) may be palpated within the orbital opening; it gives attachment to the lateral palpebral and check ligaments. The inferior border of the orbit is formed by the zygomatic bone laterally and the maxilla medially. It blends into the medial margin, which is less obvious, and is formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla. A shallow fossa behind the lower part of the medial wall houses the lacrimal sac. The anterior lacrimal crest is a guide to the location of the anterior ethmoidal artery, which may occasionally require ligation to control severe epistaxis, and which lies approximately 2.4 cm posterior to the crest. The optic canal lies approximately 4.5 cm posterior to the infraorbital margin (approximately 4.2 cm from the anterior lacrimal crest); these distances are important in orbital floor exploration in order to avoid optic nerve injury. The inferior orbital fissure lies approximately 2 cm posterolateral to the infraorbital margin; it does not contain any important structures and therefore surgery can be performed safely in this region. The infraorbital foramen, which transmits the infraorbital nerve and vessels, lies below the middle of the infraorbital margin. It commonly aligns with a vertical axis passing through maxillary tooth 5 (Raschke et al 2013) and sits an average of 2.5 cm (range $1.8-3.3 \mathrm{~cm}$ ) from the midline face and 6.4 mm (range 3.2-12.1 mm) below the inferior orbital margin, with differences noted between genders and side (Chrcanovic et al 2011, Raschke et al 2013). In neonates, the infraorbital nerve is located approximately half-way along a line drawn from the angle of the mouth to the midpoint of the palpebral fissure (Bosenberg and Kimble 1995).

The anterior surface of the maxilla is extensive and may be palpated between the infraorbital margin and the alveolar processes that bear the upper teeth. The canine eminence overlies the roots of the canine tooth and separates the incisive fossa anteriorly from the deeper canine fossa posteriorly. The bone of the canine fossa is thin and may be removed easily to access the maxillary sinus via an intraoral approach as part of a Caldwell-Luc procedure. The palatine process of the maxilla and palatine bone form the palpable roof of the mouth. The incisive/ nasopalatine foramen sits in the midline palate, immediately posterior to the incisive papilla approximately 7.4 mm from the labial surface of the alveolar ridge (Mraiwa et al 2004) and transmits the sphenopalatine artery and nasopalatine nerve. The greater palatine foramen, which

Fig. 26.8 The lateral aspect of the head and neck. A, Pterion, meningeal arteries, carotid bifurcation, mental and mandibular foramen. Key: 1, anterior branch of the middle meningeal artery: sits deep to the pterion in over half of subjects; 2 , zone of location of the pterion: in a 1 cm diameter circle centred 2.5 cm posterior and 1.5 cm superior (black arrows) to the frontozygomatic suture; 3, lateral (Sylvian) fissure: aligns anteriorly with the anterior part of the squamosal suture in a zone approximately 3 cm anterior to the external acoustic meatus; 4, mastoid line; 5, posterior branch of the middle meningeal artery: runs parallel to the zygomatic arch and sits level with the supraorbital margin on the mastoid line; 6 , asterion: sits almost always over or sometimes just below (black arrow) the transverse-sigmoid sinus junction; 7, suprameatal triangle; 8, occlusal plane; 9, zone of location (white) of the mandibular foramen: in the majority of cases, the foramen sits level with or below the occlusal plane (8), an average of 2 cm posterior to tooth 8 ; 10, zone of location (white) of the mental foramen: the foramen commonly sits between the roots of teeth 4 and 5 (range 3-6), usually level with or inferior to the tooth root apex; X (green), transverse process of C1 (atlas); X (blue), transverse process of C2 (axis); 11, zone of location (white) of the bifurcation of the common carotid artery: usually above the level of the thyroid lamina; X (red), most common level of common carotid bifurcation (C3). B, Parotid gland and duct, CN VII \& XI, cutaneous branches of cervical plexus and internal jugular vein. Key: 1, porion line; 2, zygomatic sutural line; 3, zone of location of the (fronto)temporal nerve; 4, parotid gland; 5, zone of location (white) of the parotid duct (green line): sits within 1.5 cm of the middle half of a line passing from the lower tragus to the chelion; 6, lower tragus-chelion line; 7, marginal mandibular nerve; 8, zone of emergence of the cutaneous branches of the cervical plexus (white), posterior to the middle third of sternocleidomastoid; 9, zone of location of the accessory nerve, from 3-10 cm below the tip of the mastoid process to $1-10 \mathrm{~cm}$ above the insertion of trapezius into the clavicle; 10, hyoid bone; 11, thyroid cartilage (laryngeal prominence); 12, cricothyroid ligament/membrane; 13, cricoid cartilage; 14, external jugular vein; X (blue), angle of the mandible; X (red), facial artery and anterior border of masseter crossing the lower border of the mandible; X (orange), superficial temporal artery. transmits the greater palatine artery and nerve, is commonly located in the region medial to maxillary tooth 8 (range: from level with tooth 7 to distal to tooth 8 (Sujatha et al 2005, Jaffar and Hamadah 2003) approximately 16 mm from the midline (Wang et al 1988).

## Soft tissues and viscera

The muscular, fatty and cutaneous features that so clearly differentiate individuals are readily apparent on inspection. The external features of the eyelids and eyebrows are described on page 680 and page 475, respectively. The tympanic membrane may be examined under direct vision using an auroscope and is described on page 633. The retinal vascular supply may be examined directly by ophthalmoscopy.

Temporalis is palpable if the flat of the hand is placed over the temporal region and the jaw is clenched and relaxed. The anterior border of masseter is palpable and prominent when the jaw is clenched. The masseter is thicker in boys than in girls in both the relaxed and contracted state (Charalampidou et al 2008). With the mouth open, it is possible to examine the teeth, gingiva, tongue and the palatine tonsils lying between the faucial (palatine) arches formed by palatoglossus (anterolaterally) and palatopharyngeus (posteromedially). Peritonsillar abscess (quinsy) can cause ipsilateral tonsillar enlargement with contralateral displacement of the uvula, and parapharyngeal tumours also displace the ipsilateral tonsil and palate medially. The openings of the submandibular gland ducts can be seen on either side of the lingual
frenulum at its point of intersection with the sublingual mucosal folds. The lingual nerve often passes close to the lingual side of the root of mandibular tooth 8 (Behnia et al 2000), and can sit posteriorly on the retromolar ridge (Pogrel and Goldman 2004).

## Parotid gland

The parotid gland is soft and indistinct to palpation. The superior border sits inferior to the zygomatic arch and passes from the mandibular condyle towards masseter. The anterior border passes inferiorly along the posterior border of masseter, often overlying its lateral surface, then over the mandibular angle to meet the anterior border of sternocleidomastoid, approximately 2 cm posteroinferior to the angle. The posterior border corresponds to a curve traced from the mandibular condyle to the mastoid process. The deep part of the gland lies within the prestyloid part of the parapharyngeal space. Tumours arising in this region present with medial displacement of the soft palate and tonsil. The parotid duct arises from the anterior margin of the gland and can be palpated on the anterior border of a clenched masseter. It passes along, or within 1.5 cm of, the middle half of a line drawn from the lower border of the tragus to the chelion (a bilateral landmark located at the outermost corner of the mouth where the upper and lower lips meet) (Stringer et al 2012) (see Fig 26.8B). The duct runs over masseter to its anterior border, and then bends sharply and pierces the underlying buccinator and buccal mucosa opposite maxillary tooth 7 , where the duct orifice is visible and palpable. Duct cannulation is required for

Fig. 26.9 The anterior aspect of the face. Key: 1, zone of supraorbital foramen and neurovascular bundle (white) approximately 3 cm from the midline of the face; 2, zone of location of the infraorbital foramen and neurovascular bundle (white), approximately 2.5 cm from the midline of the face: aligns with a vertical axis passing through maxillary tooth 5 ; 3 , vertical axis through maxillary tooth $5 ; 4$, zone of location of the mental foramen and neurovascular bundle (white), approximately 2.5 cm (range, apices of teeth 3-6) from the midline of the face. (Adapted from Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
sialography, ductal dilation and basket retrieval of ductal stones (sialoliths).

## Pulses

The facial artery can be palpated as it crosses the lower mandibular border immediately anterior to masseter and on the face approximately 1 cm lateral to the angle of the mouth. The superficial temporal artery is palpable immediately anterior to the tragus of the pinna. The artery divides into frontal and parietal branches approximately 2.5 cm above the zygomatic arch.

## Facial nerve

The facial nerve may be injured in its extratemporal course as a result of facial trauma and laceration, or iatrogenically during surgery involving the parotid or submandibular glands or the temporomandibular joint, or during facelift procedures. Knowledge of the topographical and surgical landmarks is therefore essential if the nerve is to be preserved during surgery.

The nerve exits the skull at the stylomastoid foramen and so is initially deep to the posterior margin of the external acoustic meatus; the nerve trunk lies approximately 1 cm inferomedial to the tip of the tragal pointer, and runs anterior to the mastoid apex and C1 transverse process, within 9 mm and 14 mm , respectively (Greyling et al 2007). It usually divides within the parotid gland into five main branches that radiate across the face (Fig. 26.10; see Fig. 30.24). Cadaveric and intraoperative microdissection studies have revealed that the course of its branches is highly variable and therefore surface coordinates only approximate their trajectory. The temporal/frontotemporal branches emerge from the superior surface of the parotid, cross the zygomatic arch and travel towards the pterion and the superolateral brow. The majority pass in the zone between two lines: line 1 (porion line) joins two points each situated 12 mm from the porion on both the supraorbitomeatal line and the infraorbitomeatal line; and line 2 (zygomatic sutural line) is a line joining the zygomaticotemporal and frontozygomatic sutures (Davies et al 2012). These branches may be injured in facial rhytidectomy, coronal or endoscopic brow lifting, and temporal craniotomy. The buccal branches run both above and below the parotid duct. The marginal mandibular nerve emerges from the anteroinferior parotid and passes anteriorly. When posterior to the facial artery, the nerve almost always lies inferior to the lower border of the mandible by an average of 1.2 cm (range $0.9-1.75 \mathrm{~cm}$ ) (Batra et al 2010). The branches that enter the neck re-enter the face by crossing the lower

Fig. 26.10 The distribution of the cutaneous branches of the trigeminal nerve and of the cervical plexus, and the motor branches of the facial nerve in the face and neck.
border of the mandible at the anterior border of masseter and pass superficial to the facial artery and vein. Regional incisions are therefore made at least 1.5 cm below the lower mandibular border to avoid nerve injury, which results in an upturned ipsilateral mouth via paralysis of depressor anguli oris and depressor labii inferioris (Chowdhry et al 2010).

## Dermatomes

Our knowledge of individual dermatome position is based on clinical evidence. The dermatomes of the face arise mainly from cutaneous branches of the three major divisions of the trigeminal nerve (see Fig. 26.10). The skin covering the front and sides of the neck, and over the angle of the mandible, and over the lateral scalp and posterior aspect of the pinna is supplied by branches of the cervical plexus (C2-C4), and the skin over the back of the head is supplied by the greater occipital nerve (C2, posterior primary ramus) (see Figs 26.10, 30.22, 43.3 and 43.76).

## SURFACE ANATOMY OF THE NECK

## Skeletal and cartilaginous landmarks

The neck extends from the pericraniocervical line superiorly to the level of the clavicle, scapula and thoracic inlet (first rib and superior manubrium) inferiorly, where it is continuous with the thoracic cavity and upper limb. The spines of the second and seventh cervical vertebrae are the most prominent and may be palpated in the midline of the posterior neck (the former via deep palpation). The remaining cervical spines are indistinct because they are covered by the ligamentum nuchae, on either side of which lie the masses of the postvertebral musculature. The transverse process of the first cervical vertebra is palpable in the hollow region posteroinferior to the mastoid apex, and deep palpation inferior to this reveals the transverse process of the second cervical vertebra.

The hyoid bone body can be felt in the midline neck a few centimetres below and behind the chin, at the junction of the skin of the anterior neck and the floor of the mouth. The greater horns may be palpated between a finger and thumb, and moved from side to side. In the adult, the body of the hyoid bone sits level with the fourth cervical vertebra (range C3-C5/6) (Mirjalili et al 2012b); it is higher in children. The laryngeal prominence (Adam's apple) of the thyroid cartilage is palpable in the midline neck, and the thyroid laminae can be felt passing posterolaterally. In the male, the prominence is usually visible, whereas in the female it is not usually apparent. The curved upper border of the thyroid cartilage, the midline thyroid notch and the superiorly located depression of the thyrohyoid membrane/ligament are easily palpable. The upper border of the thyroid cartilage usually lies between the fourth and fifth cervical vertebrae (Mirjalili et al 2012b). The firm, smooth anterior arch of the cricoid cartilage is palpable below the inferior border of the thyroid cartilage. The inferior border of the cricoid commonly sits at the level of the seventh cervical vertebra (range C5-T1); the posterior cricoid overlaps the sixth cervical vertebra (Mirjalili et al 2012b). The indentation between the thyroid and cricoid cartilages is covered by the anterior/median cricothyroid ligament, a useful site for emergency access to the airway in cases of obstruction at or above the vocal cords (cricothyroid puncture or cricothyroidotomy). In the neonate, the dimensions of the cricothyroid membrane are too small to allow safe passage of an airway (Navsa et al 2005). Confirmation of the surface anatomy of the hyoid bone, thyroid and cricoid cartilages, and suprasternal notch is essential prior to performing a tracheostomy (Ellis et al 2004).

The clavicle is a sigmoid-shaped bone that is easily visible in thin people and is palpable in all except the morbidly obese. Its medial two-thirds are rounded and convex anteriorly and the lateral third is flat and concave anteriorly. The suprasternal (jugular) notch lies between the expanded medial ends of the clavicles; the superior edge of the sternal manubrium forms its inferior border. For much of its length, the clavicle may be almost encircled by two fingers, but medially its ligamentous attachments make definition more difficult. The posterior end of the first rib may be felt indistinctly within the floor of the posterior triangle of the neck.

## Soft tissues and viscera

## Triangles and root of the neck

The neck is divided into anterior and posterior triangles by sternocleidomastoid (Fig. 26.11). In cadaveric specimens, the anterior triangle may

Fig. 26.11 The anterior and posterior triangles of the neck. Key: 1, thyroid notch with thyrohyoid ligament (indented region) above; 2, laryngeal prominence; 3, median cricothyroid ligament; 4, cricoid cartilage; 5 , isthmus of thyroid gland; 6 , greater supraclavicular fossa (of posterior triangle); 7, sternal head of sternocleidomastoid; 8, common carotid artery; 9, lesser supraclavicular fossa overlying the internal jugular vein; 10, clavicular head of sternocleidomastoid; 11, course of brachial plexus (upper trunk); 12, subclavian artery; 13, trapezius. (Adapted from Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
be further subdivided into submental, muscular, carotid and digastric triangles, and the posterior triangle may be divided into occipital and supraclavicular triangles. Above the hyoid bone, the musculature runs in a predominantly horizontal or oblique direction, and below the hyoid it runs in a vertical direction. The muscles forming the boundaries of the subtriangles of the neck are not readily palpable or visible, although they may be landmarked according to their attachment points, e.g. the two bellies of digastric lie along a line from the anterior midline chin to the lateral aspect of the hyoid body and then towards the medial part of the mastoid process.

The root of the neck is the transitional zone between the neck, thorax and both upper limbs. Communication with the thorax via the thoracic inlet is marked anteriorly by the superior manubrium. The trachea is palpable in the midline superior to the sternal notch, a region that may also contain the left brachiocephalic vein. The apices of the lungs lie posterior to the medial third of the clavicle (Mirjalili et al 2012a).

## Anterior triangle

The base of the anterior triangle is formed by the inferior border of the mandible and a line from its angle to the mastoid process. The sides are formed by the midline anteriorly and by the anterior border of sternocleidomastoid laterally. The triangle is best palpated bimanually with the examiner standing behind the subject and using both hands to examine the structures within. Inspection reveals the rounded tendinous sternal head of sternocleidomastoid, which arises from the superolateral angle of the manubrium, and the broader, more vertical clavicular head, which arises from the upper surface of the medial third of the clavicle. The indentation of the lesser supraclavicular fossa sits between the two heads, anterior to the internal jugular vein before it joins the subclavian vein posterior to the sternoclavicular joint; the fossa therefore represents an access point for central venous cannulation.

The trachea and its cartilaginous 'rings' may be palpated in the midline inferior to the cricoid cartilage and above the sternal notch. It may be deviated laterally by thyroid masses/growth, atelectasis or tension pneumothorax. The thyroid gland consists of two soft, palpable lobes lying on either side of the lower half of the laminae of the thyroid cartilage and upper part of the trachea, their lower borders extending towards the sternal end of the clavicle on each side. Swallowing may assist palpation of the gland. The lobes are joined by the isthmus (approximately 2 cm wide), which sits anterior to the second and third tracheal cartilages; these cartilages may therefore be impalpable.

Apart from a few retrovisceral nodes and some nodes deep to sternocleidomastoid, all head and neck lymph nodes groups are clinically
palpable when enlarged. Lymph nodes above the hyoid bone tend to be disposed in a horizontal plane either on or below the pericraniocervical line, and in front of and behind the pinna, whereas the deep cervical nodes run vertically and are related to the internal jugular vein. The jugulodigastric node group are palpable in the indented region posterior to the mandibular angle and anterior to sternocleidomastoid. Palpation medial and deep to the inferior border of the mandible can reveal nodes within the submental and submandibular triangles. Superficial cervical nodes lie adjacent to the external and anterior jugular veins and are landmarked with them.

The submandibular gland is palpable within the submandibular triangle. It extends approximately 2 cm beneath the lower border of the posterior part of the body of the mandible and may reach the greater horn of the hyoid bone. Its posterior border is level with the angle of the mandible and its anterior border extends approximately 4 cm anteriorly.

## Posterior triangle

The posterior triangle is bounded by the posterior border of sternocleidomastoid, the middle third of the superior surface of the clavicle (the base), and the anterior margin of trapezius. Its apex is the point where sternocleidomastoid and trapezius approximate at the superior nuchal line. The lower portion of the posterior triangle forms the greater supraclavicular fossa, an important clinical area that lies just above and behind the clavicle at the confluence of the thoracic inlet and the aditus to the axilla and arm. It is best inspected from in front but palpated from behind. Scalenus anterior and medius are palpable as firm masses in the floor of the triangle, posterior to the lower part of sternocleidomastoid. The near-vertical interscalene groove is palpable between them; at or near the level of the sixth cervical vertebra, it serves as a landmark for the upper trunk of the brachial plexus.

When the greater supraclavicular fossa is inspected, the pulsation of the great veins may be seen if the central venous pressure is raised. The fossa is also a common site in which to feel pathologically enlarged supraclavicular lymph nodes. In particular, cancers of the lung can spread to left- and right-sided nodes, and cancers of the upper gastrointestinal tract can spread to left-sided nodes. The subclavian artery may be felt pulsating as it crosses the first rib, posterior to the medial end of the clavicle, and the upper and middle trunks of the brachial plexus may be felt above and behind it. The posterior end of the first rib may be felt as a fullness in the posterior aspect of the fossa. A point approximately 2.5 cm above the middle of the medial third of the clavicle marks the level of the neck of the first rib and is thus the surface marking for the apex of the dome of the cervical pleura and lung covered by the suprapleural membrane (Sibson's fascia). Any penetrating injury (iatrogenic or otherwise) in this region will run the risk of creating a pneumothorax.

## Course of vessels

## Carotid arteries

In the neck, the common carotid artery and its continuation, the internal carotid artery, may be represented by a more or less straight line passing from the sternoclavicular joint to a point just behind the mandibular condyle. The level at which the common carotid artery bifurcates into internal and external carotid arteries is variable (Lo et al 2006). It ranges from the first to the fifth cervical vertebra (Furukawa et al 2012), and is found most commonly at the level of the third cervical vertebra (Furukawa et al 2012, Mirjalili et al 2012b). Bifurcations almost always sit above the upper border of the thyroid cartilage lamina by an average of 1.6 cm (Mirjalili et al 2012b). Almost half occur at the superior border of the thyroid cartilage, and less frequently opposite the hyoid bone or between the thyroid cartilage and hyoid bone (Al-Rafiah et al 2011). The common carotid artery may be compressed against the prominent transverse process of the sixth cervical vertebra (Chassaignac's or carotid tubercle), which sits lateral to the cricoid cartilage. Above this level, the artery is superficial and its pulsation may be readily felt beneath the anterior border of sternocleidomastoid.

## Subclavian artery

The subclavian artery enters the root of the neck behind the sternoclavicular joint. It passes through the inferior part of the palpable interscalene groove and arches upwards to reach a point approximately 2 cm above the clavicle deep to the posterior border of sternocleidomastoid, before passing across the upper surface of the first rib behind the middle of the clavicle. The subclavian pulse may be detected behind the clavicle at the lateral border of sternocleidomastoid or where it crosses the first rib.

## Subclavian vein

The subclavian vein sits anterior to the subclavian artery and follows a similar course by passing over the first rib into the root of the neck. It joins the internal jugular vein to form the brachiocephalic vein posterior to the sternoclavicular joint (Mirjalili et al 2012a) and lies closest to the clavicle at the junction of its middle and medial thirds, approximately 7 cm from the midline (Hale et al 2010). Subclavian vein cannulation is described in Chapter 29.

## Anterior jugular vein

The anterior jugular vein runs downwards from beneath the chin, approximately a finger's breadth from the midline. It turns laterally, approximately 2.5 cm from the sternal end of the clavicle, and passes beneath sternocleidomastoid to drain into the external jugular vein. The veins of each side join to form a jugular arch just above the manubrium sterni. The anterior jugular vein may be encountered if the operator drifts laterally while creating a surgical airway.

## External jugular vein

The external jugular vein lies superficial to sternocleidomastoid and may be represented by a line that starts just below and behind the angle of the mandible and runs to a point close to the lateral extent of the junction of sternocleidomastoid with the clavicle. It drains into the subclavian vein after penetrating the investing layer of deep cervical fascia and may be kinked at this point. If the proximal part of the vein is damaged, it may be held open by the surrounding fascia; air may then be sucked in, resulting in an air embolus. The external jugular vein can be distended if venous pressure is raised, e.g. by performing a Valsalva manœuvre (forced expiration against a closed glottis and mouth, and blocked nostrils), by supraclavicular digital pressure or if the vessel is kinked.

## Internal jugular vein

The internal jugular vein runs in the carotid sheath, lying just lateral or anterolateral to the pulsating carotid arteries. It therefore has similar surface markings to those described for the common and internal carotid arteries, and is represented by a broad band from the lobule of the ear to the sternoclavicular joint, where it joins the subclavian vein (Mirjalili et al 2012a). The inferior bulb of the internal jugular vein lies in the lesser supraclavicular fossa (the depression between the sternal and clavicular heads of sternocleidomastoid), where it may be accessed for central vein cannulation. In children under the age of 5 years, the vein is less than 1 cm deep to skin (Roth et al 2008). The jugular venous pulse reflects the jugular venous pressure (central venous pressure) and is a measure of cardiac function. Pulsation of the great veins may be seen in this region if the central venous pressure is raised (e.g. rightsided heart failure). Internal jugular vein cannulation is described in Chapter 29.

## Course of nerves

## Accessory nerve

The accessory nerve may follow a straight or tortuous course; descriptions vary (Symes and Ellis 2005, Mirjalili et al 2012c). Its course has traditionally been approximated by a line passing across the floor of the posterior triangle, from the junction of the upper and middle thirds of the posterior border of sternocleidomastoid (Erb's point; see Fig. 26.11) to the junction of the lower and middle thirds of the anterior border of trapezius. However, morphometric studies have demonstrated considerable positional variability. The nerve emerges from the posterior border of sternocleidomastoid approximately 6.5 cm below the tip of the mastoid process, and penetrates the anterior border of trapezius approximately 4.5 cm above the clavicular insertion of trapezius (Symes and Ellis 2005; Mirjalili et al 2012c) (Figs 26.8B, 26.10). Accessory nerves usually divide into 2-4 branches prior to trapezius (Mirjalili et al 2012c).

## Cervical plexus

The cutaneous branches of the cervical plexus emerge from behind the posterior border of the middle third of sternocleidomastoid, usually below the accessory nerve (see Figs 26.8B, 26.10). The great auricular nerve can be damaged during rhytidectomy. It passes superiorly over sternocleidomastoid towards the lobule and angle of the mandible; it can sit over the mid-belly of sternocleidomastoid, approximately 6.5 cm below the lower border of the external acoustic meatus, with the external jugular vein sitting 0.5 cm anteriorly at this position (McKinney and Katrana 1980).

## Brachial plexus

The roots and trunks of the brachial plexus can be represented by a line passing between the middle of the posterior border of sternocleidomas－ toid and the middle of the clavicle．In thin individuals，the scalene muscles are visible when the head is laterally flexed to the contralateral side；the roots／upper trunk are palpable in the almost vertical inter－ scalene groove，which is located posterior to scalenus anterior．The trunks lie in the posterior triangle of the neck，and the divisions lie behind the clavicle near the lateral border of the first rib．The cords enter the axilla above the first part of the subclavian artery，embrace its second part and give off branches around the third part．

## Cervical sympathetic ganglia

The superior cervical ganglion lies slightly anterior to the（palpable） transverse process of the second cervical vertebra，while the middle cervical ganglion，when present，lies just in front of the transverse process of the sixth cervical vertebra，the tubercle of which is palpable via the anterior neck，lateral to the cricoid cartilage．The inferior cervical ganglion may be fused with the first thoracic cervical ganglion，forming the stellate or cervicothoracic ganglion．Stellate ganglion block is often employed to perform a sympathetic nerve block to the head and neck， or to the arm（Ellis et al 2004）．

## External skull

The skull is the bony skeleton of the head. It houses the brain, the organs of special sense, and the upper parts of the respiratory and digestive systems, and provides attachments for many of the muscles of the head and neck. Movement is restricted and is found only in relation to the mandible at the temporomandibular joint and at the atlantooccipital joint for movement of the head in relation to the neck.

The skull consists of the cranium, facial skeleton and mandible. The cranium may be subdivided into the calvaria (sometimes called the cranial vault) and the basicranium (cranial base). It encloses the brain, cranial nerves, meninges, blood vessels and cerebrospinal fluid within the cranial cavity. Internally, the cranial base can be divided into three regions corresponding to the floor of the anterior, middle and posterior cranial fossae. An alternative subdivision of the skull distinguishes between the neurocranium (calvaria and basicranium) and the viscerocranium (facial skeleton), which hangs down from the front of the neurocranium and houses the organs of sight, smell and taste, as well as the openings to the respiratory and digestive systems via the nose and mouth, respectively. In clinical parlance, the terms skull base and cranial base are frequently used as though they are synonymous. Indeed, inspection of the inferior surface of a skull confirms that the middle and posterior cranial bases are the same as the middle and posterior skull bases. However, the anterior cranial base and the anterior skull base should not be used interchangeably because the anterior skull base includes the inferior surface of the facial skeleton, whereas the internal surface of the anterior cranial base is the floor of the anterior cranial fossa and may be further subdivided into a midline (central) and two lateral parts. Developmentally, the parts of the skull where the bones are derived by endochondral ossification constitute the chondrocranium; the remaining bones are derived by intramembranous ossification.

The skull is the most complex bony structure in the body: the young adult skull is composed of an average of 28 separate bones, many of which are paired; some in the median plane are single, though symmetrical. Most of the vault bones are flat, and consist of two tables or plates of compact bone enclosing a narrow layer of relatively dense cancellous marrow (diploic bone). The marrow within the skull bones is a site of haemopoiesis, at least in the young individual. These bones form by intramembranous ossification of a highly vascular connective tissue membrane and have often been referred to as 'dermal' in deference to their alleged ancient phylogenetic origin. The inner table is thinner and more brittle while the outer tends to be thicker and more resilient; this is important to remember when examining fractures to the skull caused by either blunt or sharp trauma. This bone type is also of considerable value in cranial bone grafting in the young, where the two tables can be split to produce an autograft. The skull bones vary in thickness in different regions, with the bones of the viscerocranium being rather delicate and therefore particularly susceptible to fracture.

The majority of bones in the skull articulate via fibrous joints termed sutures, which facilitate growth rather than movement in the developing skull. The three main sutural morphologies reflect the magnitude of strain placed on them. Thus the margins of adjacent bones of a suture may be smooth and meet end to end, giving a simple (butt-end) suture (e.g. median palatine suture); may be bevelled, so that the border of one bone overlaps the other (e.g. parietotemporal suture); or may present numerous projections that interlock, giving a serrated jigsaw appearance (e.g. lambdoid suture). The complexity of serrated sutures increases from the inner to the outer surface. Fusion across sutures (synostosis) can start early in the third decade, although its variability precludes using this information to assess age with any degree of accuracy. The process of fusion starts on the internal surface of the cranium first and proceeds externally; the coronal and sagittal sutures are often the first to display synostosis. By middle age, many of the larger sutures will show evidence of synostosis, although there are some that rarely show fusion, e.g. the zygomaticofacial. Premature fusion of sutures
during the early growth phase of the skull will result in various abnormalities.

The bones forming the base of the skull develop mainly via endochondral ossification, and also play an important part in the overall growth of the face and the neurocranium. The joints between bones in the skull base are primary cartilaginous joints. One of the most important is the spheno-occipital synchondrosis, between the body of the sphenoid anteriorly and the basilar part of the occipital bone posteriorly; fusion between them is generally completed between 13 and 18 years of age.

There are only two sites of synovial articulation associated with the exterior of the skull, namely: the temporomandibular joint and the atlanto-occipital joint (between the condyles of the occipital bone and the superior articular facets of the atlas). Movement at these joints does not facilitate rotation but participates in flexion and extension in the anteroposterior plane and bilateral flexion in the transverse plane.

Many important neurological and vascular structures enter and exit the skull via foramina (openings). The skull is a prime site for fractures resulting from trauma, which means that these structures are at risk of damage following head injury. In addition to the main foramina, irregular emissary foramina allow veins situated externally on the face and scalp to communicate with those lying intracranially; spread of infection along these routes may have serious clinical consequences.

In the account of the skull that follows, only generalized standard views will be considered. A more detailed account of each individual bone will be found associated with the relevant regional text (Berkovitz and Moxham 1994).

## FRONTAL (ANTERIOR) VIEW

Viewed from the front, the skull is generally ovoid in shape and is wider above than below (Fig. 27.1). The upper part is formed by the frontal bone, which underlies the forehead region above the orbits. Superomedial to each orbit is a rounded superciliary arch (more pronounced in males), between which there may be a median elevation, the glabella. The glabella may show the remains of the interfrontal (metopic) suture, which usually closes in the first postnatal year (Weinzweig et al 2003), but persists in a small percentage of adult skulls in various ethnic groups. The frontal bone articulates with the two nasal bones at the frontonasal sutures, marked by a depression at the root of the nose; the point at which the frontonasal and internasal sutures meet is the anthropometric landmark known as the nasion.

The upper part of the face is occupied by the orbits and the bridge of the nose. Each orbital opening is roughly quadrangular in shape (Ch. 41). The upper, supraorbital, margin is formed entirely by the frontal bone, interrupted at the junction of its sharp lateral two-thirds and rounded medial third by the supraorbital notch or foramen, which transmits the supraorbital vessels and nerve. The lateral margin of the orbit is formed largely by the frontal process of the zygomatic bone and is completed above by the zygomatic process of the frontal bone; the suture between them (frontozygomatic) lies in a palpable depression. The infraorbital margin is formed by the zygomatic bone laterally and the maxilla medially. Both lateral and infraorbital margins are sharp and palpable. The medial margin of the orbit is formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla.

The central part of the face is occupied mainly by the paired maxillae, separated by the anterior nasal aperture. Each maxilla contributes to the upper jaw, the floor and medial wall of the orbital cavity, the lateral wall of the nose, the floor of the nasal aperture and the bone of the cheek. The anterior nasal spine marks the upper limit of the intermaxillary suture at the lower margin of the anterior nasal aperture and is palpable in the nasal septum. The infraorbital foramen transmits

A

Fig. 27.1 A, The bones of the adult skull, frontal aspect. B, An anteroposterior view of the skull and upper cervical spine, young adult. Key: 1, sagittal suture; 2, frontal sinus; 3, crista galli; 4, mastoid air cells; 5, nasal septum; 6, inferior concha; 7, dens of axis. C, Reformatted volume rendered CT scan of anteroposterior view of the skull. (A, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the infraorbital vessels and nerve, and lies about 1 cm below the middle of the infraorbital margin. The maxillary alveolar process bears the upper teeth. The short, thick zygomatic process of the maxilla has an oblique upper surface that articulates with the zygomatic bone at the zygomaticomaxillary suture. The frontal process of the maxilla ascends posterolateral to the nasal bone to articulate with it medially, the frontal bone superiorly and the lacrimal bone laterally.

The anterior nasal aperture is piriform in shape, wider below than above and bounded by the paired nasal bones and maxillae. The upper boundary of the aperture is formed by the nasal bones while the remainder is formed by the maxillae. In life, several cartilages (septal, lateral nasal, major and minor alar) help to delineate two nasal cavities. The shape of these bones can be used quite successfully to predict the shape of the cartilaginous nose in forensic facial reconstructions (Wilkinson and Rynn 2012).

The lower part of the face, below the nose, is formed from the alveolar arch of the maxillae and the upper dentition, the body of the mandible, the alveolar process of the mandible and the lower dentition. In the midline, the mental protuberance produces the characteristic prominence of the chin. The mental foramen, which transmits the mental nerve and accompanying vessels, lies in the same vertical plane as the supraorbital and infraorbital foramina.

Anteroposterior radiographs of the skull clearly show the central location of the paranasal air sinuses in the frontal bone, maxilla and ethmoid. These can be particularly useful indicators of identity when postmortem images are compared with antemortem clinical films.

## POSTERIOR VIEW

The parietal, temporal and occipital bones form the entirety of the posterior view (Fig. 27.2). The superolateral region is occupied by the parietal bones, the mastoid region of the temporal bones makes up the inferolateral regions, and the central portion is occupied by the occipital bone, which is the reason why this aspect is also referred to as the occipital view. The parietal bones articulate with the occipital bone at the lambdoid suture, which extends inferiorly into the occipitomastoid and the parietomastoid sutures behind and above the mastoid processes, respectively. The lambda is the anthropometric point where the occipital bone meets the two parietal bones. Accessory sutural bones are islands of bone that may be found within a suture. They may arise from separate centres of ossification and they appear to have no clinical significance, being of genetic rather than pathological aetiology; their initial formation is thought to be caused by a degree of dural strain and increased sutural width (Bellary et al 2013). A large, central interparietal bone is not uncommon and is sometimes referred to as an Inca bone (see Fig. 27.2).

The external occipital protuberance is a midline elevation on the occipital bone that can become particularly well developed and palpable in males. The location of the protuberance coincides with the anthropometric inion. Superior nuchal lines extend laterally from the protuberance and represent the boundary between the scalp and the neck. Inferior nuchal lines run parallel to, and below, the superior nuchal lines; a set of highest nuchal lines may sometimes occur above the superior lines. The external occipital protuberance, nuchal lines and roughened external surface of the occipital bone between the nuchal lines all afford attachment to muscles of the neck.

## SUPERIOR VIEW

Seen from above, the contour of the calvaria varies greatly but is usually ellipsoid, or more strictly, a modified ovoid with its greatest width lying nearer to the occipital pole (Fig. 27.3). Four bones constitute this view and articulate via three well-defined sutures. The squamous part of the frontal bone is anterior, the squamous part of the occipital bone is posterior and the two parietal bones meet in the midline and separate the frontal from the occipital bone. The maximal parietal convexity on each site is palpable at the parietal tuber or eminence; it is most conspicuous in the female (retention of a paedomorphic appearance). The superior and inferior temporal lines run close to the parietal eminence but are best seen in a lateral view.

The coronal suture marks the articulation between the posterior margin of the frontal bone and the anterior margins of the two parietal bones. It descends across the calvaria and projects inferiorly until it meets the junction between the greater wing of the sphenoid and the squamous temporal bone at the pterion. The sagittal suture runs in the midline between the two parietal bones and extends from the bregma anteriorly to the lambda posteriorly. The lambdoid suture delineates the articulation between the posterior borders of the right and left parietal bones and the superior border of the occipital bone.

The bregma represents the position of the anterior fontanelle in the young child. This diamond-shaped, membrane-filled space located between the two frontal and two parietal bones of the developing fetal skull persists until approximately 18 months after birth. The lambda, at the junction of the sagittal and lambdoid sutures, represents the site of the posterior fontanelle, which persists for the first 2-3 months after birth.

A parietal foramen may pierce either or both parietal bones near the sagittal suture about 3.5 cm anterior to the lambda. It transmits a small emissary vein from the superior sagittal sinus. The vertex is the highest point on the skull and it usually occupies a position in the middle third of the sagittal suture.

## LATERAL VIEW

The skull, viewed from the side, can be subdivided into three zones: face (anterior), temporal region (middle) and occipital region (posterior) (Fig. 27.4). The face has been considered in the section on the anterior view of the skull.

The temporal region can be divided into an upper temporal fossa and a lower infratemporal fossa, separated by the position of the zygomatic arch. The upper temporal fossa is bounded inferiorly by the zygomatic arch, superiorly and posteriorly by the temporal lines, and anteriorly by the frontal process of the zygomatic bone, and is continuous inferiorly with the infratemporal fossa deep to the zygomatic arch. The temporal lines often present anteriorly as distinct ridges but become much less prominent as they arch posteriorly across the parietal bone. The inferior temporal line becomes more prominent as it curves down the posterior part of the squamous temporal bone, forming a supramastoid crest at the base of the mastoid process. The superior temporal line gives attachment to the temporal fascia while the inferior temporal line provides attachment for temporalis.

The floor of the temporal fossa is formed by the frontal and parietal bones superiorly and the greater wing of the sphenoid and squamous part of the temporal bone inferiorly. All four bones of one side meet at a roughly H -shaped sutural junction termed the pterion. This is an important anthropometric landmark because it commonly overlies both the anterior branch of the middle meningeal artery and the lateral fissure of the cerebral hemisphere (Ma et al 2012). The pterion corresponds to the site of the anterolateral (sphenoidal) fontanelle of the neonatal skull, which closes in the third month after birth.

The vertical suture between the sphenoid and temporal bones, the sphenosquamosal suture, is formed by articulation between the posterior border of the greater wing of the sphenoid and the anterior border of the squamous part of the temporal bone.

The lateral surface of the ramus of the mandible will be described briefly here because it lies within the middle region of this view of the skull. The ramus is a plate of bone projecting upwards from the body of the mandible; its lateral surface gives attachment to masseter. The ramus bears two prominent processes superiorly, the coronoid process anteriorly and the condylar process posteriorly, separated by the mandibular notch. The coronoid process is the site of insertion of temporalis; the condylar process articulates with the mandibular fossa of the temporal bone at the temporomandibular joint. The inferior and posterior borders of the mandible meet at the angle; it is more commonly splayed in the male, reflecting the larger site of attachment for medial pterygoid on the internal surface.

The zygomatic arch stands proud of the rest of the skull, and the temporal and infratemporal fossae communicate via the gap thus created. In life, this space is largely filled by temporalis. The zygomatic bone is the principal bone of the cheek together with the zygomatic processes of the maxilla and temporal bones. The term 'zygomatic arch' is generally restricted to the temporal process of the zygomatic bone and the zygomatic process of the temporal bone, which articulate at the zygomaticotemporal suture. The suture between the zygomatic process of the frontal bone and the frontal process of the zygomatic bone is the frontozygomatic suture; the suture between the maxillary margin of the zygomatic bone and the zygomatic process of the maxilla is the zygomaticomaxillary suture; and the suture between the sphenoid and zygomatic bones is the sphenozygomatic suture. As the zygomatic process of the temporal bone passes posteriorly, it widens to form the articular tubercle of the mandibular fossa anteriorly.

The temporal bone is a prominent structure on the lateral aspect of the skull. Its squamous part lies in the floor of the upper temporal fossa and its zygomatic process contributes to the structure of the cheek. Additional components visible in the lateral view of the skull are the mandibular (glenoid) fossa and its articular eminence (tubercle), the tympanic plate, the external acoustic meatus (external auditory meatus), and the mastoid and styloid processes. The mandibular fossa is bounded in front by the articular eminence and behind by the tympanic plate. The articular eminence provides a surface over which the mandibular condyle glides during mandibular movements. The tympanic plate of the temporal bone contributes most of the margin of the external acoustic meatus; the squamous part forms the posterosuperior region. The external margin is roughened to provide an attachment for the cartilaginous part of the meatus. A small depression, the suprameatal triangle, lies above and behind the meatus and is related to the lateral wall of the mastoid antrum. The mastoid process is an inferior projection of the temporal bone. It lies posteroinferior to the external acoustic meatus and is the site of attachment of sternocleidomastoid. It is in contact behind with the posteroinferior angle of the parietal bone at the parietomastoid suture and with the squamous part of the occipital bone at the occipitomastoid suture. These two sutures meet the lateral end of the lambdoid suture at the asterion. This coincides with the site of the posterolateral fontanelle in the neonatal skull, which closes during the second year. A mastoid foramen may be found near, or in, the occipitomastoid suture; it transmits an emissary vein from the sigmoid sinus. Sutural bones may appear in the parietomastoid suture.

The styloid process lies anterior and medial to the mastoid process and gives attachment to several muscles and ligaments. Its base is partly ensheathed by the tympanic plate and it descends anteromedially, its

Copyright 2013.)
tip usually reaching a point medial to the posterior margin of the mandibular ramus. The styloid process is very variably developed. Its length ranges from a few millimetres to a few centimetres and increases with age (Krmpotić Nemanić et al 2009).

The infratemporal fossa is an irregular, postmaxillary space deep to the ramus of the mandible. It communicates with the upper temporal fossa deep to the zygomatic arch. It is best visualized when the mandible is removed but, for completeness, is considered here. Its roof is the infratemporal surface of the greater wing of the sphenoid, the lateral pterygoid plate lies medially, and the ramus of the mandible and styloid process lie laterally and posteriorly, respectively. The infratemporal fossa has no anatomical floor. Its anterior and medial walls are separated above by the pterygomaxillary fissure lying between the lateral pterygoid plate and the posterior wall of the maxilla. The infratemporal fossa communicates with the pterygopalatine fossa through the pterygomaxillary fissure.

## INFERIOR VIEW

With the mandible removed, the inferior surface of the skull extends from the upper incisor teeth anteriorly to the superior nuchal lines of the occipital bone posteriorly (Fig. 27.5). The region contains many of the foramina through which structures enter and exit the cranial cavity.

The inferior surface may be conveniently subdivided into anterior, middle, posterior and lateral parts. The anterior part contains the hard palate and the dentition of the upper jaw, and lies at a lower level than the rest of the cranial base. The middle and posterior parts may be arbitrarily divided by a transverse plane passing through the anterior margin of the foramen magnum. The middle part is occupied mainly by the sphenoid bone, the apices of the petrous processes of the temporal bones, and the basilar part of the occipital bone. The lateral part contains the zygomatic arches, mandibular fossae, tympanic plates and the styloid and mastoid processes. The posterior part lies in the midline and is formed almost exclusively from the occipital bone. Whereas the middle and posterior parts are directly related to the cranial cavity (the middle and posterior cranial fossae), the anterior part is some distance from the anterior cranial fossa, being separated from it by the nasal cavities.

## ANTERIOR PART OF INFERIOR SURFACE

The bony palate within the superior alveolar arch is formed by the palatine processes of the maxillae anteriorly and the horizontal plates of the palatine bones posteriorly, all meeting at a cruciform system of sutures (see Fig. 27.5). The median palatine suture runs anteroposteriorly and divides the palate into right and left halves. This suture is

Fig. 27.5 The external surface of the base of the adult skull. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
continuous with the intermaxillary suture between the maxillary central incisor teeth. The transverse palatine (palatomaxillary) sutures run transversely across the palate between the maxillae and the palatine bones. The palate is arched sagittally and transversely; its depth and breadth are variable but are always greatest in the molar region. The incisive fossa lies behind the central incisor teeth, and the lateral incisive foramina, through which incisive canals pass to the nasal cavity, lie in its lateral walls. Median incisive foramina are present in some skulls and open on to the anterior and posterior walls of the fossa. The incisive fossa transmits the nasopalatine nerve and the termination of the greater palatine vessels. When median incisive foramina occur, the left nasopalatine nerve usually traverses the anterior foramen and the right nerve traverses the posterior foramen. The greater palatine foramen lies near the lateral palatal border of the transverse palatine suture; a vascular groove, deeper behind and shallower in front, leads forwards from the foramen. The lesser palatine foramina, usually two, lie behind the greater palatine foramen and pierce the pyramidal process of the palatine bone, which is wedged between the lower ends of the medial and lateral pterygoid plates. The palate is pierced by many other small foramina and is marked by pits for palatine glands. Variably prominent palatine crests extend medially from behind the greater palatine foramina. The posterior border projects back as the posterior nasal spine. In the adult, the alveolar arch normally bears a maximum of 16 sockets or alveoli for the teeth; the sockets vary in size and depth, and some are single and some are subdivided by septa, according to the morphology of the dental roots.

The nasal fossae lie above the hard palate and are separated by the nasal septum in the midline. The bony nasal septum is formed from the perpendicular plate of the ethmoid superiorly and the vomer inferiorly. The upper border of the vomer approximates to the inferior aspect of the body of the sphenoid, where it expands into an ala on each side. The two posterior nasal apertures (choanae) are located at the end of the nasal fossae; they are separated by the free posterior border of the vomer, and bounded below by the posterior border of the horizontal plates of the palatine bones, above by the sphenoid and laterally by the medial pterygoid plates.

## MIDDLE PART OF INFERIOR SURFACE

The middle part of the inferior surface is made up from the sphenoid, petrous parts of the temporal bones and the basiocciput (see Fig. 27.5). It extends from the posterior nares anteriorly to an artificial line drawn transversely through the anterior margin of the foramen magnum posteriorly. In the adult, the body of the sphenoid fuses with the basiocciput to form a midline bar of bone that extends posteriorly to the foramen magnum (internally, this is known as the clivus). The basiocciput bears a small midline pharyngeal tubercle, which gives attachment to the pharyngeal raphe, the highest attachment of the superior pharyngeal constrictor.

The petrous processes of the two temporal bones pass from the lateral sides of the base of the skull and fill the triangular space between the greater wing of the sphenoid anteriorly and the lateral margins of the basiocciput posteriorly. Each petrous process meets the basilar part of the occipital bone at a petro-occipital junction, which is deficient posteriorly at the jugular foramen. The petrosphenoidal junction and the groove for the pharyngotympanic tube lie between the petrous process and the infratemporal surface of the greater wing of the sphenoid. The apex of the petrous process does not meet the sphenooccipital synchondrosis; the deficit so produced is the foramen lacerum.

Pterygoid processes descend from the junction between the greater wing and body of the sphenoid, separated by a pterygoid fossa. Anteriorly, the plates are fused, except inferiorly, where they are separated by the pyramidal process of the palatine bone. Sutures are usually discernible at this site in young skulls. Laterally, the pterygoid plates are separated from the posterior maxillary surface by the pterygomaxillary fissure, which leads into the pterygopalatine fossa. The posterior border of the medial pterygoid plate is sharp, and bears a small projection near the midpoint, above which it is curved and attached to the pharyngeal end of the pharyngotympanic tube. Above, the medial pterygoid plate divides to enclose the scaphoid fossa. Below, it projects as a slender pterygoid hamulus, which curves laterally and is grooved anteriorly by the tendon of tensor veli palatini. The pterygoid hamulus gives origin to the pterygomandibular raphe. The lateral pterygoid plate projects posterolaterally and its lateral surface forms the medial wall of the infratemporal fossa. Superiorly and laterally, the pterygoid process is continuous with the infratemporal surface of the greater wing of the sphenoid bone, which forms part of the roof of the infratemporal fossa. This surface forms the posterolateral border of the inferior orbital
fissure and bears an infratemporal crest associated with the origin of the upper part of lateral pterygoid. The infraorbital and zygomatic branches of the maxillary nerve and accompanying vessels pass through the inferior orbital fissure. Laterally, the greater wing of the sphenoid articulates with the squamous part of the temporal bone.

The medial aspect of the greater wing of the sphenoid presents a crescent of foramina of which only the most posterior two, foramen ovale and foramen spinosum, can be viewed on the basal aspect. The foramen ovale lies medial to the foramen spinosum and lateral to the foramen lacerum on the infratemporal surface of the greater wing of the sphenoid bone. It transmits the mandibular division of the trigeminal nerve, the lesser petrosal nerve, the accessory meningeal branch of the maxillary artery and an emissary vein that connects the cavernous venous sinus to the pterygoid venous plexus in the infratemporal fossa. Posterolaterally, the smaller and rounder foramen spinosum transmits the middle meningeal artery and a recurrent meningeal branch of the mandibular nerve. The irregular spine of the sphenoid projects posterolateral to the foramen spinosum. The medial surface of the spine is flat and, with the adjoining posterior border of the greater wing of the sphenoid, forms the anterolateral wall of a groove that is completed posteromedially by the petrous part of the temporal bone. This groove contains the cartilaginous pharyngotympanic tube, which leads posterolaterally into the bony portion of the tube that lies within the petrous part of the temporal bone. Occasionally, the foramen ovale and foramen spinosum are confluent or the posterior edge of the foramen spinosum may be defective. A small foramen, the sphenoidal emissary foramen (of Vesalius), is sometimes found between the foramen ovale and scaphoid fossa. When present, it contains an emissary vein linking the pterygoid venous plexus in the infratemporal fossa with the cavernous sinus in the middle cranial fossa.

The foramen lacerum is bounded in front by the body and adjoining roots of the pterygoid process and greater wing of the sphenoid bone; posterolaterally, by the apex of the petrous part of the temporal bone; and medially, by the basilar part of the occipital bone. Although nearly 1 cm long, it is not traversed by any major structure. The almost circular carotid canal lies behind and posterolateral to the foramen lacerum in the petrous part of the temporal bone. The internal carotid artery enters the skull through this foramen, ascends in the carotid canal, and turns anteromedially to reach the posterior wall of the foramen lacerum. It ascends through the upper end of the foramen lacerum, accompanied by venous and sympathetic nerve plexuses. Meningeal branches of the ascending pharyngeal artery and emissary veins from the cavernous sinus also traverse the foramen lacerum. In life, the lower part of the foramen lacerum is partially occluded by cartilaginous remnants of the embryological chondrocranium. The pterygoid canal can be seen on the base of the skull at the anterior margin of the foramen lacerum, above and between the pterygoid plates of the sphenoid bone. It leads into the pterygopalatine fossa and transmits the nerve of the pterygoid canal and accompanying blood vessels.

## POSTERIOR PART OF INFERIOR SURFACE

The posterior part of the inferior surface of the skull is predominantly formed by the occipital bone (see Fig. 27.5). Prominent features are the foramen magnum and associated occipital condyles, jugular foramen, mastoid notch and the squamous part of the occipital bone up to the external occipital protuberance and the superior nuchal lines, hypoglossal canals (anterior condylar canals) and condylar canals (posterior condylar canals).

The foramen magnum lies in an anteromedian position and leads into the posterior cranial fossa. It is oval and wider behind, with its greatest diameter being anteroposterior. It contains the lower end of the medulla oblongata, meninges, cerebrospinal fluid, vertebral arteries and veins, and the accessory nerves; the apical ligament of the dens and the tectorial membrane pass through it to attach to the internal basiocciput. Anteriorly, the margin of the foramen magnum is slightly overlapped by the occipital condyles, which project down to articulate with the superior articular facets on the lateral masses of the atlas. Each occipital condyle is oval in outline and orientated obliquely so that its anterior end lies nearer the midline than its posterior end. It is markedly convex anteroposteriorly, less so transversely, and its medial aspect is roughened by ligamentous attachments. The hypoglossal canal, directed laterally and slightly forwards, traverses deep to each condyle and transmits the hypoglossal nerve, a meningeal branch of the ascending pharyngeal artery and an emissary vein from the basilar plexus. A depression, the condylar fossa, lies immediately posterior to the condyle and may contain a (posterior) condylar canal for an emissary vein from the sigmoid sinus. This fossa accommodates the posterior margin of the
atlas when the head is fully extended. A jugular process articulates with the petrous part of the temporal bone lateral to each condyle and its anterior free border forms the posterior boundary of the jugular foramen.

Laterally, the occipital bone approximates with the petrous part of the temporal bone anteriorly at the petro-occipital junction, and the mastoid process of the temporal bone more posteriorly at the occipitomastoid suture. The jugular foramen, a large, irregular hiatus, lies at the posterior end of the petro-occipital junction between the jugular process of the occipital bone and the jugular fossa of the petrous part of the temporal bone (see Fig. 37.1C) (Vogl and Bisdas 2009). A number of important structures pass through this foramen: inferior petrosal sinus (anterior); glossopharyngeal, vagus and accessory cranial nerves (middle); and internal jugular vein (posterior). A mastoid canaliculus runs through the lateral wall of the jugular fossa and transmits the auricular branch of the vagus nerve. The canaliculus for the tympanic branch of the glossopharyngeal nerve lies on the ridge between the jugular fossa and the opening of the carotid canal. A small notch, related to the inferior glossopharyngeal ganglion, may be found medially, on the upper boundary of the jugular foramen (it is more easily identified internally). The orifice of the cochlear canaliculus may be found at the apex of the notch.

The squamous part of the occipital bone exhibits the external occipital protuberance, supreme, superior and inferior nuchal lines, and the external occipital crest, all of which lie in the midline, posterior to the foramen magnum. The region is roughened for the attachment of muscles whose primary function is extension of the skull at the neck.

## LATERAL PART OF INFERIOR SURFACE

The lateral part of the inferior surface consists of the zygomatic arch and infratemporal fossa anteriorly and the mandibular fossa, tympanic plate and styloid and mastoid processes posteriorly (see Fig. 27.5). The anterior structures have been considered earlier in this chapter.

The mandibular fossa is a thin-walled, smooth, concave depression in the temporal bone and is most easily inspected when the mandible is removed. The zygomatic arch extends laterally in front of the fossa and a distinct ridge, the articular eminence, lies anterior to the fossa. Three fissures can be distinguished behind the mandibular fossa. The squamotympanic fissure extends from the spine of the sphenoid, between the mandibular fossa and the tympanic plate of the temporal bone, and curves up the anterior margin of the external acoustic meatus. A thin wedge of bone forming the inferior margin of the tegmen tympani lies within the fissure and divides the squamotympanic fissure into petrotympanic and petrosquamous fissures. The petrotympanic fissure transmits the chorda tympani branch of the facial nerve from the intracranial cavity into the infratemporal fossa. The tympanic plate forms the floor of the external acoustic meatus.

The stylomastoid foramen lies between the mastoid and styloid processes on the lateral aspect of the temporal bone. It transmits the facial nerve and the stylomastoid artery. The distance from the styloid process to the stylomastoid foramen decreases with age (Krmpotic Nemanic et al 2009). A groove, the mastoid notch, lies medial to the mastoid process and gives origin to the posterior belly of digastric. A groove related to the occipital artery often lies medial to the mastoid notch. A mastoid foramen may be present near, or in, the occipitomastoid suture; when present, it transmits an emissary vein from the sigmoid sinus. The external acoustic meatus lies in front of the mastoid process. It is surrounded inferiorly by the tympanic plate, which partly ensheathes the base of the styloid process as the vaginal process.

## CRANIAL FOSSAE (ANTERIOR, MIDDLE, POSTERIOR)

The cranial fossae are described in Chapter 28.

## DISARTICULATED INDIVIDUAL BONES

Individual bones are described in the appropriate chapters. The bones of the facial skeleton and cranial vault are described in the chapters on the face and scalp (Ch. 30), nose and paranasal sinuses (Ch. 33), external and middle ear (Ch. 37), and orbit (Ch. 41). The sphenoid and mandible are described in the chapter on the infratemporal fossa (Ch. 32) and the occipital bone is described in the chapter on the back (Ch. 43).

## JOINTS

The general characteristics of cranial sutures and the detailed anatomy of the temporomandibular joint and the atlanto-occipital joints are described in Chapter 5 and on page 541 and page 736, respectively. Sutural bones are described below on page 425.

## NEONATAL, PAEDIATRIC AND SENESCENT ANATOMY

## THE SKULL AT BIRTH

At birth, the calvaria is large in proportion to other skeletal parts, reflecting precocious cerebral maturation. The facial region is relatively small and constitutes only about one-eighth of the neonatal skull, whereas it constitutes about half of the adult skull (Fig. 27.6). Smallness of the face at birth is due mainly to the rudimentary stage of development of the mandible and maxillae; the teeth are unerupted and the maxillae are not yet pneumatized (invaded by air cells). The nose lies almost entirely between the orbits, and the lower border of the nasal aperture is only slightly lower in position than the orbital floors. Bones of the calvaria are unilaminar and lack diploë. Frontal and parietal tuberosities are prominent; in the frontal view, the greatest width occurs between the parietal tuberosities. The glabella, superciliary arches and mastoid processes are not developed and the cranial base is relatively short and narrow.

Ossification is incomplete, and many bones are still in several elements that are united by fibrous tissue or cartilage. The 'os incisivum' is continuous with the maxilla; pre- and postsphenoids may have just united, but the two halves of the frontal bone and the mandible, and the squamous, lateral and basilar parts of the occipital bone, are all separate, as are the petromastoid and squamotympanic parts of the temporal bone. The fibrous membrane that forms the calvaria remains unossified at the six angles of the parietal bones, producing six fontanelles: two single midline (anterior and posterior) and two lateral pairs (sphenoidal/anterolateral and mastoid/posterolateral). The anterior fontanelle is the largest, measuring approximately 4 cm in anteroposterior and 2.5 cm in transverse dimensions. It occupies the junction between the sagittal, coronal and frontal sutures and is rhomboid in shape. The posterior fontanelle lies at the junction between the sagittal and lambdoid sutures and is triangular in shape. The sphenoidal (anterolateral) and mastoid (posterolateral) fontanelles are small and irregular in shape and lie at the sphenoidal and mastoid angles of the parietal bones, respectively.

At birth, the orbits appear relatively large. The developing tooth germs are generally contained within the alveolar crypts, although eruption of the upper central incisor teeth can occur prior to, or shortly after, birth. Temporal bones differ greatly from their adult form. The internal ear, tympanic cavity, auditory ossicles and mastoid antrum are all almost adult in size, the tympanic plate is an incomplete ring that has usually started to fuse with the squamous part, and the mastoid process is absent. The external acoustic meatus is short, straight and wholly cartilaginous. The external aspect of the tympanic membrane faces more inferiorly than laterally, in accord with the basal cranial contour. The stylomastoid foramen is exposed on the lateral surface of the skull, the styloid process has not yet commenced ossification, the mandibular fossa is flat and more lateral, and its articular tubercle is undeveloped. The paranasal sinuses are rudimentary or absent and only the maxillary sinuses are usually identifiable.

The skull is moulded by slow compression during vaginal birth. That part of the scalp that is more central in the birth canal is often temporarily oedematous (caput succedaneum) as a result of interference with venous return. Fontanelles and the openness and width of the sutures allow bones of the cranial vault some overlap during the process of birth; the skull is compressed in one plane with compensatory orthogonal elongation. These deformations disappear within the first week after birth.

## POSTNATAL GROWTH

Although postnatal growth of the calvaria (cranial vault) and facial skeleton usually proceeds in a coordinated fashion, these regions exhibit different rates and temporal periods of expression. In general, early growth of the vault is largely influenced by cerebral maturation while growth of the facial skeleton responds to spatial requirement for the development of the teeth and the muscles of mastication. Growth

of the cranial base is largely independent of both vault and facial development, and therefore the three regions will be considered separately. (For further reading, see Belden (1998), Sgouros et al (1999), Scheuer and Black (2000) and Sperber and Guttmann (2001).)

## Growth of the calvaria

Growth of the calvaria is rapid during the first year and then continues at a slower rate until the seventh year, when it has reached almost adult dimensions. For most of this period, expansion is largely concentric; overall form is determined early in the first year and remains largely unaltered thereafter. However, the shape of the vault is not solely related to cerebral growth, but is also influenced by genetic factors that manifest in an extensive range of shapes and sizes that may be sufficient to allow an evaluation of ethnic origin. During the first and early second years, growth occurs primarily through ossification at apposed margins of bones (which possess an osteogenic layer), accompanied by some accretion and absorption of bone at surfaces in order to adapt to continually altering curvatures. Growth in breadth is said to occur at the
sagittal, sphenofrontal, sphenotemporal, occipitomastoid and petrooccipital junctions, while growth in height is said to occur at the frontozygomatic and squamosal sutures, pterion and asterion. During this period, fontanelles are closed by progressive ossification of the bones around them, but separate isolated centres of ossification may develop into sutural bones. The sphenoidal and posterior fontanelles close within 2 or 3 months of birth and the mastoid fontanelles usually close near the end of the first year. Wide variability in both the size and the timing of closure of the anterior fontanelle has been reported, but most will have closed by the middle of the second year and almost all will have closed by 24 months (Pindrik et al 2014).

Early in the first years, the calvarial bones commence interlocking at sutural junctions. Further expansion is largely achieved by accretion and absorption on external and internal bone surfaces, respectively. At the same time the bones also thicken, although this is not a uniform process. At birth, the vault is unilaminar but the tabular structure with intervening diploë is generally apparent soon thereafter. Thickening of the vault and development of external muscular markings reflect the influences of musculoskeletal maturation. The mastoid processes do not usually develop until the second year and they are pneumatized in
the sixth year (Scheuer and Black 2000). (For further reading about craniofacial morphology in preterm infants, see Paulsson and Bondemark 2009.)

## Growth of the cranial base

Growth of the cranial base is largely responsible for cranial lengthening. It occurs at the cartilaginous joints between the sphenoid and ethmoid anteriorly, and especially between the sphenoid and occipital bones posteriorly (Lieberman et al 2000). Most of the growth occurs during the first five years of life (Sgouros et al 1999); it continues at the spheno-occipital synchondrosis until mid-teenage years. The prolonged period of continued expansion reflects a significant delaying mechanism that allows the continued and relatively late eruption of the permanent dentition. There is some evidence that growth may cease at about 15 years following eruption of the second molars, and this can often lead to insufficient space for growth of the third molars. A pubertal growth spurt has been ascribed to both sexes; it tends to occur some 2 years earlier in females and is likely to continue until the eighteenth year in the male. The anterior cranial base is significantly shorter in extremely preterm infants (under 28 weeks) (Paulsson and Bondemark 2009).

## Growth of the facial skeleton

Growth of the facial skeleton occurs over a longer time period than is witnessed for the calvaria. The ethmoid and the orbital and upper nasal cavities have almost completed growth by the seventh year. Orbital and upper nasal growth is achieved by sutural accretion, with deposition of bone preferentially occurring on the facial aspects of the sutural junctions. The maxilla is carried downwards and forwards by expansion of the orbits and nasal septum and by sutural growth, especially at the fontanelles and zygomaticomaxillary and pterygomaxillary sutures. In the first year, growth in width occurs at the symphysis menti and midpalatal, internasal and frontal sutures; such growth diminishes or even ceases when the symphysis menti and frontal suture close during the first few years, even though the mid-palatal suture persists until mature years. Facial growth continues up to puberty and shows a period of expansion that is linked to the growth spurt and hormonal influences of secondary sexual alteration. After sutural growth, near the end of the second year, expansion of the facial skeleton occurs by surface accretion on the face, alveolar processes and palate, and resorption in the walls of the maxillary sinuses, the upper surface of the hard palate and the labial aspect of the alveolar process. Coordinated growth and divergence of the pterygoid processes reflect deposition and resorption of bone on appropriate surfaces.

Obliteration of the calvarial sutures progresses with age, starting between 20 and 30 years internally, and somewhat later on the exterior. Closure times vary greatly. Obliteration usually begins in the coronal or sagittal sutures and then extends into the lambdoid suture. The size of the mandible and maxillae diminish following the loss of teeth and consequent resorption of alveolar bone; this reduces the vertical depth of the face and increases the mandibular angles.

## Sutural bones

Additional ossification centres may occur in or near sutures, giving rise to isolated sutural bones (also called Wormian bones) (Bellary et al 2013). Usually irregular in size and shape, and most frequent in the lambdoid suture, they also occur at fontanelles, especially the posterior fontanelle. They may represent a pre-interparietal element, a true interparietal, or a composite. An isolated bone at the lambda is sometimes referred to as an Inca bone or Goethe's ossicle. One or more pterion ossicles or epipteric bones may appear between the sphenoidal angle of the parietal and the greater wing of the sphenoid; they vary greatly in size but are more or less symmetrical. Sutural bones usually have little morphological significance. However, they appear in great numbers in hydrocephalic skulls (Fig. 27.7), and they have therefore been linked with rapid cranial expansion.

## Craniosynostosis

Sutural growth makes an important contribution to growth of the skull, especially during the first few years of life. Premature closure of sutures (craniosynostosis) leads to restriction of growth along the sutures, producing morphological changes that may result in skull deformity (Sharma 2013). Biomechanical forces and genetically determined local

Fig. 27.7 The hydrocephalic skull of a 25 -year-old male showing numerous sutural bones. A, Lateral view. B, Posterior view. (Courtesy of the Museum of the Royal College of Surgeons of England, photograph by Mr J Carr.)
expression of growth factors have been implicated in the aetiology of premature fusion but the reasons are not fully understood. Premature fusion may occur in one or more of the cranial sutures; when the sutures around the cranial base are involved, severe limitation of facial bone growth will occur. Metabolic disorders such as rickets and familial hypophosphatasia can also result in synostosis. Raised intracranial pressure with or without hydrocephalus, visual deterioration and mental retardation may result. Scaphocephaly (sagittal craniosynostosis) is the most common and leads to lengthening of the vault in an anteroposterior direction; it can also occur in conjunction with other sutures, e.g. Crouzon's syndrome. Coronal synostosis, either unilateral (plagiocephaly) or bilateral (brachycephaly/oxycephaly), is the next most frequently seen and results in reduced anteroposterior development with marked supraorbital recession. When it is unilateral, the face develops asymmetrically and is rotated away from the side with premature fusion. Metopic craniosynostosis (trigonocephaly) and pansynostosis (turricephaly), where both the coronal and sphenofrontal sutures are involved, are much less common.

Craniofacial dysostosis syndromes, such as Crouzon's, Apert's, Saethre-Chotzen, Pfeiffer's and Carpenter's, show varying degrees of calvarial synostoses that are usually accompanied by a significant lack of growth in the midface. Early release of the calvarial synostoses does not result in normal facial growth, and a midfacial osteotomy at the Le Fort III level is usually required later in life. When significant orbital hypertelorism develops, a transcranial bipartitioning procedure is needed in order to bring the two orbits together.

Altered patterns of skull growth resulting in altered profiles can also be achieved deliberately by affecting sutural growth using binding and other pressure, as has been practised in certain cultures of the world (Fig. 27.8) (Tubbs et al 2006). The earliest known record of the practice is from Iraq and dates back to 45,000 BCE (Gerszten and Gerszten 1995).

Fig. 27.8 Intentional skull modification: characteristic elongation of the cranial vault produced by head-binding of a newborn. (Courtesy of John Langdon.)

## Congenital abnormalities affecting the skull

A large number of malformations and anomalies affect the bones and associated soft tissue structures of the skull and are the result of a localized error of morphogenesis during embryological development. Many are recognized patterns of malformation that are presumed to have the same aetiology. They do not arise as the result of just one isolated error in morphogenesis and are described as syndromes; specific texts should be consulted for further details.

## IDENTIFICATION FROM THE SKULL

There are many ways of identifying an individual; in physical and forensic anthropology, the most important concern biological and personal identity (Wilkinson and Rynn 2012). Biological identity pertains to those features that allow an individual to be classified in relation to features present in other individuals, e.g. sex, age, ethnic origin and stature, whereas personal identity establishes criteria that are characteristic and discriminatory for a particular individual, e.g. DNA, fingerprints and dental information. The skull is a useful source of information for the establishment of both biological and personal identity and is probably the most studied region of the skeleton. The foundation of this obsession has many historical roots, but fundamentally it has arisen from the importance that humans place on the concept that the skull is the repository of 'self', and that it is the means by which interpersonal communication is effected. Our face is our primary means of recognition and communication, and therefore it plays a pivotal role in establishing and reconstructing the identity of an individual (Lahr 1996).

## SEX DETERMINATION

The determination of sex from a juvenile skull is notoriously unreliable. While sexual differences have been detected in measurements of the mandible, orbits, tooth size and pattern of dental eruption, they do not reach a level of statistical discrimination that will allow accurate and reliable assessment. It is equally difficult to assign sex to the face of a child because the faces of prepubertal boys and girls are comparable; perceivable sexual dimorphism is not generally manifest until secondary sexual changes are completed. Growth in the female face ceases in advance of that of the male, and consequently, female sex-related characteristics are more paedomorphic. The defining characteristics of sex in an adult skull are therefore male in orientation and reflect the effects of the increased mass of the muscles of mastication, which attach to the mandible, and the muscles associated with maintaining the erect head. It is reported that using the skull alone, sex can be predicted with
over $80 \%$ accuracy in the adult. This is extremely encouraging, given that research has shown that the correct sex can usually be predicted from the adult living face with only $96 \%$ accuracy.

Generally speaking, the male skull is more robust and the female more gracile, although there are obvious genetic, and therefore ethnic, variations that must be considered when attempting to assign sex from a skull. The female forehead is generally higher, more vertical and more rounded than that of the male, with retention of the frontal eminences. The male mandible is more robust and larger than that of the female; it generally displays a greater height in the region of the symphysis menti, the chin is squarer, the condyles are larger, the muscle attachments are more pronounced and the gonial angle is generally less than $125^{\circ}$. A male skull has thicker and more rounded orbital margins, pronounced supraorbital ridges, and often a well-defined glabella that occupies the midline above the root of the nose. The temporal lines are more pronounced in the male and the supramastoid crest generally extends posterior to the external acoustic meatus.

Other sites of muscle attachment on the skull reflect the biomechanical requirement to keep the more robust male head erect. They include the mastoid process for sternocleidomastoid, which is generally more robust in the male and more gracile in the female, and the nuchal lines, especially the external occipital protuberance for the attachment of the ligamentum nuchae. The cranial base in the male is generally more robust and the bone is thicker, which means that this area of the skull survives inhumation particularly well and is therefore of value in sex identification from fragmentary remains.

## AGE DETERMINATION

Age is a continuous variable; to establish chronological age from a skull requires that structures change with age at a relatively constant and predictable rate. The relationship between chronological age and skeletal maturity is closest in the juvenile years, and therefore greater accuracy is achieved in the prediction of age from the juvenile than from the adult skull.

The neonatal skull has been described above. Examples of additional features that allow reliable age determination throughout the subadult years are: development of the nasal spine (by year 3), completion of the hypoglossal canal (by year 4), formation of the foramen of Huschke (by year 5), ossification of the dorsum sellae (by year 5), and fusion of the different parts of the occipital bone (by year 7). The fontanelles are usually all closed by the middle of the second year; the posterolateral is the first to close in the first 2 months after birth, and the anterior fontanelle is the last to close around the middle of the second year. The mastoid process appears in the second year and the metopic suture between the two frontal bones is usually closed by the end of the first year. The spheno-occipital synchondrosis will fuse between 11 and 16 years in the female and 13 and 18 years in the male, while the vomer and the ethmoid will fuse between 20 and 30 years of age. The last part of the skull to show active age-related growth is the jugular growth plate, a small triangular area sited posterolateral to the jugular foramen in the occipitotemporal suture. Fusion here does not begin until the third decade, and bilateral fusion may not be completed before the middle of the fourth decade; in a small proportion of individuals, the plate may remain unfused into the sixth decade. Closure of the cranial sutures is age-related but the correlation is not strong and displays strong genetic variation. Thus, while it can be said that suture closure may begin in the early part of the third decade, and it is likely that many of the sutures will be obliterated with advancing age, it is not a reliable means of establishing the age of an individual. See Scheuer and Black (2000) for further information on age determination from the juvenile skeleton.

The most accurate means of determining age from the skull (of both a living and a deceased individual) is by assessment of dental maturation. Tooth development can be studied throughout the entire juvenile age span (from the early embryo to the adolescent), and importantly, dental age and chronological age have been shown to exhibit a stronger correlation than skeletal and chronological age. Further, the teeth tend to survive inhumation successfully and are remarkably resilient to fire and explosion, ensuring their value in forensic investigations.

The chronological pattern of dental maturation is well documented and is an extremely important tool for age evaluation. Tooth development can be separated into a number of well-defined stages: deciduous mineralization (crown and root), deciduous emergence and maturation, deciduous root resorption, shedding of deciduous teeth, mineralization (crown and root) of permanent dentition, emergence and maturation of deciduous dentition, and attrition of permanent crowns. These stages do not occur in a linear fashion; while some of the
deciduous teeth are emerging, permanent teeth are already being formed. For example, mineralization of the deciduous central incisor commences around the fifteenth week post fertilization, and this is the first tooth to emerge within the first 5 months after birth. All deciduous teeth are in occlusion by around 3 years of age. The first deciduous teeth to be shed are generally the central and lateral incisors around 7 years of age, when the permanent incisors emerge. The last deciduous tooth to be shed is generally the second molar in the tenth year. The first permanent tooth to show mineralization is the first molar, which occurs around the time of birth (sometimes earlier and sometimes later); it is also the first permanent tooth to emerge at around 6 years of age, and it will reach occlusion by the end of the seventh year. The last permanent tooth to emerge is the third molar; the variability of this occurrence makes it of restricted value for age prediction.

The time taken for a crown to form can be calculated from ground sections with considerable accuracy by counting the number of daily cross-striations from the neonatal line. For permanent teeth, the time taken for the crown to form can be calculated by counting the number of the enamel striae and multiplying by the individual's periodicity. Patterns of mineralization, emergence and shedding may be supplemented by analyses of tooth length, cementum apposition, secondary dentine formation, incremental enamel lines, attrition rates, root translucency and dentine transparency (Whittaker and MacDonald 1989). Chemical analysis of the stable isotopes of carbon, oxygen and nitrogen from teeth can provide important information concerning the nature of the diet of an individual, and is used in paleodiet analysis and in studies of pathophysiology and nutrition in archaeological and living human populations (Reitsema 2013).

## DETERMINATION OF ETHNIC ORIGIN

The determination of ethnic or genetic origin is particularly difficult to achieve, although it is something that both physical and forensic anthropologists are frequently asked to attempt. The traditional view of ethnicity is that it is 'one of the major zoological subdivisions of mankind, regarded as having a common origin and exhibiting a relatively constant set of physical traits' (Bamshad and Olson 2003). Classifying groups on this basis is rather restrictive and, in our migrant modern world, somewhat artificial. It is still useful to be able to attempt to assign a 'most likely' genetic group, especially when dealing with unidentified forensic remains, but there are significant areas of overlap between the characteristics, and within any ethnic group there is often a full spectrum of representation. Yet we persist in classification on the basis of visual characteristics, and the area of the body that is most often analysed in this way is the skull.

Early anthropologists classified humans largely through geographical origins and recognized physical traits. The four traditional races of humans were: Caucasoid, Negroid, Mongoloid and Australoid. The Caucasoid race is geographically from Europe, North Africa, the Middle East, the Indian subcontinent and parts of Central Asia. Classically, the Caucasoid skull has a rounded to long shape (dolichocephalic) with a narrow nasal aperture, moderately developed supraorbital ridging, a prominent nasal spine, a steeple-shaped nasal root, little prognathism and a narrow interorbital distance. The forehead is steep, the chin is prominent, the palate is long and narrow, the cheek bones are not overly prominent, and there is a tendency to maxillary protrusion or mandibular retrusion. The Negroid race is geographically represented by Saharan, sub-Saharan and West African groups. The typical Negroid skull is also long with a wide nasal aperture, strong alveolar prognathism, low nasal root, guttering of the nasal aperture and a wide interorbital distance. The forehead is rounder, the palate is wider and the teeth are larger. The Mongoloid race is geographically represented by groups in East Asia, South East Asia, Central Asia, the Americas, Greenland, Inuit regions, Polynesia, South Asia and Eastern Europe. The typical Mongoloid skull is generally described as round with a nasal aperture of medium width, well-developed and high cheek bones, moderate prognathism, a tented nasal root, short nasal spine and shovelshaped incisors. The palate is foreshortened, the forehead is vertical, the nasal bridge is low and there is a tendency for a forward rotation of the mandible. The Australoid race is geographically represented by Australian Aborigines, Maori, Pacific Islanders, Fijians and Papuans. The skull
of this rather heterogeneous group is generally represented by a broad nasal aperture, well-developed supraorbital ridging and glabella, and a wide palate with large teeth.

There is a current resurgence in research into ethnic determination that is largely centred on genetic markers, and consequently, skeletal indicators now play a significantly reduced role in this task (Gill and Rhine 2004).

## FACIAL APPROXIMATION (RECONSTRUCTION)

Once the biological identity of an individual has been established (i.e. sex, age, stature and ethnic origin), an attempt to establish personal identity may be necessary, particularly in relation to a forensic investigation. Achieving a possible name for a victim is necessary before comparison of antemortem and postmortem data can be achieved and a positive identity established. One of the accepted ways to achieve this is to reconstruct the face from the skull, thereby producing a facial approximation that can be released to the community or the public at large in an attempt to identify the victim. Experts in this discipline utilize the many variations in the skull to reconstruct individual possible representations of the face from the material available. Biological variation will dictate the appropriate data used for tissue thickness that are applied to the skeletal scaffold.

There are fundamentally two approaches to facial reconstruction. The first approach is computer reconstruction - the skull is usually scanned by a laser three-dimensional scanner and an 'average' virtual face is wrapped around the skeletal scaffold. This approach is largely automated and requires limited training and expertise. It is rapid to achieve and relatively inexpensive, but relies on a large data set to ensure that the 'average' face utilized is appropriate. The second approach is modelled reconstruction - the skull is usually cast, and pegs are inserted into the cast at the appropriate tissue depth requirements. In the 'American' approach, a skin of clay is then moulded over the pegs to approximate the face. In the 'Manchester' method, each sequential muscle and soft tissue layer is built up around the pegs before a clay skin is moulded over the underlying structures. The modelling approach is clearly more dependent on experience, takes longer to achieve and is more costly.

There is great debate over which approach is the most accurate and, as yet, no agreement has been reached. Most practitioners state that the process achieves an approximation of one of the potential faces for the deceased and does not purport to reconstruct the actual face. The rationale is to produce an image that will jog the memory of the public and provide some possible names that will allow comparison of antemortem and postmortem identity data.

## FACIAL SUPERIMPOSITION

Once a possible name has been derived, it may be necessary to compare the skull with photographs of the suspected individual. In these circumstances, an image of the skull is superimposed on to an image of the face of the missing person (Fig. 27.9). This relies on achieving a live capture image of the skull so that it can be rotated and manipulated into an identical position and to an identical size as the photograph. Features that do not change are lined up; a photograph that shows teeth is ideal because teeth can be lined up with the dentition on the skull. The image of the skull and photograph can then be faded in and out; if this is undertaken at speed, any discrepancies will show up on the image as distortion.

## Intracranial region

The neurocranium (calvaria and cranial base) contains the brain, the intracranial portions of the cranial nerves, blood vessels, meninges and cerebrospinal fluid. Its walls are formed by parts of the frontal, ethmoid, parietal, sphenoid, temporal and occipital bones.

## INTERNAL SURFACE OF CALVARIA

The internal surface of the calvaria is deeply concave. It includes most of the frontal and parietal bones and the squamous part of the occipital bone, variously united at the coronal, sagittal and lambdoid sutures (Fig. 28.1). With increasing age, these sutures become obliterated by a gradual process that begins on their intracranial surfaces. Inconstant foramina may occur in the parietal bones near the sagittal sulcus and anterior to the lambdoid suture; they admit emissary veins associated with the superior sagittal sinus. The internal surfaces of the frontal and parietal bones are grooved by furrows that house the frontal and

Fig. 28.1 The internal surface of the cranial vault. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
parietal branches of the middle meningeal vessels; the grooves contain the openings of minute channels that admit perforating vessels to the haemopoietic marrow within the diploic bone. Impressions for cerebral gyri are less distinct on the bones of the calvaria than they are on the cranial base.

The falx cerebri, a dural partition that separates the two cerebral hemispheres of the brain, is attached anteriorly to a backward-projecting anteromedian frontal crest. The crest exhibits a groove that widens as it passes back below the sagittal suture and becomes continuous with the sagittal sulcus, which houses the superior sagittal sinus. Irregular depressions, granular foveolae, which become larger and more numerous with age, lie on either side of the sulcus and usually house arachnoid granulations.

## CRANIAL FOSSAE (ANTERIOR, MIDDLE, POSTERIOR)

The base of the cranial cavity is divided into three distinct fossae: the anterior, middle and posterior cranial fossae (Fig. 28.2). The floor of the anterior cranial fossa is at the highest level and the floor of the posterior fossa is at the lowest.

Detailed descriptions of the microsurgical anatomy of each region of the cranial base are beyond the scope of this book, and the interested reader is directed in the first instance to Rhoton (2007).

## ANTERIOR CRANIAL FOSSA

The anterior cranial fossa is formed by the frontal, ethmoid and sphenoid bones, and supports the frontal lobes of the cerebral hemispheres. Its floor is composed of the orbital plate of the frontal bone, the cribriform plate and crista galli of the ethmoid bone, and the lesser wings, jugum sphenoidale, and prechiasmatic sulcus of the sphenoid.

A perforated plate of bone, the cribriform plate of the ethmoid bone, spreads across the midline between the orbital plates of the frontal bone and is depressed below them, forming part of the roof of the nasal cavity. Olfactory nerves pass from the nasal mucosa to the olfactory bulb of the brain through numerous small foramina in the cribriform plate. Anteriorly, a spur of bone, the crista galli, projects upwards between the cerebral hemispheres and serves as an attachment for the falx cerebri. A depression between the crista galli and the crest of the frontal bone is crossed by the frontoethmoidal suture. It bears the foramen caecum, which is usually a small blind-ended depression formed by the developmental involution of a dural diverticulum that extends through the foramen caecum to the columella; in adults, it occasionally accommodates a vein draining from the nasal mucosa to the superior sagittal sinus. Failure of the foramen caecum to close may cause nasal dermoid cysts and nasoethmoidal encephalocoeles in children.

The anterior ethmoidal nerve and vessels enter the cranial cavity where the cribriform plate meets the orbital part of the frontal bone. They then pass into the roof of the nasal cavity via a small foramen by the side of the crista galli. The posterior ethmoidal canal, which transmits the posterior ethmoidal nerve and vessels, opens at the junction of the posterolateral corner of the cribriform plate and jugum sphenoidale. The convex orbital plate of the frontal bone separates the brain from the orbit and bears impressions of cerebral gyri and small grooves for meningeal vessels. Posteriorly, it articulates with the anterior border of the lesser wing of the sphenoid laterally and the jugum sphenoidale medially. The jugum sphenoidale is a flat surface on the upper aspect of the sphenoid bone that connects the two lesser wings, also known as the planum sphenoidale. The limbus of the sphenoid bone is a prominent ridge on the body of the sphenoid that forms the posterior border of the jugum sphenoidale and the anterior border of the prechiasmatic sulcus. The latter is an osseous groove that runs transversely

Fig. 28.2 The floor of cranial cavity showing the cranial fossae. (Adapted with permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer, 2013.)
between the optic canals. The optic chiasma usually lies above the prechiasmatic sulcus, while the medial orbital surface of the frontal lobes and olfactory tracts lie above the jugum sphenoidale (see Figs 28.2; 28.9).

The posterior boundary of the lesser wing forms the posterior boundary of the anterior cranial fossa; the medial end of the lesser wing constitutes the anterior clinoid process. The lesser wing and the anterior clinoid process join the sphenoid body by two roots that are separated by the optic canal. The anterior root, broad and flat, forms the roof of the optic canal and is continuous with the jugum sphenoidale, while the smaller and thicker posterior root, also known as the optic strut, joins the body of the sphenoid bone at the lateral aspect of the posterior bank of the prechiasmatic sulcus or tuberculum sellae (see Fig. 28.2). The optic strut of the anterior clinoid process separates the optic canal from the superior orbital fissure (Kerr et al 2012). Each optic canal transmits the optic nerve and ophthalmic artery.

## MIDDLE CRANIAL FOSSA

The middle cranial fossa is formed by the sphenoid and temporal bones and supports the temporal lobes of the cerebral hemispheres. It is bounded in front by the posterior aspect of the lesser and greater wings of the sphenoid, behind by the superior border of the petrous part of the temporal bone, laterally by the squamous part of the temporal bone and greater wing of the sphenoid, and medially by the lateral aspect of the sphenoid body, including the carotid sulcus, sella turcica and dorsum sellae.

The middle cranial fossa communicates with the orbits by the superior orbital fissures, each bounded above by a lesser wing, below by a greater wing, and medially by the body of the sphenoid bone and optic strut. The fissures contain the oculomotor, trochlear and abducens nerves, and the lacrimal, frontal and nasociliary branches of the ophthalmic division of the trigeminal nerve, together with filaments from the internal carotid plexus (sympathetic), the superior and inferior ophthalmic veins, the orbital branch of the middle meningeal artery, and the recurrent branch of the lacrimal artery.

The central part of the cranial base, located between both middle cranial fossae, is formed by the body of the sphenoid bone, which contains the sphenoidal sinuses. The body of the sphenoid bone is deeply concave and houses the pituitary gland (hypophysis); it is therefore termed the pituitary (hypophysial) fossa, also known as the sella turcica because it resembles the shape of a Turkish saddle (Paluzzi et al 2012) (Videos 28.1-28.3). The face and floor of the sella turcica are
located within the sphenoidal air sinuses, which is why the most direct surgical route to the pituitary fossa is the trans-sphenoidal approach. The anterior edge of the sella is formed by a bony prominence known as the tuberculum sellae, which continues anteriorly with the prechiasmatic sulcus; the posterior boundary presents a vertical pillar of bone, the dorsum sellae. The superolateral angles of the dorsum are expanded as the posterior clinoid processes. A fold of dura, the diaphragma sellae, is attached to the anterior and posterior clinoid processes and roofs over the pituitary fossa. The cavernous sinus lies lateral to the pituitary fossa. The lateral wall of the body of the sphenoid contains a shallow carotid sulcus related to the internal carotid artery as it ascends from the carotid canal and runs through the cavernous sinus.

Each anterior clinoid process covers the roof of the cavernous sinus and the paraclinoidal segment of the internal carotid artery as it leaves the cavernous sinus and pierces the dura to enter the intradural space. The anterior clinoid process gives attachment to the anterior petroclinoidal ligament, which forms the free margin of the tentorium cerebelli, and the interclinoidal ligament, which lies between the anterior and posterior clinoids. The middle clinoid process arises from the body of the sphenoid bone at the anterolateral margin of the sella turcica and may be connected to the anterior clinoid process by a thin osseous bar, formed by ossification of the caroticoclinoid ligament. The resulting caroticoclinoid foramen or ring surrounds the paraclinoidal segment of the internal carotid artery (Fernandez-Miranda et al 2012). While anterior and posterior clinoids are always present, middle clinoids are not constant. A recent study revealed that the middle clinoid process was usually identifiable in fine-cut head computed tomogramangiogram scans, and sometimes had at least one caroticoclinoid ring.

The greater wing of the sphenoid bone contains three consistent foramina and other small variable foramina. The foramen rotundum, situated just below the medial end of the superior orbital fissure, leads forwards into the medial aspect of the inferior orbital fissure and opens into the pterygopalatine fossa; it contains the maxillary nerve (second division of trigeminal nerve).

Behind the foramen rotundum is the foramen ovale, which transmits the mandibular nerve (third division of trigeminal nerve). The foramen spinosum lies just posterolateral to the foramen ovale and transmits the middle meningeal artery and veins; these vessels groove the floor and lateral wall of the middle cranial fossa. The foramen ovale and foramen spinosum open into the underlying infratemporal fossa. The small foramen of Vesalius sometimes occurs in skulls and lies anteromedial to the foramen ovale and lateral to the foramen rotundum; it transmits an emissary vein through which the cavernous sinus and pterygoid plexus communicate.

The foramen lacerum is a misnomer because it is a gap, not a true foramen, formed by the incomplete confluence of the petrosphenoidal and petroclival fissures. It may therefore also be called the sphenopetroclival synchondrosis. It lies posteromedial to the foramen ovale at the transition between the carotid sulcus of the sphenoid bone and the petrous carotid canal, bounded laterally by the lingula of the sphenoid and the petrolingual ligament extending to the petrous apex. The lower portion of the foramen lacerum is filled with fibrocartilage extending from the pharyngotympanic tube and basopharyngeal fascia. The upper portion of the foramen contains the laceral segment of the internal carotid artery and should be considered as the rostral extension of the petrous carotid canal (Tauber et al 1999). The only structures that enter or exit the intracranial cavity through the foramen lacerum are the pterygoid (Vidian) nerve and vessels, terminal branches of the ascending pharyngeal artery and small emissary veins connecting the extracranial pterygoid plexus with the intracranial cavernous sinus.

The superior border of the petrous part of the temporal bone separates the middle and the posterior cranial fossae, and is grooved by the superior petrosal sinus. The trigeminal impression, which accommodates the trigeminal ganglion, is situated on the anterior surface of the petrous part of the temporal bone near its apex. A smooth trigeminal notch leads into the impression and lies on the upper border of the petrous part, anteromedial to the groove for the superior petrosal sinus. At the level of the notch, the trigeminal nerve passes from the posterior to the middle cranial fossa, and separates the superior petrosal sinus from the underlying bone. The petrosphenoidal ligament (of Gruber) lies at the anterior end of the trigeminal notch, attached to a minute bony spicule, the petrous tubercle (Iaconetta et al 2003). The ligament runs in a superior, anterior and medial direction to attach to the posterior and lateral aspect of the posterior clinoid. The abducens nerve bends sharply across the upper petrous border and medially over the lateral edge of the dorsum sellae, and typically passes under the petrosphenoidal ligament to enter the cavernous sinus (Ozveren et al 2002). This interdural space (between dural layers), limited superiorly by the petrosphenoidal ligament, laterally by the petrous apex, and medially by the dorsum sellae, is known as Dorello's canal (Ambekar et al 2012). It is also defined as the petroclival venous confluence because it is filled with blood from the adjacent venous sinuses, namely: the inferior and superior petrosal, cavernous and basilar plexus (Barges-Coll et al 2010).

Lateral to the trigeminal impression, a narrow groove passes posterolaterally into the hiatus for the greater petrosal nerve (also known as the facial hiatus); the hiatus and groove for the lesser petrosal nerve lies even further laterally (Kakizawa et al 2007). Posterolateral to the facial hiatus, a rounded arcuate eminence is produced by the underlying superior semicircular canal. A line bisecting the angle subtended by the arcuate eminence and the greater petrosal nerve estimates the location of the roof of the internal acoustic meatus (internal auditory canal) in the middle fossa. The petrous segment of the internal carotid artery runs from the carotid foramen to the foramen lacerum within the carotid canal of the petrous part of the temporal bone. The greater petrosal nerve travels above and parallel to the petrous carotid canal, which may be dehiscent. The osseous portion of the pharyngotympanic tube and tensor tympani run parallel and just lateral to the petrous carotid canal within the floor of the middle fossa. The cochlea is situated within the petrous part of the temporal bone, just medial to the posterior aspect of the petrous carotid canal and anterior to the internal acoustic meatus and arcuate eminence. The portion of petrous bone that is limited anteriorly by the mandibular nerve, laterally by the greater petrosal nerve, medially by the superior petrosal sinus, and posteriorly by the internal acoustic meatus and cochlea is named the posteromedial or Kawase's triangle of the middle fossa. The surgical procedure known as anterior petrosectomy consists of removal of this bone in order to access the posterior fossa from the middle fossa approach (Kawase et al 1985) (Ch. 38).

The lateral surface of the petrous part of the temporal bone is formed by the tegmen tympani, a thin osseous lamina that separates the tympanic cavity (middle ear) from the middle fossa. Chronically elevated intracranial pressure may cause erosion of the tegmen tympani and spontaneous cerebrospinal fluid otorrhoea. The posterior part of the tegmen tympani forms the roof of the mastoid antrum, lateral to the arcuate eminence, and is also called the tegmen mastoideum. In young skulls, a petrosquamous suture may be visible at the lateral limit of the tegmen tympani but it is obliterated in adults. The tegmen tympani then turns down as the lateral wall of the osseous portion of the pharyngotympanic tube, and its lower border may appear in the squamotympanic fissure. Lateral to the anterior part of the tegmen tympani, the squamous part of the temporal bone is thinned over a small area that coincides with the deepest part of the mandibular fossa.

## POSTERIOR CRANIAL FOSSA

The posterior cranial fossa is formed by the sphenoid, temporal and occipital bones, and contains the cerebellum, pons and medulla oblongata. It is bounded in front by the dorsum sellae, posterior aspects of the body of the sphenoid bone, and the basilar (or clival) part of the occipital bone; behind by the squamous part of the occipital bone; and laterally by the petrous and mastoid parts of the temporal bones and by the lateral (condylar) parts of the occipital bone.

