understanding, and for their love

To

Arthur C. Guyton

For his imaginative and innovative research
For his dedication to education
For showing us the excitement and joy of physiology
And for serving as an inspirational role model

Preface

The first edition of the *Textbook of Medical Physiology* was written by Arthur C. Guyton almost 65 years ago. Unlike most major medical textbooks, which often have 20 or more authors, the first eight editions of the *Textbook of Medical Physiology* were written entirely by Dr. Guyton. He had a gift for communicating complex ideas in a clear and interesting manner that made studying physiology fun. He wrote the book to help students learn physiology, not to impress his professional colleagues.

Dr. John Hall worked closely with Dr. Guyton for almost 30 years and had the privilege of writing parts of the 9th and 10th editions and of assuming sole responsibility for completing the subsequent editions.

Dr. Michael Hall has joined in the preparation of the 14th edition of the *Textbook of Medical Physiology*. He is a physician trained in internal medicine, cardiology, and physiology and has brought new insights that have helped greatly to achieve the same goal as for previous editions—to explain, in language easily understood by students, how the different cells, tissues, and organs of the human body work together to maintain life.

This task has been challenging and fun because researchers continue to unravel new mysteries of body functions. Advances in molecular and cellular physiology have made it possible to explain some physiology principles in the terminology of molecular and physical sciences rather than in merely a series of separate and unexplained biological phenomena. However, the molecular events that underpin the functions of the body's cells provide only a partial explanation of human physiology. The total function of the human body requires complex control systems that communicate with each other and coordinate the molecular functions of the body's cells, tissues, and organs in health and disease.

The *Textbook of Medical Physiology* is not a reference book that attempts to provide a compendium of the most recent advances in physiology. It is a book that continues the tradition of being written for students. It focuses on the basic principles of physiology needed to begin a career in the health care professions, such as medicine, dentistry, and nursing, as well as graduate studies in the biological and health sciences. It should also be useful to physicians and health care professionals who wish to

review the basic principles needed for understanding the pathophysiology of human disease. We have attempted to maintain the same unified organization of the text that has been useful to students in the past and to ensure that the book is comprehensive enough that students will continue to use it during their professional careers.

Our hope is that the *Textbook of Medical Physiology* conveys the majesty of the human body and its many functions and that it stimulates students to study physiology throughout their careers. Physiology links the basic sciences and medicine. The great beauty of physiology is that it integrates the individual functions of all the body's different cells, tissues, and organs into a functional whole, the human body. Indeed, the human body is much more than the sum of its parts, and life relies upon this total function, not just on the function of individual body parts in isolation from the others.

This brings us to an important question: How are the separate organs and systems coordinated to maintain proper function of the entire body? Fortunately, our bodies are endowed with a vast network of feedback controls that achieve the necessary balances without which we would be unable to live. Physiologists call this high level of internal bodily control *homeostasis*. In disease states, functional balances are often seriously disturbed, and homeostasis is impaired. When even a single disturbance reaches a limit, the whole body can no longer live. One of the goals of this text is to emphasize the effectiveness and beauty of the body's homeostasis mechanisms as well as to present their abnormal functions in disease.

Another objective is to be as accurate as possible. Suggestions and critiques from many students, physiologists, and clinicians throughout the world have checked factual accuracy as well as balance in the text. Even so, because of the likelihood of error in sorting through many thousands of bits of information, we issue a further request for all readers to send notations of error or inaccuracy to us. Physiologists understand the importance of feedback for proper function of the human body; feedback is also important for progressive improvement of a textbook of physiology. To the many persons who have already helped, we express sincere thanks. Your feedback has helped to improve the text.

A brief explanation is needed about several features of the 14th edition. Although many of the chapters have been revised to include new principles of physiology and new figures to illustrate these principles, the text length has been closely monitored to limit the book's size so that it can be used effectively in physiology courses for medical students and health care professionals. New references have been chosen primarily for their presentation of physiological principles, for the quality of their own references, and for their easy accessibility. The selected bibliography at the end of the chapters lists mainly review papers from recently published scientific journals that can be freely accessed from the PubMed site at <https://www.ncbi.nlm.nih.gov/pubmed/>. Use of these references, as well as cross-references from them, provides much more extensive coverage of the entire field of physiology.

Our effort to be as concise as possible has, unfortunately, necessitated a more simplified and dogmatic presentation of many physiological principles than we normally would have desired. However, the bibliography can be used to learn more about the controversies and unanswered questions that remain in understanding the complex functions of the human body in health and disease.

Another feature of the book is that the print is set in two sizes. The material in large print constitutes the fundamental physiological information that students will require in virtually all of their medical studies. The material in small print and highlighted with a pale lavender background (or identified by beginning and ending double gray arrowheads in the ebook version) is of several different kinds: (1) anatomic, chemical, and other information that is needed for immediate discussion but that

most students will learn in more detail in other courses; (2) physiological information of special importance to certain fields of clinical medicine; and (3) information that will be of value to those students who wish to study specific physiological mechanisms more deeply.

The ebook version provides links to additional content including video animations and self-assessment questions that can be accessed with computers, smart phones, and electronic tablets. For additional self-assessment beyond these textbook supplements, the reader may consider using a copy of *Guyton and Hall Physiology Review*, which includes more than 1000 practice questions referenced to the textbook. We hope that these ancillary materials will assist readers in testing their understanding of basic principles of physiology.

We express sincere thanks to many persons who have helped to prepare this book, including our colleagues in the Department of Physiology and Biophysics at the University of Mississippi Medical Center who provided valuable suggestions. The members of our faculty and a brief description of the research and educational activities of the department can be found at <http://physiology.umc.edu/>. We are especially grateful to Stephanie Lucas for excellent assistance and to James Perkins for excellent illustrations. We also thank Elyse O'Grady, Jennifer Shreiner, Grace Onderlinde, Rebecca Gruliow, and the entire Elsevier team for continued editorial and production excellence.

Finally, we thank the many readers who continue to help us improve the *Textbook of Medical Physiology*. We hope that you enjoy the current edition and find it even more useful than previous editions.

John E. Hall
Michael E. Hall

Functional Organization of the Human Body and Control of the “Internal Environment”

Physiology is the science that seeks to explain the physical and chemical mechanisms that are responsible for the origin, development, and progression of life. Each type of life, from the simplest virus to the largest tree or the complicated human being, has its own functional characteristics. Therefore, the vast field of physiology can be divided into viral physiology, bacterial physiology, cellular physiology, plant physiology, invertebrate physiology, vertebrate physiology, mammalian physiology, human physiology, and many more subdivisions.

Human Physiology. The science of human physiology attempts to explain the specific characteristics and mechanisms of the human body that make it a living being. The fact that we remain alive is the result of complex control systems. Hunger makes us seek food, and fear makes us seek refuge. Sensations of cold make us look for warmth. Other forces cause us to seek fellowship and to reproduce. The fact that we are sensing, feeling, and knowledgeable beings is part of this automatic sequence of life; these special attributes allow us to exist under widely varying conditions that otherwise would make life impossible.

Human physiology links the basic sciences with medicine and integrates multiple functions of the cells, tissues, and organs into the functions of the living human being. This integration requires communication and coordination by a vast array of control systems that operate at every level—from the genes that program synthesis of molecules to the complex nervous and hormonal systems that coordinate functions of cells, tissues, and organs throughout the body. Thus, the coordinated functions of the human body are much more than the sum of its parts, and life in health, as well as in disease states, relies on this total function. Although the main focus of this book is on normal human physiology, we will also discuss, to some extent, *pathophysiology*, which is the study of disordered body function and the basis for clinical medicine.

CELLS ARE THE LIVING UNITS OF THE BODY

The basic living unit of the body is the cell. Each tissue or organ is an aggregate of many different cells held together by intercellular supporting structures.

Each type of cell is specially adapted to perform one or a few particular functions. For example, the red blood cells, numbering about 25 trillion in each person, transport oxygen from the lungs to the tissues. Although the red blood cells are the most abundant of any single type of cell in the body, there are also trillions of additional cells of other types that perform functions different from those of the red blood cell. The entire body, then, contains about 35 to 40 trillion human cells.

The many cells of the body often differ markedly from one another but all have certain basic characteristics that are alike. For example, oxygen reacts with carbohydrate, fat, and protein to release the energy required for all cells to function. Furthermore, the general chemical mechanisms for changing nutrients into energy are basically the same in all cells, and all cells deliver products of their chemical reactions into the surrounding fluids.

Almost all cells also have the ability to reproduce additional cells of their own type. Fortunately, when cells of a particular type are destroyed, the remaining cells of this type usually generate new cells until the supply is replenished.

Microorganisms Living in the Body Outnumber Human Cells. In addition to human cells, trillions of microbes inhabit the body, living on the skin and in the mouth, gut, and nose. The gastrointestinal tract, for example, normally contains a complex and dynamic population of 400 to 1000 species of microorganisms that outnumber our human cells. Communities of microorganisms that inhabit the body, often called *microbiota*, can cause diseases, but most of the time they live in harmony with their human hosts and provide vital functions that are essential for survival of their hosts. Although the importance of gut microbiota in the digestion of foodstuffs is widely recognized, additional roles for the body’s microbes in nutrition, immunity, and other functions are just beginning to be appreciated and represent an intensive area of biomedical research.

EXTRACELLULAR FLUID—THE “INTERNAL ENVIRONMENT”

About 50% to 70% of the adult human body is fluid, mainly a water solution of ions and other substances. Although

most of this fluid is inside the cells and is called *intracellular fluid*, about one-third is in the spaces outside the cells and is called *extracellular fluid*. This extracellular fluid is in constant motion throughout the body. It is transported rapidly in the circulating blood and then mixed between the blood and tissue fluids by diffusion through the capillary walls.

In the extracellular fluid are the ions and nutrients needed by the cells to maintain life. Thus, all cells live in essentially the same environment—the extracellular fluid. For this reason, the extracellular fluid is also called the *internal environment* of the body, or the *milieu intérieur*, a term introduced by the great 19th-century French physiologist Claude Bernard (1813–1878).

Cells are capable of living and performing their special functions as long as the proper concentrations of oxygen, glucose, different ions, amino acids, fatty substances, and other constituents are available in this internal environment.

Differences in Extracellular and Intracellular Fluids.

The extracellular fluid contains large amounts of sodium, chloride, and bicarbonate ions plus nutrients for the cells, such as oxygen, glucose, fatty acids, and amino acids. It also contains carbon dioxide that is being transported from the cells to the lungs to be excreted, plus other cellular waste products that are being transported to the kidneys for excretion.

The intracellular fluid contains large amounts of potassium, magnesium, and phosphate ions instead of the sodium and chloride ions found in the extracellular fluid. Special mechanisms for transporting ions through the cell membranes maintain the ion concentration differences between the extracellular and intracellular fluids. These transport processes are discussed in [Chapter 4](#).

HOMEOSTASIS—MAINTENANCE OF A NEARLY CONSTANT INTERNAL ENVIRONMENT

In 1929, the American physiologist Walter Cannon (1871–1945) coined the term *homeostasis* to describe the *maintenance of nearly constant conditions in the internal environment*. Essentially, all organs and tissues of the body perform functions that help maintain these relatively constant conditions. For example, the lungs provide oxygen to the extracellular fluid to replenish the oxygen used by the cells, the kidneys maintain constant ion concentrations, and the gastrointestinal system provides nutrients while eliminating waste from the body.

The various ions, nutrients, waste products, and other constituents of the body are normally regulated within a range of values, rather than at fixed values. For some of the body's constituents, this range is extremely small. Variations in the blood hydrogen ion concentration, for example, are normally less than 5 *nanomoles/L* (0.000000005 moles/L). The blood sodium concentration is also tightly

regulated, normally varying only a few *millimoles* per liter, even with large changes in sodium intake, but these variations of sodium concentration are at least 1 million times greater than for hydrogen ions.

Powerful control systems exist for maintaining concentrations of sodium and hydrogen ions, as well as for most of the other ions, nutrients, and substances in the body at levels that permit the cells, tissues, and organs to perform their normal functions, despite wide environmental variations and challenges from injury and diseases.

Much of this text is concerned with how each organ or tissue contributes to homeostasis. Normal body functions require integrated actions of cells, tissues, organs, and multiple nervous, hormonal, and local control systems that together contribute to homeostasis and good health.

Homeostatic Compensations in Diseases. *Disease* is often considered to be a state of disrupted homeostasis. However, even in the presence of disease, homeostatic mechanisms continue to operate and maintain vital functions through multiple compensations. In some cases, these compensations may lead to major deviations of the body's functions from the normal range, making it difficult to distinguish the primary cause of the disease from the compensatory responses. For example, diseases that impair the kidneys' ability to excrete salt and water may lead to high blood pressure, which initially helps return excretion to normal so that a balance between intake and renal excretion can be maintained. This balance is needed to maintain life, but, over long periods of time, the high blood pressure can damage various organs, including the kidneys, causing even greater increases in blood pressure and more renal damage. Thus, homeostatic compensations that ensue after injury, disease, or major environmental challenges to the body may represent trade-offs that are necessary to maintain vital body functions but, in the long term, contribute to additional abnormalities of body function. The discipline of *pathophysiology* seeks to explain how the various physiological processes are altered in diseases or injury.

This chapter outlines the different functional systems of the body and their contributions to homeostasis. We then briefly discuss the basic theory of the body's control systems that allow the functional systems to operate in support of one another.

EXTRACELLULAR FLUID TRANSPORT AND MIXING SYSTEM—THE BLOOD CIRCULATORY SYSTEM

Extracellular fluid is transported through the body in two stages. The first stage is movement of blood through the body in the blood vessels. The second is movement of fluid between the blood capillaries and the *intercellular spaces* between the tissue cells.

Figure 1-1 shows the overall circulation of blood. All the blood in the circulation traverses the entire circuit an average

Figure 1-1. General organization of the circulatory system.

of once each minute when the body is at rest and as many as six times each minute when a person is extremely active.

As blood passes through blood capillaries, continual exchange of extracellular fluid occurs between the plasma portion of the blood and the interstitial fluid that fills the intercellular spaces. This process is shown in Figure 1-2. The capillary walls are permeable to most molecules in the blood plasma, with the exception of plasma proteins, which are too large to pass through capillaries readily. Therefore, large amounts of fluid and its dissolved constituents *diffuse* back and forth between the blood and the tissue spaces, as shown by the arrows in Figure 1-2.

This process of diffusion is caused by kinetic motion of the molecules in the plasma and the interstitial fluid.

Figure 1-2. Diffusion of fluid and dissolved constituents through the capillary walls and interstitial spaces.

That is, the fluid and dissolved molecules are continually moving and bouncing in all directions in the plasma and fluid in the intercellular spaces, as well as through capillary pores. Few cells are located more than 50 micrometers from a capillary, which ensures diffusion of almost any substance from the capillary to the cell within a few seconds. Thus, the extracellular fluid everywhere in the body—both that of the plasma and that of the interstitial fluid—is continually being mixed, thereby maintaining homogeneity of extracellular fluid throughout the body.

ORIGIN OF NUTRIENTS IN THE EXTRACELLULAR FLUID

Respiratory System. Figure 1-1 shows that each time blood passes through the body, it also flows through the lungs. The blood picks up *oxygen* in alveoli, thus acquiring the oxygen needed by cells. The membrane between the alveoli and the lumen of the pulmonary capillaries, the *alveolar membrane*, is only 0.4 to 2.0 micrometers thick, and oxygen rapidly diffuses by molecular motion through this membrane into the blood.

Gastrointestinal Tract. A large portion of the blood pumped by the heart also passes through the walls of the gastrointestinal tract. Here different dissolved nutrients, including *carbohydrates*, *fatty acids*, and *amino acids*, are absorbed from ingested food into the extracellular fluid of the blood.

Liver and Other Organs That Perform Primarily Metabolic Functions. Not all substances absorbed from the gastrointestinal tract can be used in their absorbed form by the cells. The liver changes the chemical compositions of many of these substances to more usable forms, and other tissues of the body—fat cells, gastrointestinal mucosa, kidneys, and endocrine glands—help modify the absorbed substances or store them until they are needed. The liver also eliminates certain waste products produced in the body and toxic substances that are ingested.

Musculoskeletal System. How does the musculoskeletal system contribute to homeostasis? The answer is obvious and simple. Were it not for the muscles, the body could not move to obtain the foods required for nutrition. The musculoskeletal system also provides motility for protection against adverse surroundings, without which the entire body, along with its homeostatic mechanisms, could be destroyed.

REMOVAL OF METABOLIC END PRODUCTS

Removal of Carbon Dioxide by the Lungs. At the same time that blood picks up oxygen in the lungs, *carbon dioxide* is released from the blood into lung alveoli; the respiratory movement of air into and out of the lungs carries carbon dioxide to the atmosphere. Carbon dioxide is the most abundant of all the metabolism products.

Kidneys. Passage of blood through the kidneys removes most of the other substances from the plasma besides carbon dioxide that are not needed by cells. These substances include different end products of cellular metabolism, such as urea and uric acid; they also include excesses of ions and water from the food that accumulate in the extracellular fluid.

The kidneys perform their function first by filtering large quantities of plasma through the glomerular capillaries into the tubules and then reabsorbing into the blood substances needed by the body, such as glucose, amino acids, appropriate amounts of water, and many of the ions. Most of the other substances that are not needed by the body, especially metabolic waste products such as urea and creatinine, are reabsorbed poorly and pass through the renal tubules into the urine.

Gastrointestinal Tract. Undigested material that enters the gastrointestinal tract and some waste products of metabolism are eliminated in the feces.

Liver. Among the many functions of the liver is detoxification or removal of ingested drugs and chemicals. The liver secretes many of these wastes into the bile to be eventually eliminated in the feces.

REGULATION OF BODY FUNCTIONS

Nervous System. The nervous system is composed of three major parts—the *sensory input portion*, the *central nervous system* (or *integrative portion*), and the *motor output portion*. Sensory receptors detect the state of the body and its surroundings. For example, receptors in the skin alert us whenever an object touches the skin. The eyes are sensory organs that give us a visual image of the surrounding area. The ears are also sensory organs. The central nervous system is composed of the brain and spinal cord. The brain stores information, generates thoughts, creates ambition, and determines reactions that the body

performs in response to the sensations. Appropriate signals are then transmitted through the motor output portion of the nervous system to carry out one's desires.

An important segment of the nervous system is called the *autonomic system*. It operates at a subconscious level and controls many functions of internal organs, including the level of pumping activity by the heart, movements of the gastrointestinal tract, and secretion by many of the body's glands.

Hormone Systems. Located in the body are *endocrine glands*, organs and tissues that secrete chemical substances called *hormones*. Hormones are transported in the extracellular fluid to other parts of the body to help regulate cellular function. For example, *thyroid hormone* increases the rates of most chemical reactions in all cells, thus helping set the tempo of bodily activity. *Insulin* controls glucose metabolism, *adrenocortical hormones* control sodium and potassium ions and protein metabolism, and *parathyroid hormone* controls bone calcium and phosphate. Thus, the hormones provide a regulatory system that complements the nervous system. The nervous system controls many muscular and secretory activities of the body, whereas the hormonal system regulates many metabolic functions. The nervous and hormonal systems normally work together in a coordinated manner to control essentially all the organ systems of the body.

PROTECTION OF THE BODY

Immune System. The immune system includes white blood cells, tissue cells derived from white blood cells, the thymus, lymph nodes, and lymph vessels that protect the body from pathogens such as bacteria, viruses, parasites, and fungi. The immune system provides a mechanism for the body to carry out the following: (1) distinguish its own cells from harmful foreign cells and substances; and (2) destroy the invader by *phagocytosis* or by producing *sensitized lymphocytes* or specialized proteins (e.g., *antibodies*) that destroy or neutralize the invader.

Integumentary System. The skin and its various appendages (including the hair, nails, glands, and other structures) cover, cushion, and protect the deeper tissues and organs of the body and generally provide a boundary between the body's internal environment and the outside world. The integumentary system is also important for temperature regulation and excretion of wastes, and it provides a sensory interface between the body and the external environment. The skin generally comprises about 12% to 15% of body weight.

REPRODUCTION

Although reproduction is sometimes not considered a homeostatic function, it helps maintain homeostasis by generating new beings to take the place of those that are

dying. This may sound like a permissive usage of the term *homeostasis*, but it illustrates that in the final analysis, essentially all body structures are organized to help maintain the automaticity and continuity of life.

CONTROL SYSTEMS OF THE BODY

The human body has thousands of control systems. Some of the most intricate of these systems are genetic control systems that operate in all cells to help regulate intracellular and extracellular functions. This subject is discussed in Chapter 3.

Many other control systems operate *within the organs* to regulate functions of the individual parts of the organs; others operate throughout the entire body *to control the interrelationships between the organs*. For example, the respiratory system, operating in association with the nervous system, regulates the concentration of carbon dioxide in the extracellular fluid. The liver and pancreas control glucose concentration in the extracellular fluid, and the kidneys regulate concentrations of hydrogen, sodium, potassium, phosphate, and other ions in the extracellular fluid.

EXAMPLES OF CONTROL MECHANISMS

Regulation of Oxygen and Carbon Dioxide Concentrations in the Extracellular Fluid. Because oxygen is one of the major substances required for chemical reactions in cells, the body has a special control mechanism to maintain an almost exact and constant oxygen concentration in the extracellular fluid. This mechanism depends principally on the chemical characteristics of *hemoglobin*, which is present in red blood cells. Hemoglobin combines with oxygen as the blood passes through the lungs. Then, as the blood passes through the tissue capillaries, hemoglobin, because of its own strong chemical affinity for oxygen, does not release oxygen into the tissue fluid if too much oxygen is already there. However, if oxygen concentration in the tissue fluid is too low, sufficient oxygen is released to re-establish an adequate concentration. Thus, regulation of oxygen concentration in the tissues relies to a great extent on the chemical characteristics of hemoglobin. This regulation is called the *oxygen-buffering function of hemoglobin*.

Carbon dioxide concentration in the extracellular fluid is regulated in a much different way. Carbon dioxide is a major end product of oxidative reactions in cells. If all the carbon dioxide formed in the cells continued to accumulate in the tissue fluids, all energy-giving reactions of the cells would cease. Fortunately, a higher than normal carbon dioxide concentration in the blood *excites the respiratory center*, causing a person to breathe rapidly and deeply. This deep rapid breathing increases expiration of carbon dioxide and, therefore, removes excess carbon dioxide from the blood and tissue fluids. This process continues until the concentration returns to normal.

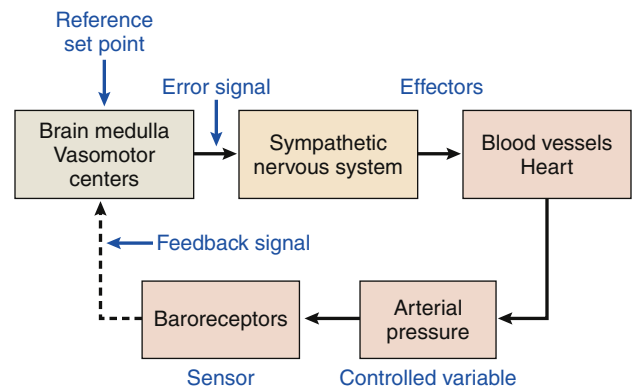

Figure 1-3. Negative feedback control of arterial pressure by the arterial baroreceptors. Signals from the sensor (baroreceptors) are sent to the medulla of the brain, where they are compared with a reference set point. When arterial pressure increases above normal, this abnormal pressure increases nerve impulses from the baroreceptors to the medulla of the brain, where the input signals are compared with the set point, generating an error signal that leads to decreased sympathetic nervous system activity. Decreased sympathetic activity causes dilation of blood vessels and reduced pumping activity of the heart, which return arterial pressure toward normal.

Regulation of Arterial Blood Pressure. Several systems contribute to arterial blood pressure regulation. One of these, the *baroreceptor system*, is an excellent example of a rapidly acting control mechanism (Figure 1-3). In the walls of the bifurcation region of the carotid arteries in the neck, and also in the arch of the aorta in the thorax, are many nerve receptors called *baroreceptors* that are stimulated by stretch of the arterial wall. When arterial pressure rises too high, the baroreceptors send barrages of nerve impulses to the medulla of the brain. Here, these impulses inhibit the *vasomotor center*, which in turn decreases the number of impulses transmitted from the vasomotor center through the sympathetic nervous system to the heart and blood vessels. Lack of these impulses causes diminished pumping activity by the heart and dilation of peripheral blood vessels, allowing increased blood flow through the vessels. Both these effects decrease the arterial pressure, moving it back toward normal.

Conversely, a decrease in arterial pressure below normal relaxes the stretch receptors, allowing the vasomotor center to become more active than usual, thereby causing vasoconstriction and increased heart pumping. The initial decrease in arterial pressure thus initiates negative feedback mechanisms that raise arterial pressure back toward normal.

Normal Ranges and Physical Characteristics of Important Extracellular Fluid Constituents

Table 1-1 lists some important constituents and physical characteristics of extracellular fluid, along with their normal values, normal ranges, and maximum limits without causing death. Note the narrowness of the normal range for each one. Values outside these ranges are often caused by illness, injury, or major environmental challenges.

Table 1-1 Important Constituents and Physical Characteristics of Extracellular Fluid

Constituent	Normal Value	Normal Range	Approximate Short-Term Nonlethal Limit	Unit
Oxygen (venous)	40	25–40	10–1000	mm Hg
Carbon dioxide (venous)	45	41–51	5–80	mm Hg
Sodium ion	142	135–145	115–175	mmol/L
Potassium ion	4.2	3.5–5.3	1.5–9.0	mmol/L
Calcium ion	1.2	1.0–1.4	0.5–2.0	mmol/L
Chloride ion	106	98–108	70–130	mmol/L
Bicarbonate ion	24	22–29	8–45	mmol/L
Glucose	90	70–115	20–1500	mg/dl
Body temperature	98.4 (37.0)	98–98.8 (37.0)	65–110 (18.3–43.3)	°F (°C)
Acid–base (venous)	7.4	7.3–7.5	6.9–8.0	pH

Most important are the limits beyond which abnormalities can cause death. For example, an increase in the body temperature of only 11°F (7°C) above normal can lead to a vicious cycle of increasing cellular metabolism that destroys the cells. Note also the narrow range for acid–base balance in the body, with a normal pH value of 7.4 and lethal values only about 0.5 on either side of normal. Whenever the potassium ion concentration decreases to less than one-third normal, paralysis may result from the inability of the nerves to carry signals. Alternatively, if potassium ion concentration increases to two or more times normal, the heart muscle is likely to be severely depressed. Also, when the calcium ion concentration falls below about one-half normal, a person is likely to experience tetanic contraction of muscles throughout the body because of the spontaneous generation of excess nerve impulses in peripheral nerves. When the glucose concentration falls below one-half normal, a person frequently exhibits extreme mental irritability and sometimes even has convulsions.

These examples should give one an appreciation for the necessity of the vast numbers of control systems that keep the body operating in health. In the absence of any one of these controls, serious body malfunction or death can result.

CHARACTERISTICS OF CONTROL SYSTEMS

The aforementioned examples of homeostatic control mechanisms are only a few of the many thousands in the body, all of which have some common characteristics, as explained in this section.