The most prominent feature in the floor of the posterior cranial fossa is the foramen magnum in the occipital bone. The medulla oblongata exits the cranial cavity through the foramen magnum to continue as the spinal cord (Ch. 20). The cerebellum is fully contained within the posterior fossa. When the lower part of the cerebellum, the tonsils, descend abnormally through the foramen magnum, they may cause compression of the medulla at the level of the foramen magnum, a condition called tonsillar herniation or Chiari malformation.

The clivus is a sloping surface that extends from the sella turcica to the foramen magnum, and is formed successively by the dorsum sellae, the posterior part of the body of the sphenoid and the basilar (clival) part of the occipital bone. The spheno-occipital synchondrosis is evident on the clivus of a growing child but not in adults. The clivus is located at the centre of the posterior skull base and separates the nasopharynx from the posterior cranial fossa. Cranial chordomas are malignant tumours that histologically are reminiscent of embryonic notochordal tissue and typically arise within the clival bone (FernandezMiranda et al 2014). The clivus reaches its final length at the age of 11 years in both sexes (Krmpotić-Nemanić et al 2005). On each side, the clivus is separated from the petrous part of the temporal bone by a petro-occipital (or petroclival) fissure, filled by a thin plate of cartilage and extending from the foramen lacerum (extracranially) and cavernous sinus (intracranially) to the jugular foramen. The intracranial margins of the fissure are grooved by the inferior petrosal sinus. Chondrosarcomas are malignant tumours composed of transformed cells that produce cartilage; their most common intracranial location is precisely the petroclival fissure.

The jugular foramen is a large opening located between the temporal and occipital bones at the posterior end of the petro-occipital fissure, above and lateral to the foramen magnum. The lower border of the jugular foramen is smooth and is formed by the lateral part of the occipital bone. The upper border is sharp and irregular, and is formed by the petrous part of the temporal bone. It contains a notch, the intrajugular process, which divides the foramen into a large posterolateral compartment, the sigmoid part, which receives the drainage of the sigmoid sinus; and a small anteromedial compartment, the petrosal part, which receives the drainage of the inferior petrosal sinus. The accessory, vagus and glossopharyngeal nerves course in the medial side of the intrajugular process; they lie between the petrosal part (which contains the inferior petrosal sinus accompanied by a meningeal branch of the ascending pharyngeal artery) and the sigmoid part (which contains the sigmoid sinus accompanied by a meningeal branch of the occipital artery). The cochlear canaliculus or aqueduct, which contains the perilymphatic 'duct', is sited in the deepest part of the intrajugular process. The jugular foramina are typically asymmetric: the right foramen is usually larger than the left, reflecting the right dominance of the sigmoid sinus and jugular vein.

The jugular tubercle is a rounded prominence located at the junction of the basilar and lateral parts of the occipital bone, just medial to the jugular foramen. The accessory, vagus and glossopharyngeal nerves cross the posterior portion of the tubercle on their way to the jugular foramen. The hypoglossal (anterior condylar) canal lies just inferior to the jugular tubercle, superior to the occipital condyle, and medial to and below the lower border of the jugular foramen (Morera et al 2010). It transmits the hypoglossal nerve and its recurrent branch, together with the meningeal branch of the ascending pharyngeal artery and an emissary vein that links the (intracranial) basilar plexus with the (extracranial) internal jugular vein. The canal may be divided by bony septa for different rootlets of the hypoglossal nerve. The occipital condyles form the lateral (or condylar) part of the occipital bone, and they lie within the anterior and lateral aspect of the foramen magnum. On each side, their medial surface bears a tubercle that gives attachments to the alar ligaments of the odontoid process, and their inferior surface is convex and articulates with the upper surface of the lateral mass of the atlas. The posterior condylar canal, when present, is located in the extracranial surface behind and above each occipital condyle; its internal orifice is posterolateral to that of the hypoglossal canal and contains the supracondylar vein and a meningeal branch of the occipital artery.

The posterior surface of the petrous part of the temporal bone forms much of the anterolateral wall of the posterior cranial fossa. It contains the internal acoustic meatus, which lies anterosuperior to the jugular foramen, and transmits the facial and vestibulocochlear nerves, the nervus intermedius and labyrinthine vessels. A small subarcuate fossa lined with dura mater lies posteriorly between the internal acoustic meatus and the opening of the vestibular aqueduct, and houses the saccus and ductus endolymphaticus and a small artery and vein. The suprameatal tubercle is a bony prominence located superiorly between the internal acoustic meatus and the petrous ridge (Seoane and Rhoton 1999).

The mastoid part of the temporal bone lies behind the petrous part of the temporal bone in the lateral wall of the posterior cranial fossa. Anteriorly, it is grooved by a wide sigmoid sulcus that runs forwards and downwards, then downwards and medially, and finally forwards to the jugular foramen; it contains the sigmoid sinus. Superiorly, where the groove touches the mastoid angle of the parietal bone, it becomes continuous with a groove that transmits the transverse sinus, and then crosses the parietomastoid suture and descends behind the mastoid antrum. A mastoid foramen, which transmits an emissary vein from the sigmoid sinus and a meningeal branch of the occipital artery, may be sited here. The lowest part of the sigmoid sulcus crosses the occipitomastoid suture and grooves the jugular process of the occipital bone. The right sigmoid sulcus is usually larger than the left.

The squamous part of the occipital bone displays a median internal occipital crest. This runs posteriorly from the foramen magnum to an internal occipital protuberance, gives attachment to the falx cerebelli, and may be grooved by the occipital sinus. The internal occipital protuberance is close to the confluence of the sinuses. It is grooved bilaterally by the transverse sinuses, which curve laterally with an upward convexity to the mastoid angles of the parietal bones. The groove for the transverse sinus is usually deeper on the right, where it is generally a continuation of the superior sagittal sinus, while on the left it is frequently a continuation of the straight sinus. On both sides, the transverse sulcus is continuous with the sigmoid sulcus. Below the transverse sulcus, the internal occipital crest separates two shallow fossae that house the cerebellar hemispheres. The posterior clinoid process and the margins of the grooves for the transverse and superior petrosal sinuses all provide anchorage for the attached margin of the tentorium cerebelli.

## MENINGES

Three concentric membranes, the meninges, envelop the brain and spinal cord. They provide support and protection for the delicate tissues they surround. The individual layers, in order from outside to inside, are the dura mater (pachymeninx), arachnoid mater and pia mater. The dura is an opaque, tough, fibrous coat that incompletely divides the cranial cavity into compartments and accommodates the dural venous sinuses. The arachnoid is much thinner than the dura and is mostly translucent. It loosely surrounds the brain, cranial nerves and vessels, spanning fissures and sulci. The pia mater is a transparent, microscopically thin membrane that follows the contours of the brain and is closely adherent to its surface.

The dura is separated from the arachnoid by a narrow subdural space. The arachnoid is separated from the pia by the subarachnoid space, which varies greatly in depth; the larger expanses are termed subarachnoid cisterns. The subarachnoid space contains cerebrospinal fluid (CSF), which is secreted by the choroid plexuses of the cerebroventricular system. CSF circulates within the subarachnoid space and is reabsorbed into the venous system through arachnoid villi and granulations associated with the dural venous sinuses.

Cranial and spinal meninges are continuous through the foramen magnum. The cranial meninges are described in this section and the spinal meninges are described on page 764.

## DURA MATER

Dura mater is thick, dense and fibrous. It is predominantly acellular, and consists mainly of densely packed fascicles of collagen fibres arranged in laminae. The fascicles run in different directions in adjacent laminae, producing a lattice-like appearance that is particularly obvious in the tentorium cerebelli and around the defects or perforations that sometimes occur in the anterior portion of the falx cerebri.

The cranial dura, which lines the cranial cavity, differs from the spinal dura mainly in its relationship to the surrounding bones. It has an inner, or meningeal, layer and an outer, or endosteal, layer. As a
general rule, the meningeal layer covers neural tissues, while the endosteal layer adheres to the osseous structures. These layers are united except where they separate to enclose the venous sinuses that drain blood from the brain. There is little histological difference between the endosteal and meningeal layers. Both contain fibroblasts, and the endosteal layer also contains osteoblasts. Focal calcification may occur in the falx cerebri and near the superior sagittal sinus.

The endosteal layer of dura adheres to the internal surfaces of the cranial bones, particularly at the sutures and the cranial base, and around the foramen magnum. Fibrous bands pass from the dura into the bones, and it is difficult to remove the dura from the suture lines in young skulls. However, as the suture lines fuse, the dura becomes separated from them. The endosteal layer of the dura is continuous with the pericranium through the cranial sutures and foramina and with the orbital periosteum through the superior orbital fissure. The meningeal layer provides tubular sheaths for the cranial nerves as they pass out through the cranial foramina, and these sheaths fuse with the epineurium as the nerves emerge from the skull. The dural sheath of the optic nerve is continuous with the ocular sclera. The dura fuses with the adventitia of major vessels, such as the internal carotid and vertebral arteries, at sites where they pierce it to enter the cranial cavity.

The inner, meningeal, layer of dura is closely applied to the arachnoid over the surface of the brain. However, the two membranes are physically joined only at sites where veins pass from the brain into venous sinuses, e.g. the superior sagittal sinus.

## Extradural haematoma

The anatomical organization of the dura, and its relationships to the major venous sinuses, sutures and blood vessels, are clinically significant. Separation of the dura from the cranial bones requires significant force, and consequently happens when high-pressure arterial bleeding takes place into the extradural or epidural space. This can result from damage to any meningeal vessel, commonly following skull fracture. The classic site for such injury is along the course of the middle meningeal artery, where a direct blow causing a fracture of the temporal and/ or parietal bones can rupture the artery and cause rapid collection of blood into the extradural space. An extradural haematoma therefore acts as a rapidly expanding intracranial mass lesion that causes acute brain compression and displacement; it is a classic medical emergency that requires immediate diagnosis and surgery through a craniotomy for epidural blood clot evacuation and coagulation of the ruptured vessel (see Fig. 28.12).

## Dural partitions

The meningeal layer of the dura is reflected inwards to form four septa, namely: the falx cerebri, falx cerebelli, diaphragma sellae and tentorium cerebelli, which partially divide the cranial cavity into compartments.

## Falx cerebri

The falx cerebri is a strong, crescent-shaped sheet that lies in the sagittal plane and occupies the longitudinal fissure between the two cerebral hemispheres (Fig. 28.3). The crescent is narrow in front, where the falx is fixed to the crista galli, and broad behind, where it blends with the tentorium cerebelli; the straight sinus runs along this line of attachment to the tentorium (see Fig. 28.3). The anterior part of the falx is thin and may have a number of irregular perforations. Its convex upper margin is attached to the internal cranial surface on each side of the midline, as far back as the internal occipital protuberance. The superior sagittal sinus runs in a cranial groove within the dura along this margin; the falx is attached to the lips of this groove. The lower edge of the falx is free and concave, and contains the inferior sagittal sinus.

## Falx cerebelli

The falx cerebelli is a small midline fold of dura mater that lies below the tentorium cerebelli and projects forwards into the posterior cerebellar notch between the cerebellar hemispheres. Its base is directed upwards and is attached to the posterior part of the inferior surface of the tentorium cerebelli in the midline. Its posterior margin contains the occipital sinus and is attached to the internal occipital crest. The lower apex of the falx cerebelli frequently divides into two small folds, which disappear at the sides of the foramen magnum

## Diaphragma sellae

The diaphragma sellae is a small, circular, horizontal sheet of dura mater. It forms a roof over the sella turcica and covers the pituitary gland. The infundibulum (also known as pituitary stalk) passes into the pituitary fossa through a central opening in the diaphragma. There is wide individual variation in the size of this opening. The diaphragma

Fig. 28.3 A, The cerebral dura mater, its reflections and associated major venous sinuses. B, An anatomical dissection of a silicon-injected specimen. (A, Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
sellae is an important landmark structure in pituitary surgery because large pituitary tumours extend above it and may adopt a characteristic dumbbell shape. A trans-sphenoidal approach is currently the preferred option for accessing pituitary tumours, irrespective of whether there is suprasellar extension beyond the diaphragma sellae.

## Tentorium cerebelli

The shape of the tentorium cerebelli (see Fig. 28.3B) is reminiscent of a single-poled tent, from which its name is derived. It lies between the cerebellum and the occipital lobes of the cerebral hemispheres, and divides the cranial cavity into supratentorial and infratentorial compartments, which contain the forebrain and hindbrain, respectively. Its concave anterior edge is free and separated from the dorsum sellae of the sphenoid bone by a large curved hiatus, the tentorial incisure or notch, which is filled by the midbrain and the anterior part of the superior aspect of the cerebellar vermis. The convex outer limit of the tentorium is attached posteriorly to the lips of the transverse sulci of the occipital bone and to the posterior inferior angles of the parietal bones, where it encloses the transverse sinuses. Laterally, it is attached to the superior borders of the petrous parts of the temporal bones, where it contains the superior petrosal sinuses. On each side, near the apex of the petrous temporal bone, the lower layer of the tentorium is evaginated anterolaterally under the superior petrosal sinus to form a recess, Meckel's cave, between the endosteal and meningeal layers in the middle cranial fossa. The cave is entered by the posterior root of the trigeminal nerve and contains cerebrospinal fluid and the trigeminal ganglion; the evaginated meningeal layer fuses in front with the anterior part of the ganglion.

The arrangement of the dura mater in the central part of the middle cranial fossa is complex. The tentorium forms the medial part of the floor of the middle cranial fossa. On both sides, the rim of the tentorial incisure is attached to the apex of the petrous temporal bone and continues forwards as a ridge of dura, known as the anterior petroclinoidal ligament, to attach to the anterior clinoid process. This ligament marks the junction of the roof and the lateral wall of the cavernous sinus. The periphery of the tentorium cerebelli (attached to the superior border of the petrous temporal bone), crosses under the free border of the tentorial incisure at the apex of the petrous temporal bone, and continues forwards to the posterior clinoid process as a rounded ridge of the dura mater known as the posterior petroclinoidal ligament. The dural extension between the anterior and posterior petroclinoidal ligaments forms the roof of the cavernous sinus. On either side, it is pierced superiorly by the oculomotor nerve and behind by the trochlear nerve, which proceed anteroinferiorly into the lateral wall of the cavernous sinus.

In the anteromedial part of the middle cranial fossa, the dura ascends as the lateral wall of the cavernous sinus, reaches the ridge produced by the anterior petroclinoidal ligament, and runs medially as the roof of
the cavernous sinus, where it is pierced by the internal carotid artery. The interclinoidal ligament, between the anterior and posterior clinoid processes, forms the medial limit of the roof of the cavernous sinus and continues medially with the diaphragma sellae. At, or just below, the opening in the diaphragma for the pituitary stalk, the dura of the diaphragma and the suprasellar arachnoid blend with each other and with the capsule of the pituitary gland; the subarachnoid space does not extend into the sella turcica.

## Transtentorial coning

Normally, the arrangement of dural partitions such as the falx cerebri and tentorium cerebelli may help to stabilize the brain within the cranial cavity. However, when there is focal brain swelling or a focal space-occupying lesion within the brain or cranial cavity, mass effect and raised intracranial pressure may cause the brain to herniate under the falx cerebri or, more significantly, through the tentorial incisure. In this case, the medial temporal lobe, and particularly the uncus, will compress the oculomotor nerve, midbrain and the posterior cerebral arteries. This life-threatening event and neurosurgical emergency, occurring in patients with supratentorial space-occupying lesions, is known as transtentorial uncal herniation. Similarly, space-occupying lesions in the smaller infratentorial compartment may cause upward herniation of the cerebellar vermis through the tentorial hiatus (upward transtentorial herniation) or downward herniation of the cerebellar tonsils through the foramen magnum (tonsillar herniation) (see Fig. 21.20); these neurosurgical emergencies require a suboccipital craniectomy.

## Innervation of the cranial dura mater

The innervation of the cranial dura mater is derived mainly from the three divisions of the trigeminal nerve, the second and third cervical spinal nerves, and the cervical sympathetic trunk (Fig. 28.4). Less wellestablished meningeal branches have been described arising from the vagus and hypoglossal nerves, and possibly from the facial and glossopharyngeal nerves.

In the anterior cranial fossa, the dura is innervated by meningeal branches of the anterior and posterior ethmoidal nerves and anterior filaments of the meningeal rami of the maxillary (nervus meningeus medius) and mandibular (nervus spinosus) divisions of the trigeminal nerve. Nervi meningeus medius and spinosus are, however, largely distributed to the dura of the middle cranial fossa, which also receives filaments from the trigeminal ganglion. The nervus spinosus re-enters the cranium through the foramen spinosum with the middle meningeal artery, and divides into anterior and posterior branches that accompany the main divisions of the artery and supply the dura mater in the middle cranial fossa and, to a lesser extent, the anterior fossa and calvarium. The anterior branch communicates with the meningeal branch of the

A
B

Fig. 28.4 The innervation of the cranial meninges.
maxillary nerve; the posterior branch also supplies the mucous lining of the mastoid air cells. The nervus spinosus contains sympathetic postganglionic fibres from the middle meningeal plexus. The nervus tentorii, a recurrent branch of the intracranial portion of the ophthalmic division of the trigeminal, supplies the supratentorial falx cerebri and the tentorium cerebelli. Intraoperative mechanical stimulation of the falx may trigger the trigeminocardiac reflex (Bauer et al 2005). The dura in the posterior cranial fossa is innervated by ascending meningeal branches of the upper cervical nerves, which enter through the anterior part of the foramen magnum (second and third cervical nerves) and through the hypoglossal canal and jugular foramen (first and second cervical nerves).

Meningeal branches from the vagus apparently start from the superior vagal ganglion and are distributed to the dura mater in the posterior cranial fossa. Those from the hypoglossal leave the nerve in its canal and supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses, and much of the floor and anterior wall of the posterior cranial fossa. These meningeal rami may not contain vagal or hypoglossal fibres but ascending, mixed sensory and sympathetic fibres from the upper cervical nerves and superior cervical sympathetic ganglion. All meningeal nerves contain a postganglionic sympathetic component, either from the superior cervical sympathetic ganglion or by communication with its perivascular intracranial extensions. The role of the autonomic nerve supply of the cranial dura mater is uncertain.

Sensory nerve endings are restricted to the dura mater and cerebral blood vessels, and are not found in either the brain itself, or in the arachnoid or pia mater. Stimulation of these nerve endings causes pain, as evidenced during awake craniotomy procedures, and is the basis of certain forms of headache. The density of dural innervation, particularly around the dural venous sinuses, increases during the later part of ges-
tation, peaking at term and subsequently decreasing during the first year of postnatal life (Davidson et al 2012).

## Dural venous sinuses

Dural venous sinuses form a complex network of venous channels that drain blood from the brain and cranial bones (see Figs 28.3, 19.11; Figs 28.5-28.6). They lie between the endosteal and meningeal layers of dura mater, are lined by endothelium and have no valves; their walls are devoid of muscular tissue (Kıliç and Akakın 2008). They develop initially as venous plexuses; most adult sinuses preserve a plexiform arrangement (to a variable degree), rather than being simple vessels with a single lumen. Plexiform arrays of small veins adjoin the superior and inferior sagittal and straight sinuses, and, less frequently, the transverse sinuses; ridges of 'spongy' venous tissue, known as venous lacunae, often project into the lumina of the superior sagittal and transverse sinuses (Browder and Kaplan 1976, Kaplan and Browder 1976).

The structure of cranial venous sinuses, their plexiform nature and their wide connections with cerebral and cerebellar veins vary considerably, particularly in earlier years, e.g. in infancy the falx cerebelli may contain large plexiform channels and venous lacunae that augment the occipital sinus. These variations must be established for the individual by catheter-based angiography, magnetic resonance (MR) venography or computed tomographic (CT) venography, when clinical necessity arises. The existence of arteriovenous shunts has been inferred from the demonstration of a connection between the middle meningeal arteries and the superior sagittal sinus (Browder and Kaplan 1976). Dural arteriovenous fistulae are thought to be acquired lesions that form in an area of thrombosis within a sinus. If the sinus remains completely thrombosed, venous drainage from these lesions takes place through

Fig. 28.6 The superior sagittal sinus and venous lacunae. A, An anatomical dissection of a silicon-injected specimen. B, The superior sagittal sinus opened up after removal of the cranial vault. Note the fibrous bands that cross the sinus from two of the venous lacunae. (A, From the Rhoton Collection.)
cortical veins, or, if the sinus is partially open, venous drainage is usually into the involved sinus. When the sinus remains closed, the elevated pressure within the cortical veins receiving the arterial flow carries the risk of haemorrhage.

The named sinuses are the superior and inferior sagittal, straight, transverse, sigmoid, occipital, cavernous, intercavernous, superior and inferior petrosal, sphenoparietal, basilar and marginal.

## Superior sagittal sinus

The superior sagittal sinus runs in the attached convex margin of the falx cerebri. It grooves the internal surface of the frontal bone, the adjacent margins of the two parietal bones and the squamous part of the occipital bone (see Figs 28.3, 28.6, 19.11). It begins near the crista galli, a few millimetres posterior to the foramen caecum, and receives primary tributaries from cortical veins of the superior part of the frontal,

Fig. 28.7 A coronal section through the vertex of the skull to show the relationships between the superior sagittal sinus, meninges and arachnoid granulations. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
parietal and occipital lobes, and from the anterior part of the orbital surface of the frontal lobe. The sinus is triangular in cross-section, with the apex directed downwards and continuous with the falx cerebri. Its lumen is invaded in its intermediate third by projections from its dural walls, which may divide its lumen into superior and inferior channels. It is narrow anteriorly, and widens gradually to approximately 1 cm in diameter as it runs backwards. At its posterior end, the sinus enters the confluence of the sinuses (also known as the torcular herophili or the torcula, although the term actually describes the bony gutter in which the confluence lies), which is situated to one side (usually the right) of the internal occipital protuberance (see Fig. 28.3). At the confluence of the sinuses, the superior sagittal sinus usually deviates to become continuous with the right transverse sinus, but it also usually connects with the occipital and contralateral transverse sinuses. The size and degree of communication of the channels meeting at the confluence are highly variable; any sinus involved may be duplicated, narrowed or widened near the confluence.

There are usually two or three lateral venous lacunae on each side of the midline, named frontal (small), parietal (large) and occipital (intermediate) lacunae; they tend to become confluent in the elderly, producing a single elongated lacuna on each side. Fine fibrous bands cross the lacunae, and numerous arachnoid granulations project into them (see Fig. 28.6; Fig. 28.7). The lacunae mainly drain diploic and meningeal veins. The cortical veins typically pass beneath the lacunae on their way to the sinus. The largest cortical vein that connects the superficial Sylvian (middle cerebral) vein and the superior sagittal sinus is the superior anastomotic vein (vein of Trolard); it often runs in the precentral, central or postcentral sulci. Near its posterior end, the superior sagittal sinus receives veins from the pericranium that pass through parietal foramina. Acute and complete thrombosis of the superior sagittal sinus is an extremely severe condition causing acute elevation of the intracranial pressure and herniation. Slow and progressive occlusion of the sinus, as is typical for sagittal meningiomas, may be compensated by the development of collateral venous drainage with no clinical consequences

## Inferior sagittal sinus

The inferior sagittal sinus is located in the posterior half or two-thirds of the free margin of the falx cerebri (see Fig. 28.3). It increases in size posteriorly, ends in the straight sinus, and receives veins from the falx and sometimes from the medial surfaces of the cerebral hemispheres (anterior pericallosal veins).

## Straight sinus

The straight sinus lies in the junction of the falx cerebri with the tentorium cerebelli (see Figs 28.3, 19.11). It runs posteroinferiorly as a continuation of the inferior sagittal sinus and drains into the transverse sinus, most commonly into the left one. It is not (or is only tenuously) continuous with the superior sagittal sinus. Its tributaries include the great cerebral vein (vein of Galen), which is formed by the convergence of the internal cerebral and basal veins, and some superior cerebellar veins. The latter may drain first into a short sinus within the tentorium, known as the medial tentorial sinus.

## Transverse sinus

The transverse sinuses begin at the confluence of sinuses and attach to the internal occipital protuberance (see Figs 28.3, 28.5). One, usually

Fig. 28.8 The relations of the brain, the middle meningeal artery and the transverse and sigmoid sinuses to the surface of the skull. The area enclosed in the yellow circle (including the pterion) is used when performing a pterional craniotomy over the frontal branch of the middle meningeal artery and lateral Sylvian fissure; the area enclosed in the green circle is used when performing a retrosigmoid craniotomy extending to the confluence of the transverse and sigmoid sinuses.
the right, is directly continuous with the superior sagittal sinus, and the other with the straight sinus. The right transverse sinus is thus typically larger and drains blood from the superficial parts of the brain, while the left transverse sinus mainly drains blood from the deep parts of the brain. On either side, the sinuses run in the attached margin of the tentorium cerebelli, first on the squama of the occipital bone, then on the mastoid angle of the parietal bone. Each follows a gentle anterolateral curve, increasing in size as it does so, to the posterolateral part of the petrous temporal bone. Here it turns down as a sigmoid sinus, which ultimately becomes continuous with the internal jugular vein. The transverse sinuses receive tributaries from the lateral temporal surface and basal surface of the temporal and occipital lobes. The inferior anastomotic vein (vein of Labbé) is the largest vein connecting the veins of the Sylvian fissure with the transverse sinus. All tributaries of each transverse sinus may drain first into a lateral tentorial sinus. The superior petrosal sinuses drain into the transition between the transverse and sigmoid sinuses on either side (see Figs 28.3, 28.5).

## Sigmoid sinus

The sigmoid sinuses are continuations of the transverse sinuses, beginning where these leave the tentorium cerebelli (see Fig. 28.5; Fig. 28.8). Each sigmoid sinus curves inferomedially in a groove on the mastoid process of the temporal bone, crosses the jugular process of the occipital

Fig. 28.9 The sellar region and adjacent middle and anterior cranial fossae, viewed from above, in a silicon-injected anatomical specimen. The dura has been removed on the right half of the specimen to show the roof of the cavernous sinus (oculomotor triangle), and the maxillary and mandibular nerves running on the floor of the middle fossa.
bone and turns forwards to the superior jugular bulb, lying posterior in the jugular foramen. Anteriorly, a thin plate of bone separates its upper part from the mastoid antrum and air cells. It connects with pericranial veins via mastoid and condylar emissary veins. Neurosurgical approaches to the lateral aspect of the posterior fossa (cerebellopontine angle) are classified as retrosigmoid, when the craniectomy is located just behind the sigmoid sinus, and presigmoid, when the mastoid bone in front of the sinus is drilled away to provide a more anterior corridor into the posterior fossa.

## Superior petrosal sinus

These small, narrow sinuses drain the cavernous sinus into the transverse sinus on either side (see Figs 28.3, 28.5; Figs 28.9-28.10). Each leaves the posterosuperior part of the cavernous sinus and runs posterolaterally in the attached margin of the tentorium cerebelli, crosses above the trigeminal nerve to lie in a groove on the superior border of the petrous part of the temporal bone and ends by joining the transverse sinus at the point where this curves down to become the sigmoid sinus. The superior petrosal sinuses may receive cerebellar and brainstem veins, such as the superior petrosal vein, and rarely the inferior cerebral and tympanic veins; they connect with the inferior petrosal sinuses and the basilar plexus.

## Inferior petrosal sinus

The inferior petrosal sinuses drain the cavernous sinus into the internal jugular veins (see Figs 28.5, 19.11). They begin at the posteroinferior aspect of the cavernous sinus and run back in the petroclival fissure, a groove between the petrous temporal and basilar occipital bones. On each side, the inferior petrosal sinus next passes through the anteromedial part of the jugular foramen, accompanied by a meningeal branch of the ascending pharyngeal artery, and descends obliquely backwards to drain into the superior jugular bulb. It sometimes drains via a vein in the hypoglossal canal to the suboccipital vertebral plexus.

The inferior petrosal sinuses are often plexiform. Each receives labyrinthine veins via the cochlear canaliculus and the vestibular aqueduct, and tributaries from the medulla oblongata, pons and inferior cerebellar surface. The venous spaces in the sphenopetroclival area, which are filled anteriorly by blood from the cavernous sinus, medially by blood from the basilar plexus, and laterally by blood from the superior petrosal sinus, typically drain into the inferior petrosal sinuses (Iaconetta et al 2003).

## Cavernous sinus

The cavernous sinuses are two large venous plexuses that lie on either side of the body of the sphenoid bone, extending from the superior orbital fissure to the apex of the petrous temporal bone, with an average length of 2 cm and width of 1 cm (see Fig. 28.5). The cavity of the cavernous sinus is formed when the two layers of dura that cover the anterior aspect of the pituitary gland separate from each other at the lateral margin of the sella; the outer (endosteal) layer continues laterally to form the anterior (or sphenoidal) wall of the cavernous sinus, while the inner (meningeal) layer remains attached to the pituitary gland and runs back towards the dorsum sellae to form the medial
(or sellar) wall of the cavernous sinus. The posterior dural wall is located behind the dorsum sellae and upper clivus, and is shared with the basilar plexus. The lateral wall extends from the superior orbital fissure to the petrous apex, and separates the cavernous sinus from Meckel's cave, which is located inferior and posterior to the sinus. The roof of the cavernous sinus is formed by the dura lining the lower margin of the anterior clinoid process anteriorly (clinoidal triangle), and the patch of dura between the anterior and posterior clinoids and the petrous apex, the oculomotor triangle (see Figs 28.9-28.10).

Each sinus contains the cavernous segment of the internal carotid artery, associated with a perivascular sympathetic plexus. The cavernous carotid artery has several portions, from proximal to distal: short ascending, posterior genu, horizontal, anterior genu. The anterior genu of the cavernous carotid artery continues as the paraclinoidal segment of the carotid artery, which typically protrudes into the sphenoidal sinus cavity. The cavernous carotid gives off two major arterial branches: the meningohypophysial and inferolateral trunks (see Fig. 28.10). The meningohypophysial trunk arises typically from the posterior genu and gives off the inferior hypophysial, tentorial and dorsal meningeal arteries. The inferolateral trunk arises a few millimetres distal to the meningohypophysial and distributes around the nerves on the lateral wall of the sinus. (For more detailed descriptions of these branches, including their main variations, see Krisht et al (1994), Reisch et al (1996), Tekdemir et al (1998b).)

Several cranial nerves run forwards through the cavernous sinus to enter the orbit via the superior orbital fissure (see Fig. 28.10). The oculomotor and trochlear nerves and the ophthalmic division of the trigeminal nerve all lie in the lateral wall of the sinus. The abducens nerve enters the cavernous sinus by passing below the petrosphenoidal ligament within a dural tunnel (Dorello's canal) just behind the short ascending portion of the cavernous carotid artery, and then runs on the inferolateral side of the horizontal portion of the cavernous carotid, just medial to the ophthalmic nerve. The space between the trochlear and ophthalmic nerves at the lateral wall of the sinus, known as the infratrochlear or Parkinson's triangle, gives access to the horizontal cavernous carotid and posterior genu, meningohypophysial trunk and abducens nerve. Unlike the ophthalmic division of the trigeminal nerve, the maxillary division of the trigeminal nerve does not run through the cavernous sinus or its lateral wall, but courses beneath the dura of the middle cranial fossa below the level of the cavernous sinus (see Fig. 28.10).

Several major venous spaces can been identified within the sinus in relation to the cavernous carotid artery: superior, posterior, inferior and lateral (modified from Harris and Rhoton 1976). The superior and inferior ophthalmic veins drain into the inferior space; the basilar plexus and inferior petrosal sinus drain into the posterior space; the superior petrosal sinus opens into the superior space; and the superficial middle cerebral vein, inferior cerebral veins and sphenoparietal sinus may drain into the lateral compartment. Veins traversing the emissary sphenoidal foramen, foramen ovale and foramen lacerum may also drain into the cavernous sinus. Less frequently, the central retinal vein and frontal tributary of the middle meningeal vein also drain into it.

Fig. 28.10 A, A lateral view of the right middle cranial fossa and lateral wall of the cavernous sinus in a silicon-injected anatomical specimen. B, The ophthalmic nerve has been retracted inferiorly to show the inside of the cavernous sinus (abducens nerve, internal carotid artery and its branches) through the infratrochlear triangle.

Tumours can arise within the cavernous sinus (meningiomas, haemangiomas, schwannomas) or extend into the cavernous sinus from adjacent regions (typically, pituitary adenomas that invade the medial wall of the sinus). Transcranial microsurgical approaches enter the cavernous sinus through the lateral wall (infratrochlear triangle) or roof (oculomotor triangle) of the sinus. Recently introduced endoscopic endonasal approaches facilitate access to the cavernous sinus from its anterior (sphenoidal) and medial (sellar) walls. (For more detailed descriptions of the microsurgical anatomy of the cavernous sinus, see Dolenc (1987), Umansky et al (1994), Seoane et al (1998), Yasuda et al (2004), Dolenc and Rogers (2009).)

## Caroticocavernous sinus fistula and cavernous sinus thrombosis

Direct communication between the intracavernous portion of the internal carotid artery and the cavernous sinus, creating a caroticocavernous sinus fistula (CCF), may occur as a result of either severe head trauma or aneurysmal vessel disease. The classic signs are ptosis, proptosis (which may be pulsatile), chemosis, periorbital oedema, and extraocular dysmotility causing diplopia secondary to a combination of third, fourth and sixth cranial nerve palsies. Hypo- or hyperaesthesia of the ophthalmic divisions of the fifth cranial nerve and a decreased corneal reflex may also be detected. There may be evidence of dilated, tortuous retinal veins and papilloedema. These changes can cause permanent blindness. CCFs are most commonly treated by passing a catheter up the carotid into the fistula, and then occluding it with dilatable balloons or flexible metal coils. Any spreading infection involving the upper nasal cavities, paranasal sinuses, cheek (especially near the medial canthus), upper lip, anterior nares, or even an upper incisor or canine tooth, may very rarely lead to septic thrombosis of the cavernous sinuses; infected thrombi pass from the facial vein or pterygoid venous
complex into the sinus via either ophthalmic veins or emissary veins that enter the cranial cavity through the foramen ovale. This is a critical medical emergency with a high risk of disseminated cerebritis and cerebral venous thrombosis.

## Intercavernous sinuses

The two cavernous sinuses are connected by superior, inferior and posterior intercavernous sinuses, and the basilar plexus (see Figs 28.5, 28.9). The superior and posterior intercavernous sinuses lie in the anterior and posterior attached borders of the diaphragma sellae and they thus form a complete circular venous sinus. The inferior intercavernous sinuses are irregular and plexiform in nature, and commonly encountered in a surgical transnasal approach to the pituitary gland. Obliteration of any intercavernous sinus has no clinical consequences because all connections are valveless and the direction of flow in them is reversible.

## Basilar venous plexus

The basilar sinus and plexus consist of interconnecting channels between the two layers of dura mater on the clivus (see Figs 28.5, 28.9). The basilar venous plexus interconnects the cavernous sinuses and inferior and superior petrosal sinuses, and joins the internal vertebral venous plexus.

## Sphenoparietal sinus

The sphenoparietal sinuses are inconstant dural venous channels lying under the lesser wings of the sphenoid bone, near their posterior edge (see Fig. 28.5). Each sinus curves medially to open into the anterior part of the cavernous sinus, and receives small veins from the adjacent dura mater and sometimes the frontal ramus of the middle meningeal vein. Each may also receive connecting rami, in its middle course, from the superficial middle cerebral vein, temporal lobe veins and the
anterior temporal diploic vein. When these connections are well developed, the sphenoparietal sinus is a large channel. It has been suggested that the term sphenoparietal sinus should be abandoned on the basis that it is not an anatomical entity, but an artificial combination of two independent meningeal vessels, namely: the parietal portion of the anterior branch of the middle meningeal veins and the sinus of the lesser wing of the sphenoid (Ruíz et al 2004).

## Occipital sinus

The occipital sinus is the smallest of the sinuses and it is typically larger in children. It lies in the attached margin of the falx cerebelli (see Fig. 28.5) and is occasionally paired. It commences near the foramen magnum in several small channels, one joining the end of the sigmoid sinus, and connects with the internal vertebral plexuses. It ends in the confluence of the sinuses (torcula).

## Marginal sinus

The marginal sinus encircles the foramen magnum. It communicates anteriorly with the basilar plexus and with the occipital sinus posteriorly. It typically drains to the sigmoid sinus or jugular bulb by small sinuses and may connect extracranially to the internal vertebral venous plexus or the paravertebral or deep cervical veins in the suboccipital region.

## Emissary veins

Emissary veins traverse cranial apertures and make connections between intracranial venous sinuses and extracranial veins. Some are relatively constant, while others may be absent. These connections are of clinical significance in determining the spread of infection from extracranial foci to venous sinuses, e.g. the spread of infection from the mastoid to the venous sinuses or from the paranasal sinuses to the cavernous sinus. They are also important because they may provide alternative drainage pathways in cases of venous sinus thrombosis.

The following emissary veins have been recognized. A mastoid emissary vein in the mastoid foramen connects the sigmoid sinus with the posterior auricular or occipital veins. A parietal emissary vein in the parietal foramen connects the superior sagittal sinus with the veins of the scalp. The venous plexus of the hypoglossal canal, which is occasionally a single vein, connects the sigmoid sinus and the internal jugular vein. A supracondylar emissary vein connects the sigmoid sinus and veins in the suboccipital triangle via the posterior condylar canal. A plexus of emissary veins (venous plexus of foramen ovale) connects the cavernous sinus to the pterygoid plexus via the foramen ovale. Two or three small veins traverse the foramen lacerum and connect the cavernous sinus and the pharyngeal veins and pterygoid plexus. A vein in the emissary sphenoidal foramen (of Vesalius) connects the cavernous sinus with the pharyngeal veins and pterygoid plexus. The internal carotid venous plexus, which passes through the carotid canal, connects the cavernous sinus and the internal jugular vein. The petrosquamous sinus is an emissary vein that courses over the lateral superior surface of the petrous part of the temporal bone. It arises from the dorsolateral portion of the transverse sinus, before its confluence with the superior petrosal sinus, and drains anteroinferiorly into the retromandibular vein and anteromedially into the pterygoid venous plexus. It usually disappears during the development of adult venous patterns in the last 3 months of prenatal life. A vein may traverse the foramen caecum and connect nasal veins with the superior sagittal sinus. An occipital emissary vein usually connects the confluence of sinuses with the occipital vein through the occipital protuberance, and also receives the occipital diploic vein. The occipital sinus connects with variably developed veins around the foramen magnum (so-called marginal sinuses) and thus with the vertebral venous plexuses; this pathway provides an alternative venous drainage when the jugular vein is blocked or tied. The ophthalmic veins are potentially emissary because they connect intracranial to extracranial veins.

## Meningeal arteries and veins and diploic veins

Despite their names, the cranial meningeal arteries are predominantly periosteal (Fig. 28.11A). Their main targets are bone and haemopoietic marrow, and only some arterial branches are distributed to the cranial dura mater per se.

The branches of the meningeal vessels lie mainly in the endosteal layer of dura. In the anterior cranial fossa, the dura is supplied by the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries and a branch of the middle meningeal artery. In the middle cranial fossa, it is supplied by the middle and accessory meningeal branches of the maxillary artery, a branch of the
ascending pharyngeal artery (entering via the foramen lacerum), branches of the internal carotid and a recurrent branch of the lacrimal artery. In the posterior fossa, the dura is supplied by the meningeal branches of the occipital artery (one enters the skull by the jugular foramen and another by the mastoid foramen), the posterior meningeal branches of the vertebral artery, occasional small branches of the ascending pharyngeal artery, which enter by the jugular foramen and hypoglossal canal, and the dorsal meningeal and tentorial arteries arising from the meningohypophysial trunk. The anatomy of the meningeal arteries explains the vascular supply for tumours arising from the meninges (meningiomas) and the architecture of dural arteriovenous fistulae and malformations. (For detailed information on the surgical anatomy of the meningeal arteries, see Lasjaunias et al (2001), Martins et al (2005).)

## Middle meningeal artery

The middle meningeal artery is the largest of the meningeal arteries. It arises from the first part of the maxillary artery in the infratemporal fossa and passes between the roots of the auriculotemporal nerve. It lies lateral to tensor veli palatini, then enters the cranial cavity through the foramen spinosum and runs in an anterolateral groove on the squamous part of the temporal bone, dividing into frontal and parietal branches (see Figs 28.10-28.11). The larger frontal (anterior) branch crosses the greater wing of the sphenoid and enters a groove or canal in the sphenoidal angle of the parietal bone (the sphenoparietal canal). It divides into branches between the dura mater and cranium; some branches ascend to the vertex. The parietal (posterior) branch curves back on the squamous temporal bone, reaches the lower border of the parietal bone anterior to its mastoid angle and divides to supply the posterior parts of the dura mater and cranium. These frontal and parietal branches anastomose with their fellows and with the anterior and posterior meningeal arteries.

Ganglionic branches supply the trigeminal ganglion and associated roots. The petrosal branch enters the hiatus for the greater petrosal nerve, supplies the facial nerve, geniculate ganglion and tympanic cavity, and anastomoses with the stylomastoid artery (El Khouly et al 2008). The superior tympanic artery runs in the canal for tensor tympani and supplies the muscle and the mucosa that lines the canal. Temporal branches traverse minute foramina in the greater wing of the sphenoid and anastomose with deep temporal arteries that supply temporalis. An anastomotic branch enters the orbit laterally in the superior orbital fissure, and anastomoses with a recurrent branch of the lacrimal artery; enlargement of this anastomosis is believed to account for the occasional origin of the lacrimal artery from the middle meningeal artery.

## Accessory meningeal artery

The accessory meningeal artery may arise from the maxillary or the middle meningeal artery. It enters the cranial cavity through the foramen ovale, and supplies the trigeminal ganglion, dura mater and bone. Its main distribution is extracranial, principally to medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, the greater wing and pterygoid processes of the sphenoid bone, the mandibular nerve and otic ganglion. It is sometimes replaced by separate small arteries.

## Meningeal veins

Meningeal veins begin from plexiform vessels in the dura mater and drain into efferent vessels in the outer dural layer that connect with lacunae associated with some of the cranial sinuses. They include the middle meningeal and the diploic veins. Intracranial veins also communicate with extracranial vessels via emissary veins.

## Middle meningeal vein (sinus)

The frontal (anterior) branch of the middle meningeal vein crosses the floor of the middle cranial fossa, from either foramen ovale or foramen spinosum, to the pterion, usually in the form of two parallel channels that accompany the middle meningeal artery. The vein subsequently passes cranially along the anterior margin of the parietal squama to empty into the venous lakes of the superior sagittal sinus. As they course under the most lateral aspect of the lesser sphenoidal wing, the anterior branches of the middle meningeal vessels are contained for a short distance within a bony canal, the sphenoparietal canal (of Trolard), which they leave to enter a groove on the internal surface of the parietal squama. The veins lie closer to the bone than the artery, and sometimes occupy separate grooves; they are particularly liable to tear in cranial fractures. Before entering the sphenoparietal canal, the anterior branch of the middle meningeal vein usually connects with the sinus of the lesser sphenoidal wing. The latter is connected medially with the anterior and superior aspect of the cavernous sinus by a channel that crosses over the superior ophthalmic vein to reach the cavernous sinus.

Fig. 28.12 A, A head CT scan showing a right-sided extradural (epidural) haematoma. The blood clot is biconvex. B, A bone flap from the same patient. Note the ramifying grooves in the inner table of the squamous parts of the temporal and parietal bones. A fracture line crossing these grooves has torn branches of the middle meningeal artery. C, An acute subdural haematoma. The crescent-shaped blood clot is causing a severe midline shift and brain herniation. D, A bilateral subacute subdural haematoma. E, A right-sided chronic subdural haematoma.

Fig. 28.11 A, The meningeal arteries. B, The diploic canals and veins after removal of the external table of the calvaria. (A, Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010. B, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer, 2013.)

The parietal (posterior) trunk of the middle meningeal vein may traverse the foramen spinosum to end in the pterygoid venous plexus. The frontal trunk may also reach this plexus via the foramen ovale, or it may end in the sphenoparietal or cavernous sinus (see Fig. 28.5). The middle meningeal vein receives meningeal tributaries and small inferior cerebral veins, and connects with the diploic and superficial middle cerebral veins. It frequently bears arachnoid granulations.

## Diploic veins

The diploic veins are large, thin-walled vessels that occupy channels in the diploë of the cranial bones (see Fig. 28.11B). Four main trunks are usually described; these are the frontal, anterior and posterior temporal, and occipital diploic veins. The frontal opens into the supraorbital vein and the superior sagittal sinus; the anterior temporal is mainly confined to the frontal bone, and opens into the sphenoparietal sinus, and one of the deep temporal veins through an aperture in the great wing of the sphenoid; the posterior temporal is situated in the parietal bone, and empties into the transverse sinus either through an opening at the
mastoid angle of the parietal bone or through the mastoid foramen; and the occipital, the largest of the four, is confined to the occipital bone, and may open externally into the occipital vein, or internally into either the transverse sinus or the confluence of the sinuses.

## Sinus pericranii

Sinus pericranii is a rare condition involving congenital or acquired anomalous connections between an extracranial blood-filled nodule and an intracranial dural venous sinus via dilated diploic and/or emissary veins of the skull (Sheu et al 2002).

## ARACHNOID AND PIA MATER

The arachnoid mater and the pia mater together are sometimes referred to as the leptomeninges. They are separated by the subarachnoid space and joined by trabeculae. They are composed of cells that share a common embryological origin from the mesenchyme that surrounds the developing nervous system. The outer layer of the arachnoid, the
dura-arachnoid interface, is formed from five or six layers of cells joined by numerous desmosomes and tight junctions. This layer forms a barrier that normally prevents permeation of CSF through the arachnoid into the subdural space. The central portion of the arachnoid is closely apposed to the outer layer, and is formed from tightly packed polygonal cells joined by desmosomes and gap junctions. The cells are more loosely packed in the inner layer of the arachnoid, where they intermingle with bundles of collagen continuous with the trabeculae that cross the subarachnoid space. The leptomeningeal cells are not surrounded by basement membrane, except where they are in contact with collagen in the inner layers of the arachnoid and on the deep aspects of the pia mater.

The anatomical relationships of the arachnoid and pia differ to some extent in the cerebral and spinal regions. The cerebral part of the arachnoid mater invests the brain loosely. It does not enter the sulci or fissures, other than the interhemispheric and Sylvian fissures, and it coats the superior surface of the pituitary fossa. The arachnoid is easily separated from the dura over the surface of the brain, but it is adherent to the adventitia of the internal carotid and the vertebral arteries where they enter the subarachnoid space. The arachnoid is reflected on to the surface of blood vessels and cranial nerves in the subarachnoid space, and this is the basis for microsurgical subarachnoid dissection to expose brain vessels and cranial nerves. The subarachnoid cisterns are cavities formed by the wide separation of the pia and arachnoid, and this is particularly common on the basal aspect of the brain, where the basal cisterns are located. Knowledge of the neural and vascular contents of each of the basal cisterns is of particular value to the neurosurgeon in the planning and execution of intracranial procedures. This is, however, beyond the scope of this chapter and the interested reader is directed in the first instance to Yasargil (1984).

## Subdural haematoma

Separation of the arachnoid and dura mater requires little physical force, which means that damage to small bridging veins in the space can result in subdural haematoma after even relatively mild head trauma. In cases of chronic or subacute subdural haematomas, the accumulation is of relatively low pressure and seldom presents as a medical emergency; even sizeable accumulations may be tolerated on
a chronic basis with mild or no symptoms, and can be surgically drained through small openings in the skull (burr-holes). In many cases, there is some predisposing factor, such as cerebral atrophy or increased size of the underlying subarachnoid space. In cases of acute subdural haematoma, there is rapid accumulation of blood in the subdural space, typically after severe head trauma, which requires emergency neurosurgical drainage through a large craniotomy or craniectomy. The distinction between subdural and extradural haematoma on a CT scan relies on the anatomical features of the clot. Extradural collections tend to be lentiform in shape, reflecting the pressure required to separate the dura and periosteum. They will not pass deep to any major dural sinus and cannot extend along the falx cerebri or tentorium cerebelli. In contrast, acute subdural haematomas tend to be biconcave in shape and often follow the line of the dura along the falx or tentorium (Fig. 28.12).

The neck extends from the base of the cranium and the inferior border of the mandible to the thoracic inlet.

## SKIN

The skin in the neck is normally under tension. Lines of greatest tension have been termed 'relaxed skin tension lines'; surgical incisions made along these lines are said to heal with minimal postoperative scarring.

## Cutaneous vascular supply and lymphatic drainage

The blood vessels supplying the skin of the neck are derived principally from the facial, occipital, posterior auricular and subclavian arteries They form a rich network within platysma and in the subdermal plexus, which accounts for the viability of the various skin flaps raised during block dissection of the neck, irrespective of whether they include platysma. Great care must be taken in their design to avoid three-point junctions if the area has been irradiated previously and its viability compromised

The anterior cervical skin is supplied mainly by the superior thyroid artery and the transverse cervical branch of the subclavian artery. The posterior skin is supplied by branches from the occipital artery and the deep cervical and transverse cervical branches of the subclavian artery. The superior skin is supplied by the occipital artery and its upper sternocleidomastoid branch, and the submandibular and submental branches of the facial artery. Inferiorly, the skin is supplied by the transverse cervical and/or suprascapular branches of the subclavian artery.

The pattern of venous drainage of the skin of the neck mirrors the arterial supply: the veins drain into the jugular and facial veins.

Many lymphatic vessels draining the superficial cervical tissues skirt the borders of sternocleidomastoid to reach the superior or inferior deep cervical nodes. Some pass over sternocleidomastoid and the posterior triangle to drain into the superficial cervical and occipital nodes (see Fig. 29.15). Lymph from the superior region of the anterior triangle drains to the submandibular and submental nodes. Vessels from the anterior cervical skin inferior to the hyoid bone pass to the anterior cervical lymph nodes near the anterior jugular veins, and their efferents go to the deep cervical nodes of both sides, including the infrahyoid, prelaryngeal and pretracheal groups. An anterior cervical node often occupies the suprasternal space.

## Cutaneous innervation

The cervical skin is innervated by branches of cervical spinal nerves, via both dorsal and ventral rami (see Fig. 45.8). The dorsal rami supply skin over the back of the neck and scalp, and the ventral rami supply skin covering the lateral and anterior portions of the neck, and the angle of the mandible (Fig. 29.1). The dorsal rami of the first, sixth, seventh and eighth cervical nerves have no cutaneous distribution in the neck The greater occipital nerve mainly supplies the scalp; it comes from the medial branch of the dorsal ramus of the second cervical nerve. The medial branches of the dorsal rami of the third, fourth and fifth cervical nerves pierce trapezius to supply skin over the back of the neck sequentially. The ventral rami of the second, third and fourth cervical nerves supply named cutaneous branches (the lesser occipital, great auricular, transverse cutaneous and supraclavicular nerves), via the cervical plexus (see Fig. 29.1) (see p. 463 for details of the motor branches of the cervical plexus).

## Lesser occipital nerve

The lesser occipital nerve is derived mainly from the second cervical nerve (although fibres from the third cervical nerve may sometimes
contribute). It first passes anterior to the plane of the accessory nerve (previously called the spinal accessory nerve; p. 310) before winding around it and becoming anterior to it. It next ascends along the posterior margin of sternocleidomastoid. Near the cranium it perforates the deep fascia and passes up on to the scalp behind the auricle to supply the skin and connect with the great auricular and greater occipital nerves and the auricular branch of the facial nerve. Its auricular branch supplies the skin on the upper third of the medial aspect of the auricle and connects with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve. It has been suggested that compression or stretching of the lesser occipital nerve contributes to cervicogenic headache (Lucas et al 1994).

## Great auricular nerve

The great auricular nerve is the largest ascending branch of the cervical plexus. It arises from the second and third cervical rami, encircles the posterior border of sternocleidomastoid, perforates the deep fascia and ascends on the muscle beneath platysma with the external jugular vein. On reaching the parotid gland, it divides into anterior and posterior branches. The anterior branch is distributed to the facial skin over the parotid gland and connects in the gland with the facial nerve. This cross-innervation between somatic sensory supply (great auricular) and parasympathetic secretomotor fibres to the parotid is considered to be

Fig. 29.1 The cutaneous branches of the cervical plexus. The accessory nerve is also shown as it crosses the posterior triangle to supply trapezius. Note that the interval between the upper attachments of sternocleidomastoid and trapezius is not normally as extensive as shown here. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
part of the anatomical basis for the phenomenon of gustatory sweating (Frey's syndrome), seen after parotidectomy with its inherent disruption of the secretomotor nerve supply. The posterior branch supplies the skin over the mastoid process and on the back of the auricle (except its upper part); a filament pierces the auricle to reach the lateral surface, where it is distributed to the lobule and concha. Efforts are made to preserve the posterior branch at parotid surgery in order to avoid a sensory deficit of the pinna. The posterior branch communicates with the lesser occipital nerve, the auricular branch of the vagus and the posterior auricular branch of the facial nerve.

## Transverse cervical cutaneous nerve

The transverse cervical cutaneous nerve arises from the second and third cervical rami. It curves round the posterior border of sternocleidomastoid near its midpoint and runs obliquely forwards, deep to the external jugular vein, to the anterior border of the muscle. It perforates the deep cervical fascia, and divides under platysma into ascending and descending branches that are distributed to the anterolateral areas of the neck. The ascending branches ascend to the submandibular region, forming a plexus with the cervical branch of the facial nerve beneath platysma. Some branches pierce platysma and are distributed to the skin of the upper anterior areas of the neck. The descending branches pierce platysma and are distributed anterolaterally to the skin of the neck, as low as the sternum.

## Supraclavicular nerves

The supraclavicular nerves arise from a common trunk formed from rami from the third and fourth cervical nerves, and emerge at the posterior border of sternocleidomastoid. Descending under platysma and the deep cervical fascia, the trunk divides into medial, intermediate and lateral (posterior) branches, which diverge to pierce the deep fascia a little above the clavicle. The medial supraclavicular nerves run inferomedially across the external jugular vein and the clavicular and sternal heads of sternocleidomastoid to supply the skin as far as the midline and as low as the second rib. They also supply the sternoclavicular joint. The intermediate supraclavicular nerves cross the clavicle to supply the skin over pectoralis major and deltoid down to the level of the second rib, next to the area of supply of the second thoracic nerve. Overlap between these nerves is minimal. The lateral supraclavicular nerves descend superficially across trapezius and the acromion, supplying the skin of the upper and posterior parts of the shoulder.

## BONES, JOINTS AND CARTILAGES

The bones and cartilages of the neck are the cervical vertebrae and the hyoid bone, and the cartilages of the upper respiratory tract, including the larynx. The cervical vertebrae, the occipital bone and the atlantooccipital and atlanto-axial joints are described in Chapter 43, and the laryngeal cartilages are described in Chapter 35.

## HYOID BONE

The U-shaped hyoid bone (Fig. 29.2) is suspended from the tips of the styloid processes by the stylohyoid ligaments. It has a body and two greater and two lesser horns, or cornua.

## Body

The body is irregular, elongated and quadrilateral. Its anterior surface is convex, faces anterosuperiorly, and is crossed by a transverse ridge with a slight downward convexity. A vertical median ridge often bisects the upper part of the body but rarely extends to the lower part. The posterior surface is smooth and concave, faces posteroinferiorly, and is separated from the epiglottis by the thyrohyoid membrane and loose areolar tissue. There is a bursa between the hyoid bone and the membrane.

Geniohyoid is attached to most of the anterior surface of the body, above and below the transverse ridge; the medial part of hyoglossus invades the lateral geniohyoid area. The lower anterior surface gives attachment to mylohyoid, the line of attachment lying above sternohyoid medially and omohyoid laterally. The lowest fibres of genioglossus, the hyoepiglottic ligament and (most posteriorly) the thyrohyoid membrane are all attached to the rounded superior border. Sternohyoid is attached to the inferior border medially and omohyoid is attached laterally. Occasionally, the medial fibres of thyrohyoid and, when present, levator glandulae thyroideae, are attached along the inferior border.

Fig. 29.2 The hyoid bone. A, Anterosuperior aspect. B, Anterosuperior aspect, showing the positions of muscular attachments. C, Lateral aspect.

## Greater cornua

In early life, the greater cornua are connected to the body by cartilage, but after middle age they are usually united by bone. They project backwards (curving posterolaterally) from the lateral ends of the body. They are horizontally flattened and taper posteriorly, and each ends in a tubercle. When the throat is gripped between finger and thumb above the thyroid cartilage, the greater cornua can be identified and the bone can be moved from side to side.

The middle pharyngeal constrictor and, more laterally (i.e. superficially), hyoglossus are attached along the whole length of the upper surface of each greater cornu. Stylohyoid is attached near the junction of the cornu with the body. The fibrous loop for the digastric tendon is attached lateral and a little posterior to hyoglossus. The thyrohyoid membrane is attached to the medial border and thyrohyoid is attached to the lateral border. The oblique inferior surface is separated from the thyrohyoid membrane by fibroareolar tissue.

## Lesser cornua

The lesser cornua are two small conical projections at the junctions of the body and greater cornua. At its base, each is connected to the body by fibrous tissue and occasionally to the greater cornu by a synovial joint that occasionally becomes ankylosed.

The middle pharyngeal constrictors are attached to the posterior and lateral aspects of the lesser cornua. The stylohyoid ligaments are attached to their apices and are often partly calcified, and the chondroglossi are attached to the medial aspects of their bases.

## Ossification

The hyoid bone develops from cartilages of the second and third pharyngeal arches, the lesser cornua from the second, the greater cornua from the third, and the body from the fused ventral ends of both. Chondrification begins in the fifth fetal week in these elements and is completed in the third and fourth months. Ossification proceeds from six centres, i.e. a pair for the body and one for each cornu. Ossification begins in the greater cornua towards the end of intrauterine life, in the body shortly before or after birth, and in the lesser cornua around puberty. The greater cornual apices remain cartilaginous until the third decade and epiphyses may occur here. They fuse with the body. Synovial joints between the greater and lesser cornua may be obliterated by ossification in later decades.

## JOINTS

The atlanto-occipital and atlanto-axial joints are described in Chapter 43.

## TRIANGLES OF THE NECK

Anterolaterally, the neck appears as a somewhat quadrilateral area, limited superiorly by the inferior border of the mandible and a line

Fig. 29.3 The anterior and posterior triangles of the neck, left lateral aspect. See the note in the caption to Figure 29.1. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
continued from the angle of the mandible to the mastoid process, inferiorly by the upper border of the clavicle, anteriorly by the anterior median line, and posteriorly by the anterior margin of trapezius. This quadrilateral area can be further divided into anterior and posterior triangles by sternocleidomastoid, which passes obliquely from the sternum and clavicle to the mastoid process and occipital bone (Fig. 29.3). It is true that these triangles and their subdivisions are somewhat arbitrary because many major structures - arteries, veins, lymphatics, nerves and some viscera - transgress their boundaries without interruption; nevertheless they have a topographical value in description. Moreover, some of their subdivisions are easily identified by inspection and palpation, and provide invaluable assistance in surface anatomical and clinical examination.

## ANTERIOR TRIANGLE OF THE NECK

The anterior triangle of the neck is bounded anteriorly by the median line of the neck and posteriorly by the anterior margin of sternocleidomastoid. Its base is the inferior border of the mandible and its projection to the mastoid process, and its apex is at the manubrium sterni. It can be subdivided into suprahyoid and infrahyoid areas above and below the hyoid bone, and into digastric, submental, muscular and carotid triangles by the passage of digastric and omohyoid across the anterior triangle (see Fig. 29.5).

## Digastric triangle

The digastric triangle is bordered above by the lower border of the mandible and its projection to the mastoid process, posteroinferiorly by the posterior belly of digastric and by stylohyoid, and anteroinferiorly by the anterior belly of digastric. It is covered by the skin, superficial fascia, platysma and deep fascia, which contain branches of the facial and transverse cutaneous cervical nerves. Its floor is formed by mylohyoid and hyoglossus. The anterior region of the digastric triangle contains the submandibular gland, which has the facial vein superficial to it and the facial artery deep to it. The submental and mylohyoid arteries and nerves lie on mylohyoid. The submandibular lymph nodes are variably related to the submandibular gland. The posterior region of the digastric triangle contains the lower part of the parotid gland. The external carotid artery, passing deep to stylohyoid, curves above the muscle, and overlaps its superficial surface as it ascends deep to the parotid gland before entering it. The internal carotid artery, internal jugular vein and vagus nerve lie deeper and are separated from the external carotid artery by styloglossus, stylopharyngeus and the glossopharyngeal nerve.

## Submental triangle

The single submental triangle is demarcated by the anterior bellies of both digastric muscles. Its apex is at the chin, its base is the body of the hyoid bone and its floor is formed by both mylohyoid muscles. It contains lymph nodes and small veins that unite to form the anterior jugular vein. The structures within the digastric and submental triangles are described in more detail with the floor of the mouth.

## Muscular triangle

The muscular triangle is bounded anteriorly by the median line of the neck from the hyoid bone to the sternum, inferoposteriorly by the anterior margin of sternocleidomastoid and posterosuperiorly by the superior belly of omohyoid. The triangle contains omohyoid, sternohyoid, sternothyroid and thyrohyoid.

## Carotid triangle

The carotid triangle is limited posteriorly by sternocleidomastoid, anteroinferiorly by the superior belly of omohyoid and superiorly by stylohyoid and the posterior belly of digastric. In the living (except the obese), the triangle is usually a small visible triangular depression, sometimes best seen with the head and cervical vertebral column slightly extended and the head contralaterally rotated. The carotid triangle is covered by the skin, superficial fascia, platysma and deep fascia containing branches of the facial and cutaneous cervical nerves. The hyoid bone forms its anterior angle and adjacent floor; it can be located on simple inspection and verified by palpation. Parts of thyrohyoid, hyoglossus and inferior and middle pharyngeal constrictor muscles form its floor. The carotid triangle contains the upper part of the common carotid artery and its division into external and internal carotid arteries. Overlapped by the anterior margin of sternocleidomastoid, the external carotid artery is first anteromedial, then anterior to the internal carotid artery. Branches of the external carotid artery are encountered in the carotid triangle. Thus the superior thyroid artery runs anteroinferiorly, the lingual artery anteriorly with a characteristic upward loop, the facial artery anterosuperiorly, the occipital artery posterosuperiorly and the ascending pharyngeal artery medial to the internal carotid artery. Arterial pulsation greets the examining finger. The superior thyroid, lingual, facial, ascending pharyngeal and sometimes the occipital veins correspond to the branches of the external carotid artery, and all drain into the internal jugular vein. The hypoglossal nerve crosses the external and internal carotid arteries. It curves round the origin of the lower sternocleidomastoid branch of the occipital artery, and at this point the superior root of the ansa cervicalis leaves it to descend anteriorly in the carotid sheath. The internal laryngeal nerve and, below it, the external laryngeal nerve lie medial to the external carotid artery below the hyoid bone. Many structures in this region, such as all or part of the internal jugular vein, associated deep cervical lymph nodes, and the vagus nerve, may be variably obscured by sternocleidomastoid, and, pedantically, are thus 'outside the triangle'.

## POSTERIOR TRIANGLE OF THE NECK

The posterior triangle is delimited anteriorly by the posterior edge of sternocleidomastoid, posteriorly by the anterior edge of trapezius, and inferiorly by the middle third of the clavicle (see Fig. 29.3). Its apex is between the attachments of sternocleidomastoid and trapezius to the occiput and is often blunted, so that the 'triangle' becomes quadrilateral. The roof of the posterior triangle is formed by the investing layer of the deep cervical fascia. The floor of the triangle is formed by the prevertebral fascia overlying splenius capitis, levator scapulae and the scalene muscles. It is crossed, approximately 2.5 cm above the clavicle, by the inferior belly of omohyoid, which subdivides it into occipital and supraclavicular triangles. The contents of the posterior triangle include fat, lymph nodes (level V), the accessory nerve, cutaneous branches of the cervical plexus, inferior belly of omohyoid, branches of the thyrocervical trunk (transverse cervical and suprascapular arteries), the third part of the subclavian artery, and the external jugular vein. The anterior and lateral groups of prevertebral muscles form the floor of the posterior triangle.

## Occipital triangle

The occipital triangle constitutes the upper and larger part of the posterior triangle, with which it shares the same borders, except that
inferiorly it is limited by the inferior belly of omohyoid. Its floor, from above down, is formed by splenius capitis, levator scapulae, and scaleni medius and posterior; semispinalis capitis occasionally appears at the apex. The triangle is covered by skin, superficial and deep fasciae, and inferiorly by platysma. The accessory nerve pierces sternocleidomastoid and crosses levator scapulae obliquely downwards and backwards to reach the deep surface of trapezius. The surface marking of its course is in a line from the junction of the superior third and inferior two-thirds of sternocleidomastoid, to the junction of the inferior third and superior two-thirds of trapezius. Cutaneous and muscular branches of the cervical plexus emerge at the posterior border of sternocleidomastoid. Inferiorly, supraclavicular nerves, transverse cervical vessels and the uppermost part of the brachial plexus cross the triangle. Lymph nodes lie along the posterior border of sternocleidomastoid from the mastoid process to the root of the neck.

## Supraclavicular triangle

The supraclavicular triangle is the lower and smaller division of the posterior triangle, with which it shares the same boundaries, except that superiorly it is limited by omohyoid. It corresponds in the living neck with the lower part of a deep, prominent hollow, namely: the greater supraclavicular fossa. Its floor contains the first rib, scalenus medius and the first slip of serratus anterior. Its size varies with the extent of the clavicular attachments of sternocleidomastoid and trapezius, and also the level of the inferior belly of omohyoid. The triangle is covered by skin, superficial and deep fasciae, and platysma, and crossed by the supraclavicular nerves. Just above the clavicle, the third part of the subclavian artery curves inferolaterally from the lateral margin of scalenus anterior across the first rib to the axilla. The subclavian vein is behind the clavicle and is not usually in the triangle, but it may rise as high as the artery and even accompany it behind scalenus anterior. The brachial plexus is partly superior, and partly posterior, to the artery and is always closely related to it. The trunks of the brachial plexus may easily be palpated here if the neck is contralaterally flexed and the examining finger is drawn across the trunks at right angles to their length. With the musculature relaxed, pulsation of the subclavian artery may be felt and the arterial flow can be controlled by retroclavicular compression against the first rib. The suprascapular vessels pass transversely behind the clavicle, below the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of sternocleidomastoid to end in the subclavian vein. It receives the transverse cervical and suprascapular veins, which form a plexus in front of the third part of the subclavian artery; occasionally, it is joined by a small vein that crosses the clavicle anteriorly from the cephalic vein. Other structures within the triangle include the nerve to subclavius, which crosses the triangle, and lymph nodes.

## CERVICAL FASCIA

The organization of the layers of the cervical fascia, and of the tissue 'spaces' they enclose, may determine the spread of disease in the head and neck, and facilitates both the differential diagnosis and the surgical management of that disease, particularly in the suprahyoid neck. Descriptions of the detailed anatomy of these layers and their associated spaces have a long and chequered history: Malgaigne (1838) commented that 'the cervical fasciae appear in a new form under the pen of each author who attempts to describe them.' The situation seems to have changed very little in the intervening years, and details of the attachments and distribution of the layers and spaces still vary in modern surgical, radiological, oncological and anatomical literature (Som and Curtin 2011, Guidera et al 2012). Interestingly, there is more consensus on why the confusion persists, e.g. the difficulties of defining what constitutes fascia, or the limits of layers that split to ensheathe muscles and neurovascular bundles and then merge with other fascial layers.

## SUPERFICIAL CERVICAL FASCIA

Like superficial fascia elsewhere in the body, the superficial cervical fascia is not a separate stratum but a zone of loose connective tissue between dermis and deep fascia, and is joined to both. It covers platysma but is hardly demonstrable as a separate layer. It may contain considerable amounts of adipose tissue, especially in females, which presumably explains why it is sometimes referred to simply as subcutaneous fat. In the lower cervical region, aponeurotic fibres of platysma gradually
fan out in this layer and either become skin ligaments or continue into the fascia covering pectoralis major and deltoid (Nash et al 2005).

## DEEP CERVICAL FASCIA

Descriptions of the organization of the deep cervical fascia are largely based on the classic work of Grodinsky and Holyoke in 1938. Conventionally, three layers - superficial investing, middle and deep - are recognized (Fig. 29.4). Details of their precise attachments and contents vary between authors. (For further reading, see Som and Curtin (2011).)

## Investing layer of deep cervical fascia

The investing or superficial layer of the deep cervical fascia encircles the neck, ensheathing trapezius and sternocleidomastoid. The portions between trapezius and sternocleidomastoid, and in the anterior triangle of the neck, are formed of areolar tissue, indistinguishable from that in the superficial cervical fascia and deep potential tissue spaces. Superiorly, the deep fascia fuses with periosteum along the superior nuchal line of the occipital bone, over the mastoid process and along the entire base of the mandible. Between the angle of the mandible and the anterior edge of sternocleidomastoid, it is particularly strong. Between the mandible and the mastoid process, it is related to the parotid gland, extending beneath it to become attached to the zygomatic arch. From this region, the strong stylomandibular ligament ascends to the styloid process. Inferiorly, along trapezius and sternocleidomastoid, the investing layer of the deep cervical fascia is attached to the acromion, clavicle and manubrium sterni, fusing with their periostea. A short distance above the manubrium, the investing layer interweaves with aponeurotic fibres of platysma and the fascia investing the strap muscles. It is organized into superficial and deep layers, which are attached to the anterior border of the manubrium, and to the posterior border and the interclavicular ligament, respectively. Between these two layers, a slit-like interval, the suprasternal space, contains a small amount of areolar tissue, the lower parts of the anterior jugular veins and the jugular venous arch, the sternal heads of the sternocleidomastoid muscles and sometimes a lymph node.

## Middle layer of deep cervical fascia

Many of the variations in the descriptions of cervical fascia concern the middle layer. (For a detailed discussion, see Som and Curtin (2011).) It is usually subdivided into a muscular layer that surrounds the infrahyoid strap muscles and a visceral layer that includes both the pretracheal and buccopharyngeal fasciae. The visceral layer extends inferiorly from the base of the skull posteriorly and the hyoid bone and thyroid cartilage anteriorly and laterally, and provides fascial sheaths of varying thickness for the thyroid gland, larynx, trachea, pharynx and oesophagus. Inferiorly, it continues into the superior mediastinum along the great vessels and fuses with the fibrous pericardium. Laterally, it merges with the investing layer of deep cervical fascia and with the carotid sheath (see Fig. 29.4).

## Deep layer of deep cervical fascia

The deep layer of cervical fascia consists of dorsal and ventral layers: the prevertebral and alar fasciae, respectively. In some descriptions, the prevertebral layer is synonymous with the deep layer.

The prevertebral fascia lies closest to the vertebral bodies, covering the anterior surface of longus capitis and longus colli. It extends inferiorly from the skull base, descending in front of longus colli into the superior mediastinum, where it blends with the anterior longitudinal ligament. It passes laterally and posteriorly as the scalene fascia, which covers the scalene muscles, splenius capitis and levator scapulae. All the ventral rami of the cervical nerves are initially behind the prevertebral fascia. The nerves to the rhomboids and serratus anterior and the proximal portions of the phrenic nerve retain this position throughout their course in the neck, but the accessory nerve lies superficial to the prevertebral fascia. As the subclavian artery and the brachial plexus emerge from behind scalenus anterior, they carry the prevertebral fascia downwards and laterally behind the clavicle as the axillary sheath. The prevertebral fascia is attached to the spinous processes of the vertebrae and forms a fascial floor for the posterior triangle of the neck.

The alar fascia is a coronally orientated sheet, attached to the transverse process of the cervical vertebrae. It lies anterior to the prevertebral fascia, from which it is separated by loose connective tissue that fills the so-called danger space (see below), and posterior to the pharynx/

Fig. 29.4 A, The layers of cervical fascia. Abbreviation: SMAS, superficial musculo-aponeurotic system. B, The deep 'spaces' in the neck. (A and B, Infrahyoid transverse section of the neck, adapted from McMinn RMH, Last's Anatomy. Redrawn with permission from Guidera AK, Dawes PJD, Stringer MD 2012 Cervical fascia: a terminological pain in the neck. ANZ Surg 82:786-791.)
oesophagus and the visceral layer of the middle deep cervical fascia, from which it is separated by loose connective tissue that fills the retropharyngeal space (see Fig. 29.4). It passes anterolaterally to fuse with the prevertebral fascia and extends inferiorly from the skull base to about the level of the seventh cervical vertebra (it varies between C6 and T4), where it fuses with the visceral layer of middle cervical fascia, thereby delimiting the lowest extent of the retropharyngeal and danger spaces.

## Carotid sheath

The conventional description of the carotid sheath is that it is a condensation of deep cervical fascia around the common and internal carotid arteries, internal jugular vein, vagus nerve and ansa cervicalis. It is thicker around the arteries than the vein, an arrangement that allows the vein to expand. Peripherally, the sheath is connected to adjacent fascial layers by loose areolar tissue. There is disagreement about whether the carotid sheath is formed by all three layers of the deep cervical fascia, or exclusively by the deep or the superficial layer, or even that it lacks a demonstrable fascial ensheathment (Guidera et al 2012).

## Suprapleural membrane (Sibson's fascia)

The suprapleural membrane (Sibson's fascia) serves as a plane of separation between the lower neck and the thorax. It is attached anteriorly to the inner border of the first rib, and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra and is covered and strengthened by a few spreading muscular fibres derived from the scaleni.

## Tissue spaces and the spread of infection and injectate

The fascial layers of the neck define a number of potential tissue 'spaces' above and below the hyoid bone. In health, the tissues within these spaces are closely applied to each other or are filled with relatively loose connective tissue. However, infections arising superiorly, such as dental, tonsillar, vertebral or intervertebral disc-related infections, can alter these relationships. The organisms responsible are often $\beta$-haemolytic streptococci or a variety of anaerobes. Streptococci produce proteolytic enzymes that digest the loose connective tissue and so open up the tissue spaces. Since there are no tissue barriers running horizontally in the neck, infections that are not treated promptly can rapidly spread from the infratemporal fossa down to the mediastinum below, cross the midline through the sublingual and submental spaces, and even track into the axilla.

Understanding the configuration of the cervical fasciae and spaces is essential for the placement of local anaesthetic cervical plexus blocks in the neck to facilitate operations such as thyroidectomy, parathyroidectomy and carotid endarterectomy (Pandit et al 2000).

The spaces are best conceptualized in terms of their location, remembering that some communicate with each other and/or with the axilla or thorax, and that some contain only loose areolar tissue whilst others contain dense connective tissue. Thus, spaces may be associated with the face (buccal, canine, masticator, parotid), suprahyoid (peritonsillar, submandibular, sublingual, parapharyngeal) or infrahyoid (anterior visceral), or extend the length of the neck (retropharyngeal, danger, prevertebral, carotid). (For further reading, see Oliver and Gillespie (2010).) Tissue spaces associated with the face are described in Chapter
31. Tissue spaces around the pharynx and larynx are described on pages 578 and 594, respectively.

## Visceral space or compartment

The visceral space or compartment contains the pharynx, cervical oesophagus, larynx, trachea, thyroid and parathyroid glands, recurrent laryngeal nerves, and the cranial sympathetic trunk. It is bounded anteriorly by the fascia that encloses the infrahyoid strap muscles (muscular layer of middle deep cervical fascia), posteriorly by the alar fascia, and laterally by the carotid sheath on either side. It may be subdivided into an anterior visceral (pretracheal) space and a posterior visceral space; these spaces communicate freely between the levels of the mid-thyroid cartilage and the inferior thyroid artery, but are separated inferiorly by the fascia associated with the artery.

## Anterior visceral (pretracheal) space

The visceral division of the middle layer of deep cervical fascia encloses the anterior visceral space, a surgical and radiological term also traditionally (and confusingly) called the 'pretracheal' space. It contains the trachea, as well as the thyroid and parathyroid glands, larynx, cervical oesophagus, recurrent laryngeal nerves and the cranial sympathetic trunks. The space extends superiorly from the hyoid bone and the attachments of the strap muscles and their fasciae to the hyoid bone and thyroid cartilage down into the anterior portion of the superior mediastinum. It communicates freely with the posterior visceral space around the sides of the larynx, the caudal portion of the pharynx and the upper cervical oesophagus, but becomes separated from the posterior visceral space at lower levels by dense connective tissue associated with the inferior thyroid artery as the latter approaches the thyroid gland. Infection usually spreads into the anterior visceral space by either perforation of the anterior wall of the oesophagus by endoscopic instrumentation, foreign bodies or trauma or from the posterior visceral space. Radiologically, the portion of the anterior visceral space between the strap fascia and the fascia of the thyroid gland is referred to as the anterior cervical space; its posterolateral border is either the carotid sheath or the fascia covering sternocleidomastoid. The anterior cervical space often provides a symmetric landmark on transverse imaging (Smoker and Harnsberger 1991).

## Posterior visceral space

The posterior visceral space lies posterior to the pharynx and cervical oesophagus, extending from the skull base down to the superior mediastinum, its caudal limit being the level of fusion between the alar and visceral layers of fascia. The posterior visceral space is often referred to as the retropharyngeal space in the upper neck.

## Prevertebral space

The prevertebral tissue space is the potential space lying between the prevertebral fascia and the vertebral column. It extends from the skull base to the coccyx, and encloses the prevertebral muscles. Almost all of the pathology that affects the prevertebral space arises from either the adjacent vertebrae or their intervertebral discs, or the spinal cord and associated nerve roots and spinal nerves. Tuberculosis of the spine may breach the space and form a Pott's abscess.

## Danger space

The danger space lies between the alar and prevertebral fascia, and extends from the skull base down to the posterior mediastinum, where the alar, visceral and prevertebral layers of deep cervical fascia fuse. The potential space so created is closed superiorly, inferiorly and laterally; infections can only enter by penetrating its walls. The danger space is so called because its loose areolar tissue offers a potential route for the rapid downward spread of infection, primarily from the retropharyngeal, parapharyngeal or prevertebral spaces, to the posterior mediastinum.

## Carotid space

The carotid sheath is a layer of loose connective tissue demarcated by adjacent portions of the investing layer of deep cervical fascia, the pretracheal fascia and the prevertebral fascia. The literature about the existence of a carotid space is confusing: some authors dispute that a potential cavity exists within the carotid sheath that could permit the spread of infections from the upper neck down into the lower neck and mediastinum, while others consider that the suprahyoid sheath should be regarded as part of the parapharyngeal space (see discussion in Som and Curtin (2011)). Infections around the carotid sheath may be restricted because, superiorly (near the hyoid bone) and inferiorly (near the root of the neck), the connective tissues adhere to the vessels.

## Cellulitis in the neck

The most common causes of cellulitis of the neck are infections arising from the region of the mandibular molar teeth and the palatine tonsils. Several fascial spaces are accessible from this area, and several anatomical factors contribute to the spread of infection. Thus, the apices of the second and, more especially, the third, mandibular molar teeth are often close to the lingual surface of the mandible. The apices of the roots of the third mandibular molars are usually, and the second molars are often, below the attachment of mylohyoid on the inner aspect of the mandible and so drain directly into the submandibular tissue space. The posterior free border of mylohyoid is close to the sockets of the third mandibular molars, and at this point, the floor of the mouth consists only of mucous membrane covering part of the submandibular salivary gland. Any virulent periapical infection of the mandibular third molar teeth may therefore penetrate the lingual plate of the mandible and is then at the entrance to the submandibular and sublingual spaces anteriorly, and the parapharyngeal and pterygoid spaces posteriorly. Infection in this area may also spread from an acute pericoronitis, particularly when the deeper tissues are opened to infection by extraction of the tooth during the acute phase.

In general, cellulitis around the jaw is only likely to develop when the tissues are infected by virulent and invasive organisms at a point where there is access to the fascial spaces; the predisposing causes do not often coincide, and cellulitis is therefore uncommon. Cellulitis in the region of the maxilla is even more uncommon, but fascial space infections may develop in various sites as the result of infected local anaesthetic needles. Since there are no barriers running horizontally with respect to the tissue spaces in the neck, infection entering in this site can rapidly spread more or less unhindered down the neck and may enter the mediastinum.

All forms of cellulitides of the neck or deep neck space infections are potentially very serious. Obstruction of the upper airway develops as a result of inflammation and oedema, compounded by salivary pooling consequent on dysphagia, and this can be quite catastrophic. This situation is very difficult to manage by conventional techniques. Increased rigidity and reduced compliance of the tissues make manœuvres such as manual anterior jaw thrust or laryngoscopy almost impossible. Specialized techniques, e.g. flexible fibreoptic-assisted tracheal intubation or surgical tracheostomy under local anaesthesia, are usually required to provide safe general anaesthesia to facilitate the surgical drainage and treatment of the cellulitis or deep space abscess. (For further reading see Hedge et al (2012), Maroldi et al (2012).)

## MUSCLES

The superficial muscles of the neck are platysma, which lies in the subcutaneous tissue of the neck, and sternocleidomastoid and trapezius. Sternocleidomastoid is a key landmark because it divides the neck into anterior and lateral regions (anterior and posterior triangles, respectively); the anterior region may be further subdivided into several smaller named triangles (see above). Muscles in the anterior region are organized into supra- and infrahyoid groups, and, with one exception, are all attached to the hyoid bone. The suprahyoid muscles, which connect the hyoid bone to the mandible and the base of the skull, include mylohyoid, geniohyoid, stylohyoid and digastric. The infrahyoid (strap) muscles, which connect the hyoid, sternum, clavicle and scapula, are arranged in two planes: a superficial plane consisting of sternohyoid and omohyoid, and a deep plane consisting of sternothyroid and thyrohyoid.

The muscles that form part of the musculoskeletal column in the neck are described in Chapter 43. They can be considered in three groups - anterior, lateral and posterior; very broadly speaking, the muscles in these groups lie anterior, lateral or posterior to the cervical vertebrae. The anterior and lateral groups include longi colli and capitis; recti capitis anterior and lateralis; and scaleni anterior, medius, posterior and minimi (when present). The posterior muscle group is composed of the cervical components of the intrinsic muscles of the back, overlaid by some of the extrinsic 'immigrant' muscles of the back that run between the upper limb and the axial skeleton (trapezius, levator scapulae; Chapter 48). The intrinsic muscles are arranged in superficial and deep layers. The superficial layer contains splenius capitis and cervicis. The deeper layers include the transversospinal group (semispinales cervicis and capitis, multifidus and rotatores cervicis), interspinales and intertransversarii, and the suboccipital group (recti capitis posterior major and minor, and obliquus capitis superior and inferior).

The muscles associated with the pharynx and larynx are described in Chapters 34 and 35, respectively.

## Platysma

Platysma is a broad sheet of muscle of varying prominence that arises from the fascia covering the upper parts of pectoralis major and deltoid. Its fibres cross the clavicle and ascend medially in the side of the neck. Anterior fibres interlace across the midline with the fibres of the contralateral muscle, below and behind the symphysis menti. Other fibres attach to the lower border of the mandible or to the lower lip, or cross the mandible to attach to skin and subcutaneous tissue of the lower face. Careful elevation of a myocutaneous flap in the subplatysmal plane as part of a neck dissection will include this muscle and its associated blood supply, thereby minimizing the risk of skin necrosis and wound breakdown.

Vascular supply Platysma is supplied by the submental branch of the facial artery and by the suprascapular artery (from the thyrocervical trunk of the subclavian artery).

Innervation Platysma is innervated by the cervical branch of the facial nerve, which descends on the deep surface of the muscle close to the angle of the mandible.

Actions Contraction diminishes the concavity between the jaw and the side of the neck, and produces tense, oblique ridges in the skin of the neck. Platysma may assist in depressing the mandible, and, via its labial and modiolar attachments, it can draw down the lower lip and corners of the mouth in expressions of horror or surprise.

## Sternocleidomastoid

Sternocleidomastoid (Fig. 29.5) descends obliquely across the side of the neck and forms a prominent surface landmark, especially when contracted. It is thick and narrow centrally, and broader and thinner at each end. The muscle is attached inferiorly by two heads. The medial or sternal head is rounded and tendinous, arises from the upper part of the anterior surface of the manubrium sterni, and ascends posterolaterally. The lateral or clavicular head, which is variable in width and contains muscular and fibrous elements, ascends almost vertically from the superior surface of the medial third of the clavicle. The two heads are separated near their attachments by a triangular interval that corresponds to a surface depression, the lesser supraclavicular fossa. As they ascend, the clavicular head spirals behind the sternal head and blends with its deep surface below the middle of the neck, forming a thick, rounded belly. Sternocleidomastoid inserts superiorly by a strong tendon into the lateral surface of the mastoid process from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line. The clavicular fibres are directed mainly to the
mastoid process; the sternal fibres are more oblique and superficial, and extend to the occiput. The direction of pull of the two heads is therefore different, and the muscle may be classed as 'cruciate' and slightly 'spiralized'.

Relations The superficial surface of sternocleidomastoid is covered by skin and platysma, between which lie the external jugular vein, the great auricular and transverse cervical nerves, and the superficial lamina of the deep cervical fascia. Near its insertion, the muscle is overlapped by a small part of the parotid gland. The deep surface of the muscle near its origin is related to the sternoclavicular joint and sternohyoid, sternothyroid and omohyoid. The anterior jugular vein crosses deep to it but superficial to the infrahyoid muscles, immediately above the clavicle. The carotid sheath and the subclavian artery are deep to these muscles. Between omohyoid and the posterior belly of digastric, the anterior part of sternocleidomastoid lies superficial to the common, internal and external carotid arteries, the internal jugular, facial and lingual veins, the deep cervical lymph nodes, the vagus nerve and the rami of the ansa cervicalis. The sternocleidomastoid branch of the superior thyroid artery crosses deep to the muscle at the upper border of omohyoid. The posterior part of sternocleidomastoid is related on its internal surface to splenius capitis, levator scapulae and the scalene muscles, the cervical plexus, the upper part of the brachial plexus, the phrenic nerve and the transverse cervical and suprascapular arteries. The occipital artery crosses deep to the muscle at, or under cover of, the lower border of the posterior belly of digastric. At this point, the accessory nerve passes deep to sternocleidomastoid, then pierces and supplies the muscle, before it reappears just above the middle of the posterior border. At its insertion, the muscle lies superficial to the mastoid process, splenius capitis, longissimus capitis and the posterior belly of digastric.

Vascular supply Sternocleidomastoid receives its blood supply from branches of the occipital and posterior auricular arteries (upper part of muscle), the superior thyroid artery (middle part of muscle) and the suprascapular artery (lower part of muscle). A superiorly based flap can be raised on sternocleidomastoid to include a paddle of skin supplied by perforator vessels (Froes et al 1999), and has been used to reconstruct the lips, floor of mouth and inner aspect of the cheeks. It is not a very reliable flap and its use has been superseded by microvascular free transfer flaps or by conventional myocutaneous flaps such as the pectoralis major flap.

Innervation Sternocleidomastoid is supplied by the accessory nerve. Branches from the ventral rami of the second, third, and sometimes

Fig. 29.5 Muscles of the neck. Note that the head is slightly extended in order to expose the suprahyoid muscles. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
fourth cervical spinal nerves also enter the muscle. Although these cervical rami were believed to be solely proprioceptive, clinical evidence suggests that some of their fibres are motor.

Actions Acting alone, each sternocleidomastoid will tilt the head towards the ipsilateral shoulder, simultaneously rotating the head so as to turn the face towards the opposite side. This movement occurs in an upward, sideways glance. A more common visual movement is a level rotation from side to side, and this probably represents the most frequent use of the sternocleidomastoids. Acting together from below, the muscles draw the head forwards and so help longi colli to flex the cervical part of the vertebral column, which is a common movement in feeding. The two sternocleidomastoids are also used to raise the head when the body is supine; when the head is fixed, they help to elevate the thorax in forced inspiration.

Branchial cysts and fistulae Branchial cysts usually present in the upper neck in early adulthood as fluctuant swellings at the junction of the upper and middle thirds of the anterior border of sternocleidomastoid. The cyst typically passes backwards and upwards through the carotid bifurcation and ends at the pharyngeal constrictor muscles, a course that brings it into intimate association with the hypoglossal, glossopharyngeal and accessory nerves. Great care must be taken to avoid damage to these nerves during surgical removal of a branchial cyst.

Branchial fistulae represent a persistent connection between the second branchial pouch and the cervical sinus (Commentary 2.2). The fistula typically presents as a small pit adjacent to the anterior border of the lower third of sternocleidomastoid, which may weep saliva and become intermittently infected. Excision involves following the tract of the fistula up the neck - often through the carotid bifurcation - and into the distal tonsillar fossa, where it opens into the pharynx.

Branchial cysts, sinuses and fistulae are thought to arise from inclusions of salivary gland tissue in lymph nodes; they may also develop around the parotid gland.

## MUSCLES OF THE ANTERIOR TRIANGLE OF THE NECK

Apart from the superficial neck muscles already described, the anterior triangle contains two of the suprahyoid muscles - namely, digastric and stylohyoid - and the four infrahyoid strap muscles (see Fig. 29.5). The other suprahyoid muscles, namely mylohyoid and geniohyoid, are described with the floor of the mouth on page 509.

## Digastric

Digastric has two bellies and lies below the mandible, extending from the mastoid process to the chin (see Fig. 29.5). The posterior belly, which is longer than the anterior, is attached in the mastoid notch of the temporal bone, and passes downwards and forwards. The anterior belly is attached to the digastric fossa on the base of the mandible near the midline, and slopes downwards and backwards. The two bellies meet in an intermediate tendon that perforates stylohyoid and runs in a fibrous sling attached to the body and greater cornu of the hyoid bone; it is sometimes lined by a synovial sheath. The two bellies of digastric mark out the borders of the submandibular triangle.

Variations Digastric may lack the intermediate tendon and is then attached midway along the body of the mandible. The posterior belly may be augmented by a slip from the styloid process or arise wholly from it. The anterior belly may cross the midline and it is not uncommon for it to fuse with mylohyoid.

Relations Superficial to digastric are platysma, sternocleidomastoid, splenius capitis, longissimus capitis and stylohyoid, the mastoid process, the retromandibular vein, and the parotid and submandibular salivary glands. Mylohyoid is medial to the anterior belly, and hyoglossus, superior oblique and rectus capitis lateralis, the transverse process of the atlas vertebra, the accessory nerve, internal jugular vein, occipital artery, hypoglossal nerve, internal and external carotid, facial and lingual arteries are all medial to the posterior belly.

Vascular supply The posterior belly is supplied by the posterior auricular and occipital arteries. The anterior belly of digastric receives its blood supply chiefly from the submental branch of the facial artery.

Innervation The anterior belly of digastric is supplied by the mylohyoid branch of the inferior alveolar nerve, and the posterior belly is
supplied by the facial nerve. The different innervation of the two parts reflects their separate derivations from the mesenchyme of the first and second branchial arches.

Actions Digastric depresses the mandible and can elevate the hyoid bone. The posterior bellies are especially active during swallowing and chewing.

## Stylohyoid

Stylohyoid arises by a small tendon from the posterior surface of the styloid process, near its base. Passing downwards and forwards, it inserts into the body of the hyoid bone at its junction with the greater cornu (and just above the attachment of the superior belly of omohyoid). It is perforated near its insertion by the intermediate tendon of digastric (see Fig. 29.5). The muscle may be absent or double. It may lie medial to the external carotid artery and may end in the suprahyoid or infrahyoid muscles.

Vascular supply Stylohyoid receives its blood supply from branches of the facial, posterior auricular and occipital arteries.

Innervation Stylohyoid is innervated by the stylohyoid branch of the facial nerve, which frequently arises with the digastric branch, and enters the middle part of the muscle.

Actions Stylohyoid elevates the hyoid bone and draws it backwards, elongating the floor of the mouth.

## Stylohyoid ligament

The stylohyoid ligament is a fibrous cord extending from the tip of the styloid process to the lesser cornu of the hyoid bone. It gives attachment to the highest fibres of the middle pharyngeal constrictor and is intimately related to the lateral wall of the oropharynx. Below, it is overlapped by hyoglossus. The ligament is derived from the cartilage of the second branchial arch, and may be partially calcified.

## INFRAHYOID MUSCLES

The infrahyoid muscles are organized so that sternohyoid and omohyoid lie superficially, and sternothyroid and thyrohyoid lie more deeply (see Fig. 29.5). The muscles are involved in movements of the hyoid bone and thyroid cartilage during vocalization, swallowing and mastication, and are mainly innervated from the ansa cervicalis.

## Sternohyoid

Sternohyoid is a thin, narrow strap muscle that arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament and the upper posterior aspect of the manubrium (see Fig. 29.5). It ascends medially and is attached to the inferior border of the body of the hyoid bone. Inferiorly, there is a considerable gap between the muscle and its contralateral fellow, but the two usually come together in the middle of their course and are contiguous above this. Sternohyoid may be absent or double, augmented by a clavicular slip (cleidohyoid), or interrupted by a tendinous intersection.