Negative Feedback Nature of Most Control Systems

Most control systems of the body act by *negative feedback*, which can be explained by reviewing some of the homeostatic control systems mentioned previously. In the regulation of carbon dioxide concentration, a high concentration of carbon dioxide in the extracellular fluid increases pulmonary ventilation. This, in turn, decreases

the extracellular fluid carbon dioxide concentration because the lungs expire greater amounts of carbon dioxide from the body. Thus, the high concentration of carbon dioxide initiates events that decrease the concentration toward normal, which is *negative* to the initiating stimulus. Conversely, a carbon dioxide concentration that falls too low results in feedback to increase the concentration. This response is also negative to the initiating stimulus.

In the arterial pressure–regulating mechanisms, a high pressure causes a series of reactions that promote reduced pressure, or a low pressure causes a series of reactions that promote increased pressure. In both cases, these effects are negative with respect to the initiating stimulus.

Therefore, in general, if some factor becomes excessive or deficient, a control system initiates *negative feedback*, which consists of a series of changes that return the factor toward a certain mean value, thus maintaining homeostasis.

Gain of a Control System. The degree of effectiveness with which a control system maintains constant conditions is determined by the *gain* of negative feedback. For example, let us assume that a large volume of blood is transfused into a person whose baroreceptor pressure control system is not functioning, and the arterial pressure rises from the normal level of 100 mm Hg up to 175 mm Hg. Then, let us assume that the same volume of blood is injected into the same person when the baroreceptor system is functioning, and this time the pressure increases by only 25 mm Hg. Thus, the feedback control system has caused a “correction” of –50 mm Hg, from 175 mm Hg to 125 mm Hg. There remains an increase in pressure of +25 mm Hg, called the “error,” which means that the control system is not 100% effective in preventing change. The gain of the system is then calculated by using the following formula:

$$\text{Gain} = \frac{\text{Correction}}{\text{Error}}$$

Thus, in the baroreceptor system example, the correction is –50 mm Hg, and the error persisting is +25 mm Hg. Therefore, the gain of the person’s baroreceptor system

Figure 1-4. Recovery of heart pumping caused by negative feedback after 1 liter of blood is removed from the circulation. Death is caused by positive feedback when 2 liters or more blood is removed.

for control of arterial pressure is -50 divided by $+25$, or -2 . That is, a disturbance that increases or decreases the arterial pressure does so only one-third as much as would occur if this control system were not present.

The gains of some other physiological control systems are much greater than that of the baroreceptor system. For example, the gain of the system controlling internal body temperature when a person is exposed to moderately cold weather is about -33 . Therefore, one can see that the temperature control system is much more effective than the baroreceptor pressure control system.

Positive Feedback May Cause Vicious Cycles and Death

Why do most control systems of the body operate by negative feedback rather than by positive feedback? If one considers the nature of positive feedback, it is obvious that positive feedback leads to instability rather than stability and, in some cases, can cause death.

Figure 1-4 shows an example in which death can ensue from positive feedback. This figure depicts the pumping effectiveness of the heart, showing the heart of a healthy human pumping about 5 liters of blood per minute. If the person suddenly bleeds a total of 2 liters, the amount of blood in the body is decreased to such a low level that not enough blood is available for the heart to pump effectively. As a result, the arterial pressure falls, and the flow of blood to the heart muscle through the coronary vessels diminishes. This scenario results in weakening of the heart, further diminished pumping, a further decrease in coronary blood flow, and still more weakness of the heart; the cycle repeats itself again and again until death occurs. Note that each cycle in the feedback results in further weakening of the heart. In other words, the initiating stimulus causes more of the same, which is *positive feedback*.

Positive feedback is sometimes known as a “vicious cycle,” but a mild degree of positive feedback can be

overcome by the negative feedback control mechanisms of the body, and the vicious cycle then fails to develop. For example, if the person in the aforementioned example bleeds only 1 liter instead of 2 liters, the normal negative feedback mechanisms for controlling cardiac output and arterial pressure can counterbalance the positive feedback and the person can recover, as shown by the dashed curve of **Figure 1-4**.

Positive Feedback Can Sometimes Be Useful. The body sometimes uses positive feedback to its advantage. Blood clotting is an example of a valuable use of positive feedback. When a blood vessel is ruptured, and a clot begins to form, multiple enzymes called *clotting factors* are activated within the clot. Some of these enzymes act on other inactivated enzymes of the immediately adjacent blood, thus causing more blood clotting. This process continues until the hole in the vessel is plugged and bleeding no longer occurs. On occasion, this mechanism can get out of hand and cause formation of unwanted clots. In fact, this is what initiates most acute heart attacks, which can be caused by a clot beginning on the inside surface of an atherosclerotic plaque in a coronary artery and then growing until the artery is blocked.

Childbirth is another situation in which positive feedback is valuable. When uterine contractions become strong enough for the baby’s head to begin pushing through the cervix, stretching of the cervix sends signals through the uterine muscle back to the body of the uterus, causing even more powerful contractions. Thus, the uterine contractions stretch the cervix, and cervical stretch causes stronger contractions. When this process becomes powerful enough, the baby is born. If they are not powerful enough, the contractions usually die out, and a few days pass before they begin again.

Another important use of positive feedback is for the generation of nerve signals. Stimulation of the membrane of a nerve fiber causes slight leakage of sodium ions through sodium channels in the nerve membrane to the fiber’s interior. The sodium ions entering the fiber then change the membrane potential, which, in turn, causes more opening of channels, more change of potential, still more opening of channels, and so forth. Thus, a slight leak becomes an explosion of sodium entering the interior of the nerve fiber, which creates the nerve action potential. This action potential, in turn, causes electrical current to flow along the outside and inside of the fiber and initiates additional action potentials. This process continues until the nerve signal goes all the way to the end of the fiber.

In each case in which positive feedback is useful, the positive feedback is part of an overall negative feedback process. For example, in the case of blood clotting, the positive feedback clotting process is a negative feedback process for the maintenance of normal blood volume. Also, the positive feedback that causes nerve signals allows the nerves to participate in thousands of negative feedback nervous control systems.

More Complex Types of Control Systems—Feed-Forward and Adaptive Control

Later in this text, when we study the nervous system, we shall see that this system contains great numbers of interconnected control mechanisms. Some are simple feedback systems similar to those already discussed. Many are not. For example, some movements of the body occur so rapidly that there is not enough time for nerve signals to travel from the peripheral parts of the body all the way to the brain and then back to the periphery again to control the movement. Therefore, the brain uses a mechanism called *feed-forward control* to cause required muscle contractions. Sensory nerve signals from the moving parts apprise the brain about whether the movement is performed correctly. If not, the brain corrects the feed-forward signals that it sends to the muscles the *next* time the movement is required. Then, if still further correction is necessary, this process will be performed again for subsequent movements. This process is called *adaptive control*. Adaptive control, in a sense, is delayed negative feedback.

Thus, one can see how complex the feedback control systems of the body can be. A person's life depends on all of them. Therefore, much of this text is devoted to discussing these life-giving mechanisms.

PHYSIOLOGICAL VARIABILITY

Although some physiological variables, such as plasma concentrations of potassium, calcium, and hydrogen ions, are tightly regulated, others, such as body weight and adiposity, show wide variation among different individuals and even in the same individual at different stages of life. Blood pressure, cardiac pumping, metabolic rate, nervous system activity, hormones, and other physiological variables change throughout the day as we move about and engage in normal daily activities. Therefore, when we discuss “normal” values, it is with the understanding that many of the body's control systems are constantly reacting to perturbations, and that variability may exist among different individuals, depending on body weight and height, diet, age, sex, environment, genetics, and other factors.

For simplicity, discussion of physiological functions often focuses on the “average” 70-kg young, lean male. However, the American male no longer weighs an average of 70 kg; he now weighs over 88 kg, and the average American female weighs over 76 kg, more than the average man in the 1960s. Body weight has also increased substantially in most other industrialized countries during the past 40 to 50 years.

Except for reproductive and hormonal functions, many other physiological functions and normal values are often discussed in terms of male physiology. However, there are clearly differences in male and female physiology beyond the obvious differences that relate to reproduction. These differences can have important consequences

for understanding normal physiology as well as for treatment of diseases.

Age-related and ethnic or racial differences in physiology also have important influences on body composition, physiological control systems, and pathophysiology of diseases. For example, in a lean young male the total body water is about 60% of body weight. As a person grows and ages, this percentage gradually decreases, partly because aging is usually associated with declining skeletal muscle mass and increasing fat mass. Aging may also cause a decline in the function and effectiveness of some organs and physiological control systems.

These sources of physiological variability—sex differences, aging, ethnic, and racial—are complex but important considerations when discussing normal physiology and the pathophysiology of diseases.

SUMMARY—AUTOMATICITY OF THE BODY

The main purpose of this chapter has been to discuss briefly the overall organization of the body and the means whereby the different parts of the body operate in harmony. To summarize, the body is actually a *social order of about 35 to 40 trillion cells* organized into different functional structures, some of which are called *organs*. Each functional structure contributes its share to the maintenance of homeostasis in the extracellular fluid, which is called the *internal environment*. As long as normal conditions are maintained in this internal environment, the cells of the body continue to live and function properly. Each cell benefits from homeostasis and, in turn, each cell contributes its share toward the maintenance of homeostasis. This reciprocal interplay provides continuous automaticity of the body until one or more functional systems lose their ability to contribute their share of function. When this happens, all the cells of the body suffer. Extreme dysfunction leads to death; moderate dysfunction leads to sickness.

The Cell and Its Functions

Each of the trillions of cells in a human being is a living structure that can survive for months or years, provided its surrounding fluids contain appropriate nutrients. Cells are the building blocks of the body, providing structure for the body's tissues and organs, ingesting nutrients and converting them to energy, and performing specialized functions. Cells also contain the body's hereditary code, which controls the substances synthesized by the cells and permits them to make copies of themselves.

ORGANIZATION OF THE CELL

A schematic drawing of a typical cell, as seen by the light microscope, is shown in [Figure 2-1](#). Its two major parts are the *nucleus* and the *cytoplasm*. The nucleus is separated from the cytoplasm by a *nuclear membrane*, and the cytoplasm is separated from the surrounding fluids by a *cell membrane*, also called the *plasma membrane*.

The different substances that make up the cell are collectively called *protoplasm*. Protoplasm is composed mainly of five basic substances—water, electrolytes, proteins, lipids, and carbohydrates.

Water. Most cells, except for fat cells, are comprised mainly of water in a concentration of 70% to 85%. Many cellular chemicals are dissolved in the water. Others are suspended in the water as solid particulates. Chemical reactions take place among the dissolved chemicals or at the surfaces of the suspended particles or membranes.

Ions. Important ions in the cell include *potassium*, *magnesium*, *phosphate*, *sulfate*, *bicarbonate*, and smaller quantities of *sodium*, *chloride*, and *calcium*. These ions are all discussed in [Chapter 4](#), which considers the interrelations between the intracellular and extracellular fluids.

The ions provide inorganic chemicals for cellular reactions and are necessary for the operation of some cellular control mechanisms. For example, ions acting at the cell membrane are required for the transmission of electrochemical impulses in nerve and muscle fibers.

Proteins. After water, the most abundant substances in most cells are proteins, which normally constitute 10% to

20% of the cell mass. These proteins can be divided into two types, *structural proteins* and *functional proteins*.

Structural proteins are present in the cell mainly in the form of long filaments that are polymers of many individual protein molecules. A prominent use of such intracellular filaments is to form *microtubules*, which provide the cytoskeletons of cellular organelles such as cilia, nerve axons, the mitotic spindles of cells undergoing mitosis, and a tangled mass of thin filamentous tubules that hold the parts of the cytoplasm and nucleoplasm together in their respective compartments. Fibrillar proteins are found outside the cell, especially in the collagen and elastin fibers of connective tissue, and elsewhere, such as in blood vessel walls, tendons, and ligaments.

The *functional proteins* are usually composed of combinations of a few molecules in tubular-globular form. These proteins are mainly the *enzymes* of the cell and, in contrast to the fibrillar proteins, are often mobile in the cell fluid. Also, many of them are adherent to membranous structures inside the cell and catalyze specific intracellular chemical reactions. For example, the chemical reactions that split glucose into its component parts and then combine these with oxygen to form carbon dioxide and water while simultaneously providing energy for cellular function are all catalyzed by a series of protein enzymes.

Lipids. Lipids are several types of substances that are grouped together because of their common property of being soluble in fat solvents. Especially important lipids

Figure 2-1. Illustration of cell structures visible with a light microscope.

Figure 2-2. Reconstruction of a typical cell, showing the internal organelles in the cytoplasm and nucleus.

are *phospholipids* and *cholesterol*, which together constitute only about 2% of the total cell mass. Phospholipids and cholesterol are mainly insoluble in water and therefore are used to form the cell membrane and intracellular membrane barriers that separate the different cell compartments.

In addition to phospholipids and cholesterol, some cells contain large quantities of *triglycerides*, also called *neutral fats*. In *fat cells (adipocytes)*, triglycerides often account for as much as 95% of the cell mass. The fat stored in these cells represents the body's main storehouse of energy-giving nutrients that can later be used to provide energy wherever it is needed in the body.

Carbohydrates. Carbohydrates play a major role in cell nutrition and, as parts of glycoprotein molecules, have structural functions. Most human cells do not maintain large stores of carbohydrates; the amount usually averages only about 1% of their total mass but increases to as much as 3% in muscle cells and, occasionally, to 6% in liver cells. However, carbohydrate in the form of dissolved glucose is always present in the surrounding extracellular fluid so

that it is readily available to the cell. Also, a small amount of carbohydrate is stored in cells as *glycogen*, an insoluble polymer of glucose that can be depolymerized and used rapidly to supply the cell's energy needs.

CELL STRUCTURE

The cell contains highly organized physical structures called *intracellular organelles*, which are critical for cell function. For example, without one of the organelles, the *mitochondria*, more than 95% of the cell's energy release from nutrients would cease immediately. The most important organelles and other structures of the cell are shown in [Figure 2-2](#).

MEMBRANOUS STRUCTURES OF THE CELL

Most organelles of the cell are covered by membranes composed primarily of lipids and proteins. These membranes include the *cell membrane*, *nuclear membrane*, *membrane of the endoplasmic reticulum*, and *membranes of the mitochondria, lysosomes, and Golgi apparatus*.

Figure 2-3. Structure of the cell membrane showing that it is composed mainly of a lipid bilayer of phospholipid molecules, but with large numbers of protein molecules protruding through the layer. Also, carbohydrate moieties are attached to the protein molecules on the outside of the membrane and to additional protein molecules on the inside.

The lipids in membranes provide a barrier that impedes movement of water and water-soluble substances from one cell compartment to another because water is not soluble in lipids. However, protein molecules often penetrate all the way through membranes, thus providing specialized pathways, often organized into actual *pores*, for passage of specific substances through membranes. Also, many other membrane proteins are *enzymes*, which catalyze a multitude of different chemical reactions, discussed here and in subsequent chapters.

Cell Membrane

The cell membrane (also called the *plasma membrane*) envelops the cell and is a thin, pliable, elastic structure only 7.5 to 10 nanometers thick. It is composed almost entirely of proteins and lipids. The approximate composition is 55% proteins, 25% phospholipids, 13% cholesterol, 4% other lipids, and 3% carbohydrates.

The Cell Membrane Lipid Barrier Impedes Penetration by Water-Soluble Substances. **Figure 2-3** shows the structure of the cell membrane. Its basic structure is a *lipid bilayer*, which is a thin, double-layered film of lipids—each layer only one molecule thick—that is

continuous over the entire cell surface. Interspersed in this lipid film are large globular proteins.

The basic lipid bilayer is composed of three main types of lipids—*phospholipids*, *sphingolipids*, and *cholesterol*. Phospholipids are the most abundant cell membrane lipids. One end of each phospholipid molecule is *hydrophilic* and soluble in water. The other end is *hydrophobic* and soluble only in fats. The phosphate end of the phospholipid is hydrophilic, and the fatty acid portion is hydrophobic.

Because the hydrophobic portions of the phospholipid molecules are repelled by water but are mutually attracted to one another, they have a natural tendency to attach to one another in the middle of the membrane, as shown in **Figure 2-3**. The hydrophilic phosphate portions then constitute the two surfaces of the complete cell membrane, in contact with *intracellular* water on the inside of the membrane and *extracellular* water on the outside surface.

The lipid layer in the middle of the membrane is impermeable to the usual water-soluble substances, such as ions, glucose, and urea. Conversely, fat-soluble substances, such as oxygen, carbon dioxide, and alcohol, can penetrate this portion of the membrane with ease.

Sphingolipids, derived from the amino alcohol *sphingosine*, also have hydrophobic and hydrophilic groups and

are present in small amounts in the cell membranes, especially nerve cells. Complex sphingolipids in cell membranes are thought to serve several functions, including protection from harmful environmental factors, signal transmission, and adhesion sites for extracellular proteins.

Cholesterol molecules in membranes are also lipids because their steroid nuclei are highly fat-soluble. These molecules, in a sense, are dissolved in the bilayer of the membrane. They mainly help determine the degree of permeability (or impermeability) of the bilayer to water-soluble constituents of body fluids. Cholesterol controls much of the fluidity of the membrane as well.

Integral and Peripheral Cell Membrane Proteins.

Figure 2-3 also shows globular masses floating in the lipid bilayer. These membrane proteins are mainly *glycoproteins*. There are two types of cell membrane proteins, *integral proteins*, which protrude all the way through the membrane, and *peripheral proteins*, which are attached only to one surface of the membrane and do not penetrate all the way through.

Many of the integral proteins provide structural *channels* (or *pores*) through which water molecules and water-soluble substances, especially ions, can diffuse between extracellular and intracellular fluids. These protein channels also have selective properties that allow preferential diffusion of some substances over others.

Other integral proteins act as *carrier proteins* for transporting substances that otherwise could not penetrate the lipid bilayer. Sometimes, these carrier proteins even transport substances in the direction opposite to their electrochemical gradients for diffusion, which is called *active transport*. Still others act as *enzymes*.

Integral membrane proteins can also serve as *receptors* for water-soluble chemicals, such as peptide hormones, that do not easily penetrate the cell membrane. Interaction of cell membrane receptors with specific *ligands* that bind to the receptor causes conformational changes in the receptor protein. This process, in turn, enzymatically activates the intracellular part of the protein or induces interactions between the receptor and proteins in the cytoplasm that act as *second messengers*, relaying the signal from the extracellular part of the receptor to the interior of the cell. In this way, integral proteins spanning the cell membrane provide a means of conveying information about the environment to the cell interior.

Peripheral protein molecules are often attached to integral proteins. These peripheral proteins function almost entirely as enzymes or as controllers of transport of substances through cell membrane *pores*.

Membrane Carbohydrates—The Cell “Glycocalyx.”

Membrane carbohydrates occur almost invariably in combination with proteins or lipids in the form of *glycoproteins* or *glycolipids*. In fact, most of the integral proteins are glycoproteins, and about one-tenth of the membrane lipid molecules are glycolipids. The *glyco-* portions of

these molecules almost invariably protrude to the outside of the cell, dangling outward from the cell surface. Many other carbohydrate compounds, called *proteoglycans*—which are mainly carbohydrates bound to small protein cores—are loosely attached to the outer surface of the cell as well. Thus, the entire outside surface of the cell often has a loose carbohydrate coat called the *glycocalyx*.

The carbohydrate moieties attached to the outer surface of the cell have several important functions:

1. Many of them have a negative electrical charge, which gives most cells an overall negative surface charge that repels other negatively charged objects.
2. The glycocalyx of some cells attaches to the glycocalyx of other cells, thus attaching cells to one another.
3. Many of the carbohydrates act as *receptors* for binding hormones, such as insulin. When bound, this combination activates attached internal proteins that in turn activate a cascade of intracellular enzymes.
4. Some carbohydrate moieties enter into immune reactions, as discussed in [Chapter 35](#).

CYTOPLASM AND ITS ORGANELLES

The cytoplasm is filled with minute and large dispersed particles and organelles. The jelly-like fluid portion of the cytoplasm in which the particles are dispersed is called *cytosol* and contains mainly dissolved proteins, electrolytes, and glucose.

Dispersed in the cytoplasm are neutral fat globules, glycogen granules, ribosomes, secretory vesicles, and five especially important organelles—the *endoplasmic reticulum*, the *Golgi apparatus*, *mitochondria*, *lysosomes*, and *peroxisomes*.

Endoplasmic Reticulum

Figure 2-2 shows the *endoplasmic reticulum*, a network of tubular structures called *cisternae* and flat vesicular structures in the cytoplasm. This organelle helps process molecules made by the cell and transports them to their specific destinations inside or outside the cell. The tubules and vesicles interconnect. Also, their walls are constructed of lipid bilayer membranes that contain large amounts of proteins, similar to the cell membrane. The total surface area of this structure in some cells—the liver cells, for example—can be as much as 30 to 40 times the cell membrane area.

The detailed structure of a small portion of endoplasmic reticulum is shown in **Figure 2-4**. The space inside the tubules and vesicles is filled with *endoplasmic matrix*, a watery medium that is different from fluid in the cytosol outside the endoplasmic reticulum. Electron micrographs show that the space inside the endoplasmic reticulum is connected with the space between the two membrane surfaces of the nuclear membrane.

Substances formed in some parts of the cell enter the space of the endoplasmic reticulum and are then directed to other parts of the cell. Also, the vast surface area of this

Figure 2-4. Structure of the endoplasmic reticulum.

reticulum and the multiple enzyme systems attached to its membranes provide the mechanisms for a major share of the cell's metabolic functions.

Ribosomes and the Rough (Granular) Endoplasmic Reticulum. Attached to the outer surfaces of many parts of the endoplasmic reticulum are large numbers of minute granular particles called *ribosomes*. Where these particles are present, the reticulum is called the *rough (granular) endoplasmic reticulum*. The ribosomes are composed of a mixture of RNA and proteins; they function to synthesize new protein molecules in the cell, as discussed later in this chapter and in [Chapter 3](#).

Smooth (Agranular) Endoplasmic Reticulum. Part of the endoplasmic reticulum has no attached ribosomes. This part is called the *smooth, or agranular, endoplasmic reticulum*. The smooth reticulum functions for the synthesis of lipid substances and for other processes of the cells promoted by intrareticular enzymes.

Golgi Apparatus

The Golgi apparatus, shown in [Figure 2-5](#), is closely related to the endoplasmic reticulum. It has membranes similar to those of the smooth endoplasmic reticulum. The Golgi apparatus is usually composed of four or more stacked layers of thin, flat, enclosed vesicles lying near one side of the nucleus. This apparatus is prominent in secretory cells, where it is located on the side of the cell from which secretory substances are extruded.

The Golgi apparatus functions in association with the endoplasmic reticulum. As shown in [Figure 2-5](#), small *transport vesicles* (also called *endoplasmic reticulum vesicles* [*ER vesicles*]) continually pinch off from the endoplasmic reticulum and shortly thereafter fuse with the Golgi apparatus. In this way, substances entrapped in ER

Figure 2-5. A typical Golgi apparatus and its relationship to the endoplasmic reticulum (ER) and the nucleus.

vesicles are transported from the endoplasmic reticulum to the Golgi apparatus. The transported substances are then processed in the Golgi apparatus to form lysosomes, secretory vesicles, and other cytoplasmic components (discussed later in this chapter).

Lysosomes

Lysosomes, shown in [Figure 2-2](#), are vesicular organelles that form by breaking off from the Golgi apparatus; they then disperse throughout the cytoplasm. The lysosomes provide an *intracellular digestive system* that allows the cell to digest the following: (1) damaged cellular structures; (2) food particles that have been ingested by the cell; and (3) unwanted matter such as bacteria. Lysosomes are different in various cell types but are usually 250 to 750 nanometers in diameter. They are surrounded by typical lipid bilayer membranes and are filled with large numbers of small granules, 5 to 8 nanometers in diameter, which are protein aggregates of as many as 40 different *hydrolase (digestive) enzymes*. A hydrolytic enzyme is capable of splitting an organic compound into two or more parts by combining hydrogen from a water molecule with one part of the compound and combining the hydroxyl portion of the water molecule with the other part of the compound. For example, protein is hydrolyzed to form amino acids, glycogen is hydrolyzed to form glucose, and lipids are hydrolyzed to form fatty acids and glycerol.

Hydrolytic enzymes are highly concentrated in lysosomes. Ordinarily, the membrane surrounding the lysosome prevents the enclosed hydrolytic enzymes from coming into contact with other substances in the cell and therefore prevents their digestive actions. However, some conditions of the cell break the membranes of lysosomes, allowing release of the digestive enzymes. These enzymes then split the organic substances with which they come in contact into small, highly diffusible substances such as

Figure 2-6. Secretory granules (secretory vesicles) in acinar cells of the pancreas.

amino acids and glucose. Some of the specific functions of lysosomes are discussed later in this chapter.

Peroxisomes

Peroxisomes are physically similar to lysosomes, but they are different in two important ways. First, they are believed to be formed by self-replication (or perhaps by budding off from the smooth endoplasmic reticulum) rather than from the Golgi apparatus. Second, they contain *oxidases* rather than hydrolases. Several of the oxidases are capable of combining oxygen with hydrogen ions derived from different intracellular chemicals to form hydrogen peroxide (H_2O_2). Hydrogen peroxide is a highly oxidizing substance and is used in association with *catalase*, another oxidase enzyme present in large quantities in peroxisomes, to oxidize many substances that might otherwise be poisonous to the cell. For example, about half the alcohol that a person drinks is detoxified into acetaldehyde by the peroxisomes of the liver cells in this manner. A major function of peroxisomes is to catabolize long-chain fatty acids.

Secretory Vesicles

One of the important functions of many cells is secretion of special chemical substances. Almost all such secretory substances are formed by the endoplasmic reticulum–Golgi apparatus system and are then released from the Golgi apparatus into the cytoplasm in the form of storage vesicles called *secretory vesicles* or *secretory granules*. **Figure 2-6** shows typical secretory vesicles inside pancreatic acinar cells; these vesicles store protein proenzymes (enzymes that are not yet activated). The proenzymes are secreted later through the outer cell membrane into the pancreatic duct and then into the duodenum, where they become activated and perform digestive functions on the food in the intestinal tract.

Mitochondria

The mitochondria, shown in **Figure 2-2** and **Figure 2-7**, are called the *powerhouses* of the cell. Without them, cells would be unable to extract enough energy from the nutrients, and essentially all cellular functions would cease.

Figure 2-7. Structure of a mitochondrion.

Mitochondria are present in all areas of each cell's cytoplasm, but the total number per cell varies from less than 100 up to several thousand, depending on the energy requirements of the cell. Cardiac muscle cells (cardiomyocytes), for example, use large amounts of energy and have far more mitochondria than fat cells (adipocytes), which are much less active and use less energy. Furthermore, the mitochondria are concentrated in those portions of the cell responsible for the major share of its energy metabolism. They are also variable in size and shape. Some mitochondria are only a few hundred nanometers in diameter and are globular in shape, whereas others are elongated and are as large as 1 micrometer in diameter and 7 micrometers long. Still others are branching and filamentous.

The basic structure of the mitochondrion, shown in **Figure 2-7**, is composed mainly of two lipid bilayer-protein membranes, an *outer membrane* and an *inner membrane*. Many infoldings of the inner membrane form shelves or tubules called *cristae* onto which oxidative enzymes are attached. The cristae provide a large surface area for chemical reactions to occur. In addition, the inner cavity of the mitochondrion is filled with a *matrix* that contains large quantities of dissolved enzymes necessary for extracting energy from nutrients. These enzymes operate in association with oxidative enzymes on the cristae to cause oxidation of nutrients, thereby forming carbon dioxide and water and, at the same time, releasing energy. The liberated energy is used to synthesize a high-energy substance called *adenosine triphosphate* (ATP). ATP is then transported out of the mitochondrion and diffuses throughout the cell to release its own energy wherever it is needed for performing cellular functions. The chemical details of ATP formation by the mitochondrion are provided in **Chapter 68**, but some basic functions of ATP in the cell are introduced later in this chapter.