Vascular supply Sternohyoid is supplied by branches from the superior thyroid artery.

Innervation Sternohyoid is innervated by branches from the ansa cervicalis (C1, 2, 3).

Actions Sternohyoid depresses the hyoid bone after it has been elevated.

## Omohyoid

Omohyoid consists of two bellies united at an angle by an intermediate tendon (see Fig. 29.5). The inferior belly is a flat, narrow band, which inclines forwards and slightly upwards across the lower part of the neck. It arises from the upper border of the scapula, near the scapular notch, and occasionally from the superior transverse scapular ligament. It then passes behind sternocleidomastoid and ends there in the intermediate tendon. The superior belly begins at the intermediate tendon, passes almost vertically upwards near the lateral border of sternohyoid, and is attached to the lower border of the body of the hyoid bone lateral to the insertion of sternohyoid. The length and form of the intermediate tendon vary, although it usually lies adjacent to the internal jugular vein at the level of the arch of the cricoid cartilage. The angulated course of the muscle is maintained by a band of deep cervical fascia, attached
below to the clavicle and the first rib, which ensheathes the tendon. A variable amount of skeletal muscle may be present in the fascial band; either belly may be absent or double; and the inferior belly may be attached directly to the clavicle and the superior is sometimes fused with sternohyoid.

Vascular supply Omohyoid is supplied by branches from the superior thyroid and lingual arteries.

Innervation The superior belly of omohyoid is innervated by branches from the superior ramus of the ansa cervicalis (C1). The inferior belly is innervated from the ansa cervicalis itself ( $\mathrm{C} 1,2$ and 3 ).

Actions Omohyoid depresses the hyoid bone after it has been elevated. It has been speculated that the muscle tenses the lower part of the deep cervical fascia in prolonged inspiratory efforts, reducing the tendency for soft parts to be sucked inwards.

## Sternothyroid

Sternothyroid is shorter and wider than sternohyoid, and lies deep and partly medial to it (see Fig. 29.5). It arises from the posterior surface of the manubrium sterni inferior to the origin of sternohyoid and from the posterior edge of the cartilage of the first rib. It is attached above to the oblique line on the lamina of the thyroid cartilage, where it delineates the upward extent of the thyroid gland. In the lower part of the neck, the muscle is in contact with its contralateral fellow, but the two diverge as they ascend.

Vascular supply Sternothyroid is supplied by branches from the superior thyroid and lingual arteries.

Innervation Sternothyroid is innervated by branches from the ansa cervicalis (C1, 2 and 3).

Actions Sternothyroid draws the larynx downwards after it has been elevated by swallowing or vocal movements. In the singing of low notes, this downward traction would be exerted with the hyoid bone relatively fixed.

## Thyrohyoid

Thyrohyoid is a small, quadrilateral muscle that may be regarded as an upward continuation of sternothyroid (see Fig. 29.5). It arises from the oblique line on the lamina of the thyroid cartilage, and passes upwards to attach to the lower border of the greater cornu and adjacent part of the body of the hyoid bone.

Vascular supply Thyrohyoid is supplied by branches from the superior thyroid and lingual arteries.

Innervation Unlike the other infrahyoid muscles, thyrohyoid is not innervated by the ansa cervicalis. In common with geniohyoid, it is supplied by fibres from the first cervical spinal nerve that branch off from the hypoglossal nerve beyond the descendens hypoglossi.

Actions Thyrohyoid depresses the hyoid bone. With the hyoid bone stabilized, it pulls the larynx upwards, e.g. when high notes are sung.

## ANTERIOR VERTEBRAL MUSCLES

The anterior vertebral group of muscles are longi colli and capitis, and recti capitis anterior and lateralis (Fig. 29.6), all of which are flexors of the head and neck to varying degrees. Together with the lateral vertebral muscles, they form the prevertebral muscle group.

## Rectus capitis anterior

Rectus capitis anterior is a short, flat muscle situated behind the upper part of longus capitis. It arises from the anterior surface of the lateral mass of the atlas and the root of its transverse process, and ascends almost vertically to the inferior surface of the basilar part of the occipital bone immediately anterior to the occipital condyle.

Vascular supply Rectus capitis anterior is supplied by branches from the vertebral and ascending pharyngeal arteries.

Innervation Rectus capitis anterior is innervated by branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Fig. 29.6 The anterior and lateral vertebral muscles. Scalenus anterior and longus capitis have been removed on the right side.

Actions Rectus capitis anterior flexes the head at the atlanto-occipital joints.

## Rectus capitis lateralis

Rectus capitis lateralis is a short, flat muscle that arises from the upper surface of the transverse process of the atlas and inserts into the inferior surface of the jugular process of the occipital bone. In view of its attachments and its relation to the ventral ramus of the first spinal nerve, rectus capitis lateralis is regarded as homologous with the posterior intertransverse muscles.

Vascular supply Rectus capitis lateralis is supplied by branches from the vertebral, occipital and ascending pharyngeal arteries.

Innervation Rectus capitis lateralis is innervated by branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Actions Rectus capitis lateralis flexes the head laterally to the same side.

## Longus capitis

Longus capitis (see Fig. 29.6) has a narrow origin from tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae, and becomes broad and thick above, where it is inserted into the inferior surface of the basilar part of the occipital bone.

Vascular supply Longus capitis is supplied by the ascending pharyngeal, ascending cervical branch of the inferior thyroid and the vertebral arteries.

Innervation Longus capitis is innervated by branches from the ventral rami of the first, second and third cervical spinal nerves.

Actions Longus capitis flexes the head.

## Longus colli

Longus colli (see Fig. 29.6) is applied to the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It can be divided into three parts, which all arise by tendinous slips. The inferior oblique part is the smallest, running upwards and laterally from the anterior surfaces of the bodies of the first two or three thoracic vertebrae to the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The superior oblique part passes upwards and medially from the anterior tubercles of the transverse processes of the third, fourth and fifth cervical vertebrae, to be attached by a narrow
tendon to the anterolateral surface of the tubercle on the anterior arch of the atlas. The vertical intermediate part ascends from the anterior surfaces of the bodies of the upper three thoracic and lower three cervical vertebrae to the fronts of the bodies of the second, third and fourth cervical vertebrae.

Vascular supply Longus colli is supplied by branches from the vertebral, inferior thyroid and ascending pharyngeal arteries.

Innervation Longus colli is innervated by branches from the ventral rami of the second, third, fourth, fifth and sixth cervical spinal nerves.

Actions Longus colli flexes the neck forwards. In addition, the oblique parts may flex it laterally, and the inferior oblique part rotates it to the opposite side. Its main antagonist is longissimus cervicis.

## LATERAL VERTEBRAL MUSCLES

Scaleni anterior, medius and posterior extend obliquely between the upper two ribs and the cervical transverse processes. Scalenus minimus (pleuralis) is associated with the suprapleural membrane and cervical pleura, and is described on page 954.

## Scalenus anterior

Scalenus anterior lies at the side of the neck deep (posteromedial) to sternocleidomastoid (see Figs 29.5, 29.18). Above, it is attached by musculotendinous fascicles to the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae. These converge, blend and descend almost vertically, to be attached by a narrow, flat tendon to the scalene tubercle on the inner border of the first rib, and to a ridge on the upper surface of the rib anterior to the groove for the subclavian artery (see Fig. 29.6).

Relations Scalenus anterior forms an important landmark in the root of the neck because the phrenic nerve passes anterior to it and the subclavian artery posterior to it; the brachial plexus lies at its lateral border. The clavicle, subclavius, sternocleidomastoid and omohyoid, lateral part of the carotid sheath, transverse cervical, suprascapular and ascending cervical arteries, subclavian vein, prevertebral fascia and phrenic nerve are all anterior to scalenus anterior. Posteriorly are the suprapleural membrane, pleura, roots of the brachial plexus and the subclavian artery; the latter two separate scalenus anterior from scalenus medius. The proximity of the muscle to the brachial plexus and subclavian artery and vein can give rise to compression syndromes. Below its attachment to the sixth cervical vertebra, the medial border of the muscle is separated from longus colli by an angular interval in which the vertebral artery and vein pass to and from the foramen transversarium of the sixth cervical vertebra. The inferior thyroid artery crosses this interval from the lateral to the medial side near its apex. The sympathetic trunk and its cervicothoracic ganglion are closely related to the posteromedial side of this part of the vertebral artery. On the left side, the thoracic duct crosses the triangular interval at the level of the seventh cervical vertebra and usually comes into contact with the medial edge of scalenus anterior. The musculotendinous attachments of scalenus anterior to anterior tubercles are separated from those of longus capitis by the ascending cervical branch of the inferior thyroid artery.

Innervation Scalenus anterior is innervated by branches from the ventral rami of the fourth, fifth and sixth cervical spinal nerves.

Actions Acting from below, scalenus anterior bends the cervical portion of the vertebral column forwards and laterally, and rotates it towards the opposite side. Acting from above, the muscle helps to elevate the first rib.

## Scalenus medius

Scalenus medius, the largest and longest of the scaleni, is attached above to the transverse process of the axis and the anterior surface of the posterior tubercles of the transverse processes of the lower five cervical vertebrae (see Fig. 29.6). It frequently extends upwards to the transverse process of the atlas. Below it is attached to the upper surface of the first rib between the tubercle of the rib and the groove for the subclavian artery.

Relations The anterolateral surface of the muscle is related to sternocleidomastoid (see Fig. 29.5). It is crossed anteriorly by the clavicle and omohyoid, and it is separated from scalenus anterior by the subclavian artery and ventral rami of the cervical spinal nerves. Levator scapulae
and scalenus posterior lie posterolateral to it. The upper two roots of the nerve to serratus anterior and the dorsal scapular nerve (to the rhomboids) pierce the muscle and appear on its lateral surface.

Innervation Scalenus medius is supplied by branches from the ventral rami of the third to eighth cervical spinal nerves.

Actions Acting from below, scalenus medius bends the cervical part of the vertebral column to the same side. Acting from above, it helps to raise the first rib. The scalene muscles, particularly scalenus medius, are active during inspiration, even during quiet breathing in the erect attitude.

## Scalenus posterior

Scalenus posterior is the smallest and most deeply situated of the scalene muscles (see Fig. 29.6). It passes from the posterior tubercles of the transverse processes of the fourth, fifth and sixth cervical vertebrae to the outer surface of the second rib, behind the tubercle for serratus anterior, where it is attached by a thin tendon.

Scalenus posterior is occasionally blended with scalenus medius. The scalene muscles vary a little in the number of vertebrae to which they are attached, in their degree of separation and in their segmental innervation.

Vascular supply All the scalene muscles are chiefly supplied by the ascending cervical branch of the inferior thyroid artery. Scalenus posterior receives an additional supply from the superficial cervical artery.

Innervation Scalenus posterior is innervated by branches from the ventral rami of the lower three cervical spinal nerves.

Actions When the second rib is fixed, scalenus posterior bends the lower end of the cervical part of the vertebral column to the same side. When its upper attachment is fixed, it helps to elevate the second rib.

## POSTERIOR VERTEBRAL MUSCLES

Splenius capitis and splenius cervicis are described in Chapter 43.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES OF THE NECK

The common carotid, internal carotid and external carotid arteries provide the major source of blood to the head and neck (Figs 29.7A, 29.8). Additional arteries arise from branches of the subclavian artery, particularly the vertebral artery.

The common, internal and external carotid arteries and accompanying veins and nerves all lie in a cleft that is bound posteriorly by the transverse processes of cervical vertebrae and attached muscles, medially by the trachea, oesophagus, thyroid gland, larynx and pharyngeal constrictors, and anterolaterally by sternocleidomastoid and, at different levels, omohyoid, sternohyoid, sternothyroid, digastric and stylohyoid muscles. The common and internal carotid arteries lie within the carotid sheath, accompanied by the internal jugular vein and the vagus nerve.

## Common carotid artery

The common carotid arteries differ on the right and left sides with respect to their origins. On the right, the common carotid arises from the brachiocephalic artery as it passes behind the sternoclavicular joint. On the left, the common carotid artery comes directly from the arch of the aorta in the superior mediastinum. The right common carotid, therefore, has only a cervical part whereas the left common carotid has cervical and thoracic parts. Following a similar course on both sides, the common carotid artery ascends, diverging laterally from behind the sternoclavicular joint to the level of the upper border of the thyroid cartilage of the larynx (C3-4 junction), where it divides into external and internal carotid arteries. This bifurcation can sometimes be at a higher or lower level (see Fig. 29.7B). The angle of bifurcation remains unchanged from infancy to adulthood. However, there is a significant change in the angle of the split between the internal and the external carotid arteries relative to the common carotid artery (Seong et al 2005). The artery may be compressed against the prominent transverse process of the sixth cervical vertebra (Chassaignac's tubercle); above this level it is superficial and its pulsation can be easily felt.

B

Fig. 29.7 A, Vessels and nerves of the neck, left lateral view. Sternocleidomastoid and the greater part of omohyoid and the internal jugular vein have been removed. Compare with Figure 29.17, which shows a deeper level of dissection. B, The variation in levels of bifurcation of the common carotid artery, related to the cervical vertebrae. (A and B, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 1\% 2013.)

Relations In the lower part of the neck, the common carotid arteries are separated by a narrow gap that contains the trachea. Above this, the arteries are separated by the thyroid gland, larynx and pharynx. Each artery is contained within the carotid sheath of deep cervical fascia, which also encloses the internal jugular vein and vagus nerve. The vein lies lateral to the artery, and the nerve lies between them and posterior to both.

The artery is crossed anterolaterally, at the level of the cricoid cartilage, by the intermediate tendon - sometimes the superior belly - of omohyoid. Below omohyoid, it is sited deeply, and covered by skin, superficial fascia, platysma, deep cervical fascia, and sternocleidomastoid, sternohyoid and sternothyroid. Above omohyoid, it is more superficial, and covered merely by skin, superficial fascia, platysma, deep cervical fascia and the medial margin of sternocleidomastoid; it is crossed obliquely from its medial to lateral side by the sternocleidomastoid branch of the superior thyroid artery. The superior root of the ansa cervicalis, joined by its inferior root from the second and third cervical spinal nerves, lies anterior to, or embedded within, the carotid sheath as it crosses it obliquely. The superior thyroid vein usually crosses near the upper border of the thyroid cartilage, and the middle thyroid vein crosses a little below the level of the cricoid cartilage. The anterior jugular vein crosses the common carotid artery above the clavicle, separated from it by sternohyoid and sternothyroid. Posterior to the
carotid sheath are the transverse processes of the fourth to sixth cervical vertebrae, to which are attached longus colli, longus capitis and tendinous slips of scalenus anterior. The sympathetic trunk and ascending cervical branch of the inferior thyroid artery lie between the common carotid artery and the muscles. Below the level of the sixth cervical vertebra, the artery is in an angle between scalenus anterior and longus colli, anterior to the vertebral vessels, inferior thyroid and subclavian arteries, sympathetic trunk and, on the left, the thoracic duct. The oesophagus, trachea, inferior thyroid artery, recurrent laryngeal nerve and, at a higher level, the larynx and pharynx are medial to the sheath and its contents. The thyroid gland overlaps it anteromedially. The internal jugular vein lies lateral and, in the lower neck, also anterior to the artery, while the vagus nerve lies posterolaterally in the angle between artery and vein.

On the right side, low in the neck, the recurrent laryngeal nerve crosses obliquely behind the artery. The right internal jugular vein diverges from it below but the left vein approaches and often overlaps its artery.

The right common carotid artery sometimes arises above the level of the sternoclavicular joint, or it may be a separate branch from the aorta. The left common carotid artery varies in origin more than the right and may arise with the brachiocephalic artery. Division of the common carotid may occur higher, near the level of the hyoid bone, or,

Fig. 29.8 The branches of the external carotid artery. Note the structures that either cross the internal jugular vein and the carotid arteries or intervene between the external and internal carotid arteries.
more rarely, at a lower level alongside the larynx. Very rarely, it ascends without division, so that either the external or internal carotid is absent, or it may be replaced by separate external and internal carotid arteries that arise directly from the aorta, on one side, or bilaterally.

Although the common carotid artery usually has no branches, it may occasionally give rise to the vertebral, superior thyroid, superior laryngeal, ascending pharyngeal, inferior thyroid or occipital arteries.

## External carotid artery

The external carotid artery (see Figs 29.7A, 29.8) begins lateral to the upper border of the thyroid cartilage, level with the intervertebral disc between the third and fourth cervical vertebrae. A little curved and with a gentle spiral, it first ascends slightly forwards and then inclines backwards and a little laterally, to pass midway between the tip of the mastoid process and the angle of the mandible. Here, in the substance of the parotid gland behind the neck of the mandible, it divides into its terminal branches, the superficial temporal and maxillary arteries. As it ascends, it gives off several large branches and diminishes rapidly in calibre. In children the external carotid is smaller than the internal carotid, but in adults the two are of almost equal size. At its origin, it is in the carotid triangle and lies anteromedial to the internal carotid artery. It later becomes anterior, then lateral, to the internal carotid as it ascends. At mandibular levels, the styloid process and its attached structures intervene between the vessels; the internal carotid is deep, and the external carotid superficial, to the styloid process. A fingertip placed in the carotid triangle perceives a powerful arterial pulsation, which represents the termination of the common carotid, the origins of external and internal carotids, and the stems of the initial branches of the external carotid.

Relations The skin and superficial fascia, the loop between the cervical branch of the facial nerve and the transverse cutaneous nerve of the neck, the deep cervical fascia and the anterior margin of sternocleidomastoid all lie superficial to the external carotid artery in the carotid triangle. The artery is crossed by the hypoglossal nerve and its vena comitans, and by the lingual, facial and, sometimes, the superior thyroid veins. Leaving the carotid triangle, the external carotid artery is crossed by the posterior belly of digastric and by stylohyoid, and ascends between these muscles and the posteromedial surface of the parotid gland, which it next enters. Within the parotid, the artery lies
medial to the facial nerve and the junction of the superficial temporal and maxillary veins. The pharyngeal wall, superior laryngeal nerve and ascending pharyngeal artery are the initial medial relations of the artery. At a higher level, it is separated from the internal carotid artery by the styloid process, styloglossus and stylopharyngeus, glossopharyngeal nerve, pharyngeal branch of vagus nerve and part of the parotid gland. The artery is equally likely to lie medial to the parotid gland, or within it.

The external carotid artery has eight named branches distributed to the head and neck. The superior thyroid, lingual and facial arteries arise from its anterior surface, the occipital and posterior auricular arteries arise from its posterior surface, and the ascending pharyngeal artery arises from its medial surface. The maxillary and superficial temporal arteries are its terminal branches within the parotid gland.

## Superior thyroid artery

The superior thyroid artery is the first branch of the external carotid artery, and arises from the anterior surface of the external carotid just below the level of the greater cornu of the hyoid bone (see Figs 29.7A, 29.8). It descends along the lateral border of thyrohyoid to reach the apex of the lobe of the thyroid gland. Lying medially are the inferior constrictor muscle and the external laryngeal nerve; the nerve is often posteromedial, and therefore at risk when the artery is being ligated. Occasionally, it may issue directly from the common carotid.

## Branches

The superior thyroid artery supplies the thyroid gland and some adjacent skin. Glandular branches are: anterior, which runs along the medial side of the upper pole of the lateral lobe to supply mainly the anterior surface; a branch that crosses above the isthmus to anastomose with its fellow of the opposite side; and posterior, which descends on the posterior border to supply the medial and lateral surfaces, and anastomoses with the inferior thyroid artery. Sometimes, a lateral branch supplies the lateral surface. The artery also has the following named branches: infrahyoid, superior laryngeal, sternocleidomastoid and cricothyroid.

Infrahyoid artery The infrahyoid artery is a small branch that runs along the lower border of the hyoid bone deep to thyrohyoid and anastomoses with its fellow of the opposite side to supply the infrahyoid strap muscles.

Superior laryngeal artery The superior laryngeal artery accompanies the internal laryngeal nerve. Deep to thyrohyoid, it pierces the lower part of the thyrohyoid membrane to supply the tissues of the upper part of the larynx. It anastomoses with its fellow of the opposite side and with the inferior laryngeal branch of the inferior thyroid artery.

Sternocleidomastoid artery The sternocleidomastoid artery descends laterally across the carotid sheath and supplies the middle region of sternocleidomastoid. Like the parent artery itself, it may arise directly from the external carotid artery.

Cricothyroid artery The cricothyroid artery crosses high on the anterior cricothyroid ligament, anastomoses with its fellow of the opposite side and supplies cricothyroid.

## Ascending pharyngeal artery

The ascending pharyngeal artery is the smallest branch of the external carotid. It is a long, slender vessel, which arises from the medial (deep) surface of the external carotid artery near the origin of that artery. It ascends between the internal carotid artery and the pharynx to the base of the cranium. The ascending pharyngeal artery is crossed by styloglossus and stylopharyngeus, and longus capitis lies posterior to it. It gives off numerous small branches to supply longus capitis and longus colli, the sympathetic trunk, the hypoglossal, glossopharyngeal and vagus nerves, and some of the cervical lymph nodes. It anastomoses with the ascending palatine branch of the facial artery and the ascending cervical branch of the vertebral artery. Its named branches are the pharyngeal, inferior tympanic and meningeal arteries.

Pharyngeal artery The pharyngeal artery gives off three or four branches to supply the constrictor muscles of the pharynx and stylopharyngeus. A variable ramus supplies the palate, and may replace the ascending palatine branch of the facial artery. The artery descends forwards between the superior border of the superior constrictor and levator veli palatini to the soft palate, and also supplies a branch to the palatine tonsil and the pharyngotympanic tube.

Inferior tympanic artery The inferior tympanic artery is a small branch that traverses the temporal canaliculus with the tympanic branch of the glossopharyngeal nerve and supplies the medial wall of the tympanic cavity.

Meningeall branches The meningeal branches are small vessels that supply the nerves that traverse the foramen lacerum, jugular foramen and hypoglossal canal, and the associated dura mater and adjoining bone. One branch, the posterior meningeal artery, reaches the cerebellar fossa via the jugular foramen, and is usually regarded as the terminal branch of the ascending pharyngeal artery.

## Lingual artery

The lingual artery provides the chief blood supply to the tongue and the floor of the mouth (see Figs 29.8, 31.8). It arises anteromedially from the external carotid artery opposite the tip of the greater cornu of the hyoid bone, between the superior thyroid and facial arteries. It often arises with the facial or, less often, with the superior thyroid artery. It may be replaced by a ramus of the maxillary artery. Ascending medially at first, it loops down and forwards, passes medial to the posterior border of hyoglossus and then runs horizontally forwards deep to it. The lingual artery next ascends again almost vertically, and courses sinuously forwards on the inferior surface of the tongue as far as its tip. The further course of the lingual artery is described on page 513 .

Relations Its relationship to hyoglossus naturally divides the lingual artery into descriptive 'thirds'. In its first part, the lingual artery is in the carotid triangle. Skin, fascia and platysma are superficial to it, while the middle pharyngeal constrictor muscle is medial. The artery ascends a little medially, then descends to the level of the hyoid bone, and the loop so formed is crossed externally by the hypoglossal nerve. The second part passes along the upper border of the hyoid bone, deep to hyoglossus, the tendons of digastric and stylohyoid, the lower part of the submandibular gland and the posterior part of mylohyoid. Hyoglossus separates it from the hypoglossal nerve and its vena comitans. Here, its medial aspect adjoins the middle constrictor muscle and it crosses the stylohyoid ligament accompanied by lingual veins. The third part is the arteria profunda linguae, which turns upwards near the anterior border of hyoglossus and then passes forwards close to the inferior lingual surface near the frenulum, accompanied by the lingual nerve. Genioglossus is a medial relation, and the inferior longitudinal muscle of the tongue lies lateral to it below the lingual mucous membrane. Near the tip of the tongue, the lingual artery anastomoses with its fellow of the opposite side. Its named branches are the suprahyoid, dorsal lingual and sublingual arteries.

## Suprahyoid artery

The suprahyoid artery is a small branch that runs along the upper border of the hyoid bone to anastomose with the contralateral artery. It supplies adjacent structures.

## Dorsal lingual arteries

The dorsal lingual arteries are described on page 513.

## Sublingual artery

The sublingual artery is described on page 513.

## Facial artery

The facial artery (see Figs 29.7, 29.8, 30.25) arises anteriorly from the external carotid in the carotid triangle, above the lingual artery and immediately above the greater cornu of the hyoid bone. In the neck, at its origin, it is covered only by the skin, platysma, fasciae and often by the hypoglossal nerve. It runs up and forwards, deep to digastric and stylohyoid. At first on the middle pharyngeal constrictor, it may reach the lateral surface of styloglossus, separated there from the palatine tonsil only by this muscle and the lingual fibres of the superior constrictor. Medial to the mandibular ramus, it arches upwards and grooves the posterior aspect of the submandibular gland. It then turns down and descends to the lower border of the mandible in a lateral groove on the submandibular gland, between the gland and medial pterygoid. Reaching the surface of the mandible, the facial artery curves round its inferior border, anterior to masseter, to enter the face; its further course is described on page 498. The artery is very sinuous throughout its extent. In the neck, this may be so that the artery is able to adapt to the movements of the pharynx during deglutition, and similarly on the face, so that the artery can adapt to movements of the mandible, lips and cheeks. Facial artery pulsation is most palpable where the artery crosses the mandibular base, and again near the corner of the mouth. Its branches in the neck are the ascending palatine, tonsillar, submental and glandular arteries.

Ascending palatine artery The ascending palatine artery arises close to the origin of the facial artery. It passes up between styloglossus and stylopharyngeus to reach the side of the pharynx, along which it ascends between the superior constrictor of the pharynx and medial pterygoid towards the cranial base. It bifurcates near levator veli palatini. One branch follows this muscle, winding over the upper border of the superior constrictor of the pharynx to supply the soft palate and to anastomose with its fellow of the opposite side and the greater palatine branch of the maxillary artery. The other branch pierces the superior constrictor muscle to supply the tonsil and pharyngotympanic tube, and to anastomose with the tonsillar and ascending pharyngeal arteries (see Fig. 34.7).

Tonsillar artery The tonsillar artery provides the main blood supply to the palatine tonsil. It ascends between medial pterygoid and styloglossus, penetrates the superior constrictor of the pharynx at the upper border of styloglossus, and enters the inferior pole of the tonsil. Its branches ramify in the tonsil and in the musculature of the posterior part of the tongue. The tonsillar artery may sometimes arise from the ascending palatine artery.

Submental artery The submental artery is the largest cervical branch of the facial artery (see Fig. 29.7). It arises as the facial artery separates from the submandibular gland and turns forwards on mylohyoid below the mandible. It supplies the overlying skin and muscles, and anastomoses with a sublingual branch of the lingual and mylohyoid branch of the inferior alveolar artery. At the chin, it ascends over the mandible, and divides into superficial and deep branches, which anastomose with the inferior labial and mental arteries to supply the chin and lower lip.

Glandular branches Three or four large vessels supply the submandibular salivary gland and associated lymph nodes, adjacent muscles and skin.

## Occipital artery

The occipital artery arises posteriorly from the external carotid artery, approximately 2 cm from its origin (see Figs 29.7A, 29.8). At its origin, the artery is crossed superficially by the hypoglossal nerve, which winds round it from behind. The artery next passes backwards, up and deep to the posterior belly of digastric, and crosses the internal carotid artery, internal jugular vein, and hypoglossal, vagus and accessory nerves. Between the transverse process of the atlas and the mastoid process, the occipital artery reaches the lateral border of rectus capitis lateralis. It then runs in the occipital groove of the temporal bone, medial to the mastoid process and attachments of sternocleidomastoid, splenius capitis, longissimus capitis and digastric, and lies successively on rectus capitis lateralis, obliquus superior and semispinalis capitis. Finally, accompanied by the greater occipital nerve, it turns upwards to pierce the investing layer of the deep cervical fascia connecting the cranial attachments of trapezius and sternocleidomastoid, and ascends tortuously in the dense superficial fascia of the scalp, where it divides into many branches (see Fig. 43.76).

The occipital artery has two main branches (upper and lower) to the upper part of sternocleidomastoid in the neck. The lower branch arises near the origin of the occipital artery, and may sometimes arise directly from the external carotid artery. It descends backwards over the hypoglossal nerve and internal jugular vein, enters sternocleidomastoid and anastomoses with the sternocleidomastoid branch of the superior thyroid artery. The upper branch arises as the occipital artery crosses the accessory nerve, and runs down and backwards superficial to the internal jugular vein. It enters the deep surface of sternocleidomastoid with the accessory nerve.

## Posterior auricular artery

The posterior auricular artery is a small vessel that branches posteriorly from the external carotid just above digastric and stylohyoid. It ascends between the parotid gland and the styloid process to the groove between the auricular cartilage and mastoid process, and divides into auricular and occipital branches, which are described with the face on page 499. In the neck, it provides branches to supply digastric, stylohyoid, sternocleidomastoid and the parotid gland. It also gives origin to the stylomastoid artery - described as an indirect branch of the posterior auricular artery in about a third of subjects - which enters the stylomastoid foramen to supply the facial nerve, tympanic cavity, mastoid antrum air cells and semicircular canals. In the young, its posterior tympanic ramus forms a circular anastomosis with the anterior tympanic branch of the maxillary artery.

Fig. 29.9 Internal carotid artery anatomy shown on volume rendering of a computed tomographic angiogram. The cervical internal carotid artery (white arrow) is a branchless vessel. Note the course of the vertebral artery (black arrow). (With permission from Kaufman JA, and Lee MJ, Carotid and vertebral arteries. In: Kaufman JA, Vascular and Interventional Radiology: The Requisites, Chapter 5, 99-118. Saunders.)

## Internal carotid artery

The internal carotid artery supplies most of the ipsilateral cerebral hemisphere, eye and accessory organs, forehead and, in part, the nose. From its origin at the carotid bifurcation (see Fig. 29.8; Fig. 29.9) (where there is usually a carotid sinus), it ascends in front of the transverse processes of the upper three cervical vertebrae to the inferior aperture of the carotid canal in the petrous part of the temporal bone. Here, it enters the cranial cavity and turns anteriorly through the cavernous sinus in the carotid groove on the side of the body of the sphenoid bone. It terminates below the anterior perforated substance by division into the anterior and middle cerebral arteries. It may be divided conveniently into cervical, petrous, cavernous and cerebral parts. Rarely, persistent embryonic branches to the basilar artery from the cervical part of the internal carotid artery may be encountered at the C1-C2 (persistent hypoglossal artery) and C2-C3 (pro-atlantal intersegmental artery) levels.

Relations The internal carotid artery is initially superficial in the carotid triangle, and then passes deeper, medial to the posterior belly of digastric. Except near the skull, the internal jugular vein and vagus nerve are lateral to it within the carotid sheath. The external carotid artery is first anteromedial, but then curves back to lie superficial. Posteriorly, the internal carotid adjoins longus capitis, and the superior cervical sympathetic ganglion lies between them. The superior laryngeal nerve crosses obliquely behind it. The pharyngeal wall lies medial to the artery, which is separated by fat and pharyngeal veins from the ascending pharyngeal artery and superior laryngeal nerve. Anterolaterally, the internal carotid artery is covered by sternocleidomastoid. Below the posterior belly of digastric, the hypoglossal nerve and superior root of the ansa cervicalis and the lingual and facial veins are superficial to the artery. At the level of the digastric, the internal carotid is crossed by stylohyoid and the occipital and posterior auricular arteries. Above the digastric, it is separated from the external carotid artery by the styloid process, styloglossus and stylopharyngeus, the glossopharyngeal nerve and the pharyngeal branch of the vagus, and the deeper part of the parotid gland. At the base of the skull, the glossopharyngeal, vagus,
accessory and hypoglossal nerves lies between the internal carotid artery and the internal jugular vein, which here has become posterior. The length of the artery varies with the length of the neck and the point of the carotid bifurcation. It may arise from the aortic arch, in which case it lies medial to the external carotid as far as the larynx, where it crosses behind it. The cervical portion is normally straight but may be very tortuous, when it lies closer to the pharynx than usual, very near the tonsil. In children, the tonsillocarotid distance increases with growth to a maximum value of 25 mm (Deutsch et al 1995). The internal carotid artery enters the cranium without giving off any branches. It may occasionally be absent.

Occlusive atherosclerotic disease within either the internal carotid or common carotid artery may cause strokes or transient ischaemic attacks (TIAs) characterized by weakness of the contralateral side. It may also result in visual disturbances characterized classically as a 'curtain' falling down over the visual field (amaurosis fugax). These episodes will be experienced in the ipsilateral eye.

## Carotid sinus and carotid body

The common carotid artery has two specialized organs near its bifurcation: the carotid sinus and the carotid body. They relay information concerning the pressure and chemical composition of the arterial blood, respectively, and are innervated principally by the carotid branch(es) of the glossopharyngeal nerve, with small contributions from the cervical sympathetic trunk and the vagus nerve.

The carotid sinus usually appears as a dilation of the lower end of the internal carotid in late adolescence (Seong et al 2005) and functions as a baroreceptor.

The carotid body is a reddish-brown, oval structure, $5-7 \mathrm{~mm}$ in height and $2.5-4 \mathrm{~mm}$ in width. It lies either posterior to the carotid bifurcation or between its branches, and is attached to, or sometimes partly embedded in, their adventitia. Occasionally, it takes the form of a group of separate nodules. Aberrant miniature carotid bodies, microstructurally similar but with diameters of $600 \mu \mathrm{~m}$ or less, may appear in the adventitia and adipose tissue near the carotid sinus.

The carotid body is surrounded by a fibrous capsule, from which septa divide the enclosed tissue into lobules. Each lobule contains glomus (type I) cells, which are separated from an extensive network of fenestrated sinusoids by sustentacular (type II) cells (Fig. 29.10). Glomus cells store a number of peptides, particularly enkephalins, bombesin and neurotensin, and amines including dopamine, serotonin (5-hydroxytryptamine, 5-HT), adrenaline (epinephrine) and noradrenaline (norepinephrine), and are therefore regarded as paraneurones. Unmyelinated axons lie in a collagenous matrix between the sustentacular cells and the sinusoidal endothelium, and many synapse on the glomus cells. They are visceral afferents, which travel in the carotid sinus nerve to join the glossopharyngeal nerve. Preganglionic sympathetic axons and fibres from the carotid sinus synapse on parasympathetic and sympathetic ganglion cells, which lie either in isolation or in small groups near the surface of each carotid body. Postganglionic axons travel to local blood vessels; the parasympathetic efferent fibres are probably vasodilatory and the sympathetic ones are vasoconstrictor.

The carotid body receives a rich blood supply from branches of the adjacent external carotid artery, which is consistent with its role as an arterial chemoreceptor. When stimulated by hypoxia, hypercapnia or increased hydrogen ion concentration (low pH ) in the blood flowing through it, it elicits reflex increases in the rate and volume of ventilation via connections with brainstem respiratory centres. The bodies are most prominent in children and normally involute in older age, when they are infiltrated by lymphocytes and fibrous tissue. Individuals with chronic hypoxia, or who live at high altitude or suffer from lung disease, may have enlarged carotid bodies as a result of hyperplasia. Disrupted carotid body maturation may play a role in sudden infant death syndrome (Porzionato et al 2013).

Other small bodies, resembling carotid bodies and also considered to be chemoreceptors, are present near the arteries of the fourth and sixth pharyngeal arches and hence are found near the aortic arch, ligamentum arteriosum and right subclavian artery; they are supplied by the vagus nerve.

## Subclavian artery

The right subclavian artery arises from the brachiocephalic trunk, the left from the aortic arch (see Figs 29.14, 29.18). For description, each is divided into a first part, from its origin to the medial border of scalenus anterior; a second part behind this muscle; and a third part from the lateral margin of scalenus anterior to the outer border

Fig. 29.10 The cellular, neural and vascular architecture of the carotid body. Functional pathways are indicated.
of the first rib, where the artery becomes the axillary artery. Each subclavian artery arches over the cervical pleura and pulmonary apex. Their first parts differ, whereas the second and third parts are almost identical.

## First part of right subclavian artery

The right subclavian artery branches from the brachiocephalic trunk behind the upper border of the right sternoclavicular joint, and passes superolaterally to the medial margin of scalenus anterior. It usually ascends 2 cm above the clavicle but this varies.

Relations The artery is deep to the skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular attachment of sternocleidomastoid, sternohyoid and sternothyroid. It is at first behind the origin of the right common carotid artery; more laterally, it is crossed by the vagus nerve, the cardiac branches of the vagus and the sympathetic chain, and by internal jugular and vertebral veins; the subclavian sympathetic loop encircles it. The anterior jugular vein diverges laterally in front of it, separated by sternohyoid and sternothyroid. Below and behind the artery are the pleura and pulmonary apex; they are separated from the artery by the suprapleural membrane, the ansa subclavia, a small accessory vertebral vein and the right recurrent laryngeal nerve, which winds round the lower and posterior part of the vessel.

## First part of left subclavian artery

The first part of the left subclavian artery springs from the aortic arch, behind the left common carotid, level with the disc between the third and fourth thoracic vertebrae. It ascends into the neck, and then arches laterally to the medial border of scalenus anterior.

Relations In the neck, near the medial border of scalenus anterior, the artery is crossed anteriorly by the left phrenic nerve and the termination of the thoracic duct. Otherwise, anterior relations are the same as those of the first part of the right subclavian artery. Posteriorly and inferiorly, the relations of both vessels are identical but the left recurrent laryngeal nerve, medial to the left subclavian artery in the thorax, is not directly related to its cervical part.

## Second part of subclavian artery

The second part of the subclavian artery lies behind scalenus anterior; it is short and constitutes the highest part of the vessel (see Fig. 29.18).

Relations The skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid and scalenus anterior are anterior. The right phrenic nerve is often described as being separated from the second part of the subclavian artery by scalenus anterior, whereas it crosses the first part of the left subclavian artery. However, both nerves may sometimes lie anterior to the muscle. The suprapleural membrane, pleura and lung, and the lower trunk of the brachial plexus are posteroinferior; the upper and middle trunks of the plexus are superior; and the subclavian vein is anteroinferior, separated by scalenus anterior.

## Third part of subclavian artery

The third part of the subclavian artery descends laterally from the lateral margin of scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. It is the most superficial part of the artery and lies partly in the supraclavicular triangle, where its pulsations may be felt and it may be compressed. The third part of the subclavian artery is the most accessible segment of the artery. Since the line of the posterior border of sternocleidomastoid approximates to the (deeper) lateral border of scalenus anterior, the artery can be felt in the anteroinferior angle of the posterior triangle. It can only be effectively compressed against the first rib: with the shoulder depressed, pressure is exerted down, back and medially in the angle between sternocleidomastoid and the clavicle. The palpable trunks of the brachial plexus may be injected with local anaesthetic allowing major surgical procedures to the arm.

Relations The skin, superficial fascia, platysma, supraclavicular nerves and deep cervical fascia are anterior. The external jugular vein crosses its medial end and here receives the suprascapular, transverse cervical and anterior jugular veins, which collectively often form a venous plexus. The nerve to subclavius descends between the veins and the artery; the latter is terminally behind the clavicle and subclavius, where it is crossed by the suprascapular vessels. The subclavian vein is anteroinferior and the lower trunk of the brachial plexus is posteroinferior, between the subclavian artery and the scalenus medius (and on the first rib). The upper and middle trunks of the brachial plexus (which are palpable here) and the inferior belly of omohyoid are superolateral. The first rib is inferior.

The right subclavian artery may arise above or below sternoclavicular level; it may be a separate aortic branch and be the first or last branch of the arch. When it is the first branch, it is in the position of a

Fig. 29.11 A dissection of the brainstem and the upper part of the spinal cord after removal of large portions of the occipital and parietal bones, the cerebellum and the roof of the fourth ventricle. On the left side, the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right side, the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been divided and have been removed, together with the vertebral spines and the contralateral laminae. The tentorium cerebelli and the transverse sinuses have been divided and their posterior portions removed.
brachiocephalic trunk. When it is the last branch, it arises from the left end of the arch, and ascends obliquely to the right behind the trachea, oesophagus and right common carotid to the first rib. When this happens, the right recurrent laryngeal nerve hooks round the common carotid artery. Sometimes, when the right subclavian artery is the last aortic branch, it passes between the trachea and oesophagus and can cause dysphagia, a condition known as dysphagia lusoria. It may perforate scalenus anterior, and very rarely may pass anterior to it. Sometimes, the subclavian vein accompanies the artery behind scalenus anterior. The artery may ascend as high as 4 cm above the clavicle or it may reach only its upper border. The left subclavian artery is occasionally combined at its origin with the left common carotid artery.

## Vertebral artery

The vertebral artery arises from the superoposterior aspect of the first part of the subclavian artery. It passes through the foramina in the transverse processes of all of the cervical vertebrae except the seventh, curves medially behind the lateral mass of the atlas and enters the cranium via the foramen magnum (Fig. 29.11). The artery joins its fellow to form the basilar artery at the lower pontine border. Occasionally, it may enter the cervical vertebral column via the fourth, fifth or seventh cervical vertebra (Fig. 29.12).

Fig. 29.12 The level of entry of the vertebral artery into the foramina transversaria of the cervical vertebrae. Note that $90 \%$ enter at the level of the sixth cervical vertebra. (Redrawn with permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Relations The first part, V1, passes back and upwards between longus colli and scalenus anterior, behind the common carotid artery and the vertebral vein. It is crossed by the inferior thyroid artery, and by the thoracic duct on the left side and the right lymphatic duct on the right side. The seventh cervical transverse process, the inferior cervical ganglion and ventral rami of the seventh and eighth cervical spinal nerves lie posterior to the artery. The second part, V2, ascends through the transverse foramina of the remaining cervical vertebrae, accompanied by a large branch from the inferior cervical ganglion and a plexus of veins that form the vertebral vein low in the neck. It lies anterior to the ventral rami of the cervical spinal nerves (C2-C6), and ascends almost vertically to pass through the transverse process of the axis, where it turns laterally to gain access to the transverse foramen of the atlas (see Fig. 29.11). The third part, V3, issues medial to rectus capitis lateralis, and curves backwards and medially behind the lateral mass of the atlas, with the first cervical ventral spinal ramus lying on its medial side. In this position, it lies in a groove on the upper surface of the posterior arch of the atlas, and it enters the vertebral canal below the inferior border of the posterior atlanto-occipital membrane. This part of the artery, covered by semispinalis capitis, lies in the suboccipital triangle The first cervical dorsal spinal ramus separates the artery from the posterior arch. The fourth part, V4, pierces the dura and arachnoid mater, and ascends anterior to the hypoglossal roots. It inclines anterior to the medulla oblongata and unites with its contralateral fellow to form the midline basilar artery at the lower border of the pons.

## Cervical branches of vertebral artery

Spinal branches The spinal branches enter the vertebral canal via the intervertebral foramina and supply the spinal cord and its membranes. They fork into ascending and descending rami, which unite with those above and below, to form two lateral anastomotic chains on the posterior surfaces of the vertebral bodies near the attachment of their pedicles. Branches from these chains supply the periosteum and vertebral bodies, and others communicate with similar branches across the midline; from these connections small rami join similar ones above and below, to form a median anastomotic chain on the posterior surfaces of the vertebral bodies.

Muscular branches Muscular branches arise from the vertebral artery as it curves round the lateral mass of the atlas. They supply the deep muscles of the suboccipital region and anastomose with the occipital, ascending and deep cervical arteries.

## Internal thoracic artery

The internal thoracic artery arises inferiorly from the first part of the subclavian artery, 2 cm above the sternal end of the clavicle, opposite the root of the thyrocervical trunk (see Fig. 51.2). It is described further on page 942 .

## Thyrocervical trunk

The thyrocervical trunk is a short, wide artery that arises from the front of the first part of the subclavian artery near the medial border of scalenus anterior, and divides almost at once into the inferior thyroid, suprascapular and superficial cervical arteries.

## Inferior thyroid artery

The inferior thyroid artery loops upwards anterior to the medial border of scalenus anterior, turns medially just below the sixth cervical transverse process, and then descends on longus colli to the lower border of the thyroid gland (see Figs 29.7A, 29.17). It passes anterior to the vertebral vessels and posterior to the carotid sheath and its contents (and usually the sympathetic trunk, whose middle cervical ganglion frequently adjoins the vessel). On the left, near its origin, the artery is crossed anteriorly by the thoracic duct as the latter curves inferolaterally to its termination. Relations between the terminal branches of the artery and recurrent laryngeal nerve are very variable and of considerable surgical importance. The artery usually passes behind the nerve as it nears the gland. However, very close to the gland, the right nerve is equally likely to be anterior, posterior or amongst the branches of the artery, and the left nerve is usually posterior. The artery is not accompanied by the inferior thyroid vein.

Muscular branches These supply the infrahyoid muscles, longus colli, scalenus anterior and the inferior pharyngeal constrictor.

Ascending cervical artery The ascending cervical artery is a small branch that arises as the inferior thyroid turns medially behind the carotid sheath and ascends on the anterior tubercles of the cervical transverse processes between scalenus anterior and longus capitis. It
supplies the adjacent muscles and gives off one or two spinal branches that enter the vertebral canal through the intervertebral foramina to supply the spinal cord and membranes and vertebral bodies, and thereby supplement the spinal branches of the vertebral artery. The ascending cervical artery anastomoses with the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

Inferior laryngeal The inferior laryngeal artery ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the lower border of the inferior constrictor and supplies the laryngeal muscles and mucosa. It anastomoses with its contralateral fellow, and with the superior laryngeal branch of the superior thyroid artery.

Pharyngeal branches These supply the lower part of the pharynx. Tracheal branches supply the trachea and anastomose with the bronchial arteries; oesophageal branches supply the oesophagus and anastomose with the oesophageal branches of the thoracic aorta; and inferior and ascending glandular branches supply the posterior and inferior regions of the thyroid gland, and anastomose with the contralateral inferior and ipsilateral superior thyroid arteries. The ascending branch also supplies the parathyroid glands.

## Suprascapular artery

The suprascapular artery descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid (see Fig. 29.7A). It then crosses anterior to the subclavian artery and brachial plexus, posterior to, and parallel with, the clavicle, subclavius and the inferior belly of omohyoid, to reach the superior scapular border.

## Superficial cervical artery

The superficial cervical artery is given off at a higher level than the suprascapular artery. It crosses anterior to the phrenic nerve, scalenus anterior and the brachial plexus, and is covered by the internal jugular vein, sternocleidomastoid and platysma. It crosses the floor of the posterior triangle to reach the anterior margin of levator scapulae, and ascends deep to the anterior part of the trapezius, which it supplies, together with the adjoining muscles and the cervical lymph nodes. It anastomoses with the superficial ramus of the descending branch of the occipital artery. About a third of the superficial cervical and dorsal scapular arteries arise in common from the thyrocervical trunk, with a superficial (superficial cervical artery) and a deep (dorsal scapular artery) branch (see Figs 26.1, 26.2). The latter passes laterally anterior to the brachial plexus and then posterior to levator scapulae.

## Costocervical trunk

On the right, this short vessel arises posteriorly from the second part of the subclavian artery, and, on the left, from its first part. It arches back above the cervical pleura to the neck of the first rib, where it divides into superior intercostal and deep cervical branches.

## Deep cervical artery

The deep cervical artery usually arises from the costocervical trunk (see Fig. 26.1). It is analogous in its first segment to a posterior branch of a posterior intercostal artery, and occasionally is a separate branch of the subclavian artery. It passes back above the eighth cervical spinal nerve between the transverse process of the seventh cervical vertebra and the neck of the first rib (sometimes between the transverse processes of the sixth and seventh cervical vertebrae). It then ascends between semispinales capitis and cervicis to the level of the second cervical vertebra. It supplies adjacent muscles and anastomoses with the deep branch of the descending branch of the occipital artery and branches of the vertebral artery. A spinal branch enters the vertebral canal between the seventh cervical and first thoracic vertebrae.

## Dorsal scapular artery

The dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It gives off a small branch (which sometimes arises directly from the subclavian artery) to scalenus anterior. It passes laterally through the brachial plexus in front of scalenus medius and then deep to levator scapulae to the superior scapular angle.

## VEINS OF THE NECK

Veins in the neck show considerable variation. They are superficial or deep to the deep fascia but are not entirely separate systems. Superficial veins are tributaries - some with specific names, given below - of the

Fig. 29.13 The veins of the neck, seen from the front. The greater part of sternocleidomastoid has been removed on the left side and the cut lower edges have been reflected over the clavicle. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
anterior, external and posterior jugular veins (Figs 29.13-29.14). They drain a much smaller volume of tissue than the deep veins. The latter drain all but the subcutaneous structures, mostly into the internal jugular vein and also into the subclavian vein.

## External jugular vein

The external jugular vein mainly drains the scalp and face, although it also drains some deeper parts. The vein is formed by the union of the posterior division of the retromandibular vein with the posterior auricular vein and begins near the mandibular angle just below or in the parotid gland (see Fig. 26.3). It descends from the angle to the midclavicle, running obliquely, superficial to sternocleidomastoid, to the root of the neck. Here, it crosses the deep fascia and ends in the subclavian vein, lateral or anterior to scalenus anterior. There are valves at its entrance into the subclavian but they do not prevent regurgitation. Its wall is adherent to the rim of the fascial opening. It is covered by platysma, superficial fascia and skin, and is separated from sternocleidomastoid by deep cervical fascia. The vein crosses the transverse cutaneous nerve and lies parallel with the great auricular nerve, posterior to its upper half. In size, the external jugular vein is inversely proportional to the other veins in the neck and may be double. Between the entrance into the subclavian vein and a point approximately 4 cm above the clavicle, the vein is often dilated, producing a so-called sinus.

Tributaries In addition to formative tributaries, the external jugular receives the posterior external jugular and, near its end, transverse cervical, suprascapular and anterior jugular veins. In the parotid gland, it is often joined by a branch from the internal jugular. The occipital vein occasionally joins it.

## Posterior external jugular vein

The posterior external jugular vein begins in the occipital scalp, and drains the skin and the superficial muscles that lie posterosuperior in the neck. It usually joins the middle part of the external jugular vein.

## Anterior jugular vein

The anterior jugular vein arises near the hyoid bone from the confluence of the superficial submandibular veins. It descends between the midline and the anterior border of sternocleidomastoid. Turning laterally, low in the neck, deep to sternocleidomastoid but superficial to the infrahyoid strap muscles, it either joins the end of the external jugular vein or may enter the subclavian vein directly (see Fig. 26.3). In size, it is usually inverse to the external jugular vein. It communicates with the internal jugular vein, and receives the laryngeal veins and sometimes a small thyroid vein. There are usually two anterior jugular veins, united just above the manubrium by a large transverse jugular arch, receiving the inferior thyroid tributaries. They have no valves and may be replaced by a midline trunk.

## Internal jugular vein

The internal jugular vein collects blood from the skull, brain, superficial parts of the face and much of the neck. It begins at the cranial base in the posterior compartment of the jugular foramen, where it is continuous with the sigmoid sinus. At its origin, it is dilated as the superior bulb, which lies below the posterior part of the tympanic floor. The internal jugular vein descends in the carotid sheath, and unites with the subclavian vein, posterior to the sternal end of the clavicle, to form the brachiocephalic vein (see Fig. 29.14). Near its termination, the vein dilates into the inferior bulb, above which is a pair of valves. The jugular bulb is a dynamic structure; it forms after 2 years of age and its size stabilizes in adulthood (Friedmann et al 2011).

Relations From above, rectus capitis lateralis, the transverse process of the atlas, levator scapulae, scalenus medius, scalenus anterior, the cervical plexus, the phrenic nerve, thyrocervical trunk, vertebral vein and the first part of the subclavian artery all lie posterior to the vein. On the left, the internal jugular crosses anterior to the thoracic duct. The internal and common carotid arteries and the vagus nerve are medial to the vein; the nerve lies between vein and arteries but posterior

Fig. 29.14 The veins of the neck, seen from the front and at a deeper level than shown in Figure 29.13. Both sternocleidomastoids have been removed, and additional dissection has exposed the thyroid gland and some of the structures that pass through the upper thoracic aperture. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
to them. Sometimes, the accessory nerve is found posterior to the vein. Superficially, the internal jugular vein is overlapped above, then covered below, by sternocleidomastoid, and is crossed by the posterior belly of digastric and the superior belly of omohyoid. The parotid gland, styloid process, accessory nerve (almost always), and the posterior auricular and occipital arteries cross the vein superior to the posterior belly of digastric. Between digastric and omohyoid, the sternocleidomastoid arteries and inferior root of the ansa cervicalis cross it, although the nerve often passes between the vein and the common carotid artery. Below omohyoid, the vein is covered by the infrahyoid muscles and sternocleidomastoid, and is crossed by the anterior jugular vein. Deep cervical lymph nodes lie along the internal jugular, mainly on its superficial aspect. At the root of the neck, the right internal jugular vein is separated from the common carotid artery, but the left usually overlaps its artery. At the base of the skull, the internal carotid artery is anterior to the vein, separated from it by the ninth to twelfth cranial nerves.

Tributaries The inferior petrosal sinus, facial, lingual, pharyngeal, superior and middle thyroid veins, and occasionally the occipital vein, are all tributaries of the internal jugular vein. The internal jugular vein may communicate with the external jugular vein. The thoracic duct opens near the union of the left subclavian and internal jugular veins, and the right lymphatic duct opens at the same site on the right.

## Inferior petrosal sinus

The inferior petrosal sinus leaves the skull through the anterior part of the jugular foramen, crosses lateral or medial to the ninth to eleventh cranial nerves, and joins the superior jugular bulb.

## Facial vein

The initial part of the facial vein as it lies on the face is described on page 500 (see Fig. 26.3). From the face, it passes over the surface of masseter, crosses the body of the mandible and enters the neck, where
it runs obliquely back under platysma. Here it lies superficial to the submandibular gland, digastric and stylohyoid (see Fig. 29.13). Just anteroinferior to the mandibular angle, it is joined by the anterior division of the retromandibular vein, and then descends superficial to the loop of the lingual artery, the hypoglossal nerve and external and internal carotid arteries, to enter the internal jugular near the greater cornu of the hyoid bone, i.e. in the upper angle of the carotid triangle. Near its end, a large branch often descends along the anterior border of sternocleidomastoid to the anterior jugular vein. Its uppermost segment, above its junction with the superior labial vein, is often termed the angular vein.

Tributaries Submental, tonsillar, external palatine (paratonsillar) and submandibular veins, vena comitans of the hypoglossal nerve (sometimes), and pharyngeal and superior thyroid veins are all tributaries of the portion of the facial vein that lies below the mandible.

## Lingual vein

The lingual veins follow two routes. The dorsal lingual veins drain the dorsum and sides of the tongue, join the lingual veins accompanying the lingual artery between hyoglossus and genioglossus, and enter the internal jugular near the greater cornu of the hyoid bone. The deep lingual vein begins near the tip of the tongue and runs back, lying near the mucous membrane on the inferior surface of the tongue. Near the anterior border of hyoglossus, it joins a sublingual vein, from the sublingual salivary gland, to form the vena comitans nervi hypoglossi, which runs back between mylohyoid and hyoglossus with the hypoglossal nerve to join the facial, internal jugular or lingual vein (see Fig. 26.3).

## Pharyngeal veins

The pharyngeal veins begin in a pharyngeal plexus external to the pharynx. They receive meningeal veins and a vein from the pterygoid canal, and usually end in the internal jugular vein, but may sometimes end in the facial, lingual or superior thyroid vein.

## Superior thyroid vein

The superior thyroid vein is formed by deep and superficial tributaries corresponding to the arterial branches in the upper part of the thyroid gland (see Figs 29.13-29.14). It accompanies the superior thyroid artery, receives the superior laryngeal and cricothyroid veins, and ends in the internal jugular or facial vein.

## Middle thyroid vein

The middle thyroid vein drains the lower part of the gland and also receives veins from the larynx and trachea. It crosses anterior to the common carotid artery to join the internal jugular vein behind the superior belly of omohyoid.

## Tympanic body

The tympanic body (glomus jugulare) is ovoid, 0.5 mm long and 0.25 mm broad, and lies in the adventitia of the upper part of the superior bulb of the internal jugular vein. It is similar in structure to the carotid body and is presumed to have a similar function. The predominant cell type has morphological similarities to adrenal chromaffin cells, and is derived from the neural crest. Cells obtained from glomus jugulare paragangliomas show spontaneous neurite outgrowth in culture and have vasoactive intestinal peptide (VIP)-like activity. The tympanic body may be present as two or more parts near the tympanic branch of the glossopharyngeal nerve or the auricular branch of the vagus as they lie within their canals in the petrous part of the temporal bone. Tumours of tympanic bodies often involve the adjacent cranial nerves and present with pulsatile tinnitus and a husky voice. These tumours grow into the hypotympanum of the middle ear; intraluminal growth, both proximally and distally, is well recognized.

## Subclavian vein

The subclavian vein is a continuation of the axillary vein and extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular vein to form the brachiocephalic vein (see Fig. 29.14). The clavicle and subclavius lie anterior to it; the subclavian artery is posterosuperior, separated by scalenus anterior and the phrenic nerve; and the first rib and pleura are inferior. The vein usually has a pair of valves 2 cm from its end. Its tributaries are the external jugular, dorsal scapular and sometimes the anterior jugular vein. At its junction with the internal jugular, the left subclavian vein receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct.

## Vertebral vein

Numerous small tributaries from internal vertebral plexuses leave the vertebral canal above the posterior arch of the atlas and join small veins from local deep muscles in the suboccipital triangle. Their union produces a vessel that enters the foramen in the transverse process of the atlas and forms a plexus around the vertebral artery. It descends through successive transverse foramina and ends as the vertebral vein. The vein emerges from the sixth cervical transverse foramen, from where it descends, at first anterior, then anterolateral, to the vertebral artery. It may join the deep cervical vein before it opens superoposteriorly into the brachiocephalic vein (see Fig. 26.4); the opening has a paired valve. As it descends, it passes behind the internal jugular vein and anterior to the first part of the subclavian artery. A small accessory vertebral vein usually descends from the vertebral plexus, traverses the seventh cervical transverse foramen and turns forwards between the subclavian artery and the cervical pleura to join the brachiocephalic vein.

Tributaries The vertebral vein connects with the sigmoid sinus by a vessel in the posterior condylar canal, when the latter exists. It also receives branches from the occipital vein, prevertebral muscles, and internal and external vertebral plexuses. It is joined by anterior vertebral and deep cervical veins (see below), and sometimes, near its end, by the first intercostal vein.

## Anterior vertebral vein

The anterior vertebral vein starts in a plexus around the upper cervical transverse processes, descends near the ascending cervical artery between attachments of scalenus anterior and longus capitis, and opens into the end of the vertebral vein.

## Deep cervical vein

The deep cervical vein accompanies its artery between semispinales capitis and cervicis. It is formed in the suboccipital region by the union of communicating branches of the occipital vein; veins from suboccipital muscles; and veins from plexuses around the cervical spines. It passes
forwards between the seventh cervical transverse process and the neck of the first rib to end in the lower part of the vertebral vein.

## Central venous access

Central venous cannulation permits monitoring of the central venous pressure and the administration of drugs directly into the central circulation.

## Internal jugular vein cannulation

Available with the Gray's Anatomy e-book

## Subclavian vein cannulation

Available with the Gray's Anatomy e-book

## CERVICAL GROUPS OF LYMPH NODES

Lymph nodes in the head and neck are distributed in terminal and outlying groups (Fig. 29.15; see Fig. 26.5). The terminal group is related to the carotid sheath and the nodes it contains are the deep cervical lymph nodes. All lymph vessels of the head and neck drain into this group, either directly from tissues or indirectly through nodes in the outlying groups. Efferents of the deep cervical nodes form the jugular trunk. The right jugular trunk collects lymph from the right arm, right half of the thorax and the right head and neck, and may end in the jugulosubclavian junction or the right lymphatic duct. The left jugular trunk usually enters the thoracic duct, but it may join the internal jugular or subclavian vein. For further reading, see Shah and Patel (2012).

Fig. 29.15 The superficial lymphatic system in the head and neck. The nodes are organized into a superficial group around the head, superficial cervical nodes along the external jugular vein, and deep cervical nodes along the internal jugular vein. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.) (

The patient is placed in the supine position with the head turned slightly towards the contralateral side．The key anatomical landmarks are the two inferior heads of sternocleidomastoid，which form two sides of a triangle with the clavicle as its base．The internal jugular vein lies between the two heads of the muscle，slightly lateral and anterior to the common carotid artery．In infants and children，cannulation of the vein carries a high incidence of carotid artery puncture；the vein overlaps the artery in the neutral position and head rotation alters the anatomical relation of the two vessels（Hong et al 2010）．After the skin has been prepared，local anaesthetic is injected around the apex of the triangle． With one hand palpating the carotid artery，the physician inserts a needle at the apex of the triangle and the tip is directed lateral to the midpoint of the triangle，with a downward angulation of $30^{\circ}$ ．From a high internal jugular approach，the needle is inserted at the midpoint of the medial border of sternocleidomastoid and directed towards the ipsilateral nipple with a downward angulation of $30-45^{\circ}$ ．When the left internal jugular vein is cannulated，additional care must be taken to avoid the thoracic duct and the cupula of the pleura，which is higher than on the right side，an arrangement that increases the risk of acci－ dental pneumothorax．The left internal jugular vein is often smaller in diameter than the right（Matthers et al 1992）．

Subclavian vein cannulation is performed with the patient supine，the head turned slightly to the opposite side，and the arms placed by the side．The bed is tilted down by $10^{\circ}$ and a small bedroll may be placed between the shoulder blades in order to ensure that the infraclavicular area is more prominent．The skin is cleaned and local anaesthetic injected into the skin 3 cm lateral to the midpoint of the clavicle．The central venous needle is then inserted from the inferior edge of the clavicle towards the suprasternal notch．The needle is directed so that it passes just below the posterior border of the clavicle；care must be taken to avoid downward direction of the needle，which may cause a pneumothorax．Gentle aspiration of the syringe is performed while the needle is being advanced until the subclavian vein is punctured．In children under the age of 3 years，the supraclavicular approach to the subclavian vein is associated with a shorter puncture time and a reduced incidence of guidewire misplacement compared with the infraclavicular approach（Byon et al 2013）．

## Lymphatic drainage of the neck

Many vessels draining the superficial cervical tissues skirt the borders of sternocleidomastoid to reach the superior or inferior deep cervical nodes. Others pass to the superficial cervical and occipital nodes. Lymph from the superior region of the anterior triangle drains to the submandibular and submental nodes. Vessels from the anterior cervical skin inferior to the hyoid bone pass to the anterior cervical lymph nodes near the anterior jugular veins. Their efferents go to the deep cervical nodes of both sides, including the infrahyoid, prelaryngeal and pretracheal groups. An anterior cervical node often occupies the suprasternal space. Lymph from tissues of the head and neck internal to the deep fascia drains to the deep cervical nodes directly or through outlying groups that include the retropharyngeal, paratracheal, lingual, infrahyoid, prelaryngeal and pretracheal groups. The lymphatic drainage associated with the nasal region, larynx and oral cavity is described in the appropriate regions. The deep cervical lymphatic nodes lie alongside the carotid sheath, and form superior and inferior groups.

Superior deep cervical nodes The superior deep cervical nodes adjoin the upper part of the internal jugular vein. Most are deep to sternocleidomastoid but a few extend beyond it. One subgroup, consisting of one large and several small nodes, is in a triangular region bounded by the posterior belly of digastric and the facial and internal jugular veins, and is known as the jugulodigastric group. It is concerned especially with drainage of the tongue. Efferents from the upper deep cervical nodes drain either to the lower group or direct to the jugular trunk.

Inferior deep cervical nodes The inferior deep cervical nodes are partly deep to sternocleidomastoid and are particularly related to the lower part of the internal jugular vein. Some are closely related to the brachial plexus and subclavian vessels. The jugulo-omohyoid node lies on, or just above, the intermediate tendon of omohyoid, and is concerned especially with lymphatic drainage from the tongue. Efferents from this lower group join the jugular lymph trunk.

Retropharyngeal nodes Retropharyngeal nodes lie between the pharyngeal and prevertebral fasciae and form a median and two lateral groups, the latter anterior to the lateral masses of the atlas along the lateral borders of longus capitis. The nodes receive afferents from the nasopharynx, pharyngotympanic tube, and atlanto-occipital and atlanto-axial joints, and drain to the upper deep cervical nodes.

Paratracheal nodes The paratracheal nodes flank both trachea and oesophagus along the recurrent laryngeal nerves. Efferents pass to the corresponding deep cervical nodes.

Infrahyoid, prelaryngeal and pretracheal nodes The infrahyoid, prelaryngeal and pretracheal nodes lie beneath the deep cervical fascia. They drain afferents from the anterior cervical nodes, and their efferents join the deep cervical nodes. Infrahyoid nodes are anterior to the thyrohyoid membrane, prelaryngeal nodes lie on the cricovocal membrane, and pretracheal nodes lie anterior to the trachea near the inferior thyroid veins.

Lingual nodes Lingual nodes are small and inconstant, and are situated on the external surface of hyoglossus and also between the genioglossi. They drain to the upper deep cervical nodes.

## Spread of malignant disease in the neck

Cancers arising in the head and neck from regions such as the thyroid gland, larynx, oral cavity and oropharynx, nasopharynx and paranasal sinuses have predictable patterns of spread through the chains of lymph nodes in the neck. When operating on malignant disease in this region, it is vitally important to understand these patterns of spread so that, for any individual cancer, the appropriate operation is undertaken. Clinical experience has shown that the lymph nodes in the neck fall into five distinct groups (see Fig. 26.5). Level I nodes lie in the submandibular triangle bounded by the anterior and posterior bellies of digastric and the lower border of the mandible above. Level II (upper jugular) nodes lie around the upper portion of the internal jugular vein and the upper part of the accessory nerve. They extend from the skull base to the bifurcation of the common carotid artery or the hyoid bone. Level III (middle jugular) nodes lie around the middle third of the internal jugular vein from the inferior border of level II to the superior belly of
omohyoid or cricothyroid membrane. Level IV (lower jugular) nodes lie around the lower third of the internal jugular vein from the inferior border of level III to the clavicle. The anterior and posterior borders for levels II, III and IV are the lateral border of sternohyoid and the posterior border of sternocleidomastoid, respectively. Level V (posterior triangle) nodes lie around the lower part of the accessory nerve and the transverse cervical vessels.

Knowing which levels of nodes are likely to be involved in the metastatic spread of a particular cancer arising in the head and neck means that appropriate nodal clearance can be undertaken. The classic radical neck dissection first described by Crile in 1906 involved a thorough clearance of levels I-V, including the sacrifice of sternocleidomastoid, the internal jugular vein and the accessory nerve. Modified radical neck dissections (so-called functional neck dissections) still remove level I-V nodes but spare either or all of sternocleidomastoid, the internal jugular vein and the accessory nerve. Selective neck dissections remove selected groups of nodes, e.g. the supra-omohyoid neck dissection removes level I-III nodes, the lateral neck dissection removes level II-IV nodes, and the posterolateral neck dissection removes level II-V nodes.

## Cervical lymphovenous portals

Lymph is returned to the systemic venous circulation via right and left lymphovenous portals sited at, or near, the junctions of the internal jugular and subclavian veins (Fig. 29.16). The arrangement of these terminations is variable. Usually, three small lymph trunks converge towards their venous junctions on either side of the body and they are joined, on the left side only, by the larger thoracic duct.

On the right side, the three trunks are the right jugular, right subclavian and right bronchomediastinal. The right jugular trunk extends from the terminal lower deep cervical nodes along the ventrolateral aspect of the internal jugular vein, and conveys all the lymph from the right half of the head and neck. The right subclavian trunk drains from the terminal apical axillary group. It extends along the axillary and subclavian veins, and conveys lymph from the right upper limb and superficial tissues of the right half of the thoraco-abdominal wall, down to the umbilicus anteriorly and iliac crest posteriorly (and includes much of the breast). The right bronchomediastinal trunk ascends over the trachea towards the lymphovenous portal and conveys lymph from the thoracic walls, the right cupula of the diaphragm and subjacent liver, the right lung, bronchi and trachea, the greater part of the 'right heart' - of clinical parlance, not the geometric right half - and a proportionately small drainage from the thoracic oesophagus.

The three right lymphatic trunks usually open independently (see Fig. 29.16B). Their orifices are clustered either on the ventral aspect of the jugulo/subclavian junction, or in the nearby wall of either of the great veins. Sometimes, one or more of the trunks may bifurcate (or even trifurcate) preterminally and then terminate via multiple orifices. Rarely, the three trunks fuse to form a short, single, right lymphatic duct (about 1 cm long) that inclines across the medial border of scalenus anterior at the root of the neck to reach the ventral aspect of the venous junction, where its orifice is guarded by a bicuspid semilunar valve. An incomplete right lymphatic duct may be present if the subclavian and jugular trunks, or any combination of their terminals, are fused. When this occurs, the bronchomediastinal trunk almost invariably opens separately.

On the left, the four trunks that converge on the left lymphovenous portal are the left jugular and left subclavian trunks, which have a disposition corresponding to that of their counterparts on the right; the left bronchomediastinal trunk, which has a drainage similar to that of the right trunk but which drains more of the heart - the 'left' and part of the 'right' hearts of clinical parlance - and more of the oesophagus; and the thoracic duct, which drains all of the rest of the body (see Fig. 29.16A).

## INNERVATION

The skin, joints, viscera and muscles of the neck are innervated by branches of the glossopharyngeal, vagus and accessory nerves, the cervical spinal nerves and the cervical sympathetic trunk.

The first and second cervical dorsal root ganglia lie on the vertebral arches of the atlas and axis, respectively. The first cervical ganglion may be absent. Smaller aberrant ganglia sometimes occur on the upper cervical dorsal roots between the ganglia and cord. The upper four cervical roots are small, and the lower four are large. In general, cervical dorsal roots have a thickness ratio to the ventral roots of $3: 1$, which is greater than is seen in other regions. The first dorsal root is an exception, being

B

Fig. 29.16 A, The termination of the right lymphatic trunk and the thoracic duct. B, Variations in the terminal lymphatic trunk nodes of the right side. (A, From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
smaller than the ventral; occasionally, it is absent. The first and second cervical roots are short, and run almost horizontally to their exit from the vertebral canal. From the third to the eighth cervical, they slope obliquely down. Obliquity and length increase successively; however, the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra. For details of the neural anastomoses between the upper cervical nerves and branches of the facial, vagus, hypoglossal and accessory nerves, see Shoja et al (2014).

## CERVICAL VENTRAL RAMI

Cervical ventral rami, except the first, appear between the anterior and posterior intertransverse muscles. The upper four form the cervical plexus, and the lower four, together with most of the first thoracic ventral ramus, form the brachial plexus. Each receives at least one grey ramus communicans, the upper four from the superior cervical sympathetic ganglion, the fifth and sixth from the middle ganglion, and the seventh and eighth from the cervicothoracic ganglion.

The first cervical ventral ramus, the suboccipital nerve, emerges above the posterior arch of the atlas, and passes forwards lateral to its lateral mass and medial to the vertebral artery. It supplies rectus capitis lateralis, emerges medial to it, descends anterior to the transverse process of the atlas and posterior to the internal jugular vein, and joins the ascending branch of the second cervical ventral ramus.

The second cervical ventral ramus issues between the vertebral arches of the atlas and axis. It ascends between their transverse processes, passes anterior to the first posterior intertransverse muscle and emerges lateral to the vertebral artery, generally between longus capitis and levator scapulae. The ramus divides into an ascending branch, which joins the first cervical nerve, and a descending branch, which joins the ascending branch of the third cervical ventral ramus.

The third cervical ventral ramus appears between longus capitis and scalenus medius. The remaining ventral rami emerge between scalenus anterior and the scalenus medius.

## Cervical plexus

The cervical plexus is formed by the ventral rami of the upper four cervical nerves, and supplies some neck muscles and the diaphragm, and areas of skin on the head, neck and chest (see Figs 26.6, 29.1). It is situated in the neck opposite a line drawn down the side of the neck from the root of the auricle to the level of the upper border of the thyroid cartilage. It lies deep to the internal jugular vein, the deep fascia and sternocleidomastoid, and anterior to scalenus medius and levator scapulae. Each ramus, except the first, divides into ascending and descending parts, which unite in communicating loops. From the first loop (C2 and 3), superficial branches supply the head and neck; cutaneous nerves of the shoulder and chest arise from the second loop (C3 and 4). Muscular and communicating branches arise from the same nerves. The branches are superficial or deep. The superficial branches perforate the cervical fascia to supply the skin, while the deep branches in general supply muscles. The superficial branches either ascend (the lesser occipital, great auricular and the transverse cutaneous nerves) or descend (supraclavicular nerves). These nerves are described in detail in this chapter on page 442. The deep branches form medial and lateral series.

## Deep branches - medial series

Communicating branches Communicating branches pass from the loop between the first and second cervical rami to the vagus and hypoglossal nerves and to the sympathetic trunk. The hypoglossal branch later leaves the hypoglossal nerve as a series of branches, namely: the meningeal, superior root of ansa cervicalis, nerves to thyrohyoid and to geniohyoid. A branch also connects the fourth and fifth cervical rami. The first four cervical ventral rami each receive a grey ramus communicans from the superior cervical sympathetic ganglion.

The superior root of the ansa cervicalis (descendens hypoglossi) (see Figs 29.7A, 29.8) leaves the hypoglossal nerve where it curves round the occipital artery and then descends anterior to or in the carotid sheath. It contains only fibres from the first cervical spinal nerve. After giving a branch to the superior belly of omohyoid, it is joined by the inferior root of the ansa from the second and third cervical spinal nerves. The two roots form the ansa cervicalis (ansa hypoglossi), from which branches supply sternohyoid, sternothyroid and the inferior belly of omohyoid. Another branch is said to descend anterior to the vessels into the thorax to join the cardiac and phrenic nerves.

Muscular branches Muscular branches supply rectus capitis lateralis (C1), rectus capitis anterior ( $\mathrm{C} 1,2$ ), longus capitis ( $\mathrm{C} 1-3$ ) and longus colli (C2-4). The inferior root of the ansa cervicalis and the phrenic nerve are additional muscular branches.

The inferior root of the ansa cervicalis (nervus descendens cervicalis) (see Figs 29.7A, 29.8) is formed by the union of a branch from the second with another from the third cervical ramus. It descends on the lateral side of the internal jugular vein, crosses it a little below the middle of the neck, and continues forwards to join the superior root anterior to the common carotid artery, forming the ansa cervicalis (ansa hypoglossi), from which all infrahyoid muscles except thyrohyoid are

Fig. 29.17 Vessels and nerves of the neck, left lateral view. The left sternocleidomastoid, the greater part of the infrahyoid group of muscles and numerous vessels have been removed in order to expose deeper structures. Compare with Figure 29.7A, which shows a more superficial level of dissection. The letters V, VI, VII, VIII refer to the anterior primary rami of $\mathrm{C} 5, \mathrm{C} 6, \mathrm{C} 7$ and C8, respectively. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
supplied. The inferior root almost always comes from the second and third cervical ventral rami, but sometimes from the second to fourth, and occasionally from the third alone. Occasionally, too, it may be derived either from the second alone or from the first to third.

Phrenic nerve The phrenic nerve arises chiefly from the fourth cervical ventral ramus but also has contributions from the third and fifth. It is formed at the upper part of the lateral border of scalenus anterior and descends almost vertically across its anterior surface behind the prevertebral fascia (see Fig. 29.7A; Figs 29.17-29.18). It descends posterior to sternocleidomastoid, the inferior belly of omohyoid (near its intermediate tendon), the internal jugular vein, transverse cervical and suprascapular arteries and, on the left, the thoracic duct. At the root of the neck, it runs anterior to the second part of the subclavian artery, from which it is separated by scalenus anterior (some accounts state that on the left side the nerve passes anterior to the first part of the subclavian artery), and posterior to the subclavian vein. The phrenic nerve enters the thorax by crossing medially in front of the internal thoracic artery.

In the neck, each nerve receives variable filaments from the cervical sympathetic ganglia or their branches and may also connect with internal thoracic sympathetic plexuses.

Accessory phrenic nerve The accessory phrenic nerve is composed of fibres from the fifth cervical ventral ramus that run in a branch of the nerve to subclavius. This lies lateral to the phrenic nerve and descends posterior (occasionally anterior) to the subclavian vein. The accessory phrenic nerve usually joins the phrenic nerve near the first rib, but may not do so until near the pulmonary hilum or beyond. The accessory phrenic nerve may be derived from the fourth or sixth cervical ventral rami or from the ansa cervicalis.

## Deep branches - lateral series

Communicating branches Lateral deep branches of the cervical plexus ( $\mathrm{C} 2,3,4$ ) may connect with the accessory nerve within sternocleidomastoid, the posterior triangle or beneath trapezius.

Muscular branches Muscular branches are distributed to sternocleidomastoid (C2, 3, 4), trapezius (C2 and possibly C3), levator scapulae ( $\mathrm{C} 3,4$ ) and scalenus medius ( $\mathrm{C} 3,4$ ). Branches to trapezius cross the posterior triangle obliquely below the accessory nerve.

## Brachial plexus

The brachial plexus is formed by the union of the ventral rami of the lower four cervical nerves and the greater part of the ventral ramus of the first thoracic spinal nerve. It may also receive contributions from the fourth cervical and second thoracic spinal nerves. As its name suggests, its branches supply the muscles, joints and skin of the upper limb. The relations and distribution of the nerves derived from the brachial plexus are described in detail in the appropriate chapters in Section 6. However, it is also mentioned here because, at its origin, the brachial plexus lies in the posterior triangle of the neck, in the angle between the clavicle and the lower posterior border of sternocleidomastoid. It emerges between the scaleni anterior and medius, superior to the third part of the subclavian artery, and is covered by platysma, deep fascia and skin, through which it is palpable (see Fig. 29.17). It is crossed by the supraclavicular nerves, the nerve to subclavius, the inferior belly of omohyoid, the external jugular vein and the superficial ramus of the transverse cervical artery. The plexus passes posterior to the medial twothirds of the clavicle, subclavius and the suprascapular vessels, and lies on the first digitation of serratus anterior and on subscapularis.

## CERVICAL DORSAL RAMI

Each cervical spinal dorsal ramus except the first divides into medial and lateral branches, and all innervate muscles. In general, only medial branches of the second to fourth, and usually the fifth, supply skin. Except for the first (sometimes called the suboccipital nerve) and second, each dorsal ramus passes back medial to a posterior intertransverse muscle, curving round the articular process into the interval

between semispinalis capitis and semispinalis cervicis. The cervical dorsal rami are described in detail on page 768 .

## CRANIAL NERVES

## Glossopharyngeal nerve

The glossopharyngeal nerve (see Figs 29.8, 29.11, Fig. 29.19) supplies motor fibres to stylopharyngeus, parasympathetic secretomotor fibres to the parotid gland (derived from the inferior salivatory nucleus), sensory fibres to the tympanic cavity, pharyngotympanic tube, fauces, tonsils, nasopharynx, uvula and posterior (postsulcal) third of the tongue, and gustatory fibres for the postsulcal part of the tongue.

The nerve leaves the skull through the anteromedial part of the jugular foramen, anterior to the vagus and accessory nerves, and in a separate dural sheath. In the foramen, it is lodged in a deep groove leading from the cochlear aqueductal depression, and is separated by the inferior petrosal sinus from the vagus and accessory nerves. The groove is bridged by fibrous tissue, which is sometimes calcified. After leaving the foramen, the nerve passes forwards between the internal jugular vein and internal carotid artery, and then descends anterior to the latter, deep to the styloid process and its attached muscles, to reach the posterior border of stylopharyngeus. It curves forwards on stylopharyngeus and either pierces the lower fibres of the superior pharyngeal constrictor or passes between it and the middle constrictor to be distributed to the tonsil, the mucosae of the pharynx and postsulcal part of the tongue, the vallate papillae, and oral mucous glands (see Fig. 34.6).

Two ganglia, superior and inferior, are situated on the glossopharyngeal nerve as it traverses the jugular foramen. The superior ganglion is in the upper part of the groove occupied by the nerve in the jugular foramen. It is small, has no branches and is usually regarded as a detached part of the inferior ganglion. The inferior ganglion is larger and lies in a notch in the lower border of the petrous part of the temporal bone. Its cells are typical unipolar neurones, whose peripheral branches convey gustatory and tactile signals from the mucosa of the tongue (posterior third, including the sulcus terminalis and vallate papillae) and general sensation from the oropharynx, where it is responsible for initiating the gag reflex.

## Communicating branches

The glossopharyngeal nerve communicates with the sympathetic trunk and vagus and facial nerves. Its inferior ganglion is connected with the

Fig. 29.19 The glossopharyngeal nerve in the anterior triangle of the neck. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
superior cervical sympathetic ganglion. Two filaments from the inferior ganglion pass to the vagus, one to its auricular branch and the other to its superior ganglion. A branch to the facial nerve arises from the glossopharyngeal nerve below the inferior ganglion, and perforates the posterior belly of digastric to join the facial nerve near the stylomastoid foramen.

## Branches of distribution

The glossopharyngeal nerve has tympanic, carotid, pharyngeal, muscular, tonsillar and lingual branches.

Tympanic nerve The tympanic nerve leaves the inferior ganglion, ascends to the tympanic cavity through the inferior tympanic

Fig. 29.20 The intercarotid plexus and its main trunks. A, Formation of the superficial trunk. B, Formation of the intermediate trunk. C, Formation of the deep trunk. (Redrawn with permission from Shoja M, Oyesiku NM, Shokouhi G, et al 2014 Anastomoses between lower cranial and upper cervical nerves: a comprehensive review with potential significance during skull base and neck operations, part II: glossopharyngeal, vagus, accessory, and hypoglossal nerves and cervical spinal nerves 1-4. Clin Anat. 2014;27(1):118-30.)
canaliculus and divides into branches that contribute to the tympanic plexus. The lesser petrosal nerve is derived from the tympanic plexus.

Carotid branch The carotid branch is often double. It arises just below the jugular foramen and descends on the internal carotid artery to the wall of the carotid sinus and to the carotid body. The nerve contains primary afferent fibres from chemoreceptors in the carotid body and from the baroreceptors lying in the carotid sinus wall. It may communicate with the inferior ganglion of the vagus, or with one of its branches, and with a sympathetic branch from the superior cervical ganglion (Fig. 29.20).

Pharyngeal branches The pharyngeal branches are three or four filaments that unite with the pharyngeal branch of the vagus and the laryngopharyngeal branches of the sympathetic trunk to form the pharyngeal plexus near the middle pharyngeal constrictor. They constitute the route by which the glossopharyngeal nerve supplies sensory fibres to the mucosa of the pharynx.

## Muscular branch The muscular branch supplies stylopharyngeus.

Tonsillar, lingual and lesser petrosal branches The tonsillar, lingual and lesser petrosal branches are described on pages 577, 514 and 562 , respectively.

## Lesions of the glossopharyngeal nerve

Damage to the glossopharyngeal nerve is rarely seen without associated involvement of other lower cranial nerves. Transient or sustained hypertension may follow surgical section of the nerve and indicates involvement of the carotid branch. Isolated lesions of the glossopharyngeal nerve lead to loss of sensation over the ipsilateral soft palate, fauces, pharynx and posterior third of the tongue, although this is difficult to assess clinically and confirmation requires galvanic stimulation. The palatal and pharyngeal (gag) reflexes are reduced or absent and salivary secretion from the parotid gland may also be reduced. Weakness of stylopharyngeus cannot be tested individually. Glossopharyngeal neuralgia consists of episodic brief but severe pain, often precipitated by swallowing and experienced in the throat, behind the angle of the jaw and within the ear. Superior jugular bulb thromboses (e.g. in otitis media) and jugular foramen syndrome (associated with nasopharyngeal carcinoma or a jugular paraganglioma) may cause lesions of the adjacent glossopharyngeal, vagus and accessory nerves, with associated weakness in the muscles supplied in the pharynx and larynx.

## Vagus nerve

The vagus is a large mixed nerve. It has a more extensive course and distribution than any other cranial nerve and runs through the neck, thorax and abdomen. Its central connections are described in Chapter 21.

The vagus exits the skull through the jugular foramen, accompanied by the accessory nerve, with which it shares an arachnoid and a dural sheath. Both nerves lie anterior to a fibrous septum that separates them from the glossopharyngeal nerve. The vagus descends vertically in the neck in the carotid sheath, between the internal jugular vein and the internal carotid artery, to the upper border of the thyroid cartilage, and then passes between the vein and the common carotid artery to the root of the neck. Its relationships in this part of its course are therefore similar to those described for these structures (see Figs 29.7A, 29.8, 29.17). Its further course differs on the two sides. The right vagus descends posterior to the internal jugular vein to cross the first part of the subclavian artery and enter the thorax. The left vagus enters the thorax between the left common carotid and subclavian arteries, and behind the left brachiocephalic vein.

After emerging from the jugular foramen, the vagus bears two marked enlargements: a small, round, superior ganglion and a larger inferior ganglion.

## Superior (jugular) ganglion

The superior ganglion is greyish, spherical and approximately 4 mm in diameter. It is connected to the inferior glossopharyngeal ganglion and the sympathetic trunk, the latter by a filament from the superior cervical ganglion.

## Inferior (nodose) ganglion

The inferior or nodose ganglion is larger than the superior ganglion, and is elongated and cylindrical in shape with a length of 25 mm and a maximum breadth of 5 mm . It is connected with the hypoglossal nerve, the loop between the first and second cervical spinal nerves, and with the superior cervical sympathetic ganglion. Most visceral afferent fibres have their cell bodies in the nodose ganglion.

Both vagal ganglia are exclusively sensory and contain somatic, special visceral and general visceral afferent neurones. The superior ganglion is chiefly somatic and most of its neurones enter the auricular nerve, whilst neurones in the inferior ganglion are concerned with visceral sensation from the heart, larynx, lungs and the alimentary tract from the pharynx to the transverse colon. Some fibres transmit impulses from taste endings in the vallecula and epiglottis. Large afferent fibres are derived from muscle spindles in the laryngeal muscles. Vagal sensory neurones in the nodose ganglion may show some somatotopic organization. Both ganglia are traversed by parasympathetic, and perhaps some sympathetic, fibres but there is no evidence that vagal parasympathetic components relay in the inferior ganglion. Preganglionic motor fibres from the dorsal vagal nucleus and the special visceral efferents from the nucleus ambiguus, which descend to the inferior vagal ganglion, commonly form a visible band, skirting the ganglion in some mammals. These larger fibres probably provide motor innervation to the larynx in the recurrent laryngeal nerve, together with some contribution to the superior laryngeal nerve supplying cricothyroid.

## Branches in the neck

The branches of the vagus in the neck are the meningeal, auricular, pharyngeal, carotid body, superior and recurrent laryngeal nerves and cardiac branches.

Meningeal branches Meningeal branches appear to start from the superior vagal ganglion and pass through the jugular foramen to be distributed to the dura mater in the posterior cranial fossa (see Fig. 28.4B).

Auricular branch The auricular branch (Arnold's nerve) arises from the superior vagal ganglion and is joined by a branch from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the temporal bone, it crosses the facial canal approximately 4 mm above the stylomastoid foramen and here supplies an ascending branch to the facial nerve. Fibres of the nervus intermedius may pass to the auricular branch at this point, which may explain the cutaneous vesiculation in the auricle that sometimes accompanies geniculate herpes. The auricular branch then traverses the tympanomastoid fissure and divides into two rami. One ramus joins the posterior auricular nerve and the other is distributed to the skin of part of the ear and to the external acoustic meatus.

Pharyngeal branch The pharyngeal branch of the vagus is the main motor nerve of the pharynx (p. 582). It emerges from the upper part of the inferior vagal ganglion, passes between the external and internal carotid arteries to the upper border of the middle pharyngeal constrictor, and divides into numerous filaments that join rami of the sympathetic trunk and glossopharyngeal nerve to form a pharyngeal plexus. A minute filament, the ramus lingualis vagi, joins the hypoglossal nerve as it curves round the occipital artery.

Branches to the carotid body Branches to the carotid body are variable in number. They may arise from the inferior ganglion or travel in the pharyngeal branch, and sometimes in the superior laryngeal nerve. They form a plexus with the glossopharyngeal rami and branches of the cervical sympathetic trunk.

Superior laryngeal nerve The superior laryngeal nerve is larger than the pharyngeal branch and issues from the middle of the inferior vagal ganglion. It receives a branch from the superior cervical sympathetic ganglion and descends alongside the pharynx, at first posterior, then medial, to the internal carotid artery, and divides into the internal and external laryngeal nerves (see Figs 29.8, 35.12).

The internal laryngeal nerve is sensory to the laryngeal mucosa down to the level of the vocal folds. It also carries afferent fibres from the laryngeal neuromuscular spindles and other stretch receptors. It descends to the thyrohyoid membrane, pierces it above the superior laryngeal artery and divides into an upper and lower branch. The upper branch is horizontal and supplies the mucosa of the pharynx, the epiglottis, vallecula and laryngeal vestibule. The lower branch descends in the medial wall of the piriform recess, supplies the aryepiglottic fold, the mucosa on the back of the arytenoid cartilage and one or two branches to transverse arytenoid (the latter unite with twigs from the recurrent laryngeal to supply the same muscle). The internal laryngeal nerve ends by piercing the inferior pharyngeal constrictor to unite with an ascending branch from the recurrent laryngeal nerve. As it ascends in the neck, it supplies branches, more numerous on the left, to the mucosa and tunica muscularis of the oesophagus and trachea, and to the inferior constrictor

The external laryngeal nerve, smaller than the internal, descends behind sternohyoid with the superior thyroid artery, but on a deeper plane. It lies first on the inferior pharyngeal constrictor, and then pierces it to curve round the inferior thyroid tubercle and reach cricothyroid, which it supplies. The nerve also gives branches to the pharyngeal plexus and the inferior constrictor. Behind the common carotid artery, the external laryngeal nerve communicates with the superior cardiac nerve and superior cervical sympathetic ganglion.

Recurrent laryngeall nerve The recurrent laryngeal nerve differs, in origin and course, on the two sides. On the right, it arises from the vagus anterior to the first part of the subclavian artery, and curves backwards below and then behind it to ascend obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the lateral lobe of the thyroid gland, it is closely related to the inferior thyroid artery and crosses either in front of, behind or between its branches. On the left, the nerve arises from the vagus on the left of the
aortic arch, curves below it immediately behind the attachment of the ligamentum arteriosum to the concavity of the aortic arch, and ascends to the side of the trachea (see Figs 57.3, 57.61). As the recurrent laryngeal nerve curves round the subclavian artery, or the aortic arch, it gives cardiac filaments to the deep cardiac plexus. On both sides, the recurrent laryngeal nerve ascends in or near a groove between the trachea and oesophagus. It is closely related to the medial surface of the thyroid gland before it passes under the lower border of the inferior constrictor, and it enters the larynx behind the articulation of the inferior thyroid cornu with the cricoid cartilage. The recurrent laryngeal nerve supplies all laryngeal muscles, except the cricothyroid, and it communicates with the internal laryngeal nerve, supplying sensory filaments to the laryngeal mucosa below the vocal folds. It also carries afferent fibres from laryngeal stretch receptors. The recurrent laryngeal nerve is described further with the larynx.

## Accessory nerve

The accessory nerve (see Figs 29.7A, 29.11, 29.17) arises from an elongated nucleus of motor neurones in the lateral aspect of the ventral horn. Some rootlets emerge directly, while others turn cranially before exiting; their line of exit is irregular rather than linear. They join to form a trunk, the accessory nerve, which ascends intradurally within the vertebral canal between the ligamentum denticulatum and the dorsal roots of the spinal nerves. The nerve enters the skull via the foramen magnum, behind the vertebral artery. It then turns upwards and passes laterally to reach the jugular foramen, which it traverses in a common dural sheath with the vagus, but separated from that nerve by a fold of arachnoid mater.

As the accessory nerve exits the jugular foramen, it runs posterolaterally and passes either medial or lateral to the internal jugular vein; occasionally, it may pass through the vein. The extradural part of the nerve then crosses the transverse process of the atlas, and is crossed by the occipital artery before descending obliquely, medial to the styloid process, stylohyoid and the posterior belly of digastric. Running with the superior sternocleidomastoid branch of the occipital artery, it reaches the upper part of sternocleidomastoid and enters its deep surface, to form an anastomosis with fibres from C2 alone, C3 alone, or C2 and C3 (the ansa of Maubrac). It may also communicate with the anterior root of the first cervical nerve (McKenzie branch).

The accessory nerve occasionally terminates in sternocleidomastoid. More commonly, it emerges a little above the midpoint of the posterior border of sternocleidomastoid, generally above the emergence of the great auricular nerve (usually within 2 cm of it) and between 4 and 6 cm from the tip of the mastoid process. However, the point of emergence is very variable. The nerve then crosses the posterior triangle on levator scapulae (see Fig. 29.7A), separated from it by the prevertebral layer of deep cervical fascia and adipose tissue. Here the nerve is relatively superficial and related to the superficial cervical lymph nodes. Some 3-5 cm above the clavicle, it passes behind the anterior border of trapezius, often dividing to form a plexus on its deep surface, which receives contributions from $\mathrm{C} 2-4$ (see below), and then enters the deep surface of the muscle.