Mitochondria are self-replicative, which means that one mitochondrion can form a second one, a third one, and so on whenever the cell needs increased amounts of ATP. Indeed, the mitochondria contain DNA similar to that found in the cell nucleus. In **Chapter 3**, we will see that DNA is the basic constituent of the nucleus that

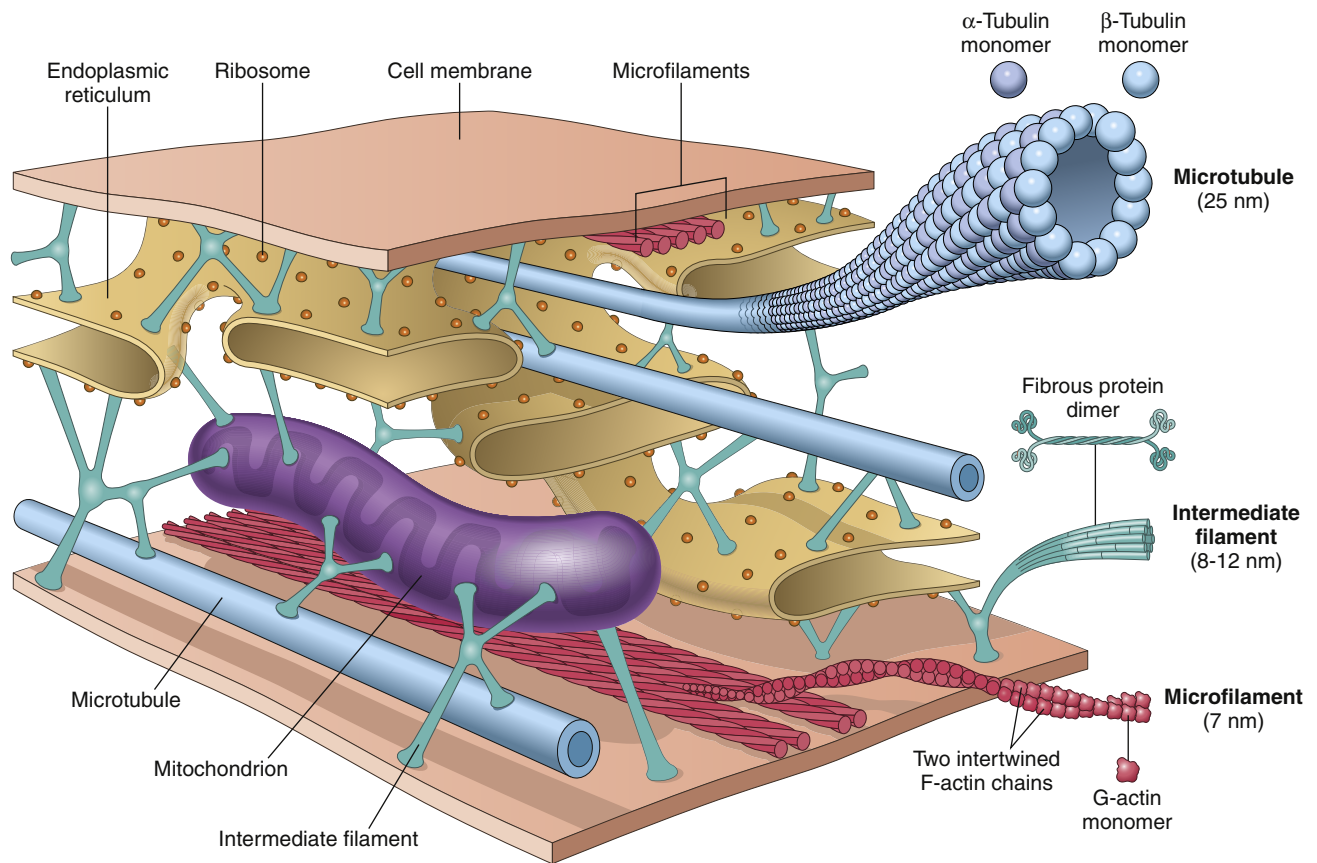

Figure 2-8. Cell cytoskeleton composed of protein fibers called microfilaments, intermediate filaments, and microtubules.

controls replication of the cell. The DNA of the mitochondrion plays a similar role, controlling replication of the mitochondrion. Cells that are faced with increased energy demands—for example, in skeletal muscles subjected to chronic exercise training—may increase the density of mitochondria to supply the additional energy required.

Cell Cytoskeleton—Filament and Tubular Structures

The cell cytoskeleton is a network of fibrillar proteins organized into filaments or tubules. These originate as precursor proteins synthesized by ribosomes in the cytoplasm. The precursor molecules then polymerize to form *filaments* (Figure 2-8). As an example, large numbers of actin *microfilaments* frequently occur in the outer zone of the cytoplasm, called the *ectoplasm*, to form an elastic support for the cell membrane. Also, in muscle cells, actin and myosin filaments are organized into a special contractile machine that is the basis for muscle contraction, as discussed in Chapter 6.

Intermediate filaments are generally strong ropelike filaments that often work together with microtubules, providing strength and support for the fragile tubulin structures. They are called *intermediate* because their average diameter is between that of narrower actin microfilaments and wider myosin filaments found in muscle cells. Their functions are mainly mechanical, and they are less dynamic than actin microfilaments or microtubules.

All cells have intermediate filaments, although the protein subunits of these structures vary, depending on the cell type. Specific intermediate filaments found in various cells include desmin filaments in muscle cells, neurofilaments in neurons, and keratins in epithelial cells.

A special type of stiff filament composed of polymerized *tubulin* molecules is used in all cells to construct strong tubular structures, the *microtubules*. Figure 2-8 shows typical microtubules of a cell.

Another example of microtubules is the tubular skeletal structure in the center of each cilium that radiates upward from the cell cytoplasm to the tip of the cilium. This structure is discussed later in the chapter (see Figure 2-18). Also, both the *centrioles* and *mitotic spindles* of cells undergoing mitosis are composed of stiff microtubules.

A major function of microtubules is to act as a *cytoskeleton*, providing rigid physical structures for certain parts of cells. The cell cytoskeleton not only determines cell shape but also participates in cell division, allows cells to move, and provides a tracklike system that directs the movement of organelles in the cells. Microtubules serve as the conveyor belts for the intracellular transport of vesicles, granules, and organelles such as mitochondria.

Nucleus

The nucleus is the control center of the cell and sends messages to the cell to grow and mature, replicate, or die. Briefly, the nucleus contains large quantities of DNA,

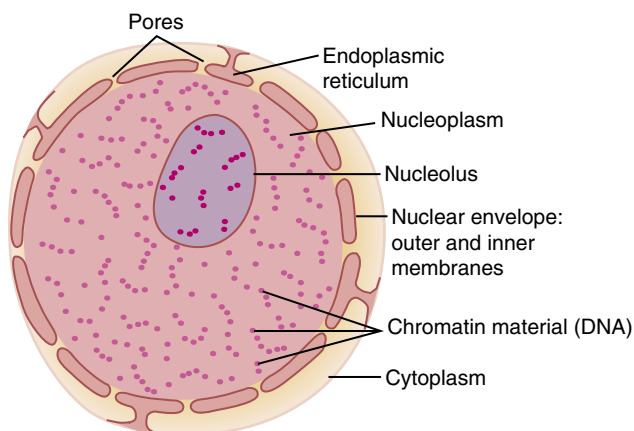

Figure 2-9. Structure of the nucleus.

which comprise the *genes*. The genes determine the characteristics of the cell's proteins, including the structural proteins, as well as the intracellular enzymes that control cytoplasmic and nuclear activities.

The genes also control and promote cell reproduction. The genes first reproduce to create two identical sets of genes; then the cell splits by a special process called *mitosis* to form two daughter cells, each of which receives one of the two sets of DNA genes. All these activities of the nucleus are discussed in [Chapter 3](#).

Unfortunately, the appearance of the nucleus under the microscope does not provide many clues to the mechanisms whereby the nucleus performs its control activities. [Figure 2-9](#) shows the light microscopic appearance of the *interphase* nucleus (during the period between mitoses), revealing darkly staining *chromatin material* throughout the nucleoplasm. During mitosis, the chromatin material organizes in the form of highly structured *chromosomes*, which can then be easily identified using the light microscope, as illustrated in [Chapter 3](#).

Nuclear Membrane. The *nuclear membrane*, also called the *nuclear envelope*, is actually two separate bilayer membranes, one inside the other. The outer membrane is continuous with the endoplasmic reticulum of the cell cytoplasm, and the space between the two nuclear membranes is also continuous with the space inside the endoplasmic reticulum, as shown in [Figure 2-9](#).

The nuclear membrane is penetrated by several thousand *nuclear pores*. Large complexes of proteins are attached at the edges of the pores so that the central area of each pore is only about 9 nanometers in diameter. Even this size is large enough to allow molecules up to a molecular weight of 44,000 to pass through with reasonable ease.

Nucleoli and Formation of Ribosomes. The nuclei of most cells contain one or more highly staining structures called *nucleoli*. The nucleolus, unlike most other organelles discussed here, does not have a limiting membrane. Instead, it is simply an accumulation of large amounts of

Figure 2-10. Comparison of sizes of precellular organisms with that of the average cell in the human body.

RNA and proteins of the types found in ribosomes. The nucleolus enlarges considerably when the cell is actively synthesizing proteins.

Formation of the nucleoli (and of the ribosomes in the cytoplasm outside the nucleus) begins in the nucleus. First, specific DNA genes in the chromosomes cause RNA to be synthesized. Some of this synthesized RNA is stored in the nucleoli, but most of it is transported outward through the nuclear pores into the cytoplasm. Here it is used in conjunction with specific proteins to assemble “mature” ribosomes that play an essential role in forming cytoplasmic proteins, as discussed in [Chapter 3](#).

COMPARISON OF THE ANIMAL CELL WITH PRECELLULAR FORMS OF LIFE

The cell is a complicated organism that required many hundreds of millions of years to develop after the earliest forms of life, microorganisms that may have been similar to present-day *viruses*, first appeared on earth. [Figure 2-10](#) shows the relative sizes of the following: (1) the smallest known virus; (2) a large virus; (3) a *Rickettsia*; (4) a *bacterium*; and (5) a *nucleated cell*. This demonstrates that the cell has a diameter about 1000 times that of the smallest virus and therefore a volume about 1 billion times that of the smallest virus. Correspondingly, the functions and anatomical organization of the cell are also far more complex than those of the virus.

The essential life-giving constituent of the small virus is a *nucleic acid* embedded in a coat of protein. This nucleic acid is composed of the same basic nucleic acid constituents (DNA or RNA) found in mammalian cells and is capable of reproducing itself under appropriate conditions. Thus, the virus propagates its lineage from generation to generation and is therefore a living structure in the same way that cells and humans are living structures.

As life evolved, other chemicals in addition to nucleic acid and simple proteins became integral parts of the organism, and specialized functions began to develop in different parts of the virus. A membrane formed

around the virus and, inside the membrane, a fluid matrix appeared. Specialized chemicals then developed inside the fluid to perform special functions; many protein enzymes appeared that were capable of catalyzing chemical reactions, thus determining the organism's activities.

In still later stages of life, particularly in the rickettsial and bacterial stages, *organelles* developed inside the organism. These represent physical structures of chemical aggregates that perform functions in a more efficient manner than what can be achieved by dispersed chemicals throughout the fluid matrix.

Finally, in the nucleated cell, still more complex organelles developed, the most important of which is the *nucleus*. The nucleus distinguishes this type of cell from all lower forms of life; it provides a control center for all cellular activities and for reproduction of new cells generation after generation, with each new cell having almost exactly the same structure as its progenitor.

FUNCTIONAL SYSTEMS OF THE CELL

In the remainder of this chapter, we discuss some functional systems of the cell that make it a living organism.

ENDOCYTOSIS—INGESTION BY THE CELL

If a cell is to live and grow and reproduce, it must obtain nutrients and other substances from the surrounding fluids. Most substances pass through the cell membrane by the processes of diffusion and *active transport*.

Diffusion involves simple movement through the membrane caused by the random motion of the molecules of the substance. Substances move through cell membrane pores or, in the case of lipid-soluble substances, through the lipid matrix of the membrane.

Active transport involves actually carrying a substance through the membrane by a physical protein structure that penetrates all the way through the membrane. These active transport mechanisms are so important to cell function that they are presented in detail in [Chapter 4](#).

Large particles enter the cell by a specialized function of the cell membrane called *endocytosis* (Video 2-1). The principal forms of endocytosis are *pinocytosis* and *phagocytosis*. Pinocytosis means the ingestion of minute particles that form vesicles of extracellular fluid and particulate constituents inside the cell cytoplasm. Phagocytosis means the ingestion of large particles, such as bacteria, whole cells, or portions of degenerating tissue.

Pinocytosis. Pinocytosis occurs continually in the cell membranes of most cells, but is especially rapid in some cells. For example, it occurs so rapidly in macrophages that about 3% of the total macrophage membrane is engulfed in the form of vesicles each minute. Even so, the pinocytotic vesicles are so small—usually only 100 to 200 nanometers in diameter—that most of them can be seen only with an electron microscope.

Figure 2-11. Mechanism of pinocytosis.

Pinocytosis is the only means whereby most large macromolecules, such as most proteins, can enter cells. In fact, the rate at which pinocytotic vesicles form is usually enhanced when such macromolecules attach to the cell membrane.

Figure 2-11 demonstrates the successive steps of pinocytosis (A–D), showing three molecules of protein attaching to the membrane. These molecules usually attach to specialized protein *receptors* on the surface of the membrane that are specific for the type of protein that is to be absorbed. The receptors generally are concentrated in small pits on the outer surface of the cell membrane, called *coated pits*. On the inside of the cell membrane beneath these pits is a latticework of fibrillar protein called *clathrin*, as well as other proteins, perhaps including contractile filaments of *actin* and *myosin*. Once the protein molecules have bound with the receptors, the surface properties of the local membrane change in such a way that the entire pit invaginates inward, and fibrillar proteins surrounding the invaginating pit cause its borders to close over the attached proteins, as well as over a small amount of extracellular fluid. Immediately thereafter, the invaginated portion of the membrane breaks away from the surface of the cell, forming a *pinocytotic vesicle* inside the cytoplasm of the cell.

What causes the cell membrane to go through the necessary contortions to form pinocytotic vesicles is still unclear. This process requires energy from within the cell, which is supplied by ATP, a high-energy substance discussed later in this chapter. This process also requires the presence of calcium ions in the extracellular fluid, which probably react with contractile protein filaments beneath the coated pits to provide the force for pinching the vesicles away from the cell membrane.

Phagocytosis. Phagocytosis occurs in much the same way as pinocytosis, except that it involves large particles rather than molecules. Only certain cells have the capability of phagocytosis—notably, tissue macrophages and some white blood cells.

Figure 2-12. Digestion of substances in pinocytotic or phagocytic vesicles by enzymes derived from lysosomes.

Phagocytosis is initiated when a particle such as a bacterium, dead cell, or tissue debris binds with receptors on the surface of the phagocyte. In the case of bacteria, each bacterium is usually already attached to a specific antibody; it is the antibody that attaches to the phagocyte receptors, dragging the bacterium along with it. This intermediation of antibodies is called *opsonization*, which is discussed in [Chapters 34 and 35](#).

Phagocytosis occurs in the following steps:

1. The cell membrane receptors attach to the surface ligands of the particle.
2. The edges of the membrane around the points of attachment evaginate outward within a fraction of a second to surround the entire particle; then, progressively more and more membrane receptors attach to the particle ligands. All this occurs suddenly in a zipper-like manner to form a closed *phagocytic vesicle*.
3. Actin and other contractile fibrils in the cytoplasm surround the phagocytic vesicle and contract around its outer edge, pushing the vesicle to the interior.
4. The contractile proteins then pinch the stem of the vesicle so completely that the vesicle separates from the cell membrane, leaving the vesicle in the cell interior in the same way that pinocytotic vesicles are formed.

LYSOSOMES DIGEST PINOCYTOTIC AND PHAGOCYTTIC FOREIGN SUBSTANCES INSIDE THE CELL

Almost immediately after a pinocytotic or phagocytic vesicle appears inside a cell, one or more *lysosomes* become attached to the vesicle and empty their *acid hydrolases* to the inside of the vesicle, as shown in [Figure 2-12](#). Thus, a *digestive vesicle* is formed inside the cell cytoplasm in which the vesicular hydrolases begin hydrolyzing the

proteins, carbohydrates, lipids, and other substances in the vesicle. The products of digestion are small molecules of substances such as amino acids, glucose, and phosphates that can diffuse through the membrane of the vesicle into the cytoplasm. What is left of the digestive vesicle, called the *residual body*, represents indigestible substances. In most cases, the residual body is finally excreted through the cell membrane by a process called *exocytosis*, which is essentially the opposite of endocytosis. Thus, the pinocytotic and phagocytic vesicles containing lysosomes can be called the *digestive organs* of the cells.

Lysosomes and Regression of Tissues and Autolysis of Damaged Cells. Tissues of the body often regress to a smaller size. For example, this regression occurs in the uterus after pregnancy, in muscles during long periods of inactivity, and in mammary glands at the end of lactation. Lysosomes are responsible for much of this regression.

Another special role of the lysosomes is the removal of damaged cells or damaged portions of cells from tissues. Damage to the cell—caused by heat, cold, trauma, chemicals, or any other factor—induces lysosomes to rupture. The released hydrolases immediately begin to digest the surrounding organic substances. If the damage is slight, only a portion of the cell is removed, and the cell is then repaired. If the damage is severe, the entire cell is digested, a process called *autolysis*. In this way, the cell is completely removed, and a new cell of the same type is formed, ordinarily by mitotic reproduction of an adjacent cell to take the place of the old one.

The lysosomes also contain bactericidal agents that can kill phagocytized bacteria before they cause cellular damage. These agents include the following: (1) *lysozyme*, which dissolves the bacterial cell wall; (2) *lysoferrin*, which binds iron and other substances before they can promote bacterial growth; and (3) acid at a pH of about 5.0, which activates the hydrolases and inactivates bacterial metabolic systems.

Autophagy and Recycling of Cell Organelles.

Lysosomes play a key role in the process of *autophagy*, which literally means “to eat oneself.” Autophagy is a housekeeping process whereby obsolete organelles and large protein aggregates are degraded and recycled ([Figure 2-13](#)). Worn-out cell organelles are transferred to lysosomes by double-membrane structures called *autophagosomes*, which are formed in the cytosol. Invagination of the lysosomal membrane and the formation of vesicles provides another pathway for cytosolic structures to be transported into the lumen of lysosomes. Once inside the lysosomes, the organelles are digested, and the nutrients are reused by the cell. Autophagy contributes to the routine turnover of cytoplasmic components; it is a key mechanism for tissue development, cell survival when nutrients are scarce, and maintenance of homeostasis. In liver cells, for example, the average mitochondrion normally has a life span of only about 10 days before it is destroyed.

Figure 2-13. Schematic diagram of autophagy steps.

SYNTHESIS OF CELLULAR STRUCTURES BY ENDOPLASMIC RETICULUM AND GOLGI APPARATUS

Endoplasmic Reticulum Functions

The extensiveness of the endoplasmic reticulum and Golgi apparatus in secretory cells has already been emphasized. These structures are formed primarily of lipid bilayer membranes, similar to the cell membrane, and their walls are loaded with protein enzymes that catalyze the synthesis of many substances required by the cell.

Most synthesis begins in the endoplasmic reticulum. The products formed there are then passed on to the Golgi apparatus, where they are further processed before being released into the cytoplasm. First, however, let us note the specific products that are synthesized in specific portions of the endoplasmic reticulum and Golgi apparatus.

Proteins Synthesis by the Rough Endoplasmic Reticulum. The rough endoplasmic reticulum is characterized by large numbers of ribosomes attached to the outer surfaces of the endoplasmic reticulum membrane. As discussed in Chapter 3, protein molecules are synthesized within the structures of the ribosomes. The ribosomes extrude some of the synthesized protein molecules directly into the cytosol, but they also extrude many more through the wall of the endoplasmic reticulum to the interior of the endoplasmic vesicles and tubules into the *endoplasmic matrix*.

Lipid Synthesis by the Smooth Endoplasmic Reticulum. The endoplasmic reticulum also synthesizes lipids, especially phospholipids and cholesterol. These lipids are rapidly incorporated into the lipid bilayer of the endoplasmic reticulum, thus causing the endoplasmic reticulum to grow more extensive. This process occurs mainly in the smooth portion of the endoplasmic reticulum.

To keep the endoplasmic reticulum from growing beyond the needs of the cell, small vesicles called *ER vesicles* or *transport vesicles* continually break away from the smooth reticulum; most of these vesicles then migrate rapidly to the Golgi apparatus.

Other Functions of the Endoplasmic Reticulum. Other significant functions of the endoplasmic reticulum, especially the smooth reticulum, include the following:

1. It provides the enzymes that control glycogen breakdown when glycogen is to be used for energy.
2. It provides a vast number of enzymes that are capable of detoxifying substances, such as drugs, that might damage the cell. It achieves detoxification by processes such as coagulation, oxidation, hydrolysis, and conjugation with glycuronic acid.

Golgi Apparatus Functions

Synthetic Functions of the Golgi Apparatus. Although a major function of the Golgi apparatus is to provide additional processing of substances already formed in the endoplasmic reticulum, it can also synthesize certain carbohydrates that cannot be formed in the endoplasmic reticulum. This is especially true for the formation of large saccharide polymers bound with small amounts of protein; important examples include *hyaluronic acid* and *chondroitin sulfate*.

A few of the many functions of hyaluronic acid and chondroitin sulfate in the body are as follows: (1) they are the major components of proteoglycans secreted in mucus and other glandular secretions; (2) they are the major components of the *ground substance*, or nonfibrous components of the extracellular matrix, outside the cells in the interstitial spaces, which act as fillers between collagen fibers and cells; (3) they are principal components of the organic matrix in both cartilage and bone; and (4) they are important in many cell activities, including migration and proliferation.

Figure 2-14. Formation of proteins, lipids, and cellular vesicles by the endoplasmic reticulum and Golgi apparatus.

Processing of Endoplasmic Secretions by the Golgi Apparatus—Formation of Vesicles. Figure 2-14 summarizes the major functions of the endoplasmic reticulum and Golgi apparatus. As substances are formed in the endoplasmic reticulum, especially proteins, they are transported through the tubules toward portions of the smooth endoplasmic reticulum that lie nearest to the Golgi apparatus. At this point, *transport vesicles* composed of small envelopes of smooth endoplasmic reticulum continually break away and diffuse to the *deepest layer* of the Golgi apparatus. Inside these vesicles are synthesized proteins and other products from the endoplasmic reticulum.

The transport vesicles instantly fuse with the Golgi apparatus and empty their contained substances into the vesicular spaces of the Golgi apparatus. Here, additional carbohydrate moieties are added to the secretions. Also, an important function of the Golgi apparatus is to compact the endoplasmic reticular secretions into highly concentrated packets. As the secretions pass toward the outermost layers of the Golgi apparatus, the compaction and processing proceed. Finally, both small and large vesicles continually break away from the Golgi apparatus, carrying with them the compacted secretory substances and diffusing throughout the cell.

The following example provides an idea of the timing of these processes. When a glandular cell is bathed in amino acids, newly formed protein molecules can be detected in the granular endoplasmic reticulum within 3 to 5 minutes. Within 20 minutes, newly formed proteins are already present in the Golgi apparatus and, within 1 to 2 hours, the proteins are secreted from the surface of the cell.

Types of Vesicles Formed by the Golgi Apparatus—Secretory Vesicles and Lysosomes. In a highly secretory cell, the vesicles formed by the Golgi apparatus are mainly *secretory vesicles* containing proteins that are secreted through the surface of the cell membrane. These secretory vesicles first diffuse to the cell membrane and then fuse with it and empty their substances to the exterior by the mechanism called *exocytosis*. Exocytosis, in most cases, is stimulated by entry of calcium ions into the cell. Calcium ions interact with the vesicular membrane and cause its fusion with the cell membrane, followed by exocytosis—opening of the membrane’s outer surface and extrusion of its contents outside the cell. Some vesicles, however, are destined for intracellular use.

Use of Intracellular Vesicles to Replenish Cellular Membranes. Some intracellular vesicles formed by the Golgi apparatus fuse with the cell membrane or with the membranes of intracellular structures such as the mitochondria and even the endoplasmic reticulum. This fusion increases the expanse of these membranes and replenishes the membranes as they are used up. For example, the cell membrane loses much of its substance every time it forms a phagocytic or pinocytotic vesicle, and the vesicular membranes of the Golgi apparatus continually replenish the cell membrane.

In summary, the membranous system of the endoplasmic reticulum and Golgi apparatus are highly metabolic and capable of forming new intracellular structures and secretory substances to be extruded from the cell.

THE MITOCHONDRIA EXTRACT ENERGY FROM NUTRIENTS

The principal substances from which cells extract energy are foods that react chemically with oxygen—carbohydrates, fats, and proteins. In the human body, essentially all carbohydrates are converted into *glucose* by the digestive tract and liver before they reach the other cells of the body. Similarly, proteins are converted into *amino acids*, and fats are converted into *fatty acids*. Figure 2-15 shows oxygen and the foodstuffs—glucose, fatty acids, and amino acids—all entering the cell. Inside the cell, they react chemically with oxygen under the influence of enzymes that control the reactions and channel the energy released in the proper direction. The details of all these digestive and metabolic functions are provided in Chapters 63 through 73.

Briefly, almost all these oxidative reactions occur inside the mitochondria, and the energy that is released is used to form the high-energy compound ATP. Then, ATP, not the original food, is used throughout the cell to energize almost all the subsequent intracellular metabolic reactions.

Figure 2-15. Formation of adenosine triphosphate (ATP) in the cell showing that most of the ATP is formed in the mitochondria. (ADP, Adenosine diphosphate; CoA, coenzyme A.)

Functional Characteristics of Adenosine Triphosphate

ATP is a nucleotide composed of the following: (1) the nitrogenous base *adenine*; (2) the pentose sugar *ribose*; and (3) three *phosphate radicals*. The last two phosphate radicals are connected with the remainder of the molecule by *high-energy phosphate bonds*, which are represented in the formula shown by the symbol \sim . *Under the physical and chemical conditions of the body*, each of these high-energy bonds contains about 12,000 calories of energy per mole of ATP, which is many times greater than the energy stored in the average chemical bond, thus giving rise to the term *high-energy bond*. Furthermore, the high-energy phosphate bond is very labile, so that it can be split instantly on demand whenever energy is required to promote other intracellular reactions.

When ATP releases its energy, a phosphoric acid radical is split away, and *adenosine diphosphate* (ADP) is formed. This released energy is used to energize many of

the cell's other functions, such as syntheses of substances and muscular contraction.

To reconstitute the cellular ATP as it is used up, energy derived from the cellular nutrients causes ADP and phosphoric acid to recombine to form new ATP, and the entire process is repeated over and over. For these reasons, ATP has been called the *energy currency* of the cell because it can be spent and reformed continually, having a turnover time of only a few minutes.

Chemical Processes in the Formation of ATP—Role of the Mitochondria.