The cervical course of the accessory nerve follows a line from the lower anterior part of the tragus to the tip of the transverse process of the atlas, and then across the sternocleidomastoid and the posterior triangle to a point on the anterior border of the trapezius 3-5 cm above the clavicle

The accessory nerve is thought to provide the sole motor supply to sternocleidomastoid; the second and third cervical nerves are believed to carry proprioceptive fibres from it. The supranuclear pathway of fibres destined for sternocleidomastoid is not simple; current evidence favours bilateral hemispheric innervation, although opinion varies as to the extent of the ipsilateral input. The motor supply to the descending (upper) and transverse (middle) portions of trapezius is primarily from the accessory nerve under predominantly contralateral supranuclear control. Usually, trapezius receives an innervation from the cervical plexus, in most cases from C3 and C4 (Tubbs et al 2011). A study using intraoperative electroneurography and histochemical analyses found that, when present, the cervical fibres did not consistently innervate all three parts of the muscle (descending, transverse and ascending), and that fibres from C2 usually travelled via the accessory nerve, while fibres from C3 and C4 innervated trapezius independently (Pu et al 2008). In addition to their motor contribution, C3 and C4 also carry proprioceptive fibres from trapezius.

On the basis of the incomplete denervation of the muscle that sometimes happens following sacrifice of both the accessory nerve and the cervical plexus, it has been suggested that trapezius receives a partial
motor supply from other sources, possibly via thoracic roots. (For a detailed review of the applied surgical anatomy of the accessory nerve plexus, see Brown (2002).)

Sensory ganglia have been described along the course of the intradural portion of the nerve.

## Lesions affecting the accessory nerve

Lesions of the accessory nerve may be sustained centrally, at its exit from the skull or in the neck. The supranuclear fibres that influence motor neurones innervating sternocleidomastoid decussate twice; a lesion of the pyramidal system above the pons therefore produces weakness of the ipsilateral sternocleidomastoid and contralateral trapezius. Episodic contraction of sternocleidomastoid and trapezius, often accompanied by contraction of other muscle groups, e.g. splenius capitis, occurs in spasmodic torticollis, a focal dystonia. In jugular foramen syndrome, caused by pathologies including nasopharyngeal carcinoma or a jugular paraganglioma, lesions of the glossopharyngeal, vagus and accessory nerves coexist. The accessory nerve can be injured more distally in the neck by trauma or by surgical exploration in the posterior triangle. If the accessory nerve is sacrificed as part of a radical neck dissection and the innervation of trapezius is lost, the patient develops intractable neuralgia due to traction on the brachial plexus caused by the unsupported weight of the shoulder and arm.

## Hypoglossal nerve

The hypoglossal nerve is motor to all the muscles of the tongue, except palatoglossus. The hypoglossal rootlets run laterally behind the vertebral artery, collected into two bundles that perforate the dura mater separately opposite the hypoglossal canal in the occipital bone, and unite after traversing it. The canal is sometimes divided by a spicule of bone. The nerve emerges from the canal in a plane medial to the internal jugular vein, internal carotid artery and ninth, tenth and eleventh cranial nerves, and passes inferolaterally behind the internal carotid artery and glossopharyngeal and vagus nerves to the interval between the artery and the internal jugular vein (see Fig. 29.8). Here, it makes a half-spiral turn round the inferior vagal ganglion and is united with it by connective tissue. It then descends almost vertically between the vessels and anterior to the vagus to a point level with the angle of the mandible, becoming superficial below the posterior belly of digastric and emerging between the internal jugular vein and internal carotid artery. It loops round the inferior sternocleidomastoid branch of the occipital artery, crosses lateral to both internal and external carotid arteries and the loop of the lingual artery a little above the tip of the greater cornu of the hyoid, and is itself crossed by the facial vein (see Figs 29.7A, 29.8, 29.17). Its course is described further on page 514.

## Communicating branches

The hypoglossal nerve communicates with the sympathetic trunk, the lingual, glossopharyngeal and vagus nerves and the pharyngeal plexus. Near the atlas, it is joined by branches from the superior cervical sympathetic ganglion and by a filament from the loop between the first cervical ventral ramus and the ascending branch of the second cervical ventral ramus that leaves the hypoglossal as the upper root of the ansa cervicalis. The vagal connections are close to the skull, and numerous filaments pass between the hypoglossal nerve and the inferior vagal ganglion in the connective tissue uniting them. As the hypoglossal nerve curves round the occipital artery, it receives the ramus lingualis vagi from the pharyngeal plexus. Near the anterior border of hyoglossus, it is connected with the lingual nerve by many filaments that ascend on the muscle.

## Branches of distribution

The branches of distribution of the hypoglossal nerve are meningeal, descending, thyrohyoid and muscular nerves.

Meningeal branches Meningeal branches leave the nerve in the hypoglossal canal and return through it to supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses, and much of the floor of the anterior wall of the posterior cranial fossa, probably through pathways other than that of the hypoglossal nerve, e.g. upper cervical spinal nerves (see Fig. 28.4B).

Descending branch The descending branch (descendens hypoglossi) contains fibres from the first cervical spinal nerve. It leaves the hypoglossal nerve when it curves around the occipital artery, and runs down on the carotid sheath. It provides a branch to the superior belly of omohyoid before joining with the descendens cervicalis to form the ansa cervicalis (see Figs 29.7A, 29.8).

Nerves to thyrohyoid and geniohyoid The nerves to thyrohyoid and geniohyoid arise near the posterior border of hyoglossus. They represent the remaining fibres from the first cervical spinal nerves.

## Lesions of the hypoglossal nerve

The hypoglossal nerve may be damaged during neck dissection. Complete hypoglossal division causes unilateral lingual paralysis and eventual hemiatrophy; the protruded tongue deviates to the paralysed side, and, on retraction, the wasted and paralysed side rises higher than the unaffected side. The larynx may deviate towards the active side in swallowing, due to unilateral paralysis of the hyoid depressors associated with loss of the first cervical spinal nerve, which runs with the hypoglossal nerve. If paralysis is bilateral, the tongue is motionless. Taste and tactile sensibility are unaffected but articulation is slow and swallowing very difficult.

The hypoglossal nerve is often used to reanimate the face in patients, particularly the elderly, whose facial nerves have been transected. Direct end-to-end, end-to-side or split-nerve grafts are reliable and offer a robust, effective and quick alternative to more complex reanimation procedures.

## CERVICAL SYMPATHETIC TRUNK

The cervical sympathetic trunk lies on the prevertebral fascia behind the carotid sheath and contains three interconnected ganglia: the superior, middle and inferior (stellate or cervicothoracic) (see Figs 29.17-29.18). There may occasionally, however, be two or four ganglia. The cervical sympathetic ganglia send grey rami communicantes to all the cervical spinal nerves but receive no white rami communicantes from them. Their spinal preganglionic fibres emerge in the white rami communicantes of the upper five thoracic spinal nerves (mainly the upper three), and ascend in the sympathetic trunk to synapse in the cervical ganglia. In their course, the grey rami communicantes may pierce longus capitis or scalenus anterior.

## Superior cervical ganglion

The superior cervical ganglion is the largest of the three ganglia (see Fig. 29.17). It lies on the transverse processes of the second and third cervical vertebrae and is probably formed from four fused ganglia, judging by its grey rami to $\mathrm{C} 1-4$. The internal carotid artery within the carotid sheath is anterior, and longus capitis is posterior. The lower end of the ganglion is united by a connecting trunk to the middle cervical ganglion. Postganglionic branches are distributed in the internal carotid nerve, which ascends with the internal carotid artery into the carotid canal to enter the cranial cavity, and in lateral, medial and anterior branches. They supply vasoconstrictor and sudomotor nerves to the face and neck, dilator pupillae and smooth muscle in the eyelids and orbitalis.

Lateral branches The lateral branches are grey rami communicantes to the upper four cervical spinal nerves and to some of the cranial nerves. Branches pass to the inferior vagal ganglion, the hypoglossal nerve, the superior jugular bulb and associated jugular glomus or glomera, and to the meninges in the posterior cranial fossa. Another branch, the jugular nerve, ascends to the cranial base and divides into two; one part joins the inferior glossopharyngeal ganglion and the other joins the superior vagal ganglion.

Medial branches The medial branches of the superior cervical ganglion are the laryngopharyngeal and cardiac. The laryngopharyngeal branches supply the carotid body and pass to the side of the pharynx, joining glossopharyngeal and vagal rami to form the pharyngeal plexus. A cardiac branch arises by two or more filaments from the lower part of the superior cervical ganglion and occasionally receives a twig from the trunk between the superior and middle cervical ganglia. It is thought to contain only efferent fibres, the preganglionic outflow being from the upper thoracic segments of the spinal cord, and to be devoid of pain fibres from the heart. It descends behind the common carotid artery, in front of longus colli, and crosses anterior to the inferior thyroid artery and recurrent laryngeal nerve. The courses on the two sides then differ. The right cardiac branch usually passes behind, but sometimes in front of, the subclavian artery and runs posterolateral to the brachiocephalic trunk to join the deep (dorsal) part of the cardiac plexus behind the aortic arch. It has other sympathetic connections. About mid-neck, it receives filaments from the external laryngeal nerve. Inferiorly, one or two vagal cardiac branches join it. As it enters the thorax, it is joined by a filament from the recurrent laryngeal nerve.

Filaments from the nerve also communicate with the thyroid branches of the middle cervical ganglion. The left cardiac branch, in the thorax, is anterior to the left common carotid artery and crosses in front of the left side of the aortic arch to reach the superficial (ventral) part of the cardiac plexus. Sometimes, it descends on the right of the aorta to end in the deep (dorsal) part of the cardiac plexus. It communicates with the cardiac branches of the middle and inferior cervical sympathetic ganglia and sometimes with the inferior cervical cardiac branches of the left vagus, and branches from these mixed nerves form a plexus on the ascending aorta.

Anterior branches The anterior branches of the superior cervical ganglion ramify on the common and external carotid arteries and the branches of the external carotid, and form a delicate plexus around each, in which small ganglia are occasionally found. The plexus around the facial artery supplies a filament to the submandibular ganglion; the plexus on the middle meningeal artery sends one ramus to the otic ganglion and another, the external petrosal nerve, to the facial ganglion. Many of the fibres coursing along the external carotid and its branches ultimately leave them to travel to facial sweat glands via branches of the trigeminal nerve.

## Middle cervical ganglion

The middle cervical ganglion is the smallest of the three and is occasionally absent, in which case it may be replaced by minute ganglia in the sympathetic trunk or may be fused with the superior ganglion. It is usually found at the level of the sixth cervical vertebra, anterior or just superior to the inferior thyroid artery, or it may adjoin the inferior cervical ganglion. It probably represents a coalescence of the ganglia of the fifth and sixth cervical segments, judging by its postganglionic rami, which join the fifth and sixth cervical spinal nerves (but sometimes also the fourth and seventh). It is connected to the inferior cervical ganglion by two or more very variable cords. The posterior cord usually splits to enclose the vertebral artery, while the anterior cord loops down anterior to, and then below, the first part of the subclavian artery, medial to the origin of its internal thoracic branch, and supplies rami to it. This loop is the ansa subclavia and is frequently multiple, lies closely in contact with the cervical pleura, and typically connects with the phrenic nerve, and sometimes with the vagus (see Fig. 29.18).

The middle cervical ganglion gives off thyroid and cardiac branches. The thyroid branches accompany the inferior thyroid artery to the thyroid gland. They communicate with the superior cardiac, external laryngeal and recurrent laryngeal nerves, and send branches to the parathyroid glands. Fibres to both glands are largely vasomotor but some reach the secretory cells. The cardiac branch, the largest sympathetic cardiac nerve, arises either from the ganglion itself or more often from the sympathetic trunk cranial or caudal to it. On the right side, it descends behind the common carotid artery, in front of or behind the subclavian artery, to the trachea, where it receives a few filaments from the recurrent laryngeal nerve before joining the right half of the deep (dorsal) part of the cardiac plexus. In the neck, it connects with the superior cardiac and recurrent laryngeal nerves. On the left side, the cardiac nerve enters the thorax between the left common carotid and subclavian arteries to join the left half of the deep (dorsal) part of the cardiac plexus. Fine branches from the middle cervical ganglion also pass to the trachea and oesophagus.

## Inferior (or cervicothoracic/stellate) ganglion

The inferior cervical ganglion (cervicothoracic/stellate) is irregular in shape and much larger than the middle cervical ganglion (see Fig. 29.18). It is probably formed by a fusion of the lower two cervical and first thoracic segmental ganglia, sometimes including the second and even third and fourth thoracic ganglia. The first thoracic ganglion may be separate, leaving an inferior cervical ganglion above it. The sympathetic trunk turns backwards at the junction of the neck and thorax, and so the long axis of the cervicothoracic ganglion becomes almost anteroposterior. The ganglion lies on or just lateral to the lateral border of longus colli between the base of the seventh cervical transverse process and the neck of the first rib (which are both posterior to it). The vertebral vessels are anterior, and the ganglion is separated from the posterior aspect of the cervical pleura inferiorly by the suprapleural membrane. The costocervical trunk of the subclavian artery branches near the lower pole of the ganglion, and the superior intercostal artery is lateral.

A small vertebral ganglion may be present on the sympathetic trunk anterior or anteromedial to the origin of the vertebral artery and directly above the subclavian artery. When present, it may provide the ansa subclavia and is also joined to the inferior cervical ganglion by fibres
enclosing the vertebral artery. It is usually regarded as a detached part of the middle cervical or inferior cervical ganglion. Like the middle cervical ganglion, it may supply grey rami communicantes to the fourth and fifth cervical spinal nerves. The inferior cervical ganglion sends grey rami communicantes to the seventh and eighth cervical and first thoracic spinal nerves, and gives off a cardiac branch, branches to nearby vessels and sometimes a branch to the vagus nerve.

The grey rami communicantes to the seventh cervical spinal nerve vary from one to five (two being the usual number). A third often ascends medial to the vertebral artery in front of the seventh cervical transverse process. It connects with the seventh cervical nerve, and sends a filament upwards through the sixth cervical transverse foramen in company with the vertebral vessels to join the sixth cervical spinal nerve as it emerges from the intervertebral foramen. An inconstant ramus may traverse the seventh cervical transverse foramen. Grey rami to the eighth cervical spinal nerve vary from three to six in number.

The cardiac branch descends behind the subclavian artery and along the front of the trachea to the deep cardiac plexus. Behind the artery, it connects with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion (the latter is often replaced by fine branches of the inferior cervical ganglion and ansa subclavia).

The branches to blood vessels form plexuses on the subclavian artery and its branches. The subclavian supply is derived from the inferior cervical ganglion and ansa subclavia, and typically extends to the first part of the axillary artery, although a few fibres may extend further. An extension of the subclavian plexus to the internal thoracic artery may be joined by a branch of the phrenic nerve.

Within the foramina transversaria and intertransverse spaces, the cervical grey rami communicantes form intersegmental arcades as they communicate with one another and the ventral rami of the upper five or six cervical spinal nerves. These arcades accompany the second part of the vertebral artery and create the appearance of a long nerve known as the vertebral nerve. Fine filaments from this nerve and the grey rami communicantes form the vertebral plexus on the surface of the vertebral artery. This plexus contains not only sympathetic efferent fibres but also somatic sensory fibres from the adventitia of the artery, whose cell bodies are located in the cervical dorsal root ganglia. The vertebral nerve sends filaments to the posterolateral corners of the cervical intervertebral discs (Bogduk et al 1988), and gives rise to the meningeal branches (sinuvertebral nerves) at each cervical segment. The vertebral plexus, which contains some neuronal cell bodies, continues into the skull along the vertebral and basilar arteries and their branches as far as the posterior cerebral artery, where it meets a plexus from the internal carotid artery. The plexus on the inferior thyroid artery reaches the thyroid gland and connects with the recurrent and external laryngeal nerves, the cardiac branch of the superior cervical ganglion, and the common carotid plexus.

## Horner's syndrome

Any condition or injury that destroys the sympathetic trunk ascending from the thorax through the neck into the face results in Horner's syndrome, characterized by a drooping eyelid (ptosis), sunken globe (enophthalmos), narrow palpebral fissure, contracted pupil (meiosis), vasodilation and lack of thermal sweating (anhydrosis) on the affected side. Classically, this is seen in patients with bronchial carcinomas that have invaded the sympathetic trunk and is also a recognized complication of cervical sympathectomy or a radical neck dissection. Avulsion of the first thoracic nerve from the spinal cord may be diagnosed by development of the syndrome after closed traction lesion of the supraclavicular brachial plexus. Congenital Horner's syndrome has been reported in association with ipsilateral internal carotid artery agenesis (Fons et al 2009). Special features of congenital Horner's syndrome are iris heterochromia, a difference in colour between the two eyes that results from interference with melanocyte pigmentation of the iris by a lack of sympathetic stimulation during development, and unilateral straight hair.

## VISCERA

The main cervical viscera are the submandibular salivary glands, the thyroid and parathyroid glands, and the cervical portions of the trachea and oesophagus.

## SUBMANDIBULAR SALIVARY GLAND

Each submandibular salivary gland is situated behind and below the ramus of the mandible, in the region of the submandibular triangle,
between the anterior and posterior bellies of digastric (see Fig. 29.7A) The gland is described in detail on page 528.

## THYROID GLAND

The thyroid gland, brownish-red and highly vascular, is placed anteriorly in the lower neck, level with the fifth cervical to the first thoracic vertebrae (see Fig. 29.17). It is ensheathed by the pretracheal layer of deep cervical fascia and consists of right and left lobes connected by a narrow, median isthmus. It usually weighs 25 g but this varies. The gland is slightly heavier in females and enlarges during menstruation and pregnancy. Estimation of the size of the thyroid gland is clinically important in the evaluation and management of thyroid disorders and can be achieved non-invasively by means of diagnostic ultrasound. Mean thyroid volume increases with age (Chanoine et al 1991). No significant difference in thyroid gland volume has been observed between males and females from 8 months to 15 years

The lobes of the thyroid gland are approximately conical. Their ascending apices diverge laterally to the level of the oblique lines on the laminae of the thyroid cartilage, and their bases are level with the fourth or fifth tracheal cartilages. Each lobe is usually 5 cm long, its greatest transverse and anteroposterior extents being 3 cm and 2 cm , respectively. The posteromedial aspects of the lobes are attached to the side of the cricoid cartilage by a lateral thyroid ligament (Berry's ligament). The isthmus connects the lower parts of the two lobes, although occasionally it may be absent. It measures 1.25 cm transversely and vertically, and is usually anterior to the second and third tracheal cartilages, although it can be higher or even sometimes lower because its site and size vary greatly. A conical pyramidal lobe often ascends towards the hyoid bone from the isthmus or the adjacent part of either lobe (more often the left). It is occasionally detached or in two or more parts. A fibrous or fibromuscular band, the levator of the thyroid gland, musculus levator glandulae thyroideae, sometimes descends from the body of the hyoid to the isthmus or pyramidal lobe. For further reading, see Mohebati and Shaha (2012).

Ectopic thyroid tissue is rare but may be found around the course of the thyroglossal duct or laterally in the neck, as well as in distant places such as the tongue (lingual thyroid), mediastinum and the subdiaphragmatic organs (Noussios et al 2011). The most frequent location of ectopic thyroid tissue is at the base of the tongue, in particular at the region of the foramen caecum; often it is the only thyroid tissue present. Small, detached masses of thyroid tissue may occur above the lobes or isthmus as accessory thyroid glands. Vestiges of the thyroglossal duct may persist between the isthmus and the foramen caecum of the tongue, sometimes as accessory nodules or cysts of thyroid tissue near the midline or even in the tongue, where they are called thyroglossal duct cysts.

## Surfaces and relations

The convex lateral (superficial) surface is covered by sternothyroid, whose attachment to the oblique thyroid line prevents the upper pole of the gland from extending on to thyrohyoid. More anteriorly lie sternohyoid and the superior belly of omohyoid, overlapped inferiorly by the anterior border of sternocleidomastoid. The medial surface of the gland is adapted to the larynx and trachea; its superior pole contacts the inferior pharyngeal constrictor and the posterior part of cricothyroid, which separate it from the posterior part of the thyroid lamina and the side of the cricoid cartilage. The external branch of the superior laryngeal nerve is medial to this part of the gland as it passes to supply cricothyroid. Inferiorly, the trachea and, more posteriorly, the recurrent laryngeal nerve and oesophagus (which is closer on the left) are medial relations. The posterolateral surface of the thyroid gland is close to the carotid sheath and overlaps the common carotid artery.

The anterior border of the gland is thin, and near the anterior branch of the superior thyroid artery it slants down medially. The posterior border is rounded and related inferiorly to the inferior thyroid artery and its anastomosis with the posterior branch of the superior thyroid artery. On the left side, the lower end of the posterior border lies near the thoracic duct. The parathyroid glands are usually related to the posterior border.

The isthmus is covered by sternothyroid, from which it is separated by pretracheal fascia. More superficially it is covered by sternohyoid, the anterior jugular veins, fascia and skin. The superior thyroid arteries anastomose along its upper border and the inferior thyroid veins leave the gland at its lower border.

# Vascular supply and lymphatic drainage 

## Arteries

The thyroid gland is supplied by the superior and inferior thyroid arteries and sometimes by an arteria thyroidea ima from the brachiocephalic trunk or aortic arch (see Figs 29.14, 29.17). The arteries are large and their branches anastomose frequently both on and in the gland, ipsilaterally and contralaterally. The superior thyroid artery, which is closely related to the external branch of the superior laryngeal nerve, pierces the thyroid fascia and then divides into anterior and posterior branches. The anterior branch supplies the anterior surface of the gland, and the posterior branch supplies the lateral and medial surfaces. The inferior thyroid artery approaches the base of the thyroid gland and divides into superior (ascending) and inferior thyroid branches to supply the inferior and posterior surfaces of the gland. The superior branch also supplies the parathyroid glands. The relationship between the inferior thyroid artery and the recurrent laryngeal nerve is highly variable and of considerable clinical importance; iatrogenic injury to the nerves that supply the larynx represents a major complication of thyroid surgery (Yalcxin 2006). The recurrent laryngeal nerve is usually related to the posterior branch of the inferior thyroid artery, which may be replaced by a vascular network (Moreau et al 1998).

## Veins

The venous drainage of the thyroid gland is usually via superior, middle and inferior thyroid veins (see Figs 29.13, 29.14, 29.17). The superior thyroid vein emerges from the upper part of the gland and runs with the superior thyroid artery towards the carotid sheath; it drains into the internal jugular vein. The middle thyroid vein collects blood from the lower part of the gland; it emerges from the lateral surface of the gland and drains into the internal jugular vein. The inferior thyroid veins arise in a glandular venous plexus, which also connects with the middle and superior thyroid veins. These veins form a pretracheal plexus, from which the left inferior vein descends to join the left brachiocephalic vein, and the right descends obliquely across the brachiocephalic artery to join the right brachiocephalic vein at its junction with the superior vena cava. The inferior thyroid veins often open via a common trunk into the superior vena cava or left brachiocephalic vein. They drain the oesophageal, tracheal and inferior laryngeal veins and have valves at their terminations.

## Lymphatics

Thyroid lymphatic vessels communicate with the tracheal plexus, and pass to the prelaryngeal nodes just above the thyroid isthmus and to the pretracheal and paratracheal nodes; some may also drain into the brachiocephalic nodes related to the thymus in the superior mediastinum. Laterally, the gland is drained by vessels lying along the superior thyroid veins to the deep cervical nodes. Thyroid lymphatics may drain directly, with no intervening node, to the thoracic duct.

## Innervation

The thyroid gland receives its innervation from the superior, middle and inferior cervical sympathetic ganglia. Postganglionic fibres from the inferior cervical ganglion form a plexus on the inferior thyroid artery, which accompanies the artery to the thyroid gland, and communicates with the recurrent laryngeal and external branch of the superior laryngeal nerves, with the superior cardiac nerve, and with the plexus on the common carotid artery.

## Imaging

The follicular nature of the thyroid gland is not resolved by current imaging techniques and thus presents a homogeneous texture on crosssectional imaging (ultrasound, computed tomography, magnetic resonance imaging (MRI)). Its superficial location makes the thyroid an ideal organ for sonographic examination (Fig. 29.21). The thyroid gland is highly vascular and demonstrates intense contrast enhancement and increased signal on $\mathrm{T}_{2}$-weighted MRI (Fig. 29.22). Radionuclide imaging of the thyroid may be performed with technetium ( ${ }^{99 \mathrm{~m}} \mathrm{Tc}$ ) pertechnetate. This readily available radionuclide is trapped by the thyroid in the same way as iodine but is not organified. It yields morphological information and will reveal the presence of ectopic thyroid tissue. Functional data can be obtained with the use of ${ }^{123}$ iodine or ${ }^{131}$ iodine, which is trapped and organified. For further reading, see Intenzo et al (2012).

Fig. 29.21 A thyroid sonogram.

Fig. 29.22 $A T_{2}$-weighted magnetic resonance image at the level of the thyroid isthmus. Vessels show flow void; compare with Figure 29.21.

## Microstructure

The thyroid gland has a thin capsule of connective tissue, which extends into the glandular parenchyma and divides each lobe into irregularly shaped and sized lobules. The functional units of the thyroid are follicles, which are spherical and cyst-like, between 0.02 and 0.9 mm in diameter. Follicles consist of a central colloid core surrounded by a single-layered epithelium resting on a basal lamina (Fig. 29.23). Colloid consists almost entirely of an iodinated glycoprotein, iodothyroglobulin, which is the inactive, stored form of the active thyroid hormones, tri-iodothyronine $\left(\mathrm{T}_{3}\right)$ and tetra-iodothyronine or thyroxine $\left(\mathrm{T}_{4}\right)$, and is produced by the follicular epithelial cells. Sufficient iodothyroglobulin is stored extracellularly within follicles to regulate the metabolic activity of the body for up to 3 months. Follicles are surrounded by a delicate connective tissue stroma, containing dense plexuses of fenestrated capillaries, extensive lymphatic networks and sympathetic nerve fibres that supply the arterioles and capillaries. Some nerve fibres end close to the follicular epithelial cells.

Follicular cells Follicular cells vary from squamous or low cuboidal to columnar, depending on their level of activity, which is controlled mainly by circulating hypophysial thyroid-stimulating hormone (TSH, thyrotropin). Resting follicles are large and lined by squamous or low cuboidal epithelium with abundant luminal colloid. Apical microvilli

Fig. 29.23 A section through parts of several human thyroid follicles, one of which is labelled ( F ), showing the follicular epithelium (arrows) enclosing a lumen filled with colloidal thyroglobulin (CT). Calcitoninsecreting $C$ cells are not readily identifiable in routine preparations of human tissue, where they appear as poorly staining (clear) cells within follicles; an example is indicated by the asterisk. A network of blood vessels (BV) within connective tissue septa surrounds the follicles. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
are short in resting cells, but elongate and often branch on stimulation by TSH. Follicles showing differing levels of activity may coexist.

Active follicular cells are highly polarized functionally. The secretion of TSH leads to endocytosis of colloidal droplets at the luminal epithelium (see Fig. 29.23). The hormone provokes the cells to extend cytoplasmic processes into the luminal colloid and sequester droplets of colloid. The iodinated thyroglobulin in the intracellular colloid droplets is then degraded by follicular cell lysosomes, liberating $\mathrm{T}_{3}$ and $\mathrm{T}_{4}$, which pass to the base of the cell, where they are released. They are exported from the thyroid mainly via the blood capillaries and lymphatics. Prolonged high levels of circulating TSH induce follicular cell hypertrophy, progressive resorption of colloid and increased stromal vascularity, and this can result in thyroid enlargement.

C cells Thyroid parenchyma also contains C (clear) cells, so called because they have pale-staining cytoplasm, which is more pronounced in some species than in the human thyroid. C cells are members of the amine precursor uptake and decarboxylation (APUD) system of dispersed neuroendocrine cells. They produce the peptide hormone calcitonin (thyrocalcitonin), which lowers blood calcium by inhibiting bone resorption and calcium recovery from renal tubule ultrafiltrate. C cells populate the middle third of each lateral lobe of the thyroid and are typically found scattered within thyroid follicles, lying inside the basal lamina but not reaching the follicle lumen. Occasionally, they occur in clusters in the interfollicular stroma, which is why they are also called parafollicular cells.

## Thyroidectomy

Apart from variable enlargement during menstruation and pregnancy, any thyroid swelling is a goitre, which may press on related structures. Symptoms most commonly are the consequence of pressure on the trachea or on the recurrent laryngeal nerves, and there may also be venous engorgement. During thyroidectomy, care must be taken when tying off the superior and inferior thyroid arteries to avoid damage to adjacent nerves. The external laryngeal nerve runs close to the superior thyroid artery, and the recurrent laryngeal nerve runs close to the inferior thyroid artery. Total thyroidectomy may be necessary in the treatment of hyperthyroidism (overactive thyroid), as well as for thyroid enlargement in the euthyroid state. The parathyroid glands and the recurrent laryngeal nerves are preserved.

## PARATHYROID GLANDS

The parathyroid glands are small, yellowish-brown, ovoid or lentiform structures, usually lying between the posterior lobar borders of the thyroid gland and its capsule. They are commonly 6 mm long, $3-4 \mathrm{~mm}$
across and 1-2 mm from back to front, each weighing about 50 mg . Typically, there are two on each side, superior and inferior, but there may be more or there may be only three or many minute parathyroid islands scattered in connective tissue near the usual sites. Very occasionally, an occult gland may follow a blood vessel into a groove on the surface of the thyroid. Normally, the inferior parathyroids migrate only to the inferior thyroid poles, but they may descend with the thymus into the thorax or they may be sessile and remain above their normal level near the carotid bifurcation. The anastomotic connection between the superior and inferior thyroid arteries that occurs along the posterior border of the thyroid gland usually passes very close to the parathyroids, and is a useful aid to their identification.

The superior parathyroid glands are more constant in location than the inferior and are usually to be found midway along the posterior borders of the thyroid gland, although they may be higher. The inferior pair are more variably situated (related to their embryological development) and may be either within the fascial thyroid sheath, below the inferior thyroid arteries and near the inferior lobar poles; or outside the sheath, immediately above an inferior thyroid artery; or in the thyroid gland near its inferior pole. These variations are surgically important (Fig. 29.24). A tumour of the inferior parathyroid situated within the fascial thyroid sheath may descend along the inferior thyroid veins anterior to the trachea into the superior mediastinum, whereas if it is outside the sheath, it may extend posteroinferiorly behind the oesophagus into the posterior mediastinum. The superior parathyroids are usually dorsal, and the inferior parathyroids ventral, to the recurrent laryngeal nerves.

The parathyroid glands are very flattened in cross-section and are not normally visible by current imaging methods, including scintigraphy, unless they are enlarged.

## Vascular supply and lymphatic drainage

Both superior and inferior parathyroid glands are usually supplied by the inferior thyroid arteries; the superior thyroid may be supplied by the superior thyroid artery or from anastomoses between the superior and inferior thyroid arteries sometimes. The glands drain into the plexus of veins on the anterior surface of the thyroid. Lymph vessels are numerous and associated with those of the thyroid and thymus glands.

## Innervation

The nerve supply is sympathetic, either direct from the superior or middle cervical ganglia, or via a plexus in the fascia on the posterior
lobar aspects. Parathyroid activity is controlled by variations in blood calcium level; it is inhibited by a rise and stimulated by a fall. The nerves are believed to be vasomotor but not secretomotor.

## Microstructure

Each parathyroid gland has a thin connective tissue capsule with intraglandular septa but lacks distinct lobules. The parathyroids synthesize and secrete parathyroid hormone (PTH, parathormone), a single-chain polypeptide of 84 amino-acid residues concerned with the control of the level and distribution of calcium and phosphorus. In childhood, the gland consists of wide, irregular, interconnecting columns of chief or principal cells separated by a dense plexus of fenestrated sinusoidal capillaries. After puberty, adipose tissue accumulates in the stroma and typically accounts for about one-third of the adult tissue mass, increasing further with age.

Chief cells differ ultrastructurally according to their level of activity; active chief cells have large Golgi complexes with numerous vesicles and small membrane-bound granules. Glycogen granules are most abundant in inactive cells, which have few of the cytoplasmic features of synthetic or secretory activity, and appear histologically as 'clear' cells. In normal human parathyroid glands, inactive chief cells outnumber active cells in a ratio of 3-5:1 (Fig. 29.25). In contrast to the thyroid, where the activities of adjacent follicular cells are coordinated, individual chief cells of the parathyroid glands go through cycles of secretory activity and rest independently, according to serum calcium levels.

A second cell type, the oxyphil (eosinophil) cell, appears just before puberty and increases in number with age. Oxyphil cells are larger than chief cells and contain more cytoplasm, which stains deeply with eosin. Their nuclei are smaller and more darkly staining than those of chief cells, and their cytoplasm is unusually rich in mitochondria. The functional significance of oxyphil cells and their relationship to chief cells are uncertain.

## ROOT OF THE NECK

The root of the neck is a zone of transition between four discrete anatomical spaces: the neck, the thorax and both upper limbs (see Fig. 29.18). It contains the subclavian vessels; common carotid artery; trunks of the brachial plexus; sympathetic trunk; phrenic, vagus and recurrent laryngeal nerves (all bilaterally); the terminal portion of the thoracic duct (on the left side only); the terminal portion of the right lymphatic duct (on the right side only); and the oesophagus and trachea

Fig. 29.24 The distribution of superior (A-C) and inferior (D-G) parathyroid glands. A, Cricothyroidal and juxtathyroidal. B, Behind the upper pole of the thyroid. C, Retropharyngeal and retro-oesophageal. D, Lower thyroid. E, Intrathymic. F, Juxtathyroidal. G, Ectopic.

Fig. 29.25 A section of the parathyroid gland, showing clusters and cords of small, tightly packed chief cells surrounded by vascular sinusoids.

Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
(in the midline). The brachiocephalic veins are formed by the union of the internal jugular and subclavian veins at the junction of the neck and thorax, behind the head of the clavicle.

The essential anatomical landmark in orientating and understanding the root of the neck is scalenus anterior, covered by the prevertebral layer of deep cervical fascia. Anteriorly lie sternocleidomastoid and subclavius, the intermediate tendon of omohyoid, the subclavian vein, branches from the thyrocervical trunk of the first part of the subclavian artery (transverse cervical, suprascapular and ascending cervical arteries), and the phrenic nerve. The nerve lies on the surface of scalenus anterior in the root of the neck, before passing between it and the subclavian vein to enter the superior mediastinum, and is the anatomical key to identifying the muscle intraoperatively. Posteriorly, the roots of the brachial plexus and the second part of the subclavian artery separate scalenus anterior from scalenus medius. Pathologies that cause impingement on either brachial plexus or subclavian artery may present clinically as an upper limb compression syndrome. The suprapleural membrane and pleura are intimate posterior relations of scalenus anterior. On each side, the apical (cervical) pleura and the apex of the lung bulge up into the root of the neck. The height to which the apical pleura rises - with reference to the first pair of ribs and costal cartilages - varies in different individuals according to the obliquity of the thoracic inlet. Posteriorly, the apical pleura typically reaches the level of the neck of the first rib; it forms a domed roof over each side of the thoracic cavity that is strengthened by the suprapleural membrane. Scalenus anterior covers the anterolateral part of the dome of the pleura and separates it from the subclavian vein. The subclavian artery crosses the dome below its summit, immediately above the vein. The costocervical trunk arches backwards from the subclavian artery and crosses the summit of the dome; its superior intercostal branch descends behind the dome, between the first intercostal nerve laterally and the first thoracic sympathetic ganglion medially.

Medial relations of scalenus anterior are longus colli and the inferior thyroid artery. The two muscles are separated by an angular interval through which the vertebral artery and vein pass to gain access to the foramen transversarium of the sixth cervical vertebra, and more anteriorly the inferior thyroid artery arches from lateral to medial on its way to the thyroid gland. The cervical sympathetic chain and the inferior cervical ganglion lie close to the posteromedial aspect of the vertebral artery here. The internal thoracic artery descends from the first part of the subclavian artery; it passes behind the brachiocephalic vein and, on the right side, is crossed by the phrenic nerve. The vagus descends anterior to the first part of the subclavian artery; on the right side only, its recurrent laryngeal branch usually turns around the lower border of the artery. The terminal portions of the thoracic duct and the right lymphatic duct, on the left and right sides, respectively, cross the triangular interval at the level of the seventh cervical vertebra, coming into contact with the medial edge of scalenus anterior.

The axillary sheath, an extension of the prevertebral fascia that accompanies the axillary artery and trunks of the brachial plexus, lies lateral to scalenus anterior.

## Cervical rib

A small additional rib (cervical rib) may develop in the root of the neck in association with the seventh cervical vertebra. It is often fibrous in nature, although in some cases it may have undergone ossification. A cervical rib may cause compression of the subclavian artery and the lower roots of the brachial plexus, in which case affected individuals will complain of pain, paraesthesia and even pallor of the affected upper limb, a condition known as thoracic outlet syndrome. The occasional co-occurrence of rudimentary or absent twelfth ribs with cervical ribs indicates that a homeotic shift had occurred over a larger part of the vertebral column in affected fetuses (Bots et al 2011). For further reading on homeotic transformations of vertebrae, see Ten Broek et al (2012).

## OESOPHAGUS - CERVICAL PORTION

The oesophagus is a muscular tube approximately 25 cm long, connecting the pharynx to the stomach. It begins in the neck, level with the lower border of the cricoid cartilage and the sixth cervical vertebra. It descends, largely anterior to the vertebral column, into the superior mediastinum. Generally vertical and median, it inclines to the left as far as the root of the neck, and also bends in an anteroposterior plane to follow the cervical curvature of the vertebral column.

Relations The trachea lies anterior to the oesophagus, attached to it by loose connective tissue. The vertebral column, longus colli and prevertebral layer of deep cervical fascia are posterior, and the common carotid artery and posterior part of the thyroid gland are lateral on each side. In the lower neck, where the oesophagus deviates to the left, it becomes closer to the left carotid sheath and thyroid gland than it is on the right. The thoracic duct ascends for a short distance along its left side. The recurrent laryngeal nerves ascend on each side in or near the groove between the trachea and the oesophagus.

Vascular supply and lymphatic drainage The cervical part of the oesophagus is mainly supplied by branches from the inferior thyroid arteries. The oesophageal veins drain into the brachiocephalic veins, and lymphatic vessels pass to retropharyngeal, paratracheal or deep cervical lymph nodes.

Innervation The cervical part of the oesophagus is innervated by the recurrent laryngeal nerves and by the sympathetic plexus around the inferior thyroid artery.

## TRACHEA - CERVICAL PORTION

The trachea is a tube $10-11 \mathrm{~cm}$ long, formed of cartilage and fibromuscular membrane. It descends from the larynx, and extends from the level of the sixth cervical vertebra to the upper border of the fifth thoracic vertebra (see Figs 29.14, 29.22). It lies approximately in the sagittal plane but its point of bifurcation is usually a little to the right. The trachea is flexible and can rapidly alter in length. It is flattened posteriorly so that in transverse section it is shaped, with some individual variation, like a letter $D$. Its external transverse diameter is 2 cm in adult males, and 1.5 cm in adult females. The lumen in live adults is 1.2 cm in transverse diameter. In children, the trachea is smaller, more deeply placed and more mobile. Tracheal diameter does not exceed 3 mm in the first postnatal year; during later childhood its diameter in millimetres is about equal to age in years.

Relations The relationships of the trachea to other cervical structures is of clinical significance: tracheostomy is not an uncommon clinical procedure (see below). Anteriorly, the cervical part of the trachea is crossed by skin and by the superficial and deep fasciae. It is also crossed by the jugular arch and overlapped by sternohyoid and sternothyroid. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomotic artery connects the bilateral superior thyroid arteries. Below and in front are the pretracheal fascia, inferior thyroid veins, thymic remnants and the arteria thyroidea ima (when it exists). In children, the brachiocephalic artery crosses obliquely in front of the trachea at or a little above the upper border of the manubrium. The left brachiocephalic vein may also rise a little above this level. The oesophagus lies posterior to the trachea and separates it from the vertebral column. The paired lobes of the thyroid gland, which descend to the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries all lie lateral to the trachea. The recurrent laryngeal nerves ascend on each side, in or near the grooves between the sides of the trachea and oesophagus.

Vascular supply and lymphatic drainage The cervical part of the trachea is mainly supplied by branches from the inferior thyroid arteries. The tracheal veins drain into the brachiocephalic veins via the inferior thyroid plexus, and lymphatic vessels drain into the pretracheal and paratracheal nodes.

Innervation The trachea is innervated by branches from the vagi, recurrent laryngeal nerves and sympathetic trunks.

Surgical airway The trachea may be accessed directly in the neck via cricothyroidotomy or tracheostomy. There are numerous indications for performing an elective tracheostomy. They include the need to provide prolonged intubation and pulmonary toilet, and to manage acute airway obstruction from supraglottic or glottic pathology or trauma (e.g. mid-face, mandibular or laryngeal fractures).

For detailed descriptions of the operative procedures, appropriate surgical texts should be consulted. It is worth emphasizing here, however, the importance of understanding the relevant regional anatomy. In creating a surgical airway, potential hazards can be avoided by dissecting in the midline. In the midline, the isthmus of the thyroid gland, which normally overlies the second and third tracheal rings, should be divided. Careful haemostasis minimizes the risk of catastrophic postoperative bleeding. A high bifurcation of the brachiocephalic trunk, or aberrant anterior jugular veins (which usually lie between the midline and anterior border of sternocleidomastoid) are additional anatomical complications (Ger and Evans 1993, Jarvis 1966, Racic et al 2005).

Cricothyroidotomy endangers the cricothyroid artery (a branch of the superior thyroid artery), which is usually found close to the midline, and which reaches the median cricothyroid ligament close to the thyroid cartilage.

## SKIN

The scalp and buccolabial tissues are described here. The structure of the eyelids is discussed on page 680 .

#### Abstract

SCALP The scalp extends from the top of the forehead in front to the superior nuchal line behind. Laterally, it projects down to the zygomatic arch and external acoustic meatus. It consists of five layers: skin, subcutaneous tissue, occipitofrontalis (epicranius) and its aponeurosis, subaponeurotic loose areolar tissue and periosteum of the skull (pericranium).

The skin of the scalp is hairy and rich in sebaceous glands; it is the most common site for sebaceous cysts. The dense subcutaneous connective tissue has the richest cutaneous blood supply in the body. The anterior and posterior muscular bellies of occipitofrontalis are connected by a tough, fibrous, epicranial aponeurosis, and this layer is therefore often called the aponeurotic layer (galea aponeurotica). These three upper layers of the scalp can easily slide on the underlying layer of loose connective tissue. A scalp flap can be raised within the plane between the galea and the pericranium without compromising either the blood or the nerve supply of the scalp because all of these structures lie in the subcutaneous layer (superficial fascia). Anteriorly based subgaleal scalp flaps (bicoronal) provide excellent access to the craniofacial skeleton for the correction of congenital deformity such as craniosynostoses; treatment of craniofacial fractures involving the frontal bone, nasoethmoidal complex, orbit or zygomatic arch; skull-base surgery; or craniotomies. Pericranial flaps can be used to separate the frontal sinus floor from the nasal cavity in the management of fractures of the posterior wall of the frontal sinus (frontal sinus cranialization). Traumatic scalp avulsion may occur if hair becomes trapped in moving machinery or a shearing force is applied in the subgaleal plane during a road traffic accident or fall injury.

The arterial blood supply to the scalp is particularly rich, and there are free anastomoses between branches of the occipital and superficial temporal vessels. Scalp lacerations continue to bleed profusely because the elastic fibres of the underlying galea aponeurotica prevent initial vessel retraction. Their repair requires a two-layer closure technique to approximate the galea aponeurotica and skin layers. The pericranial layer, if involved, cannot usually be closed because it retracts.

## EYEBROWS

The eyebrows are two arched eminences of skin that surmount the orbits. Numerous short, thick hairs are set obliquely in them. Fibres of orbicularis oculi, corrugator and the frontal part of occipitofrontalis are inserted into the dermis of the eyebrows.

## BUCCOLABIAL TISSUE

## Cheeks

The cheeks are continuous in front with the lips. The external junction is indicated by the nasolabial groove (sulcus) and further laterally by the nasolabial fold, which descends from the side of the nose to the angle of the mouth. The cheek is covered on the outer surface by skin and on the inner surface by mucosa. Each cheek contains the buccinator muscle, and a variable, but usually considerable, amount of adipose tissue, which is often encapsulated to form a biconcave mass, the buccal fat pad (of Bichat), particularly evident in infants. The walls of the cheek also contain fibrous connective tissue, vessels, nerves and numerous
small buccal mucous (salivary) glands. The buccal fat pad can be used to reconstruct small intraoral defects of the palate and buccal and retromolar regions following surgery.

## Lips

The lips are two fleshy folds surrounding the oral orifice. The centre of each lip contains a thick fibrous strand, consisting of parallel bundles of skeletal muscle fibres (orbicularis oris, together with incisivus superior and inferior, and the direct labial tractors), and their attachments to skin, mucosa or other muscle fibres. The free external surface of each lip is covered by a thin keratinized epidermis, and is continuous with the mucosa at the vermilion (red) zone of the lip. The dermis is well vascularized and contains numerous hair follicles (many of them large in the male), sebaceous glands (Fordyce spots) and sweat glands. Subcutaneous adipose tissue is scanty. The internal mucous surfaces are lined with a thick, non-keratinizing, stratified squamous epithelium. The submucosa is well vascularized and contains numerous minor salivary glands, which may be harvested for histological confirmation of Sjögren's connective tissue disease.

Between the skin and mucosa, the vermilion zone is covered with a specialized keratinized stratified squamous epithelium, which is thin near the skin, increases in thickness slightly as the mucosa is approached, and then thickens abruptly when true mucosa is reached. The epithelium is covered with transparent, dead squames and its deep surface is highly convoluted, interdigitating with abundant long dermal papillae. The latter carry a rich capillary plexus that imparts a dusky red colour. These surfaces are hairless, their dermis lacks sebaceous, sweat or mucous glands, and they are moistened with saliva by the tip of the tongue. The dense innervation of the lips is reflected in their acute sensitivity to light touch sensation, attributable mainly to the increased density of Meissner's corpuscles (see Fig 3.27) in the dermal papillae.

The size and curvature of the exposed red-lip surfaces is subject to considerable individual, gender and ethnic variation. The attainment of adult dimensions is faster in the upper than in the lower lip; the cutaneous upper lip height normally reaches its adult size at the age of 3 years in females and 6 years in males (Farkas et al 1992). In children, all lip dimensions (distances, areas, volumes) are larger in boys than in girls (Ferrario et al 2000). Upper lip length is significantly shorter in females than in males and follows the growth pattern of the upper airway. Growth plateaus between the ages of 6 and 9 years, increases again from 9 to 16 years, and plateaus between 16 and 18 years (Gonçalves et al 2011).

The line of contact between the lips, the oral fissure, lies just above the incisal edges of the anterior maxillary teeth. On each side, a labial commissure forms the angle (corner) of the mouth, usually near the first premolar tooth. The labial epithelia and internal tissues radiate over the boundaries of the commissure to become continuous with those of the cheek. With age, buccolabial (labiomarginal) grooves appear at the corners of the mouth. On each side, the upper lip is separated from the cheek laterally by the nasolabial groove and is continuous above the nasal ala with the circumalar groove (sulcus). The lower lip is separated from the chin by the mentolabial groove (sulcus).

Externally, the central region of the upper lip presents a shallow vertical groove, the philtrum, which is limited above by its attachment to the columella of the nose, and ends below in a slight tubercle limited by lateral ridges. The lower lip shows a small depression in the midline that corresponds to the tubercle. The junction between the external, hair-bearing skin and the red, hairless surface of the upper lip almost invariably takes the form of a double-curved Cupid's bow. From the centre, it rises rapidly on each side to an apex that corresponds to the lower end of each ridge of the philtrum, and then slopes gently downwards towards the angle of the mouth. The line of contact between the red-lip surfaces is typically almost horizontal. The Cupid's bow is interrupted in cleft lip anomalies.

Fig. 30.1 The distribution of relaxed skin tension lines (Kraissl's lines). A, Lateral view. B, Anterior view.

In the upper lip, a narrow band of smooth tissue related to the subnasal maxillae marks the point at which labial mucosa becomes continuous with gingival mucosa. The corresponding reflexion in the lower lip coincides approximately with the mentolabial sulcus, and here the lip is continuous with mental tissues. The upper and lower lips differ in cross-sectional profile in that neither is a simple fold of uniform thickness. The upper lip has a bulbous asymmetrical profile: the skin and red-lip have a slight external convexity, and the adjoining red-lip and mucosa a pronounced internal convexity, creating a mucosal ridge or shelf that can be wrapped around the incisal edges of the parted teeth. The lower lip is on a more posterior plane than the upper lip. In the position of neutral lip contact, the external surface of the lower lip is concave and there is little or no elevation of the internal mucosal surface. The profile of the lips can be modified by muscular activity.

## RELAXED SKIN TENSION LINES AND SKIN FLAPS ON THE FACE

The direction in which facial skin tension is greatest varies regionally. Skin tension lines, which follow the furrows formed when the skin is relaxed, are known as 'relaxed skin tension lines' (Borges and Alexander 1962). In the living face, these lines frequently (but not always) coincide with wrinkle lines (Fig. 30.1) and can therefore act as a guide in planning elective incisions.

When lesions on the face, such as scars, pigmented lesions and skin cancers, are excised, the dimensions of these lesions often require excision as an ellipse, so that the resulting defect can be closed as a straight line. If the resulting scar is to be aesthetically acceptable, it is important to make the long axis of the ellipse parallel to the natural relaxed skin tension lines, so that the scar will look like a natural skin crease. If the excision line runs contrary to the skin tension lines, the scar may be more conspicuous and will tend to stretch transversely as a result of natural expressive facial movements.

When larger lesions are excised, it may be necessary to advance or rotate adjacent soft tissue to fill the defect. The ability to raise these skin flaps is entirely dependent on the regional blood supply, and both random pattern and axial pattern skin flaps are used surgically. Because of the richness of the subdermal plexus in the face, random pattern flaps can be raised with a greater length:breadth ratio than in any other area of the body.

The following are examples of axial pattern flaps that can be used to reconstruct defects on the face and scalp. Supratrochlear/supraorbital arteries support forehead flaps that are useful for nasal reconstruction; there is usually enough skin laxity to allow the majority of the donor site to be closed directly. The frontal branch of the superficial temporal artery anastomoses in the midline with its opposite number, and consequently the entire forehead skin can be raised on a narrow pedicle based on just one of the superficial temporal arteries. These flaps can be used to repair many facial defects and also intraoral defects, but the donor site defect cannot be closed directly and must be covered by a skin graft. The parietal branch of the superficial temporal artery and the
occipital artery can support hair-bearing flaps from the scalp, which are useful for reconstructing defects involving the scalp. The nasolabial flap utilizes the lax skin just lateral to the nasolabial groove. It is not supplied by a named axial artery but rather its blood supply is provided by many small branches from the underlying facial artery. These branches run perpendicular to the skin surface. Nasolabial flaps can be either superiorly or inferiorly based.

## SOFT TISSUE

## FASCIAL LAYERS

## Fascia of scalp

The superficial fascia of the scalp is firm, dense and fibroadipose, and adheres closely to both skin and the underlying epicranius and its aponeurosis. Posteriorly, it is continuous with the superficial fascia of the back of the neck; laterally, it is prolonged into the temporal region, where it is looser in texture.

## Fascial layers and tissue planes in the face

On the basis of gross dissection and complementary histological studies, four distinct tissue planes are recognized on the face superficial to the plane of the facial nerve and its branches. From superficial to deep, these layers are the skin; a subcutaneous layer of fibroadipose tissue; the superficial musculo-aponeurotic system (SMAS); and the parotid-masseteric fascia.

## Subcutaneous fibroadipose tissue

This homogeneous layer is present throughout the face, although the degree of adiposity varies in different parts of the face and with age. Anteriorly, it crosses the nasolabial fold on to the lip; superiorly, it crosses the zygomatic arch. In both locations, the layer is more fascial than fatty. The fat content of the subcutaneous tissue in the cheek accounts for the cheek mass; part of the subcutaneous adipose tissue is the malar fat pad, a more or less discrete aggregation of fatty tissue inferolateral to the orbital margin.

## Superficial musculo-aponeurotic system (SMAS)

This is described as a single tissue plane in the face. In some areas, it is composed of muscle fibres, and elsewhere it is composed of fibrous or fibroaponeurotic tissue; it is not directly attached to bone. When traced below the level of the lower border of the mandible, it becomes continuous with platysma in the neck. Microdissection has revealed that the superficial musculo-aponeurotic system becomes indistinct on the lateral aspect of the face approximately 1 cm below the level of the zygomatic arch. Anteromedially, the superficial musculo-aponeurotic system layer becomes continuous with some of the mimetic muscles,
including zygomaticus major, frontalis and the periorbital fibres of orbicularis oculi (Yousif and Mendelson 1995).

In most areas of the face, a distinct sub-superficial musculoaponeurotic system plane can be defined deep to the superficial musculo-aponeurotic system. It is continuous with the plane between platysma and the underlying investing layer of deep cervical fascia in the neck. However, where it overlies the parotid gland, the superficial musculo-aponeurotic system is firmly blended with the superficial layer of the parotid fascia, which means that a clear sub-superficial musculoaponeurotic system plane is difficult, if not impossible, to define in the region of the parotid.

## Parotid-masseteric fascia

This is a thin, translucent and tough fascial layer that covers the parotid duct and the buccal branch of the facial nerve and interconnecting branches from the mandibular nerve as these structures all lie on the surface of masseter. Further anteriorly, the parotid-masseteric fascia overlies the buccal fat pad lying superficial to buccinator. Having crossed the surface of the buccal fat pad, the fascia blends with the epimysium on the surface of buccinator. It is continuous with the investing layer of deep cervical fascia below the lower border of the mandible.

## Parotid fascia (capsule)

The parotid gland is surrounded by a fibrous capsule called the parotid fascia or capsule. Traditionally, this has been described as an upward continuation of the investing layer of deep cervical fascia in the neck, which splits to enclose the gland within a superficial and a deep layer. The superficial layer is attached above to the zygomatic process of the temporal bone, the cartilaginous part of the external acoustic meatus, and the mastoid process. The deep layer is attached to the mandible, and to the tympanic plate, styloid and mastoid processes of the temporal bone. The prevailing view is that the deep layer of the parotid capsule is derived from the deep cervical fascia. However, the superficial layer of the parotid capsule appears to be continuous with the fascia associated with platysma, and is now regarded as a component of the superficial musculo-aponeurotic system (Mitz and Peyronie 1976, Wassef 1987, Gosain et al 1993). It varies in thickness from a thick fibrous layer anteriorly to a thin translucent membrane posteriorly. It may be traced forwards as a separate layer which passes over the masseteric fascia (itself derived from the deep cervical fascia), separated from it by a cellular layer that contains branches of the facial nerve and the parotid duct. Histologically, the parotid fascia is atypical in that it contains muscle fibres that parallel those of platysma, especially in the lower part of the parotid capsule. Although thin fibrous septa may be seen in the subcutaneous layer at the histological level, macroscopically there is little evidence of a distinct layer of superficial fascia.

The deep fascia covering the muscles forming the parotid bed (digastric and styloid group of muscles) contains the stylomandibular and mandibulostylohyoid ligaments. The stylomandibular ligament passes from the styloid process to the angle of the mandible. The more extensive mandibulostylohyoid ligament (angular tract) passes between the angle of the mandible and the stylohyoid ligament for varying distances, generally reaching the hyoid bone. It is thick posteriorly but thins anteriorly in the region of the angle of the mandible. There is some dispute as to whether the mandibulostylohyoid ligament is part of the deep cervical fascia (Ziarah and Atkinson 1981) or lies deep to it (Shimada and Gasser 1988). The stylomandibular and mandibulostylohyoid ligaments separate the parotid gland region from the superficial part of the submandibular gland, and so are landmarks of surgical interest.

## Temporoparietal and temporal fasciae

Above the level of the zygomatic arch, on the lateral side of the head, the temporoparietal fascia (superficial temporal fascia) constitutes a fascial layer that lies in the same plane as, but is not continuous with, the superficial musculo-aponeurotic system. It is quite separate from, and superficial to, the temporal fascia (deep temporal fascia). More superiorly, it blends with the galea aponeurotica. The plane between the temporoparietal fascia and the underlying deep temporal fascia contains loose areolar tissue and a small amount of fat. This tissue plane, the temporoparietal fat pad, is continuous superiorly with the subgaleal plane of loose areolar tissue in the scalp. Running superiorly in the temporoparietal fascia or just deep to it are the superficial temporal vessels, the auriculotemporal nerve and its branches, and the temporal branches of the facial nerve. When raising a bicoronal flap, identification of the temporoparietal fat pad helps to separate these two fascial layers; subsequent dissection in a plane deep to the temporoparietal fascia protects the temporal branch of the facial nerve. The
temporal fascia is a dense aponeurotic layer that lies deep to the temporoparietal fat pad and covers temporalis; the deep surface of the fascia affords attachment to the superficial fibres of temporalis. Above, it is a single layer attached along the length of the superior temporal line, blending with the periosteum. Below, at approximately the level of the superior orbital rim, it splits into superficial and deep laminae that run downwards to attach to the lateral and medial margins of the upper surface of the zygomatic arch, respectively. These fascial attachments have a clinical application in the reduction of fractures of the zygomatic complex via a Gillies approach: an instrument is inserted deep to the deep lamina of temporalis fascia through a scalp incision and used to elevate depressed zygomatic complex fractures. The fat enclosed between these two layers is termed the superficial temporal fat pad; it contains the zygomatico-orbital branch of the superficial temporal artery and a cutaneous nerve, the zygomaticotemporal branch of the maxillary nerve. The temporal fascia is overlapped by auriculares anterior and superior, the epicranial aponeurosis and part of orbicularis oculi, and the superficial temporal vessels and auriculotemporal nerve ascend over it.

## Buccopharyngeal fascia

Buccinator is covered by a thin layer of fascia, the buccopharyngeal fascia, which also covers the superior constrictor of the pharynx (Ch. 34).

## Retaining ligaments of the face

These ligaments are fascial bands at specific sites, which serve to anchor the skin to the underlying bone. The general cutaneous laxity that attends the ageing process (Commentary 4.3) renders facial skin subject to gravitational pull. However, at sites where retaining ligaments are present, the effect of gravitational pull is resisted. When performing facelift procedures, these ligaments must be surgically divided in order to facilitate redraping of facial skin. Examples of retaining ligaments in the face are the zygomatic ligament (also known as McGregor's patch) and the mandibular ligament.

## Fascial spaces

Two tissue spaces on the face may be involved in the spread of odontogenic infection. They are the buccal tissue space, lying between the skin and the surface of buccinator, and the infraorbital tissue space, lying between the bony attachments of levator labii superioris and levator anguli oris.

## BONES OF THE FACIAL SKELETON AND CRANIAL VAULT

The facial skeleton is the anterior part of the skull and includes the mandible. The bones of the nasoethmoidal and zygomaticomaxillary complexes are described here. The mandible is described in Chapter 32.

## PARIETAL BONE

The two parietal bones form most of the cranial roof and sides of the skull. Each is irregularly quadrilateral and has two surfaces, four borders and four angles (Fig. 30.2).

The external surface is convex and smooth, with a central parietal tuber (tuberosity). Curved superior and inferior temporal lines cross it and form posterosuperior arches. The temporal fascia is attached to the superior line or arch, and temporalis is attached to the inferior line or arch. The epicranial aponeurosis lies above these lines, and part of the temporal fossa lies below. Posteriorly, close to the sagittal (superior) border, an inconstant parietal foramen transmits a vein from the superior sagittal sinus and sometimes a branch of the occipital artery.

The internal surface is concave and marked by impressions of cerebral gyri and by grooves for the middle meningeal vessels. The latter ascend, inclining backwards, from the sphenoidal (anteroinferior) angle and posterior half (or more) of its inferior border. A groove for the superior sagittal sinus lies along the sagittal border and is completed by the groove on the opposite parietal bone. The falx cerebri is attached to the edges of the groove. Granular foveolae for arachnoid granulations flank the sagittal sulcus and are most pronounced in old age.

The dentated sagittal border, longest and thickest, articulates with the opposite parietal bone at the sagittal suture. The anterior part of the squamosal (inferior) border is short, thin and truncated, bevelled externally and overlapped by the greater wing of the sphenoid. The middle part of the inferior border is arched, bevelled externally and overlapped

Fig. 30.2 The left parietal bone. A, External view. B, Internal view.
by the squamous part of the temporal bone. The posterior part of the inferior border is short, thick and serrated for articulation with the mastoid part.

The frontal border is deeply serrated, bevelled externally above and internally below, and articulates with the frontal bone to form one half of the coronal suture. The occipital border, deeply dentated, articulates with the occipital bone, forming one half of the lambdoid suture.

The frontal (anterosuperior) angle, which is approximately $90^{\circ}$, is at the bregma, where sagittal and coronal sutures meet, and marks the site of the anterior fontanelle in the neonatal skull. The sphenoidal (anteroinferior) angle lies between the frontal bone and greater wing of the sphenoid. Its internal surface is marked by a deep groove or canal that carries the frontal branches of the middle meningeal vessels. The frontal, parietal, sphenoid and temporal bones usually meet at the pterion, which marks the site of the sphenoidal fontanelle in the embryonic skull. The frontal bone sometimes meets the squamous part of the temporal bone, in which case the parietal bone fails to reach the greater wing of the sphenoid bone. The rounded occipital (posterosuperior) angle is at the lambda, the meeting of the sagittal and lambdoid sutures, which marks the site of the posterior fontanelle in the neonatal skull. The blunt mastoid (posteroinferior) angle articulates with the occipital bone and the mastoid portion of the temporal bones at the asterion. Internally, it bears a broad, shallow groove for the junction of the transverse and sigmoid sinuses.

## Ossification

Each parietal bone is ossified from two centres that appear in dense mesenchyme near the tuberosity, one above the other, at about the seventh week in utero. These two centres unite early and ossification
subsequently radiates from them towards the margins. The angles are therefore the last parts to be ossified, and fontanelles occur at these sites. At birth, the temporal lines are low down; they only reach their final position after the eruption of the molar teeth. Occasionally, the parietal bone is divided by an anteroposterior suture.

## FRONTAL BONE

The frontal bone is like half of a shallow, irregular cap forming the forehead or frons (Fig. 30.3). It has three parts and contains two cavities, the frontal sinuses.

## Squamous part

The squamous part forms the major portion of the frontal bone. Its external surface has a rounded frontal tuber (tuberosity) approximately 3 cm above the midpoint of each supraorbital margin. These tubera vary, but are especially prominent in young skulls and more so in adult females than males. Below them, and separated by a shallow groove, are two curved superciliary arches, medially prominent and joined by a smooth median elevated glabella. The arches are more prominent in males; prominence depends partly on the size of the frontal sinuses, but is occasionally associated with small sinuses. The curved supraorbital margins of the orbital openings lie inferior to the superciliary arches. The lateral two-thirds of each margin are sharp, the medial third rounded; a supraorbital notch or foramen, which transmits the supraorbital vessels and nerve, lies at the junction between them. A small frontal notch or foramen lies medial to the supraorbital notch in half of skulls. Both features show sexual dimorphism. The supraorbital

Fig. 30.3 The frontal bone. A, Anterior view. B, Inferior view, including the articulations between the frontal, ethmoid and nasal bones. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
margin ends laterally in a strong, prominent zygomatic process that articulates with the zygomatic bone. A line curves posterosuperiorly from the process and divides into superior and inferior temporal lines, which are continued on the squamous part of the temporal bone. The area of the frontal bone below and behind the temporal lines is known as the temporal surface and forms the anterior part of the temporal fossa. The parietal (posterior) margin is thick, deeply serrated, and bevelled internally above and externally below. Inferiorly, it becomes a rough, triangular surface that articulates with the greater wing of the sphenoid.

The internal surface of the frontal bone is concave. Its upper, median, part displays a vertical sulcus whose edges unite below as the frontal crest. The sulcus contains the anterior part of the superior sagittal sinus. The crest ends in a small notch that is completed by the ethmoid bone to form a foramen caecum. The anterior portion of the falx cerebri is attached to the margins of the sulcus and to the frontal crest. The internal surface shows impressions of cerebral gyri, small furrows for meningeal vessels, and granular foveolae for arachnoid granulations near the sagittal sulcus.

## Nasal part

The nasal part of the frontal bone lies between the supraorbital margins. A serrated nasal notch articulates with the nasal bones inferiorly and with the frontal processes of the maxillae and the lacrimal bones
laterally. From the centre of the notch posteriorly, the bone projects anteroinferiorly behind the nasal bones and the frontal processes of the maxillae, and supports the nasal bridge. The region ends in a sharp nasal spine, on each side of which a small grooved surface partly roofs the ipsilateral nasal cavity. The nasal spine makes a very small contribution to the nasal septum; it articulates anteriorly with the crest of the nasal bones and posteriorly with the perpendicular plate of the ethmoid bone.

## Orbital parts

Most of the frontal bone is thick and consists of trabecular tissue lying between two compact laminae. In contrast, the orbital plates consist entirely of compact bone and are thin and often translucent posteriorly; indeed, they may be partly absorbed in old age.

The orbital plates form the largest part of the orbital roofs and are two thin, curved, triangular laminae separated by a wide ethmoidal notch. The orbital surface of each plate is smooth and concave, and bears a shallow anterolateral fossa for the lacrimal gland. The trochlear fovea (or spine) for attachment of a fibrocartilaginous trochlea, through which the tendon of superior oblique plays, lies below and behind the medial end of the supraorbital margin, midway between the supraorbital notch and frontolacrimal suture. The convex cerebral surface is marked by frontal gyri and faint grooves for meningeal vessels.

The quadrilateral ethmoidal notch is occupied by the cribriform plate of the ethmoid bone. Inferior to its lateral margins, the bone articulates with the labyrinths of the ethmoid bone, and impressions of the ethmoidal air cells can be seen on this surface. Two transverse grooves across each margin are converted into anterior and posterior ethmoidal canals by articulation with the ethmoid bone; these canals open on the medial orbital wall and transmit the anterior and posterior ethmoidal nerves and vessels. The posterior borders of the orbital plates are thin and serrated, and articulate with the lesser wings of the sphenoid; their lateral parts usually appear in the middle cranial fossa between the greater and lesser wings of the sphenoid.

The frontal sinuses are two irregular cavities that ascend posterolaterally for a variable distance between the frontal laminae. They are separated by a thin septum and usually deflected from the median plane, which means that they are rarely symmetrical. The sinuses are variable in size and usually larger in males. Their openings lie anterior to the ethmoidal notch and lateral to the nasal spine, and each communicates with the middle meatus in the ipsilateral nasal cavity by a frontonasal canal.

The frontal sinuses are rudimentary at birth and can barely be distinguished. They show a primary expansion with eruption of the first deciduous molars at about 18 months, and again when the permanent molars begin to appear in the sixth year. Growth is slow in the early years but it can be detected radiographically by 6 years. They reach full size after puberty, although, with advancing age, osseous absorption may lead to further enlargement. Their degree of development appears to be linked to the prominence of the superciliary arches, which is thought to be a response to masticatory stresses. The frontal sinuses are described on page 566

## Ossification

The frontal bone is ossified in fibrous mesenchyme from two primary centres that appear in the eighth week in utero, one near each frontal tuber. Ossification extends superiorly, to form half of the main part of the bone; posteriorly, to form the orbital part; and inferiorly, to form nasal parts. Two secondary centres for the nasal spine appear about the tenth year. At birth, the bone consists of two halves. The median suture usually closes in the first postnatal year, but may persist as the metopic suture in a small percentage of individuals in various ethnic groups (see Fig. 27.6A).

## ETHMOID BONE

The ethmoid bone is cuboidal and fragile (see Fig. 30.3B; Figs 30.430.6). It lies anteriorly in the cranial base and contributes to the medial
walls of the orbit, the nasal septum, and the roof and lateral walls of the nasal cavity. It has a horizontal perforated cribriform plate, a median perpendicular plate, and two lateral labyrinths that contain the ethmoidal air cells.

## Cribriform plate and crista galli

The cribriform plate fills the ethmoidal notch of the frontal bone and forms a large part of the nasal roof. It derives its name from the fact that it is penetrated by numerous foramina that transmit branches of the olfactory nerves and their associated meninges. A thick, smooth, triangular, median process, the crista galli, projects upwards from the centre of the cribriform plate. The falx cerebri is attached to its thin and curved posterior border, while its shorter, thick, anterior border articulates with the frontal bone by two small alae, so completing the foramen caecum. Its sides are generally smooth, but may show slight bulges that are related to underlying ethmoidal air cells. On both sides of the crista galli, the cribriform plate is narrow and depressed, and is related to the gyrus rectus and the olfactory bulb, which lie above it. On each side of the crista anteriorly, there is a small slit occupied by dura mater. Just anterolateral to the slit, a foramen transmits the anterior ethmoidal nerve and vessels to the nasal cavity. A groove runs forwards to the foramen caecum from the anterior ethmoidal canal.

## Perpendicular plate

The perpendicular plate is thin, flat, quadrilateral and median. It descends from the cribriform plate to form the upper part of the nasal septum, usually deviating slightly from the midline. Its anterior border articulates with the nasal spine of the frontal bone and the crests of the nasal bones, and its posterior border articulates with the crest of the body of the sphenoid bone above and the vomer below. The thick inferior border is attached to the nasal septal cartilage. Its surfaces are smooth, except for above, where numerous grooves and canals that transmit filaments of the olfactory nerves lead to medial foramina in the cribriform plate.

## Ethmoidal labyrinths

The ethmoidal labyrinths consist of thin-walled ethmoidal air cells between two vertical plates. The lateral surface (orbital plate) of the labyrinth is part of the medial orbital wall. The air cells are arranged in anterior, middle and posterior groups. On average, there are 11 anterior ethmoidal air cells, three middle and six posterior. In the disarticulated bone, many air cells are open, but in life, and in the articulated skull, they are closed by proximity to adjoining bones, except where they

Fig. 30.4 A sagittal view of the facial skeleton, viewed from the right side of the nasal septum, looking towards the left. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

B

* Probe located in the passage from the frontal sinus to the middle meatus

Fig. 30.5 A, B, Sagittal views of the facial skeleton, showing the floor of the anterior cranial fossa, the lateral wall of the nasal cavity, the hard palate and the sphenoidal air sinus. In B, the middle concha in the lateral wall of the nasal cavity has been removed to reveal the uncinate process. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
open into the nasal cavity. The superior surface is crossed by two grooves that are converted into the anterior and posterior ethmoidal canals by the frontal bone; it shows open air cells that are covered by the edges of the ethmoidal notch of the frontal bone. On the posterior surface, open air cells are covered by the sphenoidal conchae and the orbital process of the palatine bone. The middle and posterior ethmoidal air cells are covered by a thin, smooth, oblong orbital plate that articulates superiorly with the orbital plate of the frontal bone, inferiorly with the maxilla and orbital process of the palatine bone, anteriorly with the lacrimal bone, and posteriorly with the sphenoid bone. The walls of the
air cells lying anterior to the orbital plate are completed by the lacrimal bone and frontal process of the maxilla.

A thin, curved uncinate process, variable in size, projects posteroinferiorly from the labyrinth. The upper edge of this process is a medial boundary of the hiatus semilunaris in the middle meatus. The uncinate process appears in the medial wall of the maxillary sinus as it crosses the ostium of the maxillary sinus to join the ethmoidal process of the inferior nasal concha.

The medial surface of the labyrinth forms part of the lateral nasal wall. It appears as a thin lamella that descends from the inferior surface

Fig. 30.6 A, A sagittal view of the facial skeleton, showing the bones forming the lateral wall of the left orbit and the maxillary air sinus. $\mathbf{B}$, The bones forming the medial wall and the floor of the left orbit. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
of the cribriform plate and ends as the convoluted middle nasal concha. Superiorly, the surface contains numerous vertical grooves that transmit bundles of olfactory nerves. Posteriorly, it is divided by the narrow, oblique superior meatus, bounded above by the thin, curved superior nasal concha. Posterior ethmoidal air cells open into the superior meatus. The convex surface of the middle nasal concha extends along the entire medial surface of the labyrinth, anteroinferior to the superior meatus. Its lower edge is thick, and its lateral surface is concave and forms part of the middle meatus. Middle ethmoidal air cells produce a swelling, the bulla ethmoidalis, on the lateral wall of the middle meatus, and open into the meatus, either on the bulla or above it. A curved infundibulum extends up and forwards from the middle meatus and communicates with the anterior ethmoidal sinuses. In more than half of crania it continues up as the frontonasal duct to include the
drainage point for the frontal sinus. (The ethmoidal air cells are described further on page 568.)

## Ossification

The ethmoid bone ossifies in the cartilaginous nasal capsule from three centres: one in the perpendicular plate, and one in each labyrinth. The latter two appear in the orbital plates between the fourth and fifth months in utero, and extend into the ethmoidal conchae. At birth, the labyrinths, although ill-developed, are partially ossified, and the remainder are cartilaginous. The perpendicular plate begins to ossify from the median centre during the first year, and fuses with the labyrinths early in the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinths. The crista
galli ossifies during the second year. The parts of the ethmoid bone unite to form a single bone at around 3 years of age. Ethmoidal air cells begin to develop at about 3 months in utero, and are therefore present at birth; however, they are difficult to visualize radiographically until the end of the first year. They grow slowly and have almost reached adult size by the age of 12 years.

## INFERIOR NASAL CONCHA

The inferior nasal conchae are curved horizontal laminae in the lateral nasal walls (see Fig. 30.5). Each has two surfaces (medial and lateral), two borders (superior and inferior) and two ends (anterior and posterior). The medial surface is convex, much perforated, and longitudinally grooved by vessels. The lateral surface is concave and part of the inferior meatus. The superior border, thin and irregular, may be divided into three regions: an anterior region articulating with the conchal crest of the maxilla; a posterior region articulating with the conchal crest of the palatine bone; and a middle region with three processes, which are variable in size and form. The lacrimal process is small and pointed, and lies towards the front. It articulates apically with a descending process from the lacrimal bone, and at its margins with the edges of the nasolacrimal groove on the medial surface of the maxilla, thereby helping to complete the nasolacrimal canal. Most posteriorly, a thin ethmoidal process ascends to meet the uncinate process of the ethmoid bone. An intermediate thin maxillary process curves inferolaterally to articulate with the medial surface of the maxilla at the opening of the maxillary sinus. The inferior border is thick and spongiose, especially in its mid part. Both the anterior and posterior ends of the inferior nasal concha are more or less tapered, the posterior more so than the anterior.

## Ossification

Ossification is from one centre that appears at about the fifth month in utero in the incurved lower border of the cartilaginous lateral wall of the nasal capsule. The inferior concha loses continuity with the nasal capsule during ossification.

## LACRIMAL BONE

The lacrimal bones are the smallest and most fragile of the cranial bones and lie anteriorly in the medial walls of the orbits (see Figs 30.5B, 30.6B). Each has two surfaces (medial and lateral) and four borders (anterior, posterior, superior and inferior). The lateral (orbital) surface is divided by a vertical posterior lacrimal crest. Anterior to the crest is a vertical groove whose anterior edge meets the posterior border of the frontal process of the maxilla to complete the fossa that houses the lacrimal sac. The medial wall of the groove is prolonged by a descending process that contributes to the formation of the nasolacrimal canal by joining the lips of the nasolacrimal groove of the maxilla and the lacrimal process of the inferior nasal concha. A smooth part of the medial orbital wall lies behind the posterior lacrimal crest; the lacrimal part of orbicularis oculi is attached to this surface and crest. The surface ends below in the lacrimal hamulus, which, together with the maxilla, completes the upper opening of the nasolacrimal canal. The hamulus may appear as a separate lesser lacrimal bone. The anteroinferior region of the medial (nasal) surface is part of the middle meatus. Its posterosuperior part meets the ethmoid to complete some of the anterior ethmoidal air cells. The anterior border of the lacrimal bone articulates with the frontal process of the maxilla, the posterior border with the orbital plate of the ethmoid bone, the superior border with the frontal bone, and the inferior border with the orbital surface of the maxilla.

## Ossification

Ossification is from a centre that appears at about the twelfth week in utero in mesenchyme around the nasal capsule. In later life, the lacrimal bone is subject to patchy erosion.

## NASAL BONE

The nasal bones are small, oblong, variable in size and form, and placed side by side between the frontal processes of the maxillae (see Figs 30.4, 30.5, 30.6B). They jointly form the nasal bridge. Each nasal bone has two surfaces (external and internal) and four borders (superior, inferior,
lateral and mesial). The external surface has a descending concavoconvex profile and is transversely convex. It is covered by procerus and nasalis, and perforated centrally by a small foramen that transmits a vein. The internal surface, transversely concave, bears a longitudinal groove that houses the anterior ethmoidal nerve. The superior border, thick and serrated, articulates with the nasal part of the frontal bone. The inferior border, thin and notched, is continuous with the lateral nasal cartilage. The lateral border articulates with the frontal process of the maxilla. The medial border, thicker above, articulates with its fellow and projects behind as a vertical crest, thereby forming a small part of the nasal septum. It articulates from above with the nasal spine of the frontal bone, the perpendicular plate of the ethmoid bone, and the nasal septal cartilage.

## Ossification

Ossification is from a centre that appears early in the third month in utero in the mesenchyme overlying the cartilaginous anterior part of the nasal capsule.

## VOMER

The vomer is thin, flat and almost trapezoid (see Fig. 30.4). It forms the posteroinferior part of the nasal septum and presents two surfaces and four borders. Both surfaces are marked by grooves for nerves and vessels. A prominent groove for the nasopalatine nerve and vessels lies obliquely in an anteroinferior plane. The superior border is thickest, and possesses a deep furrow between projecting alae, which fits the rostrum of the body of the sphenoid bone. The alae articulate with the sphenoidal conchae, the vaginal processes of the medial pterygoid plates of the sphenoid bone, and the sphenoidal processes of the palatine bones. Where each ala lies between the body of the sphenoid and the vaginal process, its inferior surface helps to form the vomerovaginal canal. The inferior border articulates with the median nasal crests of the maxilla and palatine bones. The anterior border is the longest, and articulates in its upper half with the perpendicular plate of the ethmoid bone. Its lower half is cleft to receive the inferior margin of the nasal septal cartilage. The concave posterior border is thick and bifid above and thin below; it separates the posterior nasal apertures. The anterior extremity of the vomer articulates with the posterior margin of the maxillary incisor crest and descends between the incisive canals.

Inability to identify the vomer during antenatal ultrasound scanning in the first and early second trimesters of pregnancy has been suggested as a marker for trisomy 13 or 21, with a diagnostic accuracy of 0.985 (Mihailovic et al 2012).

## Ossification

The nasal septum is at first a plate of cartilage, part of which is ossified above to form the perpendicular plate of the ethmoid. Its anteroinferior region persists as septal cartilage. The vomer is ossified in a layer of connective tissue, which covers the cartilage posteroinferiorly on each aspect. At about the eighth week in utero, two centres appear flanking the midline, and in the twelfth week these unite below the cartilage, to form a deep groove for the nasal septal cartilage. Union of the bony lamellae progresses anterosuperiorly while the intervening cartilage is absorbed. By puberty, the lamellae are almost united, but evidence of their bilaminar origin remains in the everted alae and anterior marginal groove.

## ZYGOMATIC BONE

Each zygomatic bone forms the prominence of a cheek, contributes to the floor and lateral wall of the orbit, and the walls of the temporal and infratemporal fossae, and completes the zygomatic arch. Each is roughly quadrangular and is described as having three surfaces, five borders and two processes (Fig. 30.7).

The lateral (facial) surface is convex and is pierced near its orbital border by the zygomaticofacial foramen, which is often double and occasionally absent, and transmits the zygomaticofacial nerve and vessels. This surface gives attachment to zygomaticus major posteriorly and zygomaticus minor anteriorly. The posteromedial (temporal) surface has a rough anterior area for articulation with the zygomatic process of the maxilla, and a smooth, concave posterior area that extends up posteriorly on its frontal process as the anterior aspect of the temporal fossa. It also extends back on the medial aspect of the

Fig. 30.7 The zygomatic bone. A, Anterolateral aspect, showing muscle attachments. B, Posterolateral aspect.
temporal process as an incomplete lateral wall for the infratemporal fossa. The zygomaticotemporal foramen pierces this surface near the base of the frontal process. The smooth and concave orbital surface forms the anterolateral part of the floor and adjoining lateral wall of the orbit, and extends up on the medial aspect of its frontal process. It usually bears zygomatico-orbital foramina that represent the openings of canals leading to the zygomaticofacial and zygomaticotemporal foramina.

The smoothly concave anterosuperior (orbital) border forms the inferolateral circumference of the orbital opening, and separates the orbital and lateral surfaces of the bone. The anteroinferior (maxillary) border articulates with the maxilla. Its medial end tapers to a point above the infraorbital foramen. A part of levator labii superioris is attached at this surface. The posterosuperior (temporal) border is sinuous, convex above and concave below, and is continuous with the posterior border of the frontal process and upper border of the zygomatic arch. The temporal fascia is attached to this border. There is often a small, easily palpable, marginal tubercle below the frontozygomatic suture. The posteroinferior border is roughened for the attachment of masseter. The serrated posteromedial border articulates with the greater wing of the sphenoid bone above, and the orbital surface of the maxilla below. Between these serrated regions a short, concave, non-articular part usually forms the lateral edge of the inferior orbital fissure. Occasionally absent, the fissure is then completed by the articulation of the maxilla and sphenoid (or with a small sutural bone between them).

The frontal process, thick and serrated, articulates above with the zygomatic process of the frontal bone and behind with the greater wing of the sphenoid bone. A tubercle of varying size and form, Whitnall's tubercle, is usually present on its orbital aspect, within the orbital opening and about 1 cm below the frontozygomatic suture. This tubercle provides attachment for the lateral palpebral ligament, the suspensory ligament of the eye, and part of the aponeurosis of levator palpebrae superioris. The temporal process, directed backwards, has an oblique, serrated end that articulates with the zygomatic process of the temporal bone to complete the zygomatic arch.

## Ossification

Ossification is from one centre that appears in fibrous tissue about the eighth week in utero. The bone is sometimes divided by a horizontal suture into a larger upper and smaller lower part.

## MAXILLA

The maxillae are the largest of the facial bones, other than the mandible, and jointly form the whole of the upper jaw. Each bone forms the greater part of the floor and lateral wall of the nasal cavity, and of the floor of the orbit; contributes to the infratemporal and pterygopalatine fossae; and bounds the inferior orbital and pterygomaxillary fissures. Each maxilla has a body and four processes, namely: the zygomatic, frontal, alveolar and palatine processes (see Fig. 30.6; Fig. 30.8).

## Body

The body of the maxilla is roughly pyramidal, and has anterior, infratemporal (posterior), orbital and nasal surfaces that enclose the maxillary sinus.

## Anterior surface

This surface faces anterolaterally and displays inferior elevations overlying the roots of teeth. There is a shallow incisive fossa above the incisors to which depressor septi is attached. A slip of orbicularis oris is attached to the alveolar border below this fossa, and nasalis is attached superolateral to it. Lateral to the incisive fossa is a larger, deeper canine fossa; levator anguli oris is attached to the bone of this fossa. The incisive and canine fossae are separated by the canine eminence, which overlies the socket of the canine tooth. The infraorbital foramen lies above the fossa and transmits the infraorbital vessels and nerve. Above the foramen, a sharp border separates the anterior and orbital surfaces of the bone and contributes to the infraorbital margin. Levator labii superioris is attached here above the infraorbital foramen and levator anguli oris below it. Medially, the anterior surface ends at a deeply concave nasal notch, terminating in a pointed process that, with its contralateral fellow, forms the anterior nasal spine. Nasalis and depressor septi are attached to the anterior surface near the notch.

## Infratemporal surface

This surface is concave and faces posterolaterally, forming the anterior wall of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and a ridge (jugal crest) that ascends to it from the first molar socket. Near its centre are the openings of two or three alveolar canals, which transmit posterior superior alveolar vessels and nerves. Posteroinferior is the maxillary tuberosity, roughened superomedially where it articulates with the pyramidal process of the palatine bone. A few fibres of medial pterygoid are attached here. Above the tuberosity, the smooth anterior boundary of the pterygopalatine fossa is grooved by the maxillary nerve as it passes laterally and slightly upwards into the infraorbital groove on the orbital surface.

## Orbital surface

This surface is smooth and triangular, and forms most of the floor of the orbit. Anteriorly, its medial border bears a lacrimal notch, behind which it articulates with the lacrimal bone, the orbital plate of the ethmoid and, posteriorly, with the orbital process of the palatine bone. Its posterior border is smoothly rounded and forms most of the anterior edge of the inferior orbital fissure. The infraorbital groove lies centrally. The anterior border is part of the orbital margin, and is continuous medially with the lacrimal crest of the frontal process of the maxilla. The infraorbital groove transmits the infraorbital vessels and nerve, and begins midway on the posterior border, where it is continuous with a groove on the posterior surface. It passes forwards into the infraorbital canal, which opens on the anterior surface below the infraorbital margin. Near its midpoint, the infraorbital canal gives off a small lateral branch, the canalis sinuosus, which transmits the anterior superior alveolar nerve and vessels. The canalis sinuosus descends in the orbital floor lateral to the infraorbital canal, curves medially in the anterior wall of the maxillary sinus, and then passes below the infraorbital foramen to the margin of the anterior nasal aperture in front of the anterior end of the inferior concha. It follows the lower margin of the aperture and opens near the nasal septum in front of the incisive canal. The site of the attachment of inferior oblique may be indicated by a small depression in the bone at the anteromedial corner of the orbital surface, lateral to the lacrimal groove.

## Nasal surface

This surface displays posterosuperiorly a large, irregular maxillary hiatus that leads into the maxillary sinus. Parts of air sinuses that are

Fig. 30.8 A, The maxilla, lateral view. B, The maxilla and palatine bone, medial view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
completed by articulation with the ethmoid and lacrimal bones lie at the upper border of the hiatus. The smooth concave surface below the hiatus is part of the inferior meatus. Posteriorly, the surface is roughened where it articulates with the perpendicular plate of the palatine bone. This surface is traversed by a groove that descends forwards from the mid-posterior border, and is converted into a greater palatine canal by the perpendicular plate. Anterior to the hiatus, a deep nasolacrimal groove, continuous above with the lacrimal groove, makes up about two-thirds of the circumference of the nasolacrimal canal. The rest is contributed by the descending part of the lacrimal bone and the lacrimal process of the inferior nasal concha. This canal conveys the nasolacrimal duct to the inferior meatus. More anteriorly, an oblique conchal crest articulates with the inferior nasal concha. The concavity below it is part of the inferior meatus, while the surface above it is part of the atrium of the middle meatus.

## Zygomatic process

Anterior, infratemporal and orbital surfaces of the maxilla converge at a pyramidal projection, the zygomatic process. Anteriorly, the process merges into the facial surface of the body of the maxilla. Posteriorly, it is concave and continuous with the infratemporal surface. Superiorly, it is roughly serrated for articulation with the zygomatic bone. Inferiorly, a bony arched ridge, the zygomatico-alveolar ridge or jugal crest, separates the facial (anterior) and infratemporal surfaces.

## Frontal process

The frontal process projects posterosuperiorly between the nasal and lacrimal bones. Its lateral surface is divided by a vertical anterior
lacrimal crest, which gives attachment to the medial palpebral ligament and is continuous below with the infraorbital margin. A small, palpable tubercle at the junction of the crest and orbital surface is a guide to the lacrimal sac. The smooth area anterior to the lacrimal crest merges below with the anterior surface of the body of the maxilla. Parts of orbicularis oculi and levator labii superioris alaeque nasi are attached here. Behind the crest, a vertical groove combines with a groove on the lacrimal bone to complete the lacrimal fossa. The medial surface is part of the lateral nasal wall. A rough subapical area articulates with the ethmoid, and closes anterior ethmoidal air cells. Below this, an oblique ethmoidal crest articulates posteriorly with the middle nasal concha, and anteriorly underlies the agger nasi, a ridge anterior to the concha on the lateral nasal wall. The ethmoidal crest forms the upper limit of the atrium of the middle meatus. The frontal process articulates above with the nasal part of the frontal bone. Its anterior border articulates with the nasal bone and its posterior border articulates with the lacrimal bone.

## Alveolar process

The alveolar process is thick and arched, wide behind, and socketed for the roots of the upper teeth. The eight sockets on each side vary according to the tooth type. The socket for the canine is deepest, the sockets for the molars are widest and subdivided into three by septa, those for the incisors and second premolar are single, and that for the first premolar is usually double. Buccinator is attached to the external alveolar aspect as far forwards as the first molar. In articulated maxillae, the processes form the alveolar arch. Occasionally, a variably prominent maxillary torus is present in the midline of the palate.

## Palatine process

The palatine process, thick and horizontal, projects medially from the lowest part of the medial aspect of the maxilla. It forms a large part of the nasal floor and hard palate, and is much thicker in front. Its inferior surface is concave and uneven, and with its contralateral fellow it forms the anterior three-quarters of the osseous (hard) palate. The palatine process displays numerous vascular foramina and depressions for palatine glands and, posterolaterally, two grooves that transmit the greater palatine vessels and nerves. The infundibular incisive fossa is placed between the two maxillae, behind the incisor teeth. The median intermaxillary palatal suture runs posterior to the fossa, and although a little uneven, is usually relatively flat on its oral aspect. Its bony margins are sometimes raised into a prominent longitudinal palatine torus. Two lateral incisive canals, each ascending into its half of the nasal cavity, open in the incisive fossa; they transmit the terminations of the greater palatine artery and nasopalatine nerve. Two additional median openings, anterior and posterior incisive foramina, are occasionally present; they transmit the nasopalatine nerves, the left usually passing through the anterior, and the right through the posterior foramen. On the inferior palatine surface, a fine groove, sometimes termed the incisive suture, and prominent in young skulls, may be observed in adults. It extends anterolaterally from the incisive fossa to the interval between the lateral incisor and canine teeth. The superior surface of the palatine process is smooth, is concave transversely, and forms most of the nasal floor. The incisive canal lies anteriorly, near its median margin. The lateral border is continuous with the body of the maxilla. The medial border, thicker in front, is raised into a nasal crest that, with its contralateral fellow, forms a groove for the vomer. The front of this ridge rises higher as an incisor crest, prolonged forwards into a sharp process that, with its fellow, forms an anterior nasal spine. The posterior border is serrated for articulation with the horizontal plate of the palatine bone.

## Maxillary sinus

The maxillary sinus is the largest of the paranasal sinuses and is situated in the body of the maxilla. It is described in detail on page 568.

## Ossification

The maxilla ossifies from a single centre in a sheet of mesenchyme that appears above the canine fossa at about the sixth week in utero and spreads into the rest of the maxilla and its processes. The pattern of spread of ossification may initially leave an unmineralized zone roughly corresponding to a site where a premaxillary suture may occur. However, this deficiency is soon ossified; there is no evidence of a separate centre of ossification for the incisor-bearing portion of the maxilla (i.e. premaxilla).

The maxillary sinus appears as a shallow groove on the nasal aspect at about the fourth month in utero. Though small at birth, the sinus is identifiable radiologically. After birth, it enlarges with the growing maxilla, though it is only fully developed following the eruption of the permanent dentition. The infraorbital vessels and nerve are, for a time, in an open groove in the orbital floor; the anterior part of the groove is subsequently converted into a canal by a lamina that grows in from the lateral side.

At birth, the transverse and sagittal maxillary dimensions are greater than the vertical. The frontal process is prominent, but the body is little more than an alveolar process because the alveoli reach almost to the orbital floor. In adults, the vertical dimension is the greatest, reflecting the development of the alveolar process and enlargement of the sinus. When teeth are lost, the bone reverts towards its infantile shape; its height diminishes, the alveolar process is absorbed, and the lower parts of the bone contract and become reduced in thickness at the expense of the labial wall.

## PALATINE BONE

The palatine bones are posteriorly placed in the nasal cavity, between the maxillae and the pterygoid processes of the sphenoid bones. They contribute to the floor and lateral walls of the nose, to the floor of the orbit and the hard palate, to the pterygopalatine and pterygoid fossae, and to the inferior orbital fissures. Each has two plates (horizontal and perpendicular), arranged as an L-shape, and three processes (pyramidal, orbital and sphenoidal) (Fig. 30.9).

Fig. 30.9 The palatine bone, posterior view.

## Horizontal plate

The horizontal plate is quadrilateral, with two surfaces (nasal and palatine) and four borders (anterior, posterior, lateral and medial). The nasal surface, transversely concave, forms the posterior nasal floor. The palatine surface forms the posterior quarter of the bony palate with its contralateral fellow. There is often a curved palatine crest near its posterior margin. The posterior border is thin and concave; the expanded tendon of tensor veli palatini is attached to it and to its adjacent surface behind the palatine crest. Medially, with its contralateral fellow, the posterior border forms a median posterior nasal spine to which the uvular muscle is attached. The anterior border is serrated and articulates with the palatine process of the maxilla. The lateral border is continuous with the perpendicular plate of the palatine bone and is marked by a greater palatine groove. The medial border is thick and serrated, and articulates with its contralateral fellow in the midline, forming the posterior part of the nasal crest which articulates with the posterior part of the lower edge of the vomer.

## Perpendicular plate

The perpendicular plate is thin and oblong, and has two surfaces (nasal and maxillary) and four borders (anterior, posterior, superior and inferior) (see Figs 30.8B, 30.9). The nasal surface bears two crests (conchal and ethmoidal) and shows areas that contribute to the inferior, middle and superior meatuses. Inferiorly, the nasal surface is concave where it contributes to part of the inferior meatus. Above this is a horizontal conchal crest that articulates with the inferior concha. Above the conchal crest, the surface presents a shallow depression that forms part of the middle meatus; it is limited above by an ethmoidal crest for the middle nasal concha, above which a narrow, horizontal groove forms part of the superior meatus.

The maxillary surface is largely rough and irregular, and articulates with the nasal surface of the maxilla. Posterosuperiorly, it forms a smooth medial wall to the pterygopalatine fossa. Its anterior area, also smooth, overlaps the maxillary hiatus from behind to form a posterior part of the medial wall of the maxillary sinus. A deep, obliquely descending greater palatine groove (converted into a canal by the maxilla) lies posteriorly on this maxillary surface; it transmits the greater palatine vessels and nerve.

The anterior border is thin and irregular. Level with the conchal crest, a pointed lamina projects below and behind the maxillary process of the inferior concha; it articulates with it and so appears in the medial wall of the maxillary sinus. The posterior border articulates via a serrated suture with the medial pterygoid plate. It is continuous above with the sphenoidal process of the palatine bone and expands below into its pyramidal process. Orbital and sphenoidal processes project from the superior border and are separated by the sphenopalatine notch, which is converted into a foramen by articulation with the body of the sphenoid. This foramen connects the pterygopalatine fossa to the posterior part of the superior meatus, and transmits sphenopalatine vessels and the posterior superior nasal nerves. The inferior border is continuous with the lateral border of the horizontal plate and bears the lower end of the greater palatine groove in front of the pyramidal process.

## Pyramidal process

The pyramidal process slopes down posterolaterally from the junction of the horizontal and perpendicular palatine plates into the angle between the pterygoid plates of the sphenoid bone. On its posterior surface, a smooth, grooved triangular area, limited on each side by rough articular furrows that articulate with the pterygoid plates, completes the lower part of the pterygoid fossa. Anteriorly, the lateral surface articulates with the maxillary tuberosity. This area gives attachment to fibres of the superficial head of medial pterygoid. Posteriorly, a smooth triangular area appears low in the infratemporal fossa between the tuberosity and the lateral pterygoid plate. The inferior surface, near its union with the horizontal plate, bears the lesser palatine foramina, which transmit the lesser palatine nerves and vessels.

## Orbital process

The orbital process is directed superolaterally from in front of the perpendicular plate and has a constricted 'neck'. It encloses an air sinus and presents three articular and two non-articular surfaces. Of the articular surfaces, the oblong anterior (maxillary) surface faces down and anterolaterally, and articulates with the maxilla. The posterior (sphenoidal) surface is directed up and posteromedially, and bears the opening of an air sinus. It usually communicates with the sphenoidal sinus and is completed by a sphenoidal concha. The medial (ethmoidal) surface faces anteromedially and articulates with the labyrinth of the ethmoid bone. The sinus of the orbital process sometimes opens on the surface, and communicates with the posterior ethmoidal air cells. More rarely, it opens on both the ethmoidal and sphenoidal surfaces, and communicates with both posterior ethmoidal air cells and the sphenoidal sinus.

Of the non-articular surfaces, the triangular superior (orbital) surface is directed superolaterally to the posterior part of the orbital floor. The lateral surface is oblong, faces the pterygopalatine fossa, and is separated from the orbital surface by a rounded border that forms a medial part of the lower margin of the inferior orbital fissure. This surface may present a groove, directed superolaterally, for the maxillary nerve, and is continuous with the groove on the upper posterior surface of the maxilla. The border between the lateral and posterior surfaces descends anterior to the sphenopalatine notch.

## Sphenoidal process

The sphenoidal process is a thin plate that is smaller and lower than the orbital process, and is directed superomedially. Its superior surface articulates with the sphenoidal concha and, above it, with the root of the medial pterygoid plate. It carries a groove that contributes to the formation of the palatovaginal canal. The concave inferomedial surface forms part of the roof and lateral wall of the nose. Posteriorly, the lateral surface articulates with the medial pterygoid plate, while its smooth anterior region forms part of the medial wall of the pterygopalatine fossa. The posterior border articulates with the vaginal process of the medial pterygoid plate. The anterior border is the posterior edge of the sphenopalatine notch. The medial border articulates with the ala of the vomer. The sphenopalatine notch, between the two processes, is converted into a foramen by articulation with the body of the sphenoid bone.

## Ossification

Ossification is in mesenchyme from one centre in the perpendicular plate that appears during the eighth week in utero. From this centre, ossification spreads into all parts. At birth, the height of the perpendicular plate equals the width of the horizontal plate, but in adults it is almost twice as great, a change in proportions that accords with those that occur in the maxilla.

## FRACTURES OF THE FACIAL SKELETON

Trauma to the face is common; outcomes are related to the mechanism of the injury in terms of its severity and to delays in treatment. Both soft and hard tissues are affected. Moderate to severe injuries produce facial skeletal disruption that compromises masticatory and orbital function. Inadequate skeletal support of soft tissues contributes to facial asymmetry, and the additional loss of soft tissues and subsequent scarring merely compound this. Some fractures pass through neural
foramina, damage branches of the trigeminal nerve and result in sensory deficits. Fracture configurations vary according to the amount of energy absorbed and local anatomical factors that constitute sites of weakness.

The direction and magnitude of the applied forces determine the displacement of these fractures, which are modified according to muscle attachments and the state of the dentition. For example, an unerupted mandibular third molar may produce a weak point at the mandibular angle.

The lateral pterygoid muscles frequently displace a fractured mandibular condyle medially. Masseter, temporalis and medial pterygoid may stabilize fractures of the mandible when vertically or horizontally favourable, but displace those that are vertically and horizontally unfavourable. Severe injuries to the middle third of the face may result in craniofacial dysjunction, the middle third sliding inferiorly down the angulated and strong anterior skull base. This causes an apparent lengthening of the face and a dish-faced appearance. Airway obstruction may result from this downward and backward displacement. Fractures of the anterior mandible may cause loss of support of the muscles controlling the anterior tongue position and may also contribute to loss of the airway.

Although the fractures caused by severe injuries are often complex, it is convenient to describe them as arising in the upper, middle and lower thirds of the face, even though fractures may involve one or more of these areas. Upper third fractures involve the frontal bones. Middle third fractures involve the nasoethmoidal complex, orbit, zygomatic complex and maxilla. Lower third fractures correspond to fractures of the mandible (Video 30.1).

## Upper third of face

Fractures in the upper third of the face are almost invariably comminuted and are often associated with fractures of the middle third of the face. Fractures of the frontal bone may involve the frontal sinuses and/ or orbital roof. If the frontonasal duct is traumatized, its drainage may be impaired, which predisposes to ascending intracranial infection and mucocele development within the frontal sinuses (Eljamel and Foy 1990; Fig. 30.10). This risk may be minimized with frontonasal stents or frontonasal duct and frontal sinus obliteration with autogenous bone graft. Fractures that involve both the anterior and the posterior walls of the frontal sinus also carry a risk of early and delayed intracranial infection, and often it is necessary to obliterate the frontal sinuses or cranialize the frontal sinuses in order to prevent this complication. Cranialization of the frontal sinuses involves the removal of the posterior wall and all frontal sinus mucosa, typically through a frontal craniotomy approach. Fractures of the posterior wall of the frontal sinus may be associated with dural tears (and cerebrospinal rhinorrhoea), which must be repaired at the same time. Fractures involving the orbital roof may be associated with displacement of the globe of the eye, diplopia and supraorbital nerve injury.

## Middle third of face

The middle third of the face is defined as that area bounded above by a transverse line connecting the two zygomaticofrontal sutures, passing through the frontomaxillary and frontonasal sutures, and limited below by the occlusal plane of the maxillary teeth. Posteriorly, the region is limited by the sphenoethmoidal junction, but it includes the free margins of the pterygoid plates inferiorly. Fractures of the middle third of the facial skeleton (Le Fort 1901) may involve the maxillae, palatine bones, zygomatic bones, zygomatic processes of the temporal bones, nasal bones, vomer, ethmoid bone together with its nasal conchae, and the body and greater and lesser wings of the sphenoid bone. A classification system that subdivides the fractures into central block fractures and those that involve the lateral middle third is now largely of historical value, but finds use as an initial description that is later elaborated by defining extensions of the fracture pattern into the upper third and the cranium.

## Central middle third of face

The majority of the skeleton of the central middle third is composed of wafer-thin sheets of cortical bone with stronger reinforcements, i.e. the palate and alveolar process; the lateral rim of the piriform aperture extending upwards (via the canine fossa) to the medial orbital rim, and finally to the glabella; the zygomatic buttress and its connections to the inferior and lateral orbital margins and the zygomatic arch; and the orbital rims and the pterygoid plates. Whatever the fracture configuration, pterygoid plate disruption is seen in all examples of maxillary

Fig. 30.10 A compound craniofacial fracture with disruption of the anterior and posterior walls of the frontal sinus, torn dura, and intracranial bone. Treatment is directed at establishing a safe sinus, i.e. sealing off the frontonasal duct and removing all traces of sinus epithelium. It is also important to establish an intact fronto-orbital bar, to enable an accurate scaffold on which to attach the root of the nose and midface, if implicated in the fracture pattern, and to assure good cosmesis.
fracture. The strength lies in the facial surface of the skeleton, which, although thin in most areas, is cross-braced. The design is ideally suited to transmit occlusal forces vertically to the skull base.

Central middle third fractures may involve the nasoethmoidal complex in isolation or as part of a more complex Le Fort pattern of injury. Le Fort I, II or III fractures inevitably involve the infratemporal fossa. The bones of the midface transmit the forces of impact directly to the cranium. The most important strut related to the infratemporal and pterygopalatine fossae is the pterygomaxillary strut. Fractures involving this strut may extend elsewhere to involve the cranial base and orbit. The associated soft tissue damage that accompanies these fractures may damage nerves, blood vessels and muscles. Injuries to the second or third divisions of the trigeminal nerve or the chorda tympani nerve result in altered sensation to the oral cavity, face and jaws, including impaired taste; fractures extending into the orbit may result in decreased visual acuity and ophthalmoplegia, and neural damage to motor nerves or direct damage to muscles may result in problems with chewing, swallowing, speech, middle ear function and eye movements; injuries involving the pterygopalatine or otic ganglia interfere with lacrimation, nasal secretions and salivation. Facial deformity with lack of nasal projection asymmetry and occlusal disturbance and vertical and anteroposterior malposition of the globe are often seen.

Nasoethmoidal complex Fractures may involve the osteocartilaginous framework of the nose in isolation or as part of complex injuries that also involve the paranasal sinuses and/or the orbits (Fig. 30.11).

Simple fractures involve the nasal bones and/or frontal process of the maxilla. Only if there is displacement of the bones is a closed reduction of the fracture required. The terminal branch of the anterior ethmoidal nerve and its accompanying vessels are at risk when injuries involve the dorsum of the nose.

Complex nasal injuries may include nasofrontal suture disjunction, nasolacrimal and frontonasal duct injury, and fracture of the ethmoidal complex (Markowitz et al 1991). The skeletal foundation of the nasoethmoidal complex consists of a strong triangular-shaped frame. However, all these structures are fragile and any force sufficient to fracture the frame results in severe comminution and displacement. The ethmoidal air cells act as a crumple zone protecting the skull base from mechanical forces. A severe impact delivered to the midface, particularly over the bridge of the nose, may result in these structures being driven backwards between the orbits. This may result in traumatic hypertelorism, producing an increase in distance between the pupils. Associated displacement of the medial canthal ligaments results in traumatic telecanthus. Increased intercanthal distance (normal range 24-39 mm in Caucasians) may be corrected using microplates, stainless steel wire and acrylic canthal splints. Damage to the lacrimal system requires approximation of the severed canalicular ends or dacryocystorhinostomy. Comminution of the cribriform plates of the ethmoid may result in dural tears and cerebrospinal rhinorrhoea. Often, nasoethmoidal fractures are combined with more extensive fractures of the frontal bone. The complexity of the injury has implications for subsequent facial reconstruction (Video 30.2, Fig. 30.12).

Le Fort I fractures (Guerin's fracture) Le Fort I fractures consist of a horizontal fracture line above the level of the floor of the nose involving the lower third of the nasal septum. The mobile segment consists of the palate, the alveolar process and the lower thirds of the pterygoid plates.

Le Fort II fractures (pyramidal fracture) Le Fort II fractures are pyramidal fractures involving the maxillary bones. From the nasal bridge, the fracture enters the medial wall of the orbit to involve the lacrimal bone and then crosses the inferior orbital rim, usually at the junction of the medial third and lateral two-thirds, and often involves the infraorbital foramen. The fracture line then runs beneath the zygomaticomaxillary suture, traversing the lateral wall of the maxillary sinus to extend posteriorly and horizontally across the pterygoid plates. The zygomatic bones and arches remain attached to the skull base.

Le Fort IIII fractures Le Fort III fractures run parallel with the base of the skull, separating the entire midfacial skeleton from the cranial base. The fracture extends through the nasal base and continues posteriorly across the ethmoid bone. The fracture then crosses the lesser wing of the sphenoid and, on occasion, involves the optic foramen. Usually, however, it slopes down medially, passing below the optic foramen to reach the pterygomaxillary fissure and pterygopalatine fossa. From the base of the inferior orbital fissure, the fracture runs laterally and upwards, separating the greater wing of the sphenoid from the zygomatic bone, to reach the frontozygomatic suture. It also extends
downwards and backwards across the pterygopalatine fossa to involve the root of the pterygoid plates. The zygomatic arch is usually fractured at the zygomaticotemporal suture (Le Fort 1901).

Open reduction and internal fixation are conducted through aesthetically favourable incisions in the hairline, upper eyelid, oral cavity and lower eyelid (subciliary and transconjunctival) (Fig. 30.13).

## Lateral middle third of face

Fractures of the lateral middle third involve the zygomaticomaxillary complex (Fig. 30.14). The zygomatic bone forms the prominence of the cheek. Since the most common cause of a zygomatic fracture is a blow from a fist, depressed fractures of the zygomaticomaxillary complex are a common injury. These injuries may be sustained in isolation or in association with orbital blowout fractures. Isolated zygomatic arch fractures from a well-directed lateral blow are also common.

Classic zygomatic complex fractures involve the zygomaticomaxillary, zygomaticotemporal, zygomaticofrontal and sphenozygomatic sutures. The fracture line extends from the lateral wall of the orbit laterally into the infratemporal fossa at the zygomaticofrontal suture. From this point, the fracture line extends inferiorly to join the most lateral aspect of the inferior orbital fissure, continues inferiorly along the posterior surface of the zygomatic buttress - where it communicates with the lateral bulge of the maxillary antrum - and runs around the zygomatic buttress, high in the buccal sulcus in the upper molar region, and then extends upwards towards the infraorbital foramen. It finally runs laterally along the floor of the orbit to reach the lateral extension of the inferior orbital fissure. Clinical signs may include facial asymmetry, infraorbital nerve paraesthesia/anaesthesia, limitation of mouth opening (if there is impingement of the coronoid process by a depressed arch fracture) and signs of orbital blowout fracture (see below; Videos 30.3 and 30.4).

As zygomatic fractures involve the maxillary sinus (the lateral wall of which is frequently comminuted) and the infratemporal fossa, there is potential for spread of infection between these structures and then via foraminae in the skull base to the middle cranial fossa. Patients with zygomatic complex fractures must be advised to refrain from sneezing or nose-blowing, which may force air from the antrum into the surrounding tissues (surgical emphysema) or into the orbit, resulting in proptosis of the eye. While the zygoma may be reduced transorally (the Keen approach) or via the brow (Dingman approach) or a cheek-hook technique (Poswillo approach), it is perhaps the Gillies temporal approach that is worthy of mention here because it exploits the anatomy of the region (Gillies et al 1927). The incision is hidden in the hairline and the approach depends on the fact that the superior temporal fascia is attached to the superior temporal line of the skull superiorly and the zygomatic arch inferiorly, and that temporalis runs under the arch. An incision through the temporalis fascia, but not through the muscle, therefore allows a metal elevator to be passed from the hairline to the zygomatic arch and body. Outward traction, coupled with rotation, allows precise localization of the bone.

Orbital fractures The orbit is invariably involved in fractures of the zygomatic bone and in Le Fort II and III fractures. The orbit may also be involved in fractures of the frontal bone and extensive nasal complex injuries. Direct blunt trauma to the globe may result in displacement of the globe and fracture of the thin orbital floor (or medial wall) without associated rim involvement and is known as a 'blowout' fracture (Ahmas et al 2006). This protective mechanism of injury helps to maintain the integrity of the globe itself in preference to the orbital walls. There may be associated herniation of periorbital fat (Fig. 30.15) and/or inferior rectus, resulting in restriction of eye movement, diplopia, ipsilateral lowering of pupillary height, and enophthalmos (due to increased orbital volume) (Manson et al 1986). Fortunately, the optic foramen, which is situated within the lesser wing of the sphenoid bone, is surrounded by dense bone and is only rarely involved in fractures. Direct injury to the optic nerve is therefore unusual. The orbital floor is normally repaired by the insertion of an alloplastic or autogenous graft (Fig. 30.16) (Ellis and Tan 2003).

## Lower third of face (mandible)

The mandible is essentially a tubular bone bent into a blunt V shape (Ch. 32). This basic configuration is modified by sites of muscle attachment, principally masseter and medial pterygoid at the angle, and temporalis at the coronoid process. The presence of teeth, particularly those with long roots such as the canines, or of unerupted teeth produces lines of weakness in the mandible. When the teeth are lost or fail to develop, the subsequent progressive resorption of the alveolar bone means that the mandible reverts to its underlying tubular structure. Like

Fig. 30.11 An extended naso-orbito-ethmoid (NOE) fracture. The frontal sinus and frontal bone fracture (red arrows) need to be reconstructed to provide a stable platform for the NOE. The NOE fracture (blue arrows) extends into the anterior maxilla and blends with the extended comminuted zygomatic fracture (green arrows).

Fig. 30.12 A typical high-energy pan-facial injury. This injury demonstrates several complicated levels of Le Fort type maxillary fracture. The red arrows demonstrate the Le Fort III pattern (although the major fragment is further comminuted). The green arrows demonstrate the Le Fort II pattern, and the dark blue arrows demonstrate the Le Fort I pattern, although the maxilla is itself fractured sagittally (purple arrows). There are also bilateral condylar neck fractures and a mandibular symphysial fracture (light blue arrows). Note the avulsed lower left premolar and dental fracture of the right incisor (yellow arrows). Exclusion of inhaled dental teeth and fragments is important.

Fig. 30.13 Various examples of plating configurations and titanium alloplastic reconstructions. The aim of surgery is to reconstruct anatomy in order to provide a scaffold on which to overlay the soft tissues.

Fig. 30.14 A typical left zygomatic fracture. In this case, navigation planning takes the normal green right side and mirrors to the left. The red and orange outlines indicate where the bone should be.

Fig. 30.15 Image fusion of computed tomography and magnetic resonance imaging, showing an extensive left medial wall fracture (arrows). There is obvious herniation of orbital contents and disruption of the soft tissue contents of the orbit.
all tubular bones, the strength of the mandible resides in a dense cortical plate, thickened anteriorly and at its lower border; it follows that the mandible is strongest anteriorly in the midline and is progressively weaker posteriorly towards the condylar processes. Again, like all tubular bones, the mandible has great resistance to compressive forces, but fractures at sites of tensile strain. It is liable to particular patterns of distribution of tensile strain when forces are applied to it. Anterior forces applied to the mental symphysis, or over the body of the mandible, lead to strain at the condylar necks and also along the lingual cortical plates on the contralateral side in the molar region. The mandible therefore often fractures at two sites and isolated fractures are relatively unusual. In order of frequency, fractures occur most commonly at the neck of the condyle, the angle, the parasymphysial region and the body of the mandible.

## Condylar process

The condyle is protected from direct injury by the zygomatic arches. Fractures occur usually by the transmission of force following a blow to the front of the mandible or to the contralateral body. Fractures are seen at all levels of the condyle (Loukota et al 2005). Except in children, most condylar fractures are not intracapsular, and occur in the neck. They usually run obliquely downwards and backwards from the mandibular notch. The condyle is usually displaced anteromedially (because of the attachment of lateral pterygoid to the temporomandibular joint disc, capsule and anterior border of the neck of the condyle). Nowadays, most condylar fractures are managed by open reduction and early mobilization.

## Angle of mandible

The majority of fractures of the mandible run posteriorly and inferiorly from the alveolar bone to the angle. The presence of a third molar tooth produces a line of weakness, and a fracture line will pass through its socket. The unopposed pull of the powerful elevator muscles (masseter, medial pterygoid and temporalis) will typically displace the posterior fragment superiorly, anteriorly and medially.

## Ramus and coronoid process

Fractures at the ramus exhibit very little displacement as a consequence of the splinting activity of medial pterygoid medially and masseter laterally, the pterygomasseteric sling; their wide attachments to the ramus extend across the fracture lines. Similarly, the coronoid process is rarely displaced significantly because it is splinted by the tendinous insertion of temporalis.

## Body of mandible

Most fractures of the body of the mandible occur as the result of direct trauma and tend to be concentrated in the first molar or canine region. The more anterior the site of the fracture, the more the upward displacement of the elevators is counteracted by the downward pull of geniohyoid and the anterior belly of digastric. When teeth are present, displacement is limited by the dental occlusion (i.e. further displacement is resisted by the lower and upper teeth), whereas displacement may be considerable in an edentulous patient.

## Campbell's lines

Campbell's lines are five lines that are systematically traced when assessing maxillofacial radiographs. Line 1 joins the two zygomaticofrontal sutures; it runs along the superior orbital margins and crosses the midline in the region of the glabella. Line 2 runs along the zygomatic bone and the inferior orbital margin, crosses the frontal process of the maxilla and lateral wall of the nose, and then passes through the nasal septum to follow a similar course to the contralateral zygomatic bone. Line 3 begins at the condyle of the mandible, passes across the mandibular notch and coronoid process of the mandible, then crosses the maxillary sinus from its lateral to medial walls and continues through the lateral wall of the nose at the level of the nasal floor; it follows a similar course on the contralateral side. Line 4 follows the occlusal plane of the upper and lower teeth, and line 5 follows the lower border of the mandible.

## Cranial base

The cranial base - clinically regarded as, the frontal, ethmoid, sphenoid and occipital bones - is a relatively solid platform inclined at an angle of $45^{\circ}$ to the maxillary occlusal plane. Fractures of the cranial base are not readily visible on normal radiographs and are best detected on CT scans. They result in bleeding in the floor of the middle cranial fossa, which often presents as bruising over the mastoid process (Battle's sign). These fractures may be associated with dural tears and escape of
cerebrospinal fluid from the nose (rhinorrhoea) or ruptured tympanic membrane (otorrhoea). Alternatively, if this membrane remains intact, it may be seen as blue and bulging (haemotympanum).

## SKELETAL ACCESS SURGERY

The craniofacial skeleton has an excellent blood supply and so can be dismantled as a series of osteoplastic flaps. The surgical disarticulation of the craniofacial skeleton has been used to gain access to otherwise inaccessible sites in order to allow the surgeon to attend to pathology in the skull base, cervical spine and anterior and posterior cranial fossae. The aim is to provide increased and more direct exposure of both the pathology and the adjacent vital structures without the need to resect uninvolved structures. The craniofacial skeleton can be divided into a series of modular osteotomies, which permit both independent and conjoined mobilization.

The zygomatic and nasal bones and the maxilla may be exposed and mobilized, and pedicled on the overlying soft tissues either unilaterally or bilaterally. These approaches improve access to the nasal cavity, maxillary, ethmoidal and sphenoidal sinuses, the soft palate and nasopharynx, and the infratemporal fossa and pharyngeal space. The exposures may be extended to gain access to the anterior and middle cranial fossae, cavernous sinus, clivus, craniocervical junction and upper cervical vertebrae.

A variety of different access osteotomies have been described and found to be useful in specific clinical situations. Most of the osteotomies described follow the conventional patterns of facial fractures described above. The entire hemimaxilla and zygoma can be mobilized, and pedicled on the soft tissues of the face by making bone cuts that follow the lines of a Le Fort II fracture on one side. The osteotomy is completed by dividing the upper alveolus and palate just to the side of the nasal septum and perpendicular plate of the vomer. The maxilla may be mobilized at the Le Fort I level and down-fractured, pedicled on the palatoglossal muscles and soft tissue attachments. This gives good access to the nasopharynx, clivus and upper cervical spine, particularly if the palate is divided in the midline.

Lateral zygomatic osteotomies may be performed to gain access to the orbital apex and infratemporal fossa. The surgical approach is from behind using a hemi- or bicoronal flap. The zygomatic complex is mobilized inferiorly, pedicled on masseter. When combined with a mandibular ramus osteotomy, access is gained to the retromaxillary area and pterygoid space as well as to the infratemporal fossa. In combination with a frontotemporal craniotomy, the zygomatic osteotomy has been used for access to the middle cranial fossa, cavernous sinus, apex of the petrous temporal bone and the interpeduncular cistern.

Dividing the lower lip in the midline, and dividing the mandible either in the midline or just in front of the mental foramen, allows the hemimandible to be swung laterally. The technique is used to give improved access to the floor of the mouth, the base of the tongue, tonsillar fossa, soft palate, oropharynx, posterior pharyngeal wall, supraglottic larynx and pterygomandibular region. By extending the dissection laterally, access is gained to the pterygoid space, infratemporal fossa and parapharyngeal space. By dissecting more medially, access is gained to the nasopharynx, lower part of the clivus and all seven of the cervical vertebrae. A modification of the mandibular swing procedure increases access up to the skull base, by combining the classic mandibular swing with a horizontal osteotomy of the mandibular ramus above the level of the lingula.

## MUSCLES OF THE FACE

Craniofacial muscles are associated with the orbital margins and eyelids, external nose and nostrils, lips, cheeks and mouth, pinna, scalp and cervical skin, and collectively are often called, not very accurately, 'muscles of facial expression' (Fig. 30.17). Their organization differs from that of muscles in most other regions of the body because there is no deep membranous fascia beneath the skin of the face, and many small slips of muscle that are attached to the facial skeleton insert directly into the skin.

Although these muscles produce movements of the facial skin that reflect emotions, it is usually argued that their primary function is to act as sphincters and dilators of the facial orifices and that the function of facial expression has developed secondarily. Embryologically, they are derived from the mesenchyme of the second branchial arch and so are innervated by the facial nerve. Topographically and functionally, the muscles of facial expression may be subdivided into epicranial, circumorbital and palpebral, nasal, and buccolabial groups (Fig. 30.18).

Fig. 30.16 A, A typical large medial wall and floor fracture. The bone here, the lamina papyracea, is the thinnest in the orbit. The intact medial wall on the right side is outlined in green. $\mathbf{B}$, In this case, the intact right medial wall (green line) was mirrored; the red line outlines the defect on the left orbit. C, A titanium plate was then placed through a transconjunctival incision, with lateral cantholysis; the position was checked with intraoperative navigation.

## EPICRANIAL MUSCLE GROUP

## Epicranius

Epicranius consists of occipitofrontalis and temporoparietalis.

## Occipitofrontalis

Occipitofrontalis covers the dome of the skull from the highest nuchal lines to the eyebrows. It is a broad, musculofibrous layer and consists of four thin, muscular quadrilateral parts, two occipital and two frontal, connected by the epicranial aponeurosis. Each occipital part (occipitalis) arises by tendinous fibres from the lateral two-thirds of the highest nuchal line of the occipital bone and the adjacent region of the mastoid part of the temporal bone, and extends forwards to join the aponeurosis. The gap between the two occipital parts is occupied by an extension of the epicranial aponeurosis. Each frontal part (frontalis) is adherent to the superficial fascia, particularly of the eyebrows. Although frontalis has no bony attachments of its own, its fibres blend with those of adjacent muscles - procerus, corrugator supercilii and orbicularis oculi - and ascend to join the epicranial aponeurosis in front of the coronal suture.

Vascular supply Occipitofrontalis is supplied by branches of the superficial temporal, ophthalmic, posterior auricular and occipital arteries.

Innervation The occipital part of occipitofrontalis is supplied by the posterior auricular branch of the facial nerve, and the frontal part is supplied by the temporal branches of the facial nerve.

Actions Acting from above, the frontal parts raise the eyebrows and the skin over the root of the nose (e.g. as in expressions of surprise or
horror). Acting from below, the frontal parts draw the scalp forwards, throwing the forehead into transverse wrinkles. The occipital parts draw the scalp backwards. Acting alternately, the occipital and frontal parts can move the entire scalp backwards and forwards.

Variations A thin muscular slip, transversus nuchae, is sometimes present. It arises from the external occipital protuberance or from the superior nuchal line, either superficial or deep to trapezius. It is frequently inserted with auricularis posterior but may blend with the posterior edge of sternocleidomastoid.

## Epicranial aponeurosis

The epicranial aponeurosis covers the upper part of the cranium and, with the epicranial muscle, forms a continuous fibromuscular sheet that extends from the occiput to the eyebrows. Posteriorly, between the occipital parts of occipitofrontalis, it is attached to the external protuberance and highest nuchal line of the occipital bone. Anteriorly, it splits to enclose the frontal parts and sends a short, narrow prolongation between them. Laterally, the anterior and superior auricular muscles are attached to it; the aponeurosis is thinner, and continues over the temporal fascia to the zygomatic arch. It is united to the skin lying over the cranial vault by fibrous superficial fascia, but it is connected more loosely to the underlying pericranium by areolar tissue, an arrangement that allows it to move freely, carrying with it the skin of the scalp.

## Temporoparietalis

Temporoparietalis is a variably developed sheet of muscle that lies between the frontal parts of occipitofrontalis and the anterior and superior auricular muscles.

## CIRCUMORBITAL AND PALPEBRAL MUSCLE GROUP

The circumorbital and palpebral group of muscles are orbicularis oculi, corrugator supercilii and levator palpebrae superioris. The first two are described here; levator palpebrae superioris is described on page 670.

## Orbicularis oculi

Orbicularis oculi is a broad, flat, elliptical muscle that surrounds the circumference of the orbit and spreads into the adjacent regions of the eyelids, anterior temporal region, infraorbital cheek and superciliary region (see Fig. 30.18). It has orbital, palpebral and lacrimal parts, and a small ciliary bundle.

The orbital part arises from the nasal component of the frontal bone, the frontal process of the maxilla and from the medial palpebral ligament. The fibres form complete ellipses, without interruption on the lateral side, where there is no bony attachment. The upper orbital fibres blend with the frontal part of occipitofrontalis and corrugator supercilii. Many of them are inserted into the skin and subcutaneous tissue of the eyebrow and constitute depressor supercilii. Inferiorly and medially, the ellipses overlap or blend to some extent with adjacent muscles (levator labii superioris alaeque nasi, levator labii superioris and zygomaticus minor). At the extreme periphery, sectors of complete, and sometimes incomplete, ellipses have a loose areolar connection with the temporal extension of the epicranial aponeurosis

The palpebral part arises from the medial palpebral ligament, mainly from its superficial surface, and from the bone immediately above and below the ligament. The fibres sweep across the eyelids anterior to the orbital septum, interlacing at the lateral commissure to form the lateral palpebral raphe. A small group of fine fibres, close to the margin of each eyelid behind the eyelashes, constitutes the ciliary bundle.

The lacrimal part arises from the upper part of the lacrimal crest, and the adjacent lateral surface, of the lacrimal bone. It passes laterally behind the nasolacrimal sac (where some fibres are inserted into the associated fascia) and divides into upper and lower slips. Some fibres are inserted into the tarsi of the eyelids close to the lacrimal canaliculi, but most continue across in front of the tarsi and interlace in the lateral palpebral raphe.

Vascular supply Orbicularis oculi is supplied by branches of the facial, superficial temporal, maxillary and ophthalmic arteries.

Innervation Orbicularis oculi is supplied by temporal and zygomatic branches of the facial nerve.

Actions Orbicularis oculi is the sphincter muscle of the eyelids and plays an important role in facial expression and various ocular reflexes. The orbital portion is usually activated under voluntary control. Contraction of the upper orbital fibres produces vertical furrowing above the bridge of the nose, narrowing of the palpebral fissure, and bunching and protrusion of the eyebrows, which reduces the amount of light entering the eyes. Eye closure is largely affected by lowering of the upper eyelid but there is also considerable elevation of the lower eyelid. The palpebral portion can be contracted voluntarily, to close the lids gently as in sleep, or reflexly, to close the lids protectively in blinking. The palpebral part has upper depressor and lower elevator fascicles. The lacrimal part of the muscle draws the eyelids and the lacrimal papillae medially, thereby exerting traction on the lacrimal fascia, and may aid drainage of tears by dilating the lacrimal sac. It may also influence pressure gradients within the lacrimal gland and ducts. This activity may assist in the sinuous flow of tears across the cornea, direct the lacrimal punctum into the lacus lacrimalis, and express secretions of the ciliary and tarsal glands. When the entire orbicularis oculi muscle contracts, the skin is thrown into folds that radiate from the lateral angle of the eyelids. Such folds, when permanent, cause wrinkles in middle age (the so-called 'crow's feet').

## Corrugator supercilii

Corrugator supercilii is a small pyramidal muscle located at the medial end of each eyebrow, lying deep to the frontal part of occipitofrontalis and orbicularis oculi, with which it is partially blended (see Fig. 30.18 A ). It arises from bone at the medial end of the superciliary arch and its fibres pass laterally and slightly upwards to exert traction on the skin above the middle of the supraorbital margin.

Vascular supply Corrugator supercilii is supplied by branches from adjacent arteries, mainly from the superficial temporal and ophthalmic arteries.

Innervation Corrugator supercilii is innervated by temporal branches of the facial nerve.

Actions Corrugator supercilii cooperates with orbicularis oculi to draw the eyebrows medially and downwards to shield the eyes in bright sunlight. It is also involved in frowning. The combined action of the two muscles produces mainly vertical wrinkles on the supranasal strip of the forehead.

## NASAL MUSCLE GROUP

The nasal muscle group, which consists of procerus, nasalis and depressor septi, is described on page 558.

## BUCCOLABIAL MUSCLE GROUP

The shape of the mouth and the posture of the lips are controlled by a complex three-dimensional assembly of muscular slips (Yousif and Mendelson 1995). These include elevators, retractors and evertors of the upper lip (levator labii superioris alaeque nasi, levator labii superioris, zygomaticus major and minor, levator anguli oris and risorius); depressors, retractors and evertors of the lower lip (depressor labii inferioris, depressor anguli oris, and mentalis); a compound sphincter (orbicularis oris, incisivus superior and inferior); and buccinator (see Fig. 30.18).

## Levator labii superioris alaeque nasi

Levator labii superioris alaeque nasi is described on page 559.

## Levator labii superioris

Levator labii superioris arises from the maxilla and zygomatic bone above the infraorbital foramen. Its fibres converge into the muscular substance of the upper lip between the lateral slip of levator labii superioris alaeque nasi and zygomaticus minor.

Vascular supply Levator labii superioris is supplied by the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator labii superioris is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Levator labii superioris elevates and everts the upper lip. Acting with other muscles, it modifies the nasolabial furrow. In some faces, this furrow is a highly characteristic feature and it is often deepened in expressions of sadness or seriousness.

## Zygomaticus major

Zygomaticus major arises from the zygomatic bone, just in front of the zygomaticotemporal suture, and passes to the angle of the mouth where it blends with the fibres of levator anguli oris, orbicularis oris and more deeply placed muscular bands.

Vascular supply Zygomaticus major is supplied by the superior labial branch of the facial artery.

Innervation Zygomaticus major is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Zygomaticus major draws the angle of the mouth upwards and laterally, as in laughing.

## Zygomaticus minor

Zygomaticus minor arises from the lateral surface of the zygomatic bone immediately behind the zygomaticomaxillary suture, and passes downwards and medially into the muscular substance of the upper lip. Superiorly, it is separated from levator labii superioris by a narrow triangular interval and, inferiorly, it blends with this muscle.

Vascular supply Zygomaticus minor is supplied by the superior labial branch of the facial artery.

Innervation Zygomaticus minor is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Zygomaticus minor elevates the upper lip, exposing the maxillary teeth. It also assists in deepening and elevating the nasolabial furrow. Acting together, the main elevators of the lip - levator labii superioris alaeque nasi, levator labii superioris and zygomaticus minor - curl the upper lip in smiling and in expressing smugness, contempt or disdain.

## Levator anguli oris

Levator anguli oris arises from the canine fossa of the maxilla, just below the infraorbital foramen, and inserts into and below the angle of the mouth. Its fibres mingle there with other muscle fibres (zygomaticus major, depressor anguli oris, orbicularis oris). Some superficial fibres curve anteriorly and attach to the dermal floor of the lower part of the nasolabial furrow. The infraorbital nerve and accompanying vessels enter the face via the infraorbital foramen between the origins of levator anguli oris and levator labii superioris.

Vascular supply Levator anguli oris is supplied by the superior labial branch of the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator anguli oris is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Levator anguli oris raises the angle of the mouth in smiling, and contributes to the depth and contour of the nasolabial furrow.

## Malaris

Malaris is a thin sheet of muscle that is sometimes found covering and blending with zygomaticus major and minor, and levator labii superioris. It is subject to considerable variation (Zufferey 2013). When present, it is continuous with the inferior limit of orbicularis oculi, from which it is possibly derived. Its fibres incline medially and downwards. Some of its superficial fascicles have a dermal attachment to the nasolabial ridge and sulcus, and others pass directly to the angle of the mouth and to the outer third of the upper lip to intersect with bundles of orbicularis oris.

## Mentalis

Mentalis is a conical fasciculus lying at the side of the frenulum of the lower lip. The fibres arise from the incisive fossa of the mandible and descend to attach to the skin of the chin.

Vascular supply Mentalis is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Mentalis is innervated by the mandibular branch of the facial nerve.

Actions Mentalis raises the lower lip, wrinkling the skin of the chin. It raises the base of the lower lip and therefore helps in protruding and everting the lower lip in drinking and also in expressing doubt or disdain.

## Depressor labii inferioris

Depressor labii inferioris is a quadrilateral muscle that arises from the oblique line of the mandible, between the symphysis menti and the mental foramen. It passes upwards and medially into the skin and mucosa of the lower lip, blending with its contralateral fellow and with orbicularis oris. Below and laterally, it is continuous with platysma.

Vascular supply Depressor labii inferioris is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Depressor labii inferioris is innervated by the mandibular branch of the facial nerve.

Actions Depressor labii inferioris draws the lower lip downwards and a little laterally in masticatory activity, and may assist in eversion of the lower lip. It contributes to the expressions of irony, sorrow, melancholy and doubt.

## Depressor anguli oris

Depressor anguli oris has a long, linear origin from the mental tubercle of the mandible and its continuation, the oblique line, below and lateral to depressor labii inferioris. It converges into a narrow fasciculus that blends at the angle of the mouth with orbicularis oris and risorius, and some fibres continue into levator anguli oris. Depressor anguli oris is continuous below with platysma and cervical fasciae. Some of its fibres may pass below the mental tubercle and cross the midline to interlace with their contralateral fellows, thereby forming transversus menti (the 'mental sling').

Vascular supply Depressor anguli oris is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Depressor anguli oris is innervated by the buccal and mandibular branches of the facial nerve.

Actions Depressor anguli oris draws the angle of the mouth downwards and laterally in opening the mouth and in expressing sadness. During opening of the mouth, the mentolabial sulcus becomes more horizontal and its central part deepens.

## Buccinator

The muscle of the cheek, buccinator, is a thin quadrilateral muscle that occupies the interval between the maxilla and the mandible (see Fig. 30.18 D ). Its upper and lower boundaries are attached to the outer surfaces of the alveolar processes of the maxilla and mandible, respectively, opposite the molar teeth, and its posterior border is attached to the anterior margin of the pterygomandibular raphe. In addition, a few fibres spring from a fine tendinous band that bridges the interval between the maxilla and the pterygoid hamulus, between the tuberosity of the maxilla and the upper end of the pterygomandibular raphe. On its way to the soft palate, the tendon of tensor veli palatini pierces the pharyngeal wall in the small gap that lies behind this tendinous band. The posterior part of buccinator is deeply placed, internal to the mandibular ramus and in the plane of the medial pterygoid plate. Its anterior component curves out behind the third molar tooth to lie in the submucosa of the cheek and lips. The fibres of buccinator converge towards the modiolus near the angle of the mouth. Here the central (pterygomandibular) fibres intersect, those from below cross to the upper part of orbicularis oris, and those from above cross to the lower part. The highest (maxillary) and lowest (mandibular) fibres of buccinator continue forwards to enter their corresponding lips without decussation. As buccinator courses through the cheek and modiolus, substantial numbers of its fibres are diverted internally to attach to submucosa.

Relations Posteriorly, buccinator lies in the same plane as the superior pharyngeal constrictor, which arises from the posterior margin of the pterygomandibular raphe, and is covered there by the buccopharyngeal fascia. Superficially, the buccal pad of fat separates the posterior part of buccinator from the ramus of the mandible, masseter and part of temporalis. Anteriorly, the superficial surface of buccinator is related to zygomaticus major, risorius, levator and depressor anguli oris, and the parotid duct. It is crossed by the facial artery, facial vein and branches of the facial and buccal nerves. The deep surface of buccinator is related to the buccal glands and mucous membrane of the mouth. The parotid duct pierces buccinator opposite the third upper molar tooth, and lies on the deep surface of the muscle before opening into the mouth opposite the maxillary second molar tooth.

Vascular supply Buccinator is supplied by branches from the facial artery and the buccal branch of the maxillary artery.

Innervation Buccinator is supplied by the buccal branch of the facial nerve.

Actions Buccinator compresses the cheek against the teeth and gums during mastication, and assists the tongue in directing food between the teeth. As the mouth closes, the teeth glide over the buccolabial mucosa, which must be retracted progressively from their occlusal surfaces by buccinator and other submucosally attached muscles. When the cheeks have been distended with air, the buccinators expel it between the lips, an activity important when playing wind instruments, and which accounts for the name of the muscle (Latin buccinator $=$ trumpeter).

## Pterygomandibular raphe

The pterygomandibular raphe is a thin band of tendinous fibres that stretches from the hamulus of the medial pterygoid plate down to the posterior end of the mylohyoid line of the mandible. It is easily palpated medially, where it is covered by the mucous membrane of the mouth, and laterally it is separated from the ramus of the mandible by a quantity of adipose tissue. It gives attachment posteriorly to the superior constrictor of the pharynx, and anteriorly to the central part of buccinator. The pterygomandibular raphe (see Fig. 31.1) is a useful anatomical landmark for the administration of inferior alveolar nerve blocks because the nerve lies lateral to it.

## Orbicularis oris

Orbicularis oris is so named because it was once assumed that the oral fissure was surrounded by a series of complete ellipses of striated muscle that acted together in the manner of a sphincter. However, it is now recognized that the muscle actually consists of four substantially
independent quadrants (upper, lower, left and right), each of which contains a larger pars peripheralis and a smaller pars marginalis. Marginal and peripheral parts are apposed along lines that correspond externally to the lines of junction between the vermilion zone of the lip and the skin. Thus, orbicularis oris is composed of eight segments, each of which is named systematically according to its location. Each segment resembles a fan that has its stem at the modiolus and is open in peripheral segments and almost closed in marginal segments.

## Pars peripheralis

Pars peripheralis has, in each quadrant, a lateral stem attached to the labial side of the modiolus over its full thickness, from apex to base, including the corresponding upper or lower cornu. Most of these stem fibres are thought to originate within the modiolus (although it is possible that some are direct continuations from the other modiolar muscles). The consensus view is that stem fibres are reinforced directly by fibres from buccinator (upper fibres and decussating lower central fibres), levator anguli oris and the superficial part of zygomaticus major in the upper lip, and from buccinator (lower fibres and decussating upper central fibres) and depressor anguli oris in the lower lip.

The fibres of orbicularis oris enter their respective superior and inferior labial areas, and diverge to form triangular muscular sheets. These are thickest at the junctions between skin and the vermilion zone, and become progressively thinner as they reach the limits of the labial region (as defined above). The greater part of each sheet enters the free lip, where its fibres aggregate into cylindrical bundles orientated parallel to the vermilion zone. Fibres of the direct labial tractors pass to their submucosal attachments between these cylindrical bundles and between pars peripheralis and pars marginalis. In the upper lip, the highest fibres run near the nasolabial sulcus, a few fibres attach to the sulcus, and a few to the nasal ala and septum. In the lower lip, the lowest fibres reach and attach to the mentolabial sulcus. A small proportion of the main body of fibres is thought to end in the labial connective tissue, dermis or submucosa as it traverses its quadrant of free lip. Most fibres continue towards the median plane and cross some 5 mm into the opposite half-lip. At this point, the fibres from the two sides interlace on their way to their dermal insertions, creating the ridges of the philtrum of the upper lip and the less marked corresponding depression in the lower lip.

## Pars marginalis

Pars marginalis of orbicularis oris is developed to a unique extent in human lips and is closely associated with speech and the production of some kinds of musical tone. In each quadrant, the pars marginalis consists of a single (occasionally double) band of narrow-diameter muscle fibres lodged within the tissues of each vermilion zone. At their medial end, the marginal fibres meet and interlace with their contralateral fellows and then attach to the dermis of the vermilion zone a few millimetres beyond the median plane in a manner similar to pars peripheralis. At their lateral ends, the fibres converge and attach to the deepest part of the modiolar base along a horizontal strip level with the buccal angle.

The relations between pars marginalis and pars peripheralis are complex. In a full-thickness section of an upper lip at right angles to the vermilion zone, the cylindrical bundles of peripheralis fibres form an $S$ shape, with an external convexity above and an internal convexity below; the classic analogy is to the shank and initial curved part of a hook. Beyond peripheralis, the hook shape is completed by the blunted triangular profile of marginalis, which occupies the core of the vermilion zone with its base adjacent to peripheralis and its apex reaching upwards and anteriorly towards the junction between vermilion zone and skin. In a similar section through the lower lip, peripheralis bundles form a continuous curve that is concave towards the external surface. This is surmounted by the flattened triangular profile of marginalis, which curves anteriorly, its apex again nearing the vermilion/cutaneous junction. Thus, throughout the vermilion zones of both lips, marginalis lies substantially anterior to the adjacent bundles of peripheralis. However, as the muscles are traced laterally beyond the vermilion zone and across the buccal angle, this relationship alters and marginalis becomes inverted as it wraps progressively around the adjacent edge of peripheralis to reach its deep (submucosal) surface, and maintains this position up to its attachment at the modiolar base.

Vascular supply Orbicularis oris is supplied mainly by the superior and inferior labial branches of the facial artery, the mental and infraorbital branches of the maxillary artery, and the transverse facial branch of the superficial temporal artery.

Nerve supply Orbicularis oris is supplied by the buccal and mandibular branches of the facial nerve.

Actions The actions of orbicularis oris are considered in detail in the next section.

## Incisivus labii superioris

Incisivus labii superioris has a bony origin from the floor of the incisive fossa of the maxilla above the eminence of the lateral incisor tooth. Initially, it lies deep to the superior part of orbicularis oris pars peripheralis. Arching laterally, its fibre bundles become intercalated between, and parallel to, the orbicular bundles. Approaching the modiolus, it segregates into superficial and deep parts; the former blends partially with levator anguli oris and attaches to the body and apex of the modiolus, and the latter is attached to the superior cornu and base of the modiolus.

## Incisivus labii inferioris

Incisivus labii inferioris, an accessory muscle of the orbicularis oris muscle complex, has many features in common with incisivus labii superioris. Its osseous attachment is to the floor of the incisive fossa of the mandible, lateral to mentalis and below the eminence of the lateral incisor tooth. Curving laterally and upwards, it blends to some extent with the inferior part of orbicularis oris pars peripheralis before reaching the modiolus, where superficial bundles attach to the apex and body, and deep bundles attach to the base and inferior cornu.

## Platysma

Platysma is described as a muscle of the neck but it is considered here as a contributor to the orbicularis oris muscle complex. It has mandibular, labial and modiolar parts. Pars mandibularis attaches to the lower border of the body of the mandible. Posterior to this attachment, a substantial flattened bundle separates and passes superomedially to the lateral border of depressor anguli oris, where a few fibres join this muscle. The remainder continue deep to depressor anguli oris and reappear at its medial border. Here, they continue within the tissue of the lateral half of the lower lip, as a direct labial tractor, platysma pars labialis. Pars labialis occupies the interval between depressor anguli oris and depressor labii inferioris, and is in the same plane as these muscles. The adjacent margins of all three muscles blend and they have similar labial attachments. Platysma pars modiolaris constitutes all the remaining bundles posterior to pars labialis, other than a few fine fascicles that end directly in buccal dermis or submucosa. Pars modiolaris is posterolateral to depressor anguli oris and passes superomedially, deep to risorius, to apical and subapical modiolar attachments.

## Risorius

Risorius is a highly variable muscle that ranges from one or more slender fascicles to a wide, thin, superficial fan. Its peripheral attachments may include some or all of the following: the zygomatic arch, parotid fascia, fascia over the masseter anterior to the parotid, fascia enclosing platysma pars modiolaris, and fascia over the mastoid process. Its fibres converge to apical and subapical attachments at the modiolus.

Vascular supply Risorius is supplied mainly by the superior labial branch of the facial artery.

Nerve supply Risorius is supplied by buccal branches of the facial nerve.

Actions Risorius pulls the corner of the mouth laterally in numerous facial activities, including grinning and laughing.

## MOVEMENTS OF THE FACE AND LIPS

## Direct labial tractors

Direct labial tractors, as their name suggests, pass directly into the tissues of the lips and not via the modioli. In broad terms, the force exerted by tractors is directed vertically at an approximate right angle to the oral fissure. Their action will therefore elevate and/or evert the whole, or part, of the upper lip and depress and/or evert the whole, or part, of the lower lip. The tractors are, from medial to lateral, the labial part of levator labii superioris alaeque nasi; levator labii superioris and zygomaticus minor in the upper lip; and depressor labii inferioris and platysma pars labialis in the lower lip.

In both upper and lower lips, the tractors blend into a continuous sheet that divides into a series of superimposed coronal sheets that are anterior to the muscle bundles of orbicularis oris pars peripheralis as they enter the free lip. The sheets may be divided into three groups at

Fig. 30.19 A, A sagittal section of the upper lip in repose. On the left is thin skin with oblique hair follicles; on the right is thick mucosa with mucous glands and mucosal shelf; between them is the vermilion zone. B, As A but slightly contracted, forming a narrowed profile (labial cord).
increasing depths from the skin surface, each with a distinct zone of attachment (Fig. 30.19). The superficial group comprises a succession of fine fibre bundles, which curve anteriorly a short distance before attaching in a series of horizontal rows to the dermis between the hair follicles, sebaceous glands and sweat glands. The intermediate group attaches to the dermis of the vermilion zone, which they reach by two routes: the more superficial bundles continue past the skin/vermilion junction, then curve posteriorly over orbicularis oris pars marginalis to punctate attachments on the ventral half of the dermis of the vermilion zone, while the deeper bundles first pass posteriorly between pars peripheralis and pars marginalis, then curve anteriorly to punctate attachments on the dorsal half of the dermis of the vermilion zone. The deep group is closely applied to the anterior surface of orbicularis oris pars peripheralis, and sends fine tractor fibres between its parallel bundles to attach posteriorly into the submucosa and periglandular connective tissue.

## Movements of the lips

The various groups of direct labial tractors may act together or individually, and their effects may involve a complete labial quadrant or be restricted to a short segment. For example, partial contraction of the superior labial tractors can result in localized elevation of a segment of the upper lip, in a postural expression reminiscent of the 'canine snarl'. Normally, however, the activity of the tractors is modified by the superimposed activity of orbicularis oris and the modiolar muscles. The resultant actions range from delicate adjustments of the tension and profile of the lip margins to large increases of the oral fissure with eversion of the lips.

Lip protrusion is passive in its initial stages. It may be suppressed by powerful contraction of the whole of orbicularis oris or enhanced by selective activation of parts of the direct labial tractors. However, lip movements must accommodate separation of the teeth brought about by mandibular depression at the temporomandibular joints. Beyond a certain range of mouth opening, labial movements are almost completely dominated by mandibular movements. Thus, over the last $2.5-3 \mathrm{~cm}$ interincisal distance of wide jaw separation, strong contraction of orbicularis oris cannot effect lip contact, and instead it causes full-thickness inflection of upper and lower lips, including the vermilion zone, towards the oral cavity, wrapping them around the incisal edges, canine cusps and premolar occlusal surfaces. The involvement of the lips in speech is described in Chapter 35, but some aspects relevant to the actions of orbicularis oris pars marginalis will be described here. Contraction of marginalis is considered to alter the cross-sectional profile of the free margin of the vermilion zone such that both the gentle bulbous profile of the upper lip and the smooth posterosuperior convexity of the lower lip change to a narrow, symmetric, triangular profile. The transformed rims, whose length and tension can be delicately controlled, have been named labial cords. They are known to be involved in the production of some consonantal (labial) sounds. A labial cord may also function as a 'vibrating reed' in whistling or playing a wind instrument such as the trumpet.

## The modiolus and its role in facial movements

On each side of the face, a number of muscles converge towards a focus just lateral to the buccal angle, where they interlace to form a dense, compact, mobile, fibromuscular mass called the modiolus. This can be palpated most effectively by using the opposed thumb and index finger to compress the mucosa and skin simultaneously. At least nine muscles, depending on the classification employed, are attached to each modiolus. Moreover, the muscles lie in different planes, their modiolar stems are often spiralized, and most divide into two bundles - some into three or four, each of them interlacing and attaching in a distinctive way. Not surprisingly, therefore, the three-dimensional organization of the modiolus has proved difficult to analyse.

The shape and dimensions of the modiolus are given approximately because they are subject to individual, age, sexual and ethnic variation. Furthermore, the modiolus has no precise histological boundaries, and is an irregular zone where dense, compact, interlacing tissue grades into the stems of individually recognizable muscles. The modiolus has the rough form of a blunt cone. The base of the cone (basis moduli) is adjacent and adherent to the mucosa. It is roughly elliptical in outline and extends vertically 20 mm above and 20 mm below a horizontal line through the buccal angle. It also extends laterally a similar distance from the angle. The blunt apex of the cone (apex moduli) is 4 mm across, and is centred approximately 12 mm lateral to the buccal angle. From mucosa to dermis, the thickness of the mass is usually 10 mm , divided approximately equally into basal, central and apical parts. The central body has an oblique fibrous cleft or channel that transmits the facial artery, an arrangement that may limit the extent to which it is compressed by contraction of the buccolabial musculature. The cone shape is modified by two round-edged flanges (or cornua) that extend into the lateral free lip tissues above and below the corner of the mouth. The tip of the superior cornu extends 5.5 mm medial to the buccal angle, the tip of the inferior cornu only 3.5 mm . With these additions, the modiolar base becomes kidney-shaped, with the buccal angle projecting towards the hilum.

The apex of the modiolus is deep and adherent to the panniculus carnosus, which extends posteromedially as a thin, sloping sheet down to the buccal angle. There, its free border forms a crescentic, narrow, flexible, subcutaneous, fibroelastic cord that accommodates the varying postures of the modioli, lips, mouth and jaws.

Controlled three-dimensional mobility of the modioli enables them to integrate the activities of the cheeks, lips and oral fissure, the oral vestibule and the jaws. Such activities include biting, chewing, drinking, sucking, swallowing, changes in vestibular contents and pressure, the innumerable subtle variations involved in speech, the modulation (and occasional generation) of musical tones, production of harsher sounds in shouting and screaming, crying, and all the permutations of facial expression, ranging from mere hints to gross distortion, symmetric or asymmetric. Major modiolar movements appear to involve many, if not all, of its associated muscles, and there is little value in considering the actions of the individual muscles in isolation. While the most obvious determinant of modiolar position and mobility is the balance between the forces exerted by muscles that are directly attached to it, another influential factor is the degree of separation or 'gape' between the upper and lower teeth. Starting from the occlusal position, and with the lips maintained in contact, the teeth can be separated by approximately 1.25 cm near the midline, and the mentolabial sulcus descends by a similar distance. With further separation, the lips part, and as gape increases to its maximum, interlabial and interdental distances approach 4 cm , at which point the mentolabial sulcus has descended a further 2 cm . In this posture, the modiolus has descended about 1 cm to lie over the interdental space, into which its basal and surrounding buccal mucosa projects a few millimetres, and its cornua diverge into their respective lips at an obtuse angle to each other, the dispositions of the modiolar muscles being correspondingly modified. The general hexagonal shape of the labial area changes as the mouth and jaws open progressively. In maximal opening, the distance between the superior and inferior boundaries has increased by $3-3.5 \mathrm{~cm}$ at the centre; the transverse distance between its lateral angles has decreased by 1 cm and the angles are obtuse; the nasolabial sulci are longer, straighter and more vertical; and the inferior buccolabial sulci are less deep and curved. These soft tissue changes radiate from the bilateral modioli.

With the lips in contact and the teeth in tight occlusion, the modiolus can move a few millimetres in all directions. However, mobility is maximal when there is $2-3 \mathrm{~mm}$ clearance between the teeth; the apex of the modiolus may then move vertically upwards 10 mm , downwards 5 mm , posterolaterally 10 mm , and anteromedially 10 mm , these movements occurring in the curved planes of the cheek and lips.

Fig. 30.20 The arteries and veins of the left side of the face, head and neck and their main branches. The infraorbital artery is shown in Figure 26.1.

Specific movements of the modiolus may occur to any point, and along any path, within the boundaries of the envelope of movement thus defined. When the mouth is opened wide, the modiolus becomes immobile. From the neutral position, the modiolus may be displaced superficially along its apicobasal axis for up to $5-10 \mathrm{~mm}$ by liquids or solids in the vestibule, or by an increase in air pressure that 'balloons' the cheeks and lips.

Many activities take place in three phases. Initially, a particular modiolar muscle group becomes dominant over its antagonists and the modiolus is rapidly relocated. Next, the modiolus is transiently fixed in this new site by simultaneous contraction of modiolar muscles, principally zygomaticus major, levator anguli oris, depressor anguli oris and platysma pars modiolaris, and this provides a fixed base from which the main physiological effectors, buccinator and orbicularis oris, carry out their specific actions. These actions are usually integrated with partial separation or closure of the jaws, and with varying degrees of activity in the direct labial tractors. All these factors combine to determine the positions of the lips and oral fissure from moment to moment. Modiolar movements may be bilaterally symmetrical, unilateral or asymmetrical.

## MUSCLES OF MASTICATION

Masseter and temporalis, two of the muscles of mastication, are seen on the face. Masseter covers the ramus of the mandible, and temporalis lies over the temporal fossa. These muscles are described in detail with the other main muscles of mastication in Chapter 32.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE FACE AND SCALP

## ARTERIES

The main arterial supply to the face is derived from the facial and superficial temporal arteries, with additional supply from branches of the maxillary and ophthalmic arteries. The back of the scalp is supplied by the posterior auricular and occipital arteries. There are numerous anastomoses between the branches.

## Facial artery

The facial artery arises in the neck from the external carotid artery (see Figs 26.1, 29.8). It initially lies beneath platysma, passing on to the face at the anteroinferior border of masseter, where its pulse can be felt as it crosses the mandible. The artery is deep to skin, the fat of the cheek and, near the angle of the mouth, zygomaticus major and risorius, and superficial to buccinator and levator anguli oris. It may pass over or through levator labii superioris, and pursues a tortuous course along the side of the nose towards the medial corner of the eye. At its termination, it is embedded in levator labii superioris alaeque nasi.

Occasionally, the facial artery barely extends beyond the angle of the mouth, in which case its normal territory beyond this region is taken over by an enlarged transverse facial branch from the superficial temporal artery and by branches from the contralateral facial artery. The facial vein is posterior to the artery and runs a more direct course across the face. At the anterior border of masseter, the two vessels are in contact, whereas in the neck the vein is superficial to the artery.

The facial artery supplies branches to the muscles and skin of the face (Fig. 30.20). Its named branches on the face are the premasseteric artery, the superior and inferior labial arteries and the lateral nasal artery. The part of the artery distal to its terminal branch is called the angular artery.

Premasseteric artery The premasseteric artery is small and inconstant. When present, it passes upwards along the anterior border of masseter and supplies the surrounding tissues.

Inferior labial artery The inferior labial artery arises near the angle of the mouth, passes upwards and forwards under depressor anguli oris, and then penetrates orbicularis oris to run sinuously near the margin of the lower lip, between the muscle and the mucous membrane. It supplies the inferior labial glands, mucous membrane and muscles, and anastomoses with its contralateral fellow and with the mental branch of the inferior alveolar artery.

Superior labial artery The superior labial artery is larger and more tortuous than the inferior labial artery. It pursues a similar course along the superior labial margin, between the mucous membrane and orbicularis oris, anastomoses with its contralateral fellow, and supplies the
upper lip. It gives off an alar branch and a septal branch, which ramifies anteroinferiorly in the nasal septum.

Lateral nasal artery The lateral nasal artery is given off by the side of the nose, supplies the dorsum and alae of nose, and anastomoses with its contralateral fellow. The lateral nasal artery may be replaced by a branch from the superior labial artery.

## Superficial temporal artery

The superficial temporal artery is the smaller terminal branch of the external carotid artery (see Figs 26.1, 30.20). It arises in the parotid gland behind the neck of the mandible, where it is crossed by temporal and zygomatic branches of the facial nerve. Initially deep, it becomes superficial as it passes over the posterior root of the zygomatic process of the temporal bone, where its pulse can be felt. It then runs up the scalp for approximately 4 cm and divides into frontal (anterior) and parietal (posterior) branches. The artery is accompanied by corresponding veins, and by the auriculotemporal nerve, which lies just posterior to it.

The superficial temporal artery supplies the skin and muscles at the side of the face and in the scalp, the parotid gland and the temporomandibular joint. It is occasionally biopsied when a histological diagnosis of giant cell arteritis is required. The named branches of the superficial temporal artery are the transverse facial, auricular, zygomaticoorbital, middle temporal, frontal and parietal arteries. The relative sizes of the frontal, parietal and transverse facial branches vary; the frontal and parietal branches may be absent, and the transverse facial may replace a shortened transverse facial artery.
Transverse facial artery The transverse facial artery arises before the superficial temporal artery emerges from the parotid gland. It traverses the gland, crosses masseter between the parotid duct and the zygomatic arch (accompanied by one or two facial nerve branches), and divides into numerous branches that supply the parotid gland and duct, masseter and adjacent skin. The branches anastomose with the facial, masseteric, buccal, lacrimal and infraorbital arteries, and may have a direct origin from the external carotid artery.

Auricular artery The branches of the auricular artery are distributed to the lobule and lateral surface of the auricle and to the external acoustic meatus.

Zygomatico-orbital artery The zygomatico-orbital artery may arise independently from the superficial temporal artery or from its middle temporal or parietal branches. It runs close to the upper border of the zygomatic arch, between the two layers of temporal fascia, to the lateral orbital angle. It supplies orbicularis oculi and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery. A welldeveloped zygomatico-orbital artery is associated with a delayed division into frontal and parietal branches.

Middle temporal artery The middle temporal artery arises just above the zygomatic arch and perforates the temporal fascia to supply temporalis. It anastomoses with the deep temporal branches of the maxillary artery.
Frontal (anterior) branch The frontal branch passes upwards towards the frontal tuberosity and supplies the muscles, skin and pericranium in this region. It anastomoses with its contralateral fellow and with the supraorbital and supratrochlear branches of the ophthalmic artery.

Parietal (posterior) branch The parietal branch is larger than the frontal branch of the superficial temporal artery. It curves upwards and backwards, remains superficial to the temporal fascia, and anastomoses with its contralateral fellow and with the posterior auricular and occipital arteries.

## Facial branches of the maxillary artery

The maxillary artery is the larger of the two terminal branches of the external carotid artery, and has three branches that supply the face, namely: the mental, buccal and infraorbital arteries (see Figs 26.1, 26.2).
Mental artery The mental artery arises from the first part of the maxillary artery as a terminal branch of the inferior alveolar artery. It emerges on to the face from the mandibular canal at the mental foramen, supplies muscles and skin in the chin region, and anastomoses with the inferior labial and submental arteries.

Buccal artery The buccal artery is a branch of the second part of the maxillary artery. It emerges on to the face from the infratemporal fossa, crosses buccinator to supply the cheek, and anastomoses with the infraorbital artery and with branches of the facial artery.

Infraorbital artery The infraorbital artery arises from the third part of the maxillary artery. It runs through the infraorbital foramen and on to the face, supplying the lower eyelid, the lateral aspect of the nose and the upper lip. The infraorbital artery has extensive anastomoses with the transverse facial and buccal arteries and with branches of the ophthalmic and facial arteries.

## Facial branches of the ophthalmic artery

The ophthalmic artery is a branch of the internal carotid artery (see Fig. 41.3). Its supratrochlear, supraorbital, lacrimal, medial palpebral and external (dorsal) nasal branches supply the face (see Fig. 30.20).

Supratrochlear artery The supratrochlear artery emerges from the orbit on to the face at the frontal notch. It supplies the medial parts of the upper eyelid, forehead and scalp, and anastomoses with the supraorbital artery and with its contralateral fellow.

Supraorbital artery The supraorbital artery leaves the orbit through the supraorbital notch or foramen. It divides into superficial and deep branches that supply the skin and muscle of the upper eyelid, forehead and scalp. It anastomoses with the supratrochlear artery, frontal branch of the superficial temporal and its contralateral fellow. At the supraorbital margin, it often sends a branch to the diploë of the frontal bone and may also supply the mucoperiosteum in the frontal sinus.

Lacrimal artery The lacrimal artery appears on the face at the upper lateral corner of the orbit and supplies the lateral part of the eyelids. Within the orbit, it gives off a zygomatic artery, which subdivides into zygomaticofacial and zygomaticotemporal arteries. The zygomaticofacial artery passes through the lateral wall of the orbit to emerge on to the face at the zygomaticofacial foramen, and supplies the region overlying the prominence of the cheek. The zygomaticotemporal artery also passes through the lateral wall of the orbit, via the zygomaticotemporal foramen, and supplies the skin over the non-beard part of the temple. The lacrimal artery anastomoses with the deep temporal branch of the maxillary artery and the transverse facial branch of the superficial temporal artery.

Medial palpebral arteries Superior and inferior medial palpebral arteries arise from the ophthalmic artery below the trochlea. They descend behind the nasolacrimal sac to enter the eyelids, where each divides into two branches that course laterally along the edges of the tarsal plates, forming the superior and inferior arches and supplying the eyelids. They anastomose with branches of the supraorbital, zygomaticoorbital and lacrimal arteries. The inferior arch also anastomoses with the facial artery.

External (dorsal) nasal artery The external nasal artery is a terminal branch of the anterior ethmoidal artery, which arises from the ophthalmic artery. It emerges at the junction of the nasal bone and the lateral nasal cartilage and supplies the skin covering the external nose.

## Occipital artery

The occipital artery arises in the neck from the external carotid artery (see Fig. 29.8). It runs in a groove on the temporal bone, medial to the mastoid process. Accompanied by the greater occipital nerve, the occipital artery enters the back of the scalp by piercing the investing layer of deep cervical fascia that connects the cranial attachments of trapezius and sternocleidomastoid. Tortuous branches run between the skin and the occipital belly of occipitofrontalis, anastomosing with the opposite occipital, posterior auricular and superficial temporal arteries, as well as with the transverse cervical branch of the subclavian artery. These branches supply the occipital belly of occipitofrontalis and the skin and pericranium associated with the scalp as far forwards as the vertex. The artery may give off a meningeal branch, which traverses the parietal foramen.

## Posterior auricular artery

The posterior auricular artery arises in the neck from the external carotid artery and ascends between the auricle and mastoid process. It supplies
the cranial surface of the auricle via its auricular branch, and the occipital belly of occipitofrontalis and the scalp behind and above the auricle via its occipital branch. The posterior auricular artery anastomoses with the occipital artery.

## VEINS

The veins of the face are subject to considerable variations; the following description concerns those that are relatively constant (see Fig. 30.20).

## Supratrochlear vein

The supratrochlear vein starts on the forehead from a venous network connected to the frontal tributaries of the superficial temporal vein. Veins from this network form a single trunk that descends to the bridge of the nose, near the midline and parallel with its contralateral fellow. The veins are joined by a nasal arch across the nose. They then diverge, each joining a supraorbital vein to form the facial vein near the medial canthus of the eye.

## Supraorbital vein

The supraorbital vein begins near the zygomatic process of the frontal bone, connecting with branches of the superficial and middle temporal veins. It passes medially above the orbital opening, pierces orbicularis oculi and unites with the supratrochlear vein near the medial canthus of the eye to form the facial vein. A branch passes through the supraorbital notch, where it receives veins from the frontal sinus and frontal diploë, and subsequently connects with the superior ophthalmic vein.

## Facial vein

The facial vein is the main vein of the face. After receiving the supratrochlear and supraorbital veins, it travels obliquely downwards by the side of the nose, passes under zygomaticus major, risorius and platysma, descends to the anterior border and then passes over the surface of masseter. It crosses the body of the mandible and runs down in the neck to drain into the internal jugular vein. The facial vein initially lies behind the more tortuous facial artery but crosses the artery at the lower border of the mandible. The uppermost segment of the facial vein, above its junction with the superior labial vein, is also called the angular vein; any infection of the mouth or face can spread via the angular veins to the cavernous sinuses, resulting in thrombosis.

Tributaries Near its origin, the facial vein connects with the superior ophthalmic vein, both directly and via the supraorbital vein, and so is linked to the cavernous sinus. The facial vein receives tributaries from the side of the nose and, below this, an important deep facial vein from the pterygoid venous plexus. It also receives the inferior palpebral, superior and inferior labial, buccinator, parotid and masseteric veins, and other tributaries that join it below the mandible.

## Superficial temporal vein

A widespread venous network across the scalp receives branches from the supratrochlear, supraorbital, posterior auricular and occipital veins. Anterior and posterior tributaries from this network unite above the zygomatic arch to form the superficial temporal vein on each side. The vein accompanies its artery, usually lying behind it; crosses the posterior root of the zygoma; and enters the parotid gland, where it joins the maxillary vein to form the retromandibular vein.

Tributaries The tributaries are the parotid veins, rami draining the temporomandibular joint, anterior auricular, transverse facial and middle temporal veins. The middle temporal vein receives the orbital vein (formed by the lateral palpebral veins), pierces the temporal fascia and then passes back between the layers of the fascia to join the superficial temporal vein just above the level of the zygomatic arch.

## Buccal, mental and infraorbital veins

The buccal, mental and infraorbital veins drain the cheek and chin regions and pass into the pterygoid venous plexus.

## Posterior auricular and occipital veins

The posterior auricular vein arises in a parieto-occipital network that also drains into tributaries of the occipital and superficial temporal veins. It descends behind the auricle to join the posterior division of the retromandibular vein in, or just below, the parotid gland, to form the external jugular vein. It receives a stylomastoid vein and tributaries from the cranial surface of the auricle, drains the region of the scalp behind the ear and drains into the external jugular vein. The occipital vein begins in a posterior network in the scalp, pierces the cranial attachment of trapezius, turns into the suboccipital triangle and joins the deep cervical and vertebral veins. It may be joined by a vein draining the diploë in the occipital bone and then passes to either the internal jugular, posterior auricular, deep cervical or vertebral veins. Emissary veins connect the occipital vein to the intracranial venous sinuses via the mastoid and parietal foramina and through the posterior condylar canal and occipital protuberances.

## LYMPHATIC DRAINAGE OF THE FACE AND SCALP

Lymph vessels from the frontal region above the root of the nose drain to the submandibular nodes (Fig. 30.21; see Fig. 29.15). Vessels from the rest of the forehead, temporal region, upper half of the lateral auricular aspect and anterior wall of the external acoustic meatus drain to the superficial parotid nodes, which lie just anterior to the tragus, either on or deep to the parotid fascia. These nodes also drain lateral vessels from the eyelids and skin of the zygomatic region, and their efferent vessels pass to the upper deep cervical nodes. A strip of scalp above the auricle, the upper half of the cranial aspect and margin of the auricle, and the posterior wall of the external acoustic meatus all drain to the upper deep cervical and posterior auricular nodes. The posterior auricular nodes are superficial to the mastoid attachment of sternocleidomastoid and deep to auricularis posterior, and drain to the upper deep cervical nodes. The auricular lobule, floor of the external acoustic meatus and skin over the mandibular angle and lower parotid region all drain to the superficial cervical or upper deep cervical nodes. Superficial cervical nodes lie along the external jugular vein superficial to sternocleidomastoid. Some efferents pass round the anterior border of sternocleidomastoid to the upper deep cervical nodes, while others

Fig. 30.22 The cutaneous innervation of the face and neck, showing dermatomes (in bold). (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
follow the external jugular vein to the lower deep cervical nodes in the subclavian triangle.

The occipital region of the scalp drains partly to the occipital nodes, and partly to a vessel that runs along the posterior border of sternocleidomastoid to the lower deep cervical nodes. Occipital nodes are commonly superficial to the upper attachment of trapezius but occasionally lie in the superior angle of the posterior triangle.

There are usually three submandibular nodes, internal to the deep cervical fascia in the submandibular triangle. One lies at the anterior pole of the submandibular gland, and two flank the facial artery as it reaches the mandible. Other nodes are often embedded in the gland or deep to it. Submandibular nodes drain a wide area, including vessels from the submental, buccal and lingual groups of nodes, and their efferents pass to the upper and lower deep cervical nodes. The external nose, cheek, upper lip and lateral parts of the lower lip drain directly to the submandibular nodes; the afferent vessels may have a few buccal nodes along their course and near the facial vein. The mucous membrane of the lips and cheek drains to the submandibular nodes, and the lateral part of the cheek drains to the parotid nodes. The central part of the lower lip, buccal floor and tip of the tongue all drain to the submental nodes, which lie on mylohyoid between the anterior bellies of the digastric muscles. These nodes receive afferents bilaterally, some decussating across the chin; their efferents pass to the submandibular and jugulo-omohyoid nodes.

## INNERVATION

The numerous muscles of facial expression are supplied by the facial nerve, while the two muscles of mastication that relate to the face are innervated by the mandibular division of the trigeminal nerve. The sensory innervation is primarily from the three divisions of the trigeminal nerve, with smaller contributions from the cervical spinal nerves. The detailed innervation of the auricle is considered on page 629.

## TRIGEMINAL NERVE

Three large areas of the face can be mapped out to indicate the peripheral nerve fields associated with the three divisions of the trigeminal
nerve. The fields are not horizontal but curve upwards (Fig. 30.22), apparently because the facial skin moves upwards with growth of the brain and skull. Embryologically, each division of the trigeminal nerve is associated with a developing facial process that gives rise to a specific area of the adult face: the ophthalmic nerve is associated with the frontonasal process, the maxillary nerve with the maxillary process, and the mandibular nerve with the mandibular process.

## Ophthalmic nerve

The cutaneous branches of the ophthalmic nerve supply the conjunctiva, skin over the forehead, upper eyelid and much of the external surface of the nose.

## Supratrochlear nerve

The supratrochlear nerve is the smaller terminal branch of the frontal nerve. It runs anteromedially in the roof of the orbit, passes above the trochlea, and supplies a descending filament to the infratrochlear branch of the nasociliary nerve. The nerve emerges between the trochlea and the supraorbital foramen at the frontal notch, curves up on the forehead close to the bone with the supratrochlear artery, and supplies the conjunctiva and the skin of the upper eyelid. It then ascends beneath the corrugator and the frontal belly of occipitofrontalis before dividing into branches that pierce these muscles to supply the skin of the lower forehead near the midline.

## Supraorbital nerve

The supraorbital nerve is the larger terminal branch of the frontal nerve. It traverses the supraorbital notch or foramen and supplies palpebral filaments to the upper eyelid and conjunctiva. It ascends on the forehead with the supraorbital artery, and divides into medial and lateral branches that supply the skin of the scalp nearly as far back as the lambdoid suture. These branches are at first deep to the frontal belly of occipitofrontalis. The medial branch perforates the muscle to reach the skin, while the lateral branch pierces the epicranial aponeurosis.

## Lacrimal nerve

The lacrimal nerve is the smallest of the main ophthalmic branches and pierces the orbital septum to end in the lateral region of the upper eyelid, which it supplies. It anastomoses with filaments of the facial
nerve. Occasionally, it is absent, in which case it is replaced by the zygomaticotemporal nerve; the relationship is reciprocal, and when the zygomaticotemporal nerve is absent it is replaced by a branch of the lacrimal nerve.

## Infratrochlear nerve

The infratrochlear nerve branches from the nasociliary nerve. It leaves the orbit below the trochlea and supplies the skin of the eyelids, the conjunctiva, lacrimal sac, lacrimal caruncle and the side of the nose above the medial canthus.

## External nasal nerve

The external nasal nerve is the terminal branch of the anterior ethmoidal nerve. It descends through the lateral wall of the nose and supplies the skin of the nose below the nasal bones, excluding the alar portion around the external nares.

## Maxillary nerve

The maxillary nerve passes through the orbit to supply the skin of the lower eyelid, the prominence of the cheek, the alar part of the nose, part of the temple, and the upper lip. It has three cutaneous branches: the zygomaticotemporal, zygomaticofacial and infraorbital nerves.

## Zygomaticotemporal nerve

The zygomaticotemporal nerve traverses a canal in the zygomatic bone and emerges into the anterior part of the temporal fossa, where it ascends between the bone and temporalis before piercing the temporal fascia about 2 cm above the zygomatic arch to supply the skin of the temple. It communicates with the facial and auriculotemporal nerves. As it pierces the deep layer of the temporal fascia, it sends a slender twig between the two layers of the fascia towards the lateral angle of the eye. It was thought that the branch carried parasympathetic postganglionic fibres from the pterygopalatine ganglion to the lacrimal gland; it is now believed that these fibres innervate the lacrimal gland directly.

## Zygomaticofacial nerve

The zygomaticofacial nerve traverses the inferolateral angle of the orbit and emerges on the face through a foramen in the zygomatic bone. It perforates orbicularis oculi to supply the skin on the prominence of the cheek and forms a plexus with zygomatic branches of the facial nerve and palpebral branches of the maxillary nerve. Occasionally, the nerve is absent.

## Infraorbital nerve

The infraorbital nerve emerges on to the face at the infraorbital foramen, where it lies between levator labii superioris and levator anguli oris. It gives off palpebral, nasal and superior labial branches. The palpebral branches ascend deep to orbicularis oculi, pierce the muscle to supply the skin in the lower eyelid, and join with the facial and zygomaticofacial nerves near the lateral canthus. Nasal branches supply the skin of the side of the nose and of the movable part of the nasal septum, and join the external nasal branch of the anterior ethmoidal nerve. Superior labial branches, which are large and numerous, descend behind levator labii superioris to supply the skin of the anterior part of the cheek and upper lip. They are joined by branches from the facial nerve to form the infraorbital plexus. The infraorbital nerve is commonly implicated in trigeminal neuralgia, and is amenable to cryotherapy where medical therapy fails.

## Mandibular nerve

The mandibular nerve supplies skin over the mandible, the lower lip, the fleshy part of the cheek, part of the auricle of the ear and part of the temple via the buccal, mental and auriculotemporal nerves.

## Buccal nerve

The buccal nerve emerges on to the face from behind the ramus of the mandible and passes laterally in front of masseter to unite with the buccal branches of the facial nerve. It supplies the skin over the anterior part of buccinator.

## Mental nerve

The mental nerve is the terminal branch of the inferior alveolar nerve. It enters the face through the mental foramen, where it is directed backwards, and supplies the skin of the lower lip and labial gingivae. Occasionally, the mental nerve is important aetiologically in the pain of trigeminal neuralgia, and it is amenable to cryotherapy surgery.

## Auriculotemporal nerve

The auriculotemporal nerve emerges on to the face behind the temporomandibular joint within the superior surface of the parotid gland. It ascends posterior to the superficial temporal vessels, passes over the posterior root of the zygoma, and divides into superficial temporal branches (see Figs 32.20, 32.25). The cutaneous branches of the auriculotemporal nerve supply the tragus and part of the adjoining auricle of the ear and the posterior part of the temple. The nerve may be damaged during parotid gland surgery, resulting in impaired sensation of the tragus and temple. It communicates with the temporofacial division of the facial nerve, usually by two rami that pass anterolaterally behind the neck of the mandible. These communications anchor the facial nerve close to the lateral surface of the condylar process of the mandible and limit its mobility during surgery. Communications with the temporal and zygomatic branches of the facial nerve loop around the transverse facial and superficial temporal vessels.

## FACIAL NERVE

The facial nerve emerges from the base of the skull at the stylomastoid foramen and almost immediately gives off the nerves to the posterior belly of digastric and stylohyoid, and the posterior auricular nerve, which supplies the occipital belly of occipitofrontalis and some of the auricular muscles (Fig. 30.23).

The nerve next enters the parotid gland high up on its posteromedial surface and passes forwards and downwards behind the mandibular ramus. Within the substance of the gland, it branches into superior (temporofacial) and inferior (cervicofacial) trunks, usually just behind and superficial to the retromandibular vein. The trunks branch further to form a parotid plexus (pes anserinus). Five main terminal branches arise from the plexus; they diverge within the gland and leave by its anteromedial surface, medial to its anterior margin, to supply the muscles of facial expression (see Fig. 30.23). Six distinctive anastomotic patterns were originally classified by Davis et al (1956) and these are illustrated in Figure 30.24. Numerous microdissection studies have demonstrated that branching patterns and anastomoses between branches, both within the parotid and on the face, exhibit considerable individual variation (e.g. Lineaweaver et al 1997, Kwak et al 2004); the account that follows is therefore an overview. In surgical terms, these anastomoses are important, and presumably explain why accidental or deliberate division of a small branch often fails to result in the expected facial nerve weakness. The surface anatomy of the facial nerve is described on page 412.

The temporal branch usually divides into anterior and posterior rami soon after piercing the parotidomasseteric fascia below the zygomatic arch; there is often a middle (frontal) ramus. These rami cross the arch in subcutaneous tissue and above the arch lie in the subgaleal space, where their course is extremely variable. Twigs supply intrinsic muscles on the lateral surface of the auricle, and the anterior and superior auricular muscles, and communicate with the zygomaticotemporal branch of the maxillary nerve and the auriculotemporal branch of the mandibular nerve. The more anterior branches supply the frontal belly of occipitofrontalis, orbicularis oculi and corrugator, and join the supraorbital and lacrimal branches of the ophthalmic nerve.

Zygomatic branches are generally multiple. They cross the zygomatic bone to the lateral canthus of the eye and supply orbicularis oculi; they may also supply muscles innervated by the buccal branch. Twigs communicate with filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The buccal branch is usually single. It has a close relationship to the parotid duct for about 2.5 cm after emerging from the parotid gland, and typically lies below the duct. Superficial branches run beneath the subcutaneous fat and superficial musculo-aponeurotic system (SMAS). Some branches pass deep to procerus and join the infratrochlear and external nasal nerves. Upper deep branches supply zygomaticus major and levator labii superioris, and form an infraorbital plexus with the superior labial branches of the infraorbital nerve. They also supply levator anguli oris, zygomaticus minor, levator labii superioris alaeque nasi and the small nasal muscles; these branches are sometimes described as lower zygomatic branches. Lower deep branches supply buccinator and orbicularis oris; they communicate with filaments of the buccal branch of the mandibular nerve.

There are usually two marginal mandibular branches. They run forwards towards the angle of the mandible under platysma, and then turn upwards across the body of the mandible to pass under depressor anguli oris. The branches supply risorius and the muscles of the lower lip and chin, and filaments communicate with the mental nerve. The marginal

Fig. 30.24 The pattern of branching of the facial nerve. (Modified with permission from Berkovitz BKB, Moxham BJ 2002 Head and Neck Anatomy. London: Martin Dunitz, and from Davis RA, Anson BJ, Budinger JM, Kurth IE 1956 Surgical anatomy of the facial nerve and parotid gland based upon a study of 350 cervicofacial halves. Surg Gynecol Obstet 102:385-412, with permission from the American College of Surgeons.)
mandibular branch has an important surgical relationship with the lower border of the mandible.

The cervical branch emerges from the lower part of the parotid gland and runs anteroinferiorly under platysma to the front of the neck. Typically single, it supplies platysma and communicates with the transverse cutaneous cervical nerve.

Cutaneous branches of the facial nerve accompany the auricular branch of the vagus; they are believed to innervate the skin on both auricular aspects, in the conchal depression and over its eminence.

## Lesions of the facial nerve

Facial paralysis may be due to an upper motor neurone lesion (when frontalis is partially spared because of the bilateral innervation of the muscles of the upper part of the face) or a lower motor neurone lesion (when all branches may be involved). Ipsilateral lower motor neurone facial paralysis is most commonly idiopathic (Bell's palsy). There are a large number of other recognized causes, including geniculate herpes zoster (Ramsay Hunt syndrome) and tumours of the parotid and temporal bone; sadly, a number are the iatrogenic results of parotid and

Fig. 30.25 The principal immediate deep relations of the parotid gland. The outline of the parotid gland is indicated by the interrupted black line.
vestibular schwannoma surgery. Only those muscles innervated by degenerating or demyelinating branches of the facial nerve become weak.

The facial nerve is routinely isolated as part of a superficial parotidectomy operation, typically in the treatment of parotid tumours, when that part of the gland lying superficial to the plane of the facial nerve is removed along with the tumour. Although this can affect all the branches of the facial nerve, the weakness is often confined to the territory innervated by the marginal mandibular branch, which is most likely to be stretched during surgical intervention and is manifested by a weakness of the lower lip on the affected side.

## CERVICAL SPINAL NERVES

Cervical spinal nerves have cutaneous branches that supply areas of skin in the face and scalp (see Fig. 30.22). The named branches are the great auricular and lesser occipital nerves, which are part of the cervical plexus and are described on page 442 (see Fig. 29.1), and the greater occipital nerve, which is described on page 768 (see Figs 43.76, 45.8).

## PAROTID SALIVARY GLAND

The paired parotid glands are the largest of the salivary glands. Each has an average weight of 25 g and is an irregular, lobulated, yellowish mass, lying largely below the external acoustic meatus between the mandible and sternocleidomastoid. The gland also projects forwards on to the surface of masseter (see Fig. 30.23B). Sometimes, a small, usually detached, part called the accessory parotid gland (pars accessoria or socia parotidis) lies between the zygomatic arch above and the parotid duct below (Fromer 1977). The overall shape of the parotid gland is variable. Viewed laterally, in half of cases it is roughly triangular in outline. Sometimes, however, the gland is more or less of even width throughout, and the upper and lower poles are rounded.

In its usual inverted pyramidal form, the parotid gland presents a small superior surface, and superficial, anteromedial and posteromedial surfaces. It tapers inferiorly to a blunt apex. The concave superior surface is related to the cartilaginous part of the external acoustic meatus and posterior aspect of the temporomandibular joint. Here, the auriculotemporal nerve curves round the neck of the mandible, embedded in the capsule of the gland. The apex overlaps the posterior belly of digastric and the carotid triangle to a variable extent.

The superficial surface is covered by skin and superficial fascia, which contains the facial branches of the great auricular nerve, superficial parotid lymph nodes and the posterior border of platysma. It extends upwards to the zygomatic arch, backwards to overlap sternocleidomastoid, downwards to its apex posteroinferior to the mandibular angle, and forwards to lie on masseter below the parotid duct.

The anteromedial surface is grooved by the posterior border of the mandibular ramus. It covers the posteroinferior part of masseter, the lateral aspect of the temporomandibular joint and the adjoining part of the mandibular ramus. It passes forwards, medial to the ramus of the mandible, to reach medial pterygoid. The gland may therefore be subdivided into a larger superficial part and a smaller part, the deep 'lobe', deep to the ramus, the two being joined by an isthmus. Branches of the facial nerve emerge on the face from the anterior margin of this surface.

The posteromedial surface is moulded to the mastoid process, sternocleidomastoid, posterior belly of the digastric, and the styloid process and its associated muscles. The external carotid artery grooves this surface before entering the gland, and the internal carotid artery and internal jugular vein are separated from the gland by the styloid process and its associated muscles (Fig. 30.25). The anteromedial and posteromedial surfaces meet at a medial margin that may project so deeply that it contacts the lateral wall of the pharynx.

Deep lobe tumours The deep 'lobe' of the gland extends behind the mandibular ramus, where its deep surface lies immediately lateral to the superior constrictor of the pharynx. When a parotid tumour, either benign or malignant, develops in the deep 'lobe', the mass presents as a swelling in the lateral wall of the oropharynx and not as a facial swelling.

## STRUCTURES WITHIN THE PAROTID GLAND

The external carotid artery, retromandibular vein and facial nerve (Langdon 1998), either in part or in whole, traverse the gland and branch within it. The external carotid artery enters the posteromedial surface and divides into the maxillary artery, which emerges from the anteromedial surface, and the superficial temporal artery, which gives off its transverse facial branch in the gland and ascends to leave its upper limit (see Fig. 30.23). The posterior auricular artery may also branch from the external carotid artery within the gland, leaving by its posteromedial surface.

The retromandibular vein, formed by the union of the maxillary and superficial temporal veins (which enter near the points of exit of the corresponding arteries), is superficial to the external carotid artery. It descends in the parotid gland and emerges behind the apex of the gland, where it usually divides into an anterior branch, which passes forwards to join the facial vein, and a posterior branch, which joins the posterior auricular vein to form the external jugular vein. Occasionally, it is not connected to the external jugular vein, which is then small, and the anterior jugular vein is enlarged.

## PAROTID CAPSULE

The parotid gland is enclosed within an unyielding parotid capsule derived from the investing layer of deep cervical fascia. Acute inflammation of the parotid gland (acute sialadenitis) may cause exquisite pain in the pre-auricular region as a result of stretching of the capsule and stimulation of the great auricular nerve. The pain is usually exacerbated at mealtimes when the gustatory stimulus to the gland results in further turgor within the capsule. Causes of acute sialadenitis include parotid duct obstruction (calculus, mucus plug and duct stricture) and mumps.

## PAROTID DUCT

The average dimensions of the parotid duct are 5 cm long and 3 mm wide (although it is narrower at its oral orifice). It begins by the confluence of two main tributaries within the anterior part of the parotid gland; the duct appears at the anterior border of the upper part of the gland and passes horizontally across masseter, approximately midway between the angle of the mouth and the zygomatic arch (see Figs $30.18 \mathrm{C}, 30.25,31.39$ ). If the duct arises lower down, it may run obliquely upwards. It crosses masseter, turns medially at its anterior border at almost a right angle, and traverses the buccal fat pad and buccinator opposite the crown of the upper third molar tooth. The duct then runs obliquely forwards for a short distance between buccinator and the oral mucosa before it opens on a small papilla opposite the second upper molar crown. The submucosal passage of the duct serves as a valvular mechanism, preventing inflation of the gland with raised intraoral pressures. While crossing masseter, the duct lies between the upper and lower buccal branches of the facial nerve, and may receive the accessory parotid duct.

The accessory part of the gland (Fromer 1977) and the transverse facial artery lie above the parotid duct; the buccal branch of the mandibular nerve, emerging from beneath temporalis and masseter, lies just below, at the anterior border of masseter. The parotid duct may be crossed by anastomosing branches between the zygomatic and buccal branches of the facial nerve.

The ramifications of the ductal systems, and their patterns and calibres, can be demonstrated radiographically by injecting a radio-opaque substance into the parotid duct via a cannula. In a lateral parotid sialogram, the main duct can be seen to be formed near the centre of the posterior border of the mandibular ramus by the union of two or three ducts that ascend or descend, respectively, at right angles to the main duct. As it crosses the face, the main duct also receives from above five or six ductules from the accessory parotid gland (Fig. 30.26). As it curves round the anterior border of masseter, it is often compressed and its shadow is attenuated. Deep lacerations of the cheek, where the integrity of the parotid duct is in doubt, should be explored and repaired using microsurgical techniques, to prevent saliva leaking into the soft tissues of the cheek and subsequent sialocele formation.

Fig. 30.26 An oblique lateral radiograph showing a normal parotid duct outlined after injection of radio-opaque contrast medium (sialogram). Note that here the main duct is formed by the union of three smaller ducts at the posterior border of the ramus of the mandible. (Courtesy of $\operatorname{Dr} \mathrm{N}$ Drage.)