On entry into the cells, glucose is converted by enzymes in the *cytoplasm* into *pyruvic acid* (a process called *glycolysis*). A small amount of ADP is changed into ATP by the energy released during this conversion, but this amount accounts for less than 5% of the overall energy metabolism of the cell.

About 95% of the cell's ATP formation occurs in the mitochondria. The pyruvic acid derived from carbohydrates, fatty acids from lipids, and amino acids from proteins is eventually converted into the compound *acetyl-coenzyme A* (CoA) in the matrix of mitochondria. This substance, in turn, is further dissolved (for the purpose of extracting its energy) by another series of enzymes in the mitochondrion matrix, undergoing dissolution in a sequence of chemical reactions called the *citric acid cycle*, or *Krebs cycle*. These chemical reactions are so important that they are explained in detail in [Chapter 68](#).

In this citric acid cycle, acetyl-CoA is split into its component parts, *hydrogen atoms* and *carbon dioxide*. The carbon dioxide diffuses out of the mitochondria and eventually out of the cell; finally, it is excreted from the body through the lungs.

The hydrogen atoms, conversely, are highly reactive; they combine with oxygen that has also diffused into the mitochondria. This combination releases a tremendous amount of energy, which is used by mitochondria to convert large amounts of ADP to ATP. The processes of these reactions are complex, requiring the participation of many protein enzymes that are integral parts of mitochondrial *membranous shelves* that protrude into the mitochondrial matrix. The initial event is the removal of an electron from the hydrogen atom, thus converting it to a hydrogen ion. The terminal event is the combination of hydrogen ions with oxygen to form water and the release of large amounts of energy to globular proteins that protrude like knobs from the membranes of the mitochondrial shelves; these proteins are called *ATP synthetase*. Finally, the enzyme ATP synthetase uses the energy from the hydrogen ions to convert ADP to ATP. The newly formed ATP is transported out of the mitochondria into all parts of the cell cytoplasm and nucleoplasm, where it energizes multiple cell functions.

This overall process for formation of ATP is called the *chemiosmotic mechanism* of ATP formation. The chemical and physical details of this mechanism are presented

Figure 2-16. Use of adenosine triphosphate (ATP; formed in the mitochondrion) to provide energy for three major cellular functions—membrane transport, protein synthesis, and muscle contraction. (ADP, Adenosine diphosphate.)

in [Chapter 68](#), and many of the detailed metabolic functions of ATP in the body are discussed in [Chapters 68 through 72](#).

Uses of ATP for Cellular Function. Energy from ATP is used to promote three major categories of cellular functions: (1) *transport* of substances through multiple cell membranes; (2) *synthesis of chemical compounds* throughout the cell; and (3) *mechanical work*. These uses of ATP are illustrated by the examples in [Figure 2-16](#): (1) to supply energy for the transport of sodium through the cell membrane; (2) to promote protein synthesis by the ribosomes; and (3) to supply the energy needed during muscle contraction.

In addition to the membrane transport of sodium, energy from ATP is required for the membrane transport of potassium, calcium, magnesium, phosphate, chloride, urate, and hydrogen ions and many other ions, as well as various organic substances. Membrane transport is so important to cell function that some cells—the renal tubular cells, for example—use as much as 80% of the ATP that they form for this purpose alone.

In addition to synthesizing proteins, cells make phospholipids, cholesterol, purines, pyrimidines, and many other substances. Synthesis of almost any chemical compound requires energy. For example, a single protein molecule might be composed of as many as several thousand amino acids attached to one another by peptide linkages. The formation of each of these linkages requires energy derived from the breakdown of four high-energy bonds; thus, many thousand ATP molecules must release their energy as each protein molecule is formed. Indeed, some cells use as much as 75% of all the ATP formed in the cell

Figure 2-17. Ameboid motion by a cell.

simply to synthesize new chemical compounds, especially protein molecules; this is particularly true during the growth phase of cells.

Another use of ATP is to supply energy for special cells to perform mechanical work. We discuss in [Chapter 6](#) that each contraction of a muscle fiber requires the expenditure of large quantities of ATP energy. Other cells perform mechanical work in other ways, especially by *ciliary* and *ameboid motion*, described later in this chapter. The source of energy for all these types of mechanical work is ATP.

In summary, ATP is readily available to release its energy rapidly wherever it is needed in the cell. To replace ATP used by the cell, much slower chemical reactions break down carbohydrates, fats, and proteins and use the energy derived from these processes to form new ATP. More than 95% of this ATP is formed in the mitochondria, which is why the mitochondria are called the *powerhouses* of the cell.

LOCOMOTION OF CELLS

The most obvious type of movement in the body is that which occurs in skeletal, cardiac, and smooth muscle cells, which constitute almost 50% of the entire body mass. The specialized functions of these cells are discussed in [Chapters 6 through 9](#). Two other types of movement—*ameboid locomotion* and *ciliary movement*—occur in other cells.

AMEBOID MOVEMENT

Ameboid movement is a crawling-like movement of an entire cell in relation to its surroundings, such as movement of white blood cells through tissues. This type of movement gets its name from the fact that amoebae move in this manner, and amoebae have provided an excellent tool for studying the phenomenon.

Typically, ameboid locomotion begins with the protrusion of a *pseudopodium* from one end of the cell. The pseudopodium projects away from the cell body and partially secures itself in a new tissue area; then the remainder of the cell is pulled toward the pseudopodium. [Figure 2-17](#)

demonstrates this process, showing an elongated cell, the right-hand end of which is a protruding pseudopodium. The membrane of this end of the cell is continually moving forward, and the membrane at the left-hand end of the cell is continually following along as the cell moves.

Mechanism of Ameboid Locomotion. Figure 2-17 shows the general principle of ameboid motion. Basically, this results from the continual formation of new cell membrane at the leading edge of the pseudopodium and continual absorption of the membrane in the mid and rear portions of the cell. Two other effects are also essential for forward movement of the cell. The first is attachment of the pseudopodium to surrounding tissues so that it becomes fixed in its leading position while the remainder of the cell body is being pulled forward toward the point of attachment. This attachment is caused by *receptor proteins* that line the insides of exocytotic vesicles. When the vesicles become part of the pseudopodial membrane, they open so that their insides evert to the outside, and the receptors now protrude to the outside and attach to ligands in the surrounding tissues.

At the opposite end of the cell, the receptors pull away from their ligands and form new endocytotic vesicles. Then, inside the cell, these vesicles stream toward the pseudopodial end of the cell, where they are used to form new membrane for the pseudopodium.

The second essential effect for locomotion is to provide the energy required to pull the cell body in the direction of the pseudopodium. A moderate to large amount of the protein *actin* is in the cytoplasm of all cells. Much of the actin is in the form of single molecules that do not provide any motive power; however, these molecules polymerize to form a filamentous network, and the network contracts when it binds with an actin-binding protein such as *myosin*. The entire process is energized by the high-energy compound ATP. This is what occurs in the pseudopodium of a moving cell, where such a network of actin filaments forms anew inside the enlarging pseudopodium. Contraction also occurs in the ectoplasm of the cell body, where a preexisting actin network is already present beneath the cell membrane.

Types of Cells That Exhibit Ameboid Locomotion.

The most common cells to exhibit ameboid locomotion in the human body are the *white blood cells* when they move out of the blood into the tissues to form *tissue macrophages*. Other types of cells can also move by ameboid locomotion under certain circumstances. For example, fibroblasts move into a damaged area to help repair the damage, and even the germinal cells of the skin, although ordinarily completely sessile cells, move toward a cut area to repair the opening. Cell locomotion is also especially important in the development of the embryo and fetus after fertilization of an ovum. For example, embryonic cells often must migrate long distances from their sites of origin to new areas during the development of special structures.

Some types of cancer cells, such as sarcomas, which arise from connective tissue cells, are especially proficient at ameboid movement. This partially accounts for their relatively rapid spreading from one part of the body to another, known as *metastasis*.

Control of Ameboid Locomotion—Chemotaxis. An important initiator of ameboid locomotion is the process called *chemotaxis*, which results from the appearance of certain chemical substances in the tissues. Any chemical substance that causes chemotaxis to occur is called a *chemotactic substance*. Most cells that exhibit ameboid locomotion move toward the source of a chemotactic substance—that is, from an area of lower concentration toward an area of higher concentration. This is called *positive chemotaxis*. Some cells move away from the source, which is called *negative chemotaxis*.

How does chemotaxis control the direction of ameboid locomotion? Although the answer is not certain, it is known that the side of the cell most exposed to the chemotactic substance develops membrane changes that cause pseudopodial protrusion.

CILIA AND CILIARY MOVEMENTS

There are two types of cilia, *motile* and *nonmotile*, or *primary*, cilia. Motile cilia can undergo a whiplike movement on the surfaces of cells. This movement occurs mainly in two places in the human body, on the surfaces of the respiratory airways and on the inside surfaces of the uterine tubes (fallopian tubes) of the reproductive tract. In the nasal cavity and lower respiratory airways, the whiplike motion of motile cilia causes a layer of mucus to move at a rate of about 1 cm/min toward the pharynx, in this way continually clearing these passageways of mucus and particles that have become trapped in the mucus. In the uterine tubes, cilia cause slow movement of fluid from the ostium of the uterine tube toward the uterus cavity; this movement of fluid transports the ovum from the ovary to the uterus.

As shown in Figure 2-18, a cilium has the appearance of a sharp-pointed straight or curved hair that projects 2 to 4 micrometers from the surface of the cell. Often, many motile cilia project from a single cell—for example, as many as 200 cilia on the surface of each epithelial cell inside the respiratory passageways. The cilium is covered by an outcropping of the cell membrane, and it is supported by 11 microtubules—nine double tubules located around the periphery of the cilium and two single tubules down the center, as demonstrated in the cross section shown in Figure 2-18. Each cilium is an outgrowth of a structure that lies immediately beneath the cell membrane, called the *basal body* of the cilium.

The *flagellum of a sperm* is similar to a motile cilium; in fact, it has much the same type of structure and same type of contractile mechanism. The flagellum, however, is much longer and moves in quasisinusoidal waves instead of whiplike movements.

Figure 2-18. Structure and function of the cilium. (Modified from Satir P: *Cilia*. *Sci Am* 204:108, 1961.)

In the inset of **Figure 2-18**, movement of the motile cilium is shown. The cilium moves forward with a sudden, rapid whiplike stroke 10 to 20 times per second, bending sharply where it projects from the surface of the cell. Then it moves backward slowly to its initial position. The rapid, forward-thrusting, whiplike movement pushes the fluid lying adjacent to the cell in the direction that the cilium moves; the slow dragging movement in the backward direction has almost no effect on fluid movement. As a result, the fluid is continually propelled in the direction of the fast-forward stroke. Because most motile ciliated cells have large numbers of cilia on their surfaces, and because all the cilia are oriented in the same direction, this is an effective means for moving fluids from one part of the surface to another.

Mechanism of Ciliary Movement. Although not all aspects of ciliary movement are known, we are aware of the following elements. First, the nine double tubules and two single tubules are all linked to one another by a complex of protein cross-linkages; this total complex of tubules and cross-linkages is called the *axoneme*. Second, even after removal of the membrane and destruction of other elements of the cilium in addition to the axoneme,

the cilium can still beat under appropriate conditions. Third, two conditions are necessary for continued beating of the axoneme after removal of the other structures of the cilium: (1) the availability of ATP; and (2) appropriate ionic conditions, especially appropriate concentrations of magnesium and calcium. Fourth, during forward motion of the cilium, the double tubules on the front edge of the cilium slide outward toward the tip of the cilium, whereas those on the back edge remain in place. Fifth, multiple protein arms composed of the protein *dynein*, which has adenosine triphosphatase (ATPase) enzymatic activity, project from each double tubule toward an adjacent double tubule.

Given this basic information, it has been determined that the release of energy from ATP in contact with the ATPase dynein arms causes the heads of these arms to “crawl” rapidly along the surface of the adjacent double tubule. If the front tubules crawl outward while the back tubules remain stationary, bending occurs.

The way in which cilia contraction is controlled is not well understood. The cilia of some genetically abnormal cells do not have the two central single tubules, and these cilia fail to beat. Therefore, it is presumed that some signal, perhaps an electrochemical signal, is transmitted along these two central tubules to activate the dynein arms.

Nonmotile Primary Cilia Serve as Cell Sensory “Antennae.” *Primary cilia* are nonmotile and generally occur only as a single cilium on each cell. Although the physiological functions of primary cilia are not fully understood, current evidence indicates that they function as cellular “sensory antennae,” which coordinate cellular signaling pathways involved in chemical and mechanical sensation, signal transduction, and cell growth. In the kidneys, for example, primary cilia are found in most epithelial cells of the tubules, projecting into the tubule lumen and acting as a flow sensor. In response to fluid flow over the tubular epithelial cells, the primary cilia bend and cause flow-induced changes in intracellular calcium signaling. These signals, in turn, initiate multiple effects on the cells. Defects in signaling by primary cilia in renal tubular epithelial cells are thought to contribute to various disorders, including the development of large fluid-filled cysts, a condition called *polycystic kidney disease*.

Genetic Control of Protein Synthesis, Cell Function, and Cell Reproduction

Genes, which are located in the nuclei of all cells of the body, control heredity from parents to children, as well as the daily functioning of all the body's cells. The genes control cell function by determining which structures, enzymes, and chemicals are synthesized within the cell.

Figure 3-1 shows the general schema of genetic control. Each gene, which is composed of *deoxyribonucleic acid* (DNA), controls the formation of another nucleic acid, *ribonucleic acid* (RNA); this RNA then spreads throughout the cell to control formation of a specific protein. The entire process, from *transcription* of the genetic code in the nucleus to *translation* of the RNA code and the formation of proteins in the cell cytoplasm, is often referred to as *gene expression*.

Because the human body has approximately 20,000 to 25,000 different genes that code for proteins in each cell, it is possible to form a large number of different cellular proteins. In fact, RNA molecules transcribed from the same segment of DNA—the same gene—can be processed in more than one way by the cell, giving rise to alternate versions of the protein. The total number of different proteins produced by the various cell types in humans is estimated to be at least 100,000.

Some of the cellular proteins are *structural proteins*, which, in association with various lipids and carbohydrates, form structures of the various intracellular organelles discussed in [Chapter 2](#). However, most of the proteins are *enzymes* that catalyze different chemical reactions in the cells. For example, enzymes promote all the oxidative reactions that supply energy to the cell, along with synthesis of all the cell chemicals, such as lipids, glycogen, and adenosine triphosphate (ATP).

CELL NUCLEUS GENES CONTROL PROTEIN SYNTHESIS

In the cell nucleus, large numbers of genes are attached end on end in extremely long, double-stranded helical molecules of DNA having molecular weights measured in the billions. A very short segment of such a molecule is shown in [Figure 3-2](#). This molecule is composed of several simple chemical compounds bound together in a regular pattern, the details of which are explained in the next few paragraphs.

Building Blocks of DNA

Figure 3-3 shows the basic chemical compounds involved in the formation of DNA. These compounds include the following: (1) *phosphoric acid*; (2) a sugar called *deoxyribose*; and (3) four nitrogenous *bases* (two purines, *adenine* and *guanine*, and two pyrimidines, *thymine* and *cytosine*). The phosphoric acid and deoxyribose form the two helical strands that are the backbone of the DNA molecule, and the nitrogenous bases lie between the two strands and connect them, as illustrated in [Figure 3-2](#).

Nucleotides

The first stage of DNA formation is to combine one molecule of phosphoric acid, one molecule of deoxyribose, and one of the four bases to form an acidic nucleotide. Four separate nucleotides are thus formed, one for each of the four bases: *deoxyadenylic*, *deoxythymidyllic*, *deoxyguanylic*, and *deoxycytidyllic acids*. [Figure 3-4](#) shows the chemical

Figure 3-1 The general schema whereby genes control cell function. *mRNA*, Messenger RNA.

Figure 3-2 The helical double-stranded structure of the gene. The outside strands are composed of phosphoric acid and the sugar deoxyribose. The internal molecules connecting the two strands of the helix are purine and pyrimidine bases, which determine the “code” of the gene.

Figure 3-3 The basic building blocks of DNA.

structure of deoxyadenylic acid, and **Figure 3-5** shows simple symbols for the four nucleotides that form DNA.

Nucleotides Are Organized to Form Two Strands of DNA Loosely Bound to Each Other

Figure 3-2 shows the manner in which multiple nucleotides are bound together to form two strands of DNA. The two strands are, in turn, loosely bonded with each other by weak cross-linkages, as illustrated in **Figure 3-6** by the central dashed lines. Note that the backbone of each DNA strand is composed of alternating phosphoric acid and deoxyribose molecules. In turn, purine and pyrimidine bases are attached to the sides of the deoxyribose molecules. Then, by means of loose *hydrogen bonds* (dashed

Figure 3-4. Deoxyadenylic acid, one of the nucleotides that make up DNA.

Figure 3-5. Symbols for the four nucleotides that combine to form DNA. Each nucleotide contains phosphoric acid (P), deoxyribose (D), and one of the four nucleotide bases: adenine (A); thymine (T); guanine (G); or cytosine (C).

lines) between the purine and pyrimidine bases, the two respective DNA strands are held together. Note the following caveats, however:

1. Each purine base *adenine* of one strand always bonds with a pyrimidine base *thymine* of the other strand.
2. Each purine base *guanine* always bonds with a pyrimidine base *cytosine*.

Thus, in **Figure 3-6**, the sequence of complementary pairs of bases is CG, CG, GC, TA, CG, TA, GC, AT, and AT. Because of the looseness of the hydrogen bonds, the two strands can pull apart with ease, and they do so many times during the course of their function in the cell.

To put the DNA of **Figure 3-6** into its proper physical perspective, one could merely pick up the two ends and twist them into a helix. Ten pairs of nucleotides are present in each full turn of the helix in the DNA molecule.

GENETIC CODE

The importance of DNA lies in its ability to control the formation of proteins in the cell, which it achieves by means of a *genetic code*. That is, when the two strands of a DNA molecule are split apart, the purine and pyrimidine bases projecting to the side of each DNA strand are exposed, as shown by the top strand in **Figure 3-7**. It is these projecting bases that form the genetic code.

The genetic code consists of successive “triplets” of bases—that is, each three successive bases is a *code word*. The successive triplets eventually control the sequence of amino acids in a protein molecule that is to be synthesized in the cell. Note in **Figure 3-6** that the top strand of DNA, reading from left to right, has the genetic code GGC, AGA, CTT, with the triplets being separated from one another by the arrows. As we follow this genetic code through **Figure 3-7** and **Figure 3-8**, we see that these three respective triplets are responsible for successive placement of the three amino acids, *proline*, *serine*, and *glutamic acid*, in a newly formed molecule of protein.

TRANSCRIPTION—TRANSFER OF CELL NUCLEUS DNA CODE TO CYTOPLASM RNA CODE

Because DNA is located in the cell nucleus, yet most of the cell functions are carried out in the cytoplasm, there must be some means for DNA genes of the nucleus to control chemical reactions of the cytoplasm. This control

Figure 3-6. Arrangement of deoxyribose nucleotides in a double strand of DNA.

Figure 3-7. Combination of ribose nucleotides with a strand of DNA to form a molecule of RNA that carries the genetic code from the gene to the cytoplasm. The *RNA polymerase* enzyme moves along the DNA strand and builds the RNA molecule.

Figure 3-8. A portion of an RNA molecule showing three RNA codons—CCG, UCU, and GAA—that control attachment of the three amino acids, proline, serine, and glutamic acid, respectively, to the growing RNA chain.

is achieved through the intermediary of another type of nucleic acid, RNA, the formation of which is controlled by DNA of the nucleus. Thus, as shown in [Figure 3-7](#), the code is transferred to RNA in a process called *transcription*. The RNA, in turn, diffuses from the nucleus through nuclear pores into the cytoplasmic compartment, where it controls protein synthesis.

RNA IS SYNTHESIZED IN THE NUCLEUS FROM A DNA TEMPLATE

During RNA synthesis, the two strands of DNA separate temporarily; one of these strands is used as a template for synthesis of an RNA molecule. The code triplets in the DNA result in the formation of *complementary* code triplets (called *codons*) in the RNA. These codons, in turn, will control the sequence of amino acids in a protein to be synthesized in the cell cytoplasm.

Building Blocks of RNA. The basic building blocks of RNA are almost the same as those of DNA, except for two differences. First, the sugar deoxyribose is not used in RNA formation. In its place is another sugar of slightly different composition, *ribose*, which contains an extra hydroxyl ion appended to the ribose ring structure. Second, thymine is replaced by another pyrimidine, *uracil*.

Formation of RNA Nucleotides. The basic building blocks of RNA form *RNA nucleotides*, exactly as described previously for DNA synthesis. Here again, four separate nucleotides are used to form RNA. These nucleotides contain the bases *adenine*, *guanine*, *cytosine*, and *uracil*. Note that these bases are the same as in DNA, except that uracil in RNA replaces thymine in DNA.

“Activation” of RNA Nucleotides. The next step in the synthesis of RNA is “activation” of RNA nucleotides by an enzyme, *RNA polymerase*. This activation occurs by adding two extra phosphate radicals to each nucleotide to form

triphosphates (shown in [Figure 3-7](#) by the two RNA nucleotides to the far right during RNA chain formation). These last two phosphates are combined with the nucleotide by *high-energy phosphate bonds* derived from ATP in the cell.

The result of this activation process is that large quantities of ATP energy are made available to each of the nucleotides. This energy is used to promote chemical reactions that add each new RNA nucleotide at the end of the developing RNA chain.

RNA CHAIN ASSEMBLY FROM ACTIVATED NUCLEOTIDES USING THE DNA STRAND AS A TEMPLATE

As shown in [Figure 3-7](#), assembly of RNA is accomplished under the influence of an enzyme, *RNA polymerase*. This large protein enzyme has many functional properties necessary for formation of RNA, as follows:

1. In the DNA strand immediately ahead of the gene to be transcribed is a sequence of nucleotides called the *promoter*. The RNA polymerase has an appropriate complementary structure that recognizes this promoter and becomes attached to it, which is the essential step for initiating the formation of RNA.
2. After the RNA polymerase attaches to the promoter, the polymerase causes unwinding of about two turns of the DNA helix and separation of the unwound portions of the two strands.
3. The polymerase then moves along the DNA strand, temporarily unwinding and separating the two DNA strands at each stage of its movement. As it moves along, at each stage it adds a new activated RNA nucleotide to the end of the newly forming RNA chain through the following steps:
 - a. First, it causes a hydrogen bond to form between the end base of the DNA strand and the base of an RNA nucleotide in the nucleoplasm.

- b. Then, one at a time, the RNA polymerase breaks two of the three phosphate radicals away from each of these RNA nucleotides, liberating large amounts of energy from the broken high-energy phosphate bonds. This energy is used to cause covalent linkage of the remaining phosphate on the nucleotide with the ribose on the end of the growing RNA chain.
- c. When the RNA polymerase reaches the end of the DNA gene, it encounters a new sequence of DNA nucleotides called the *chain-terminating sequence*, which causes the polymerase and the newly formed RNA chain to break away from the DNA strand. The polymerase then can be used again and again to form more new RNA chains.
- d. As the new RNA strand is formed, its weak hydrogen bonds with the DNA template break away because the DNA has a high affinity for rebonding with its own complementary DNA strand. Thus, the RNA chain is forced away from the DNA and is released into the nucleoplasm.

Therefore, the code that is present in the DNA strand is eventually transmitted in *complementary* form to the RNA chain. The ribose nucleotide bases always combine with the deoxyribose bases in the following combinations:

DNA Base	RNA Base
guanine	Cytosine
cytosine	Guanine
adenine	Uracil
thymine	adenine

There Are Several Different Types of RNA. As research on RNA has continued to advance, many different types of RNA have been discovered. Some types of RNA are involved in protein synthesis, whereas other types serve gene regulatory functions or are involved in posttranscriptional modification of RNA. The functions of some types of RNA, especially those that do not appear to code for proteins, are still mysterious. The following six types of RNA play independent and different roles in protein synthesis:

1. *Precursor messenger RNA* (pre-mRNA) is a large, immature, single strand of RNA that is processed in the nucleus to form mature messenger RNA (mRNA). The pre-RNA includes two different types of segments, called *introns*, which are removed by a process called splicing, and *exons*, which are retained in the final mRNA.
2. *Small nuclear RNA* (snRNA) directs the splicing of pre-mRNA to form mRNA.
3. *Messenger RNA* (mRNA) carries the genetic code to the cytoplasm for controlling the type of protein formed.
4. *Transfer RNA* (tRNA) transports activated amino acids to the ribosomes to be used in assembling the protein molecule.
5. *Ribosomal RNA*, along with about 75 different proteins, forms *ribosomes*, the physical and chemical

structures on which protein molecules are actually assembled.

6. *MicroRNAs* (miRNAs) are single-stranded RNA molecules of 21 to 23 nucleotides that can regulate gene transcription and translation.

MESSENGER RNA—THE CODONS

Messenger RNA molecules are long single RNA strands that are suspended in the cytoplasm. These molecules are composed of several hundred to several thousand RNA nucleotides in unpaired strands, and they contain *codons* that are exactly complementary to the code triplets of the DNA genes. **Figure 3-8** shows a small segment of mRNA. Its codons are CCG, UCU, and GAA, which are the codons for the amino acids proline, serine, and glutamic acid. The transcription of these codons from the DNA molecule to the RNA molecule is shown in **Figure 3-7**.

RNA Codons for the Different Amino Acids. **Table 3-1** lists the RNA codons for the 20 common amino acids found in protein molecules. Note that most of the amino acids are represented by more than one codon; also, one codon represents the signal “start manufacturing the protein molecule,” and three codons represent “stop manufacturing the protein molecule.” In **Table 3-1**, these two

Table 3-1 RNA Codons for Amino Acids and for Start and Stop

Amino Acid	RNA Codons					
Alanine	GCU	GCC	GCA	GCG		
Arginine	CGU	CGC	CGA	CGG	AGA	AGG
Asparagine	AAU	AAC				
Aspartic acid	GAU	GAC				
Cysteine	UGU	UGC				
Glutamic acid	GAA	GAG				
Glutamine	CAA	CAG				
Glycine	GGU	GGC	GGA	GGG		
Histidine	CAU	CAC				
Isoleucine	AUU	AUC	AUA			
Leucine	CUU	CUC	CUA	CUG	UUA	UUG
Lysine	AAA	AAG				
Methionine	AUG					
Phenylalanine	UUU	UUC				
Proline	CCU	CCC	CCA	CCG		
Serine	UCU	UCC	UCA	UCG	AGC	AGU
Threonine	ACU	ACC	ACA	ACG		
Tryptophan	UGG					
Tyrosine	UAU	UAC				
Valine	GUU	GUC	GUA	GUG		
Start (CI)	AUG					
Stop (CT)	UAA	UAG	UGA			

CI, Chain-initiating; CT, chain-terminating.

types of codons are designated CI for “chain-initiating” or “start” codon and CT for “chain-terminating” or “stop” codon.

TRANSFER RNA—THE ANTICODONS

Another type of RNA that is essential for protein synthesis is called transfer RNA (tRNA) because it transfers amino acids to protein molecules as the protein is being synthesized. Each type of tRNA combines specifically with 1 of the 20 amino acids that are to be incorporated into proteins. The tRNA then acts as a *carrier* to transport its specific type of amino acid to the ribosomes, where protein molecules are forming. In the ribosomes, each specific type of tRNA recognizes a particular codon on the mRNA (described later) and thereby delivers the appropriate amino acid to the appropriate place in the chain of the newly forming protein molecule.