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The parotid gland receives its arterial supply from the external carotid artery and its branches within and near the gland. The veins drain to the external jugular vein via local tributaries.

Lymph nodes occur in the skin overlying the parotid gland (preauricular nodes) and in the substance of the gland. There are usually ten lymph nodes present in the gland; the majority lie in the superficial part of the gland above the plane related to the facial nerve. Lymph from the parotid gland drains to the upper deep cervical lymph nodes.

## INNERVATION

Preganglionic nerves travel in the lesser petrosal branch of the glossopharyngeal nerve and synapse in the otic ganglion (Ch. 32 and see Fig. 26.7). Postganglionic secretomotor fibres reach the gland via the auriculotemporal nerve.

Gustatory sweating (Frey's syndrome or auriculotemporal syndrome) Gustatory sweating (auriculotemporal syndrome) commonly develops after parotid surgery or other surgery or trauma that results in opening of the parotid capsule. It is thought to reflect aberrant innervation of sweat glands on the face by regrowing parasympathetic secretomotor axons that would previously have innervated the parotid gland. Frey's syndrome is characterized by sweating, warmth and redness of the face as a result of salivary stimulation by the smell or taste of food. The management of Frey's syndrome is difficult. Denervation by tympanic neurectomy or auriculotemporal nerve avulsion has been advocated but is often not curative. The symptoms can be managed by the subcutaneous infiltration of purified botulinum toxin into the affected area and use of antiperspirant.

Microstructure of the salivary glands is described in Chapter 31.

An outline of how the mandibular branch of the facial nerve is at risk in all incisions at the lower border of the mandible, in submandibular gland excision, incision of space-occupying dental infections, and neck dissection. A detailed knowledge of this structure is essential.

## Oral cavity

The mouth or oral cavity extends from the lips and cheeks externally to the anterior pillars of the fauces internally, where it continues into the oropharynx. The mouth can be subdivided into the vestibule external to the teeth and the oral cavity proper internal to the teeth (Fig. 31.1). The palate forms the roof of the mouth and separates the oral and nasal cavities. The floor of the mouth is formed by the mylohyoid muscles and is occupied mainly by the tongue. The lateral walls of the mouth are defined by the cheeks and retromolar regions. Three pairs of major salivary glands (parotid, submandibular and sublingual) and numerous minor salivary glands (labial, buccal, palatal, lingual) open into the mouth. The muscles in the oral cavity are associated with the lips, cheeks, floor of the mouth and tongue. The muscles of the lips and cheeks are described with the face in Chapter 30. The muscles of the soft palate are described with the pharynx in Chapter 34 (Berkovitz and Moxham 2002).

The mouth is concerned primarily with the ingestion and mastication of food, which is mainly the function of the teeth. The mouth is also associated with phonation and ventilation.

## CHEEKS

The external features of the cheeks are described on page 475. Internally, the mucosa of the cheek is tightly adherent to buccinator and is thus stretched when the mouth is opened and wrinkled when closed. Ectopic sebaceous glands may be evident as yellow patches (Fordyce spots). Their numbers increase in puberty and in later life.

Few structural landmarks are visible. The parotid duct drains into the cheek opposite the maxillary second molar tooth at a small parotid papilla. A hyperkeratinized line (the linea alba) may be seen at a position related to the occlusal plane of the teeth. In the retromolar region, a fold of mucosa containing the pterygomandibular raphe extends from the upper to the lower alveolus. The entrance to the pterygomandibular space (which contains the lingual and inferior alveolar nerves) lies lateral to this fold and medial to the ridge produced by the anterior border of the ramus of the mandible; this is the site for injection for an inferior alveolar nerve block, commonly used to anaesthetize the ipsilateral lower teeth and gums.

## Vascular supply and innervation

The cheek receives its arterial blood supply principally from the buccal branch of the maxillary artery, and is innervated by cutaneous branches of the maxillary division of the trigeminal nerve, via the zygomaticofacial and infraorbital nerves, and by the buccal branch of the mandibular division of the trigeminal nerve.

## LIPS

The external features of the lips are described on page 475. The central part of the lips contains orbicularis oris. Internally, the labial mucosa is smooth and shiny, and shows small elevations caused by underlying mucous glands.

Fig. 31.1 The oral cavity. The tongue and soft palate have been removed. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The position and activity of the lips are important in controlling the degree of protrusion of the incisors. With normal (competent) lips, the tips of the maxillary incisors lie below the upper border of the lower lip, and this arrangement helps to maintain the 'normal' inclination of the incisors. When the lips are incompetent, the maxillary incisors may not be so controlled and the lower lip may even lie behind them, thus producing an exaggerated proclination of these teeth. A tight, or overactive, lip musculature may be associated with retroclined maxillary incisors. The lips are kept moist both by tongue deposition of saliva and by numerous minor salivary glands within them. These glands are liable to trauma by the teeth, particularly in the lower lip; this can produce a mucocele as a result of either extravasation of saliva into the submucosal tissues or retention of saliva within the gland or its duct.

## Vascular supply and innervation

The lips are mainly supplied by the superior and inferior labial branches of the facial artery. The upper lip is innervated by superior labial branches of the infraorbital nerve, and the lower lip is innervated by the mental branch of the mandibular division of the trigeminal.

## ORAL VESTIBULE

The oral vestibule is a slit-like space between the lips or cheeks on one side and the teeth on the other. When the teeth occlude, the vestibule is a closed space that only communicates with the oral cavity proper in the retromolar regions behind the last molar tooth on each side. Where the mucosa that covers the alveolus of the jaw is reflected on to the lips and cheeks, a trough or sulcus is formed, which is called the fornix vestibuli. A variable number of sickle-shaped folds containing loose connective tissue run across the fornix vestibuli. In the midline, these are the upper and lower labial frena (or frenula). Other folds may traverse the fornix near the canines or premolars. The folds in the lower fornix are said to be more pronounced than those in the upper fornix (Fig. 31.2).

The upper labial frenulum is normally attached well below the alveolar crest. A large frenulum with an attachment near or on the crest may be associated with a midline gap (diastema) between the maxillary first incisors. This can be corrected by simple surgical removal of the frenulum (frenulectomy) because it contains no structures of clinical importance. Prominent frena may compromise the stability of dentures.

## ORAL MUCOSA

The oral mucosa is continuous with the skin at the labial margins (vermilion border) and with the pharyngeal mucosa at the oropharyngeal isthmus. It varies in structure, function and appearance in different regions of the oral cavity and is traditionally divided into lining, masticatory and specialized mucosae (Presland and Dale 2000).

Fig. 31.2 An anterior view of the dentition in centric occlusion, with the lips retracted. Note the pale pink, stippled gingivae and the red, shiny, smooth alveolar mucosa. The degree of overbite is rather pronounced, and the gingiva and its epithelial attachment have receded on to the root of the upper left canine. Note the frena (arrows).

## LINING MUCOSA

The lining mucosa is red in colour, and covers the soft palate, ventral surface of the tongue, floor of the mouth, alveolar processes excluding the gingivae, and the internal surfaces of the lips and cheeks. It has a non-keratinized stratified squamous epithelium, which overlies a loosely fibrous lamina propria, and the submucosa contains some fat deposits and collections of minor mucous salivary glands. The oral mucosa covering the alveolar bone - which supports the roots of the teeth - and the necks (cervical region) of the teeth is divided into two main components. That portion lining the lower part of the alveolus is loosely attached to the periosteum via a diffuse submucosa and is termed the alveolar mucosa. It is delineated from the masticatory gingival mucosa, which covers the upper part of the alveolar bone and the necks of the teeth, by a well-defined junction, the mucogingival junction. The alveolar mucosa appears dark red; the gingival appears pale pink (see Fig. 31.2). These colour differences relate to differences in the type of keratinization and the proximity to the surface of underlying small blood vessels, which may sometimes be seen coursing beneath the alveolar mucosa.

## MASTICATORY MUCOSA AND THE GINGIVAE

Masticatory mucosa, i.e. mucosa that is subjected to masticatory stress, is bound firmly to underlying bone or to the necks of the teeth, and forms a mucoperiosteum in the gingivae and palatine raphe. Gingival, palatal and dorsal lingual mucosae are keratinized or parakeratinized (Schroeder and Listgarten 1997).

The gingivae may be further subdivided into the attached gingivae and the free gingivae. Attached gingivae are firmly bound to the periosteum of the alveolus and to the teeth, whereas free gingivae, which constitute approximately a 1 mm margin of the gingivae, lie unattached around the cervical region of each tooth. The free gingival groove between the free and attached gingivae corresponds roughly to the floor of the gingival sulcus that separates the inner surface of the attached gingivae from the enamel. The interdental papilla is that part of the gingivae that fills the space between adjacent teeth. The surface of the attached gingivae is characteristically stippled, although there is considerable inter-individual variation in the degree of stippling, and variation according to age, sex and the health of the gingivae. The free gingivae are not stippled. A mucogingival line delineates the attached gingivae on the buccal surface of the upper and lower jaws (see Fig. 31.2) and the lingual surface of the lower jaw from the alveolar mucosa. There is no corresponding obvious division between the attached gingivae and the remainder of the palatal mucosa because this whole surface is orthokeratinized masticatory mucosa, which is pink.

A submucosa is absent from the gingivae and the midline palatine raphe, but is present over the rest of the hard palate. Posterolaterally, it is thick where it contains mucous salivary glands and the greater palatine nerves and vessels, and it is anchored to the periosteum of the maxillae and palatine bones by collagenous septa.

## Vascular supply and lymphatic drainage

The gingival tissues derive their blood supply from the maxillary and lingual arteries. The buccal gingivae around the maxillary cheek teeth are supplied by gingival and perforating branches from the posterior superior alveolar artery and by the buccal branch of the maxillary artery. The labial gingivae of anterior teeth are supplied by labial branches of the infraorbital artery and by perforating branches of the anterior superior alveolar artery. The palatal gingivae are supplied primarily by branches of the greater palatine artery.

The buccal gingivae associated with the mandibular cheek teeth are supplied by the buccal branch of the maxillary artery and by perforating branches from the inferior alveolar artery. The labial gingivae around the anterior teeth are supplied by the mental artery and by perforating branches of the incisive artery. The lingual gingivae are supplied by perforating branches from the inferior alveolar artery and by its lingual branch, and by the main lingual artery, a branch of the external carotid artery.

No accurate description is available concerning the venous drainage of the gingivae, although it may be assumed that buccal, lingual, greater palatine and nasopalatine veins are involved. These veins run into the pterygoid plexuses (apart from the lingual veins, which may pass directly into the internal jugular veins).

The lymph vessels of the labial and buccal gingivae of the maxillary and mandibular teeth unite to drain into the submandibular nodes,
though in the labial region of the mandibular incisors they may drain into the submental lymph nodes. The lingual and palatal gingivae drain into the jugulodigastric group of nodes, either directly or indirectly through the submandibular nodes.

## Innervation

The nerves supplying the gingivae in the upper jaw come from the maxillary nerve via its greater palatine, nasopalatine, and anterior, middle and posterior superior alveolar branches (see Table 31.2). Surgical division of the nasopalatine nerve, e.g. during the removal of an ectopic canine tooth, causes no obvious sensory deficit in the anterior part of the palate, which suggests that the territory of the greater palatine nerve reaches as far forwards as the gingivae lingual to the incisor teeth or that the nerve has large regenerative potential. The mandibular nerve innervates the gingivae in the lower jaw by its inferior alveolar, lingual and buccal branches.

## SPECIALIZED ORAL MUCOSA

The specialized mucosa covering the anterior two-thirds of the dorsum of the tongue is described on page 515 .

## OROPHARYNGEAL ISTHMUS

The oropharyngeal isthmus lies between the soft palate and the dorsum of the tongue, and is bounded on both sides by the palatoglossal arches. Each palatoglossal arch runs downwards, laterally and forwards, from the soft palate to the side of the tongue, and consists of palatoglossus and its covering mucous membrane (Fig. 31.3). The approximation of the arches shuts off the mouth from the oropharynx, and is essential for deglutition.

## FLOOR OF THE MOUTH

The floor of the mouth is a small, horseshoe-shaped region situated beneath the movable part of the tongue and above the muscular diaphragm formed by the mylohyoid muscles. A fold of tissue, the lingual frenulum, extends on to the inferior surface of the tongue from near the base of the tongue. It occasionally extends across the floor of the mouth to be attached on to the mandibular alveolus, a condition called ankyloglossia (known colloquially as a 'tongue tie'); historically, the 'tied' frenulum has been divided to aid speech but the evidence for this procedure is scanty. However, there is some evidence that frenulotomy
may aid breast feeding (National Institute for Health and Clinical Excellence 2005, Webb et al 2013). The submandibular salivary ducts open into the mouth at the sublingual papilla (caruncle), which is a large, centrally positioned protuberance at the base of the tongue.

The sublingual folds lie on either side of the sublingual papilla and cover the underlying submandibular ducts and sublingual salivary glands. The blood supply of the floor of the mouth is described with the blood supply of the tongue. The main muscle forming the floor of the mouth is mylohyoid, with geniohyoid lying immediately above it.

## Mylohyoid

Mylohyoid lies superior to the anterior belly of digastric and, with its contralateral fellow, forms a muscular floor for the oral cavity. It is a flat, triangular sheet attached to the whole length of the mylohyoid line of the mandible (Fig. 31.4A; see Figs 31.1, 31.7, 31.10). The mylohyoid line is of variable length, sometimes ending before the lower third molar (wisdom) tooth. The posterior fibres of mylohyoid pass medially and slightly downwards to the front of the body of the hyoid bone near its lower border. The middle and anterior fibres from each side decussate in a median fibrous raphe that stretches from the symphysis menti to the hyoid bone. The median raphe is sometimes absent, in which case the two muscles form a continuous sheet, or it may be fused with the anterior belly of digastric. In about one-third of subjects, there is a hiatus in the muscle through which a process of the sublingual gland protrudes.

Relations The inferior (external) surface is related to platysma, the anterior belly of digastric the superficial part of the submandibular gland, the facial and submental vessels, and the mylohyoid vessels and nerve. The superior (internal) surface is related to geniohyoid, part of hyoglossus and styloglossus, the hypoglossal and lingual nerves, the submandibular ganglion, the sublingual gland, the deep part of the submandibular gland and its duct, the lingual and sublingual vessels, and, posteriorly, the mucous membrane of the mouth.

Vascular supply Mylohyoid receives its arterial supply from the sublingual branch of the lingual artery, the maxillary artery, via the mylohyoid branch of the inferior alveolar artery, and the submental branch of the facial artery.

Innervation Mylohyoid is supplied by the mylohyoid branch of the inferior alveolar nerve, which can sometimes also supply accessory innervation to the posterior mandibular teeth.

Actions Mylohyoid elevates the floor of the mouth in the first stage of deglutition. It may also elevate the hyoid bone or depress the mandible.

## Geniohyoid

Geniohyoid is a narrow muscle that lies above the medial part of mylohyoid (see Figs 31.6, 31.10). It arises from the inferior mental spine (genial tubercle) on the back of the symphysis menti, and runs backwards and slightly downwards to attach to the anterior surface of the body of the hyoid bone. The paired muscles are contiguous and may occasionally fuse with each other or with genioglossus.

Vascular supply The blood supply to geniohyoid is derived from the lingual artery (sublingual branch).

Innervation Geniohyoid is supplied by the first cervical spinal nerve, through the hypoglossal nerve.

Actions Geniohyoid elevates the hyoid bone and draws it forwards, and therefore acts partly as an antagonist to stylohyoid. When the hyoid bone is fixed, geniohyoid depresses the mandible.

## PALATE

The palate forms the roof of the mouth and is divisible into two regions, namely: the hard palate in front and soft palate behind.

## SOFT PALATE

The soft palate is described with the pharynx on page 575.

## HARD PALATE

The hard palate is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones (see Figs 30.8B, 30.9, 31.16A). The hard palate is bounded in front and at the sides by the tooth-bearing alveolus of the upper jaw and is continuous posteriorly with the soft palate. It is covered by a thick mucosa bound tightly to the underlying periosteum. In its more lateral regions, it also possesses a submucosa containing the main neurovascular bundle. The mucosa is covered by keratinized stratified squamous epithelium, which shows regional variations and may be ortho- or parakeratinized.

The periphery of the hard palate consists of gingivae. A narrow ridge, the palatine raphe, devoid of submucosa, runs anteroposteriorly in the midline. An oval prominence, the incisive papilla, lies at the anterior extremity of the raphe. It covers the incisive fossa at the oral opening of the incisive canal and also marks the position of the fetal nasopalatine canal. Irregular transverse ridges or rugae, each containing a core of dense connective tissue, radiate outwards from the palatine raphe in the anterior half of the hard palate; their pattern is unique to the individual.

The submucosa in the posterior half of the hard palate contains minor mucous-type salivary glands. They secrete via numerous small ducts, which often drain into a larger duct that opens bilaterally at the paired palatine foveae. These depressions, sometimes a few millimetres deep, flank the midline raphe at the posterior border of the hard palate. They provide a useful landmark for the extent of an upper denture; they cause an overextended denture to become unstable when the soft palate moves during deglutition and mastication. The upper surface of the hard palate is the floor of the nasal cavity and is covered by ciliated respiratory epithelium.

## Vascular supply and lymphatic drainage of the hard palate

The palate derives its blood supply principally from the greater palatine artery, a branch of the third part of the maxillary artery. The greater palatine artery descends with its accompanying nerve in the palatine canal, where it gives off two or three lesser palatine arteries, which are transmitted through the lesser palatine canals and foramina to supply the soft palate and tonsil, and anastomose with the ascending palatine branch of the facial artery. The greater palatine artery emerges on to the oral surface of the palate at the greater palatine foramen adjacent to the second maxillary molar and runs in a curved groove near the alveolar border of the hard palate to the incisive canal. It ascends this canal and anastomoses with septal branches of the nasopalatine artery to supply the gingivae, palatine glands and mucous membrane.

The veins of the hard palate accompany the arteries and drain largely to the pterygoid plexus.

## Innervation of the hard palate

The sensory nerves of the hard palate are the greater palatine and nasopalatine branches of the maxillary nerve, which all pass through the pterygopalatine ganglion. The greater palatine nerve descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen, runs forwards in a groove on the inferior surface of the bony palate almost to the incisor teeth and supplies the gums and the mucosa and glands of the hard palate (see Fig. 31.3). It also communicates with the terminal filaments of the nasopalatine nerve. As it leaves the greater palatine canal, it supplies palatine branches to both surfaces of the soft palate. The lesser (middle and posterior) palatine nerves, which are much smaller, descend through the greater palatine canal and emerge through the lesser palatine foramina in the tubercle of the palatine bone to supply the uvula, tonsil and soft palate. The nasopalatine nerves enter the palate at the incisive foramen and are branches of the maxillary nerve that pass through the pterygopalatine ganglion to supply the anterior part of the hard palate behind the incisor teeth.

Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion, and travel through it without synapsing to join the nerve of the pterygoid canal and the greater petrosal nerve to the facial ganglion, where their cell bodies are situated. The central processes of these neurones traverse the sensory root of the facial nerve (nervus intermedius) to pass to the gustatory nucleus in the nucleus of the tractus solitarius. Parasympathetic postganglionic secretomotor fibres from the pterygopalatine ganglion run with the nerves to supply the palatine mucous glands.

## TONGUE

The tongue is a highly muscular organ of deglutition, taste and speech. It is partly oral and partly pharyngeal in position, and is attached by its muscles to the hyoid bone, mandible, styloid processes, soft palate and the pharyngeal wall. It has a root, an apex, a curved dorsum and an inferior surface. Its mucosa is normally pink and moist, and is attached closely to the underlying muscles. The dorsal mucosa is covered by numerous papillae, some of which bear taste buds. Intrinsic muscle fibres are arranged in a complex interlacing pattern of longitudinal, transverse, vertical and horizontal fasciculi, and this allows great mobility. Fasciculi are separated by a variable amount of adipose tissue, which increases posteriorly. The root of the tongue is attached to the hyoid bone and mandible, and between them it is in contact inferiorly with geniohyoid and mylohyoid. The dorsum (posterosuperior surface) is generally convex in all directions at rest. It is divided by a V-shaped sulcus terminalis into an anterior, oral (presulcal) part that faces upwards, and a posterior, pharyngeal (postsulcal) part that faces posteriorly. The anterior part forms about two-thirds of the length of the tongue. The two limbs of the sulcus terminalis run anterolaterally to the palatoglossal arches from a median depression, the foramen caecum, which marks the site of the upper end of the embryonic thyroid diverticulum (thyroglossal duct). The oral and pharyngeal parts of the tongue differ in their mucosa, innervation and developmental origins.

## ORAL (PRESULCAL) PART

The presulcal part of the tongue is located in the floor of the oral cavity. It has an apex touching the incisor teeth, a margin in contact with the gums and teeth, and a superior surface (dorsum) related to the hard and soft palates. On each side, in front of the palatoglossal arch, there are four or five vertical folds, the foliate papillae, which represent vestiges of larger papillae found in many other mammals. The dorsal mucosa has a longitudinal median sulcus and is covered by filiform, fungiform and circumvallate papillae (Fig. 31.5). The mucosa on the inferior (ventral) surface is smooth, purplish and reflected on to the oral floor and gums; it is connected to the oral floor anteriorly by the lingual frenulum. The deep lingual vein, which is visible, lies lateral to the frenulum on either side. The plica fimbriata (fimbriated fold), a fringed mucosal ridge directed anteromedially towards the apex of the tongue, lies lateral to the vein. This part of the tongue develops from the lingual swellings of the mandibular arch and from the tuberculum impar, and this embryological derivation explains its sensory innervation.

## PHARYNGEAL (POSTSULCAL) PART

The postsulcal part of the tongue constitutes its base and lies posterior to the palatoglossal arches. Although it forms the anterior wall of the oropharynx, it is described here for convenience. Its mucosa is reflected laterally on to the palatine tonsils and pharyngeal wall, and posteriorly on to the epiglottis by a median and two lateral glossoepiglottic folds, which surround two depressions or valleculae. The pharyngeal part of the tongue is devoid of papillae and exhibits low elevations. There are underlying lymphoid nodules, which are embedded in the submucosa and collectively termed the lingual tonsil. The ducts of small seromucous glands open on the apices of these elevations. The postsulcal part of the tongue develops from the hypobranchial eminence. On the rare occasions that the thyroid gland fails to migrate away from the tongue during development, it remains in the postsulcal part of the tongue as a functioning lingual thyroid gland.

## MUSCLES OF THE TONGUE

The tongue is divided by a median fibrous septum, attached to the body of the hyoid bone. There are extrinsic and intrinsic muscles in each half,

Fig. 31.5 The dorsum of the tongue, adjoining palatoglossal and palatopharyngeal arches, and epiglottis. The palatine tonsils lie in the tonsillar recesses between the palatoglossal and palatopharyngeal arches.
the former extending outside the tongue and moving it bodily, the latter wholly within it and altering its shape. The extrinsic musculature consists of four pairs of muscles, namely: genioglossus, hyoglossus, styloglossus (and chondroglossus) and palatoglossus.

## Genioglossus

Genioglossus is triangular in sagittal section, lying near and parallel to the midline. It arises from a short tendon attached to the superior genial tubercle behind the mandibular symphysis, above the origin of geniohyoid. From this point, it fans out backwards and upwards (Fig. 31.6). The inferior fibres of genioglossus are attached by a thin aponeurosis to the upper anterior surface of the hyoid body near the midline (a few fasciculi passing between hyoglossus and chondroglossus to blend with the middle constrictor of the pharynx). Intermediate fibres pass backwards into the posterior part of the tongue, and superior fibres ascend forwards to enter the whole length of the ventral surface of the tongue from root to apex, intermingling with the intrinsic muscles. The muscles of opposite sides are separated posteriorly by the lingual septum. Anteriorly, they are variably blended by decussation of fasciculi across the midline. The attachment of the genioglossi to the genial tubercles prevents the tongue from sinking back and obstructing respiration; therefore, anaesthetists pull the mandible forwards to obtain the full benefit of this connection. In infants and children, 'chin lift' and 'jaw thrust' are standard resuscitative manœuvres that rely on this anatomical arrangement to relieve obstruction of the pharynx by the tongue falling back.

Vascular supply Genioglossus is supplied by the sublingual branch of the lingual artery and the submental branch of the facial artery.

Innervation Genioglossus is innervated by the hypoglossal nerve.
Actions Genioglossus brings about the forward traction of the tongue to protrude its apex from the mouth. Acting bilaterally, the two muscles depress the central part of the tongue, making it concave from side to side. Acting unilaterally, the tongue diverges to the opposite side.

## Hyoglossus

Hyoglossus is thin and quadrilateral, and arises from the whole length of the greater cornu and the front of the body of the hyoid bone (see Fig. 31.6). It passes vertically up to enter the side of the tongue between styloglossus laterally and the inferior longitudinal muscle medially. Fibres arising from the body of the hyoid overlap those from the greater cornu.

Fig. 31.6 Muscles of the tongue and pharynx. Palatoglossus is not shown here but is depicted in Figure 34.3A, see also Fig. 34.6.

Relations Hyoglossus is related at its superficial surface to the digastric tendon, stylohyoid, styloglossus and mylohyoid, the lingual nerve and submandibular ganglion, the sublingual gland, the deep part of the submandibular gland and duct, the hypoglossal nerve and the deep lingual vein. By its deep surface it is related to the stylohyoid ligament, genioglossus, the middle constrictor and the inferior longitudinal muscle of the tongue, and the glossopharyngeal nerve. Posteroinferiorly, it is separated from the middle constrictor by the lingual artery. This part of the muscle is in the lateral wall of the pharynx, below the palatine tonsil. Passing deep to the posterior border of hyoglossus are, in descending order: the glossopharyngeal nerve, stylohyoid ligament and lingual artery.

Vascular supply Hyoglossus is supplied by the sublingual branch of the lingual artery and the submental branch of the facial artery.

Innervation Hyoglossus is innervated by the hypoglossal nerve.
Actions Hyoglossus depresses the tongue.

## Chondroglossus

Sometimes described as a part of hyoglossus, this muscle is separated from it by some fibres of genioglossus, which pass to the side of the pharynx. It is about 2 cm long, and arises from the medial side and base of the lesser cornu and the adjoining part of the body of the hyoid It ascends to merge into the intrinsic musculature between hyoglossus and genioglossus. A small slip occasionally springs from the cartilago triticea and enters the tongue with the posterior fibres of hyoglossus.

Vascular supply, innervation and actions These are similar to those described for hyoglossus.

## Styloglossus

Styloglossus is the shortest and smallest of the three muscles attached to the styloid process (see Fig. 31.6). It arises from the anterolateral aspect of the styloid process near its apex, and from the styloid end of the stylomandibular ligament (Mérida-Velasco et al 2006). Passing downwards and forwards, it divides at the side of the tongue into a longitudinal part, which enters the tongue dorsolaterally to blend with the inferior longitudinal muscle in front of hyoglossus, and an oblique part, overlapping hyoglossus and decussating with it.

Vascular supply Styloglossus is supplied by the sublingual branch of the lingual artery.

Actions Styloglossus draws the tongue up and backwards.

## Stylohyoid ligament

The stylohyoid ligament is a fibrous cord that extends from the tip of the styloid process to the lesser cornu of the hyoid bone (see Fig. 31.6). It gives attachment to some fibres of styloglossus and the middle constrictor of the pharynx, and is closely related to the lateral wall of the oropharynx. Below it is overlapped by hyoglossus. The ligament is derived embryologically from the second branchial arch. It may be partially calcified.

## Palatoglossus

Palatoglossus is closely associated with the soft palate in function and innervation, and is described with the other palatal muscles.

## Intrinsic muscles

The intrinsic muscles of the tongue are the bilateral superior and inferior longitudinal, the transverse and the vertical (Fig. 31.7).

## Superior longitudinal

The superior longitudinal muscle constitutes a thin stratum of oblique and longitudinal fibres lying beneath the mucosa of the dorsum of the tongue. It extends forwards from the submucous fibrous tissue near the epiglottis and from the median lingual septum to the lingual margins. Some fibres are inserted into the mucous membrane.

## Inferior longitudinal

The inferior longitudinal muscle is a narrow band of muscle close to the inferior lingual surface between genioglossus and hyoglossus. It extends from the root of the tongue to the apex. Some of its posterior fibres are connected to the body of the hyoid bone. Anteriorly, it blends with styloglossus.

## Transverse

The transverse muscles pass laterally from the median fibrous septum to the submucous fibrous tissue at the lingual margin, blending with palatopharyngeus.

## Vertical

The vertical muscles extend from the dorsal to the ventral aspects of the tongue in the anterior borders.

Vascular supply of intrinsic muscles The intrinsic muscles are supplied by the lingual artery.

Innervation of intrinsic muscles All intrinsic lingual muscles are innervated by the hypoglossal nerve.

Fig. 31.7 A coronal section through the tongue, the mouth and the body of the mandible opposite the lower first molar tooth.

Fig. 31.8 The left half of the tongue, viewed from the medial side, showing the lingual artery and ramifications of the hypoglossal and lingual nerves.

Actions The intrinsic muscles alter the shape of the tongue. Thus, contraction of the superior and inferior longitudinal muscles tend to shorten the tongue, but the former also turns the apex and sides upwards to make the dorsum concave, while the latter pulls the apex down to make the dorsum convex. The transverse muscle narrows and elongates the tongue, while the vertical muscle makes it flatter and wider. Acting alone or in pairs and in endless combination, the intrinsic muscles give the tongue precise and highly varied mobility, important not only in alimentary function but also in speech.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE TONGUE

## Lingual artery

The tongue and the floor of the mouth are supplied chiefly by the lingual artery, which arises from the anterior surface of the external carotid artery. It passes between hyoglossus and the middle constrictor of the pharynx to reach the floor of the mouth, accompanied by the lingual veins and the glossopharyngeal nerve. At the anterior border of hyoglossus, the lingual artery bends sharply upwards (Fig. 31.8). It is covered by the mucosa of the tongue and lies between genioglossus medially and the inferior longitudinal muscle laterally. Near the tip of the tongue, it anastomoses with its contralateral fellow; this contribution is important in maintaining the blood supply to the tongue in any surgical resection of the tongue. The branches of the lingual artery form a rich anastomotic network, which supplies the musculature of the tongue, and a very dense submucosal plexus. Named branches of the lingual artery in the floor of the mouth are the dorsal lingual, sublingual and deep lingual arteries.

## Dorsal lingual arteries

The dorsal lingual arteries are usually two or three small vessels. They arise medial to hyoglossus and ascend to the posterior part of the
dorsum of the tongue. The vessels supply its mucous membrane and the palatoglossal arch, tonsil, soft palate and epiglottis. They anastomose with their contralateral fellows.

## Sublingual artery

The sublingual artery arises at the anterior margin of hyoglossus. It passes forwards between genioglossus and mylohyoid to the sublingual gland, and supplies the gland, mylohyoid and the buccal and gingival mucous membranes. One branch pierces mylohyoid and joins the submental branches of the facial artery. Another branch courses through the mandibular gingivae to anastomose with its contralateral fellow. A single artery arises from this anastomosis and enters a small foramen (lingual foramen) on the mandible, situated in the midline on the posterior aspect of the symphysis immediately above the genial tubercles.

## Deep lingual artery

The deep lingual artery is the terminal part of the lingual artery and is found on the inferior surface of the tongue near the lingual frenulum.

In addition to the lingual artery, the tonsillar and ascending palatine branches of the facial and ascending pharyngeal arteries also supply tissue in the root of the tongue. In the region of the valleculae, epiglottic branches of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery.

## Lingual veins

The lingual veins are formed from the union of the dorsal lingual and deep lingual veins and the vena comitans of the hypoglossal nerve. The veins draining the tongue follow two routes. Dorsal lingual veins drain the dorsum and sides of the tongue, join the lingual veins accompanying the lingual artery between hyoglossus and genioglossus, and empty into the internal jugular vein near the greater cornu of the hyoid bone. The deep lingual vein begins near the tip of the tongue and runs back just beneath the mucous membrane on the inferior surface of the tongue. It joins a sublingual vein from the sublingual salivary gland near the anterior border of hyoglossus and forms the vena comitans nervi hypoglossi, which runs back with the hypoglossal nerve between mylohyoid and hyoglossus to join the facial, internal jugular or lingual vein. The lingual veins usually join the facial and retromandibular veins (anterior division) to form the common facial vein, which drains into the internal jugular vein.

## Lymphatic drainage

The mucosa of the pharyngeal part of the dorsal surface of the tongue contains many lymphoid follicles aggregated into dome-shaped groups: the lingual tonsils. Each group is arranged around a central deep crypt, or invagination, which opens on to the surface epithelium. The ducts of mucous glands open into the bases of the crypts. Small isolated follicles also occur beneath the lingual mucosa. The lymphatic drainage of the tongue can be divided into three main regions: marginal, central and dorsal. The anterior region of the tongue drains into marginal and central vessels, and the posterior part of the tongue behind the circumvallate papillae drains into the dorsal lymph vessels. The more central regions may drain bilaterally, and this must be borne in mind when

Fig. 31.9 The lymphatic drainage of the tongue. Removal of sternocleidomastoid has exposed the whole chain of deep cervical lymph nodes.
planning to remove malignant tumours of the tongue that are approaching the midline. If the tumour has a propensity for lymphatic spread, both cervical chains may be involved.

## Marginal vessels

Marginal vessels from the apex of the tongue and the lingual frenulum area descend under the mucosa to widely distributed nodes. Some vessels pierce mylohyoid as it contacts the mandibular periosteum to enter either the submental or anterior or middle submandibular nodes, or else to pass anterior to the hyoid bone to the jugulo-omohyoid node. Vessels arising in the plexus on one side may cross under the frenulum to end in contralateral nodes. Efferent vessels of median submental nodes pass bilaterally. Some vessels pass inferior to the sublingual gland and accompany the companion vein of the hypoglossal nerve to end in jugulodigastric nodes. One vessel often descends further to reach the jugulo-omohyoid node, and passes either superficial or deep to the intermediate tendon of digastric.

Vessels from the lateral margin of the tongue cross the sublingual gland, pierce mylohyoid and end in the submandibular nodes. Others end in the jugulodigastric or jugulo-omohyoid nodes. Vessels from the posterior part of the lingual margin traverse the pharyngeal wall to the jugulodigastric lymph nodes (Fig. 31.9).

## Central vessels

The regions of the lingual surface draining into the marginal or central vessels are not distinct. Central lymphatic vessels ascend between the fibres of the two genioglossi; most pass between the muscles and diverge to the right or left to follow the lingual veins to the deep cervical nodes, especially the jugulodigastric and jugulo-omohyoid nodes. Some pierce mylohyoid to enter the submandibular nodes.

## Dorsal vessels

Vessels draining the postsulcal region and the circumvallate papillae run posteroinferiorly. Those near the median plane may pass bilaterally. They turn laterally, joining the marginal vessels, and all pierce the pharyngeal wall, passing around the external carotid arteries to reach the jugulodigastric and jugulo-omohyoid lymph nodes. One vessel may descend posterior to the hyoid bone, perforating the thyrohyoid membrane to end in the jugulo-omohyoid node.

## INNERVATION OF THE TONGUE

The muscles of the tongue, with the exception of palatoglossus, are supplied by the hypoglossal nerve. Palatoglossus is supplied via the pharyngeal plexus. The pathways for proprioception associated with the tongue musculature are unknown, but presumably may involve the lingual, glossopharyngeal or hypoglossal nerves, and the cervical spinal nerves that communicate with the hypoglossal nerve.

The sensory innervation of the tongue reflects its embryological development: the anterior two-thirds (presulcal part) is derived from first arch mesenchyme and the posterior third (postsulcal part) from third arch mesenchyme. The nerve of general sensation to the anterior two-thirds is the lingual nerve. Taste sensation travels in the chorda tympani branch of the facial nerve. The nerve supplying both general and taste sensation to the posterior third is the glossopharyngeal nerve. An additional area in the region of the valleculae is supplied by the internal laryngeal branch of the vagus nerve.

## Lingual nerve

The lingual nerve is sensory to the mucosa of the floor of the mouth, mandibular lingual gingivae and mucosa of the presulcal part of the tongue (excluding the circumvallate papillae). It also carries postganglionic parasympathetic fibres from the submandibular ganglion to the sublingual and anterior lingual glands.

The lingual nerve arises from the posterior trunk of the mandibular nerve in the infratemporal fossa (see Fig. 32.23), where it is joined by the chorda tympani branch of the facial nerve and often by a branch of the inferior alveolar nerve. It then passes below the mandibular attachment of the superior pharyngeal constrictor and pterygomandibular raphe, closely applied to the periosteum of the medial surface of the mandible. Here it lies opposite the distal (posterior) root of the third molar tooth, where it is covered only by the gingival mucoperiosteum. In about 1 in 7 cases, the lingual nerve may be located above the lingual bony plate and is susceptible to damage during surgery in the region. It next passes medial to the mandibular attachment of mylohyoid, which carries it progressively away from the mandible, and separates it from the alveolar bone covering the mesial root of the third molar tooth. The lingual nerve then passes downwards and forwards on the deep surface of mylohyoid (i.e. the surface nearer the mucosa covering the floor of the mouth), crossing the lingual sulcus beneath the mucosa. In this position, it lies on the deep portion of the submandibular gland, which bulges over the top of the posterior border of mylohyoid. It passes below the submandibular duct, which crosses it from medial to lateral, and curves upwards, forwards and medially to enter the tongue by medial and lateral branches (see Fig. 31.8; Fig. 31.10). Within the tongue, the medial branch sends small branches to the medial part of the ventrolateral tongue, and the lateral branch runs along the lateral border of the tongue and sends larger branches to innervate the mucosa of the anterior tip of the tongue. The lingual nerve is connected to the submandibular ganglion (see Fig. 32.23) by two or three branches. It forms connecting loops with twigs of the hypoglossal nerve at the anterior margin of hyoglossus (Fitzgerald and Law 1958) and within the tongue (Zur et al 2004).

The lingual nerve is at risk during surgical removal of (impacted) lower third molars: patients occasionally develop lingual sensory disturbance postoperatively but this is rarely persistent (Renton 2011). The nerve is also at risk during operations to remove the submandibular salivary gland because the duct must be dissected from the lingual nerve, and because its connection to the submandibular ganglion pulls it into the operating field.

## Glossopharyngeal nerve

The glossopharyngeal nerve is distributed to the posterior third of the tongue and the circumvallate papillae. It communicates with the lingual nerve. The course of the glossopharyngeal nerve in the neck is described on page 465 .

## Hypoglossal nerve

The course of the hypoglossal nerve in the neck is described on page 468. After crossing the loop of the lingual artery a little above the tip of the greater cornu of the hyoid, it inclines upwards and forwards on hyoglossus, passing deep to stylohyoid, the tendon of digastric and the posterior border of mylohyoid. Between mylohyoid and hyoglossus, the hypoglossal nerve lies below the deep part of the submandibular gland, the submandibular duct and the lingual nerve, with which it communicates. It then passes on to the lateral aspect of genioglossus, continuing forwards in its substance as far as the tip of the tongue (see Fig. 31.8). It distributes fibres to styloglossus, hyoglossus and genioglossus and to the intrinsic muscles of the tongue. Cadaveric tongues stained using Sihler's stain (a whole mount nerve staining technique that renders a large specimen transparent while counterstaining all nerves) or acetylcholinesterase or silver stains show the basic mammalian intralingual pattern of hypoglossal nerve distribution but with notable

differences, even from non-human primates. Thus, many muscle fibres, particularly in the transverse group of intrinsic muscles, contain multiple en grappe motor end-plates (suggesting that they are some variant of slow tonic muscle fibres). Presumably, these specializations facilitate the fine motor control of tongue shape that is required in speech and swallowing (Mu and Sanders 2010) (Fig. 31.11). If the nerve suffers either iatrogenic or pathological damage, the tongue, on protrusion, will deviate towards the affected side and there may also be wasting of the muscles on the affected side.

## Special sensory innervation of the tongue

The sense of taste is dependent on scattered groups of sensory cells, the taste buds, which occur in the oral cavity and pharynx, and are particularly plentiful on the lingual papillae of the dorsal lingual mucosa.

## Dorsal lingual mucosa

The dorsal mucosa is somewhat thicker than the ventral and lateral mucosae, is directly adherent to underlying muscular tissue with no discernible submucosa, and is covered by numerous papillae. The dorsal epithelium consists of a superficial stratified squamous epithelium, which varies from non-keratinized stratified squamous epithelium posteriorly, to fully keratinized epithelium overlying the filiform papillae more anteriorly. These features probably reflect the fact that the apex of the tongue is subject to greater dehydration than the posterior and ventral parts and is subject to more abrasion during mastication. The underlying lamina propria is a dense fibrous connective tissue, with numerous elastic fibres, and is continuous with similar tissue extending between the lingual muscle fasciculi. It contains numerous vessels and nerves from which the papillae are supplied, and also large lymph plexuses and lingual glands.

## Lingual papillae

Lingual papillae are projections of the mucosa covering the dorsal surface of the tongue (see Fig. 31.5). They are limited to the presulcal part of the tongue, produce its characteristic roughness and increase the area of contact between the tongue and the contents of the mouth. There are four principal types, named filiform, fungiform, foliate and circumvallate papillae, and all except the filiform papillae bear taste buds. Papillae are more visible in the living when the tongue is dry.

## Filiform papillae

Filiform papillae are minute, conical or cylindrical projections that cover most of the presulcal dorsal area, and are arranged in diagonal rows that extend anterolaterally, parallel with the sulcus terminalis, except at the lingual apex, where they are transverse. They have irregular cores of connective tissue and their epithelium, which is keratinized, may split into whitish fine secondary processes (Fig. 31.12). Their

Fig. 31.12 The dorsal surface of the anterior tongue showing nonkeratinized fungiform papillae (left) and two keratinized filiform papillae (centre and right) with non-keratinized regions between. (With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)
functions appear to be to increase the friction between the tongue and food, and to facilitate the movement of particles by the tongue within the oral cavity.

## Fungiform papillae

Fungiform papillae occur mainly on the lingual margin but also irregularly on the dorsal surface, where they may occasionally be numerous (see Fig. 31.12). They differ from filiform papillae because they are larger, rounded and deep red in colour, this last reflecting their thin, non-keratinized epithelium and highly vascular connective tissue core. Each usually bears one or more taste buds on its apical surface.

## Foliate papillae

Foliate papillae lie bilaterally in two zones at the sides of the tongue near the sulcus terminalis, each formed by a series of red, leaf-like mucosal ridges, covered by a non-keratinized epithelium. They bear numerous taste buds.

## Circumvallate papillae

Circumvallate papillae are large cylindrical structures, varying in number from 8 to 12, which form a V-shaped row immediately in front of the sulcus terminalis on the dorsal surface of the tongue. Each papilla, $1-2 \mathrm{~mm}$ in diameter, is surrounded by a slight circular mucosal elevation (vallum or wall), which is separated from the papilla by a circular sulcus (Figs 31.13-31.14). The papilla is narrower at its base than its

B, A section of a circumvallate papilla showing pale barrel-shaped taste buds $(B)$ in its walls. Other abbreviations: P, apical pore. (A, courtesy of S Franey and with permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Embryology and Histology, 4th ed. Edinburgh: Mosby; B, with permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)
apex and the entire structure is generally covered with non-keratinized stratified squamous epithelium. Numerous taste buds are scattered in both walls of the sulcus, and small serous glands (of von Ebner) open into the sulcal base.

## Taste buds

Taste buds are microscopic barrel-shaped epithelial structures that contain chemosensory cells in synaptic contact with the terminals of gustatory nerves. They are numerous on all types of lingual papillae (except filiform papillae), particularly on their lateral aspects. Taste buds are not restricted to the papillae; they are scattered over almost the entire dorsal and lateral surfaces of the tongue and, rarely, on the epiglottis and lingual aspect of the soft palate. Each taste bud is linked by synapses at its base to one of three cranial nerves that carry taste, i.e. the facial, glossopharyngeal or vagus. They share some physiological features with neurones, e.g. action potential generation and synaptic transmission, and are therefore often referred to as paraneurones.

There is considerable individual variation in the distribution of taste buds in humans. They are most abundant on the posterior parts of the tongue, especially around the walls of the circumvallate papillae and their surrounding sulci, where there is an average of 250 taste buds for each of the 8-12 papillae. Over 1000 taste buds are distributed over the sides of the tongue, particularly over the more posterior folds of the foliate papillae, whereas they are rare, and sometimes even absent, on fungiform papillae ( 53 per papilla). Taste buds have been described on the fetal epiglottis and soft palate but most disappear from these sites during postnatal development.

## Microstructure of taste buds

Each taste bud is a barrel-shaped cluster of 50-150 fusiform cells, which lies within an oval cavity in the epithelium and converges apically on a gustatory pore, a $2 \mu \mathrm{~m}$ wide opening on the mucosal surface. The whole structure is about $70 \mu \mathrm{~m}$ in height by $40 \mu \mathrm{~m}$ across and is separated by a basal lamina from the underlying lamina propria. A small fasciculus of afferent nerve fibres penetrates the basal lamina and spirals around the sensory cells. Chemical substances dissolved in the oral saliva diffuse through the gustatory pores of the taste buds to reach the taste receptor cell membranes, where they cause membrane depolarization.

## Innervation of taste buds

Individual nerve fibres branch to give a complex distribution of taste bud innervation. Each fibre may have many terminals, which may spread to innervate widely separated taste buds or may innervate more than one sensory cell in each bud. Conversely, individual buds may receive the terminals of several different nerve fibres. These convergent and divergent patterns of innervation may be of considerable functional importance.

The gustatory nerve for the anterior part of the tongue, excluding the circumvallate papillae, is the chorda tympani, which travels via the lingual nerve. In most individuals, taste fibres run in the chorda tympani to cell bodies in the facial ganglion, but occasionally they diverge to the otic ganglion, which they reach via the greater petrosal nerve. Taste buds in the inferior surface of the soft palate are supplied mainly by the facial nerve, through the greater petrosal nerve, pterygopalatine ganglion and lesser palatine nerve; they may also be supplied by the glossopharyngeal nerve. Taste buds in the circumvallate papillae, postsulcal part of the tongue and in the palatoglossal arches and the oropharynx are innervated by the glossopharyngeal nerve, and those in the extreme pharyngeal part of the tongue and epiglottis receive fibres from the internal laryngeal branch of the vagus.

Each taste bud receives two distinct classes of fibre: one branches in the periphery of the bud to form a perigemmal plexus, whereas the other forms an intragemmal plexus within the bud itself, which innervates the bases of the receptor cells. The perigemmal fibres contain various neuropeptides including calcitonin gene-related peptide (CGRP) and substance P , and appear to represent free sensory endings. Intragemmal fibres branch within the taste bud and each forms a series of synapses.

## Central connections

On entering the brainstem, gustatory afferents constitute the tractus solitarius and terminate in the rostral third of the nucleus solitarius of the medulla oblongata.

## Taste discrimination

Historically, gustatory receptors have been reported to detect four main qualities of taste sensation; these so-called basic tastes are salt (typically NaCl ), sour (typically acids), sweet (typically sugars) and
bitter (typically quinine). More recently, a fifth basic taste has been identified, namely umami (Japanese for delicious taste), which is a glutamate-like receptor stimulated by monosodium glutamate (Smith and Margolskee 2006).

Although it is commonly stated that particular areas of the tongue are specialized to detect these different tastes, evidence indicates that all areas of the tongue are responsive to all taste stimuli. Each afferent nerve fibre is connected to widely separated taste buds and may respond to several different chemical stimuli. Some respond to all four classic categories, others to fewer or only one. Within a particular class of tastes, receptors are also differentially sensitive to a wide range of similar chemicals. Moreover, taste buds alone are able to detect only a rather restricted range of chemical substances in aqueous solution. It is difficult to separate the perceptions of taste and smell because the oral and nasal cavities are continuous. Indeed, much of what is perceived as taste is the result of airborne odorants from the oral cavity that pass through the nasopharynx to the olfactory area above it (Linden 1998).

Perceived sensations of taste are the results of the processing (presumably central) of a complex pattern of responses from particular areas of the tongue.

In newborn infants, oral sucrose has been shown to reduce procedural pain from single events; the mechanism of this nociceptive effect is not yet fully understood (Stevens et al 2013).

## Autonomic innervation of the tongue

The parasympathetic innervation of the various lingual mucous glands is via the chorda tympani branch of the facial nerve, which synapses in the submandibular ganglion; postganglionic branches are distributed to the lingual mucosa either via the lingual nerve or via plexuses around the lingual arteries.

The postganglionic sympathetic supply to lingual glands and vessels arises from the carotid plexus (fibres derived from neurones in the superior cervical ganglion) and enters the tongue through plexuses around the lingual arteries. Isolated nerve cells, perhaps postganglionic parasympathetic neurones, have been reported in the postsulcal region; presumably, they innervate glandular tissue and vascular smooth muscle.

## TEETH

## INTRODUCTION AND TERMINOLOGY

Humans have two generations of teeth: the deciduous (primary) dentition (Fig. 31.15) and the permanent (secondary) dentition. The first deciduous teeth erupt into the mouth at about 6 months after birth and all of the deciduous teeth have erupted by 3 years of age. The first
permanent molar erupts around 6 years, and thence the deciduous teeth are exfoliated one by one, to be replaced by their permanent successors. A complete permanent dentition is present when the third molars erupt at around the age of 18-21 years. In the complete deciduous dentition, there are 20 teeth, 5 in each jaw quadrant. In the complete permanent dentition, there are 32 teeth, 8 in each jaw quadrant (Berkovitz et al 2009).

There are three basic tooth forms in both dentitions: incisiform, caniniform and molariform. Incisiform teeth (incisors) are cutting teeth and have thin, blade-like crowns. Caniniform teeth (canines) are piercing or tearing teeth and have a single, stout, pointed, cone-shaped crown. Molariform teeth (molars and premolars) are grinding teeth and possess a number of cusps on an otherwise flattened biting surface. Premolars are bicuspid teeth that are restricted to the permanent dentition and replace the deciduous molars.

The tooth-bearing region of the jaws can be divided into four quadrants: the right and left maxillary and mandibular quadrants. A tooth may thus be identified according to the quadrant in which it is located (e.g. a right maxillary tooth or a left mandibular tooth). In both the deciduous and permanent dentitions, the incisors may be distinguished according to their relationship to the midline. Thus, the incisor nearest the midline is the central (first) incisor and the incisor that is more laterally positioned is termed the lateral (second) incisor. The permanent premolars and the permanent and deciduous molars can also be distinguished according to their mesiodistal relationships. The molar most mesially positioned is designated the first molar, and the one behind it is the second molar. In the permanent dentition, the tooth most distally positioned is the third molar. The mesial premolar is the first premolar, and the premolar behind it is the second premolar.

The terminology used to indicate tooth surfaces is shown in Figure 31.16B. The aspect of teeth adjacent to the lips or cheeks is termed labial or buccal, that adjacent to the tongue being lingual (or palatal in the maxilla). Labial and lingual surfaces of an incisor meet medially at a mesial surface and distally at a distal surface, terms that are also used to describe the equivalent surfaces of premolar and molar (postcanine) teeth. On account of the curvature of the dental arch, mesial surfaces of postcanine teeth are directed anteriorly and distal surfaces are directed posteriorly. Thus, the point of contact between the central incisors is the datum point for mesial and distal. The biting or occlusal surfaces of postcanine teeth are tuberculated by cusps that are separated by fissures forming a pattern characteristic of each tooth. The biting surface of an incisor is the incisal edge.

## TOOTH MORPHOLOGY

There are two incisors, a central and a lateral, in each half jaw or quadrant (see Fig. 31.16; Fig. 31.17). In labial view, the crowns are trapezoid,

Fig. 31.16 The permanent teeth: occlusal aspect. A, The upper dental arch. B, The lower dental arch. The terminology employed for the identification of teeth according to their location is shown in the lower jaw; the same terminology is used to describe the teeth in the upper jaw.

Fig. 31.15 The primary dentition. An anterior view of the complete deciduous (primary) dentition at age 3 years. (Courtesy of Miss Victoria Clark.)

Natal and/or neonatal teeth (teeth present at birth and teeth erupted within the first month of life, respectively) are rare, with an incidence of 1 in 3000 births. More than $90 \%$ of natal and neonatal teeth are prematurely erupted deciduous mandibular incisors, while less than $10 \%$ are supernumerary. Several syndromes have been associated with natal teeth, namely: Ellis-van Creveld, Hallermann-Streiff, JadassohnLewandowski and Pierre Robin syndromes. Histological features are failure of root formation, a large vascular pulp, irregular dentine formation and a failure of cementum formation (Mhaske et al 2013).

Fig. 31.17 The permanent upper and lower teeth of the right side: labial and buccal surfaces.
and the maxillary incisors (particularly the central) are larger than the mandibular. On eruption, the biting or incisal edges initially have three tubercles or mamelons, which are rapidly removed by wear. In mesial or distal view, their labial profiles are convex while their lingual surfaces are concavo-convex (the convexity near the cervical margin is caused by a low ridge or cingulum, which is prominent only on upper incisors). The roots of incisors are single and rounded in maxillary teeth, but flattened mesiodistally in mandibular teeth. The upper lateral incisor may be congenitally absent or may have a reduced form (peg-shaped lateral incisor).

Behind each lateral incisor is a canine tooth with a single cusp (hence the American term cuspid) instead of an incisal edge. The maxillary canine is stouter and more pointed than the mandibular canine, whose cusp tip is inclined lingually. The canine root, which is the longest of any tooth, produces a bulge (canine eminence) on the alveolar bone externally, particularly in the upper jaw. Although canines usually have single roots, those of the lower jaw may sometimes be bifid.

Distal to the canines are two premolars, each with a buccal and lingual cusp (hence the term bicuspid). The occlusal surfaces of the maxillary premolars are oval (the long axis is buccopalatal) and a mesiodistal fissure separates the two cusps. In buccal view, premolars resemble the canines but are smaller. The maxillary first premolar has two roots (one buccal, one palatal) but may have one root, or very rarely three roots (two buccal and one palatal); this makes the tooth more likely to fracture on removal. The maxillary second premolar usually has one root. The occlusal surfaces of the mandibular premolars are more circular or squarer than those of the upper premolars. The buccal cusp of the mandibular first premolar towers above a diminutive lingual cusp to which it is connected by a ridge separating the mesial and distal occlusal pits. In the mandibular second premolar, a mesiodistal fissure usually separates a buccal from two smaller lingual cusps. Each lower premolar has one root, but very rarely the root of the first is bifid. Rarely, lower second premolars fail to develop.

Posterior to the premolars are three molars whose size decreases distally. Each has a large rhomboid (upper jaw) or rectangular (lower jaw) occlusal surface with four or five cusps. The maxillary first molar has a cusp at each corner of its occlusal surface, and the mesiopalatal cusp is connected to the distobuccal by an oblique ridge. A smaller cusplet or tubercle (cusplet of Carabelli) usually appears on the mesiopalatal cusp (most commonly in Caucasian groups). The tooth has three widely separated roots: two buccal, of which the mesiobuccal is larger and broader and the distobuccal is rounder and smaller, and one large palatal. Their proximity to the maxillary air sinus is thought to be the reason first molar roots are wide apart and second and third molar roots are converged. The smaller maxillary second molar has a reduced or occasionally absent distopalatal cusp. Its three roots show varying degrees of fusion. The maxillary third molar, the smallest, is very variable in form. It usually has three cusps (the distopalatal being absent) and commonly the three roots are fused.

The mandibular first molar has three buccal and two lingual cusps on its rectangular occlusal surface, the smallest cusp being distal. The cusps of this tooth are all separated by fissures. It has two widely separated roots: one mesial and one distal. The smaller mandibular second molar is like the first, but has only four cusps (it lacks the distal cusp

Fig. 31.18 The deciduous upper and lower teeth of the right side: labial and buccal surfaces.

Fig. 31.19 A, The upper deciduous dentition. Note the channels (arrows) leading to the developing permanent teeth. B, The lower deciduous dentition. (With permission from Berkovitz BKB, Moxham BJ 1994 Color Atlas of the Skull. London: Mosby.)
of the first molar) and its two roots are closer together. The mandibular third molar is smaller still and, like the upper third molar, is variable in form. Its crown may resemble that of the lower first or second molar and its roots are frequently fused. One or more third molars (upper or lower) often fail to develop.

## Deciduous teeth

The incisors, canine and premolars of the permanent dentition replace two deciduous incisors, a deciduous canine and two deciduous molars in each jaw quadrant (Figs 31.18-31.19). The deciduous incisors and canine are shaped like their successors but are smaller and whiter and become extremely worn in older children. The deciduous second molars resemble the first permanent molars rather than their successors, the

Fig. 31.20 The development of the deciduous (blue) and permanent (yellow) teeth. (Modified with permission from Schour I, Massler M 1941 The development of the human dentition. J Am Dent Assoc 28:1153-1160.)
premolars. The upper first deciduous molar has a triangular occlusal surface (its rounded 'apex' is palatal), and a fissure separates a double buccal cusp from the palatal cusp. The lower first deciduous molar is long and narrow; its two buccal cusps are separated from its two lingual cusps by a zigzagging mesiodistal fissure. Both deciduous molars have large buccal protuberances on their mesial aspect. Upper deciduous molars have three roots (fusion of the palatal and distobuccal root is commonplace), and lower deciduous molars have two roots. These roots diverge more than those of permanent teeth because each developing premolar tooth crown is accommodated directly under the crown of its deciduous predecessor. The roots of deciduous teeth are progressively resorbed by osteoclast-like cells (odontoclasts) prior to being shed.

## Eruption of teeth

Information on the sequence of development and eruption of teeth into the oral cavity (Fig. 31.20) is important in clinical practice and also in forensic medicine and archaeology. Dental development is one of the best indicators of chronological age when no record of birth exists (Garn et al 1965). The tabulated data provided in Table 31.1 are largely based on European-derived populations and there is evidence of ethnic variation. When a permanent tooth erupts, about two-thirds of the root is formed and it takes about another 3 years for the root to be completed. For deciduous teeth, root completion is more rapid. The developmental stages of initial calcification and crown completion are less affected by environmental influences than is eruption, the timing of which may be modified by several factors such as early tooth loss and severe malnutrition.

Figure 31.21 shows the panoramic appearance of the dentition seen with orthopantomograms at the time of birth and at $21 / 2,61 / 2,10$ and 16 years of age.

## Dental alignment and occlusion

It is possible to bring the jaws together so that the teeth meet or occlude in many positions. When opposing occlusal surfaces meet with maximal 'intercuspation' (i.e. maximum contact), the teeth are said to be in

## Table 31.1 Chronology of the human dentition

| Dentition | Tooth | First evidence of calcification (weeks in utero for deciduous teeth) | Crown completed (months) | Eruption (months) | Root completed (years) |
| :---: | :---: | :---: | :---: | :---: | :---: |

centric occlusion. In this position, the lower teeth are normally opposed symmetrically and lingually with respect to the upper. Some important features of centric occlusion in a normal (idealized) dentition may be noted. Each lower postcanine tooth is slightly in front of its upper equivalent and the lower canine occludes in front of the upper. Buccal

Fig. 31.21 Orthopantomograms of the dentition at birth (A), $21 / 2$ years (B), $61 / 2$ years $(C), 10$ years (D) and 16 years (E). cusps of the lower postcanine teeth lie between the buccal and palatal cusps of the upper teeth. Thus, the lower postcanine teeth are slightly lingual and mesial to their upper equivalents. Lower incisors bite against the palatal surfaces of upper incisors, the latter normally obscuring about one-third of the crowns of the lower. This vertical overlap of incisors in centric occlusion is the overbite. The extent to which upper incisors are anterior to lowers is termed the overjet. In the most habitual jaw position, the resting posture, the teeth are slightly apart, the gap between them being the freeway space or interocclusal clearance. During mastication, especially with lateral jaw movements, the food is comminuted, which facilitates the early stages of digestion.

The ideal occlusion is a rather subjective concept. If there is an ideal occlusion, it can only presently be defined in broad functional terms. Therefore, the occlusion can be considered 'ideal' when the teeth are aligned such that the masticatory loads are within physiological range and act through the long axes of as many teeth in the arch as possible; mastication involves alternating bilateral jaw movements (and not habitual, unilateral biting preferences as a result of adaptation to occlusal interference); lateral jaw movements occur without undue mechanical interference; in the rest position of the jaw, the gap between teeth (the freeway space) is correct for the individual concerned; and the tooth alignment is aesthetically pleasing to its possessor.

Variations from the ideal occlusion may be termed malocclusions (although these could be regarded as normal, since they are more commonly found in the population: the majority of the population in the USA has some degree of occlusal 'disharmony'). However, the majority of malocclusions should be regarded as anatomical variations rather than abnormalities, as they are rarely involved in masticatory dysfunction or pain, although they may be aesthetically displeasing.

## Variations in tooth number, size and form

The incidence of variation in number and form, which is often related to ethnicity, is rare in deciduous teeth but not uncommon in the permanent dentition. One or more teeth may fail to develop, a condition known as hypodontia. Conversely, additional or supernumerary teeth may form, producing hyperdontia (Fig. 31.22). The third permanent molar is the most frequently missing tooth. In declining order of incidence, other missing teeth are the maxillary lateral incisors, maxillary or mandibular second premolars, mandibular central incisors and maxillary first premolars.

## GENERAL ARRANGEMENT OF DENTAL TISSUES

A tooth consists of a crown covered by very hard translucent enamel and a root covered by yellowish bone-like cementum (Fig. 31.26A). These meet at the neck or cervical margin. A longitudinal ground section (Fig. 31.26B) reveals that the body of a tooth is mostly dentine with an enamel covering over 2 mm thick, while the cementum is much thinner. The dentine surrounds a central pulp cavity, expanded at its coronal end into a pulp chamber and narrowed in the root as a pulp canal, opening at or near its tip by an apical foramen, occasionally multiple. The pulp is a soft connective tissue, continuous with the periodontal ligament via the apical foramen. It contains vessels for the support of the dentine and sensory nerves.

The root is surrounded by alveolar bone, its cementum separated from the osseous socket (alveolus) by the connective tissue of the periodontal ligament, approximately 0.2 mm thick (Fig. 31.27). Coarse

Hyperdontia affects the maxillary arch much more commonly than the mandibular dentition. The extra teeth are usually situated on the palatal aspect of the permanent incisors or distal to the molars. More rarely, additional premolars develop. Supernumerary teeth in the incisor region can often impede the eruption of the permanent teeth (Figs 31.23-31.24) and indeed this is often the first indication of their presence. A supernumerary tooth situated between the central incisors is known as a mesiodens. Teeth may be unusually large (macrodontia) or small (microdontia), e.g. the crowns of maxillary central incisors may be abnormally wide mesiodistally; in contrast, a common variant of the maxillary lateral incisor has a small, peg-shaped crown. Epidemiological studies reveal that hyperdontia tends to be associated with macrodontia, and hypodontia with microdontia (Fig. 31.25), the most severely affected individuals representing the extremes of a continuum of variation. Together with family studies, this indicates that the causation is multifactorial, combining polygenic and environmental influences.

Some differences in the form of teeth display geographical variation and are of anthropological and forensic interest. Mongoloid dentitions tend to have shovel-shaped maxillary incisors with enlarged palatal marginal ridges. The additional cusp of Carabelli is commonly found on the mesiopalatal aspect of maxillary first permanent or second deciduous molars in Caucasian but rarely in Mongoloid dentitions. In African races, the mandibular second permanent molar often has five rather than four cusps.

bundles of collagen fibres，embedded at one end in cementum，cross the periodontal ligament to enter the osseous alveolar wall，these insert－ ing bundles of collagen being termed Sharpey＇s fibres．Near the cervical margin，the tooth，periodontal ligament and adjacent bone are covered by the gingiva．On its internal surface，the gingiva is attached to the tooth surface by the junctional epithelium，a zone of profound clinical importance because just above it is a slight recess，the gingival sulcus． As the sulcus is not necessarily self－cleansing，dental plaque may accu－ mulate in it and this predisposes to periodontal disease．

## Enamel

Enamel is an extremely hard and rigid material that covers the crowns of teeth．It is a heavily mineralized epithelial cell secretion，containing

Fig．31．22 A plaster cast of the maxilla of a 25 －year－old male showing 1 supplemental premolar and 12 peg－shaped supernumerary teeth on the palatal side of the permanent teeth．（With permission from Berkovitz BKB， Holland GR，Moxham BJ 2009 Oral Anatomy，Histology and Embryology， 4th ed．Edinburgh：Mosby．Courtesy of Royal College of Surgeons of England．）
$95-96 \%$ by weight crystalline apatites（ $88 \%$ by volume）and less than $1 \%$ organic matrix．The organic matrix comprises mainly unique enamel proteins，amelogenins and non－amelogenins such as enamelins and tuftelins．Although comprising a very small percentage of the weight and volume of enamel，the organic matrix permeates the whole of enamel．As its formative cells are lost from the surface during tooth eruption，enamel is incapable of further growth．Repair is limited to the remineralization of minute carious lesions．

Enamel reaches a maximum thickness of 2.5 mm over cusps and thins at the cervical margins．It is composed of closely packed enamel prisms or rods．In longitudinal section，enamel prisms extend from close to the enamel－dentine junction to within $20 \mu \mathrm{~m}$ of the surface， where they are generally replaced by prismless（non－prismatic，

Journal of Human Evolution 44:307-329; E, Courtesy of Dr AD Beynon.)
aprismatic) enamel (Fig. 31.28A). In cross-section, the prisms are mainly horseshoe-shaped and are arranged in rows that are staggered, such that the tails of the prisms in one row lie between the heads of the prism in the row above (prism pattern 3) (Fig. 31.28B) and the tails are directed rootwards. The appearance of prism boundaries results from sudden changes in crystallite orientation. Prisms have a diameter of approximately $5 \mu \mathrm{~m}$, and are packed with flattened hexagonal hydroxyapatite crystals, far larger than those found in collagen-based mineralized tissues.

Two types of incremental lines are visible in enamel: short-term and long-term. At intervals that average $4 \mu \mathrm{~m}$ - with a range of $2-3 \mu \mathrm{~m}$ at the enamel-dentine junction and $4-6 \mu \mathrm{~m}$ in outer enamel - along its length, each prism is crossed by a line, probably reflecting diurnal swelling and shrinking in diameter during its growth. This short-term daily growth line is known as a cross-striation (Fig. 31.28C). The longer-term incremental lines pass from the enamel-dentine junction obliquely to the surface, where they end in shallow furrows, perikymata, visible on newly erupted teeth (Fig. 31.28D). Each line, known as an enamel stria (of Retzius) (Fig. 31.28E), usually represents a period of between 7 and 9 days of enamel growth with a modal value of 9 days. This is known as an individual's periodicity and it is constant in all teeth from the same individual. Periodicities of $6,10,11$ and perhaps even 12 days have been reported, but collectively they account for less than $10 \%$ of the observed periodicities in large samples of teeth (Reid and Dean 2006).

A prominent striation, the neonatal line, is formed in teeth whose mineralization spans birth. Neonatal lines are present in the enamel and dentine of teeth mineralizing at the time of birth (all the deciduous teeth and the first permanent molars) and are therefore of forensic importance, indicating that an infant has survived for a few days after birth. They reflect a disturbance in mineralization during the first few days after birth. Other accentuated lines can be observed throughout enamel growth; these are generally reflections in disturbances in ameloblast secretion caused by illness or nutritional deficiencies. In serious cases, these disturbances will manifest as hypoplasia (enamel thinning on the tooth surface)

## Dentine

 It is a tough and compliant composite material, with a mineral contenof $70 \%$ dry weight (largely crystalline hydroxyapatite with some calcium carbonate) and $20 \%$ organic matrix (type I collagen, glycosaminoglycans and phosphoproteins). Its conspicuous feature is the regular pattern of microscopic dentinal tubules, $3 \mu \mathrm{~m}$ in diameter, which extend from the pulpal surface to the enamel-dentine junction. The tubules show lateral and terminal branching near the enamel-dentine junction (Fig. 31.29A) and may project a short distance into the enamel (enamel spindles). Each tubule encloses a single cytoplasmic process of an odontoblast whose cell body lies in a pseudostratified layer that lines the pulpal surface. Processes are believed to extend the full thickness of dentine in newly erupted teeth, but in older teeth they may be partly withdrawn and occupy only the pulpal third, while the outer regions contain probably only extracellular fluid. The diameter of the dentine tubule is narrowed by deposition of peritubular dentine. This is different from normal dentine (intertubular dentine) because it is more highly mineralized and lacks a collagenous matrix. Peritubular dentine can therefore be identified by microradiography (Fig. 31.29B). In time, it may completely fill the tubule, a process that gives rise to translucent dentine and that commences in the apical region of the root.

The outermost zone $(10-20 \mu \mathrm{~m})$ of dentine differs in the crown and the root. In the crown, it is referred to as mantle dentine and differs in the orientation of its collagen fibres. In the root, the peripheral zone presents a granular layer - with less overall mineral - beyond which is a hyaline layer that lacks a tubular structure and may function to produce a good bond between the cementum and dentine.

Dentine is formed slowly throughout life, and so there is always an unmineralized zone of predentine at the surface of the mineralized dentine, adjacent to the odontoblast layer at the periphery of the pulp. Biochemical changes within the mineralizing matrix mean that predentine stains differently to the matrix of the mineralized dentine. The predentine-dentine border is generally scalloped, because dentine mineralizes both linearly and as microscopic spherical aggregates of crystals (calcospherites). Dentine, like enamel, is deposited incrementally, and exhibits both short- and long-term incremental lines (Dean 2000). Long-term lines are known as Andresen lines and in the mid-axial region are approximately $20 \mu \mathrm{~m}$ apart; they represent increments of about $6-12$ days (Fig. 31.29C). Daily incremental lines (von Ebner lines) in the mid-axial plane are typically $4 \mu \mathrm{~m}$ apart; they are considerably closer together ( $1-2 \mu \mathrm{~m}$ apart) at the enamel-dentine junction and in root dentine. Where mineralization spans birth (i.e. all deciduous teeth and usually the first permanent molars), a neonatal line is

Fig. 31.29 Dentine. A, A ground longitudinal section showing branching of dentine tubules near the enamel-dentine junction (arrow). B, A microradiograph of transversely sectioned dentinal tubules surrounded by a more radiopaque and therefore more mineralized zone of peritubular dentine. $\mathbf{C}$, A ground longitudinal section viewed in polarized light showing alternate light and dark bands representing long-period incremental lines (Andresen lines). The bands are orientated approximately at right angles to the direction of the dentinal tubules (arrows). Fig. 31.30 A longitudinal ground section of an incisor tooth.
formed in dentine similar to that which is seen in enamel, and it signals the abrupt change in both environment and nutrition that occurs at birth. As with enamel, disturbances in growth of dentine will exhibit as accentuated lines, commonly called contour lines of Owen.

Primary dentine formation proceeds at a steady but declining rate as first the crown and then the root is completed. A slow and intermittent deposition of dentine (regular secondary dentine) continues throughout life and further reduces the size of the pulp chamber; it is distinguished from primary dentine by the reduction and less regular arrangement of dentinal tubules within it. The presence of the odontoblast process means that dentine is a vital tissue. It responds to adverse external stimuli - such as rapidly advancing caries, excessive wear or tooth breakage - by forming poorly mineralized dead tracts, in which the odontoblasts of the affected region die and the tubules remain empty (tertiary dentine). A dead tract may be sealed from the pulp by a thin zone of sclerosed dentine and the deposition of irregular (tertiary) dentine by newly differentiated pulp cells (Fig. 31.30).

## Dental pulp

Dental pulp provides the nutritive support for the synthetic activity of the odontoblast layer. It is a well-vascularized, soft, loose connective tissue, enclosed by dentine and continuous with the periodontal ligament via apical and accessory foramina. Several thin-walled arterioles enter by the apical foramen and run longitudinally within the pulp to an extensive subodontoblastic plexus. Blood flow rate per unit volume of tissue is greater in the pulp than in other oral tissues, and tissue fluid pressures within the pulp appear to be unusually high.

As well as typical connective tissue cells, pulp uniquely contains the cell bodies of odontoblasts whose long processes occupy the dentinal tubules. Pulp also has dendritic antigen-presenting cells. Approximately $60 \%$ of pulpal collagen is type I, and the bulk of the remainder is type III. As dentine deposition increases with age, the pulp recedes until the whole of the crown may be removed without accessing the pulp.

Dental pulp is extensively innervated by unmyelinated postganglionic vasoconstrictor sympathetic nerve fibres from the superior cervical
ganglion, which enter with the arterioles, and by myelinated (A $\delta$ ) and unmyelinated (C) sensory nerve fibres from the trigeminal ganglion, which traverse the pulp longitudinally and ramify as a plexus (Raschkow's plexus) beneath the odontoblast layer (Figs 31.31-31.32). Here, any myelinated nerve fibres lose their myelin sheaths and continue into the odontoblast layer, and some enter the dentinal tubules, especially the region beneath the cusps. Stimulation of dentine, whether by thermal, mechanical or osmotic means, evokes a pain response. Pulp nerves release numerous neuropeptides such as CGRP, substance $P$ and neuropeptide Y that maintain homeostasis within the pulp.

## Cementum

Cementum is a bone-like tissue that covers the dental roots, and is $50 \%$ by weight mineralized (mainly hydroxyapatite crystals). However, unlike bone, cementum is avascular and lacks nerves. The cementum generally overlaps the enamel slightly, although it may meet it end on. Occasionally, the two tissues may fail to meet, in which case dentine is exposed in the mouth. If the exposed dentinal tubules remain patent, then the teeth may be sensitive to stimuli such as cold water. In older teeth, the root may become exposed in the mouth as a consequence of occlusal drift and gingival recession, and cementum is often abraded away by incorrect tooth brushing and dentine is exposed.

Like bone, cementum is perforated by Sharpey's fibres, which represent the attachment bundles of collagen fibres in the periodontal ligament (extrinsic fibres). New layers of cementum, which are deposited incrementally throughout life to compensate for tooth movements, incorporate new Sharpey's fibres. Incremental lines are irregularly spaced. The first (primary) cementum to be formed is thin (up to $200 \mu \mathrm{~m}$ ) and acellular, and contains only extrinsic fibres. Cementum formed later (secondary cementum) towards the root apex is produced more rapidly and contains cells, the cementocytes, lying in lacunae joined by canaliculi. The latter are mainly directed towards their source of nutrients from the periodontal ligament. This cementum contains mainly intrinsic collagen fibres of cementoblastic origin, which lie parallel to the surface. Varying arrangements of layering between cellular and acellular cement occur. With increasing age, cellular cement may reach a thickness of a millimetre or more around the apices and at the branching of the roots, where it compensates for the loss of enamel by attrition. Cementum is not remodelled but small areas of resorption with evidence of repair may be seen.

## Periodontal ligament

The principal functions of the periodontal ligament are to support the teeth, generate the force of tooth eruption and provide sensory information about tooth position and forces to facilitate reflex jaw activity during chewing movements. The periodontal ligament is a soft, dense, fibrous connective tissue 0.2 mm wide, which contains cells associated with the development and maintenance of alveolar bone (osteoblasts and osteoclasts) and of cementum (cementoblasts and odontoclasts). It also contains a network of epithelial cells (epithelial cell rests of Malassez, ERM cells), which are embryological remnants of an epithelial root sheath. Although their function remains speculative, ERM cells have been implicated in root development and protection against root resorption, and in reparative/regenerative functions of the pulp and periodontal tissues such as apexogenesis and periodontal healing

Fig. 31.31 A longitudinal section of a tooth and its surrounding tissues.

Fig. 31.32 A longitudinal demineralized section of a tooth stained with a silver impregnation technique. Note the small bundle of nerves within the pulp (*); one of the fine axons from the bundle (A) passes between the odontoblasts (B) lining the surface of the predentine (C)
(Keinan and Cohen 2013). Proliferation of ERM cells may play a role in the evolution of odontogenic cysts and tumours.

The majority of collagen fibres of the periodontal ligament are arranged as variously orientated dense fibre bundles that connect alveolar bone and cementum, and which may help to resist movement in specific directions (Fig. 31.33; see Fig. 31.31). About $80 \%$ of the collagen in the periodontal ligament is type I, most of the remainder being type III. The rate of turnover of collagen is probably the highest of any site in the body, for reasons that are as yet unclear. A very small volume of fibres are oxytalan (pre-elastin) fibres. Fibroblast density in human periodontal ligament tissue decreases with age (Krieger et al 2013).

The periodontal ligament is innervated by autonomic and sensory fibres, the former carrying vasomotor information and the latter carrying nociceptive and proprioceptive information. Three types of nerve endings have been identified: free nerve endings (originating from myelinated and unmyelinated nerve fibres), Ruffini-like endings (mostly found at the apical part of the periodontal ligament) and lamellated corpuscles (for further reading, see Huang et al (2011)). The periodontal ligament has a rich blood supply; the vessels tend to lie towards the bone side of the periodontal ligament and the capillaries are fenestrated (see below for further details).

## Alveolar bone

That part of the maxilla or mandible that supports and protects the teeth is known as alveolar bone. An arbitrary boundary at the level of the root apices of the teeth separates the alveolar processes from the

Fig. 31.34 The anterior part of the left side of the mandible, with superficial bone removed on the buccal side to show the roots of a number of teeth, some of which have also been sectioned vertically. Note the cortical plate of compact bone lining the sockets of the teeth (the lamina dura of radiographs; see Fig. 31.36), and the flat table of bone surmounting the interdental bone septa. In this specimen, the mandibular canal is widely separated from the roots of the teeth, a variable condition.
body of the mandible or the maxilla (Fig. 31.34). Like bone in other sites, alveolar bone functions as a mineralized supporting tissue, gives attachment to muscles, provides a framework for bone marrow and acts as a reservoir for ions, especially calcium. It is dependent on the presence of teeth for its development and maintenance, and requires functional stimuli to maintain bone mass. Where teeth are congenitally absent - as in anodontia, for example - it is poorly developed, and it atrophies after tooth extraction, which can cause difficulties in the prosthodontic rehabilitation of patients.

The alveolar tooth-bearing portion of the jaws consists of outer and inner alveolar plates. The individual sockets are separated by plates of bone termed the interdental septa, while the roots of multirooted teeth are divided by inter-radicular septa. The compact layer of bone that lines the tooth socket has been called either the cribriform plate, on account of its content of vascular (Volkmann's) canals, which pass from the alveolar bone into the periodontal ligament; or bundle bone, because numerous bundles of Sharpey's fibres pass into it from the periodontal ligament (Fig. 31.35).

Fig. 31.35 A decalcified section of a root of a tooth showing Sharpey's fibres from the periodontal ligament entering alveolar bone (A). The Sharpey's fibres in bone (thick arrows) are seen to be thicker, but less numerous, than those entering the cementum (B) on the tooth surface (thin arrows). Van Gieson stain. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Embryology and Histology, 4th ed. Edinburgh: Mosby.)

Fig. 31.36 A bite-wing radiograph of teeth and surrounding bone. Note the different radiopacities of enamel and dentine. In a healthy tooth, such as the first molar illustrated here, the lamina dura is complete and appears as a radiopaque line. In the case of the adjacent second molar tooth, in which the bulk of the crown has been lost due to dental caries, an abscess (*) has formed at the base of the tooth and, as a result, the lamina dura has lost its continuity. (Courtesy of Ms Nadine White.)

In clinical radiographs, the bone lining the alveolus commonly appears as a continuous dense white line about $0.5-1 \mathrm{~mm}$ thick: the lamina dura (Fig. 31.36). However, this appearance gives a misleading impression of the density of alveolar bone; the X-ray beam passes tangentially through the socket wall, and so the radiopacity of the lamina dura is an indication of the quantity of bone the beam has passed through, rather than the degree of mineralization of the bone. Superimposition also obscures the Volkmann's canals. Chronic infections of the dental pulp spread into the periodontal ligament, which leads to resorption of the lamina dura around the root apex. The presence of a continuous lamina dura around the apex of a tooth therefore usually indicates a healthy apical region (except in acute infections where resorption of bone has not yet begun).

On the labial and buccal aspects of upper teeth, the two cortical plates usually fuse, and there is very little cancellous bone between them, except where the buccal bone thickens over the molar teeth near the root of the zygomatic arch. It is easier and more convenient to extract upper and lower teeth by widening the tooth socket in a buccal direction due to its thinness. Anteriorly in the lower jaw, labial and lingual plates are thin, but in the molar region the buccal plate is thickened as the external oblique line. Near the lower third molar, the lingual bone is much thinner than the buccal and it is important to realize that the lingual nerve is easily damaged by poor technique.

## VASCULAR SUPPLY AND LYMPHATIC <br> DRAINAGE OF THE TEETH AND SUPPORTING STRUCTURES

The main arteries to the teeth and their supporting structures are derived from the maxillary artery, one of the two terminal branches of the external carotid artery. The upper teeth are supplied by branches from the superior alveolar arteries, and the lower teeth by branches from the inferior alveolar arteries.

## Superior alveolar arteries

The upper jaw is supplied by posterior, middle and anterior superior alveolar (dental) arteries. The posterior superior alveolar artery usually arises from the third part of the maxillary artery in the pterygopalatine fossa. It descends on the infratemporal surface of the maxilla, and divides to give branches that enter the alveolar canals to supply molar and premolar teeth, adjacent bone and the maxillary sinus, and other branches that continue over the alveolar process to supply the gingivae. The middle and anterior superior alveolar arteries are branches from the infraorbital artery.

The infraorbital artery often arises with the posterior superior alveolar artery. It enters the orbit posteriorly through the inferior orbital fissure and runs in the infraorbital groove and canal with the infraorbital nerve. When the small middle superior alveolar artery is present, it runs down the lateral wall of the maxillary sinus and forms anastomotic arcades with the anterior and posterior vessels, terminating near the canine tooth. The anterior superior alveolar artery curves through the canalis sinuosus to supply the upper incisor and canine teeth and the mucous membrane in the maxillary sinus. The canalis sinuosus swerves laterally from the infraorbital canal and inferomedially below it in the wall of the maxillary sinus, following the rim of the anterior nasal aperture, between the alveoli of canine and incisor teeth and the nasal cavity. It ends near the nasal septum where its terminal branch emerges. The canal may be up to 55 mm long.

## Inferior alveolar artery

The inferior alveolar (dental) artery, a branch of the maxillary artery, descends in the infratemporal fossa posterior to the inferior alveolar nerve. Here, it lies between bone laterally and the sphenomandibular ligament medially. Before entering the mandibular foramen it gives off a mylohyoid branch, which pierces the sphenomandibular ligament to descend with the mylohyoid nerve in its groove on the inner surface of the ramus of the mandible. The mylohyoid artery ramifies superficially on the muscle and anastomoses with the submental branch of the facial artery. The inferior alveolar artery then traverses the mandibular canal with the inferior alveolar nerve to supply the mandibular molars and premolars, and divides into the incisive and mental branches near the first premolar.

The incisive branch continues below the incisor teeth (which it supplies) to the midline, where it anastomoses with its fellow, although few anastomotic vessels cross the midline. In the canal, the arteries supply the mandible, tooth sockets and teeth via branches that enter the minute hole at the apex of each root to supply the pulp. The mental artery leaves the mental foramen and supplies the chin; it anastomoses with the submental and inferior labial arteries. Near its origin, the inferior alveolar artery has a lingual branch, which descends with the lingual nerve to supply the lingual mucous membrane. The pattern of branching of the inferior alveolar artery reflects that of the nerves of the same name.

## Arterial supply of periodontal ligaments

The periodontal ligaments supporting the teeth are supplied by dental branches of alveolar arteries. One branch enters the alveolus apically and sends two or three small rami into the dental pulp through the apical foramen, and other rami into the periodontal ligament. Interdental arteries ascend in the interdental septa, sending branches at right angles into the periodontal ligament, and terminate by communicating with gingival vessels that also supply the cervical part of the ligament. The periodontal ligament therefore receives its blood from three sources: from the apical region; ascending interdental arteries; and descending vessels from the gingivae. These vessels anastomose with each other, which means that when the pulp of a tooth is removed during endodontic treatment, the attachment tissues of the tooth remain vital.

Table 31.2 Innervation of the teeth and gingivae

| Maxilla | Nasopalatine nerve | Greater palatine nerve |  | Palatal gingivae |
| :---: | :---: | :---: | :---: | :---: |
|  | Anterior superior alveolar nerve | Middle superior alveolar nerve | Posterior superior alveolar nerve | Teeth |
|  | Infraorbital nerve | Posterior superior alveolar nerve and buccal nerve |  | Buccal gingivae |
|  | 23 | 5 | 7 | Tooth position |

## Venous drainage of the teeth

Veins accompanying the superior alveolar arteries drain the upper jaw and teeth anteriorly into the facial vein, or posteriorly into the pterygoid venous plexus. Veins from the lower jaw and teeth collect either into larger vessels in the interdental septa or into plexuses around the root apices and thence into several inferior alveolar veins. Some of these veins drain through the mental foramen to the facial vein; others drain via the mandibular foramen to the pterygoid venous plexus.

## Lymphatic drainage of the teeth

The lymph vessels from the teeth usually run directly into the ipsilateral submandibular lymph nodes. Lymph from the mandibular incisors, however, drains into the submental lymph nodes. Occasionally, lymph from the molars may pass directly into the jugulodigastric group of nodes.

## INNERVATION OF THE TEETH

The regional innervation of the teeth and gingivae is shown in Table 31.2. The teeth in the upper jaw are supplied by the superior alveolar nerves, while those in the lower jaw are supplied by the inferior alveolar nerve (Rodella et al 2012).

## Superior alveolar nerves

The teeth in the upper jaw are supplied by the three superior alveolar (dental) nerves that arise from the maxillary nerve in the pterygopalatine fossa or in the infraorbital groove and canal. The posterior superior alveolar (dental) nerve leaves the maxillary nerve in the pterygopalatine fossa and runs anteroinferiorly to pierce the infratemporal surface of the maxilla, at which point it is possible to perform a local anaesthetic block that will anaesthetize the pulps of the premolar and molar ipsilateral teeth; it then descends under the mucosa of the maxillary sinus. After supplying the lining of the sinus, the nerve divides into small branches that link up as the molar part of the superior alveolar plexus, supplying twigs to the molar teeth. It also supplies a branch to the upper gingivae and the adjoining part of the cheek.

The middle superior alveolar (dental) nerve arises from the infraorbital nerve as it runs in the infraorbital groove, and runs downwards and forwards in the lateral wall of the maxillary sinus. It ends in small branches that link up with the superior dental plexus, supplying small rami to the upper premolar teeth. This nerve is variable, and it may be duplicated or triplicated, or absent.

The anterior superior alveolar (dental) nerve leaves the lateral side of the infraorbital nerve near the midpoint of its canal and traverses the canalis sinuosus in the anterior wall of the maxillary sinus. It curves first under the infraorbital foramen, then passes medially towards the nose, and finally turns downwards and divides into branches to supply the incisor and canine teeth. It assists in the formation of the superior dental plexus and it gives off a nasal branch, which passes through a minute canal in the lateral wall of the inferior meatus to supply the mucous membrane of the anterior area of the lateral wall as high as the opening of the maxillary sinus, and the floor of the nasal cavity. It communicates with the nasal branches of the pterygopalatine ganglion and finally emerges near the root of the anterior nasal spine to supply the adjoining part of the nasal septum.

Fig. 31.39 The salivary glands of the left side. The cranial region of the superficial part of the submandibular gland has been excised and mylohyoid has been cut and turned down to expose a portion of the deep part of the gland.

## Inferior alveolar (dental) nerve

The course of the inferior alveolar nerve in the infratemporal fossa is described on page 551. Just before entering the mandibular canal, the inferior alveolar nerve gives off a small mylohyoid branch that pierces the sphenomandibular ligament and enters a shallow groove on the medial surface of the mandible, following a course roughly parallel to its parent nerve. It passes below the origin of mylohyoid to lie on the superficial surface of the muscle, between it and the anterior belly of digastric, both of which it supplies. It gives a few filaments to supply the skin over the point of the chin.

In the mandibular canal, the inferior alveolar nerve runs downwards and forwards, generally below the apices of the teeth until below the first and second premolars, where it divides into terminal incisive and mental branches. The incisive branch continues forwards in a bony canal or in a plexiform arrangement, giving off branches to the first premolar, canine and incisor teeth, and the associated labial gingivae. The lower central incisor teeth receive a bilateral innervation, fibres probably crossing the midline within the periosteum to re-enter the bone via numerous canals in the labial cortical plate.

The mental nerve passes upwards, backwards and outwards to emerge from the mandible via the mental foramen between and just below the apices of the premolar teeth. It immediately divides into three branches, two of which pass upwards and forwards to form an incisor plexus labial to the teeth, supplying the gingiva (and probably the periosteum). From this plexus and the dental branches, fibres turn downwards and then lingually to emerge on the lingual surface of the mandible on the posterior aspect of the symphysis or opposite the premolar teeth, probably communicating with the lingual or mylohyoid nerve. The third branch of the mental nerve passes through the intermingled fibres of depressor anguli oris and platysma to supply the skin of the lower lip and chin. Branches of the mental nerve also communicate with terminal filaments of the mandibular branch of the facial nerve.

Variations in the fascicular organization of the inferior alveolar nerve are clinically important when extracting impacted third molars. The nerve may appear as a single bundle lying a few millimetres below the roots of the teeth, or it may lie much lower and almost reach the lower border of the bone, so that it gives off a variable number of large rami that pass anterosuperiorly towards the roots before dividing to supply the teeth and interdental septa. Only rarely is it plexiform. The nerve may lie on the lingual or buccal side of the mandible (slightly more commonly on the buccal side). Even when the third molar tooth is in a normal position, the nerve may be so intimately related to it that it grooves its root. Exceptionally, the nerve may be similarly related to the second molar.

## Pain sensation in teeth

The teeth are supplied by nociceptors that generate pain sensation of a very high order. The mechanism underlying this sensitivity is of considerable clinical significance and is controversial. Currently, the most widely accepted view is that fluid movements through the dentine tubules stimulate nerve endings at the periphery of the dental pulp (hydrodynamic hypothesis).

## Local analgesia

## SALIVARY GLANDS

Salivary glands are compound, tubuloacinar exocrine glands whose ducts open into the oral cavity. They secrete saliva, a fluid that lubricates food to assist deglutition, moistens the buccal mucosa, which is important for speech, and provides an aqueous solvent necessary for taste and a fluid seal for sucking and suckling. Salivary glands also secrete digestive enzymes, e.g. salivary amylase, and antimicrobial agents, e.g. immunoglobulin A (IgA), lysozyme and lactoferrin, into saliva. Conditions in which there is a significant decrease in the production of saliva (xerostomia) may result in periodontal inflammation and dental caries. An illustration of the position of the major salivary glands and their ducts is given in Figure 31.39.

The major salivary glands are the paired parotid, submandibular and sublingual glands. In addition, there are numerous minor salivary glands scattered throughout the mouth.

Approximately 0.5 l of saliva is secreted per day. Salivary flow rates are typically $0.3 \mathrm{ml} / \mathrm{min}$ when unstimulated, and rise to $1.5-2 \mathrm{ml} / \mathrm{min}$ when stimulated. Flow rate is negligible during sleep. In the unstimulated state, the parotid gland contributes $20 \%$, the submandibular gland $65 \%$, and the sublingual and minor salivary glands $15 \%$ of the daily output of saliva. When stimulated, the parotid contribution rises to $50 \%$.

## PAROTID GLAND

The parotid gland is the largest salivary gland and is almost entirely serous. The parotid duct runs through the cheek and drains into the mouth opposite the maxillary second permanent molar tooth. The parotid gland is described in detail on page 504.

The failure of complete anaesthesia to the mandibular teeth following an inferior alveolar nerve block, which is meant to anaesthetize the nerve before its entrance into the mandibular canal, indicates that there are alternative pathways for sensory nerves to the teeth. Knowledge of these alternative pathways is important in helping clinicians to obtain complete dental anaesthesia. These alternative pathways involve anatomical variation in the distribution of the inferior alveolar nerve, the buccal branch of the mandibular nerve, the mylohyoid nerve, the lingual nerve, the deep temporal nerves and the cervical plexus.

The inferior alveolar nerve may give multiple branches before entering the mandibular canal, one or more of which may escape anaesthesia following inferior alveolar nerve block. They may then re-enter the mandible via small accessory foramina in the retromolar region to supply sensation to the molar teeth.

The buccal branch of the mandibular nerve, which supplies the buccal gingivae of the molar teeth, may also possess a branch that passes through a small retromolar foramen to supply the molar teeth. Occasionally, mandibles may present with retromolar foramina.

Although primarily a motor nerve supplying mylohyoid and the anterior belly of the digastric, the mylohyoid nerve carries some sensory fibres that may enter the mandible via one or more small retromental foramina in the vicinity of the genial tubercles to supply some sensation to the anterior teeth.

Communications exist between the inferior alveolar and lingual nerves. If the lingual nerve is not anaesthetized during an inferior alveolar nerve block, this pathway could account for any remaining sensation in the teeth.