Transfer RNA, which contains only about 80 nucleotides, is a relatively small molecule in comparison with mRNA. It is a folded chain of nucleotides with a cloverleaf appearance similar to that shown in Figure 3-9. At one end of the molecule there is always an adenylic acid to which the transported amino acid attaches at a hydroxyl group of the ribose in the adenylic acid.

Because the function of tRNA is to cause attachment of a specific amino acid to a forming protein chain, it is essential that each type of tRNA also have specificity for a particular codon in the mRNA. The specific code in the tRNA that allows it to recognize a specific codon is again a triplet of nucleotide bases and is called an *anticodon*. This anticodon is located approximately in the middle of the tRNA molecule (at the bottom of the cloverleaf configuration shown in Figure 3-9). During formation of the protein molecule, the anticodon bases combine loosely by hydrogen bonding with the codon bases of the mRNA. In this way, the respective amino acids are lined up one after another along the mRNA chain, thus establishing the

appropriate sequence of amino acids in the newly forming protein molecule.

RIBOSOMAL RNA

The third type of RNA in the cell is ribosomal RNA, which constitutes about 60% of the *ribosome*. The remainder of the ribosome is protein, including about 75 types of proteins that are both structural proteins and enzymes needed to manufacture proteins.

The ribosome is the physical structure in the cytoplasm on which proteins are actually synthesized. However, it always functions in association with the other two types of RNA; *tRNA* transports amino acids to the ribosome for incorporation into the developing protein, whereas *mRNA* provides the information necessary for sequencing the amino acids in proper order for each specific type of protein to be manufactured. Thus, the ribosome acts as a manufacturing plant in which the protein molecules are formed.

Formation of Ribosomes in the Nucleolus. The DNA genes for the formation of ribosomal RNA are located in five pairs of chromosomes in the nucleus. Each of these chromosomes contains many duplicates of these particular genes because of the large amounts of ribosomal RNA required for cellular function.

As the ribosomal RNA forms, it collects in the *nucleolus*, a specialized structure lying adjacent to the chromosomes. When large amounts of ribosomal RNA are being synthesized, as occurs in cells that manufacture large amounts of protein, the nucleolus is a large structure, whereas in cells that synthesize little protein, the nucleolus may not even be seen. Ribosomal RNA is specially processed in the nucleolus, where it binds with ribosomal proteins to form granular condensation products that are primordial subunits of ribosomes. These subunits are then released from the nucleolus and transported through the large pores of the nuclear envelope to almost all parts of the cytoplasm. After the subunits enter the cytoplasm, they are assembled to form mature functional ribosomes. Therefore, proteins are formed in the cytoplasm of the cell, but not in the cell nucleus, because the nucleus does not contain mature ribosomes.

miRNA AND SMALL INTERFERING RNA

A fourth type of RNA in the cell is *microRNA* (miRNA); miRNA are short (21 to 23 nucleotides) single-stranded RNA fragments that regulate gene expression (Figure 3-10). The miRNAs are encoded from the transcribed DNA of genes, but they are not translated into proteins and are therefore often called *noncoding RNA*. The miRNAs are processed by the cell into molecules that are complementary to mRNA and act to decrease gene expression. The generation of miRNAs involves special processing of longer primary precursor RNAs called *primary miRNAs*, which are the primary transcripts of the gene.

Figure 3-9. A messenger RNA strand is moving through two ribosomes. As each codon passes through, an amino acid is added to the growing protein chain, which is shown in the right-hand ribosome. The transfer RNA molecule transports each specific amino acid to the newly forming protein.

Figure 3-10. Regulation of gene expression by microRNA (miRNA). Primary miRNA (pri-miRNA), the primary transcripts of a gene processed in the cell nucleus by the microprocessor complex, are converted to pre-miRNAs. These pre-miRNAs are then further processed in the cytoplasm by *dicer*, an enzyme that helps assemble an RNA-induced silencing complex (RISC) and generates miRNAs. The miRNAs regulate gene expression by binding to the complementary region of the RNA and repressing translation or promoting degradation of the messenger RNA (mRNA) before it can be translated by the ribosome.

The pri-miRNAs are then processed in the cell nucleus by the *microprocessor complex* to pre-miRNAs, which are 70-nucleotide, stem loop structures. These pre-miRNAs are then further processed in the cytoplasm by a specific *dicer enzyme* that helps assemble an *RNA-induced silencing complex* (RISC) and generates miRNAs.

The miRNAs regulate gene expression by binding to the complementary region of the RNA and promoting repression of translation or degradation of the mRNA before it can be translated by the ribosome. miRNAs are believed to play an important role in normal regulation of cell function, and alterations in miRNA function have been associated with diseases such as cancer and heart disease.

Another type of miRNA is *small interfering RNA* (siRNA), also called *silencing RNA* or *short interfering RNA*. The siRNAs are short, double-stranded RNA molecules, comprised of 20 to 25 nucleotides, that interfere with expression of specific genes. siRNAs generally refer to synthetic miRNAs and can be administered to silence expression of specific genes. They are designed to avoid nuclear processing by the microprocessor complex and, after the siRNA enters the cytoplasm, it activates the RISC silencing complex, blocking the translation of mRNA. Because siRNAs can be tailored for any specific sequence in the gene, they can be used to block translation of any mRNA and therefore expression by any gene for which the nucleotide sequence is known. Researchers have proposed that siRNAs may become useful therapeutic tools to silence genes that contribute to the pathophysiology of diseases.

TRANSLATION—FORMATION OF PROTEINS ON THE RIBOSOMES

When a molecule of mRNA comes in contact with a ribosome, it travels through the ribosome, beginning at a predetermined end of the RNA molecule specified by an appropriate sequence of RNA bases called the *chain-initiating codon*. Then, as shown in [Figure 3-9](#), while the mRNA travels through the ribosome, a protein molecule is formed, a process called *translation*. Thus, the ribosome reads the codons of the mRNA in much the same way that a tape is read as it passes through the playback head of a tape recorder. Then, when a “stop” (or “chain-terminating”) codon slips past the ribosome, the end of a protein molecule is signaled, and the protein molecule is freed into the cytoplasm.

Polyribosomes. A single mRNA molecule can form protein molecules in several ribosomes at the same time because the initial end of the RNA strand can pass to a successive ribosome as it leaves the first, as shown at the bottom left in [Figure 3-9](#) and [Figure 3-11](#). The protein molecules are in different stages of development in each ribosome. As a result, clusters of ribosomes frequently occur, with 3 to 10 ribosomes being attached to a single mRNA at the same time. These clusters are called *polyribosomes*.

An mRNA can cause formation of a protein molecule in any ribosome; there is no specificity of ribosomes for given types of protein. The ribosome is simply the physical manufacturing plant in which the chemical reactions take place.

Many Ribosomes Attach to the Endoplasmic Reticulum. In [Chapter 2](#), we noted that many ribosomes become attached to the endoplasmic reticulum. This attachment occurs because the initial ends of many forming protein molecules have amino acid sequences that immediately attach to specific receptor sites on the endoplasmic reticulum, causing these molecules to penetrate the

Figure 3-11. The physical structure of the ribosomes, as well as their functional relationship to messenger RNA, transfer RNA, and the endoplasmic reticulum during the formation of protein molecules.

reticulum wall and enter the endoplasmic reticulum matrix. This process gives a granular appearance to the portions of the reticulum where proteins are being formed and are entering the matrix of the reticulum.

Figure 3-11 shows the functional relationship of mRNA to the ribosomes and the manner in which the ribosomes attach to the membrane of the endoplasmic reticulum. Note the process of translation occurring in several ribosomes at the same time in response to the same strand of mRNA. Note also the newly forming polypeptide (protein) chains passing through the endoplasmic reticulum membrane into the endoplasmic matrix.

It should be noted that except in glandular cells, in which large amounts of protein-containing secretory vesicles are formed, most proteins synthesized by the ribosomes are released directly into the cytosol instead of into the endoplasmic reticulum. These proteins are enzymes and internal structural proteins of the cell.

Chemical Steps in Protein Synthesis. Some of the chemical events that occur in the synthesis of a protein molecule are shown in **Figure 3-12**. This Fig. shows representative reactions for three separate amino acids, AA₁, AA₂, and AA₂₀. The stages of the reactions are as follows:

1. Each amino acid is *activated* by a chemical process in which ATP combines with the amino acid to form an *adenosine monophosphate complex with the amino acid*, giving up two high-energy phosphate bonds in the process.
2. The activated amino acid, having an excess of energy, then *combines with its specific tRNA to form an amino acid-tRNA complex* and, at the same time, releases the adenosine monophosphate.
3. The tRNA carrying the amino acid complex then comes in contact with the mRNA molecule in the ribosome, where the anticodon of the tRNA attaches temporarily to its specific codon of the mRNA, thus lining up the amino acid in the appropriate sequence to form a protein molecule.

Then, under the influence of the enzyme *peptidyl transferase* (one of the proteins in the ribosome), *peptide bonds* are formed between the successive amino acids, thus adding progressively to the protein chain. These

chemical events require energy from two additional high-energy phosphate bonds, making a total of four high-energy bonds used for each amino acid added to the protein chain. Thus, the synthesis of proteins is one of the most energy-consuming processes of the cell.

Peptide Linkage—Combination of Amino Acids. The successive amino acids in the protein chain combine with one another according to the typical reaction.

In this chemical reaction, a hydroxyl radical (OH⁻) is removed from the COOH portion of the first amino acid, and a hydrogen (H⁺) of the NH₂ portion of the other amino acid is removed. These combine to form water, and the two reactive sites left on the two successive amino acids bond with each other, resulting in a single molecule. This process is called *peptide linkage*. As each additional amino acid is added, an additional peptide linkage is formed.

SYNTHESIS OF OTHER SUBSTANCES IN THE CELL

Many thousand protein enzymes formed in the manner just described control essentially all the other chemical reactions that take place in cells. These enzymes promote synthesis of lipids, glycogen, purines, pyrimidines, and hundreds of other substances. We discuss many of these synthetic processes in relation to carbohydrate, lipid, and protein metabolism in **Chapters 68 through 70**. These substances each contribute to the various functions of the cells.

CONTROL OF GENE FUNCTION AND BIOCHEMICAL ACTIVITY IN CELLS

From our discussion thus far, it is clear that the genes control both the physical and chemical functions of the cells. However, the degree of activation of respective genes must also be

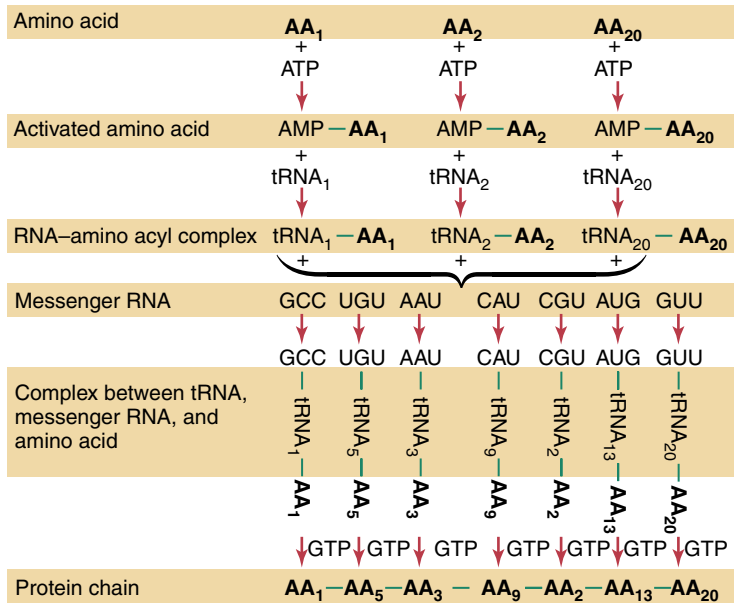

Figure 3-12. Chemical events in the formation of a protein molecule. AMP, Adenosine monophosphate; ATP, adenosine triphosphate; GTP, guanosine triphosphate; tRNA, transfer RNA.

controlled; otherwise, some parts of the cell might overgrow or some chemical reactions might overact until they kill the cell. Each cell has powerful internal feedback control mechanisms that keep the various functional operations of the cell in step with one another. For each gene ($\approx 20,000$ – $25,000$ genes in all), at least one such feedback mechanism exists.

There are basically two methods whereby the biochemical activities in the cell are controlled: (1) *genetic regulation*, in which the degree of activation of the genes and the formation of gene products are themselves controlled, and (2) *enzyme regulation*, in which the activity levels of already formed enzymes in the cell are controlled.

GENETIC REGULATION

Genetic regulation, or regulation of *gene expression*, covers the entire process from transcription of the genetic code in the nucleus to the formation of proteins in the cytoplasm. Regulation of gene expression provides all living organisms with the ability to respond to changes in their environment. In animals that have many different types of cells, tissues, and organs, differential regulation of gene expression also permits the different cell types in the body to each perform their specialized functions. Although a cardiac myocyte contains the same genetic code as a renal tubular epithelial cell, many genes are expressed in cardiac cells that are not expressed in renal tubular cells. The ultimate measure of gene “expression” is whether (and how much) of the gene products (proteins) are produced because proteins carry out cell functions specified by the genes. Regulation of gene expression can occur at any point in the pathways of transcription, RNA processing, and translation.

The Promoter Controls Gene Expression. Synthesis of cellular proteins is a complex process that starts with transcription of DNA into RNA. Transcription of DNA is

Figure 3-13. Gene transcription in eukaryotic cells. A complex arrangement of multiple clustered enhancer modules is interspersed with insulator elements, which can be located upstream or downstream of a basal promoter containing TATA box (TATA), proximal promoter elements (response elements, RE), and initiator sequences (INR).

controlled by regulatory elements found in the promoter of a gene (**Figure 3-13**). In eukaryotes, which includes all mammals, the basal promoter consists of a sequence of bases (TATAAA) called the *TATA box*, the binding site for the *TATA-binding protein* and several other important *transcription factors* that are collectively referred to as the *transcription factor IID complex*. In addition to the transcription factor IID complex, this region is where transcription factor IIB binds to both the DNA and RNA polymerase 2 to facilitate transcription of the DNA into RNA. This basal promoter is found in all protein-coding genes, and the polymerase must bind with this basal promoter before it can begin traveling along the DNA strand to synthesize RNA. The *upstream promoter* is located farther upstream from the transcription start site and contains several binding sites for positive or negative transcription factors that can affect transcription through interactions with proteins bound to the basal promoter. The structure and transcription factor binding sites in the

upstream promoter vary from gene to gene to give rise to the different expression patterns of genes in different tissues.

Transcription of genes in eukaryotes is also influenced by *enhancers*, which are regions of DNA that can bind transcription factors. Enhancers can be located a great distance from the gene they act on or even on a different chromosome. They can also be located upstream or downstream of the gene that they regulate. Although enhancers may be located far from their target gene, they may be relatively close when DNA is coiled in the nucleus. It is estimated that there are more than 100,000 gene enhancer sequences in the human genome.

In the organization of the chromosome, it is important to separate active genes that are being transcribed from genes that are repressed. This separation can be challenging because multiple genes may be located close together on the chromosome. The separation is achieved by chromosomal *insulators*. These insulators are gene sequences that provide a barrier so that a specific gene is isolated against transcriptional influences from surrounding genes. Insulators can vary greatly in their DNA sequence and the proteins that bind to them. One way an insulator activity can be modulated is by *DNA methylation*, which is the case for the mammalian insulin-like growth factor 2 (IGF-2) gene. The mother's allele has an insulator between the enhancer and promoter of the gene that allows for the binding of a transcriptional repressor. However, the paternal DNA sequence is methylated such that the transcriptional repressor cannot bind to the insulator, and the IGF-2 gene is expressed from the paternal copy of the gene.

Other Mechanisms for Control of Transcription by the Promoter. Variations in the basic mechanism for control of the promoter have been discovered in the past three decades. Without giving details, let us list some of them:

1. A promoter is frequently controlled by transcription factors located elsewhere in the genome. That is, the regulatory gene causes the formation of a regulatory protein that in turn acts as an activator or repressor of transcription.
2. Occasionally, many different promoters are controlled at the same time by the same regulatory protein. In some cases, the same regulatory protein functions as an activator for one promoter and as a repressor for another promoter.
3. Some proteins are controlled not at the starting point of transcription on the DNA strand but farther along the strand. Sometimes, the control is not even at the DNA strand itself but occurs during the processing of the RNA molecules in the nucleus before they are released into the cytoplasm. Control may also occur at the level of protein formation in the cytoplasm during RNA translation by the ribosomes.
4. In nucleated cells, the nuclear DNA is packaged in specific structural units, the *chromosomes*. Within

each chromosome, the DNA is wound around small proteins called *histones*, which in turn are held tightly together in a compacted state by still other proteins. As long as the DNA is in this compacted state, it cannot function to form RNA. However, multiple control mechanisms are being discovered that can cause selected areas of chromosomes to become decompacted one part at a time, so that partial RNA transcription can occur. Even then, specific *transcriptor factors* control the actual rate of transcription by the promoter in the chromosome. Thus, still higher orders of control are used to establish proper cell function. In addition, signals from outside the cell, such as some of the body's hormones, can activate specific chromosomal areas and specific transcription factors, therefore controlling the chemical machinery for function of the cell.

Because there are many thousands of different genes in each human cell, the large number of ways in which genetic activity can be controlled is not surprising. The gene control systems are especially important for controlling intracellular concentrations of amino acids, amino acid derivatives, and intermediate substrates and products of carbohydrate, lipid, and protein metabolism.

CONTROL OF INTRACELLULAR FUNCTION BY ENZYME REGULATION

In addition to control of cell function by genetic regulation, cell activities are also controlled by intracellular inhibitors or activators that act directly on specific intracellular enzymes. Thus, enzyme regulation represents a second category of mechanisms whereby cellular biochemical functions can be controlled.

Enzyme Inhibition. Some chemical substances formed in the cell have direct feedback effects to inhibit the specific enzyme systems that synthesize them. Almost always, the synthesized product acts on the first enzyme in a sequence, rather than on the subsequent enzymes, usually binding directly with the enzyme and causing an allosteric conformational change that inactivates it. One can readily recognize the importance of inactivating the first enzyme because this prevents buildup of intermediary products that are not used.

Enzyme inhibition is another example of negative feedback control. It is responsible for controlling intracellular concentrations of multiple amino acids, purines, pyrimidines, vitamins, and other substances.

Enzyme Activation. Enzymes that are normally inactive often can be activated when needed. An example of this phenomenon occurs when most of the ATP has been depleted in a cell. In this case, a considerable amount of cyclic adenosine monophosphate (cAMP) begins to be formed as a breakdown product of ATP. The presence of this cAMP, in turn, immediately activates the glycogen-splitting enzyme phosphorylase, liberating glucose mole-

cules that are rapidly metabolized, with their energy used for replenishment of the ATP stores. Thus, cAMP acts as an enzyme activator for the enzyme phosphorylase and thereby helps control intracellular ATP concentration.

Another interesting example of both enzyme inhibition and enzyme activation occurs in the formation of the purines and pyrimidines. These substances are needed by the cell in approximately equal quantities for the formation of DNA and RNA. When purines are formed, they *inhibit* the enzymes that are required for formation of additional purines. However, they *activate* the enzymes for formation of pyrimidines. Conversely, the pyrimidines inhibit their own enzymes but activate the purine enzymes. In this way, there is continual cross-talk between the synthesizing systems for these two substances, resulting in almost exactly equal amounts of the two substances in the cells at all times.

Summary. There are two principal mechanisms whereby cells control proper proportions and quantities of different cellular constituents: (1) genetic regulation; and (2) enzyme regulation. The genes can be activated or inhibited, and likewise, the enzyme systems can be activated or inhibited. These regulatory mechanisms usually function as feedback control systems that continually monitor the cell's biochemical composition and make corrections as needed. However, on occasion, substances from outside the cell (especially some of the hormones discussed in this text) also control the intracellular biochemical reactions by activating or inhibiting one or more of the intracellular control systems.

THE DNA-GENETIC SYSTEM CONTROLS CELL REPRODUCTION

Cell reproduction is another example of the ubiquitous role that the DNA-genetic system plays in all life processes. The genes and their regulatory mechanisms determine cell growth characteristics and when or whether cells will divide to form new cells. In this way, the all-important genetic system controls each stage in the development of the human, from the single-cell fertilized ovum to the whole functioning body. Thus, if there is any central theme to life, it is the DNA-genetic system.

Life Cycle of the Cell

The life cycle of a cell is the period from cell reproduction to the next cell reproduction. When mammalian cells *are not inhibited and are reproducing as rapidly as they can*, this life cycle may be as little as 10 to 30 hours. It is terminated by a series of distinct physical events called *mitosis* that cause division of the cell into two new daughter cells. The events of mitosis are shown in **Figure 3-14** and described later. The actual stage of mitosis, however, lasts for only about 30 minutes, and thus more than 95% of the life cycle of even rapidly reproducing cells is represented by the interval between mitosis, called *interphase*.

Except in special conditions of rapid cellular reproduction, inhibitory factors almost always slow or stop the

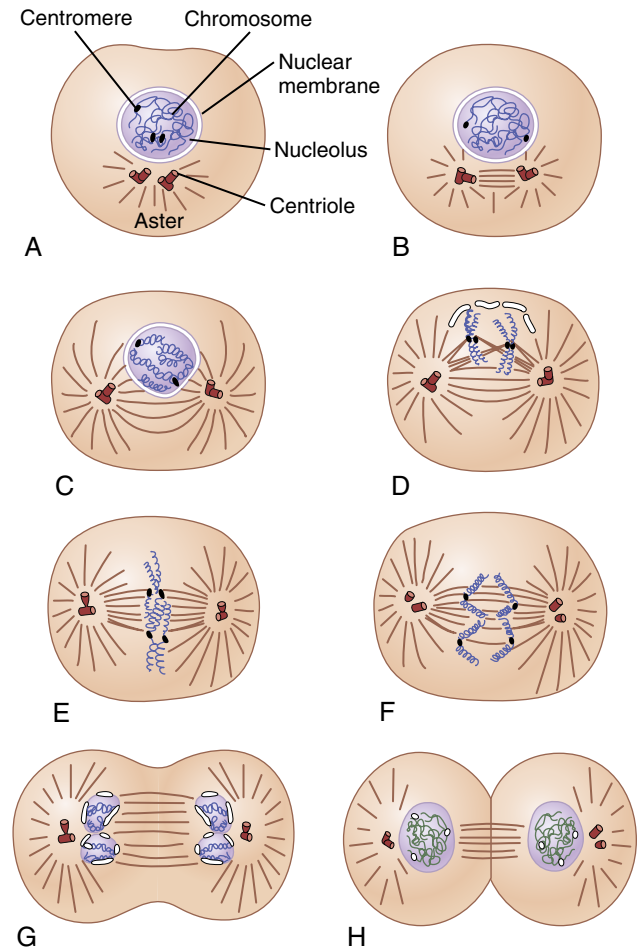

Figure 3-14. Stages of cell reproduction. A, B, C, Prophase. D, Pro-metaphase. E, Metaphase. F, Anaphase. G, H, Telophase.

uninhibited life cycle of the cell. Therefore, different cells of the body actually have life cycle periods that vary from as little as 10 hours for highly stimulated bone marrow cells to an entire lifetime of the human body for many nerve cells.

Cell Reproduction Begins with Replication of DNA

The first step of cell reproduction is *replication (duplication) of all DNA in the chromosomes*. It is only after this replication has occurred that mitosis can take place.

The DNA begins to be duplicated 5 to 10 hours before mitosis, and the duplication is completed in 4 to 8 hours. The net result is two exact *replicas* of all DNA. These replicas become the DNA in the two new daughter cells that will be formed at mitosis. After replication of the DNA, there is another period of 1 to 2 hours before mitosis begins abruptly. Even during this period, preliminary changes that will lead to the mitotic process are beginning to take place.

DNA Replication. DNA is replicated in much the same way that RNA is transcribed from DNA, except for a few important differences:

1. Both strands of the DNA in each chromosome are replicated, not just one of them.

Figure 3-15. DNA replication, showing the replication fork and leading and lagging strands of DNA.

- Both entire strands of the DNA helix are replicated from end to end, rather than small portions of them, as occurs in the transcription of RNA.
- Multiple enzymes called *DNA polymerase*, which is comparable to RNA polymerase, are essential for replicating DNA. DNA polymerase attaches to and moves along the DNA template strand, adding nucleotides in the 5' to 3' direction. Another enzyme, *DNA ligase*, causes bonding of successive DNA nucleotides to one another, using high-energy phosphate bonds to energize these attachments.
- Replication fork formation.** Before DNA can be replicated, the double-stranded molecule must be “unzipped” into two single strands (**Figure 3-15**). Because the DNA helices in each chromosome are approximately 6 centimeters in length and have millions of helical turns, it would be impossible for the two newly formed DNA helices to uncoil from each other were it not for some special mechanism. This uncoiling is achieved by *DNA helicase* enzymes that break the hydrogen bonding between the base pairs of the DNA, permitting the two strands to separate into a Y shape known as the *replication fork*, the area that will be the template for replication to begin.
DNA is directional in both strands, signified by a 5' and 3' end (see **Figure 3-15**). Replication progresses only in the 5' to 3' direction. At the replication fork one strand, the *leading strand*, is oriented in the 3' to 5' direction, toward the replication fork, while the *lagging strand* is oriented 5' to 3', away from the replication fork. Because of their different orientations, the two strands are replicated differently.
- Primer binding.** Once the DNA strands have been separated, a short piece of RNA called an *RNA primer* binds to the 3' end of the leading strand. Primers are generated by the enzyme *DNA primase*.

Primers always bind as the starting point for DNA replication.

- Elongation.** DNA polymerases are responsible for creating the new strand by a process called *elongation*. Because replication proceeds in the 5' to 3' direction on the leading strand, the newly formed strand is continuous. The lagging strand begins replication by binding with multiple primers that are only several bases apart. DNA polymerase then adds pieces of DNA, called *Okazaki fragments*, to the strand between primers. This process of replication is discontinuous because the newly created Okazaki fragments are not yet connected. An enzyme, *DNA ligase*, joins the Okazaki fragments to form a single unified strand.
- Termination.** After the continuous and discontinuous strands are both formed, the enzyme *exonuclease* removes the RNA primers from the original strands, and the primers are replaced with appropriate bases. Another exonuclease “proofreads” the newly formed DNA, checking and clipping off any mismatched or unpaired residues.

Another enzyme, *topoisomerase*, can transiently break the phosphodiester bond in the backbone of the DNA strand to prevent the DNA in front of the replication fork from being overwound. This reaction is reversible, and the phosphodiester bond reforms as the topoisomerase leaves.

Once completed, the parent strand and its complementary DNA strand coils into the double helix shape. The process of replication therefore produces two DNA molecules, each with one strand from the parent DNA and one new strand. For this reason, DNA replication is often described as *semiconservative*; half of the chain is part of the original DNA molecule and half is brand new.

DNA Repair, DNA “Proofreading,” and “Mutation.” During the hour or so between DNA replication and

the beginning of mitosis, there is a period of active repair and “proofreading” of the DNA strands. Wherever inappropriate DNA nucleotides have been matched up with the nucleotides of the original template strand, special enzymes cut out the defective areas and replace them with appropriate complementary nucleotides. This repair process, which is achieved by the same DNA polymerases and DNA ligases that are used in replication, is referred to as *DNA proofreading*.