Although the deep temporal nerves are primarily motor, it has been suggested that terminal branches may pass from the substance of temporalis to enter the mandible through foramina in the retromolar region to supply some sensation to molar teeth.

In the cervical plexus, the great auricular nerve, formed by the anterior primary rami of the second and third cervical spinal nerves, supplies skin over the angle of the mandible (p. 442). It is possible that this nerve may provide a branch that penetrates the mandible to supply one or more of the cheek teeth.

If a successful inferior alveolar nerve block does not completely anaesthetize teeth in a jaw quadrant, additional local injections of anaesthetic solution around the tooth in question may be necessary to block the alternative pathways described above. In addition, there is the possibility of overlap across the midline involving the incisive and mylohyoid nerves. In children, there is evidence to suggest that the lingula is variable in position and its position from the occlusion plane increases with age. It is therefore not considered an appropriate landmark for inferior alveolar nerve block (Ezoddini Ardakani et al 2010).

Impacted mandibular third molars In many subjects, there is a disproportion between the size of the teeth and the size of the jaws, such that there is insufficient space for all the teeth to erupt. As the third mandibular molar teeth (the wisdom teeth) are the last to erupt, they are often impeded in their eruption and either become impacted or remain unerupted deeply within the jaw bone. If the tooth is completely covered by bone and mucosa, it is very unlikely to cause any symptoms, and the subject remains unaware of its presence unless the tooth is seen on a routine dental radiograph. Very rarely, the surrounding dental follicle may undergo cystic degeneration, which can 'hollow out' the jaw, usually the mandible, to a considerable degree. The developing cyst may displace the tooth as it expands and the tooth may end up as far away as the condylar neck or coronoid process.

More commonly, the erupting wisdom tooth erupts partially before impacting against the distal aspect of the second molar. When this occurs, symptoms are common due to recurrent soft tissue inflammation and infection around the partially erupted tooth caused by food impaction. This condition is known as pericoronitis and, if the infecting organism is virulent, the infection may rapidly spread into the adjacent tissue spaces as described elsewhere. The tooth only merits surgical removal if the patient suffers a severe bout or multiple bouts of pericoronitis. Surgery is not immediately indicated because it is associated with a degree of morbidity: the lingual and inferior alveolar nerves, which are often in close proximity to the tooth, may be damaged during its removal.

The lingual nerve passes across the surface of the periosteum lingually to the lower wisdom tooth, separated from the tooth only by a cortical plate of bone no thicker than an eggshell. Damage to this nerve results in altered sensation (paraesthesia) to the ipsilateral side of the tongue and floor of mouth.

A major problem when extracting mandibular third molar teeth, especially if they are impacted, is possible damage to the inferior alveolar nerve. Indeed, surgical treatment may only necessitate the removal of the crown, leaving behind the roots (after suitable root filling). Maxillary third molars are only rarely impacted because they erupt posteroinferiorly. A clear radiograph is required before any tooth extraction is undertaken in order to alert the dental surgeon to any problems that may be encountered. For example, although the inferior alveolar nerve and its accompanying vessels generally lie beneath the roots of the third permanent molar in the mandibular canal, the neurovascular bundle may occupy a higher position, close to the roots, and may even run between the roots. This may be evident in routine periapical or orthopantomograph radiographs as a constriction or deviation of the mandibular canal or as a radiolucent canal overlying the roots of the third molar (Fig. 31.37). In this situation, the inferior alveolar nerve is at risk during extraction of third molars; damage to the nerve may result in paraesthesia in the distribution of the mental nerve, with consequent altered sensation or numbness in the lower lip. The root of a mandibular premolar may occasionally be unusually long and may be in close relationship to the mental nerve, which may then be at risk during extraction of this tooth.

Routine radiographs are no longer considered satisfactory for revealing the close relationship of the inferior alveolar nerve to the third molars; cone beam computed tomography (CBCT) is the method of choice to show this relationship in three dimensions. CBCT is also routinely used prior to insertion of a dental implant to determine not only the exact position of the inferior alveolar nerve and its mental branch but also the topography of the surrounding bone, to establish whether it is suitable for receiving a dental implant.

Fig. 31.37 A radiograph indicating that the mandibular canal containing the inferior alveolar canal and its contents (arrow) are closely related to the roots of the impacted permanent mandibular third molar. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Histology and Embryology, 4th ed. Edinburgh, Mosby.)

It is technically possible to achieve profound regional anaesthesia by depositing local anaesthetic solution adjacent to the trigeminal nerve trunks or their branches within the infratemporal fossa. These injections can either be performed transorally - posterior superior alveolar nerve block, maxillary nerve block, inferior alveolar nerve block, lingual nerve block and mandibular nerve block - or, more rarely, by an external route through the skin of the face - maxillary nerve block, inferior alveolar nerve block and mandibular nerve block.

In the case of the mandible, the anterior teeth can be anaesthetized by simple diffusion techniques, as the bone is relatively thin. However, this is not adequate for the cheek teeth due to the increased thickness of the bone. In this case, the inferior alveolar nerve has to be anaesthetized before it enters the inferior alveolar canal. The needle has to be placed within the pterygomandibular space to achieve a successful inferior alveolar nerve block. The lingual nerve is also usually blocked, as it lies close to the inferior alveolar nerve. Because of the other structures within the infratemporal fossa, it is important for the operator to have a detailed knowledge of the anatomy in this region in order to understand, and therefore try to avoid, the complications that may arise. Any damage to blood vessels in the infratemporal fossa - generally, the pterygoid venous plexus - can lead to haematoma formation. In extreme cases, bleeding can track through the inferior orbital fissure, resulting in a retrobulbar haematoma, which can lead to loss of visual acuity or blindness. Intravascular injection of local anaesthetic solution (which usually contains adrenaline (epinephrine)) can have profound systemic effects, and for this reason an aspirating syringe is always used to check that the needle has not entered a vessel prior to injection (vessels in this area that theoretically may be entered include the maxillary and internal carotid arteries). If the needle is placed too medially, it may enter medial pterygoid; if directed too laterally, it may penetrate temporalis. In either case, there will be a lack of anaesthesia, followed later by trismus. If the needle is placed too deeply, anaesthetic solution may cause a temporary facial nerve palsy due to loss of conduction from the facial nerve in the region of the parotid gland. Local anaesthetic solution may enter the orbit via the inferior orbital fissure and give orbital symptoms, the most likely being a temporary paralysis of the abducens nerve with loss of activity of lateral rectus.

The root apices of the maxillary cheek teeth are close to, and may even invaginate, the maxillary sinus. The permanent tooth most commonly involved is the second molar, followed by the first molar; less frequently, premolars and the third molar may be involved. The likelihood of cavitation of the maxillary sinus increases significantly after tooth extraction. During removal of fractured root apices in this region, care must therefore be taken to ensure that the root fragment is not pushed into the sinus. Similarly, during root canal treatment, care must be taken to ensure that any filling material is not pushed into the sinus. When routine radiographs fail to provide sufficient definition of the close relationship between the floor of the maxillary sinus and root apices, CBCT may be necessary to provide additional detail (Fig. 31.38).

Fig. 31.38 A, A routine orthopantomogram showing the roots of the permanent maxillary molar teeth and the maxillary sinus $(\mathrm{M})$. The precise relationship of the root apices to the floor of the maxillary sinus is not clear. B, Cone beam computed tomography of the same patient shown in A; the image in the sagittal plane clearly shows the two buccal root apices (arrow) of the permanent maxillary second molar tooth invaginating into the maxillary sinus (M). ## SUBMANDIBULAR SALIVARY GLAND

The submandibular gland is irregular in shape and about the size of a walnut. It consists of a larger superficial and a smaller deep part, continuous with each other around the posterior border of mylohyoid. It is a seromucous (but predominantly serous) gland.

## Superficial part of the submandibular gland

The superficial part of the gland is situated in the digastric triangle, where it reaches forwards to the anterior belly of digastric and back to the stylomandibular ligament, by which it is separated from the parotid gland. Above, it extends medial to the body of the mandible. Below, it usually overlaps the intermediate tendon of digastric and the insertion of stylohyoid. This part of the submandibular gland presents inferior, lateral and medial surfaces, and is partially enclosed between two layers of deep cervical fascia that extend from the greater cornu of the hyoid bone. The superficial layer is attached to the lower border of the mandible and covers the inferior surface of the gland. The deep layer is attached to the mylohyoid line on the medial surface of the mandible and covers the medial surface of the gland.

The inferior surface, covered by skin, platysma and deep fascia, is crossed by the facial vein and the cervical branch of the facial nerve. Near the mandible, the submandibular lymph nodes are in contact with the gland and some may be embedded within it.

The lateral surface is related to the submandibular fossa on the medial surface of the body of the mandible and the mandibular attachment of medial pterygoid. The facial artery grooves its posterosuperior part, lies at first deep to the gland and then emerges between its lateral surface and the mandibular attachment of the medial pterygoid to reach the lower border of the mandible.

The medial surface is related anteriorly to mylohyoid, from which it is separated by the mylohyoid nerve and vessels and branches of the submental vessels. More posteriorly, it is related to styloglossus, the stylohyoid ligament and the glossopharyngeal nerve, which separate it from the pharynx. In its intermediate part, the medial surface is related to hyoglossus, from which it is separated by styloglossus, the lingual nerve, submandibular ganglion, hypoglossal nerve and deep lingual vein (sequentially from above down). Below, the medial surface is related to the stylohyoid muscle and the posterior belly of digastric.

## Deep part of the submandibular gland

The deep part of the gland extends forwards to the posterior end of the sublingual gland. It lies between mylohyoid inferolaterally, hyoglossus and styloglossus medially, the lingual nerve superiorly, and the hypoglossal nerve and deep lingual vein inferiorly (see Figs 31.10, 31.39).

## Vascular supply and lymphatic drainage

The arteries supplying the gland are branches of the facial and lingual arteries. The lymph vessels drain into the deep cervical group of lymph nodes (particularly the jugulo-omohyoid node), interrupted by the submandibular nodes.

## Innervation

The secretomotor supply to the submandibular gland is derived from the submandibular ganglion. The vasomotor supply is derived from the superior cervical ganglion.

## Submandibular ganglion

This small, fusiform body is a peripheral parasympathetic ganglion. It lies on the upper part of hyoglossus, superior to the deep part of the submandibular gland and inferior to the lingual nerve, to which it is connected by several filaments. The posterior filament is the motor, parasympathetic root. It conveys preganglionic fibres from the superior salivatory nucleus in the brainstem via the facial, chorda tympani and lingual nerves to the ganglion, where they synapse. Five or six postganglionic secretomotor branches from the ganglion supply the submandibular gland and its duct, and the sublingual and anterior lingual glands, by travelling either through the anterior filaments that connect the submandibular gland to the lingual nerve or along adjacent blood vessels to their targets. Neuronal cell bodies and small ganglia have been described in the interlobular connective tissue stroma of human
submandibular ganglia, close to salivary parenchymal cells and blood vessels (Tosios et al 2010). The sympathetic root is derived from the plexus on the facial artery and consists of postganglionic fibres from the superior cervical ganglion that traverse the submandibular ganglion without synapsing. These fibres are vasomotor to the blood vessels of the submandibular and sublingual glands. Sensory fibres derived from the lingual nerve may also pass through the ganglion.

## Submandibular duct

The submandibular duct is about 5 cm long and has a thinner wall than the parotid duct. It begins from numerous tributaries in the superficial part of the gland and emerges from the medial surface of this part of the gland behind the posterior border of mylohyoid. It traverses the deep part of the gland, and then passes at first up and slightly back for approximately 5 mm , this sharp bend over the free edge of mylohyoid being known as the genu of the duct. It then runs forwards between mylohyoid and hyoglossus, passing between the sublingual gland and genioglossus to open in the floor of the mouth on the summit of the sublingual papilla at the side of the frenulum of the tongue (see Figs $31.4,31.10$ ). It lies between the lingual and hypoglossal nerves on hyoglossus but, at the anterior border of the muscle, it is crossed laterally by the lingual nerve, terminal branches of which ascend on its medial side. As the duct traverses the deep part of the gland, it receives small tributaries draining this part of the gland. It has been suggested previously that the genu of the duct predisposes to the stasis of saliva and thereby encourages salivary stone (sialolith) formation, but this is somewhat controversial and largely unproven

Like the parotid gland, the duct system of the submandibular gland can be visualized by sialography (Fig. 31.40).

## SUBLINGUAL SALIVARY GLAND

The sublingual gland is the smallest of the main salivary glands; each gland is narrow, flat, shaped like an almond, and weighs approximately 4 g . The sublingual gland lies on mylohyoid, and is covered by the mucosa of the floor of the mouth, which is raised as a sublingual fold (see Fig. 31.4). The anterior end of the contralateral sublingual gland lies in front, and the deep part of the submandibular gland lies behind. The mandible above the anterior part of the mylohyoid line, the sublingual fossa, is lateral, and genioglossus is medial, separated from the gland by the lingual nerve and submandibular duct.

The sublingual glands are seromucous but predominantly mucous.

## Vascular supply, innervation and lymphatic drainage

The arterial supply is from the sublingual branch of the lingual artery and the submental branch of the facial artery. Innervation is via the submandibular ganglion. Lymphatic drainage is to the submental nodes.

Fig. 31.40 A sialogram showing a normal submandibular duct (long arrow). Unusually, a sublingual duct is also evident (short arrow). (Courtesy of Dr N Drage.)

## Sublingual ducts

The sublingual gland has 8-20 excretory ducts (see Fig. 31.10). Smaller sublingual ducts open, usually separately, from the posterior part of the gland on to the summit of the sublingual fold (a few sometimes open into the submandibular duct). Small rami from the anterior part of the gland sometimes form a major sublingual duct (Bartholin's duct), which opens with, or near to, the orifice of the submandibular duct. This duct may be visualized occasionally in a submandibular sialogram (see Fig. 31.40).

## Ranula

If the ducts draining any salivary gland become obstructed, the gland itself is at risk of developing a retention cyst where the retained secretions dilate the gland itself rather like a balloon. This phenomenon is seen mostly in the minor salivary glands that line the lips and oral cavity, where it is known as a mucocele. Trauma, such as persistent lip biting, results in scarring of the overlying oral mucosa and obstruction of the small drainage duct. When trauma occurs in the floor of the mouth and obstructs the drainage duct/s of the sublingual gland, the resulting retention cyst is known as a ranula. (Ranula is the Latin name for a frog and is used here because the tense cystic swelling is said to resemble the throat of a croaking frog.)

A ranula usually presents as a large, tense, bluish swelling anteriorly in the floor of the mouth just to one side of the midline, which often displaces the tongue (Fig. 31.41). Occasionally, the developing retention cyst herniates through a midline dehiscence where the two mylohyoid muscles fail to meet in the midline anteriorly, and then the ranula may present as a submental swelling or as a combined submental and floor-of-mouth swelling, a 'plunging' ranula (Harrison et al 2013). The treatment for a ranula is excision of the sublingual gland responsible.

## MINOR SALIVARY GLANDS

The minor salivary glands of the mouth include the labial, buccal, palatoglossal, palatal and lingual glands. The labial and buccal glands contain both mucous and serous elements. The palatoglossal glands are mucous glands and are located around the pharyngeal isthmus. The palatal glands are mucous glands and occur in both the soft and hard palates. The anterior and posterior lingual glands are mainly mucous. The anterior glands are embedded within muscle near the ventral surface of the tongue and open by means of four or five ducts near the lingual frenulum, and the posterior glands are located in the root of the tongue. The deep posterior lingual glands are predominantly serous. Serous glands (of von Ebner) occur around the circumvallate papillae; their secretion is watery, and they probably assist in gustation by spreading taste stimuli over the taste buds and then washing them away.

## MICROSTRUCTURE

Salivary glands have numerous lobes composed of smaller lobules separated by dense connective tissue that is continuous with the capsule of the gland, and contains excretory (collecting) ducts, blood vessels, lymph vessels, nerve fibres and small ganglia. Each lobule has a single duct, whose branches terminate at dilated secretory 'end-pieces', which are tubular or acinar in shape (Fig. 31.42). Their primary secretion is modified as it flows through intercalated, striated and excretory ducts into one or more main ducts that discharge saliva into the oral cavity. They contain a variable amount of intralobular adipose tissue; adipocytes are particularly numerous in the parotid gland.

The secretory end-pieces of the human parotid gland are almost exclusively serous acini (Fig. 31.43A); mucous tubules or acini are rare. In the submandibular gland, secretory units are predominantly serous acini, with some mucous tubules and acini (Fig. 31.43B). Mucous tubules are often associated with groups of serous cells at their blind ends, appearing as crescent-shaped serous demilunes in routine histological preparations. However, this appearance is a fixation artefact, as tissue prepared by rapid freezing methods lacks serous demilunes and the serous secretory cells align with mucous cells around a common lumen (Yamashina et al 1999). In the sublingual gland, mucous tubules and acini predominate (Fig. 31.43C) but serous cells also occur, as acini or as serous demilunes.

Serous cells are approximately pyramidal in shape. Their nuclei vary in shape and position, but are more rounded and situated less basally than in mucous cells. Apically, the cytoplasm is filled by proteinaceous secretory (zymogen) granules with high amylase activity. Additionally, serous cells secrete kallikrein, lactoferrin and lysozyme, an antibacterial enzyme whose synthesis has been localized in particular to the serous demilunes of the submandibular and sublingual glands, and which is important in the defence against oral pathogens. In the human parotid and submandibular glands, zymogen granules also show a positive periodic acid-Schiff staining reaction, which indicates the presence of polysaccharides, and some texts refer to these cells as seromucous. Mucous cells are cylindrical and have flattened, basal nuclei. Their apical cytoplasm is typically packed with large, pale-staining and electrontranslucent secretory droplets. The histological appearance of serous and mucous cells will vary according to the stage in the secretory cycle.

## Ducts

Intercalated, striated (both intralobular) and extralobular collecting ducts lead consecutively from the secretory end-pieces. The lining cells of intercalated ducts are flat nearest the secretory end-piece but become cuboidal. Intercalated ducts function primarily as a conduit for saliva but, together with the striated ducts, may also modify its content of electrolytes and secrete IgA. Striated ducts are lined by a low columnar epithelium and are so called because their lining cells have characteristic basal striations. The latter are regions of highly infolded basal plasma membrane, between which lie columns of vertically aligned mitochondria. The nuclei are consequently displaced by the basal striations from a typical ductal basal position to a central or even apical location (see Fig. 31.43). Infolding of the basal plasma membrane and local abundance of mitochondria are typical features of epithelial cells that actively transport electrolytes. Here, the cells transport potassium and bicarbonate into saliva; they produce a hypotonic saliva by reabsorbing sodium and chloride ions in excess of water. Striated ducts modify electrolyte composition and secrete IgA, lysozyme and kallikrein. IgA is produced by subepithelial plasma cells and transported transcytotically across the epithelial barrier to be secreted, once it has been dimerized by epithelial secretory component, into the saliva (Garrett et al 1998). This is also a function of serous acinar cells and other secretory epithelia, notably the lactating breast. The intralobular ductal system of the sublingual gland is less well developed than that of the parotid and submandibular glands.

Collecting ducts are metabolically relatively inert conduits that run within interlobular connective tissue septa in the glands. They transport saliva to the main duct, which opens on to the mucosal surface of the buccal cavity. The lining epithelium of collecting ducts varies. It may be pseudostratified columnar, stratified cuboidal or columnar in the larger ducts, and has a distinct basal layer. It becomes a stratified squamous epithelium near the buccal orifice.

## Myoepithelial cells

Myoepithelial cells (see Fig. 31.42) are contractile cells associated with secretory end-pieces and with much of the ductal system (Ogawa 2003).

Fig. 31.42 The architecture of a generalized salivary gland. Solid black arrows indicate the direction of transport of salivary components, and the open white arrow the direction of salivary flow. The innervation of the ducts, secretory units and arterioles is shown.

They lie between the basal lamina and the epithelial cells proper. They extend numerous cytoplasmic processes around serous acini and are often termed basket cells. Myoepithelial cells associated with ducts are more fusiform in shape and are aligned along the length of the duct. Their cytoplasm contains abundant actin microfilaments, which mediate contraction.

Although stimulated by the autonomic nervous system, the precise functional role of myoepithelial cells in salivary secretion awaits clarification (Garrett 1998). Functional studies clearly indicate that myoepithelial activity can accelerate the initial outflow of saliva, reduce luminal volume, contribute to the secretory pressure, support the underlying parenchyma, reduce back-permeation of fluid and help salivary flow to overcome increases in peripheral resistance (although, if this is excessive, it may lead to sialectatic damage of striated ducts, thereby increasing overall permeability).

## Basal cells

A population of basal cells is present in the striated and collecting ducts (Riva et al 1992). They are sparsely distributed in the striated ducts and more densely distributed in the collecting ducts, in which they form a continuous layer as the ducts pass further towards the hilum. A small population of basal cells is found on the abluminal surface of ductal cells associated with both striated and collecting ducts. These cells can be distinguished from other parenchymal cells by a combination of their morphology, their co-expression of cytokeratin 14 and the antiapoptotic factor cl-2, and a proliferative index of about $3 \%$, which is the highest of any cell in the region. Basal cells have been implicated as potential stem cells during turnover and/or cell regeneration in salivary glands and during metaplasia, when oncocytes and sebaceous cells may appear. However, some cell division is seen in all parenchymal cell types, including myoepithelial cells, and all these cells may be involved in salivary gland regeneration

## Lymph nodes

Lymph nodes are situated both on the surface and within the parotid gland, but are not found within the other salivary glands.

## CONTROL OF SALIVARY GLAND ACTIVITY

The observed wide and rapid variation in the composition, quantity and rate of salivary secretion in response to various stimuli suggests an elaborate control mechanism. Secretion may be continuous but at a low resting level, and may also occur spontaneously. It is mainly a response to the drying of the oral and pharyngeal mucosae. A rapid increase can be superimposed on the resting level, e.g. during mastication or when stimulated by the autonomic innervation. The controlled variation in the activity of the many types of salivary effector cells (serous, seromucous and mucous secretory cells, myoepithelial cells, epithelial cells of all the ductal elements and the smooth muscle of local blood vessels) affects the quantity and quality of saliva. There is no clear evidence that circulating hormones evoke secretion directly at physiological levels but they may alter the response of glandular cells to neural stimuli.

The control of salivation depends on reflex nerve impulses. The afferent inputs to the reflex arc pass to brainstem salivatory centres, especially from taste and mechanoreceptors in the mouth. A variety of other sensory modalities in and around the mouth are also involved, e.g. smell, for certain aspects of submandibular secretion in humans. The afferent input is integrated centrally by the salivatory centres, which are themselves influenced by higher centres. The latter may provide facilitatory or inhibitory influences, which presumably explains why the mouth becomes dry under stress. The efferent drive to the glands passes via parasympathetic and sympathetic outputs from the centres. Relatively little is known about the connections of the preganglionic parasympathetic neurones in the salivatory centres, and virtually nothing is known about either the central location of the sympathetic preganglionic neurones, or the output pathways. No peripheral inhibitory mechanisms exist in the glands (Garrett et al 1999).

The typical pattern of innervation is shown in Figure 31.42, but details vary in different glands and with age. Only the more constant features are illustrated and described here. Cholinergic nerves often accompany ducts and arborize freely around secretory end-pieces, but adrenergic nerves usually enter glands along arteries and ramify with them. The main secretomotor nerves are predominantly unmyelinated axons; the few myelinated axons that have been seen are presumably either preganglionic efferent or visceral afferent. Within the glands, the nerve fibres intermingle, such that cholinergic and adrenergic axons

Fig. 31.43 The microstructure of the salivary glands. A, The parotid gland. B, Mixed secretory units of the submandibular gland. C, Mucous acini in the sublingual gland. Asterisks indicate the lumen of a striated duct. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
often lie in adjacent invaginations of one Schwann cell. Secretion and vasoconstriction are mediated via separate sympathetic axons. A single parasympathetic axon may, through serial en passant terminals, induce vasodilation, secretion and myoepithelial contraction.

Secretory end-pieces are usually the most densely innervated structures in the gland; individual cells often have both cholinergic and adrenergic innervation. Secretion of water and electrolytes, which creates the foundation for the volume of saliva secreted, is the outcome of a complex set of processes that is largely induced by parasympathetic impulses. Secretion of protein is an ongoing constitutive process wherever it occurs. The regulated exocytosis of pre-packaged proteins, which is the principal source of protein secretion into saliva, depends on the relative levels of activity in sympathetic and parasympathetic fibres.

The ductal elements of salivary glands can markedly modify the composition of saliva. They are less densely innervated than secretory
end-pieces but their activity is also under neural control. Adrenal aldosterone promotes resorption of sodium and release of potassium into saliva by striated ductal cells, as it does in kidney tubules. Myoepithelial contraction is stimulated mainly by adrenergic innervation but there may be an additional role for cholinergic axons.

## Age changes in salivary glands

A wide range of age changes has been documented in salivary glands. In neonates, acini and ducts are immature and widely separated by abundant vascular connective tissue. After the age of 6 months, glandular structure is more compact and there are numerous lymphocytic foci (Scott 1979). Over the age of 50 years, the amount of glandular tissue decreases and the amount of fibrous tissue, adipocytes, inflammatory cells and oncocytes increases. An increase in duct volume has also been described, although it may in part reflect shrinkage of acini, giving the appearance of duct-like forms (Scott 1986).

With such a significant loss of parenchyma (in both major and minor glands), it might be assumed that there would be a reduction in the amount of saliva produced in the aged population, giving rise to the clinical condition of xerostomia (dry mouth). However, in healthy, unmedicated individuals, this is not the case. This could be interpreted as the result of salivary glands being able to produce more saliva than is needed, but is more likely to be a secondary effect related to the increased use of medication (many drugs depress salivary production and many, such as antidepressants and antihistamines, are anticholinergic). Saliva is important in the maintenance of oral health; decreased secretion from the salivary glands results in an increased incidence in oral conditions such as periodontal disease, dental caries and candidal infections ('thrush').

## TISSUE SPACES AROUND THE JAWS

The dissemination of infection in soft tissues is influenced by the natural barriers presented by bone, muscle and fascia. However, the tissue spaces around the jaws are primarily defined by muscles, principally mylohyoid, buccinator, masseter, medial pterygoid, superior constrictor and orbicularis oris (Fig. 31.44). None of these 'spaces' is actually empty and they should merely be regarded as potential spaces that are normally occupied by loose connective tissue. It is only when inflammatory products such as hyaluronase destroy the loose connective tissue that a definable space is produced.

The spaces are paired except for the submental, sublingual and palatal spaces.

## POTENTIAL TISSUE SPACES AROUND THE LOWER JAW

The important potential tissue spaces of the lower jaw are the submental, submandibular, sublingual, buccal, submasseteric, parotid, pterygomandibular, peritonsillar, parapharyngeal and retropharyngeal spaces (see Fig. 31.44) (Langdon et al 2002).

The submental and submandibular spaces are located below the inferior border of the mandible beneath mylohyoid, in the suprahyoid region of the neck. The submental space lies beneath the chin in the midline, between the mylohyoid muscles and the investing layer of deep cervical fascia. It is bounded laterally by the two anterior bellies of the digastric muscles. The submental space communicates posteriorly with the two submandibular spaces. The submandibular space is situated between the anterior and posterior bellies of the digastric muscle and communicates with the sublingual space around the posterior free border of mylohyoid. The sublingual space lies in the floor of the mouth, above the mylohyoid muscles, and is continuous across the midline; it communicates with the submandibular spaces over the posterior free borders of the mylohyoid muscles, helped by the submandibular gland's slight extension over this edge.

The remaining tissue spaces are illustrated in Figure 31.44B. The buccal space is located in the cheek, on the lateral side of buccinator. The submasseteric spaces are a series of spaces between the lateral surface of the ramus of the mandible and masseter; they are formed because the fibres of masseter have multiple insertions on to most of the lateral surface of the ramus. The pterygomandibular space lies between the medial surface of the ramus of the mandible and medial pterygoid, and the parotid space lies behind the ramus of the mandible, in and around the parotid gland. The parapharyngeal space is bounded by the superior constrictor of the pharynx and the medial surface of

Fig. 31.44 Potential tissue spaces around the jaws. A, A coronal section showing the sublingual and submandibular spaces in the floor of the mouth and the possible routes for the spread of infections from periapical dental abscesses (left). B, A horizontal section through the mandibular molar region showing the associated tissue spaces. C, An inferior view of the floor of the mouth (suprahyoid region of the neck) showing the position of the submandibular and sublingual tissue spaces. medial pterygoid. It is restricted to the infratemporal region of the head and the suprahyoid region of the neck, and communicates with the retropharyngeal space, which itself extends into the retrovisceral space in the lower part of the neck (the tissue spaces of the neck are described on p .446 , and those of the pharynx on p .578 ). The peritonsillar space lies around the palatine tonsil between the pillars of the fauces, and is part of the intrapharyngeal space. It is bounded by the medial surface of the superior constrictor of the pharynx and its mucosa.

## POTENTIAL TISSUE SPACES AROUND THE UPPER JAW

The tissue spaces of the upper jaw are usually associated with spread of infection from the teeth. They are the canine (infraorbital), palatal and infratemporal spaces. The canine (infraorbital) space associated with the canine fossa lies between levator labii superioris and the zygomaticus muscles. The palatal space is not truly a tissue space in the hard palate, since the mucosa there is firmly bound to the periosteum. However, inflammation can strip away some of this periosteum to produce a well-circumscribed abscess. The infratemporal space is the upper extremity of the pterygomandibular space. It is closely related to the maxillary tuberosity and therefore the upper molars.

## DENTAL ABSCESS

Abscesses developing in relation to the apices of roots ultimately penetrate the surrounding bone where it is thinnest. The position of the resultant swelling in the soft tissues is largely determined by the relationship between muscle attachments and the sinus (the path taken by the infected material) in the bone. Thus, in the lower incisor region,
because the labial bone is thin, abscesses generally appear as a swelling in the labial sulcus, above the attachment of mentalis. The abscess may open below mentalis, when it will point beneath the chin. If an abscess from a lower postcanine tooth opens below the attachment of buccinator, the swelling is in the face; if it opens above, the swelling is in the buccal sulcus of the mouth. If an abscess opens lingually above mylohyoid, the swelling is in the lingual sulcus; if it is below, the swelling is in the neck. Third molar abscesses tend to track into the neck rather than the mouth because mylohyoid ascends posteriorly and the termination of its attachment is variable, sometimes terminating before the position of the third molar and thereby allowing relatively unhindered access into the tissue spaces of the neck

Apart from canine teeth, which have long roots, abscesses on upper teeth usually open buccally below, rather than above, the attachment of buccinator. Because its root apex is occasionally curved towards the palate, abscesses of the upper lateral incisors may track into the palatal submucosa. Abscesses of upper canines often open facially just below the orbit. Here, the swelling may obstruct drainage in the angular part of the facial vein, which has no valves, and it is therefore possible for infected material to travel via the angular and ophthalmic veins into the cavernous sinus, potentially causing a cavernous sinus thrombosis. Abscesses on the palatal roots of upper molars usually open on the palate. Upper second premolars and first and second molars are related to the maxillary sinus. When this is large, the root apices of these teeth may be separated from its cavity solely by the lining mucosa. Sinus infections may stimulate the nerves entering the teeth, simulating toothache in the ipsilateral premolars and molars; this phenomenon is known as referred pain. Upper first premolars and third molars may be closely related to the maxillary sinus.

With loss of teeth, alveolar bone is extensively resorbed. Thus, in the edentulous mandible, the mental nerve, originally inferior to premolar roots, may lie near the crest of the bone. In the edentulous maxilla, the
sinus may enlarge to approach the oral surface of the bone. Both of these facts are of importance when planning surgery in this area.

Occasional bony prominences, termed the torus mandibularis, torus maxillaris and torus palatinus, may lie lingual to the lower premolars or molars, or the upper molars. They lie in the midline of the palate
and may need surgical removal before satisfactory dentures can be fitted.

Severe systemic infections during the time the teeth are developing may lead to faults in enamel, which are visible as horizontal lines (cf. Harris's growth lines).

# Infratemporal and pterygopalatine fossae and temporomandibular joint 

## INFRATEMPORAL FOSSA

The infratemporal fossa lies deep to the ramus of the mandible. It communicates with the temporal fossa superiorly deep to the zygomatic arch, the orbit anteriorly through the inferior orbital fissure, and the pterygopalatine fossa medially through the pterygomaxillary fissure. It also communicates with the middle fossa through the foramina ovale and spinosum. The major structures that occupy the infratemporal fossa are the lateral and medial pterygoid muscles, the mandibular division of the trigeminal nerve, the chorda tympani branch of the facial nerve, the otic parasympathetic ganglion, the maxillary artery and the pterygoid venous plexus.

The infratemporal fossa has a roof and anterior, lateral and medial walls, and is open to the neck posteroinferiorly, i.e. it has no anatomical floor. Approximately $80 \%$ of the roof is formed by the infratemporal surface of the greater wing of the sphenoid. The remainder is formed by the infratemporal surface of the temporal bone, ending at the articular eminence of the temporomandibular joint and the spine of the sphenoid on the deep medial aspect. It contains the foramina ovale and spinosum. The anterior wall is formed by the posterior surface of the maxilla, ending inferiorly at the maxillary tuberosity. The inferior orbital fissure forms the upper limit of the anterior wall, meeting the pterygomaxillary fissure at right angles. The medial wall is formed anteriorly by the lateral pterygoid plate of the pterygoid process of the sphenoid, and more posteromedially by the pharynx and tensor and levator veli palatini. It contains the pterygomaxillary fissure, across which structures pass between the infratemporal and pterygopalatine fossae (Fig. 32.1). The lateral wall is formed by the medial surface of the ramus of the mandible.

Lateral pterygoid provides a key to understanding the relationships of structures within the infratemporal fossa. This muscle lies in the roof of the fossa and runs anteroposteriorly in a more or less horizontal plane from the region of the pterygoid plates to the mandibular condyle (see Fig. 32.1). Branches of the mandibular nerve and the main origin of medial pterygoid are deep relations and the maxillary artery is superficial. The buccal branch of the mandibular nerve passes between the two heads of lateral pterygoid. Medial pterygoid and the lingual and
inferior alveolar nerves emerge below its inferior border, and the deep temporal nerves and vessels emerge from its upper border. A venous network, the pterygoid venous plexus, lies around and within lateral pterygoid and is important in the spread of infection.

## BONES

The sphenoid bone, the paired maxillae and temporal bones, the palatine bones and the mandible collectively provide the skeletal framework to the infratemporal and pterygopalatine regions. The mandible and the two temporal bones articulate at the right and left temporomandibular joints. The disarticulated maxilla and palatine bone are described on pages 484 and 486 , respectively the temporal bone is described on page 624, and the sphenoid and mandible are described here.

## Sphenoid bone

The sphenoid bone lies in the base of the skull between the frontal, temporal and occipital bones. It has a central body, paired greater and lesser wings that spread laterally from the body, and two pterygoid processes that descend from the junction of the body and greater wings (Fig. 32.3).

## Body

The body of the sphenoid is cuboidal. It contains two air sinuses, separated by a septum. Its cerebral (superior) surface articulates in front with the cribriform plate of the ethmoid bone. Anteriorly lies the smooth jugum sphenoidale, which is related to the gyri recti and olfactory tracts. The jugum is bounded behind by the anterior border of the sulcus chiasmaticus, which leads laterally to the optic canals. Posteriorly lies the tuberculum sellae, behind which is the deeply concave sella turcica. In life, the sella contains the hypophysis cerebri in the hypophysial fossa. Its anterior edge is completed laterally by two middle clinoid processes, while posteriorly the sella turcica is bounded by a square dorsum sellae, the superior angles of which bear variable posterior clinoid processes. The diaphragma sella and the tentorium cerebelli are attached to the clinoid processes. On each side, below the

Fig. 32.1 A, The pterygopalatine fossa after detachment of the mandible and removal of the zygomatic arch. B, Anteromedial view. C, Lateral view; the arrows show that the floor of the temporal fossa is open medially to the infratemporal fossa and laterally to the region containing the masseter. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

There is a lack of consensus in the surgical literature with regard to both the boundaries and contents of the infratemporal fossa. Thus, the fossa is sometimes defined as the anatomical space beneath the floor of the middle fossa, incorporating the remainder of the subcranial temporal bone as part of the roof, with the exception of the glenoid fossa of the temporomandibular joint. In this description, the fossa is limited posteriorly by the prevertebral fascia and includes the internal carotid artery, the internal jugular vein, the lower cranial nerves, the cervical sympathetic trunk, and the styloid process with its attached muscles and ligaments. Alternatively, the 'extended' infratemporal fossa is said to consist of the parapharyngeal and masticator spaces (Fig. 32.2) (Falcon et al 2010, Hosseini et al 2012, Bejjani et al 1998, Joo et al 2013).

Fig. 32.2 The 'extended' infratemporal fossa. The boundaries of the infratemporal fossa are delineated by the dotted line. Note that the lateral pterygoid plate and pharyngotympanic tube constitute the medial wall of the fossa, and that the temporomandibular joint (TMJ) forms part of its lateral wall. The carotid and jugular foramina lie in the posterior part of this extended infratemporal fossa. (Adapted with permission from Berkovitz BKB, Moxham BJ, Telling D 1994 Color Atlas of the Skull, London, Mosby and Hosseini SMS, Razfar A, Carrau RL, et al. Endonasal transpterygoid approach to the infratemporal fossa: correlation of endoscopic and multiplanar CT anatomy. Head and Neck.
2012;34:313-320.)

Fig. 32.3 The sphenoid bone. A, Anterior view. B, Posterior view. C, Superior view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
dorsum sellae, a small petrosal process articulates with the apex of the petrous part of the temporal bone. The body of the sphenoid slopes directly into the basilar part of the occipital bone posterior to the dorsum sellae; together these bones form the clivus. In the growing child, this is the site of the spheno-occipital synchondrosis; premature closure of this joint gives rise to the skull appearances seen in achondroplasia.

The lateral surfaces of the body are united with the greater wings and the medial pterygoid plates. A broad carotid sulcus accommodates both the internal carotid artery and the cranial nerves associated with the cavernous sinus above the root of each wing. The sulcus is deepest posteriorly. It is overhung medially by the petrosal part of the temporal bone and has a sharp lateral margin, the lingula, which continues back over the posterior opening of the pterygoid canal.五

A median triangular, bilaminar sphenoidal crest on the anterior surface of the body of the sphenoid makes a small contribution to the nasal septum. The anterior border of the crest joins the perpendicular plate of the ethmoid bone, and a sphenoidal sinus opens on each side of it. In the articulated state, the sphenoidal sinuses are closed anteroinferiorly by the sphenoidal conchae, which are largely destroyed when disarticulating a skull. Each half of the anterior surface of the body of the sphenoid possesses a superolateral depressed area joined to the ethmoidal labyrinth that completes the posterior ethmoidal sinuses; a lateral margin that articulates with the orbital plate of the ethmoid above and the orbital process of the palatine bone below; and an inferomedial, smooth, triangular area, which forms the posterior nasal roof, and near whose superior angle lies the orifice of a sphenoidal sinus.

The inferior surface of the body of the sphenoid bears a median triangular sphenoidal rostrum, embraced above by the diverging lower margins of the sphenoidal crest. The narrow anterior end of the rostrum fits into a fissure between the anterior parts of the alae of the vomer and the posterior ends of the sphenoidal conchae flank the rostrum, articulating with its alae. A thin vaginal process projects medially from the base of the medial pterygoid plate on each side of the posterior part of the rostrum, behind the apex of the sphenoidal concha.

## Greater wings

The greater wings of the sphenoid curve broadly superolaterally from the body. Posteriorly, each is triangular, fitting the angle between the petrous and squamous parts of the temporal bone at a sphenosquamosal suture. The cerebral surface contributes to the anterior part of the middle cranial fossa. Deeply concave, its undulating surface is adapted to the anterior gyri of the temporal lobe of the cerebral hemisphere. The foramen rotundum lies anteromedially and transmits the maxillary nerve. Posterolateral to the foramen rotundum is the foramen ovale, which transmits the mandibular nerve, accessory meningeal artery and sometimes the lesser petrosal nerve, although the latter nerve may have its own canaliculus innominatus medial to the foramen spinosum. A small emissary sphenoidal foramen (foramen of Vesalius), which transmits a small vein from the cavernous sinus, sometimes lies medial to the foramen ovale (on one or both sides). The foramen spinosum, which transmits the middle meningeal artery and meningeal branch of the mandibular nerve, lies behind the foramen ovale.

The lateral surface is vertically convex and divided by a transverse infratemporal crest into temporal (upper) and infratemporal (lower) surfaces. Temporalis is attached to the temporal surface. The infratemporal surface is directed downwards and, with the infratemporal crest, is the site of attachment of the upper fibres of lateral pterygoid. It contains the foramen ovale and foramen spinosum. The small downwardprojecting spine of the sphenoid lies posterior to the foramen spinosum; the sphenomandibular ligament is attached to its tip. The medial side of the spine bears a faint anteroinferior groove for the chorda tympani nerve and appears in the lateral wall of the sulcus for the pharyngotympanic (auditory) tube. Medial to the anterior end of the infratemporal crest, a ridge passes downwards to the front of the lateral pterygoid plate, thereby forming a posterior boundary of the pterygomaxillary fissure.

The quadrilateral orbital surface of the greater wing faces anteromedially and forms the posterior part of the lateral wall of the orbit. It has a serrated upper edge, which articulates with the orbital plate of the frontal bone, and a serrated lateral margin, which articulates with the zygomatic bone. Its smooth inferior border is the posterolateral edge of the inferior orbital fissure, and its sharp medial margin forms the inferolateral edge of the superior orbital fissure, on which a small tubercle gives partial attachment to the common anular ocular tendon. Below the medial end of the superior orbital fissure, a grooved area forms the posterior wall of the pterygopalatine fossa; the latter is pierced by the foramen rotundum.

The irregular margin of the greater wing, from the body of the sphenoid to the spine, is an anterior limit of the medial half of the foramen lacerum. It also displays the posterior aperture of the pterygoid canal. Its lateral half articulates with the petrous part of the temporal bone at a sphenopetrosal synchondrosis. Inferior to this, the sulcus tubae contains the cartilaginous pharyngotympanic (auditory) tube. Anterior to the spine of the sphenoid the concave squamosal margin is serrated bevelled internally below, externally above - for articulation with the squamous part of the temporal bone. The tip of the greater wing, bevelled internally, articulates with the sphenoidal angle of the parietal bone at the pterion. Medial to this, a triangular rough area articulates with the frontal bone; its medial angle is continuous with the inferior boundary of the superior orbital fissure, and its anterior angle joins the zygomatic bone by a serrated articulation. Fractures of the zygomatic
bone preferentially pass through this articulation with the greater wing because it is a line of weakness in the lateral orbit.

## Lesser wings

The lesser wings of the sphenoid are triangular pointed plates that protrude laterally from the anterosuperior regions of the body. The superior surface of each wing is smooth and related to the frontal lobe of the cerebral hemisphere. The inferior surface is a posterior part of the orbital roof and upper boundary of the superior orbital fissure, and overhangs the middle cranial fossa. The posterior border projects into the lateral fissure of the cerebral hemisphere. The medial end of the lesser wing forms the anterior clinoid process. The anterior and middle clinoid processes are sometimes united to form a caroticoclinoid foramen. The lesser wing is connected to the body by a thin, flat anterior root and a thick, triangular posterior root (the optic strut), between which lies the optic canal. The optic strut extends from the base of the anterior clinoid process to the body and separates the optic canal from the superior orbital fissure. The optic canal is bounded by the body of the sphenoid medially, the lesser wing superiorly, and the optic strut inferiorly and laterally.

## Superior orbital fissure

The superior orbital fissure connects the cranial cavity with the orbit. It is bounded medially by the body of the sphenoid, above by the lesser wing of the sphenoid, below by the medial margin of the orbital surface of the greater wing, and laterally, between the greater and lesser wings, by the frontal bone. The contents of the superior orbital fissure are described on p. 667 (see Fig. 41.4).

## Pterygoid processes

The pterygoid processes descend perpendicularly from the junctions of the greater wings and body. Each consists of a medial and lateral plate, whose upper parts are fused anteriorly. The plates are separated below by the angular pterygoid fissure, whose margins articulate with the pyramidal process of the palatine bone, and diverge behind. Medial pterygoid lies in the cuneiform pterygoid fossa between the plates. Above is the small, oval, shallow scaphoid fossa, which is formed by division of the upper posterior border of the medial plate. Part of tensor veli palatini is attached to the fossa. The anterior surface of the root of the pterygoid process is broad and triangular, and forms the posterior wall of the pterygopalatine fossa; it is pierced by the anterior opening of the pterygoid canal.

## Lateral pterygoid plate

The lateral pterygoid plate is broad, thin and everted. The lateral surface forms part of the medial wall of the infratemporal fossa; the lower part of lateral pterygoid is attached to it. The medial surface is the lateral wall of the pterygoid fossa; most of the deep head of medial pterygoid is attached to it. The upper part of its anterior border is a posterior boundary of the pterygomaxillary fissure, and the lower part articulates with the palatine bone. The posterior border is free.

## Medial pterygoid plate

The medial pterygoid plate is narrower and longer than the lateral. Its lower end is continued into an unciform projection, the pterygoid hamulus, which curves laterally. The pterygomandibular raphe is attached to the hamulus, and the tendon of tensor veli palatini winds around the hamulus. The lateral surface forms the medial wall of the pterygoid fossa and the medial surface provides a lateral boundary of the posterior nasal aperture. The medial plate is prolonged above on the inferior aspect of the body of the sphenoid as a thin vaginal process that articulates anteriorly with the sphenoidal process of the palatine bone and medially with the ala of the vomer. The plate articulates with the posterior border of the perpendicular plate of the palatine bone in the lower part of its anterior margin. Inferiorly, it bears a furrow, which is converted anteriorly into the palatovaginal canal by the sphenoidal process of the palatine bone. The palatovaginal canal transmits pharyngeal branches of the maxillary artery and pterygopalatine ganglion. The pharyngobasilar fascia is attached to the whole of the posterior margin of the medial plate, and the superior pharyngeal constrictor is attached to its lower end. The small pterygoid tubercle is found at the upper end of the plate, just below the posterior opening of the pterygoid canal. The processus tubarius, which supports the cartilaginous pharyngeal end of the pharyngotympanic tube, projects back near the midpoint of the margin of the medial pterygoid plate.

Though adjacent, the medial and lateral pterygoid plates have distinct roles. The lateral plate is the province of the infratemporal fossa and masticator space, forming part of the medial boundary of the infratemporal fossa and providing origin to the lateral and medial
pterygoids. The medial plate is functionally related to the pharynx, providing attachment for the pharyngobasilar fascia, superior constrictor and pterygomandibular raphe.

Midface fractures Midface fractures at Le Fort I, II and III levels invariably involve the pterygoid plates; displacement of the outlines of these bones radiographically confirms the diagnosis.

## Sphenoidal conchae

The sphenoidal conchae are two thin, curved small plates, attached anteroinferiorly to the body of the sphenoid bone. The superior concave surface of each forms the anterior wall and part of the floor of a sphenoidal sinus. In situ, each has vertical quadrilateral anterior and horizontal triangular posterior parts. The anterior part consists of a superolateral depressed area, which completes the posterior ethmoidal sinuses and joins below with the orbital process of a palatine bone, and a smooth and triangular inferomedial area, which forms part of the nasal roof and is perforated above by the round opening connecting the sphenoidal sinus and spheno-ethmoidal recess.

Anterior parts of the two bones meet in the midline, and protrude as the sphenoidal crest. The horizontal part appears in the nasal roof and completes the sphenopalatine foramen. Its medial edge articulates with the rostrum of the sphenoid and the ala of the vomer. Its apex, directed posteriorly, is superomedial to the vaginal process of the medial pterygoid plate and joins the posterior part of the ala. A small conchal part sometimes appears in the medial wall of the orbit, lying between the orbital plate of the ethmoid in front, the orbital process of the palatine bone below and the frontal bone above.

## Ossification

Until the seventh or eighth month in utero, the sphenoid body has a presphenoidal part, anterior to the tuberculum sellae, with which the lesser wings are continuous, and a postsphenoidal part, consisting of the sella turcica and dorsum sellae, and integral with the greater wings and pterygoid processes. Much of the bone is preformed in cartilage. There are six ossification centres for the presphenoidal parts and eight for the postsphenoidal parts.

## Presphenoidal part

At about the ninth week of fetal life, a centre appears in each wing, lateral to the optic canal, and a little later two bilateral centres appear in the presphenoidal body. Each sphenoidal concha has a centre, appearing superoposteriorly in the nasal capsule in the fifth month in utero. As this enlarges, it partly surrounds a posterosuperior expansion of the nasal cavity, which becomes the sphenoidal sinus. The posterior conchal wall is absorbed and the sinus invades the presphenoidal component. In the fourth year, the concha fuses with the ethmoidal labyrinth and, before puberty, it fuses with the sphenoid and palatine bones. Its anterior deficiency persists as an opening for the sphenoidal sinus.

## Postsphenoidal part

The first centres appear in the greater wings at about the eighth week of fetal life, one in the basal cartilage of each wing below the foramen rotundum. These centres only contribute to the root of the greater wing (near the foramen rotundum and pterygoid canal). The remainder of the greater wing and the lateral pterygoid plate are ossified in mesenchyme. At about the fourth month of fetal life, two centres appear, flanking the sella turcica, and soon fuse. The medial pterygoid plates are also ossified in 'membrane', a centre in each probably appearing in about the ninth or tenth week. The hamulus is chondrified during the third fetal month and at once begins to ossify. Medial and lateral pterygoid plates join at about the sixth fetal month. During the fourth month, a centre appears for each lingula, soon joining the body. The optic canal in the neonate is relatively large and has a keyhole or 'figure of eight' shape rather than the circular profile seen in the adult (Lang 2001).

## Postnatal details

Presphenoidal and postsphenoidal parts fuse at about the eighth month in utero but an unciform cartilage persists after birth in lower parts of the junction. At birth, the bone is tripartite and consists of a central part (body and lesser wings) and two lateral parts (each consisting of a greater wing and pterygoid process). During the first year, the greater wings and body unite around the pterygoid canals, and the lesser wings extend medially above the anterior part of the body, meeting to form the smooth, elevated jugum sphenoidale. By the twenty-fifth year, sphenoid and occipital bones are completely fused. An occasional vascular foramen, often erroneously termed the craniopharyngeal canal, is occasionally seen in the anterior part of the hypophysial fossa.

Although the sphenoidal sinus can be identified in the fourth month of fetal life as an evagination of the posterior part of the nasal capsule, by birth it represents an outgrowth of the spheno-ethmoidal recess. Pneumatization of the body of the sphenoid commences at around 7 months of age and a distinct cell is visible by the age of 2 years. Pneumatization spreads first into the presphenoid and later invades the postsphenoid part. The sinus reaches full size in adolescence, but often enlarges further by absorption of its walls as age advances.

Certain parts of the sphenoid are connected by ligaments that may occasionally ossify, e.g. the pterygospinous ligament between the sphenoidal spine and the upper part of the lateral pterygoid plate; the interclinoid ligament joining the anterior to the posterior clinoid process; and the caroticoclinoid ligament that connects the anterior to the middle clinoid process.

Premature synostosis of the junction between pre- and postsphenoidal parts, or of the spheno-occipital suture, produces a characteristic appearance, obvious in profile, of an abnormal depression of the nasal bridge.

## Stylohamular plane

Available with the Gray's Anatomy e-book

## Mandible

The mandible is the largest, strongest and lowest bone in the face. It has a horizontally curved body that is convex forwards, and two broad rami that ascend posteriorly (Fig. 32.5). The body of the mandible supports the mandibular teeth within the alveolar process. The rami bear the coronoid and condylar processes. Each condyle articulates with the adjacent temporal bone at the temporomandibular joint.

## Body

The body is somewhat U-shaped. It has external and internal surfaces separated by upper and lower borders. Anteriorly, the upper external surface shows an inconstant faint median ridge indicating the site of the fused symphysis menti. Inferiorly, this ridge divides to enclose a triangular mental protuberance; its base is centrally depressed but raised on each side as a mental tubercle. The mental protuberance and mental tubercles constitute the chin. The mental foramen, from which the mental neurovascular bundle emerges, lies below either the interval between the premolar teeth, or the second premolar tooth, midway between the upper and lower borders of the body. The posterior border of the foramen is smooth and accommodates the nerve as it emerges posterolaterally. A faint external oblique line ascends backwards from each mental tubercle, and sweeps below the mental foramen; it becomes more marked as it continues into the anterior border of the ramus.

The lower border of the body, the base, extends posterolaterally from the mandibular symphysis into the lower border of the ramus behind the third molar tooth. Near the midline on each side, there is a rough digastric fossa, which gives attachment to the anterior belly of digastric. Behind the fossa, the base is thick and rounded: it has a slight anteroposterior convexity that changes to a gentle concavity as the ramus is approached, and so the base has an overall sinuous profile.

The upper border, the alveolar part, contains 16 alveoli for the roots of the lower teeth. It consists of buccal and lingual plates of bone joined by interdental and inter-radicular septa. Near the second and third molar teeth, the external oblique line is superimposed on the buccal plate. As in the maxilla, the form and depth of the tooth sockets is related to the morphology of the roots of the mandibular teeth. The sockets of the incisor, canine and premolar teeth usually contain a single root, while those for the three molar teeth each contain two or three roots. The third molar is variable in its position and root presentation. It may be impacted vertically, horizontally, mesially or distally, and its roots may be bulbous, hooked, divergent or convergent, and occasionally embrace the mandibular (inferior dental) canal. The internal surface of the mandible is divided by an oblique mylohyoid line that gives attachment to mylohyoid (and, above its posterior end, to the superior pharyngeal constrictor, some retromolar fascicles of buccinator, and the pterygomandibular raphe behind the third molar). The mylohyoid line extends from a point approximately 1 cm from the upper border behind the third molar as far forwards as the mental symphysis; it is sharp and distinct near the molars but faint further forwards. The mylohyoid groove extends downwards and forwards from the ramus below the posterior part of the mylohyoid line and contains the mylohyoid neurovascular bundle. The area below the line is a slightly concave submandibular fossa and is related to the submandibular gland. The area above the line widens anteriorly into a triangular

A plane exists between the pharyngeal side wall and the infratemporal fossa/masticator space. It is readily identified by palpating the tip of the styloid process and with gentle blunt finger dissection passing anteriorly and medially to the pterygoid hamulus at the lower border of the medial pterygoid plate. Termed the 'stylohamular plane' (Friedman et al 1981), it defines the medial and superior boundary of the infratemporal fossa and is the medial boundary for tumours confined to the infratemporal fossa. With resections using the stylohamular plane as a guide, the internal carotid, internal jugular vein and the vagus nerve should not be at risk because they are deep to the styloid apparatus (Fig. 32.4).

Fig. 32.4 The stylohamular plane (dotted line). Key: 1, pterygoid hamulus; 2, styloid process; 3, foramen spinosum; 4, foramen ovale; 5, lateral pterygoid plate.

sublingual fossa and is related to the sublingual gland; the bone is covered by mucosa above the sublingual fossa as far back as the third molar. In an edentulous subject, it may be necessary to reduce any ridge-like prominence of the mylohyoid line in order for dentures to fit without traumatizing the overlying oral mucosa.

Above the anterior ends of the mylohyoid lines, the posterior symphysial aspect bears a small elevation, often divided into upper and lower parts, the mental spines (genial tubercles). The spines are sometimes fused to form a single eminence, or they may be absent, in which case their position is indicated merely by an irregularity of the surface. The upper part gives attachment to genioglossus, the lower part to geniohyoid. Midline lingual (genial) foramina, above and/or below the genial tubercles, and lateral lingual foramina in the premolar region are present in most mandibles and are of importance in the vascular supply to the symphysis. A rounded elevation of compact bone, the torus mandibularis, sometimes develops above the mylohyoid line; it is most prominent in the premolar region, is usually bilateral and only of clinical significance if repeatedly traumatized.

## Ramus

The mandibular ramus is quadrilateral, and has two surfaces (lateral and medial), four borders (superior, inferior, anterior and posterior) and two processes (coronoid and condylar). The lateral surface is relatively featureless and bears the (external) oblique ridge in its lower part. The mandibular foramen, through which the inferior alveolar neurovascular bundle passes to gain access to the mandibular canal (see below), is sited midway between the anterior and posterior borders of the ramus about level with the occlusal surfaces of the teeth. It is overlapped anteromedially by a thin, sharp, triangular spine, the lingula, to which the sphenomandibular ligament is attached, and which is also the landmark for an inferior alveolar local anaesthetic block injection. Below and behind the foramen, the mylohyoid groove runs obliquely downwards and forwards.

The inferior border is continuous with the mandibular base and meets the posterior border at the angle, which is typically everted in males but frequently inverted in females. The thin superior border bounds the mandibular incisure (sigmoid or mandibular notch, incisura semilunaris), which is surmounted in front by the somewhat triangular, flat coronoid process and behind by the condylar process. The thick, rounded posterior border extends from the condyle to the angle, and is gently convex backwards above and concave below. The anterior border is thin above, where it is continuous with the edge of the coronoid process, and thicker below, where it is continuous with the external oblique line. The temporal crest is a ridge that descends on the medial side of the coronoid process from its tip to the bone just behind the third molar tooth. The triangular depression between the temporal crest and the anterior border of the ramus is the retromolar fossa (retromolar trigone).

The ramus and its processes provide attachment for the four primary muscles of mastication. Masseter is attached to the lateral surface, medial pterygoid is attached to the medial surface, temporalis is inserted into the coronoid process and lateral pterygoid is attached to the condyle. The thickness of the ramus decreases markedly behind the external oblique line laterally, the temporal crest medially, and above the lingula; there may be fusion of the lateral and medial cortical plates. This is of importance in mandibular ramus osteotomies and also influences the frequency of fractures of the mandibular angle.

## Antilingula

Available with the Gray's Anatomy e-book

## Mandibular canal

The mandibular foramen leads into the mandibular canal, which runs downwards and forwards within the ramus, gently curving inferiorly within the body under the roots of the molar teeth, with which it communicates by small openings, and ascending in the premolar region to the mental foramen. The canal is not always easy to define on plain X-rays, especially anterior to the mental foramen. Its walls may be formed either by a thin layer of cortical bone or, more frequently, by trabecular bone. Although the buccal-lingual and superior-inferior positions of the canal vary considerably between mandibles, in general, the mandibular canal is situated nearer the lingual cortical plate in the posterior two-thirds of the bone, and closer to the labial cortical plate in the anterior third. Bilateral symmetry (location of the canal in each half of the mandible) is reported to be common. Near the mental foramen, the inferior alveolar nerve branches into the mental nerve, which ultimately leaves the mandible via the mental foramen, and the incisive nerve, which remains within the bone and supplies the anterior
teeth. The mental nerve may extend anteriorly for $2-3 \mathrm{~mm}$ within the mandible before curving back to the mental foramen (the 'anterior loop' of the mental nerve). Appreciation of the three-dimensional course of the mandibular canal during its passage through the mandible from the mandibular to the mental foramina is essential if damage to the inferior alveolar nerve is to be avoided in third molar surgery, mandibular osteotomies, dental implant surgery and harvesting of mandibular bone grafts.

## Coronoid process

The coronoid process projects upwards and slightly forwards as a triangular plate of bone. Its posterior border bounds the mandibular incisure, and its anterior border continues into that of the ramus.

## Coronoid hyperplasia

Available with the Gray's Anatomy e-book

## Condylar process

The mandibular condyle varies considerably in both size and shape. When viewed from above, the condyle is roughly ovoid in outline, its anteroposterior dimension (approximately 1 cm ) being roughly half its mediolateral dimension. The long axis of the condyle is at right angles to the mandibular ramus but, due to the flare of the ramus, the lateral pole of the condyle is slightly anterior to the medial; if the long axes of the two condyles are extended, they meet at an obtuse angle, varying from $145^{\circ}$ to $160^{\circ}$, at the anterior border of the foramen magnum. The slender neck of the condyle, which expands transversely upwards, joins the ramus to the articular head. The pterygoid fovea, a small depression situated on the anterior surface of the neck below the articular surface, receives part of the attachment of lateral pterygoid.

The condyle consists of a core of cancellous bone covered by a thin outer layer of compact bone whose intra-articular aspect is covered by layers of fibrocartilage. The condyle is one of the most common sites for mandibular fractures.

## Condylar hyperplasia

## Available with the Gray's Anatomy e-book

## Accessory foramina of the mandible

Accessory mandibular foramina are usually unnamed and infrequently described, and yet they are numerous. They may transmit auxiliary nerves to the teeth (from facial, mylohyoid, buccal, transverse cervical cutaneous, lingual and other nerves), and their occurrence is significant in dental anaesthetic blocking techniques. The innervation of the teeth is discussed on page 526. The accessory lingual foramina in the mandibular symphysis are particularly relevant in dental implant surgery and osteotomies, e.g. genioplasty, at this site (see below).

## Ossification

The mandible forms in dense fibromembranous tissue lateral to the inferior alveolar nerve and its incisive branch, and also in the lower parts of Meckel's cartilage (first branchial arch). Each half is ossified from a centre that appears near the mental foramen at about the sixth week in utero. From this site, ossification spreads medially and posterocranially to form the body and ramus, first below, and then around, the inferior alveolar nerve and its incisive branch. Ossification then spreads upwards, initially forming a trough, and later crypts, for the developing teeth. By the tenth week, Meckel's cartilage below the incisor rudiments is surrounded and invaded by bone. The mandibular condyle and coronoid process do not develop from the primary (Meckel's) cartilage but from secondary cartilages that appear later (Fig. 32.6). A conical mass, the condylar cartilage, extends from the mandibular head downwards and forwards in the ramus, and contributes to its growth in height. Although it is largely replaced by bone by midfetal life, its proximal end persists as proliferating cartilage under the fibrous articular lining until about the third decade. Another secondary cartilage, which soon ossifies, appears along the anterior coronoid border, and disappears before birth. One or two cartilaginous nodules also occur at the symphysis menti. At about the seventh month in utero, these may ossify as variable mental ossicles in symphysial fibrous tissue; they unite with adjacent bone before the end of the first postnatal year.

## Age changes in the mandible

At birth, the two halves of the mandible are united by a fibrous symphysis menti (Fig. 32.7B). The anterior ends of both rudiments are covered by cartilage, separated only by a symphysis. Until fusion occurs, new cells are added to each cartilage from symphysial fibrous tissue,

The term 'antilingula' has been used to describe an inconstant bony prominence on the lateral aspect of the ramus. This localized bulge, initially thought to be the result of the entrance of the inferior alveolar neurovascular bundle into the medial ramus, has been used as a guide to the position of the mandibular foramen in mandibular osteotomies. However, there is little correlation between the position of the antilingula and the mandibular foramen. It has been suggested that the prominence (when present) on the lateral ramus could reflect the insertion of fibres of masseter (Lang 1995, Hogan and Ellis 2006, Park 2014).

The availability of computed tomography (CT), cone beam CT (СВСТ) imaging and computer-assisted intraoperative navigation permits the assessment of the course of the mandibular canal throughout its length both prior to and during any surgical procedure that could place the inferior alveolar nerve and/or the mental nerve at risk (Aizenbud et al 2012, Wittwer 2012).

Elongation of the coronoid process may be found bilaterally or unilaterally, resulting in progressive, painless restriction of mandibular opening, due to the impingement of the coronoid process on the medial aspect of the zygomatic arch(es). This rare condition is more common in males and usually presents in the middle of the third decade, although it has been reported in neonates. The aetiology is unknown. Treatment involves the resection of the coronoid process(es) (Satoh et al 2006, McLoughlin et al 1995, Mulder et al 2012).

Hyperplasia of the mandibular condyle is a rare unilateral condition that results in facial asymmetry and an altered occlusion (bite). The condition may occur at any age and, if it occurs prior to puberty, growth may not cease at the end of the growth period. Reports vary as to male:female ratio. Although condylar hyperplasia is said to be selflimiting, removal of the growth site in the condyle may be necessary to arrest the condition. Correction of the asymmetry of the jaw is usually performed; however, self-correction of the asymmetry has been reported. A variety of classification systems have been suggested (Obwegeser and Make 1986, Nitzan et al 2008, Nitzan 2009, Wolford 2014).

and ossification on its mandibular side proceeds towards the midline. When the latter process overtakes the former and ossification extends into median fibrous tissue, the symphysis fuses. At this stage, the body is a mere shell, which encloses the imperfectly separated sockets of deciduous teeth. The mandibular canal is near the lower border, and the mental foramen opens below the first deciduous molar and is directed forwards. The condyle is almost in line with the occlusal plane of the mandible and the coronoid projects above the condyle. During the first three postnatal years, the two halves join at their symphysis from below upwards, although separation near the alveolar margin may persist into the second year. The body elongates, especially behind the mental foramen, providing space for three additional teeth. During the first and second years, as a chin develops, the mental foramen alters direction; it no longer faces forwards but now faces backwards, as in the adult mandible, and accommodates the changing direction of the emerging mental nerve.

In general terms, increase in height of the body of the mandible is achieved primarily by formation of alveolar bone associated with the developing and erupting teeth, although some bone is also deposited on the lower border. Increase in length of the mandible is accomplished by deposition of bone on the posterior surface of the ramus and concomitant compensatory resorption on the anterior surface (accompanied by deposition of bone on the posterior surface of the coronoid process and resorption on the anterior surface of the condylar process); a part of the ramus is therefore modelled into an addition to the mandibular body. Increase in width of the mandible is produced by deposition of bone on the outer surface of the mandible and resorption on the inner surface. An increase in the comparative size of the ramus compared with the body of the mandible occurs during postnatal growth and tooth eruption.

The role of the condylar cartilages in mandibular growth remains controversial. One view states that continued proliferation of this cartilage is primarily responsible for the increase in both the mandibular length and the height of the ramus. Alternatively, there is persuasive experimental evidence that proliferation of the condylar cartilage is an adaptive response to function, rather than being genetically determined. Condylar growth and remodelling have been shown to be influenced significantly by local factors - notably, movement and loading of the temporomandibular joint - and to be relatively immune to systemic influences such as vitamin C and D deficiency. Considering the changes that occur in the dentition throughout life, continuous adaptation of the temporomandibular articulation is required in order to maintain functional occlusal alignment between the upper and lower arches of teeth; this adaptation is thought to be largely the result of ongoing condylar remodelling.

In adults, alveolar and subalveolar regions are about equal in depth, and the mental foramen appears midway between the upper and lower borders. If teeth are lost, alveolar bone is resorbed, and both the mental foramen and the mandibular canal come to lie closer to the superior border (see Fig. 32.7A). The mental foramen is placed higher than the mandibular canal posterior to it, and so resorption of the alveolus in edentulous patients exposes the nerve at the foramen, i.e. prior to the nerve in the mandibular canal (Cawood and Howell 1988, Lang 1995, Eufinger et al 1997).

## Bone resorption in the mandible

Available with the Gray's Anatomy e-book

## Blood supply of the mandible

The blood supply to the body of the mandible is derived from its principal nutrient artery, the inferior alveolar artery, and from the vessels supplying genioglossus, geniohyoid and the anterior belly of digastric (which are all attached to its lingual aspect between the mental foramina). The blood supply to these muscles is from the sublingual branch of the lingual artery and the submental branch of the facial artery. Branches of these vessels may perforate the lingual cortical plate through lateral lingual foramina in the premolar region and genial foramina in the midline, when these foramina are present (Fig. 32.10). Anastomoses between these vessels are common. A branch of the submental artery may anastomose with the mental artery, permitting retrograde vascular supply to the body and symphysis (relevant in mandibular fractures). The vascular supply to the mandibular symphysis is of importance in dental implant surgery. The ramus, including the mandibular angle, is supplied by the inferior alveolar artery and from the vessels supplying masseter and medial pterygoid. Vessels supplying temporalis supply the coronoid process. The vascular supply to the mandibular condyle, temporomandibular joint and the individual

The pattern of bone resorption (atrophy) of the mandible following the loss of teeth is said to be in a centrifugal ('down and out') direction, compared to a centripetal direction in the maxilla. These differences produce a progressive increase in the incongruity of the alveolar processes of the jaws. Bone loss is not limited to the alveolar part; it can involve the base (basal bone) to varying degrees. Progressive remodelling of the mandible and maxilla accompany the bone loss; it is not limited to the body of the mandible but also involves the coronoid process and the mandibular condyle, and reduction in both the height and width of the ramus. This bone loss has implications in denture construction, dental implant surgery and mandibular fractures (Figs 32.8-32.9) (Aziz and Najjar 2009, Ellis and Price 2008, Cawood and Howell 1988, Eufinger et al 1997, Sutton et al 2004).

masticatory muscles is described below (Janfanza et al 2001, McDonnel et al 1994, Jacobs et al 2007, Romanos et al 2012, Nakajima et al 2014).

## Endosseous blood supply to the mandible via lingual foramina

Available with the Gray's Anatomy e-book

## TISSUE SPACES

Descriptions of the various 'spaces' in the head and neck and the fascial arrangements of the head and neck in the literature lack clarity, and are variable and open to misinterpretation. There is even controversy as to what constitutes 'fascia' (Guidera et al 2012). No gold standard exists as to what constitutes cervical fascia; however, the landmark paper by Grodinsky and Holyoke (1938) is suggested as a useful initial point of reference.

The contents of the infratemporal fossa are contained within a welldefined space that is bounded by and incorporates the masticatory muscles; this is termed the masticator space. The masticator space is closed posteriorly by the attachment of the deep cervical fascia, medial pterygoid and masseter (pterygomasseteric sling), and anteriorly, lateral to the ramus, by the firm attachment of masseter (the submasseteric space is a potential space). The masticator space is closed superiorly by both the temporal fascia laterally and the firm attachment of temporalis to the bone of the temporal fossa (the deep temporal space is also only a potential space). Medial to the ramus of the mandible, the pterygomandibular space (part of the masticator space) communicates freely with the pterygopalatine fossa, offering little resistance to the spread of infection or tumours. Posteriorly penetrating maxillary tumours directly involve the masticator space/infratemporal fossa and the pterygopalatine fossa. Resection of the masticator space has been termed a 'compartment' resection of the mandible (McMahon et al 2013, Blanchaert and Ord 1998) (Fig. 32.12).

Above the level of the zygomatic arch, the temporal fascia provides both the superior and lateral limits, by its attachments to the superior temporal line and the zygomatic arch, respectively. Below the zygomatic arch, the investing layer of deep cervical fascia (superficial layer of deep cervical fascia) splits into two laminae to enclose masseter, the lower part of temporalis and medial pterygoid, further defining the boundaries of the masticator space. The superficial (lateral) lamina covers masseter and attaches to the zygomatic arch, and the deep (medial) lamina runs on the deep surface of medial pterygoid, attaching to the skull base medial to the foramen ovale (Guidera et al 2014). This fascial covering of the masticatory muscles is felt to be distinct from the parotid fascia (capsule). The contents of the masticator space are temporalis, masseter, medial and lateral pterygoid, the ramus and coronoid process of the mandible, the mandibular nerve and otic ganglion, the maxillary artery and the pterygoid venous plexus, and part of the buccal fat pad anterolaterally. The submasseteric, pterygomandibular, superficial and deep temporal spaces are contained within.

The superficial temporal space lies between the temporal fascia laterally and temporalis medially. The deep temporal space, like the submasseteric space, is a potential space. It lies between temporalis laterally and the temporal fossa of the skull medially. Both spaces are in communication with the remainder of the masticator space inferiorly.

There is debate as to the upper limit of the masticator space, with the suggestion that it should be at the level of the zygomatic arch. Since both temporal spaces communicate with the remainder of the masticator space, a single masticator space incorporating the temporal fascia, muscles and temporal spaces is favoured (Guidera et al 2014).

## TEMPOROMANDIBULAR JOINT

The temporomandibular joint (TMJ) is a synovial joint between the glenoid fossa (mandibular fossa) of the temporal bone above and the mandibular condyle. It is unusual in that its articular surfaces are lined by fibrocartilage, rather than hyaline cartilage; fibrocartilage is less susceptible to degeneration and has a greater repair capacity. The joint cavity is divided into upper and lower compartments ('spaces') by a fibrocartilaginous articular disc.

The anterior limit of the glenoid fossa is the articular eminence. This transverse ridge of dense bone, tilted down at an angle of approximately $25^{\circ}$ to the occlusal plane, forms most of the articular surface of the mandibular fossa. It is strongly convex in the sagittal plane with a slight concavity in the coronal plane. It extends out laterally to the zygomatic
arch as the articular tubercle. The roof of the glenoid fossa, by contrast, is thin and often translucent when held to the light, confirmation that this is not a major load-bearing area of the joint (Hylander 2006). The posterior wall is formed by the tympanic plate, which also forms the anterior wall of the external acoustic meatus.

The anterior articular area of the fossa (articular fossa) is formed entirely from the squamous portion of the temporal bone and lined by articular tissue that extends anteriorly beyond the articular summit on to the preglenoid plane. The squamotympanic fissure marks the junction with the posterior non-articular (tympanic) area. The tegmen tympani, a bony plate of the petrous temporal, intervenes in the medial aspect of the fissure, where the squamotympanic fissure becomes the petrotympanic fissure. The postglenoid tubercle at the root of the zygomatic arch, just anterior to the squamotympanic fissure, separates the squamotympanic fissure laterally from the tympanic plate.

The condylar head, tilted forwards on the neck at an angle of approximately $30^{\circ}$ (physiological anteversion), articulates with the fossa on its anterior and superior surfaces. Like the eminence, both its slope and shape are variable, influenced by age, function and dentition. In the coronal plane, its shape varies from that of a gable (particularly marked in those whose diet is hard) to roughly horizontal (in the edentulous).

It is probably impossible to measure the pressure developed on the articular surfaces of the human jaw joint when biting; however, direct measurement of loads across the joint in animals has demonstrated significant intermittent loading during mastication. There is also irrefutable theoretical evidence based on Newtonian mechanics that the jaw joint is a weight-bearing joint. With a vertical bite force of 500 N on the left first molar, the right condyle must support a load of well over 300 N (Osborn 1995). The non-working condyle is more loaded than the condyle on the working side, which may help explain why patients with a fractured condyle choose to bite on the side of the fracture.

## FIBROUS CAPSULE

The lower part of the joint is surrounded by tight fibres, which attach the condyle of the mandible to the disc (collateral ligament). The upper part of the joint is surrounded by loose fibres, which attach the disc to the temporal bone (Fig. 32.13). Thus the articular disc is attached separately to the temporal bone and to the mandibular condyle, forming what could be considered two joint capsules. These attachments stabilize the disc but allow rotation over the condyle. Longer fibres joining the condyle directly to the temporal bone may be regarded as reinforcing. The capsule is attached above to the anterior edge of the preglenoid plane, posteriorly to the lips of the squamotympanic fissure, between these to the edges of the articular fossa, and below to the periphery of the neck of the mandible.

## LIGAMENTS

The ligaments of the temporomandibular joint are the temporomandibular (lateral) ligament, the sphenomandibular ligament and the stylomandibular ligament.

## Temporomandibular (lateral) ligament

The broad temporomandibular ligament, reinforcing the joint capsule laterally, is attached above to the articular tubercle on the root of the zygomatic process of the temporal bone (see Fig. 32.13). It extends downwards and backwards at an angle of approximately $45^{\circ}$ to the horizontal, to attach to the lateral surface and posterior border of the neck of the condyle, deep to the parotid gland. A short, almost horizontal, band of collagen connects the articular tubercle in front to the lateral pole of the condyle behind. It may function to prevent posterior displacement of the resting condyle and also initiates translation of the condyle on mouth opening.

## Sphenomandibular ligament

The sphenomandibular ligament is medial to, and normally separate from, the capsule (see Fig. 32.13). It is a flat, thin band that descends from the spine of the sphenoid and widens as it reaches the lingula of the mandibular foramen; it has an average width at its insertion into the mandible of about 12 mm . Some fibres traverse the medial end of the petrotympanic fissure and attach to the anterior malleolar process. This part is a vestige of the dorsal end of Meckel's cartilage.

The endosseous supply of the mandibular symphysis via the lingual foramina，and the rich vascular supply to the anterior floor of the mouth are of particular importance in dental implant surgery and oste－ otomies，e．g．genioplasty，at this site．

Foramina at the level of，or above，the genial tubercle（superior genial foramen）and below the genial tubercle（inferior genial foramen） are almost always found（McDonnel et al 1994，Jacobs et al 2007）． Lateral lingual foramina are usually identified，with an average distance above the lower border of the mandible of 5 mm （Romanos et al 2012）． The superior genial foramen may contain a branch of the lingual artery and nerve．The inferior foramen may contain a branch of the sublingual or submental arteries and a branch of the mylohyoid nerve．The lateral foramen may contain a branch of the submental artery（Jacobs et al 2007，Nakajima et al 2014）．Although the relative contributions from the individual vessels vary，anastomoses between these perforating vessels and the inferior alveolar artery，within the mandible，are common．The soft tissues in the anterior floor of the mouth adjacent to the mandible are supplied by contributions from the sublingual， submental and mylohyoid arteries；there are considerable anastomoses between them（Romanos et al 2012，Nakajima et al 2014，Loukas et al 2008，Flanagan 2003）．Brisk，potentially life－threatening haemorrhage has been reported with dental implant placement in the mandibular symphysis，usually associated with perforation of the lingual cortical plate of the mandible（Romanos et al 2012，Loukas et al 2008，Woo et al 2006，Dubois et al 2010）（Fig．32．11）and death has resulted from genioplasty，secondary to haemorrhage in the anterior floor of the mouth（personal communication）．The precise source of the haemor－ rhage can be difficult to detect and may arise from both within the mandible and the soft tissues in the floor of the mouth，from any of the above－named vessels．The anastomoses between the vessels may result in haemorrhage on both sides of mylohyoid and thus into the sublingual and the submental／submandibular spaces bilaterally．As the lateral and midline lingual foramina are closer to the lower border of the mandible，caution with longer implants has been recommended in this region．

Fig．32．11 A three－dimensional reformatted CT image showing an implant perforating the lingual cortical plate（arrow），leading to haemorrhage in the anterior floor of the mouth．A tracheostomy was required to secure the airway．（With permission from Dubois L，de Lange J，Baas E，Van Ingen J． Excessive bleeding in the floor of the mouth after endosseous implant placement：a report of two cases．Int J Oral Maxillofac Surg 2010；39：412－415．）

Fig. 32.13 The left temporomandibular joint. A, Lateral aspect. B, Medial aspect.

With the jaw closed, there is approximately 5 mm slack within the ligament, but it becomes taut when the jaw is about half open. Superiorly, lateral pterygoid, the auriculotemporal nerve and the maxillary artery and vein are lateral to the ligament, the nerve and vessels running between the ligament and the condylar neck. The chorda tympani lies medially and occasionally grooves the spine of the sphenoid. Anteroinferiorly, the inferior alveolar nerve and vessels and a parotid lobule separate the ligament from the ramus of the mandible. The vessels and nerves to mylohyoid pierce the ligament adjacent to the lingula. Medial pterygoid is inferolateral. The sphenomandibular ligament is separated from the pharynx by fat and a pharyngeal vein.

## Stylomandibular ligament

The stylomandibular ligament is a thickened band of deep cervical fascia that stretches from the apex and adjacent anterior aspect of the styloid process to the angle and posterior border of the mandible (see Fig. 32.13). Its position and orientation indicate that it cannot mechanically constrain any normal movements of the mandible and does not seem to warrant the status of a ligament of the joint.

## SYNOVIAL MEMBRANE

The synovial membrane lines the inside of the capsule of the joint but does not cover the disc or the articular surfaces (condyle, fossa or
articular eminence). The synovium is most abundant in the bilaminar zone of the articular disc, forming loose folds posteriorly when the condyle is positioned in the glenoid fossa. These folds disappear when the condyle is protruded and the synovium is stretched.

## Synovial fluid and joint lubrication

The coefficient of friction between the articulating surfaces of the temporomandibular joint is almost zero (Nickel et al 2006), reflecting the net result of a combination of adequate joint lubrication, the surface structure of the articulating surfaces and the articular disc. Joint lubrication depends on the synovial fluid, which also provides protection and nutrition to the articular surfaces and is the sole supplier of nutrients to the avascular disc. Surface active phospholipids (SAPLs) and hyaluronic acid are the key lubricants of the joint and act to protect the articular surfaces. It has been hypothesized that abnormalities of the joint lubrication system, e.g. changes resulting from uncontrolled oxidative stress, may play a role in the onset of temporomandibular joint disorders (Nitzan 2001).

## ARTICULAR SURFACES

The anterior and superior surfaces of the mandibular condyle, and the articular eminence and preglenoid plane of the squamous temporal bone are the principal articulating surfaces of the joint. This is reflected in the thickness of the articular tissue covering these surfaces. The fibrocartilaginous covering of the condyle is composed of four distinct layers (De Bont et al 1984). The most superficial layer consists of densely packed fibres of type I collagen that is arranged mostly parallel to the articular surface and aligned in an anteroposterior direction (this can be seen as striation on arthroscopy - Video 32.1). This covers a thin cellular layer, the proliferative zone that is continuous with the cambial layer of the periosteum beyond the margins of the joint. The third layer, of hypertrophic cartilage, is rich in intercellular matrix; it contains chondrocytes scattered throughout its depth, and randomly orientated fibres of collagen type II. The fourth layer, immediately above the subchondral bone, is the zone of calcification. Although the number of chondrocytes within the hypertrophic zone decreases with age, undifferentiated mesenchymal cells have been identified in postmortem specimens of all ages (Hansson et al 1977). This indicates that a capacity for proliferation and repair persists in condylar cartilage, and may be the reason why condylar remodelling occurs throughout life (Robinson 1993, Toller 1974).

## ARTICULAR DISC

The articular disc divides the joint into a superior (discotemporal) space and an inferior (discomandibular) space, both filled with synovial fluid. The transversely oval disc is composed of avascular dense fibrous connective tissue with some chondrification in areas of maximum loading (Fig. 32.14). It has a thick margin, which forms a peripheral anulus and a central depression in its lower surface that accommodates the articular surface of the mandibular condyle. The depression probably develops as a mechanical response to pressure from the condyle as it rotates inside the anulus. The disc is stabilized on the condyle in three ways. Its edges are fused with the part of the capsular ligament that tightly surrounds the lower joint compartment and is attached around the neck of the condyle; well-defined bands in the capsular ligament attach the disc to the medial and lateral poles of the condyle (collateral ligaments), and additionally, the thick anulus prevents the disc sliding off the condyle (self-centring capability - see below), provided that the condyle and disc are firmly lodged against the articular fossa (as is normally the case).

In sagittal section, the disc has three distinct parts: an anterior band, a thinner intermediate zone and a posterior band. The posterior band is the thickest. Its upper surface is concavo-convex where it fits against the convex articular eminence and the concavity of the articular fossa. Posteriorly, the disc is attached to a richly vascularized and innervated region, the bilaminar zone (posterior attachment), which splits into two laminae; unlike the rest of the disc, its normal function is to provide attachment rather than intra-articular support. The upper lamina is composed of fibroelastic tissue and is attached to the squamotympanic fissure. There is a condensation of elastic fibres in the medial portion of the upper lamina, which is visible as the posterior oblique protuberance on arthroscopy (see Video 32.1). The lower lamina is composed of fibrous non-elastic tissue and is attached to the posterior aspect of the condyle. The intervening connective tissue between the upper and lower laminae contains a vascular plexus and is well innervated, but the

Fig. 32.14 Sagittal sections through the right temporomandibular joint. A, Note the relationship of the external acoustic meatus and articular disc to the mandibular condyle. B, The microstructure of condylar cartilage. (A, Courtesy of Professor Cristina Manzanares Céspedes, Anatomy and Human Embryology Unit, Bellvitge Campus, University of Barcelona.)
central part of the disc itself is avascular and not innervated. With anterior movement of the disc-condyle complex, the volume of the posterior attachment increases as a result of the negative pressures generated, resulting in an influx of blood into the venous plexus. This pumping mechanism is important in the nutrition of the joint (Stegenga and de Bont 2006).

## Upper and lower joint compartments

The upper joint space contains approximately 1.2 ml of synovial fluid and the lower approximately 0.9 ml . Both spaces may be considerably distended with fluid for diagnostic purposes in temporomandibular joint arthrography, for therapeutic purposes in arthrocentesis, and to improve access and visibility in arthroscopy. Both joint spaces have an anterior and posterior recess or pouch, and are lined by synovium, which has a grey hue when viewed through an arthroscope (see Video 32.1).

## Functions of the articular disc

The articulating surfaces of the mandibular condyle and the articular fossa are highly incongruent. Wear of the articular surfaces may be reduced by the presence of a deformable articular disc, which not only distributes compressive joint loading over a larger contact area but also significantly reduces the frictional force on the condyle and the articular fossa by separating slide and rotation into different joint compartments.

The disc may aid joint lubrication by storing fluid squeezed out from loaded areas to create a weeping lubricant. In addition, its flexibility, due to its high water content and viscoelastic properties, allows it to function almost like a fluid, further reducing friction within the joint and thereby aiding joint lubrication. The friction between the articulating surfaces in the absence of the disc is 2-3 times greater than with the disc in situ.

The role of the disc in relation to joint stability is controversial. One view is that a deformable and viscoelastic disc stabilizes the condyle within the joint by filling the changing and irregular joint space created
during movement. The disc moves in an almost congruent manner relative to the condyle controlled by neuromuscular forces: the upper head of lateral pterygoid anteriorly and the elastic tissue in the bilaminar region posteriorly together pull the disc forwards or backwards. In addition, the shape of the disc with its thick, 'self-seating' anulus helps to prevent the disc sliding off the condyle. An alternative view is that a slippery articular disc doubles the number of virtually friction-free sliding surfaces, and so destabilizes the condyle in the same way that stepping on a banana skin destabilizes the foot. These two roles are not mutually exclusive. A deformable disc stabilizes the condyle within the joint whilst, by doubling the friction-free surfaces, the disccondyle assembly slides freely under compressive loading and so is 'destabilized'.

## RELATIONS

Superiorly, the thin roof of the glenoid fossa has a mean thickness of 0.9 mm (range $0.2-4 \mathrm{~mm}$ ) and separates the upper joint space from the middle cranial fossa. This bony partition is occasionally fenestrated by inflammatory processes or inadvertently during surgery to the joint, particularly for release of ankylosis, and rarely by the condyle being driven superiorly by violent trauma to the mandible. The maxillary artery and its proximal branches, most notably the middle meningeal artery, lie medially, just beyond the joint capsule. The uppermost part of the parotid capsule enclosing the branches of the facial nerve that supply the muscles of the upper face, including orbicularis oculi, are lateral to the joint capsule; the thread-like nerves are at risk during surgical approach to the joint. The upper part of the infratemporal fossa, which contains the two heads of lateral pterygoid, is anterior to the condyle (Fig. 32.15). It is into this space anterior to the articular eminence that the condyle is displaced in cases of dislocation of the temporomandibular joint or fracture dislocation of the condylar head due to the vector of pull from lateral pterygoid, which inserts into the anterior condylar neck. Posteriorly, the tympanic plate and tegmen tympani separate the joint from the middle ear cavity. Perforation through this

The articular disc is designed to withstand compressive and shearing loads, and has viscoelastic properties, allowing it both to deform when loaded and to conform to the surfaces causing this deformation. Removal of the disc increases surface friction within the joint by 2-3 times compared to joints with an intact disc. Long-term follow-up of patients who have had the disc removed ('discectomy') demonstrates that the joint undergoes significant remodelling similar to that seen in osteoarthrosis. There is flattening, slight roughening and sclerosis of the condylar head and articular fossa. These changes, which are believed to be adaptive responses of the condyle and fossa to the absence of an intervening disc, collectively produce a broader contact, decreasing the load per unit area.

The main purpose of collagen in tissue is to resist tensile forces. The orientation of the collagen fibres in the disc varies in the individual regions, reflecting the direction of the tensile forces imparted to the disc. In the intermediate zone, they are predominantly orientated in an anteroposterior direction. Around the periphery, the collagen forms a ring-like structure with a three-dimensional framework of collagen fibrils. In the posterior and anterior bands, the predominant orientation is lateral-medial and superior-inferior. Type 1 collagen, similar to that found in the superficial layers of the head of the condyle and the articular fossa, predominates in the disc.

Chondroitin sulphate and dermatan sulphate are the principal glycosaminoglycans (GAGs) in the intercellular matrix. GAGs are very hydrophilic and, as such, play an important role in the resistance and distribution of compressive load applied to the temporomandibular joint. Their concentration varies with the area of the disc, being highest in the superficial layer of the intermediate zone (Nickel and McLachlan 1994, Tanaka et al 2006, Miloro and Henrickson 2010, Detamore and Athanasiou 2003, Obrez and Gallo 2006, Paegle et al 2003).

thin, bony wall into the middle ear is a recognized complication of temporomandibular joint arthroscopy.

## VASCULAR SUPPLY AND INNERVATION

The articular tissues and the dense part of the articular disc have no nerve supply. The nerve supply to the temporomandibular joint is from branches from the mandibular division of the trigeminal nerve, mostly through the auriculotemporal branch, along with branches from the masseteric and deep temporal nerves. Postganglionic sympathetic nerves supply the tissues associated with the capsular ligament and the looser posterior bilaminar extension of the disc. The temporomandibular joint capsule, lateral ligament and retroarticular tissue contain mechanoreceptors and nociceptors. The input from mechanoreceptors provides a source of proprioceptive sensation that helps control mandibular posture and movement.

The joint derives its arterial supply from the superficial temporal artery laterally and the maxillary artery medially. Penetrating vessels that supply lateral pterygoid may also supply the condyle. Veins drain the anterior aspect of the joint and associated tissues into the plexus surrounding lateral pterygoid; posteriorly, they drain into the vascular region that separates the two laminae of the bilaminar region of the disc. Positive and negative pressure produced by forward and backward movement of the condyle shunts blood between these regions. Lymphatics drain deeply to the upper cervical lymph nodes surrounding the internal jugular vein.

## JAW MOVEMENTS

## Movements of the condyle in the temporomandibular joint

The major function of the mandible is to exert, via the teeth, the force necessary to break down food into smaller particles and so facilitate digestion. Pure vertical movements of the lower teeth create a crushing force that is ineffective in breaking up tough fibrous food. Humans use a lateral movement of the lower jaw to create a shear force that enhances the effectiveness of the power stroke of mastication. Bodily lateral movement of the whole jaw, the Bennett shift, is insignificant. Extensive lateral movement is only possible when the jaw is rotated horizontally about one condyle while the other condyle slides backwards and forwards. The temporomandibular joint is structurally adapted to accommodate both sliding/translation and rotation/hinging in a sagittal plane. Sliding/translation occurs because the capsular ligament that surrounds the upper joint compartment is loose, whereas the capsular
ligament that encloses the lower joint compartment is tight, and only allows the condyle to rotate over the depression inside the anulus of the articular disc. The normal range of maximum mouth opening measured between the upper and lower incisor tips is $35-50 \mathrm{~mm}$, the first $15-25 \mathrm{~mm}$ of which is due to hinging of the condyle; the remainder is due to condylar translation. The adult range of movements is reached at around 10 years in females and 15 years in males. Lateral excursions of the chin can normally achieve $8-12 \mathrm{~mm}$ of movement at the lower incisors. At the limit of normal opening, the condyle has translated on to the peak or just beyond the peak of the articular eminence. Translation beyond this results in subluxation and dislocation of the joint.

## Symmetrical opening

Symmetrical jaw opening is associated with preparation for incising. At the start, each mandibular condyle rotates in the lower joint compartment inside the anulus of its disc. After a few degrees of opening, the condyle continues rotating inside its disc and, in addition, both slide forwards down the articular eminence of the upper joint compartment. Without this forward slide or translation, it becomes impossible to continue opening the jaw beyond a gape of approximately 25 mm .

Opinions differ as to why this forward slide should occur; the fact that the condyle in a cadaver still slides forwards when the jaw is rotated open suggests that it is not a neuromuscular response but rather the result of mechanical constraints. When the jaw is rotated open, the temporomandibular ligament rapidly becomes taut (Osborn 1995). The taut ligament acts as a constraint that allows the mandible only two rotary movements: it can swing about the upper attachment of the ligament and rotate about the lower attachment. The lower end of the taut ligament acts as a moving fulcrum that converts the downward and backward pull of the opening rotary force (created at the front by digastric and geniohyoid) into one that drives the condyle upwards and forwards into the concavity of the overlying articular disc. This now pushes the disc forward. Swing about the upper attachment creates space above for the disc to slide further forwards, which is possible because the upper part of the capsular ligament is loose. The two movements, rotation and swing, are inextricably linked by the taut ligament and, via the condyle, combine to keep the disc in firm contact with the articular eminence while the jaw is opened. The disc is stabilized by its tight attachment to the condyle (collateral ligament) and by the thickened margins of its anulus that prevent it sliding through the thinner compressed region between the centre of the condyle and the articular eminence.