Because of repair and proofreading, mistakes are rarely made in the DNA replication process. When a mistake is made, it is called a *mutation*. The mutation may cause formation of some abnormal protein in the cell rather than a needed protein, which may lead to abnormal cellular function and sometimes even cell death. Given that many thousands of genes exist in the human genome, and that the period from one human generation to another is about 30 years, one would expect as many as 10 or many more mutations in the passage of the genome from parent to offspring. As a further protection, however, each human genome is represented by two separate sets of chromosomes, one derived from each parent, with almost identical genes. Therefore, one functional gene of each pair is almost always available to the child, despite mutations.

CHROMOSOMES AND THEIR REPLICATION

The DNA helices of the nucleus are packaged in chromosomes. The human cell contains 46 chromosomes arranged in 23 pairs. Most of the genes in the two chromosomes of each pair are identical or almost identical to each other, so it is usually stated that the different genes also exist in pairs, although occasionally this is not the case.

In addition to DNA, there is a large amount of protein in the chromosome, composed mainly of many small molecules of electropositively charged *histones*. The histones are organized into vast numbers of small, bobbin-like cores. Small segments of each DNA helix are coiled sequentially around one core after another.

The histone cores play an important role in regulation of DNA activity because as long as the DNA is packaged tightly, it cannot function as a template for formation of RNA or replication of new DNA. Furthermore, some of the regulatory proteins *decondense* the histone packaging of the DNA and allow small segments at a time to form RNA.

Several nonhistone proteins are also major components of chromosomes, functioning as chromosomal structural proteins and, in connection with the genetic regulatory machinery, as activators, inhibitors, and enzymes.

Replication of the chromosomes in their entirety occurs during the next few minutes after replication of the DNA helices has been completed; the new DNA helices collect new protein molecules as needed. The two newly formed chromosomes remain attached to each other (until time

for mitosis) at a point called the *centromere* located near their center. These duplicated but still attached chromosomes are called *chromatids*.

CELL MITOSIS

The actual process whereby the cell splits into two new cells is called *mitosis*. Once each chromosome has been replicated to form the two chromatids, mitosis follows automatically within 1 or 2 hours in many cells.

Mitotic Apparatus: Function of the Centrioles. One of the first events of mitosis takes place in the cytoplasm in or around the small structures called *centrioles* during the latter part of interphase. As shown in [Figure 3-14](#), two pairs of centrioles lie close to each other near one pole of the nucleus. These centrioles, like the DNA and chromosomes, are also replicated during interphase, usually shortly before replication of the DNA. Each centriole is a small cylindrical body about 0.4 micrometer long and about 0.15 micrometer in diameter, consisting mainly of nine parallel tubular structures arranged in the form of a cylinder. The two centrioles of each pair lie at right angles to each other. Each pair of centrioles, along with attached *pericentriolar material*, is called a *centrosome*.

Shortly before mitosis takes place, the two pairs of centrioles begin to move apart from each other. This movement is caused by polymerization of protein microtubules growing between the respective centriole pairs and actually pushing them apart. At the same time, other microtubules grow radially away from each of the centriole pairs, forming a spiny star called the *aster*; in each end of the cell. Some of the spines of the aster penetrate the nuclear membrane and help separate the two sets of chromatids during mitosis. The complex of microtubules extending between the two new centriole pairs is called the *spindle*, and the entire set of microtubules plus the two pairs of centrioles is called the *mitotic apparatus*.

Prophase. The first stage of mitosis, called *prophase*, is shown in [Figure 3-14A, B, and C](#). While the spindle is forming, the chromosomes of the nucleus (which in interphase consist of loosely coiled strands) become condensed into well-defined chromosomes.

Prometaphase. During the prometaphase stage (see [Figure 3-14D](#)), the growing microtubular spines of the aster fragment the nuclear envelope. At the same time, multiple microtubules from the aster attach to the chromatids at the centromeres, where the paired chromatids are still bound to each other. The tubules then pull one chromatid of each pair toward one cellular pole and its partner toward the opposite pole.

Metaphase. During the metaphase stage (see [Figure 3-14E](#)), the two asters of the mitotic apparatus are pushed farther apart. This pushing is believed to occur because the microtubular spines from the two asters, where they interdigitate with each other to form the mitotic spindle,

push each other away. Minute contractile protein molecules called “*molecular motors*,” which may be composed of the muscle protein *actin*, extend between the respective spines and, using a stepping action as in muscle, actively slide the spines in a reverse direction along each other. Simultaneously, the chromatids are pulled tightly by their attached microtubules to the very center of the cell, lining up to form the *equatorial plate* of the mitotic spindle.

Anaphase. During the anaphase stage (see **Figure 3-14F**), the two chromatids of each chromosome are pulled apart at the centromere. All 46 pairs of chromatids are separated, forming two separate sets of 46 *daughter chromosomes*. One of these sets is pulled toward one mitotic aster, and the other is pulled toward the other aster, as the two respective poles of the dividing cell are pushed still farther apart.

Telophase. In the telophase stage (see **Figure 3-14G and H**), the two sets of daughter chromosomes are pushed completely apart. Then, the mitotic apparatus dissipates, and a new nuclear membrane develops around each set of chromosomes. This membrane is formed from portions of the endoplasmic reticulum that are already present in the cytoplasm. Shortly thereafter, the cell pinches in two, midway between the two nuclei. This pinching is caused by the formation of a contractile ring of *microfilaments* composed of *actin* and probably *myosin* (the two contractile proteins of muscle) at the juncture of the newly developing cells that pinches them off from each other.

CONTROL OF CELL GROWTH AND CELL REPRODUCTION

Some cells grow and reproduce all the time, such as the blood-forming cells of the bone marrow, the germinal layers of the skin, and the epithelium of the gut. Many other cells, however, such as smooth muscle cells, may not reproduce for many years. A few cells, such as the neurons and most striated muscle cells, do not reproduce during the entire life of a person, except during the original period of fetal life.

In certain tissues, an insufficiency of some types of cells causes them to grow and reproduce rapidly until appropriate numbers of these cells are again available. For example, in some young animals, seven-eighths of the liver can be removed surgically, and the cells of the remaining one-eighth will grow and divide until the liver mass returns to almost normal. The same phenomenon occurs for many glandular cells and most cells of the bone marrow, subcutaneous tissue, intestinal epithelium, and almost any other tissue except highly differentiated cells such as nerve and muscle cells.

The mechanisms that maintain proper numbers of the different types of cells in the body are still poorly understood. However, experiments have shown at least three ways in which growth can be controlled. First, growth often is controlled by *growth factors* that come from other

parts of the body. Some of these growth factors circulate in the blood, but others originate in adjacent tissues. For example, the epithelial cells of some glands, such as the pancreas, fail to grow without a growth factor from the underlying connective tissue of the gland. Second, most normal cells stop growing when they have run out of space for growth. This phenomenon occurs when cells are grown in tissue culture; the cells grow until they contact a solid object, and then growth stops. Third, cells grown in tissue culture often stop growing when minute amounts of their own secretions are allowed to collect in the culture medium. This mechanism, too, could provide a means for negative feedback control of growth.

Telomeres Prevent the Degradation of Chromosomes. A *telomere* is a region of repetitive nucleotide sequences located at each end of a chromatid (**Figure 3-16**). Telomeres serve as protective caps that prevent the chromosome from deterioration during cell division. During cell division, a short piece of “primer” RNA attaches to the DNA strand to start the replication. However, because the primer does not attach at the very end of the DNA strand, the copy is missing a small section of the DNA. With each cell division, the copied DNA loses additional nucleotides from the telomere region. The nucleotide sequences provided by the telomeres therefore prevent the degradation of genes near the ends of chromosomes. Without telomeres, the genomes would progressively lose information and be truncated after each cell division. Thus, the telomeres can be considered to be disposable chromosomal buffers that help maintain stability of the genes but are gradually consumed during repeated cell divisions.

Figure 3-16. Control of cell replication by telomeres and telomerase. The cells’ chromosomes are capped by telomeres, which, in the absence of telomerase activity, shorten with each cell division until the cell stops replicating. Therefore, most cells of the body cannot replicate indefinitely. In cancer cells, telomerase is activated, and telomere length is maintained so that the cells continue to replicate themselves uncontrollably.

Each time a cell divides, an average person loses 30 to 200 base pairs from the ends of that cell's telomeres. In human blood cells, the length of telomeres ranges from 8000 base pairs at birth to as low as 1500 in older people. Eventually, when the telomeres shorten to a critical length, the chromosomes become unstable, and the cells die. This process of telomere shortening is believed to be an important reason for some of the physiological changes associated with aging. Telomere erosion can also occur as a result of diseases, especially those associated with oxidative stress and inflammation.

In some cells, such as stem cells of the bone marrow or skin that must be replenished throughout life, or germ cells in the ovaries and testes, the enzyme *telomerase* adds bases to the ends of the telomeres so that many more generations of cells can be produced. However, telomerase activity is usually low in most cells of the body, and after many generations the descendent cells will inherit defective chromosomes, become *senescent*, and cease dividing. This process of telomere shortening is important in regulating cell proliferation and maintaining gene stability. In cancer cells, telomerase activity is abnormally activated so that telomere length is maintained, making it possible for the cells to replicate over and over again uncontrollably (see [Figure 3-16](#)). Some scientists have therefore proposed that telomere shortening protects us from cancer and other proliferative diseases.

Regulation of Cell Size. Cell size is determined almost entirely by the amount of functioning DNA in the nucleus. If replication of the DNA does not occur, the cell grows to a certain size and thereafter remains at that size. Conversely, use of the chemical *colchicine* makes it possible to prevent formation of the mitotic spindle and therefore prevent mitosis, even though replication of the DNA continues. In this event, the nucleus contains far greater quantities of DNA than it normally does, and the cell grows proportionately larger. It is assumed that this cell growth results from increased production of RNA and cell proteins, which, in turn, cause the cell to grow larger.

CELL DIFFERENTIATION

A special characteristic of cell growth and cell division is *cell differentiation*, which refers to changes in the physical and functional properties of cells as they proliferate in the embryo to form the different body structures and organs. The following description of an especially interesting experiment helps explain these processes.

When the nucleus from an intestinal mucosal cell of a frog is surgically implanted into a frog ovum from which the original ovum nucleus was removed, the result is often the formation of a normal frog. This experiment demonstrates that even the intestinal mucosal cell, which is a well-differentiated cell, carries all the necessary genetic information for development of all structures required in the frog's body.

Therefore, it has become clear that differentiation results not from loss of genes but from selective repression of different gene promoters. In fact, electron micrographs suggest that some segments of DNA helices that are wound around histone cores become so condensed that they no longer uncoil to form RNA molecules. One explanation for this is as follows. It has been supposed that the cellular genome begins at a certain stage of cell differentiation to produce a regulatory *protein* that forever after represses a select group of genes. Therefore, the repressed genes never function again. Regardless of the mechanism, mature human cells each produce a maximum of about 8000 to 10,000 proteins rather than the potential 20,000 to 25,000 or more that would be produced if all genes were active.

Embryological experiments have shown that certain cells in an embryo control differentiation of adjacent cells. For example, the *primordial chordamesoderm* is called the *primary organizer* of the embryo because it forms a focus around which the remainder of the embryo develops. It differentiates into a *mesodermal axis* that contains segmentally arranged *somites* and, as a result of *inductions* in the surrounding tissues, causes the formation of essentially all the organs of the body.

Another instance of induction occurs when the developing eye vesicles come into contact with the ectoderm of the head and cause the ectoderm to thicken into a lens plate that folds inward to form the lens of the eye. Therefore, a large share of the embryo develops as a result of such inductions, with one part of the body affecting another part, and this part affecting still other parts.

Thus, although our understanding of cell differentiation is still hazy, we are aware of many control mechanisms whereby differentiation *could* occur.

APOPTOSIS—PROGRAMMED CELL DEATH

The many trillions of the body's cells are members of a highly organized community in which the total number of cells is regulated not only by controlling the rate of cell division, but also by controlling the rate of cell death. When cells are no longer needed or become a threat to the organism, they undergo a suicidal *programmed cell death*, or *apoptosis*. This process involves a specific proteolytic cascade that causes the cell to shrink and condense, disassemble its cytoskeleton, and alter its cell surface so that a neighboring phagocytic cell, such as a macrophage, can attach to the cell membrane and digest the cell.

In contrast to programmed death, cells that die as a result of an acute injury usually swell and burst due to loss of cell membrane integrity, a process called cell *necrosis*. Necrotic cells may spill their contents, causing inflammation and injury to neighboring cells. Apoptosis, however, is an orderly cell death that results in disassembly and phagocytosis of the cell before any leakage of its contents occurs, and neighboring cells usually remain healthy.

Apoptosis is initiated by activation of a family of proteases called *caspases*, which are enzymes that are synthesized and stored in the cell as inactive *procaspases*. The mechanisms of activation of caspases are complex but, once activated, the enzymes cleave and activate other procaspases, triggering a cascade that rapidly breaks down proteins within the cell. The cell thus dismantles itself, and its remains are rapidly digested by neighboring phagocytic cells.

A tremendous amount of apoptosis occurs in tissues that are being remodeled during development. Even in adult humans, billions of cells die each hour in tissues such as the intestine and bone marrow and are replaced by new cells. Programmed cell death, however, is normally balanced by formation of new cells in healthy adults. Otherwise, the body's tissues would shrink or grow excessively. Abnormalities of apoptosis may play a key role in neurodegenerative diseases such as Alzheimer disease, as well as in cancer and autoimmune disorders. Some drugs that have been used successfully for chemotherapy appear to induce apoptosis in cancer cells.

CANCER

Cancer may be caused by *mutation* or by some other *abnormal activation* of cellular genes that control cell growth and cell mitosis. *Proto-oncogenes* are normal genes that code for various proteins that control cell adhesion, growth and division. If mutated or excessively activated, proto-oncogenes can become abnormally functioning *oncogenes* capable of causing cancer. As many as 100 different oncogenes have been discovered in human cancers.

Also present in all cells are *antioncogenes*, also called *tumor suppressor genes*, which suppress the activation of specific oncogenes. Therefore, loss or inactivation of antioncogenes can allow activation of oncogenes that lead to cancer.

For several reasons, only a minute fraction of the cells that mutate in the body ever lead to cancer:

- First, most mutated cells have less survival capability than normal cells, and they simply die.
- Second, only a few of the mutated cells that survive become cancerous because most mutated cells still have normal feedback controls that prevent excessive growth.
- Third, cells that are potentially cancerous are often destroyed by the body's immune system before they grow into a cancer.

Most mutated cells form abnormal proteins within their cell bodies because of their altered genes, and these proteins activate the body's immune system, causing it to form antibodies or sensitized lymphocytes that react against the cancerous cells, destroying them. In people whose immune systems have been suppressed, such as in persons taking immunosuppressant drugs after kidney or heart transplantation, the probability that a cancer will develop is multiplied as much as fivefold.

- Fourth, the simultaneous presence of several different activated oncogenes is usually required to cause a cancer. For example, one such gene might promote rapid reproduction of a cell line, but no cancer occurs because another mutant gene is not present simultaneously to form the needed blood vessels.

What is it that causes the altered genes? Considering that many trillions of new cells are formed each year in humans, a better question might be to ask why all of us do not develop millions or billions of mutant cancerous cells. The answer is the incredible precision with which DNA chromosomal strands are replicated in each cell before mitosis can take place, along with the proofreading process that cuts and repairs any abnormal DNA strand before the mitotic process is allowed to proceed. Yet, despite these inherited cellular precautions, probably one newly formed cell in every few million still has significant mutant characteristics.

Thus, chance alone is all that is required for mutations to take place, so we can suppose that a large number of cancers are merely the result of an unlucky occurrence. However, the probability of mutations can be greatly increased when a person is exposed to certain chemical, physical, or biological factors, including the following:

1. *Ionizing radiation*, such as x-rays, gamma rays, particle radiation from radioactive substances, and even ultraviolet light, can predispose individuals to cancer. Ions formed in tissue cells under the influence of such radiation are highly reactive and can rupture DNA strands, causing many mutations.
2. *Chemical substances* of certain types may also cause mutations. It was discovered long ago that various aniline dye derivatives are likely to cause cancer, and thus workers in chemical plants producing such substances, if unprotected, have a special predisposition to cancer. Chemical substances that can cause mutation are called *carcinogens*. The carcinogens that currently cause the greatest number of deaths are those in cigarette smoke. These carcinogens cause over 30% of all cancer deaths and at least 85% of lung cancer deaths.
3. *Physical irritants* can also lead to cancer, such as continued abrasion of the linings of the intestinal tract by some types of food. The damage to the tissues leads to rapid mitotic replacement of the cells; the more rapid the mitosis, the greater the chance for mutation.
4. *Hereditary tendency* to cancer occurs in some families. This hereditary tendency results from the fact that most cancers require not one mutation but two or more mutations before cancer occurs. In families that are particularly predisposed to cancer, it is presumed that one or more cancerous genes are already

mutated in the inherited genome. Therefore, far fewer additional mutations must take place in such family members before a cancer begins to grow.

5. *Certain types of oncoviruses* can cause various types of cancer. Some examples of viruses associated with cancers in humans include *human papilloma virus* (HPV), *hepatitis B and hepatitis C virus*, Epstein-Barr virus, human immunodeficiency virus (HIV), human T-cell leukemia virus, Kaposi sarcoma–associated herpes virus (KSHV), and Merkel cell polyomavirus. Although the mechanisms whereby oncoviruses cause cancer are not fully understood, there are at least two potential ways. In the case of DNA viruses, the DNA strand of the virus can insert itself directly into one of the chromosomes, thereby causing a mutation that leads to cancer. In the case of RNA viruses, some of these viruses carry with them an enzyme called *reverse transcriptase* that causes DNA to be transcribed from the RNA. The transcribed DNA then inserts itself into the animal cell genome, leading to cancer.

Invasive Characteristic of the Cancer Cell. The major differences between a cancer cell and a normal cell are as follows:

1. The cancer cell does not respect usual cellular growth limits because these cells presumably do not require all the same growth factors that are necessary to cause growth of normal cells.
2. Cancer cells are often far less adhesive to one another than are normal cells. Therefore, they tend to wander through the tissues, enter the blood stream, and be transported all through the body, where they form *nidi* for numerous new cancerous growths.
3. Some cancers also produce *angiogenic factors* that cause many new blood vessels to grow into the cancer, thus supplying the nutrients required for cancer growth.

Why Do Cancer Cells Kill? Cancer tissue competes with normal tissues for nutrients. Because cancer cells continue to proliferate indefinitely, with their numbers multiplying every day, cancer cells soon demand essentially all the nutrition available to the body or to an essential part of the body. As a result, normal tissues gradually sustain nutritive death.

Some cancers cause disruption of vital organ functions. For example, a lung cancer might replace healthy tissue to the extent that the lungs cannot absorb enough oxygen to maintain tissues in the rest of the body.

Transport of Substances Through Cell Membranes

Figure 4-1 lists the approximate concentrations of important electrolytes and other substances in the *extracellular fluid* and *intracellular fluid*. Note that the extracellular fluid contains a large amount of *sodium* but only a small amount of *potassium*. The opposite is true of the intracellular fluid. Also, the extracellular fluid contains a large amount of *chloride* ions, whereas the intracellular fluid contains very little of these ions. However, the concentrations of *phosphates* and *proteins* in the intracellular fluid are considerably greater than those in the extracellular fluid. These differences are extremely important to the life of the cell. The purpose of this chapter is to explain how the differences are brought about by the cell membrane transport mechanisms.

	EXTRACELLULAR FLUID	INTRACELLULAR FLUID
Na ⁺	142 mEq/L	10 mEq/L
K ⁺	4 mEq/L	140 mEq/L
Ca ²⁺	2.4 mEq/L	0.0001 mEq/L
Mg ²⁺	1.2 mEq/L	58 mEq/L
Cl ⁻	103 mEq/L	4 mEq/L
HCO ₃ ⁻	24 mEq/L	10 mEq/L
Phosphates	4 mEq/L	75 mEq/L
SO ₄ ²⁻	1 mEq/L	2 mEq/L
Glucose	90 mg/dl	0 to 20 mg/dl
Amino acids	30 mg/dl	200 mg/dl ?
Cholesterol	0.5 g/dl	2 to 95 g/dl
Phospholipids		
Neutral fat		
PO ₂	35 mm Hg	20 mm Hg ?
PCO ₂	46 mm Hg	50 mm Hg ?
pH	7.4	7.0
Proteins	2 g/dl (5 mEq/L)	16 g/dl (40 mEq/L)

Figure 4-1. Chemical compositions of extracellular and intracellular fluids. The question marks indicate that the precise values for intracellular fluid are unknown. The red line indicates the cell membrane.

THE CELL MEMBRANE IS A LIPID BILAYER WITH CELL MEMBRANE TRANSPORT PROTEINS

The structure of the membrane covering the outside of every cell of the body is discussed in **Chapter 2** and illustrated in **Figure 2-3** and **Figure 4-2**. This membrane consists almost entirely of a *lipid bilayer* with large numbers of protein molecules in the lipid, many of which penetrate all the way through the membrane.

The lipid bilayer is not miscible with the extracellular fluid or the intracellular fluid. Therefore, it constitutes a barrier against movement of water molecules and water-soluble substances between the extracellular and intracellular fluid compartments. However, as shown in **Figure 4-2** by the leftmost arrow, lipid-soluble substances can diffuse directly through the lipid substance.

The membrane protein molecules interrupt the continuity of the lipid bilayer, constituting an alternative pathway through the cell membrane. Many of these penetrating proteins can function as *transport proteins*. Some proteins have watery spaces all the way through the molecule and allow free movement of water, as well as selected ions or molecules; these proteins are called *channel proteins*. Other proteins, called *carrier proteins*, bind with molecules or ions that are to be transported, and conformational changes in the protein molecules then move the substances through the interstices of the protein to the

Figure 4-2. Transport pathways through the cell membrane and the basic mechanisms of transport.

Figure 4-3. Diffusion of a fluid molecule during one thousandth of a second.

other side of the membrane. Channel proteins and carrier proteins are usually selective for the types of molecules or ions that are allowed to cross the membrane.

“Diffusion” Versus “Active Transport.” Transport through the cell membrane, either directly through the lipid bilayer or through the proteins, occurs via one of two basic processes, *diffusion* or *active transport*.

Although many variations of these basic mechanisms exist, *diffusion* means random molecular movement of substances molecule by molecule, either through intermolecular spaces in the membrane or in combination with a carrier protein. The energy that causes diffusion is the energy of the normal kinetic motion of matter.

In contrast, *active transport* means movement of ions or other substances across the membrane in combination with a carrier protein in such a way that the carrier protein causes the substance to move against an energy gradient, such as from a low-concentration state to a high-concentration state. This movement requires an additional source of energy besides kinetic energy. A more detailed explanation of the basic physics and physical chemistry of these two processes is provided later in this chapter.

DIFFUSION

All molecules and ions in the body fluids, including water molecules and dissolved substances, are in constant motion, with each particle moving in its separate way. The motion of these particles is what physicists call “heat”—the greater the motion, the higher the temperature—and the motion never ceases, except at absolute zero temperature. When a moving molecule, A, approaches a stationary molecule, B, the electrostatic and other nuclear forces of molecule A repel molecule B, transferring some of the energy of motion of molecule A to molecule B. Consequently, molecule B gains kinetic energy of motion, whereas molecule A slows down, losing some of its kinetic energy. As shown in **Figure 4-3**, a single molecule in a solution bounces among the other molecules—first in one direction, then another, then another, and so forth—randomly bouncing thousands of times each second. This continual movement of molecules among one another in liquids or gases is called *diffusion*.

Ions diffuse in the same manner as whole molecules, and even suspended colloid particles diffuse in a similar manner, except that the colloids diffuse far less rapidly than molecular substances because of their large size.

DIFFUSION THROUGH THE CELL MEMBRANE

Diffusion through the cell membrane is divided into two subtypes, called *simple diffusion* and *facilitated diffusion*. Simple diffusion means that kinetic movement of molecules or ions occurs through a membrane opening or through intermolecular spaces without interaction with carrier proteins in the membrane. The rate of diffusion is determined by the amount of substance available, the velocity of kinetic motion, and the number and sizes of openings in the membrane through which the molecules or ions can move.

Facilitated diffusion requires interaction of a carrier protein. The carrier protein aids passage of molecules or ions through the membrane by binding chemically with them and shuttling them through the membrane in this form.

Simple diffusion can occur through the cell membrane by two pathways: (1) through the interstices of the lipid bilayer if the diffusing substance is lipid-soluble; and (2) through watery channels that penetrate all the way through some of the large transport proteins, as shown to the left in **Figure 4-2**.

Diffusion of Lipid-Soluble Substances Through the Lipid Bilayer.

The *lipid solubility* of a substance is an important factor for determining how rapidly it diffuses through the lipid bilayer. For example, the lipid solubilities of oxygen, nitrogen, carbon dioxide, and alcohols are high, and all these substances can dissolve directly in the lipid bilayer and diffuse through the cell membrane in the same manner that diffusion of water solutes occurs in a watery solution. The rate of diffusion of each of these substances through the membrane is directly proportional to its lipid solubility. Especially large amounts of oxygen can be transported in this way; therefore, oxygen can be delivered to the interior of the cell almost as though the cell membrane did not exist.

Diffusion of Water and Other Lipid-Insoluble Molecules Through Protein Channels.

Even though water is highly insoluble in the membrane lipids, it readily passes through channels in protein molecules that penetrate all the way through the membrane. Many of the body’s cell membranes contain protein “pores” called *aquaporins* that selectively permit rapid passage of water through the membrane. The aquaporins are highly specialized, and there are at least 13 different types in various cells of mammals.

The rapidity with which water molecules can diffuse through most cell membranes is astounding. For example, the total amount of water that diffuses in each direction

through the red blood cell membrane during each second is about 100 times as great as the volume of the red blood cell.

Other lipid-insoluble molecules can pass through the protein pore channels in the same way as water molecules if they are water-soluble and small enough. However, as they become larger, their penetration falls off rapidly. For example, the diameter of the urea molecule is only 20% greater than that of water, yet its penetration through the cell membrane pores is about 1000 times less than that of water. Even so, given the astonishing rate of water penetration, this amount of urea penetration still allows rapid transport of urea through the membrane within minutes.

DIFFUSION THROUGH PROTEIN PORES AND CHANNELS—SELECTIVE PERMEABILITY AND “GATING” OF CHANNELS

Computerized three-dimensional reconstructions of protein pores and channels have demonstrated tubular pathways all the way from the extracellular to the intracellular fluid. Therefore, substances can move by simple diffusion directly along these pores and channels from one side of the membrane to the other.

Pores are composed of integral cell membrane proteins that form open tubes through the membrane and are always open. However, the diameter of a pore and its electrical charges provide selectivity that permits only certain molecules to pass through. For example, *aquaporins* permit rapid passage of water through cell membranes but exclude other molecules. Aquaporins have a narrow pore that permits water molecules to diffuse through the membrane in single file. The pore is too narrow to permit passage of any hydrated ions. As discussed in Chapters 28 and 76, the density of some aquaporins (e.g., aquaporin-2) in cell membranes is not static but is altered in different physiological conditions.

The protein channels are distinguished by two important characteristics: (1) they are often *selectively permeable* to certain substances; and (2) many of the channels can be opened or closed by *gates* that are regulated by electrical signals (*voltage-gated channels*) or chemicals that bind to the channel proteins (*ligand-gated channels*). Thus, ion channels are flexible dynamic structures, and subtle conformational changes influence gating and ion selectivity.