As forward slide of the condyle continues, the controlling influence exerted by the temporomandibular ligament diminishes. The lingula of the mandible moves away from the spine of the sphenoid, tautening the originally slack sphenomandibular ligament, which now acts in the same way as the temporomandibular ligament, to maintain the condyle against the articular eminence. Symmetrical opening thus appears to consist of at least three separate phases: an early phase controlled by the temporomandibular ligament and articular eminence; a short middle phase in which either both temporomandibular and sphenomandibular ligaments, or neither, act to constrain movements; and a late phase controlled by the sphenomandibular ligament and articular eminence.

## Changes in disc position during movement

With the teeth in occlusion, the condyle is in the glenoid fossa and the intra-articular disc sits on the condylar head, with its posterior band at the 12 o'clock position from the centre of the condylar head in the sagittal plane (Fig. 32.16A). As mouth opening begins (Fig. 32.16B), the condyle rotates within the lower joint space and the disc remains stationary. At about mid-opening, the condyle and disc begin to move forwards together so that their relative position is maintained (Fig. 32.16C). At maximum gape (Fig. 32.16D), the condylar head slides further anteriorly than the disc; the disc is rotated backwards relative to the condyle by the pull of the elastic superior lamina of the posterior attachment, so that the anterior band of the articular disc is above the summit of the condyle. This differential movement results in the disc moving only about half the distance of the condyle. Mouth closure involves the disc moving back in tandem with the condyle under the influence of the elastic fibres in the upper lamina of the bilaminar area posterior to the disc itself (Fig. 32.16E), which also reverses its angular rotation (Fig. 32.16F) to reassume the starting position of the cycle.

The changes in disc position may become out of phase with the condyle, causing obstruction to smooth mandibular movement. The disc is typically pulled anteromedially by the lateral pterygoid, so preventing forward translation of the condyle. With the disc in this position, the posterior band of the disc is anterior to the condyle, which

Fig. 32.16 Changing relationships of the condyle of the mandible, the articular disc and the articular surface of the temporal bone during one complete opening $(A \rightarrow D)$ and closing ( $D \rightarrow A$ ) cycle of the mouth.
causes an obstruction to forward translation of the condyle. As the force from the condyle on the disc increases, the elastic posterior attachments of the disc are stretched until the resistance to movement is overcome and the disc reduces into a normal relationship with the condyle, which is associated with an audible click (audible to the patient and occasionally to others). Once the normal disc-condyle relation is re-established, the mouth is free to achieve maximum opening (see Fig. 32.16C,D). The disc may then snap back in front of the condyle on mouth closure. This phenomenon is called reciprocal clicking or disc displacement with reduction. If the disc remains completely anterior to the condylar head and does not reduce into a normal relationship with the condyle during opening, the condyle is prevented from further forward translation and mouth opening is restricted. This is a common clinical condition and is known appropriately as closed lock or disc displacement without reduction (see below).

## Eccentric jaw opening

Jaw movement during mastication can be divided into three parts: opening, closing and power strokes. Eccentric jaw opening is associated with preparing for the power stroke of mastication. The mandibular condyle on the non-working side slides back and forth during lateral movements associated with the power stroke on the working side. Although the jaw muscles now have the major control over mandibular movements, the temporomandibular and sphenomandibular ligaments keep the condyle firmly against its articular eminence during opening.

## Eccentric and symmetrical jaw closing

During closure of the jaw, the masticatory muscles act in combination to force the joint surfaces together. This compresses the joint tissues and
potentially shortens the ligaments so that they no longer constrain jaw movements. Under these conditions, jaw movements and the positions of the condyles are controlled by neuromuscular processes (within the limits of constraints imposed by the articular eminence, the occluding surfaces of the teeth and the presence of food between them). Note that the non-working condyle moves the furthest, and is the most heavily loaded, during the power stroke of mastication. The loads on each joint, balancing and working, drive each condyle more forcefully into its articular eminence.

## The envelope of motion

The envelope of motion is the volume of space within which all movements of a point on the mandible have to occur because the limits are set by anatomical features, i.e. by the shape or size of the upper and lower jaws, by tooth contacts, and by the attachment of muscle and ligaments. The mandibular movements at these extremes are termed 'border movements'.

In consciously controlled movement of the jaw from the rest position to the fully opened position, the trajectory of the mandibular incisal edge is two-phased. The first phase is a hinge-like movement during which the condyles are retruded within the mandibular fossae. When the teeth are opened by approximately 25 mm , the second phase of opening occurs by anterior movement or protrusion of the condyles down the articular eminences with further rotation.

If conscious effort is used, a closure path can then be followed in which the jaw is closed to an extreme protruded tooth contact position, after which it has to be retruded to the starting position. Similar considerations apply to lateral movements; mandibular rotation around a retruding condyle and the protraction of the opposite condyle are
anatomically limiting factors that are again rarely encountered in normal function.

Although all mandibular movement occurs within or along the border movements, knowledge of the extent of border movements provides little information on the nature of the movements during chewing or on the free ('empty'), habitual movements during both opening and closing, which have a more limited trajectory.

## Disc position and internal derangement

Considerable attention has been directed at abnormalities of disc position (collectively known as internal derangements) as a cause of joint noises (clicking), limitation of jaw movement and/or pain. The position of the disc is considered to be normal when, with the mandible at rest, the posterior band is positioned in the 12 o'clock position from the centre of the condyle in the sagittal plane. Displacement of the disc anteromedially is most common. MRI and arthrography have demonstrated that, although disc position and clinical symptoms are often linked, a significant proportion of subjects with apparently normal temporomandibular joint function have disc displacement on imaging and, conversely, patients with normally positioned discs may have severe restriction of mouth opening. Similarly, individuals with displaced discs who have undergone disc repositioning surgery often show functional improvement despite persistent displacement of their intraarticular disc and vice versa.

It is appreciated that limited mouth opening is not always related to disc displacement or non-reducibility but may be the result of impaired joint lubrication and disc mobility. It is also suggested that, in an otherwise asymptomatic jaw with normal movements, an anteriorly 'displaced' disc could be considered a normal variant (Stegenga and de Bont 2006) or, at the least, not an indication for treatment.

It would appear that the adaptive remodelling capacity of the joint (both the mandibular condyle and articular fossa) and adequate joint lubrication are important for maintaining function of the temporomandibular joint.

## DEVELOPMENT OF THE TEMPOROMANDIBULAR JOINT

The bony components of the secondary jaw joint develop in membrane as two separate condensations of neural crest mesenchyme between the eighth and twelfth week in utero. This arrangement is different from that seen with most synovial joints, where a single blastema cavitates to form a joint space and the articulating bones are derived from the same condensation of tissue. The separate development of the temporal and condylar parts of the temporomandibular joint means that the articular surface of each bone is covered by a persisting layer of proliferative cells that is continuous with the periosteum surrounding each separate bony component (Fig. 32.17).

## MUSCLES

The four principal muscles of mastication are medial and lateral pterygoid, temporalis and masseter; their actions produce movements of the mandible at the temporomandibular joints.

The infratemporal fossa contains medial and lateral pterygoid and the tendon of temporalis. Masseter lies on the face, on the lateral surface of the ramus of the mandible, but will be considered here.

Fig. $32.17 \mathrm{~A}, \mathrm{~B}$,
Development of the temporomandibular joint; the temporal and condylar components of the joint develop from two separate condensations of neural crest mesenchyme.

## Masseter

Masseter (Fig. 32.18) is a quadrilateral muscle that consists of three layers that blend anteriorly. The superficial layer is the largest. It arises by a thick aponeurosis from the maxillary process of the zygomatic bone and from the anterior two-thirds of the inferior border of the zygomatic arch. Its fibres pass downwards and backwards, to insert into the angle and lower posterior half of the lateral surface of the mandibular ramus. The superficial fibres are angled approximately $10^{\circ}$ from the vertical, as is visible in lean individuals. In the coronal (frontal) plane, the muscle forms a $10^{\circ}$ angle with the mandibular ramus. Intramuscular tendinous septa in this layer are responsible for the ridges on the surface of the ramus. The middle layer of masseter arises from the medial aspect of the anterior two-thirds of the zygomatic arch and from the lower border of the posterior third of this arch. It inserts into the central part of the ramus of the mandible. The deep layer arises from the deep surface of the zygomatic arch and inserts into the upper part of the mandibular ramus and into its coronoid process. The deep fibres run vertically, and are evident just anterior to the temporomandibular joint, where they are not covered by the more superficial layers. There is still debate as to whether fibres of masseter are attached to the anterolateral part of the articular disc of the temporomandibular joint. Hypertrophy of the masseter may occur either unilaterally or bilaterally. The aetiology is uncertain and there may be associated prominence of the mandibular angle. Treatment may involve surgical reduction of the deep aspect of the muscle and contouring of the mandibular angle or injections of botulinum toxin to paralyse the motor nerves.

Relations Skin, platysma, risorius, zygomaticus major, the parotid gland and duct, branches of the facial nerve and the transverse facial branches of the superficial temporal vessels are all superficial relations. Temporalis and the ramus of the mandible lie deep to masseter. The anterior margin of masseter is separated from buccinator and the buccal branch of the mandibular nerve by a buccal pad of fat and crossed by the facial vein. The posterior margin of the muscle is overlapped by the parotid gland. The masseteric nerve and artery reach the deep surface of masseter by passing over the mandibular incisure (mandibular notch).
Vascular supply Masseter is supplied by the masseteric branch of the maxillary artery, the facial artery and the transverse facial branch of the superficial temporal artery.

Innervation Masseter is supplied by the masseteric branch of the anterior trunk of the mandibular nerve.

Fig. 32.18 Masseter and temporalis muscles. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Actions Masseter elevates the mandible to occlude the teeth in mastication and has a small effect in side-to-side movements, protraction and retraction. Its electrical activity in the resting position of the mandible is minimal.

Submasseteric space infections The submasseteric space is a potential space (see 'masticator space', p. 541) produced by the firm attachment of masseter to the ramus. Sometimes, infection around a mandibular third molar tooth tracks backwards, lateral to the mandibular ramus, and pus localizes deep to the attachment of masseter in the submasseteric tissue space. Such an abscess, lying deep to this thick muscle, produces little visible swelling but is accompanied by profound muscle spasm and severe limitation of jaw opening (trismus).

## Temporalis

Temporalis (see Figs $32.18,32.20$ ) arises from the whole of the temporal fossa up to the inferior temporal line - except the part formed by the zygomatic bone - and from the deep surface of the temporal fascia. Its fibres converge and descend into a tendon that passes through the gap between the zygomatic arch and the side of the skull. A plane exists beneath the temporal fascia, which is attached to the superior surface of the zygomatic arch, and the muscle, which passes beneath the arch. An elevator introduced into this plane through an incision above the hairline may therefore be placed beneath a fractured zygomatic arch or bone in order to reduce the fracture (Gillies approach). Temporalis is attached to the medial surface, apex, anterior and posterior borders of the coronoid process and to the anterior border of the mandibular ramus almost up to the third molar tooth. Its anterior fibres are orientated vertically, the most posterior fibres almost horizontally, and the intervening fibres with intermediate degrees of obliquity, in the manner of a fan. Fibres of temporalis may occasionally gain attachment to the articular disc. Though less common than enlargement of masseter, hypertrophy of temporalis may develop unilaterally or bilaterally, producing prominence of the temporal fossa, which may be considered unsightly; botulinum toxin to paralyse the motor nerves is the preferred treatment for this condition.

Relations Skin, auriculares anterior and superior, temporal fascia, superficial temporal vessels, the auriculotemporal nerve, temporal branches of the facial nerve, the zygomaticotemporal nerve, the epicranial aponeurosis, the zygomatic arch and the masseter muscle are all superficial relations. Posterior relations of temporalis are the temporal
fossa above and the major components of the infratemporal fossa below. Behind the tendon of the muscle, the masseteric nerve and vessels traverse the mandibular notch. The anterior border is separated from the zygomatic bone by a mass of fat.

Vascular supply Temporalis is supplied by deep temporal branches from the second part of the maxillary artery, which enter on its deep aspect, and middle temporal branches from the superficial temporal artery, which enter on its lateral aspect. The anterior deep temporal artery supplies $20 \%$ of the muscle anteriorly; the posterior deep temporal artery, entering the mid-portion of the muscle, supplies $40 \%$ of the muscle in the mid-region; and the middle temporal artery, entering the muscle posteriorly, supplies $40 \%$ of the muscle in its posterior region. Considerable vascular anastomoses are present within the muscle (Cheung 1996).

Innervation Temporalis is supplied by the anterior, middle and posterior deep temporal branches of the anterior trunk of the mandibular nerve.

Actions Temporalis elevates the mandible and so closes the mouth and approximates the teeth. This movement requires both the upward pull of the anterior fibres and the backward pull of the posterior fibres because the head of the mandibular condyle rests on the articular eminence when the mouth is open. The muscle also contributes to side-to-side grinding movements. The posterior fibres retract the mandible after it has been protruded. The posterior fibres of temporalis, which are almost horizontal, are the only source of mandibular retrusion.

## Lateral pterygoid

Lateral pterygoid (Fig. 32.20) is a short, thick muscle consisting of two parts. The upper head arises from the infratemporal surface and infratemporal crest of the greater wing of the sphenoid bone. The lower head arises from the lateral surface of the lateral pterygoid plate. From the two origins, the fibres converge, and pass backwards and laterally, to be inserted into a depression on the front of the neck of the mandible (the pterygoid fovea). A part of the upper head may be attached to the capsule of the temporomandibular joint and to the anterior and medial borders of its articular disc. Unlike the other muscles of mastication, lateral pterygoid is not pennate, nor does it have a significant number of Golgi tendon organs associated with its attachments.

Fig. 32.20 Arteries and nerves of the head; deeper lateral regions. Most of the zygomatic arch and the ramus and body of the mandible have been removed; masseter has been cut and reflected laterally. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The arterial supply is axial，i．e．the vessels run the entire length of the muscle．It is this vascular arrangement that permits the use of tem－ poralis as an inferiorly based pedicled flap，either dynamic or static （increased length being obtained with division of the coronoid process）， for the reconstruction of a variety of local facial and oral defects and in the treatment of facial paralysis．The temporalis fascia can be incorpo－ rated with the flap．The muscle may be split longitudinally（along its
long axis），retaining its axial supply from individual arteries；the vessels are identified at operation if necessary，with a Doppler．A further vas－ cular advantage is that the arterial supply is disposed medially（deep temporal）and laterally（middle temporal），and there are few vessels in the mid－sagittal plane，which means that splitting of the muscle flap in the sagittal plane is possible（Fig．32．19）（Cheung 1996）．

Fig．32．19 The arterial network of the human temporalis．A，Lateral plane．B，Coronal plane．In the lateral plane，the muscle is supplied by the three primary arteries：the anterior deep temporal artery in the anterior portion，the posterior deep temporal artery in the mid－portion and the middle deep temporal artery in the posterior portion．In the coronal plane，the arterial distribution is concentrated mainly lateral（L）and medial（M）with less vascular density in the mid－sagittal region of the muscle．（With permission from Cheung LK． The vascular anatomy of the human temporalis muscle：implications for surgical splitting techniques．Int J Oral Maxillofac Surg 1996；25：414－421．）

Relations The mandibular ramus and masseter, the maxillary artery, which crosses either deep or superficial to the muscle, and the superficial head of medial pterygoid and the tendon of temporalis are all superficial relations. Deep to the muscle are the deep head of medial pterygoid, the sphenomandibular ligament, the middle meningeal artery and the mandibular nerve. The upper border is related to the temporal and masseteric branches of the mandibular nerve and the lower border is related to the lingual and inferior alveolar nerves. A deeply placed posterior superior alveolar nerve block has been known also to anaesthetize the lingual nerve. The buccal nerve and the maxillary artery pass between the two heads of the muscles. In temporomandibular joint dysfunction syndrome, spasm of lateral pterygoid can give rise to tenderness when palpating behind the maxillary tuberosity high in the buccal sulcus (the pterygoid sign).

Vascular supply Lateral pterygoid is supplied by pterygoid branches from the maxillary artery that are given off as the artery crosses the muscle and from the ascending palatine branch of the facial artery.

Innervation The nerves to lateral pterygoid (one for each head) arise from the anterior trunk of the mandibular nerve, deep to the muscle. The upper head and the lateral part of the lower head receive their innervation from a branch given off from the buccal nerve. However, the medial part of the lower head has a branch arising directly from the anterior trunk of the mandibular nerve.

Actions Lateral pterygoid has assumed a specialized role in mandibular opening that is mediated by its horizontally orientated fibres. When left and right muscles contract together, the condyle is pulled forwards and slightly downwards. This protrusive movement alone has little or no function except to assist in opening the jaw. Digastric and geniohyoid are the main jaw opening muscles; unlike lateral pterygoid, when acting alone, they rotate the jaw open, provided other muscles attached to the hyoid prevent it from being pulled forwards. If only one lateral pterygoid contracts, the jaw rotates about a vertical axis passing roughly through the opposite condyle and is pulled medially towards the opposite side. This contraction, together with that of the adjacent medial pterygoid (both attached to the lateral pterygoid plate), provides most of the strong medially directed component of the force used when grinding food between teeth of the same side. It is arguably the most important function of the inferior head of lateral pterygoid.

It is often stated that the upper head is used to pull the articular disc forwards when the jaw is opened. However, electromyographic studies (e.g. McNamara 1973, Juniper 1981) have demonstrated that the upper and lower heads are reciprocally innervated, so that the lower head contracts during mouth opening whilst the upper head relaxes, the situation reversing during closure. An explanation for this surprising activity is as follows (Osborn 1995). Most of the power of a clenching force is due to contractions of masseter and temporalis. The associated backward pull of temporalis is greater than the associated forward pull of (superficial) masseter, and so their combined jaw-closing action potentially pulls the condyle backwards. This is prevented by the simultaneous contraction of the upper head of lateral pterygoid, which stabilizes the condylar head against the articular eminence during closure, particularly during biting and mastication.

## Medial pterygoid

Medial pterygoid (see Fig. 32.20) is a thick, quadrilateral muscle with two heads of origin. Mirroring masseter (which lies laterally), its fibres descend posteroinferiorly at an angle of about $10^{\circ}$ to the vertical. In the coronal plane, it forms a $30^{\circ}$ angle with the ramus. The major component is the deep head that arises from the medial surface of the lateral pterygoid plate of the sphenoid bone and is therefore deep to the lower head of lateral pterygoid. The small, superficial head arises from the maxillary tuberosity and the pyramidal process of the palatine bone, and therefore lies on the lower head of lateral pterygoid. The fibres of medial pterygoid descend posterolaterally and are attached by a strong tendinous lamina to the posteroinferior part of the medial surface of the ramus and angle of the mandible, as high as the mandibular foramen and almost as far forwards as the mylohyoid groove. This area of attachment is often ridged. Inferior alveolar nerve block injection can occasionally cause haemorrhage into the muscle, which may give rise to painful trismus. Medial pterygoid and masseter act together to support the angle of the mandible as the pterygomasseteric sling. Their strong muscle attachments resist lengthening of the mandibular ramus surgically.

Relations The lateral surface of medial pterygoid is related to the mandibular ramus, from which it is separated above its insertion by
lateral pterygoid, the sphenomandibular ligament, the maxillary artery, the inferior alveolar vessels and nerve, the lingual nerve and a process of the parotid gland. The medial surface is related to tensor veli palatini and is separated from the superior pharyngeal constrictor by styloglossus and stylopharyngeus and by some areolar tissue.
Vascular supply Medial pterygoid derives its main arterial supply from the pterygoid branches of the maxillary artery.
Innervation Medial pterygoid is innervated by the medial pterygoid branch of the mandibular nerve.
Actions The medial pterygoid muscles assist in elevating the mandible. Acting with the lateral pterygoids, they protrude it. When the medial and lateral pterygoids of one side act together, the corresponding side of the mandible is rotated both forwards and to the opposite side, with the opposite mandibular head as a vertical axis. Alternating activity in the left and right sets of muscles produces side-to-side movements, which are used to triturate food.

## Pterygospinous ligament

The pterygospinous ligament, which is occasionally replaced by muscle fibres, stretches between the spine of the sphenoid bone and the posterior border of the lateral pterygoid plate near its upper end. It is sometimes ossified, and then completes a foramen that transmits the branches of the mandibular nerve to temporalis, masseter and lateral pterygoid.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Maxillary artery

The maxillary artery, the larger terminal branch of the external carotid artery, arises behind the neck of the mandible and is at first embedded in the parotid gland. It then crosses the infratemporal fossa to enter the pterygopalatine fossa through the pterygomaxillary fissure. The artery is widely distributed to the mandible, maxilla, teeth, muscles of mastication, palate, nose and cranial dura mater (see Fig. 32.20; Fig. 32.21). It will be described in three parts: mandibular, pterygoid and pterygopalatine.

The mandibular part runs horizontally by the medial surface of the ramus. It passes between the neck of the mandible and the sphenomandibular ligament, parallel with and slightly below the auriculotemporal nerve. It next crosses the inferior alveolar nerve and skirts the lower border of lateral pterygoid. The pterygoid part ascends obliquely forwards medial to temporalis and is usually superficial to the lower head of lateral pterygoid. When it runs deep to lateral pterygoid, it lies between the muscle and branches of the mandibular nerve, and may project as a lateral loop between the two parts of lateral pterygoid. Asymmetry in this pattern of distribution may occur between the right and left infratemporal fossae, and ethnic differences have been reported. Where the maxillary artery runs superficial to the lower head of lateral pterygoid, the most common pattern is that the artery passes lateral to the inferior alveolar, lingual and buccal nerves. Less frequently, only the buccal nerve crosses the artery laterally, and rarely the artery passes deep to all the branches of the mandibular nerve. The pterygopalatine part passes between the two heads of lateral pterygoid to reach the pterygomaxillary fissure before it passes into the pterygopalatine fossa, where it terminates as the third part of the maxillary artery.

The mandibular part of the maxillary artery has five branches that all enter bone, namely: deep auricular, anterior tympanic, middle meningeal, accessory meningeal and inferior alveolar arteries. The pterygoid part of the maxillary artery has five branches that do not enter bone but supply muscle, and include deep temporal, pterygoid, masseteric and buccal arteries. The branches of the pterygopalatine part of the artery accompany similarly named branches of the maxillary nerve (including those associated with the pterygopalatine ganglion) and are described on page 552.

## Deep auricular artery

The deep auricular artery pierces the osseous or cartilaginous wall of the external acoustic meatus and supplies the skin of the external acoustic meatus and part of the tympanic membrane. A small branch contributes to the arterial supply of the temporomandibular joint.

## Anterior tympanic artery

The anterior tympanic artery passes through the petrotympanic fissure to supply part of the lining of the middle ear and accompanies the chorda tympani nerve.

A

Fig. 32.21 A, Vessels and nerves of the head, exposed at a level deeper than that shown in Figure 32.20. Note the pterygoid venous plexus. B-E, Variations in the course of the maxillary artery. B, The maxillary artery passes medial to lateral pterygoid, and to the lingual and inferior alveolar nerves. C, The artery passes between the lingual and inferior alveolar nerves. D, The artery passes through a loop formed by the inferior alveolar nerve. $\mathbf{E}$, The middle meningeal artery branches off distal to the inferior alveolar artery. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Middle meningeal artery

The middle meningeal artery is the main source of blood to the bones of the vault of the skull (Fig. 32.22). It may arise either directly from the first part of the maxillary artery or from a common trunk with the inferior alveolar artery. When the maxillary artery lies superficial to lateral pterygoid, the middle meningeal artery is usually the first branch of the maxillary artery. However, when the maxillary artery takes a deep course in relation to the muscle, this is not usually the case. The middle meningeal artery ascends between the sphenomandibular ligament and lateral pterygoid, passes between the two roots of the auriculotemporal nerve, and leaves the infratemporal fossa through the foramen spinosum to enter the cranial cavity medial to the midpoint of the zygomatic bone. Its further course is described on page 439.

## Accessory meningeal artery

The accessory meningeal artery runs through the foramen ovale into the middle cranial fossa and may arise directly from the maxillary artery or as a branch of the middle meningeal artery itself. In its course in the infratemporal fossa, the accessory meningeal artery is closely related to tensor and levator veli palatini and usually runs deep to the mandibular nerve. Although it runs intracranially, its main distribution is extracranial, principally to medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, the greater wing and pterygoid processes of the sphenoid, branches of the mandibular nerve and the otic ganglion. The accessory meningeal artery is sometimes replaced by separate small arteries.

## Inferior alveolar artery

The inferior alveolar artery descends in the infratemporal fossa posterior to the inferior alveolar nerve, between the ramus laterally and the sphenopalatine ligament medially. Two anterior branches are given off the artery prior to its entry into the mandibular foramen. The further course of the artery is described on page 526.

## Deep temporal arteries

The arterial supply to the temporalis in the coronal plane is concentrated mainly on its medial and lateral aspects. The anterior and posterior branches of the deep temporal arteries pass between temporalis and the pericranium, producing shallow grooves in the bone. They anastomose with the middle temporal branch of the superficial temporal artery situated laterally (Cheung 1996). The anterior deep temporal artery connects with the lacrimal artery by small branches which perforate the zygomatic bone and greater wing of the sphenoid.

## Masseteric artery

The masseteric artery, which is small, accompanies the masseteric nerve as it passes behind the tendon of temporalis through the mandibular incisure (notch) to enter the deep surface of masseter (see Fig. 32.20). Its branches can also supply the temporomandibular joint. The masseteric artery anastomoses with the masseteric branches of the facial artery and with the transverse facial branch of the superficial temporal artery.

C

Fig. 32.22 Variations in the origin of the middle meningeal artery. A, The middle meningeal artery branches off proximal to the inferior alveolar artery. B, The artery branches off opposite the inferior alveolar artery. C, The artery branches off distal to the inferior alveolar artery. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Pterygoid arteries

The pterygoid arteries are irregular in number and origin, and are distributed to lateral and medial pterygoid.

## Buccal artery

The buccal artery runs obliquely forwards between medial pterygoid and the attachment of temporalis, and supplies the skin and mucosa over buccinator, accompanying the lower part of the buccal branch of the mandibular nerve (see Fig. 32.21A). It anastomoses with branches of the facial and infraorbital arteries. A small lingual branch may be given off to accompany the lingual nerve and supply structures in the floor of the mouth.

## Maxillary veins and the pterygoid venous plexus

## Maxillary vein

The maxillary vein is a short trunk that accompanies the first part of the maxillary artery (see Fig. 32.21 A ). It is formed from the confluence of veins from the pterygoid plexus and passes back between the sphenomandibular ligament and the neck of the mandible, to enter the parotid gland. It unites within the substance of the gland with the superficial temporal vein to form the retromandibular vein.

## Pterygoid venous plexus

The pterygoid plexus of veins consists of copious large-calibre veins surrounding the pterygoid segment of the maxillary artery. It is found partly between temporalis and lateral pterygoid, and partly between the two pterygoid muscles. Sphenopalatine, deep temporal, pterygoid, masseteric, buccal, alveolar (dental), greater palatine and middle meningeal veins and a branch or branches from the inferior ophthalmic vein are all tributaries. The plexus connects with the facial vein via the deep facial vein, with the cavernous sinus through veins that pass through the sphenoidal emissary foramen (of Vesalius), foramen ovale and foramen lacerum and with the orbit via the inferior ophthalmic vein(s). Its deep temporal tributaries often connect with tributaries of the anterior diploic veins and thus with the middle meningeal veins.

## Lymphatic drainage

Lymphatic drainage of the infratemporal fossa (and the temporal fossa) is to the superior deep cervical nodes.

## INNERVATION

The infratemporal fossa contains the major subdivisions of the mandibular branch of the trigeminal nerve, together with the chorda tympani, which enters the fossa and joins the lingual nerve, and the otic ganglion, which is functionally related to the parotid gland. The main sensory branches of the mandibular nerve extend beyond the infratemporal fossa and their distribution to the face is described on page 502.

## Mandibular nerve

The mandibular nerve is the largest trigeminal division and is a mixed nerve. Its sensory branches supply the teeth and gums of the mandible,
the skin in the temporal region, part of the auricle - including the external meatus and tympanic membrane - and the lower lip, the lower part of the face and the mucosa of the anterior two-thirds (presulcal part) of the tongue and the floor of the oral cavity (see Figs 32.20, 32.21A; Fig. 32.23). The motor branches innervate the muscles of mastication. The large sensory root emerges from the lateral part of the trigeminal ganglion and exits the cranial cavity through the foramen ovale. The small motor root passes under the ganglion and through the foramen ovale to unite with the sensory root just outside the skull. As it descends from the foramen ovale, the nerve is usually around 4 cm from the surface and a little anterior to the neck of the mandible. The mandibular nerve immediately passes between tensor veli palatini, which is medial, and lateral pterygoid, which is lateral, and gives off a meningeal branch and the nerve to medial pterygoid from its medial side. The nerve then divides into a small anterior and large posterior trunk. The anterior division gives off branches to the four main muscles of mastication and a buccal branch that is sensory to the cheek. The posterior division gives off three main sensory branches - the auriculotemporal, lingual and inferior alveolar nerves - and motor fibres that supply mylohyoid and the anterior belly of digastric.

As is the case with the extraocular muscles, the masticatory muscles function as a group; only when pathology intervenes do their individual actions, or lack of action, become apparent. Wasting of the masticatory muscles, most evident in the temporal fossa, happens when tumours affect the motor root of the mandibular nerve. The mandible deviates to the side of the pathology as a result of the unopposed action of the contralateral lateral and medial pterygoids.

## Meningeal branch (nervus spinosus)

The meningeal branch re-enters the cranium through the foramen spinosum with the middle meningeal artery. It divides into anterior and posterior branches, which accompany the main divisions of the middle meningeal artery and supply the dura mater in the middle cranial fossa and, to a lesser extent, in the anterior fossa and calvarium.

## Nerve to medial pterygoid

The nerve to medial pterygoid is a slender ramus that enters the deep aspect of the muscle. It supplies one or two filaments that pass through the otic ganglion without interruption to supply tensor tympani and tensor veli palatini.

## Anterior trunk of mandibular nerve

The anterior trunk of the mandibular nerve gives rise to the buccal nerve, which is sensory, and the masseteric, deep temporal and lateral pterygoid nerves, which are all motor.

## Buccal nerve

The buccal nerve passes between the two heads of lateral pterygoid (see Fig. 32.23). It descends deep to the tendon of temporalis, passes laterally in front of masseter, and anastomoses with the buccal branches of the facial nerve. It carries the motor fibres to lateral pterygoid, and these are given off as the buccal nerve passes through the muscle. It may also give off the anterior deep temporal nerve. The buccal nerve supplies sensation to the skin over the anterior part of buccinator and the buccal mucous membrane, together with the posterior part of the buccal gingivae adjacent to the second and third molar teeth.

## Nerve to masseter

The nerve to masseter passes laterally above lateral pterygoid, on to the skull base, anterior to the temporomandibular joint and posterior to

Fig. 32.23 Arteries and nerves of the head, deepest lateral regions. Compare with Figures 32.20 and 32.21A. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the tendon of temporalis. It crosses the posterior part of the mandibular notch with the masseteric artery and ramifies on and enters the deep surface of masseter. It also provides articular branches that supply the temporomandibular joint.

## Deep temporal nerves

The deep temporal nerves usually consist of two branches, anterior and posterior, although there may be a middle branch. They pass above lateral pterygoid to enter the deep surface of temporalis. The anterior nerve frequently arises as a branch of the buccal nerve. The small posterior nerve sometimes arises in common with the nerve to masseter.

## Nerve to lateral pterygoid

The nerve to lateral pterygoid enters the deep surface of the muscle. It may arise separately from the anterior division of the mandibular nerve or from the buccal nerve.

## Posterior trunk of mandibular nerve

The posterior trunk of the mandibular nerve is larger than the anterior and is mainly sensory, although it receives fibres from the motor root for the nerve to mylohyoid. It divides into auriculotemporal, lingual and inferior alveolar (dental) nerves (see Fig. 32.20A).

## Auriculotemporal nerve

The auriculotemporal nerve usually has two roots that encircle the middle meningeal artery. It runs back under lateral pterygoid on the surface of tensor veli palatini, passes between the sphenomandibular ligament and the neck of the mandible, and then runs laterally behind the temporomandibular joint related to the upper part of the parotid gland. Emerging from behind the joint, it ascends over the posterior root of the zygoma, posterior to the superficial temporal vessels, and divides into superficial temporal branches. It communicates with the facial nerve and otic ganglion. The rami to the facial nerve, usually two, pass anterolaterally behind the neck of the mandible to join the facial nerve at the posterior border of masseter. Filaments from the otic ganglion join the roots of the auriculotemporal nerve close to their origin. The sensory distribution of the auriculotemporal nerve on the face is described on page 502.

## Lingual nerve

The lingual nerve is sensory to the mucosa of the anterior two-thirds of the tongue, the floor of the mouth and the mandibular lingual gingivae. It arises from the posterior trunk of the mandibular nerve and at first runs beneath lateral pterygoid and superficial to tensor veli palatini, where it is joined by the chorda tympani branch of the facial nerve, and often by a branch of the inferior alveolar nerve. Emerging from under cover of lateral pterygoid, the lingual nerve then runs downwards and forwards on the surface of medial pterygoid (see Fig. 32.23), and is thus carried progressively closer to the medial surface of the mandibular ramus. It becomes intimately related to the bone a few millimetres below and behind the junction of the vertical ramus and horizontal body of the mandible. Here it lies anterior to, and slightly deeper than, the inferior alveolar (dental) nerve. It next passes below the mandibular attachment of the superior pharyngeal constrictor and pterygomandibular raphe, closely applied to the periosteum of the medial surface of the mandible, until it lies opposite the posterior root of the third molar tooth, where it is covered only by the gingival mucoperiosteum. At this point, it usually lies approximately 3 mm below the alveolar crest with a mean distance from the bone of 2 mm . Significantly, in more than $25 \%$ of cases, the nerve may be in direct contact with the bone at this site, but sometimes it lies above the alveolar crest. It next passes medial to the mandibular origin of mylohyoid, and this carries it progressively away from the mandible, and separates it from the alveolar bone covering the mesial root of the third molar tooth (Pogrel et al 1995). The rest of the nerve is described with the mouth and oral cavity on page 514.

## Inferior alveolar (dental) nerve

The inferior alveolar nerve descends behind lateral pterygoid. At the lower border of the muscle, the nerve passes between the sphenomandibular ligament and the mandibular ramus, and enters the mandibular canal via the mandibular foramen (Barker and Davies 1972). Below lateral pterygoid, it is accompanied by the inferior alveolar artery (see Fig. 32.23), a branch of the first part of the maxillary artery, which also enters the canal with associated veins. The subsequent course of the inferior alveolar nerve is described on page 527 .

The anterior deep temporal nerve may arise from the buccal nerve, and the posterior deep temporal nerve may arise from the nerve to masseter. In addition, branches from the buccal and masseteric nerves may supply the inferior aspect of the muscle independently from the deep temporal nerves. Discrete neuromuscular subunits have been identified within the muscle based on the anterior, middle and posterior deep temporal nerves, suggesting the possibility of individual dynamic muscle flaps, each with a different vector, in the treatment of facial palsy (Chang et al 2013) (Fig. 32.24).

Fig. 32.24 The foramen ovale, inferolateral view. Nerves supplying temporalis originate from the anterior trunk of the mandibular division of the trigeminal nerve V3 (arrow). Key: 1, (long) buccal nerve; 2, anterior deep temporal nerve; 3, middle deep temporal nerve; 4, posterior deep temporal nerve; 5 , nerve to masseter. Evidence for the functional compartmentalization of the temporalis muscle: a 3-dimensional study of innervation. J Oral Maxillofac Surg 2013;71:1170-1177.)

## Neural anastomoses with the mandibular nerve

Available with the Gray's Anatomy e-book

## Otic ganglion

The otic ganglion is a small (major diameter $3-4 \mathrm{~mm}$ ), oval, flat reddish-grey ganglion situated just below the foramen ovale. It is a peripheral parasympathetic ganglion related topographically to the mandibular nerve but connected functionally with the glossopharyngeal nerve (see Fig. 37.13). Near its junction with the trigeminal motor root, the mandibular nerve lies lateral to the ganglion; tensor veli palatini lies medially, separating the ganglion from the cartilaginous part of the pharyngotympanic tube, and the middle meningeal artery is posterior to the ganglion. The otic ganglion usually surrounds the origin of the nerve to medial pterygoid.

Like all parasympathetic ganglia, there are three roots: motor, sympathetic and sensory. Only the parasympathetic fibres relay in the ganglion (see Fig. 26.7). The motor, parasympathetic, root of the otic ganglion is the lesser petrosal nerve, conveying preganglionic fibres from the glossopharyngeal nerve, which originate from neurones in the inferior salivatory nucleus. The lesser petrosal nerve runs intracranially in the middle cranial fossa on the anterior surface of the petrous bone before passing through either the foramen ovale or the sphenopetrosal fissure or the innominate canal of Arnold (a canal in the greater wing of the sphenoid close to the foramen spinosum), to join the otic ganglion. The nerve synapses in the otic ganglion, and postganglionic fibres pass by a communicating branch to the auriculotemporal nerve and so to the parotid gland. The sympathetic root arises from a plexus on the middle meningeal artery. It contains postganglionic fibres from the superior cervical sympathetic ganglion, which traverse the otic ganglion without relay and emerge with parasympathetic fibres in the connection with the auriculotemporal nerve to supply blood vessels in the parotid gland. The sensory fibres from the gland are derived from the auriculotemporal nerve. Clinical observations suggest that in humans the gland also receives secretomotor fibres through the chorda tympani.

## Branches

A branch connects the otic ganglion to the chorda tympani nerve, while another ramus ascends to join the nerve of the pterygoid canal. These branches may form an additional pathway by which gustatory fibres from the anterior two-thirds of the tongue may reach the facial ganglion without traversing the middle ear, and they do not synapse in the otic ganglion. Motor branches to tensor veli palatini and tensor tympani, derived from the nerve to medial pterygoid, also pass through the ganglion without synapsing. (For further reading, see Senger et al (2014).)

## Chorda tympani

The chorda tympani nerve enters the infratemporal fossa region by passing through the medial end of the petrotympanic fissure behind the capsule of the temporomandibular joint. The nerve descends medial to the spine of the sphenoid bone - which it sometimes grooves - lying posterolateral to tensor veli palatini. It is crossed medially by the middle meningeal artery, the roots of the auriculotemporal nerve and by the inferior alveolar nerve (see Fig. 32.23). The chorda tympani joins the posterior aspect of the lingual nerve at an acute angle. It carries taste fibres for the anterior two-thirds of the tongue and efferent preganglionic parasympathetic (secretomotor) fibres destined for the submandibular ganglion in the floor of the mouth.

## SPREAD OF INFECTION FROM THE INFRATEMPORAL FOSSA

Infections from most teeth in the upper jaw or the front of the lower jaw usually drain harmlessly into the oral cavity, either via the vestibule buccally, or via the palate or mouth lingually. In contrast, a pericoronitis that affects a mandibular third molar tooth that communicates with the oral cavity, or, less commonly, either a dental abscess associated with this tooth, or a postoperative infection, may spread along tissue planes. Spread may be buccal; submandibular; submental; parapharyngeal; sublingual; less commonly, submasseteric; and, more rarely, infratemporal. The main symptom caused by infection of the pterygomandibular region is trismus (painful reflex muscle spasm), which usually affects medial pterygoid. There are few anatomical barriers to
the spread of infection between neighbouring tissue spaces from the pterygomandibular space. When the submandibular, sublingual and submental areas are affected either unilaterally or bilaterally (bilateral involvement is known as Ludwig's angina), there is a risk that the airway may become obstructed. Infection may (potentially) spread further, usually to the parapharyngeal, and occasionally to the retropharyngeal, spaces or the tissue planes of the face above, when it may even reach the orbit via the inferior orbital fissure. Life-threatening cavernous sinus thrombosis is a remote possibility once infection has spread to the orbit, with further spread directly through the superior orbital fissure into the cranial cavity. Infection may also spread to the cavernous sinus from the pterygoid plexus and ophthalmic veins (Smyth 2007, Guidera et al 2014) (Fig. 32.26).

## PTERYGOPALATINE FOSSA

The pterygopalatine fossa is a small pyramidal space below the apex of the orbit on the lateral side of the skull. Placed between the infratemporal fossa laterally and the nasopharynx medially, it functions as a neurovascular conduit. The body of the sphenoid forms the roof, the posterior boundary is the root of the pterygoid process and adjoining anterior surface of the greater wing of the sphenoid, and the anterior boundary is the superomedial part of the infratemporal surface (posterior wall) of the maxilla. The perpendicular plate of the palatine bone, with its orbital and sphenoidal processes, forms the medial boundary, and the pterygomaxillary fissure is the lateral boundary. There are two openings in the posterior wall of the pterygopalatine fossa: the foramen rotundum, which transmits the maxillary nerve, and the pterygoid canal (Vidian canal), which transmits the nerve of the pterygoid canal (Vidian nerve). When the anterior aspect of the pterygoid plate is examined in a disarticulated sphenoid, the foramen rotundum is seen to lie above and lateral to the pterygoid canal (see Figs 32.3A, B).

The fossa communicates with the nasal cavity via the sphenopalatine foramen; with the orbit via the medial end of the inferior orbital fissure; and with the infratemporal fossa via the pterygomaxillary fissure, which lies between the back of the maxilla and the pterygoid process of the sphenoid and transmits the maxillary artery. It also communicates with the middle fossa via foramen rotundum and the pterygoid canal, and with the oral cavity via the greater palatine canal, which opens in the posterolateral aspect of the hard palate. Its proximity to these adjacent areas permits the ready spread of both tumours and infection.

The main contents of the pterygopalatine fossa are the third part of the maxillary artery, the maxillary nerve and many of its branches, and the pterygopalatine ganglion.

## Maxillary artery

The maxillary artery passes through the pterygomaxillary fissure from the infratemporal fossa into the pterygopalatine fossa, where it terminates as the third part of the maxillary artery. The artery has a variable and tortuous course in its short passage through the pterygopalatine fossa, where it gives off numerous branches, including the posterior superior alveolar and infraorbital arteries and the artery of the pterygoid canal (Vidian artery), and terminates in the sphenopalatine and greater palatine arteries.

## Posterior superior alveolar artery

The posterior superior alveolar artery arises from the maxillary artery within the pterygopalatine fossa and runs through the pterygomaxillary fissure on to the maxillary tuberosity. It gives off branches that penetrate the bone here to supply the maxillary molar and premolar teeth and the maxillary air sinus, and other branches that supply the buccal mucosa. Occasionally, the posterior superior alveolar artery arises from the infraorbital artery.

## Infraorbital artery

The infraorbital artery enters the orbit through the inferior orbital fissure. It runs on the floor of the orbit in the infraorbital groove and infraorbital canal, and emerges on to the face at the infraorbital foramen to supply the lower eyelid, part of the cheek, the side of the external nose, and the upper lip. While within the infraorbital canal, it gives off the anterior superior alveolar artery, which runs downwards to supply the anterior teeth and the anterior part of the maxillary sinus. A middle superior alveolar artery is also often described. When present, it branches from the infraorbital artery within the infraorbital canal and runs inferiorly along the lateral wall of the maxillary sinus towards the region of the canine and lateral incisor teeth, anastomosing with the anterior and posterior superior alveolar arteries.

Extensive anastomoses, which may be sensory-to-sensory, sensory-tomotor or motor-to-motor, exist between the lower cranial nerves and upper cervical nerves. Variable anastomoses exist between all three of the divisions of the trigeminal nerve with branches of the facial nerve. The connection between the lingual nerve and the chorda tympani branch of the facial is the most familiar interconnection with the mandibular nerve. Connections have almost always been demonstrated between the auriculotemporal nerve and branches of the facial nerve (Fig. 32.25). The buccal branch may communicate with the buccal and zygomatic branches of the facial via the 'communicating buccal nerve'. Interconnections between the mental nerve and the buccal and marginal mandibular branch of the facial have been demonstrated. It is suggested that one possible explanation for these trigeminal-facial interconnections relates to the proprioceptive innervation of the facial musculature. A branch from the auriculotemporal may join the inferior alveolar nerve within the infratemporal fossa with evident implications for referred pain. The functional significance of some of the neural connections has yet to be determined (Shoja et al 2014).

Fig. 32.25 Anastomoses of the auriculotemporal nerve with the temporofacial division of the facial nerve, and of the great auricular nerve with the cervicofacial division of the facial nerve in the parotid and periparotid regions. (With permission from Shoja MM, Oyesiku NM, Grissenauer CJ et al. Anastomoses between lower cranial and upper cervical nerves: a comprehensive review with potential significance during skull base and neck operations, Part 1: Trigeminal, facial and vestibulocochlear nerves. Clin Anat. 2014;27(1):118-30.)

Fig. 32.26 A, Ludwig's angina: spread of infection from an infected lower left third molar to the pterygomandibular space and thence into the submandibular, sublingual and submental spaces bilaterally. The infection is life-threatening due to restricted mouth opening and a compromised airway. B, In this case, the airway was secured with awake fibreoptic intubation followed by tracheostomy. Aggressive through-and-through drainage was initiated (note the grey discolouration of the tissues). Prior to the availability of antibiotics, Ludwig's angina had a mortality rate of $75 \%$. Aggressive early treatment with surgical drainage and intravenous antibiotics has reduced the mortality to approximately $5 \%$. The narrow white arrow indicates the cut edge of mylohyoid. The broad white arrow indicates through-and-through corrugated drains. (Smyth AG 2007 Management of orofacial infections. In: Ward-Booth P, Schendel SA, Hausamen JE (eds) Maxillofacial Surgery, 2nd ed. Ch. 80, pp. 1550-71.)

Some authors describe anterior and posterior 'compartments' of the pterygopalatine fossa, where the anterior compartment contains the third part of the maxillary artery and its branches, and the posterior compartment contains the maxillary division of the trigeminal nerve and the nerve of the pterygoid canal, together with the pterygopalatine ganglion and its branches (Figs 32.27-32.28) (Alfieri et al 2003, Cavallo et al 2005, Falcon et al 2010).

## Artery of the pterygoid canal

The artery of the pterygoid canal (Vidian artery) usually arises as a branch of the distal part of the maxillary artery or sometimes as a branch of the petrous segment of the internal carotid artery. It passes through the pterygoid canal and anastomoses with the pharyngeal, ethmoidal and sphenopalatine arteries in the pterygopalatine fossa and with the ascending pharyngeal, accessory meningeal, ascending palatine and descending palatine arteries in the oropharynx and around the pharyngotympanic tube. Through these complex anastomoses, the artery of the pterygoid canal contributes to the supply of part of the pharyngotympanic tube, the tympanic cavity and the upper part of the pharynx. It may also anastomose with the artery of the foramen rotundum and so communicate with branches of the cavernous portion of the internal carotid artery.

## Pharyngeal artery

The pharyngeal branch of the maxillary artery passes through the palatovaginal canal, accompanying the nerve of the same name, and is distributed to the mucosa of the nasal roof, nasopharynx, sphenoidal air sinus and pharyngotympanic tube.

## Greater (descending) palatine artery

The greater palatine artery leaves the pterygopalatine fossa through the greater (anterior) palatine canal, within which it gives off two or three lesser palatine arteries. The greater palatine artery supplies the inferior meatus of the nose, then passes on to the roof of the hard palate at the greater (anterior) palatine foramen and runs forwards to supply the hard palate and the palatal gingivae of the maxillary teeth. It gives off a branch that runs up into the incisive canal to anastomose with the nasopalatine artery, and so contribute to the arterial supply of the nasal septum. The lesser palatine arteries emerge on to the palate through the lesser (posterior) palatine foramen, or foramina, and supply the soft palate.

## Sphenopalatine artery

The sphenopalatine artery and the greater palatine artery are the terminal branches of the maxillary artery. The sphenopalatine artery is the principal artery supplying the mucosa of the nose. It enters the nasal cavity through the sphenopalatine foramen posterior to the superior meatus. From here, its posterior lateral nasal branches ramify over the conchae and meatuses, anastomosing with the ethmoidal arteries and nasal branches of the greater palatine artery to supply the frontal, maxillary, ethmoidal and sphenoidal air sinuses. The sphenopalatine artery next crosses anteriorly on the inferior surface of the sphenoid and ends on the nasal septum in a series of posterior septal branches that anastomose with the ethmoidal arteries (see Fig. 33.9).

## Spatial arrangement of the neurovascular contents in the pterygopalatine fossa

The maxillary artery and its branches are located in a plane anterior to the maxillary nerve, pterygopalatine ganglion and the nerve of the pterygoid canal. This spatial arrangement is particularly relevant in endoscopic approaches to the pterygopalatine fossa (Video 32.2). The veins accompanying the third (pterygopalatine) part of the maxillary artery, in common with those accompanying the second (pterygoid) part, are in the form of a venous plexus. Profuse haemorrhage may be encountered from this pterygopalatine venous plexus.

## Maxillary nerve

The maxillary division of the trigeminal nerve is wholly sensory (Fig. 32.30). It leaves the skull via the foramen rotundum and enters the upper part of the pterygopalatine fossa, from which all its extracranial branches are derived. The meningeal branch is given off in the middle fossa. Crossing the pterygopalatine fossa, the nerve gives off two large ganglionic branches that contain fibres destined for the nose, palate and pharynx, and these pass through the pterygopalatine ganglion without synapsing. It then inclines sharply laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla in the inferior orbital fissure (which is continuous posteriorly with the pterygopalatine fossa); it lies outside the orbital periosteum, and gives off its zygomatic and then posterior superior alveolar branches. About halfway between the orbital apex and the orbital rim, the maxillary nerve turns medially to enter the infraorbital canal as the infraorbital nerve. The subsequent course of the maxillary nerve is described on page 502.

The maxillary nerve gives off many of its branches in the pterygopalatine fossa. They can be subdivided into those that come directly from the nerve, and those that are associated with the pterygopalatine parasympathetic ganglion. Named branches from the main trunk are meningeal, ganglionic, zygomatic, posterior, middle and anterior superior alveolar and infraorbital nerves. Named branches from the pterygopalatine ganglion are orbital, nasopalatine, posterior superior nasal, greater (anterior) palatine, lesser (posterior) palatine and pharyngeal.

## Meningeal nerve

The meningeal branch of the maxillary nerve arises within the middle cranial fossa and runs with the middle meningeal vessels. It contributes to the innervation of the dura mater.

## Ganglionic branches

There are usually two ganglionic branches that connect the maxillary nerve to the pterygopalatine ganglion.

## Zygomatic nerve

The zygomatic branch of the maxillary nerve leaves the pterygopalatine fossa through the inferior orbital fissure together with the maxillary nerve. Its subsequent course is described on page 502.

## Posterior superior alveolar nerve

The posterior superior alveolar nerve leaves the maxillary nerve in the pterygopalatine fossa. Its subsequent course and distribution are described on page 526.

## Infraorbital nerve

The infraorbital nerve can be regarded as the terminal branch of the maxillary nerve. It leaves the pterygopalatine fossa to enter the orbit at the inferior orbital fissure, and its subsequent course and distribution are described on page 502.

## Orbital branches

Fine orbital branches enter the orbit through the inferior orbital fissure and supply orbital periosteum. Some fibres also pass through the posterior ethmoidal foramen to supply the sphenoidal and ethmoidal sinuses. The orbital branches are believed to join branches of the internal carotid nerve to form a 'retro-orbital' plexus, from which orbital structures such as the lacrimal gland and orbitalis receive an autonomic innervation (Ruskell 2004).

## Nasopalatine nerve

The nasopalatine nerve leaves the pterygopalatine fossa through the sphenopalatine foramen and enters the nasal cavity. It passes across the cavity to the back of the nasal septum, runs downwards and forwards on the septum in a groove in the vomer, and then turns down through the incisive fossa in the anterior part of the hard palate to enter the roof of the mouth (see Fig. 33.11). When an anterior and a posterior incisive foramen exist in this fossa, the left nasopalatine nerve passes through the anterior foramen, and the right nerve passes through the posterior foramen. The nasopalatine nerve supplies the lower part of the nasal septum and the anterior part of the hard palate, where it communicates with the greater palatine nerve. The nasopalatine artery, a branch of the maxillary artery, accompanies the nasopalatine nerve, ending in the incisive canal, where it anastomoses with greater palatine artery and the septal branch of the superior labial artery.

## Posterior superior nasal nerves <br> (lateral and medial)

The posterior superior alveolar nerves enter the back of the nasal cavity through the sphenopalatine foramen. Lateral posterior superior nasal nerves (about six) innervate the mucosa lining the posterior part of the superior and middle nasal conchae and the posterior ethmoidal sinuses. Two or three medial posterior superior nasal nerves cross the nasal roof below the opening of the sphenoidal sinus to supply the mucosa of the posterior part of the roof and of the nasal septum.

## Palatine nerves (greater and lesser)

The greater and lesser palatine nerves pass downwards from the pterygopalatine ganglion through the greater palatine canal. The greater palatine nerve descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen and runs forwards in a groove on the inferior surface of the bony palate almost to the incisor teeth. It supplies the gingivae, mucosa and glands of the hard palate and also communicates with the terminal filaments of the nasopalatine nerve. In the greater palatine canal, it gives off posterior inferior nasal branches that emerge through the perpendicular plate of the palatine bone and ramify over the inferior nasal concha and walls of the middle

The internal carotid artery-external carotid artery communication via the artery of the pterygoid canal is one of a number of collateral vascular pathways that exist between the external carotid artery and branches of the petrous and intracavernous segments of the internal carotid artery. Albeit small and difficult to demonstrate angiographically, these vascular connections may nevertheless provide the arterial supply for arteriovenous malformations, dural-based fistulae and skull base tumours, and may also compensate for occlusion of the internal carotid artery. They also pose a risk of inadvertent embolization of the brain parenchyma during interventional angiography of the external carotid artery system.

In view of the extensive communications between the artery of the pterygoid canal and the highly vascular nasopharyngeal mucosa, for example, embolization of the external carotid artery branches may result in incomplete obliteration of a vascular nasopharyngeal lesion when the artery of the pterygoid canal arises from the internal carotid artery. Conversely, the collateral circulation provided by the artery of the pterygoid canal may play a role in maintaining cerebral circulation if there is stenosis of the petrous internal carotid artery proximal to the point where the artery of the pterygoid canal joins it; the flow in the post-stenotic segment of the internal carotid artery will be supplemented from the external carotid artery via the artery of the pterygoid canal (Fig. 32.29) (Tubbs et al 2007, Takeuchi et al 2005, Allen et al 2005).

As the greater palatine artery runs the length of the hard palate, it permits axial mucoperiosteal flaps to be raised, if necessary bilaterally, for the reconstruction of local defects. It is also possible to pedicle the entire mucoperiosteum of the hard palate on a single greater palatine artery. The vascular supply to the denuded palatal bone is sufficient, presumably from its nasal surface, to permit regeneration of the palatal soft tissue. Contracture of the regenerated tissue does not occur because the defect lies over the palatal bone (Gullane and Arena 1977, Gullane and Arena 1985, Salins and Benjamin 2009).

Ligation of the sphenopalatine artery may be necessary in the control of refractory epistaxis. It is usually located endoscopically at the posterior/inferior end of the middle turbinate. Multiple branches may be encountered. The sphenopalatine artery provides the axial blood supply to the nasal septal mucosal flap (nasoseptal flap) used in endoscopic skull-base repair, a reflection of its contribution to the vascular supply to the nasal cavity (Hadad et al 2006).

and inferior meatuses. As it leaves the greater palatine canal, it gives off branches that are distributed to both surfaces of the adjacent part of the soft palate (see Fig. 31.3).

The lesser (middle and posterior) palatine nerves are much smaller than the greater palatine nerve. They descend through the greater palatine canal, from which they diverge low down to emerge through the lesser palatine foramina in the tubercle or pyramidal process of the palatine bone. They innervate the uvula, tonsil and soft palate.

Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion. They pass through the ganglion without synapsing and leave via the greater petrosal nerve. Their cell bodies are located in the facial ganglion and their central processes pass via the sensory root of the facial nerve (nervus intermedius) to the gustatory nucleus in the nucleus of the tractus solitarius.

## Pharyngeal nerve

The pharyngeal branch of the maxillary nerve leaves the pterygopalatine ganglion posteriorly. It passes through the palatovaginal canal with the pharyngeal branch of the maxillary artery and supplies the mucosa of the nasopharynx behind the pharyngotympanic tube.

## Neural anastomoses with the maxillary nerve

Available with the Gray's Anatomy e-book

## Pterygopalatine ganglion

The pterygopalatine ganglion, the largest of the peripheral parasympathetic ganglia, is well protected, deep in the pterygopalatine fossa.

Extensive anastomoses, which may be sensory-to-sensory, sensory-tomotor or motor-to-motor, exist between the lower cranial nerves and upper cervical nerves. Variable anastomoses exist between all three of the divisions of the trigeminal nerve with branches of the facial nerve. The majority of trigeminal nerve interconnections are with the facial nerve. Connections between the zygomaticotemporal branch of the maxillary nerve and the temporal branches of the facial nerve, and the zygomaticofacial branch of the maxillary nerve and the zygomatic branches of the facial nerve have been demonstrated (Shoja et al 2014). The connection between the zygomaticotemporal and lacrimal nerves in the orbit providing parasympathetic secretomotor fibres to the lacrimal gland, as was once thought, is less certain. It is more likely that the postganglionic orbital branches pass through the inferior orbital fissure and innervate the lacrimal gland directly (Ruskell 2004). It has been suggested that one possible explanation for these trigeminal-facial interconnections relates to the proprioceptive innervation of the facial musculature but the functional significance of some of the neural connections has yet to be determined.

Immediately anterior to the pterygoid canal, the ganglion lies below and medial to the foramen rotundum and the maxillary nerve, and lateral to the sphenopalatine foramen (see Fig. 32.30B). It is flattened and reddish-grey in colour, and lies just below the maxillary nerve as it crosses the pterygopalatine fossa. The majority of the 'branches' of the ganglion are connected with it morphologically but not functionally, because they are primarily sensory branches of the maxillary nerve. Thus they pass through the ganglion without synapsing and enter the maxillary nerve through its ganglionic branches; they convey some parasympathetic fibres to the palatine, pharyngeal and nasal mucous glands.

Preganglionic parasympathetic fibres destined for the pterygopalatine ganglion run initially in the greater petrosal branch of the facial nerve, and then in the nerve of the pterygoid canal (Vidian nerve), after the greater petrosal unites with the deep petrosal nerve. The nerve of the pterygoid canal enters the ganglion posteriorly. Postganglionic parasympathetic fibres leave the ganglion; some may join the maxillary nerve via a ganglionic branch and then travel via the zygomatic and
zygomaticotemporal branches of the maxillary nerve to the lacrimal gland, but most are thought to travel by orbital branches to the gland (see above). The parasympathetic supply to the pre-ocular part of the central artery of the retina is believed to be derived mainly from the pterygopalatine ganglion and is vasodilatory (Ch. 42). Preganglionic secretomotor fibres of uncertain origin also travel in the nerve of the pterygoid canal. They synapse in the pterygopalatine ganglion, and postganglionic fibres are distributed to palatine, pharyngeal and nasal mucous glands via palatine and nasal branches of the maxillary nerve.

Postganglionic sympathetic fibres pass through the ganglion without synapsing and supply blood vessels and orbitalis. They arise in the superior cervical ganglion and travel via the internal carotid plexus and deep petrosal nerve to enter the pterygopalatine ganglion within the nerve of the pterygoid canal.

General sensory fibres destined for distribution via orbital, nasopalatine, superior alveolar, palatine and pharyngeal branches of the maxillary division of the trigeminal nerve run through the ganglion without synapsing.

## Box 33.1 A note on terminology

'The advent of endoscopic sinus surgery led to a resurgence of interest in the detailed anatomy of the internal nose and paranasal sinuses. However, the official Terminologia Anatomica used by basic anatomists omits many of the structures of surgical importance. This led to numerous clinical anatomy papers and much discussion about the exact names and definitions for the structures of surgical relevance. The European position paper on the anatomical terminology of the internal nose and paranasal sinuses was conceived to re-evaluate the anatomical terms in common usage by endoscopic sinus surgeons and to compare this with the official Terminologia Anatomica' (Lund et al 2014).
Where appropriate, the terms used in this chapter are those commonly used in surgical practice as set out in the 'European position paper on the anatomical terminology of the internal nose and paranasal sinuses' (Table 33.1). Conflicts inevitably arise but hopefully have been minimized. The terms 'concha' and 'turbinate' are often used interchangeably but anatomists rarely use the latter term, while clinicians rarely use the former; in this chapter, concha is used to describe the bony structure seen in dried skulls, while turbinate is used to describe the bony structures, together with their overlying soft tissue and mucosa, that are encountered during surgery. 'Ethmoturbinal' does not appear in Terminologia Anatomica but is the collective term for the superior and middle turbinates, occasionally supplemented by a supreme turbinate. With regard to the terms 'skull base' and 'cranial base', although they are frequently used as though synonymous (the term 'skull base' is favoured in the position paper), the anterior skull base includes the inferior surface of the facial skeleton and will therefore be distinguished from the anterior cranial base, which is delimited by the inner and outer surfaces of the anterior cranial fossa (Ch. 27).

Box 33.1 and Table 33.1 present a note on terminology relating to the structures described in this chapter.

## NOSE

The nose is the first part of the upper respiratory tract and is responsible for warming, humidifying and, to some extent, filtering inspired air. It also houses the olfactory epithelium, which contains olfactory receptor neurones responsible for detecting airborne odorant molecules.

The nose may be subdivided into an external nose, which opens anteriorly on to the face through the nostrils or nares, and an internal chamber, divided sagittally by a septum into right and left cavities, which open posteriorly into the nasopharynx through the posterior nasal apertures or choanae. The nasal cavities are housed in a supporting framework composed of bone and fibroelastic cartilages. The larger bones in this framework contain air-filled spaces lined with respiratory epithelium, described collectively as the paranasal sinuses. The sinuses and the nasolacrimal ducts drain into the nasal cavity via openings in its lateral walls (Fig. 33.1).

## EXTERNAL NOSE

The external nose is a pyramidal structure located in the midline of the midface and attached to the facial skeleton. Its upper angle or root is

Fig. 33.1 An overview of the spatial relationships between the nasal cavity, paranasal sinuses and nasolacrimal ducts. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
continuous with the forehead, and its free tip forms the apex, which projects anteriorly. The overall shape of the external nose is very variable. The lateral surfaces of the nose unite in the median plane to form the dorsum, which is narrowest at the medial canthus. The lobule is an area containing the tip of the nose. Its base contains two ellipsoidal apertures, the external nares or nostrils, which open on to its inferior surface, separated by the nasal septum and columella. The columella usually projects below the alar margin. The alar sulcus is a groove in the skin bounding the nasal alae above and joining the nasiolabial sulcus. Below, it curves towards the tip of the nose but does not reach it.

## FACIAL AND NASAL PROPORTIONS

Available with the Gray's Anatomy e-book

## SKIN AND SOFT TISSUE

The skin and soft tissue covering the nose vary in thickness. They are usually thin over the dorsum in the mid third, especially at the osseocartilaginous junction, the rhinion, and loosely connected to the nasal aponeurosis and the muscle fibres that fan out within it. It is thicker over the nasofrontal angle, and at the tip, where it has numerous large sebaceous glands and is more adherent. These variations affect the final nasal contour and profile after rhinoplasty.

The skin of the nose is separated from the underlying osteocartilaginous framework by four layers. These are the superficial fatty panniculus; the fibromuscular layer, a continuation of the facial superficial musculo-aponeurotic system (SMAS) (see chapter 30); the deep fatty layer; and the periosteum or perichondrium.

Table 33.1 Terminology

|  | Present 'surgical' terminology | Rhinological and anatomical synonyms (textbooks, literature) | Terminologia Anatomica | Suggested English terminology (position paper) | Frequency of variant in literature* |
| :---: | :---: | :---: | :---: | :---: | :---: |

＊The frequency of specific variations in the anatomy varies considerably in the literature，which relates to the definitions used，the methodology utilized，i．e．anatomical dissection or imaging，whether the study included normal controls and／or patients with chronic rhinosinusitis（CRS），and the ethnicity of the subjects．
（With permission from Lund VJ，Stammberger H，Fokkens WJ，et al 2014 European position paper on the anatomical terminology of the internal nose and paranasal sinuses．Rhinology 50：Supp 24：1－34．）

The proportions of the nose and face，both from in front and from the side，are of enormous significance to the rhinoplastic surgeon．Aesthetic proportions of the nose vary depending on sex，age，ethnicity and facial characteristics；however，ranges of normality are described to assist in aesthetic assessment（Akguner et al 1998）．The female nose is slightly smaller and narrower than the male nose；it is often slightly concave in profile view，with a slightly obtuse nasolabial angle（increased tip rota－ tion）．In terms of overall proportion，the face may be divided into hori－ zontal thirds and vertical fifths，with the nose occupying the middle section of each．The width of the nose is roughly $70 \%$ of the length；the width of the alar base is usually equal to the intercanthal distance．The height of the nose is defined by tip projection，where the proportion of the length of a line from the tip to the alar groove to the length of a line from nasion to alar groove is in the range of $0.55-0.60$ ．The nasola－ bial angle，reflecting upward rotation of the nose from the upper lip， normally lies within a range of $105-120^{\circ}$ in females and $90-105^{\circ}$ in males．On basal view，the nose is roughly shaped as an equilateral tri－ angle．The nares usually measure $1.5-2 \mathrm{~cm}$ anteroposteriorly and $0.5-1 \mathrm{~cm}$ transversely，and are narrower in front；they occupy approxi－ mately two－thirds of the height of the base．The midline columella， containing the caudal end of the nasal septum and the medial crura of the lower lateral cartilages，usually extends $3-5 \mathrm{~mm}$ below the nares on lateral views（Fig．33．2）．

Fig．33．2 The adult male nose．A，Basal view．B，Frontal view．The face can be divided into horizontal thirds and vertical fifths，with the nose filling the central segment in terms of both width and height．The basal view may also be divided into horizontal thirds，with the nostrils filling the lower two－thirds．

## Soft tissue areas of the nose

Four soft tissue areas of the nose lack cartilaginous support. They have been given numerous eponymous names and descriptions, but were reclassified by Huizing (2003).

## Paraseptal soft tissue area

The supratip area contains the paired lateral cartilages, which gradually separate from the septum to a level just above the septal angle. The amount of flare varies, and encloses a small paraseptal soft tissue triangle on each side of the septum.

## Lateral soft tissue area

The lateral margin of the lateral cartilage, the piriform aperture and the cranial margin of the lateral crus of the major alar cartilage enclose a triangle containing loose fibroareolar tissue, the transverse portion of nasalis, and one or more small sesamoid cartilages.

## Caudal lobular notch

The domal segment of the intermediate crus of the major alar cartilage has a small indentation. The apex of the nostril is a soft tissue triangle with little soft tissue separating the internal and external skin. Incisions in this area may cause unsightly scarring and deformity.

## Alar soft tissue area

The lateral crus fails to extend to the lateral limit of the lobule, forming the fourth soft tissue area.

## BONES AND CARTILAGE

## Bony skeleton of the external nose

The piriform aperture has sharp edges. It is bounded below and laterally by the maxilla and above by the nasal bones (Fig. 33.3). The lateral part of the inferior edge of the piriform aperture merges into its lateral wall, which is formed by the frontal process of the maxilla. It is bounded above by the nasal part of the frontal bone and superomedially by the lateral edge of the nasal bone.

The paired nasal bones vary in thickness and width, which is of significance in planning osteotomies. They are thickest and widest at the nasofrontal suture, narrow at the nasofrontal angle before they widen, and become thinner $9-12 \mathrm{~mm}$ below the nasofrontal angle. They average 25 mm in length but this can vary widely. The perpendicular plate of the ethmoid bone (part of the bony nasal septum) articulates with the undersurface of the nasal bones and provides support to the dorsum of the nose. A midline bony spine deep to the fused nasal bone projects inwards to articulate with the perpendicular plate of the ethmoid and fuses with the fibrous tissue connecting the lateral nasal cartilages and cartilaginous septum. This is known as the keystone area and provides essential support to the nasal dorsum.

Fractures of the nasal bones The most common injury to the facial skeleton is a fracture of the nasal bones. In simple fractures, the break often occurs between the proximal thicker bone and the thinner
bone distally. Displaced fractures require reduction to avoid cosmetic deformity. The terminal branch of the anterior ethmoidal nerve and its accompanying vessels are at risk when injuries involve the dorsum of the nose.

## Cartilaginous skeleton of the external nose

The cartilaginous framework consists of the paired lateral and major cartilages and several minor alar nasal cartilages (see Fig. 33.3).

## Lateral (superior/upper lateral) nasal cartilage

The lateral nasal cartilage is triangular, and its anterior margin is thicker than the posterior margin. The upper part fuses with the septal cartilage, but anteroinferiorly, it may be separated from it by a narrow fissure. The superior margin of the lateral nasal cartilage is attached to the nasal bone and frontal process of the maxilla, and the inferior margin is connected by fibrous tissue to the lateral crus of the major alar cartilage. Laterally, the cartilage is attached indirectly to the margins of the piriform aperture by loose fibroareolar connective tissue, which may also contain one or more small sesamoid cartilages. The angle formed between the caudal end of the lower lateral and the septum, the internal nasal valve, is usually between 10 and $15^{\circ}$ and represents the narrowest cross-sectional area and the area of greatest airflow resistance. Structural abnormalities in this area are likely to produce symptomatic nasal obstruction.

## Major alar (lower lateral) cartilage

The major alar cartilage is a highly complex, thin, flexible plate, which is integral to the nasal lobule. It lies below the upper lateral cartilage and curves acutely around the anterior part of its naris. The medial part, the narrow medial crus (septal process), is loosely connected by fibrous tissue to its contralateral counterpart and to the anteroinferior part of the septal cartilage. The intermediate crus forms the margin of the apex of the nostril. The domes give rise to the tip-defining points of the nose. The lateral crus lies lateral to the naris and runs superolaterally away from the margin of the nasal ala. The upper border of the lateral crus of the major alar cartilage is attached by fibrous tissue to the lower border of the lateral nasal cartilage. Its lateral border is connected to the frontal process of the maxilla by a tough fibrous membrane containing three or four minor alar cartilages. The junction between the lateral crura of the major alar and lateral cartilages is variable; the two edges may form a 'scroll', with an outcurving of the lateral cartilage meeting an incurving of the major alar cartilage, in which case the lateral crus is then the more lateral at the junction. The lateral crus is shorter than the lateral margin of the naris; the most lateral part of the margin of the ala nasi is fibroadipose tissue covered by skin. In front, the angulations or 'domes' between the medial and lateral crurae of the major alar cartilages are separated by a notch palpable at the tip of the nose.

## Alar cartilage morphology

Available with the Gray's Anatomy e-book

## MUSCLES

The nasal muscle group includes procerus, nasalis, dilator naris anterior, depressor septi and levator labii superioris alaeque nasi (Fig. 33.4, see Figs $30.17,30.18$ ). These muscles are involved in respiration and facial expression. Any or all of these muscles may be absent in cleft lip deformities with corresponding functional and aesthetic consequences.

## Procerus

Procerus is a small pyramidal muscle that lies close to, and is often partially blended with, the medial side of the frontal part of occipitofrontalis. It arises from a fascial aponeurosis attached to the periosteum covering the lower part of the nasal bone, the perichondrium covering the upper part of the lateral nasal cartilage, and the aponeurosis of the transverse part of nasalis. It is inserted into the glabellar skin over the lower part of the forehead between the eyebrows.

Vascular supply Procerus is supplied mainly by branches from the facial artery.

Innervation Procerus is supplied by temporal and lower zygomatic branches from the facial nerve (a supply from the buccal branch has been described).

Fig. 33.4 The nasal musculature. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Actions Procerus draws down the medial angle of the eyebrow and produces transverse wrinkles over the bridge of the nose. It is active in frowning and 'concentration', and helps to reduce the glare of bright sunlight. Not surprisingly, it is a common target in non-surgical facial rejuvenation techniques, using botulinum toxin.

## Nasalis

Nasalis consists of transverse and alar components. The transverse part (compressor naris) is attached to the maxilla above and lateral to the incisive fossa, and lateral to the alar part. Its fibres pass upwards and medially, and expand into a thin aponeurosis that merges with its counterpart across the bridge of the nose, with the aponeuroses of procerus, and with fibres from levator labii superioris alaeque nasi. Fibres from the transverse part may also blend with the skin of the nasolabial and alar folds. The alar part (pars alaris or dilator naris posterior) is attached to the maxilla above the lateral incisor and canine, lateral to the bony attachment of depressor septi, and medial to the transverse part, with which it partly merges. Its fibres pass upwards and anteriorly, and are attached to the skin of the ala above the lateral crus of the lower lateral cartilage, and to the posterior part of the mobile septum. The pars alaris helps to produce the upper ridge of the philtrum.

Dilator naris anterior (also known as apicis nasi or the small dilator muscle of the nose) is a very small muscle attached to the upper lateral cartilage, the alar part of nasalis, the caudal margin of the lateral crus and the lateral alar crus. It encircles the naris and acts as a primary dilator of the nostril.

Vascular supply Nasalis is supplied by branches from the facial artery and from the infraorbital branch of the maxillary artery.

Innervation Nasalis is supplied by the buccal branch of the facial nerve. It may also be supplied by the zygomatic branch of the facial nerve.

Actions The transverse part compresses the nasal aperture at the junction of the vestibule and the nasal cavity. The alar parts draw the alae and posterior part of the columella downwards and laterally, and so assist in widening the nares and in elongating the nose. They are active immediately before inspiration. Dilator naris anterior and the alar part of nasalis (dilator naris posterior) probably function to prevent collapse of the nasal valve during inspiration. Their electromyographic activity is directly proportional to ventilatory resistance and is modified by signals that travel from pulmonary mechano- and pressure receptors via afferent vagal pathways to the brainstem respiratory centre; the efferent limb of the reflex arc runs in the facial nerve.

## Depressor septi

Depressor septi lies immediately deep to the mucous membrane of the upper lip. It is usually attached to the periosteum covering the maxilla

The medial crus has two components, a footplate segment and a columellar segment, which angulate with each other in two planes; they diverge in the basal plane, and rotate upwards in the lateral plane. There is usually asymmetry in the pairs of medial crura.

The medial crus joins the intermediate crus at what is usually the most convex point of the columella, known as the columellar breakpoint.

The intermediate crus is also described in two components. The lobular segment is usually flared and forms the transition between the medial crus and the domal segment of the intermediate crus. The domal segment may be convex, producing an aesthetically pleasing tip; flat, giving a 'boxy' appearance; or convex, producing a 'double-dome'. The domal or tip-defining points are usually formed by the most anterior projection of the domal segment. The amount of divergence of the domes, and the thickness of the overlying soft tissue envelope, determine the relative position of the tip-defining points. The dome projects up to $8-10 \mathrm{~mm}$ caudal, and $3-6 \mathrm{~mm}$ anterior, to the anterior septal angle, the difference between the two creating the supratip break-point. Disruption of this relationship with rhinoplasty, with loss of projection of the tip, may produce a 'polybeak' deformity.

Classically, transverse connective tissue fibres have been described binding the medial and intermediate crura; interdomal, intercrural and septocrural ligaments have been described. Cadaveric studies by Zhai et al (1995) disputed the presence of transverse fibres, and found that all connective tissue fibres run parallel to the cartilages. These findings notwithstanding, the fibrous connections along the length of the medial and intermediate crura form a single functional unit in the tip.

The large lateral crus determines the shape of the alar lateral wall. Medially, it is a continuation of the intermediate crus, while laterally it connects with accessory cartilages. It runs at the caudal edge of the alar rim in the anterior half, then moves cephalically, leaving a soft tissue area in the rim laterally. Typically, the longitudinal axis of the lateral crus forms an angle of $45^{\circ}$ with the septum. More vertical, or cephalic, positioning results in a 'parenthesis' tip deformity.

The lateral crus may take a highly variable position, being either convex or concave, or a combination of both, in medial and lateral portions; asymmetry from side to side has been reported in over half of anatomical specimens.

A chain of lateral accessory cartilages with dense fibrous attachments connect to the lateral crus and the piriform aperture, and to the anterior nasal spine through connection in the floor of the nose.

## Tip support

The inherent strength and shape of the cartilaginous framework, and its attachments to surrounding structures, provide support to the tip of the nose. Typically, 'major' and 'minor' tip support mechanisms are described.

Major tip support mechanisms The major mechanisms supporting the tip are: the size, shape and strength of the major alar cartilages; the medial crural footplate attachment to the caudal part of the septum; the attachment of the caudal border of the lateral cartilages to the cephalic border of the major alar cartilages; and the cartilaginous dorsal septum.

Minor tip support mechanisms The minor mechanisms supporting the tip are: the ligamentous sling spanning the domes of the lower lateral cartilages (i.e. the interdomal ligament); the sesamoid complex of major alar cartilages; the attachment of the major alar cartilages to the overlying skin/soft tissue envelope; the nasal spine; and the membranous septum.

Rhinoplasty approaches, either through an intercartilaginous incision between the lateral and the major alar cartilages (closed rhinoplasty), or through an incision caudal to the major alar cartilages and degloving the entire cartilaginous framework (open rhinoplasty), disrupt the tip support mechanisms; the integrity of these mechanisms must be restored during the procedure to prevent loss of tip support and subsequent tip ptosis.
above the central and lateral incisors and the anterior nasal spine, and to the fibres of orbicularis oris above the central incisor. Its fibres pass to the columella, the mobile part of the nasal septum and the base of the medial crus of the nasal cartilage. A few muscle slips may pass between the medial crura into the nasal tip. Depressor septi may be absent or rudimentary.

Vascular supply Depressor septi is supplied by the superior labial branch of the facial artery.

Innervation Depressor septi is innervated by the buccal branch, and sometimes by the zygomatic branch, of the facial nerve.

Actions Depressor septi pulls the columella, the tip of the nose and the nasal septum downwards. It tenses the nasal septum at the start of nasal inspiration and, with the alar part of nasalis, widens the nasal aperture, as well as causing the nose to 'dip' when some people smile.

## Levator labii superioris alaeque nasi

Levator labii superioris alaeque nasi arises from the upper part of the frontal process of the maxilla and, passing obliquely downwards and laterally, divides into medial and lateral slips. The medial slip blends into the perichondrium of the lateral crus of the major alar cartilage of the nose and the skin over it. The lateral slip is prolonged into the lateral part of the upper lip, where it blends with levator labii superioris and orbicularis oris. Superficial fibres of the lateral slip curve laterally across the front of levator labii superioris and attach along the floor of the dermis at the upper part of the nasolabial furrow and ridge.

Vascular supply Levator labii superioris alaeque nasi is supplied by the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator labii superioris alaeque nasi is innervated by zygomatic and superior buccal branches of the facial nerve.

Actions The lateral slip raises and everts the upper lip and raises, deepens and increases the curvature of the top of the nasolabial furrow. The medial slip pulls the lateral crus superiorly, displaces the circumalar furrow laterally, and modifies its curvature; it is a dilator of the naris. Depressor septi and the medial slip of levator labii superioris alaeque nasi are sometimes described as secondary nasal dilators; there is little evidence that either of these muscles has any direct influence on the nasal valve.

## Anomalous nasal muscles

Anomalous, inconstant, nasal muscles have been described. They include anomalous nasi, attached to the frontal process of the maxilla, procerus, transverse part of nasalis and the upper lateral cartilage (i.e. in a region normally devoid of muscle), and compressor narium minor, which passes between the anterior part of the lower lateral cartilage and the skin near the margins of the nares. The existence of a small levator septi nasi has been questioned.

## Superficial muscular aponeurotic system (SMAS)

Available with the Gray's Anatomy e-book

## CUTANEOUS VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Nasal skin receives its blood supply from branches of the facial, ophthalmic and infraorbital arteries. The alae and lower part of the nasal septum are supplied by lateral nasal and septal branches of the facial artery, and the lateral aspects and dorsum of the nose are supplied by the dorsal nasal branch of the ophthalmic artery and the infraorbital branch of the maxillary artery. The venous networks draining the external nose do not run parallel to the arteries but correspond to arteriovenous territories of the face. The frontomedian region of the face, including the nose, drains to the facial vein, and the orbitopalpebral area of the face, including the root of the nose, drains to the ophthalmic veins. The connections of the veins of the nose, upper lip and cheek (the 'danger triangle of the face') with the drainage area of the valveless ophthalmic veins, and hence to the cavernous sinus, are clinically significant because they can be a route for spreading infection that initiates thrombosis of the major intracranial sinuses. Lymph drainage is primarily to the submandibular group of nodes, although lymph draining from the root of the nose drains to superficial parotid nodes.

Fig. 33.5 A posterior view of the choanae.

## CUTANEOUS INNERVATION

Nasal skin is innervated by the infratrochlear and external nasal branches of the nasociliary nerve (ophthalmic division, trigeminal nerve), and the nasal branch of the infraorbital nerve (maxillary division, trigeminal nerve).

## NASAL CAVITY

The nasal cavity is an irregular space between the roof of the mouth and the cranial base. It is wider below than above, and widest and vertically deepest in its central region, where it is divided by a vertical, midline, osseocartilaginous septum. The bony part of the septum reaches the posterior limit of the cavity.

The nasal cavity communicates with the paranasal sinuses and opens into the nasopharynx through a pair of oval openings, the posterior nasal apertures or choanae. The latter are separated by the posterior border of the vomer, and each is limited above by the vaginal process of the medial pterygoid plates, laterally by the perpendicular plate of the palatine bone and the medial pterygoid plate, and below by the horizontal plate of the palatine bone (Fig. 33.5). The parameters of the intranasal spaces depend on age and gender: growth is usually completed by the age of 16 (Samoliński et al 2007). The adult choana typically measures 2.5 cm in vertical height and 1.3 cm transversely; size is not usually affected by deviations of the nasal septum. The vomerovaginal and palatovaginal canals are found in the roof of this region.

Each half of the nasal cavity has a vestibule, roof, floor, medial (septal) and lateral walls.

## NASAL VESTIBULE

The nasal vestibule lies just inside the naris. It is limited above and behind by a curved ridge, the limen nasi, raised where the greater ala of the lateral cartilaginous crus overlaps the lower edge of the lateral nasal cartilage on each side. On the septal side of the nasal cavity, the superior edge of the medial crus of the major alar cartilage (the medial intumescence) marks the boundary between the nasal vestibule and the nasal cavity. The medial wall of the vestibule is formed by a mobile septum consisting of the columella (which does not contain cartilage) and the underlying medial crura of the alar cartilages.

## ROOF

The roof is horizontal in its central part and slopes downwards in front and behind (see Fig. 33.3D and E). The anterior slope is formed by the nasal spine of the frontal bones and by the nasal bones. The central region is formed by the cribriform plate of the ethmoid bone, which separates the nasal cavity from the floor of the anterior cranial fossa. It contains numerous small perforations that transmit the olfactory nerves and their ensheathing meningeal layers, and a separate anterior foramen that transmits the anterior ethmoidal nerve and vessels. The height of the cranial base is greatest anteriorly; hence, when dissecting along the cranial base during sinus surgery, it is safest to do so from back to front, addressing the lower-lying posterior region first to avoid inadvertent

Although each muscle is independent in terms of innervation and function, the mimetic muscles of the nose form a continuous layer with connections between all the muscular and ligamentous components (Saban et al 2008). Thus, the superficial muscular aponeurotic system is continuous from the nasofrontal process to the nasal tip, splitting at the caudal end of the lateral cartilage into superficial and deep layers, each with medial and lateral components (Oneal et al 1999). Dissection in rhinoplasty is usually performed in a sub-superficial muscular aponeurotic system plane. (For further information on the superficial muscular aponeurotic system, see p. 476.)
intracranial penetration. Posteriorly, the roof of the nasal cavity is formed by the anterior aspect of the body of the sphenoid, interrupted on each side by an opening of a sphenoidal sinus, and the sphenoidal conchae or superior conchae.

## FLOOR

The floor of the nasal cavity is smooth and concave transversely, and slopes up from the anterior to the posterior apertures. The greater part is formed by the palatine processes of the maxillae, which articulate posteriorly with the horizontal plates of the palatine bones at the palatomaxillary suture (see Figs 33.3D, E). Anteriorly, near the septum, a small infundibular opening in the bone of the nasal floor leads into the incisive canals that descend to the incisive fossa; this opening is marked by a slight depression in the overlying mucosa.

The floor of the nose may be deficient as a result of congenital clefting of the hard and/or soft palate.

## MEDIAL WALL

The medial wall of each nasal cavity is the nasal septum, a thin sheet of bone (posteriorly) and cartilage (anteriorly) that lies between the roof and floor of the cavity (see Figs 30.4, 33.3D).

## Bony septum

The septum is usually relatively featureless but sometimes exhibits ridges or bony spurs. The posterosuperior part of the septum and its posterior border are formed by the vomer, which extends from the body of the sphenoid to the nasal crest of the palatine bones and maxilla (see Fig. 30.4). The nasopalatine nerves and vessels groove its surface. (The nasopalatine artery, also known as the septal artery, is a branch of the maxillary artery; it leaves the pterygopalatine fossa through a canal inside the palatine bone, runs parallel to the nasopalatine nerve and ends in the incisive canal, where it anastomoses with the greater palatine artery.) The anterosuperior part of the septum is formed by the perpendicular plate of the ethmoid, which is continuous above with the cribriform plate and the frontal bone. Other bones that make minor contributions to the septum at the upper and lower limits of the medial wall are the nasal bones and the nasal spine of the frontal bones (anterosuperior), the rostrum and crest of the sphenoid (posterosuperior), and the nasal crests of the maxilla and palatine bones (inferior).

## Cartilaginous septum

The septal cartilage is almost quadrilateral and may extend back (especially in children) for some distance between the vomer and the perpendicular plate of the ethmoid. Its anterosuperior margin is connected above to the posterior border of the internasal suture, and the distal end of its superior portion is continuous with the upper lateral cartilages. The anteroinferior border is connected by fibrous tissue on each side to the medial crurae of the major alar cartilage. Anteroinferiorly, the cartilaginous septum is attached to the anterior nasal spine, which is formed by anterior projections of each maxillary crest, and it has a strong, tongue-in-groove attachment with the premaxilla and vomer. The cartilaginous septum anterior to the spine is essential in tip support and should not be excised during septal surgery in order to prevent columellar retraction or loss of tip support. The posterosuperior border joins the perpendicular plate of the ethmoid, while the posteroinferior border is attached to the vomer and, anterior to that, to the nasal crest and anterior nasal spine of the maxilla. The anteroinferior part of the nasal septum between the nares is devoid of cartilage and is therefore called the membranous septum; it is continuous with the columella anteriorly.

Above the incisive canals, at the lower edge of the septal cartilage, a depression pointing downwards and forwards is all that remains of the nasopalatine canal, which connected the nasal and buccal cavities in early fetal life. Near this recess, a minute orifice leads back into a blind tubule, 2-6 mm long, which lies on each side of the septum and houses remnants of the vomeronasal organ (see below).

## LATERAL WALL

The lateral wall of the nasal cavity is formed anteroinferiorly by the maxilla and its anterior and posterior fontanelles (bony deficiencies in

Fig. 33.6 The lateral wall of the nasal cavity. The conchae have been removed to show the positions of the ostia of the paranasal sinuses and the nasolacrimal duct. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
the medial wall of the maxilla that are obliterated to varying degrees by fibrous tissue); posteriorly by the perpendicular plate of the palatine bone; and superiorly by the labyrinth of the ethmoid bone (Fig. 33.6; see Figs 33.3E, 30.5). It contains three projections of variable size: the inferior, middle and superior nasal conchae or turbinates.

The conchae curve inferomedially in general, each roofing a groove, or meatus, which is open to the nasal cavity. The middle concha may also curve inferolaterally; less commonly, it may sometimes be expanded by an enclosed air cell to form a so-called 'concha bullosa', or occasionally may have a concave medial surface, known as a paradoxical turbinate. The main features of the lateral nasal wall are a rounded elevation, the bulla ethmoidalis, and a curved cleft, the hiatus semilunaris, formed by the posterior edge of the uncinate process and the anterior face of the ethmoidal bulla. This constitutes the medial limit of the ethmoidal infundibulum, a slit-like space that leads towards the maxillary ostium. The maxillary ostium is normally found lateral to the anteroinferior aspect of the uncinate process. The latter may be attached to either the lateral nasal wall (50\%), or the anterior cranial fossa (25\%) or the middle concha ( $25 \%$ ). Where the uncinate process is attached determines whether the frontal sinus drains lateral to the ethmoidal infundibulum or into it. If the uncinate process is attached to the lateral wall, the frontal sinus will drain into the middle meatus and not into the ethmoidal infundibulum, whereas with the other configurations, the sinus will drain into the infundibulum, and thus near or into the maxillary ostium. Agger nasi air cells are anterior ethmoidal air cells that lie anterior to the ethmoidal bulla (see Fig. 33.6). The posterior fontanelle lies posterior to the uncinate process where there is no bone in the medial wall of the maxillary sinus, inferoposterior to the hiatus, and frequently has an accessory opening (Fig. 33.7).

## Inferior concha and inferior meatus

The inferior concha is a thin, curved, independent bone (for more details, see p. 483). It articulates with the nasal surface of the maxilla and the perpendicular plate of the palatine bone. Its free lower border is gently curved and the subjacent inferior meatus reaches the nasal floor. The inferior meatus is the largest meatus, extending along almost all the lateral nasal wall. It is deepest at the junction of its anterior and middle thirds, where it admits the inferior opening of the nasolacrimal

C, An endoscopic view of the nose showing the middle turbinate and the pneumatized uncinate process in the middle meatus (asterisk). $\mathbf{D}$, An endoscopic view of the nose demonstrating a deviated nasal septum (asterisk) making contact with the left inferior turbinate. E, An endoscopic view of the posterior nasal space.
canal. The canal is formed by the articulations between the lacrimal groove of the maxilla, the descending process of the lacrimal bone and the lacrimal process of the inferior concha. During postnatal development, the ostium of the nasolacrimal duct moves upwards and is increasingly hidden under the over-arching inferior concha. Inconsistent epithelial folds (the valve of Hasner) may remain at its distal opening.

## Middle concha and middle meatus

The middle concha is a medial process of the ethmoidal labyrinth and may be pneumatized (conchal sinus). It extends back to articulate with the perpendicular plate of the palatine bone. The region beneath it is the middle meatus, which is deeper in front than behind, lies below and lateral to the middle concha, and continues anteriorly into a shallow fossa above the vestibule, termed the atrium of the middle meatus.

## Sphenopalatine foramen

The sphenopalatine foramen, which is really a fissure, transmits the sphenopalatine artery and nasopalatine and superior nasal nerves from the pterygopalatine fossa. It is posterior to the middle meatus, and bounded above by the body and concha of the sphenoid, below by the superior border of the perpendicular plate of the palatine bone, and in front and behind by the orbital and sphenoidal processes of the palatine bone, respectively. The crista ethmoidalis, a small bony crest formed by the attachment of the basal lamella of the middle turbinate to the ascending palatine bone, is found anterior to the foramen, and is a reliable surgical landmark.

## Ethmoturbinals

The ethmoturbinals are the superior and middle turbinates, occasionally supplemented by a supreme turbinate. They appear during weeks nine and ten of gestation as multiple folds on the developing lateral nasal wall and subsequently fuse into three or four ridges, each with an anterior (ascending) and a posterior (descending) ramus, separated by grooves. The first ridge develops into the agger nasi and the uncinate process. The second is thought to become the ethmoidal bulla and the fourth, if present, develops into the superior and supreme turbinates. The third is known as the basal lamella of the middle turbinate.

## Attachments of the basal lamella of the middle turbinate

An understanding of the attachment of the middle turbinate to the roof and lateral wall of the nose is essential when undertaking sinus surgery. Anteriorly, it attaches to the crista ethmoidalis of the maxilla, and posteriorly it attaches to the crista ethmoidalis of the palatine bone, anterior to the sphenopalatine foramen. In between these points, the insertion lies in three different planes. The anterior third inserts vertically into the cranial base. The middle third turns laterally across the cranial base to the lamina papyracea, where it turns inferiorly; it may be indented by either anterior or posterior ethmoidal cells, but separates the two groups of cells. The posterior third runs horizontally, attaching to the lamina and the medial wall of the middle turbinate.

## Superior concha and superior meatus

The superior concha is a medial process of the ethmoidal labyrinth and presents as a small curved lamina, posterosuperior to the middle concha. It roofs the superior meatus and is the shortest and shallowest of the three conchae. Above the superior concha, the sphenoidal sinus opens into the triangular sphenoethmoidal recess, which separates the superior concha and anterior aspect of the body of the sphenoid. The superior meatus is a short oblique passage extending about halfway along the upper border of the middle concha. The posterior ethmoidal sinuses open, via a variable number of apertures, into its anterior part.

## Highest (supreme) nasal concha

Occasionally, a fourth concha, the highest or supreme nasal concha, appears on the lateral wall of the sphenoethmoidal recess. The passage immediately below it is called the supreme nasal meatus; it may contain an opening for the posterior ethmoidal sinus.

## Functions of the nasal turbinates