Selective Permeability of Protein Channels. Many protein channels are highly selective for transport of one or more specific ions or molecules. This selectivity results from specific characteristics of the channel, such as its diameter, shape, and the nature of the electrical charges and chemical bonds along its inside surfaces.

Potassium channels permit passage of potassium ions across the cell membrane about 1000 times more readily than they permit passage of sodium ions. This high degree of selectivity cannot be explained entirely by the

Figure 4-4. The structure of a potassium channel. The channel is composed of four subunits (only two of which are shown), each with two transmembrane helices. A narrow selectivity filter is formed from the pore loops, and carbonyl oxygens line the walls of the selectivity filter, forming sites for transiently binding dehydrated potassium ions. The interaction of the potassium ions with carbonyl oxygens causes the potassium ions to shed their bound water molecules, permitting the dehydrated potassium ions to pass through the pore.

molecular diameters of the ions because potassium ions are slightly larger than sodium ions. Using x-ray crystallography, potassium channels were found to have a *tetrameric structure* consisting of four identical protein subunits surrounding a central pore (Figure 4-4). At the top of the channel pore are *pore loops* that form a narrow *selectivity filter*. Lining the selectivity filter are *carbonyl oxygens*. When hydrated potassium ions enter the selectivity filter, they interact with the carbonyl oxygens and shed most of their bound water molecules, permitting the dehydrated potassium ions to pass through the channel. The carbonyl oxygens are too far apart, however, to enable them to interact closely with the smaller sodium ions, which are therefore effectively excluded by the selectivity filter from passing through the pore.

Different selectivity filters for the various ion channels are believed to determine, in large part, the specificity of various channels for cations or anions or for particular ions, such as sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}), that gain access to the channels.

One of the most important of the protein channels, the *sodium channel*, is only 0.3 to 0.5 nanometer in diameter, but the ability of sodium channels to discriminate sodium ions among other competing ions in the surrounding fluids is crucial for proper cellular function.

Figure 4-5. Transport of sodium and potassium ions through protein channels. Also shown are conformational changes in the protein molecules to open or close the “gates” guarding the channels.

The narrowest part of the sodium channel’s open pore, the *selectivity filter*, is lined with *strongly negatively charged* amino acid residues, as shown in the top panel of [Figure 4-5](#). These strong negative charges can pull small *dehydrated* sodium ions away from their hydrating water molecules into these channels, although the ions do not need to be fully dehydrated to pass through the channels. Once in the channel, the sodium ions diffuse in either direction according to the usual laws of diffusion. Thus, the sodium channel is highly selective for passage of sodium ions.

Gating of Protein Channels. Gating of protein channels provides a means of controlling ion permeability of the channels. This mechanism is shown in both panels of [Figure 4-5](#) for selective gating of sodium and potassium ions. Some of the gates are thought to be gate-like extensions of the transport protein molecule, which can close the opening of the channel or can be lifted away from the opening by a conformational change in the shape of the protein molecule.

The opening and closing of gates are controlled in two principal ways:

1. **Voltage gating.** In the case of voltage gating, the molecular conformation of the gate or its chemical bonds responds to the electrical potential across the cell membrane. For example, in the top panel of [Figure 4-5](#), a strong negative charge on the inside of the cell membrane may cause the outside sodium gates to remain tightly closed. Conversely, when the inside of the membrane loses its negative charge, these gates open suddenly and allow sodium to pass inward through the sodium pores. This process is the basic mechanism for eliciting action potentials in nerves that are responsible for nerve signals. In

the bottom panel of [Figure 4-5](#), the potassium gates are on the intracellular ends of the potassium channels, and they open when the inside of the cell membrane becomes positively charged. The opening of these gates is partly responsible for terminating the action potential, a process discussed in [Chapter 5](#).

2. **Chemical (ligand) gating.** Some protein channel gates are opened by the binding of a chemical substance (a ligand) with the protein, which causes a conformational or chemical bonding change in the protein molecule that opens or closes the gate. One of the most important instances of chemical gating is the effect of the neurotransmitter acetylcholine on the *acetylcholine receptor* which serves as a ligand-gated ion channel. Acetylcholine opens the gate of this channel, providing a negatively charged pore about 0.65 nanometer in diameter that allows uncharged molecules or positive ions smaller than this diameter to pass through. This gate is exceedingly important for the transmission of nerve signals from one nerve cell to another (see [Chapter 46](#)) and from nerve cells to muscle cells to cause muscle contraction (see [Chapter 7](#)).

Open-State Versus Closed-State of Gated Channels.

[Figure 4-6A](#) shows two recordings of electrical current flowing through a single sodium channel when there was an approximately 25-millivolt potential gradient across the membrane. Note that the channel conducts current in an all-or-none fashion. That is, the gate of the channel snaps open and then snaps closed, with each open state lasting for only a fraction of a millisecond, up to several milliseconds, demonstrating the rapidity with which changes can occur during the opening and closing of the protein gates. At one voltage potential, the channel may remain closed all the time or almost all the time, whereas at another voltage, it may remain open either all or most of the time. At in-between voltages, as shown in the figure, the gates tend to snap open and closed intermittently, resulting in an average current flow somewhere between the minimum and maximum.

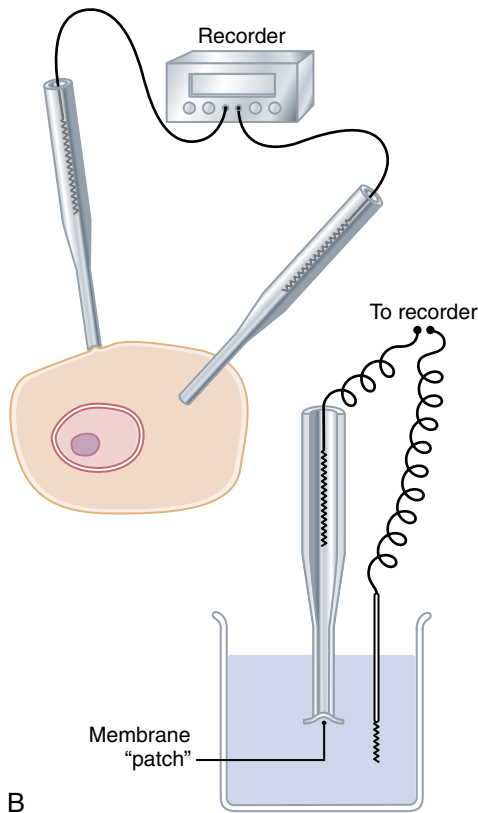

Patch Clamp Method for Recording Ion Current Flow Through Single Channels.

The patch clamp method for recording ion current flow through single protein channels is illustrated in [Figure 4-6B](#). A micropipette with a tip diameter of only 1 or 2 micrometers is abutted against the outside of a cell membrane. Suction is then applied inside the pipette to pull the membrane against the tip of the pipette, which creates a seal where the edges of the pipette touch the cell membrane. The result is a minute membrane “patch” at the tip of the pipette through which electrical current flow can be recorded.

Alternatively, as shown at the bottom right in [Figure 4-6B](#), the small cell membrane patch at the end of the pipette can be torn away from the cell. The pipette with its sealed patch is then inserted into a free solution, which

A

B

Figure 4-6. **A**, Recording of current flow through a single voltage-gated sodium channel, demonstrating the all or none principle for opening and closing of the channel. **B**, Patch clamp method for recording current flow through a single protein channel. To the left, the recording is performed from a “patch” of a living cell membrane. To the right, the recording is from a membrane patch that has been torn away from the cell.

allows the concentrations of ions both inside the micropipette and in the outside solution to be altered as desired. Also, the voltage between the two sides of the membrane can be set, or “clamped,” to a given voltage.

It has been possible to make such patches small enough so that only a single channel protein is found in the membrane patch being studied. By varying the concentrations of different ions, as well as the voltage across the membrane, one can determine the transport characteristics of the single channel, along with its gating properties.

Figure 4-7. Effect of concentration of a substance on the rate of diffusion through a membrane by simple diffusion and facilitated diffusion. This graph shows that facilitated diffusion approaches a maximum rate, called the V_{max} .

FACILITATED DIFFUSION REQUIRES MEMBRANE CARRIER PROTEINS

Facilitated diffusion is also called *carrier-mediated diffusion* because a substance transported in this manner diffuses through the membrane with the help of a specific carrier protein. That is, the carrier *facilitates* diffusion of the substance to the other side.

Facilitated diffusion differs from simple diffusion in the following important way. Although the rate of simple diffusion through an open channel increases proportionately with the concentration of the diffusing substance, in facilitated diffusion the rate of diffusion approaches a maximum, called V_{max} , as the concentration of the diffusing substance increases. This difference between simple diffusion and facilitated diffusion is demonstrated in **Figure 4-7**. The figure shows that as the concentration of the diffusing substance increases, the rate of simple diffusion continues to increase proportionately but, in the case of facilitated diffusion, the rate of diffusion cannot rise higher than the V_{max} level.

What is it that limits the rate of facilitated diffusion? A probable answer is the mechanism illustrated in **Figure 4-8**. This Figure shows a carrier protein with a pore large enough to transport a specific molecule partway through. It also shows a binding receptor on the inside of the protein carrier. The molecule to be transported enters the pore and becomes bound. Then, in a fraction of a second, a conformational or chemical change occurs in the carrier protein, so that the pore now opens to the opposite side of the membrane. Because the binding force of the receptor is weak, the thermal motion of the attached molecule causes it to break away and be released on the opposite side of the membrane. The rate at which molecules can be transported by this mechanism can never be greater than the rate at which the carrier protein molecule can undergo change back and forth between its two states. Note specifically, though, that this mechanism allows the transported molecule to move—that is, diffuse—in either direction through the membrane.

Figure 4-8. Postulated mechanism for facilitated diffusion.

Among the many substances that cross cell membranes by facilitated diffusion are *glucose* and most of the *amino acids*. In the case of glucose, at least 14 members of a family of membrane proteins (called *GLUT*) that transport glucose molecules have been discovered in various tissues. Some of these GLUT proteins transport other monosaccharides that have structures similar to that of glucose, including galactose and fructose. One of these, glucose transporter 4 (*GLUT4*), is activated by insulin, which can increase the rate of facilitated diffusion of glucose as much as 10- to 20-fold in insulin-sensitive tissues. This is the principal mechanism whereby insulin controls glucose use in the body, as discussed in [Chapter 79](#).

FACTORS THAT AFFECT NET RATE OF DIFFUSION

By now, it is evident that many substances can diffuse through the cell membrane. What is usually important is the *net* rate of diffusion of a substance in the desired direction. This net rate is determined by several factors.

Net Diffusion Rate Is Proportional to the Concentration Difference Across a Membrane. [Figure 4-9A](#) shows a cell membrane with a high concentration of a substance on the outside and a low concentration of a substance on the inside. The rate at which the substance diffuses *inward* is proportional to the concentration of molecules on the *outside* because this concentration determines how many molecules strike the outside of the membrane each second. Conversely, the rate at which molecules diffuse *outward* is proportional to their concentration *inside* the membrane. Therefore, the rate of net diffusion into the cell is proportional to the concentration on the outside *minus* the concentration on the inside:

$$\text{Net diffusion} \propto (C_o - C_i)$$

Figure 4-9. Effect of concentration difference (**A**), electrical potential difference affecting negative ions (**B**), and pressure difference (**C**) to cause diffusion of molecules and ions through a cell membrane. C_o , concentration outside the cell; C_i , concentration inside the cell; P_1 pressure 1; P_2 pressure 2.

in which C_o is the concentration outside and C_i is the concentration inside the cell.

Membrane Electrical Potential and Diffusion of Ions—The “Nernst Potential.” If an electrical potential is applied across the membrane, as shown in [Figure 4-9B](#), the electrical charges of the ions cause them to move through the membrane even though no concentration difference exists to cause movement. Thus, in the left panel of [Figure 4-9B](#), the concentration of *negative* ions is the same on both sides of the membrane, but a positive charge has been applied to the right side of the membrane, and a negative charge has been applied to the left, creating an electrical gradient across the membrane. The positive charge attracts the negative ions, whereas the negative charge repels them. Therefore, net diffusion occurs from left to right. After some time, large quantities of negative ions have moved to the right, creating the condition shown in the right panel of [Figure 4-9B](#), in which a concentration difference of the ions has developed in the direction opposite to the electrical potential difference. The concentration difference now tends to move the ions to the left, whereas the electrical difference tends to move them to the right. When the concentration difference rises high enough, the two effects balance each other. At normal body temperature (98.6°F; 37°C), the electrical difference that will balance a given concentration difference

of *univalent* ions—such as Na^+ ions—can be determined from the following formula, called the *Nernst equation*:

$$\text{EMF (in millivolts)} = \pm 61 \log \frac{C_1}{C_2}$$

in which EMF is the electromotive force (voltage) between side 1 and side 2 of the membrane, C_1 is the concentration on side 1, and C_2 is the concentration on side 2. This equation is extremely important in understanding the transmission of nerve impulses and is discussed in Chapter 5.

Effect of a Pressure Difference Across the Membrane.

At times, a considerable pressure difference develops between the two sides of a diffusible membrane. This pressure difference occurs, for example, at the blood capillary membranes in all tissues of the body. The pressure in many capillaries is about 20 mm Hg greater inside than outside.

Pressure actually means the sum of all the forces of the different molecules striking a unit surface area at a given instant. Therefore, having a higher pressure on one side of a membrane than on the other side means that the sum of all the forces of the molecules striking the channels on that side of the membrane is greater than on the other side. In most cases, this situation is caused by greater numbers of molecules striking the membrane per second on one side than on the other side. The result is that increased amounts of energy are available to cause a net movement of molecules from the high-pressure side toward the low-pressure side. This effect is demonstrated in Figure 4-9C, which shows a piston developing high pressure on one side of a pore, thereby causing more molecules to strike the pore on this side and, therefore, more molecules to diffuse to the other side.

OSMOSIS ACROSS SELECTIVELY PERMEABLE MEMBRANES—“NET DIFFUSION” OF WATER

By far, the most abundant substance that diffuses through the cell membrane is water. Enough water ordinarily diffuses in each direction through the red blood cell membrane per second to equal about *100 times the volume of the cell itself*. Yet, the amount that normally diffuses in the two directions is balanced so precisely that zero net movement of water occurs. Therefore, the volume of the cell remains constant. However, under certain conditions, a *concentration difference for water* can develop across a membrane. When this concentration difference for water develops, net movement of water does occur across the cell membrane, causing the cell to swell or shrink, depending on the direction of the water movement. This process of net movement of water caused by a concentration difference of water is called *osmosis*.

To illustrate osmosis, let us assume the conditions shown in Figure 4-10, with pure water on one side of the cell membrane and a solution of sodium chloride on the

Figure 4-10. Osmosis at a cell membrane when a sodium chloride solution is placed on one side of the membrane and water is placed on the other side.

other side. Water molecules pass through the cell membrane with ease, whereas sodium and chloride ions pass through only with difficulty. Therefore, sodium chloride solution is actually a mixture of permeant water molecules and nonpermeant sodium and chloride ions, and the membrane is said to be *selectively permeable* to water but much less so to sodium and chloride ions. Yet, the presence of the sodium and chloride has displaced some of the water molecules on the side of the membrane where these ions are present and, therefore, has reduced the concentration of water molecules to less than that of pure water. As a result, in the example shown in Figure 4-10, more water molecules strike the channels on the left side, where there is pure water, than on the right side, where the water concentration has been reduced. Thus, net movement of water occurs from left to right—that is, *osmosis* occurs from the pure water into the sodium chloride solution.

Osmotic Pressure

If in Figure 4-10 pressure were applied to the sodium chloride solution, osmosis of water into this solution would be slowed, stopped, or even reversed. The amount of pressure required to stop osmosis is called the *osmotic pressure* of the sodium chloride solution.

The principle of a pressure difference opposing osmosis is demonstrated in Figure 4-11, which shows a selectively permeable membrane separating two columns of fluid, one containing pure water and the other containing a solution of water and any solute that will not penetrate the membrane. Osmosis of water from chamber B into chamber A causes the levels of the fluid columns to become farther and farther apart, until eventually a pressure difference develops between the two sides of the membrane that is great enough to oppose the osmotic effect. The pressure difference across the membrane at this point is equal to the osmotic pressure of the solution that contains the nondiffusible solute.

Figure 4-11. Demonstration of osmotic pressure caused by osmosis at a semipermeable membrane.

Importance of Number of Osmotic Particles (Molar Concentration) in Determining Osmotic Pressure.

The osmotic pressure exerted by particles in a solution, whether they are molecules or ions, is determined by the number of particles per unit volume of fluid, not by the mass of the particles. The reason for this is that each particle in a solution, regardless of its mass, exerts, on average, the same amount of pressure against the membrane. That is, large particles, which have greater mass (m) than small particles, move at a slower velocity (v). The small particles move at higher velocities in such a way that their average kinetic energies (k), as determined by the following equation,

$$k = \frac{mv^2}{2}$$

are the same for each small particle as for each large particle. Consequently, the factor that determines the osmotic pressure of a solution is the concentration of the solution in terms of the number of particles (which is the same as its *molar concentration* if it is a nondissociated molecule), not in terms of mass of the solute.

Osmolality—The Osmole. To express the concentration of a solution in terms of numbers of particles, a unit called the *osmole* is used in place of grams.

One osmole is 1 gram molecular weight of osmotically active solute. Thus, 180 grams of glucose, which is 1 gram molecular weight of glucose, is equal to 1 osmole of glucose because glucose does not dissociate into ions. If a solute dissociates into two ions, 1 gram molecular weight of the solute will become 2 osmoles because the number of osmotically active particles is now twice as great as for the nondissociated solute. Therefore, when fully dissociated, 1 gram molecular weight of sodium chloride, 58.5 grams, is equal to 2 osmoles.

Thus, a solution that has 1 osmole of solute dissolved in each kilogram of water is said to have an *osmolality of 1 osmole per kilogram*, and a solution that has 1/1000 osmole dissolved per kilogram has an osmolality of 1 milliosmole per kilogram. The normal osmolality of the extracellular and intracellular fluids is about 300 milliosmoles per kilogram of water.

Relationship of Osmolality to Osmotic Pressure. At normal body temperature, 37°C (98.6°F), a concentration of 1 osmole per liter will cause 19,300 mm Hg osmotic pressure in the solution. Likewise, 1 milliosmole per liter concentration is equivalent to 19.3 mm Hg osmotic pressure. Multiplying this value by the 300-milliosmolar concentration of the body fluids gives a total calculated osmotic pressure of the body fluids of 5790 mm Hg. The measured value for this, however, averages only about 5500 mm Hg. The reason for this difference is that many ions in the body fluids, such as sodium and chloride ions, are highly attracted to one another; consequently, they cannot move entirely unrestrained in the fluids and create their full osmotic pressure potential. Therefore, on average, the actual osmotic pressure of the body fluids is about 0.93 times the calculated value.

The Term Osmolarity. *Osmolarity* is the osmolar concentration expressed as *osmoles per liter of solution* rather than osmoles per kilogram of water. Although, strictly speaking, it is osmoles per kilogram of water (osmolality) that determines osmotic pressure, the quantitative differences between osmolarity and osmolality are less than 1% for dilute solutions such as those in the body. Because it is far more practical to measure osmolarity than osmolality, measuring osmolarity is the usual practice in physiological studies.

ACTIVE TRANSPORT OF SUBSTANCES THROUGH MEMBRANES

At times, a large concentration of a substance is required in the intracellular fluid, even though the extracellular fluid contains only a small concentration. This situation is true, for example, for potassium ions. Conversely, it is important to keep the concentrations of other ions very low inside the cell, even though their concentrations in the extracellular fluid are high. This situation is especially true for sodium ions. Neither of these two effects could occur by simple diffusion because simple diffusion eventually equilibrates concentrations on the two sides of the membrane. Instead, some energy source must cause excess movement of potassium ions to the inside of cells and excess movement of sodium ions to the outside of cells. When a cell membrane moves molecules or ions uphill against a concentration gradient (or uphill against an electrical or pressure gradient), the process is called *active transport*.

Some examples of substances that are actively transported through at least some cell membranes include

sodium, potassium, calcium, iron, hydrogen, chloride, iodide, and urate ions, several different sugars, and most of the amino acids.

Primary Active Transport and Secondary Active Transport. Active transport is divided into two types according to the source of the energy used to facilitate the transport, *primary active transport* and *secondary active transport*. In primary active transport, the energy is derived directly from the breakdown of adenosine triphosphate (ATP) or some other high-energy phosphate compound. In secondary active transport, the energy is derived secondarily from energy that has been stored in the form of ionic concentration differences of secondary molecular or ionic substances between the two sides of a cell membrane, created originally by primary active transport. In both cases, transport depends on *carrier proteins* that penetrate through the cell membrane, as is true for facilitated diffusion. However, in active transport, the carrier protein functions differently from the carrier in facilitated diffusion because it is capable of imparting energy to the transported substance to move it against the electrochemical gradient. The following sections provide some examples of primary active transport and secondary active transport, with more detailed explanations of their principles of function.

PRIMARY ACTIVE TRANSPORT

Sodium-Potassium Pump Transports Sodium Ions Out of Cells and Potassium Ions into Cells

Among the substances that are transported by primary active transport are sodium, potassium, calcium, hydrogen, chloride, and a few other ions. The active transport mechanism that has been studied in greatest detail is the *sodium-potassium* ($\text{Na}^+\text{-K}^+$) pump, a transporter that pumps sodium ions outward through the cell membrane of all cells and, at the same time, pumps potassium ions from the outside to the inside. This pump is responsible for maintaining the sodium and potassium concentration differences across the cell membrane, as well as for establishing a negative electrical voltage inside the cells. Indeed, [Chapter 5](#) shows that this pump is also the basis of nerve function, transmitting nerve signals throughout the nervous system.

Figure 4-12 shows the basic physical components of the $\text{Na}^+\text{-K}^+$ pump. The *carrier protein* is a complex of two separate globular proteins—a larger one called the α subunit, with a molecular weight of about 100,000, and a smaller one called the β subunit, with a molecular weight of about 55,000. Although the function of the smaller protein is not known (except that it might anchor the protein complex in the lipid membrane), the larger protein has three specific features that are important for the functioning of the pump:

1. It has three *binding sites for sodium ions* on the portion of the protein that protrudes to the inside of the cell.

Figure 4-12. Postulated mechanism of the sodium-potassium pump. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Pi, phosphate ion.

2. It has two *binding sites for potassium ions* on the outside.
3. The inside portion of this protein near the sodium binding sites has adenosine triphosphatase (ATPase) activity.

When two potassium ions bind on the outside of the carrier protein and three sodium ions bind on the inside, the ATPase function of the protein becomes activated. Activation of the ATPase function leads to cleavage of one molecule of ATP, splitting it to adenosine diphosphate (ADP) and liberating a high-energy phosphate bond of energy. This liberated energy is believed to cause a chemical and conformational change in the protein carrier molecule, extruding three sodium ions to the outside and two potassium ions to the inside.

As with other enzymes, the $\text{Na}^+\text{-K}^+$ ATPase pump can run in reverse. If the electrochemical gradients for Na^+ and K^+ are experimentally increased to the degree that the energy stored in their gradients is greater than the chemical energy of ATP hydrolysis, these ions will move down their concentration gradients, and the $\text{Na}^+\text{-K}^+$ pump will synthesize ATP from ADP and phosphate. The phosphorylated form of the $\text{Na}^+\text{-K}^+$ pump, therefore, can either donate its phosphate to ADP to produce ATP or use the energy to change its conformation and pump Na^+ out of the cell and K^+ into the cell. The relative concentrations of ATP, ADP, and phosphate, as well as the electrochemical gradients for Na^+ and K^+ , determine the direction of the enzyme reaction. For some cells, such as electrically active nerve cells, 60% to 70% of the cell's energy requirement may be devoted to pumping Na^+ out of the cell and K^+ into the cell.

The $\text{Na}^+\text{-K}^+$ Pump Is Important for Controlling Cell Volume. One of the most important functions of the $\text{Na}^+\text{-K}^+$ pump is to control the cell volume. Without function of this pump, most cells of the body would swell until they burst.

The mechanism for controlling the volume is as follows. Inside the cell are large numbers of proteins and other organic molecules that cannot escape from the cell. Most of these proteins and other organic molecules are negatively charged and, therefore, attract large numbers of potassium, sodium, and other positive ions. All these molecules and ions then cause osmosis of water to the interior of the cell. Unless this process is checked, the cell will swell indefinitely until it bursts. The normal mechanism for preventing this outcome is the $\text{Na}^+\text{-K}^+$ pump. Note again that this mechanism pumps three Na^+ ions to the outside of the cell for every two K^+ ions pumped to the interior. Also, the membrane is far less permeable to sodium ions than to potassium ions and, once the sodium ions are on the outside, they have a strong tendency to stay there. This process thus represents a net loss of ions out the cell, which also initiates osmosis of water out of the cell.

If a cell begins to swell for any reason, the $\text{Na}^+\text{-K}^+$ pump is automatically activated, moving still more ions to the exterior and carrying water with them. Therefore, the $\text{Na}^+\text{-K}^+$ pump performs a continual surveillance role in maintaining normal cell volume.

Electrogenic Nature of the $\text{Na}^+\text{-K}^+$ Pump. The fact that the $\text{Na}^+\text{-K}^+$ pump moves three Na^+ ions to the exterior for every two K^+ ions that are moved to the interior means that a net of one positive charge is moved from the interior of the cell to the exterior of the cell for each cycle of the pump. This action creates positivity outside the cell but results in a deficit of positive ions inside the cell; that is, it causes negativity on the inside. Therefore, the $\text{Na}^+\text{-K}^+$ pump is said to be *electrogenic* because it creates an electrical potential across the cell membrane. As discussed in [Chapter 5](#), this electrical potential is a basic requirement in nerve and muscle fibers for transmitting nerve and muscle signals.

Primary Active Transport of Calcium Ions

Another important primary active transport mechanism is the *calcium pump*. Calcium ions are normally maintained at an extremely low concentration in the intracellular cytosol of virtually all cells in the body, at a concentration about 10,000 times less than that in the extracellular fluid. This level of maintenance is achieved mainly by two primary active transport calcium pumps. One, which is in the cell membrane, pumps calcium to the outside of the cell. The other pumps calcium ions into one or more of the intracellular vesicular organelles of the cell, such as the sarcoplasmic reticulum of muscle cells and the mitochondria in all cells. In each of these cases, the carrier protein penetrates the membrane and functions as an enzyme ATPase, with the same capability to cleave ATP as the ATPase of the sodium carrier protein. The difference is that this protein has a highly specific binding site for calcium instead of for sodium.

Primary Active Transport of Hydrogen Ions

Primary active transport of hydrogen ions is especially important at two places in the body: (1) in the gastric glands of the stomach; and (2) in the late distal tubules and cortical collecting ducts of the kidneys.

In the gastric glands, the deep-lying *parietal cells* have the most potent primary active mechanism for transporting hydrogen ions of any part of the body. This mechanism is the basis for secreting hydrochloric acid in stomach digestive secretions. At the secretory ends of the gastric gland parietal cells, the hydrogen ion concentration is increased as much as a million-fold and then is released into the stomach, along with chloride ions, to form hydrochloric acid.

In the renal tubules, special *intercalated cells* found in the late distal tubules and cortical collecting ducts also transport hydrogen ions by primary active transport. In this case, large amounts of hydrogen ions are secreted from the blood into the renal tubular fluid for the purpose of eliminating excess hydrogen ions from the body fluids. The hydrogen ions can be secreted into the renal tubular fluid against a concentration gradient of about 900-fold. Yet, as discussed in [Chapter 31](#), most of these hydrogen ions combine with tubular fluid buffers before they are eliminated in the urine.

Energetics of Primary Active Transport

The amount of energy required to transport a substance actively through a membrane is determined by how much the substance is concentrated during transport. Compared with the energy required to concentrate a substance 10-fold, concentrating it 100-fold requires twice as much energy, and concentrating it 1000-fold requires three times as much energy. In other words, the energy required is proportional to the *logarithm* of the degree that the substance is concentrated, as expressed by the following formula:

$$\text{Energy (in calories per osmole)} = 1400 \log \frac{C_1}{C_2}$$

Thus, in terms of calories, the amount of energy required to concentrate 1 osmole of a substance 10-fold is about 1400 calories, whereas to concentrate it 100-fold, 2800 calories are required. One can see that the energy expenditure for concentrating substances in cells or for removing substances from cells against a concentration gradient can be tremendous. Some cells, such as those lining the renal tubules and many glandular cells, expend as much as 90% of their energy for this purpose alone.

SECONDARY ACTIVE TRANSPORT— CO-TRANSPORT AND COUNTER-TRANSPORT

When sodium ions are transported out of cells by primary active transport, a large concentration gradient of

sodium ions across the cell membrane usually develops, with a high concentration outside the cell and a low concentration inside. This gradient represents a storehouse of energy, because the excess sodium outside the cell membrane is always attempting to diffuse to the interior. Under appropriate conditions, this diffusion energy of sodium can pull other substances along with the sodium through the cell membrane. This phenomenon, called *co-transport*, is one form of *secondary active transport*.

For sodium to pull another substance along with it, a coupling mechanism is required; this is achieved by means of still another carrier protein in the cell membrane. The carrier in this case serves as an attachment point for both the sodium ion and the substance to be co-transported. Once they are both attached, the energy gradient of the sodium ion causes the sodium ion and the other substance to be transported together to the interior of the cell.

In *counter-transport*, sodium ions again attempt to diffuse to the interior of the cell because of their large concentration gradient. However, this time, the substance to be transported is on the inside of the cell and is transported to the outside. Therefore, the sodium ion binds to the carrier protein, where it projects to the exterior surface of the membrane, and the substance to be counter-transported binds to the interior projection of the carrier protein. Once both have become bound, a conformational change occurs, and energy released by the action of the sodium ion moving to the interior causes the other substance to move to the exterior.

Co-Transport of Glucose and Amino Acids Along with Sodium Ions

Glucose and many amino acids are transported into most cells against large concentration gradients; the mechanism of this action is entirely by co-transport, as shown in [Figure 4-13](#). Note that the transport carrier protein has two binding sites on its exterior side, one for sodium and one for glucose. Also, the concentration of sodium ions is high on the outside and low on the inside, which provides energy for the transport. A special property of the transport protein is that a conformational change to allow sodium movement to the interior will not occur until a glucose molecule also attaches. When they both become attached, the conformational change takes place, and the sodium and glucose are transported to the inside of the cell at the same time. Hence, this is a *sodium-glucose co-transporter*. Sodium-glucose co-transporters are especially important for transporting glucose across renal and intestinal epithelial cells, as discussed in Chapters 28 and 66.

Sodium co-transport of amino acids occurs in the same manner as for glucose, except that it uses a different set of transport proteins. At least five *amino acid transport proteins* have been identified, each of which is responsible for transporting one subset of amino acids with specific molecular characteristics.

Figure 4-13 Postulated mechanism for sodium co-transport of glucose.

Figure 4-14. Sodium counter-transport of calcium and hydrogen ions.

Sodium co-transport of glucose and amino acids occurs especially through the epithelial cells of the intestinal tract and the renal tubules of the kidneys to promote absorption of these substances into the blood. This process will be discussed in later chapters.

Other important co-transport mechanisms in at least some cells include co-transport of potassium, chloride, bicarbonate, phosphate, iodine, iron, and urate ions.

Sodium Counter-Transport of Calcium and Hydrogen Ions

Two especially important counter-transporters (i.e., transport in a direction opposite to the primary ion) are *sodium-calcium counter-transport* and *sodium-hydrogen counter-transport* ([Figure 4-14](#)).

Sodium-calcium counter-transport occurs through all or almost all cell membranes, with sodium ions moving to the interior and calcium ions to the exterior; both are bound to the same transport protein in a counter-transport mode. This mechanism is in addition to the primary active transport of calcium that occurs in some cells.

Sodium-hydrogen counter-transport occurs in several tissues. An especially important example is in the *proximal tubules* of the kidneys, where sodium ions move from the lumen of the tubule to the interior of the tubular cell and hydrogen ions are counter-transported into the tubule lumen. As a mechanism for concentrating hydrogen ions, counter-transport is not nearly as powerful as the primary active transport of hydrogen ions that occurs in the more distal renal tubules, but it can transport extremely *large numbers of hydrogen ions*, thus making it a key to hydrogen ion control in the body fluids, as discussed in detail in [Chapter 31](#).

Figure 4-15. Basic mechanism of active transport across a layer of cells.

ACTIVE TRANSPORT THROUGH CELLULAR SHEETS

At many places in the body, substances must be transported all the way through a cellular sheet instead of simply through the cell membrane. Transport of this type occurs through the following: (1) intestinal epithelium; (2) epithelium of the renal tubules; (3) epithelium of all exocrine glands; (4) epithelium of the gallbladder; and (5) membrane of the choroid plexus of the brain, along with other membranes.

The basic mechanism for transport of a substance through a cellular sheet is as follows: (1) *active transport* through the cell membrane *on one side* of the transporting cells in the sheet; and then (2) either *simple diffusion* or *facilitated diffusion* through the membrane *on the opposite side* of the cell.

Figure 4-15 shows a mechanism for the transport of sodium ions through the epithelial sheet of the intestines, gallbladder, and renal tubules. This figure shows that the epithelial cells are connected together tightly at the luminal pole by means of junctions. The brush border on the luminal surfaces of the cells is permeable to both sodium ions and water. Therefore, sodium and water diffuse readily from the lumen into the interior of the cell. Then, at the basal and lateral membranes of the cells, sodium ions are actively transported into the extracellular fluid of the surrounding connective tissue and blood vessels. This action creates a high sodium ion concentration gradient across these membranes, which in turn causes osmosis of water. Thus, active transport of sodium ions at the basolateral sides of the epithelial cells results in the transport not only of sodium ions but also of water.

It is through these mechanisms that almost all nutrients, ions, and other substances are absorbed into the

blood from the intestine. These mechanisms are also how the same substances are reabsorbed from the glomerular filtrate by the renal tubules.

Numerous examples of the different types of transport discussed in this chapter are provided throughout this text.

Membrane Potentials and Action Potentials

Electrical potentials exist across the membranes of virtually all cells of the body. Some cells, such as nerve and muscle cells, generate rapidly changing electrochemical impulses at their membranes, and these impulses are used to transmit signals along the nerve or muscle membranes. In other types of cells, such as glandular cells, macrophages, and ciliated cells, local changes in membrane potentials also activate many of the cell's functions. This chapter reviews the basic mechanisms whereby membrane potentials are generated at rest and during action by nerve and muscle cells. See Video 5-1.

BASIC PHYSICS OF MEMBRANE POTENTIALS

Membrane Potentials Caused by Ion Concentration Differences Across a Selectively Permeable Membrane

In **Figure 5-1A**, the potassium concentration is great *inside* a nerve fiber membrane but very low *outside* the membrane. Let us assume that the membrane in this case is permeable to the potassium ions but not to any other ions. Because of the large potassium concentration gradient from the inside toward the outside, there is a strong tendency for potassium ions to diffuse outward through the membrane. As they do so, they carry positive electrical charges to the outside, thus creating electropositivity outside the membrane and electronegativity inside the membrane because of negative anions that remain behind and do not diffuse outward with the potassium. Within about 1 millisecond, the potential difference between the inside and outside, called the *diffusion potential*, becomes great enough to block further net potassium diffusion to the exterior, despite the high potassium ion concentration gradient. In the normal mammalian nerve fiber, *the potential difference is about 94 millivolts, with negativity inside the fiber membrane.*

Figure 5-1B shows the same phenomenon as in **Figure 5-1A**, but this time with a high concentration of sodium ions *outside* the membrane and a low concentration of sodium ions *inside*. These ions are also positively charged. This time, the membrane is highly permeable to the sodium ions but is impermeable to all other ions. Diffusion of the positively charged sodium ions to the inside

creates a membrane potential of opposite polarity to that in **Figure 5-1A**, with negativity outside and positivity inside. Again, the membrane potential rises high enough within milliseconds to block further net diffusion of sodium ions to the inside; however, this time, in the mammalian nerve fiber, *the potential is about 61 millivolts positive inside the fiber.*

Thus, in both parts of **Figure 5-1**, we see that a concentration difference of ions across a selectively permeable membrane can, under appropriate conditions, create a membrane potential. Later in this chapter, we show that many of the rapid changes in membrane potentials observed during nerve and muscle impulse transmission result from such rapidly changing diffusion potentials.

The Nernst Equation Describes the Relationship of Diffusion Potential to the Ion Concentration Difference Across a Membrane. The diffusion potential across a membrane that exactly opposes the net diffusion of a particular ion through the membrane is called the *Nernst potential* for that ion, a term that was introduced in **Chapter 4**. The magnitude of the Nernst potential is determined by the *ratio* of the concentrations of that specific ion on the two sides of the membrane. The greater this ratio, the greater the tendency for the ion to diffuse in one direction and therefore the greater the Nernst potential required to prevent additional net diffusion. The following equation, called the *Nernst equation*, can be used to calculate the Nernst potential for any univalent ion at the normal body temperature of 98.6°F (37°C):

$$\text{EMF (millivolts)} = \pm \frac{61}{z} \times \log \frac{\text{Concentration inside}}{\text{Concentration outside}}$$

where EMF is the electromotive force and z is the electrical charge of the ion (e.g., +1 for K^+).

When using this formula, it is usually assumed that the potential in the extracellular fluid outside the membrane remains at zero potential, and the Nernst potential is the potential inside the membrane. Also, the sign of the potential is positive (+) if the ion diffusing from inside to outside is a negative ion, and it is negative (–) if the ion is positive. Thus, when the concentration of positive potassium ions on the inside is 10 times that on the outside, the log of 10 is 1, so the Nernst potential calculates to be –61 millivolts inside the membrane.

Figure 5-1 **A**, Establishment of a diffusion potential across a nerve fiber membrane, caused by diffusion of potassium ions from inside the cell to outside the cell through a membrane that is selectively permeable only to potassium. **B**, Establishment of a diffusion potential when the nerve fiber membrane is permeable only to sodium ions. Note that the internal membrane potential is negative when potassium ions diffuse and positive when sodium ions diffuse because of opposite concentration gradients of these two ions.

The Goldman Equation Is Used to Calculate the Diffusion Potential When the Membrane Is Permeable to Several Different Ions. When a membrane is permeable to several different ions, the diffusion potential that develops depends on three factors: (1) the polarity of the electrical charge of each ion; (2) the permeability of the membrane (P) to each ion; and (3) the concentration (C) of the respective ions on the inside (i) and outside (o) of the membrane. Thus, the following formula, called the *Goldman equation* or the *Goldman-Hodgkin-Katz equation*, gives the calculated membrane potential on the *inside* of the membrane when two univalent positive ions, sodium (Na^+) and potassium (K^+), and one univalent negative ion, chloride (Cl^-), are involved:

$$\text{EMF (millivolts)} = -61 \times \log \frac{C_{\text{Na}^+} P_{\text{Na}^+} + C_{\text{K}^+} P_{\text{K}^+} + C_{\text{Cl}^-} P_{\text{Cl}^-}}{C_{\text{Na}^+} P_{\text{Na}^+} + C_{\text{K}^+} P_{\text{K}^+} + C_{\text{Cl}^-} P_{\text{Cl}^-}}$$

Several key points become evident from the Goldman equation. First, sodium, potassium, and chloride ions are the most important ions involved in the development of membrane potentials in nerve and muscle fibers, as well as in the neuronal cells. The concentration gradient of each of these ions across the membrane helps determine the voltage of the membrane potential.

Second, the quantitative importance of each of the ions in determining the voltage is proportional to the membrane permeability for that particular ion. If the membrane has zero permeability to sodium and chloride ions, the membrane potential becomes entirely dominated by the concentration gradient of potassium ions alone, and the resulting potential will be equal to the Nernst potential for potassium. The same holds true for each of the other two ions if the membrane should become selectively permeable for either one of them alone.

Third, a positive ion concentration gradient from *inside* the membrane to the *outside* causes electronegativity

Table 5-1 Resting Membrane Potential in Different Cell Types

Cell Type	Resting Potential (mV)
Neurons	-60 to -70
Skeletal muscle	-85 to -95
Smooth muscle	-50 to -60
Cardiac muscle	-80 to -90
Hair (cochlea)	-15 to -40
Astrocyte	-80 to -90
Erythrocyte	-8 to -12
Photoreceptor	-40 (dark) to -70 (light)

inside the membrane. The reason for this phenomenon is that excess positive ions diffuse to the outside when their concentration is higher inside than outside the membrane. This diffusion carries positive charges to the outside but leaves the nondiffusible negative anions on the inside, thus creating electronegativity on the inside. The opposite effect occurs when there is a gradient for a negative ion. That is, a chloride ion gradient from the outside to the inside causes negativity inside the cell because excess negatively charged chloride ions diffuse to the inside while leaving the nondiffusible positive ions on the outside.

Fourth, as explained later, the permeability of the sodium and potassium channels undergoes rapid changes during transmission of a nerve impulse, whereas the permeability of the chloride channels does not change greatly during this process. Therefore, rapid changes in sodium and potassium permeability are primarily responsible for signal transmission in neurons, which is the subject of most of the remainder of this chapter.

Resting Membrane Potential of Different Cell Types.

In some cells, such as the cardiac pacemaker cells discussed in [Chapter 10](#), the membrane potential is continuously changing, and the cells are never “resting.” In many other cells, even excitable cells, there is a quiescent period in which a resting membrane potential can be measured. [Table 5-1](#) shows the approximate resting membrane potentials of some different types of cells. The membrane potential is obviously very dynamic in excitable cells such as neurons, in which action potentials occur. However, even in nonexcitable cells, the membrane potential (voltage) also changes in response to various stimuli, which alter activities for the various ion transporters, ion channels, and membrane permeability for sodium, potassium, calcium, and chloride ions. The resting membrane potential is, therefore, only a brief transient state for many cells.

Electrochemical Driving Force. When multiple ions contribute to the membrane potential, the equilibrium potential for any of the contributing ions will differ from the membrane potential, and there will be an *electrochemical driving force* (V_{df}) for each ion that tends to cause net

Figure 5-2 Measurement of the membrane potential of the nerve fiber using a microelectrode.

movement of the ion across the membrane. This driving force is equal to the difference between the membrane potential (V_m) and the equilibrium potential of the ion (V_{eq}). Thus, $V_{df} = V_m - V_{eq}$.

The arithmetic sign of V_{df} (positive or negative) and the valence of the ion (cation or anion) can be used to predict the direction of ion flow across the membrane, into or out of the cell. For cations such as Na^+ and K^+ , a positive V_{df} predicts ion movement out of the cell down its electrochemical gradient, and a negative V_{df} predicts ion movement into the cell. For anions, such as Cl^- , a positive V_{df} predicts ion movement into the cell, and a negative V_{df} predicts ion movement out of the cell. When $V_m = V_{eq}$, there is no net movement of the ion into or out of the cell. Also, the direction of ion flux through the membrane reverses as V_m becomes greater than or less than V_{eq} ; hence, the equilibrium potential (V_{eq}) is also called the *reversal potential*.

Measuring the Membrane Potential

The method for measuring the membrane potential is simple in theory but often difficult in practice because of the small size of most of the cells and fibers. **Figure 5-2** shows a small micropipette filled with an electrolyte solution. The micropipette is impaled through the cell membrane to the interior of the fiber. Another electrode, called the *indifferent electrode*, is then placed in the extracellular fluid, and the potential difference between the inside and outside of the fiber is measured using an appropriate voltmeter. This voltmeter is a highly sophisticated electronic apparatus that is capable of measuring small voltages despite extremely high resistance to electrical flow through the tip of the micropipette, which has a lumen diameter usually less than 1 micrometer and a resistance of more than 1 million ohms. For recording rapid *changes* in the membrane potential during transmission of nerve impulses, the microelectrode is connected to an oscilloscope, as explained later in the chapter.

The lower part of **Figure 5-3** shows the electrical potential that is measured at each point in or near the nerve fiber membrane, beginning at the left side of the figure and passing to the right. As long as the electrode is outside the neuronal membrane, the recorded potential

Figure 5-3 Distribution of positively and negatively charged ions in the extracellular fluid surrounding a nerve fiber and in the fluid inside the fiber. Note the alignment of negative charges along the inside surface of the membrane and positive charges along the outside surface. The *lower panel* displays the abrupt changes in membrane potential that occur at the membranes on the two sides of the fiber.

is zero, which is the potential of the extracellular fluid. Then, as the recording electrode passes through the voltage change area at the cell membrane (called the *electrical dipole layer*), the potential decreases abruptly to -70 millivolts. Moving across the center of the fiber, the potential remains at a steady -70 -millivolt level but reverses back to zero the instant it passes through the membrane on the opposite side of the fiber.

To create a negative potential inside the membrane, only enough positive ions to develop the electrical dipole layer at the membrane itself must be transported outward. The remaining ions inside the nerve fiber can be both positive and negative, as shown in the upper panel of **Figure 5-3**. Therefore, transfer of an incredibly small number of ions through the membrane can establish the normal resting potential of -70 millivolts inside the nerve fiber, which means that only about $1/3,000,000$ to $1/100,000,000$ of the total positive charges inside the fiber must be transferred. Also, an equally small number of positive ions moving from outside to inside the fiber can reverse the potential from -70 millivolts to as much as $+35$ millivolts within as little as $1/10,000$ of a second. Rapid shifting of ions in this manner causes the nerve signals discussed in subsequent sections of this chapter.

RESTING MEMBRANE POTENTIAL OF NEURONS

The resting membrane potential of large nerve fibers when they are not transmitting nerve signals is about -70 millivolts. That is, the potential *inside the fiber* is 70 millivolts more negative than the potential in the extracellular fluid on the outside of the fiber. In the next few paragraphs, the transport properties of the resting nerve membrane for

Figure 5-4 Functional characteristics of the Na⁺-K⁺ pump and the K⁺ "leak" channels. The K⁺ leak channels also leak Na⁺ ions into the cell slightly but are much more permeable to K⁺. ADP, Adenosine diphosphate; ATP, adenosine triphosphate.

sodium and potassium and the factors that determine the level of this resting potential are explained.

Active Transport of Sodium and Potassium Ions Through the Membrane—the Sodium-Potassium (Na⁺-K⁺) Pump. Recall from Chapter 4 that all cell membranes of the body have a powerful Na⁺-K⁺ pump that continually transports sodium ions to the outside of the cell and potassium ions to the inside, as illustrated on the left side in Figure 5-4. Note that this is an *electrogenic pump* because three Na⁺ ions are pumped to the outside for each two K⁺ ions to the inside, leaving a net deficit of positive ions on the inside and causing a negative potential inside the cell membrane.

The Na⁺-K⁺ pump also causes large concentration gradients for sodium and potassium across the resting nerve membrane. These gradients are as follows:

- Na⁺ (outside): 142 mEq/L
- Na⁺ (inside): 14 mEq/L
- K⁺ (outside): 4 mEq/L
- K⁺ (inside): 140 mEq/L

The ratios of these two respective ions from the inside to the outside are as follows:

$$\text{Na}^+_{\text{inside}} / \text{Na}^+_{\text{outside}} = 0.1$$

$$\text{K}^+_{\text{inside}} / \text{K}^+_{\text{outside}} = 35.0$$

Leakage of Potassium Through the Nerve Cell Membrane. The right side of Figure 5-4 shows a channel protein (sometimes called a *tandem pore domain, potassium channel*, or *potassium [K⁺] "leak" channel*) in the nerve membrane through which potassium ions can leak, even in a resting cell. The basic structure of potassium channels was described in Chapter 4 (Figure 4-4). These K⁺ leak

Figure 5-5 Establishment of resting membrane potentials under three conditions. **A**, When the membrane potential is caused entirely by potassium diffusion alone. **B**, When the membrane potential is caused by diffusion of both sodium and potassium ions. **C**, When the membrane potential is caused by diffusion of both sodium and potassium ions plus pumping of both these ions by the Na⁺-K⁺ pump.

channels may also leak sodium ions slightly but are far more permeable to potassium than to sodium, normally about 100 times as permeable. As discussed later, this differential in permeability is a key factor in determining the level of the normal resting membrane potential.

Origin of the Normal Resting Membrane Potential

Figure 5-5 shows the important factors in the establishment of the normal resting membrane potential. They are as follows.

Contribution of the Potassium Diffusion Potential.

In Figure 5-5A, we assume that the only movement of ions through the membrane is diffusion of potassium ions, as demonstrated by the open channels between the potassium symbol (K⁺) inside and outside the mem-

brane. Because of the high ratio of potassium ions inside to outside, 35:1, the Nernst potential corresponding to this ratio is -94 millivolts because the logarithm of 35 is 1.54, and this, multiplied by -61 millivolts, is -94 millivolts. Therefore, if potassium ions were the only factor causing the resting potential, the resting potential *inside the fiber* would be equal to -94 millivolts, as shown in the figure.

Contribution of Sodium Diffusion Through the Nerve Membrane. Figure 5-5B shows the addition of slight permeability of the nerve membrane to sodium ions, caused by the minute diffusion of sodium ions through the K^+ - Na^+ leak channels. The ratio of sodium ions from inside to outside the membrane is 0.1, which gives a calculated Nernst potential for the inside of the membrane of $+61$ millivolts. Also shown in Figure 5-5B is the Nernst potential for potassium diffusion of -94 millivolts. How do these interact with each other, and what will be the summated potential? This question can be answered by using the Goldman equation described previously. Intuitively, one can see that if the membrane is highly permeable to potassium but only slightly permeable to sodium, the diffusion of potassium contributes far more to the membrane potential than the diffusion of sodium. In the normal nerve fiber, the permeability of the membrane to potassium is about 100 times as great as its permeability to sodium. Using this value in the Goldman equation, and considering only sodium and potassium, gives a potential inside the membrane of -86 millivolts, which is near the potassium potential shown in the figure.

Contribution of the Na^+ - K^+ Pump. In Figure 5-5C, the Na^+ - K^+ pump is shown to provide an additional contribution to the resting potential. This figure shows that continuous pumping of three sodium ions to the outside occurs for each two potassium ions pumped to the inside of the membrane. The pumping of more sodium ions to the outside than the potassium ions being pumped to the inside causes a continual loss of positive charges from inside the membrane, creating an additional degree of negativity (about -4 millivolts additional) on the inside, beyond that which can be accounted for by diffusion alone.

Therefore, as shown in Figure 5-5C, the net membrane potential when all these factors are operative at the same time is about -90 millivolts. However, additional ions, such as chloride, must also be considered in calculating the membrane potential.

In summary, the diffusion potentials alone caused by potassium and sodium diffusion would give a membrane potential of about -86 millivolts, with almost all of this being determined by potassium diffusion. An additional -4 millivolts is then contributed to the membrane potential by the continuously acting electrogenic Na^+ - K^+ pump, and there is a contribution of chloride ions. As mentioned previously, the resting membrane potential

Figure 5-6 Typical action potential recorded by the method shown in the upper panel.

varies in different cells from as low as around -10 millivolts in erythrocytes to as high as -90 millivolts in skeletal muscle cells.

NEURON ACTION POTENTIAL

Nerve signals are transmitted by *action potentials*, which are rapid changes in the membrane potential that spread rapidly along the nerve fiber membrane. Each action potential begins with a sudden change from the normal resting negative membrane potential to a positive potential and ends with an almost equally rapid change back to the negative potential. To conduct a nerve signal, the action potential moves along the nerve fiber until it comes to the fiber's end.

The upper panel of Figure 5-6 shows the changes that occur at the membrane during the action potential, with the transfer of positive charges to the interior of the fiber at its onset and the return of positive charges to the exterior at its end. The lower panel shows graphically the successive changes in membrane potential over a few 10,000ths of a second, illustrating the explosive onset of the action potential and the almost equally rapid recovery.

The successive stages of the action potential are as follows.

Resting Stage. The resting stage is the resting membrane potential before the action potential begins. The membrane is said to be “polarized” during this stage because of the -70 millivolts negative membrane potential that is present.

Depolarization Stage. At this time, the membrane suddenly becomes permeable to sodium ions, allowing rapid diffusion of positively charged sodium ions to the interior of the axon. The normal polarized state of -70 millivolts is immediately neutralized by the inflowing, positively charged sodium ions, with the potential rising rapidly in the positive direction—a process called *depolarization*. In large nerve fibers, the great excess of positive sodium ions moving to the inside causes the membrane potential to actually overshoot beyond the zero level and to become somewhat positive. In some smaller fibers, as well as in many central nervous system neurons, the potential merely approaches the zero level and does not overshoot to the positive state.

Repolarization Stage. Within a few 10,000ths of a second after the membrane becomes highly permeable to sodium ions, the sodium channels begin to close, and the potassium channels open to a greater degree than normal. Then, rapid diffusion of potassium ions to the exterior re-establishes the normal negative resting membrane potential, which is called *repolarization* of the membrane.

To explain more fully the factors that cause both depolarization and repolarization, we will describe the special characteristics of two other types of transport channels through the nerve membrane, the voltage-gated sodium and potassium channels.

VOLTAGE-GATED SODIUM AND POTASSIUM CHANNELS

The necessary factor in causing both depolarization and repolarization of the nerve membrane during the action potential is the *voltage-gated sodium channel*. A *voltage-gated potassium channel* also plays an important role in increasing the rapidity of repolarization of the membrane. *These two voltage-gated channels are in addition to the Na^+ - K^+ pump and the K^+ leak channels.*

Activation and Inactivation of the Voltage-Gated Sodium Channel

The upper panel of **Figure 5-7** shows the voltage-gated sodium channel in three separate states. This channel has two *gates*—one near the outside of the channel called the *activation gate*, and another near the inside called the *inactivation gate*. The upper left of the figure depicts the state of these two gates in the normal resting membrane when the membrane potential is -70 millivolts. In this state, the activation gate is closed, which prevents any entry of sodium ions to the interior of the fiber through these sodium channels.

Activation of the Sodium Channel. When the membrane potential becomes less negative than during the resting state, rising from -70 millivolts toward zero, it finally reaches a voltage—usually somewhere around -55 millivolts—that causes a sudden conformational

Figure 5-7 Characteristics of the voltage-gated sodium (*top*) and potassium (*bottom*) channels, showing successive activation and inactivation of the sodium channels and delayed activation of the potassium channels when the membrane potential is changed from the normal resting negative value to a positive value.

change in the activation gate, flipping it all the way to the open position. During this *activated state*, sodium ions can pour inward through the channel, increasing the sodium permeability of the membrane as much as 500- to 5000-fold.

Inactivation of the Sodium Channel. The upper right panel of **Figure 5-7** shows a third state of the sodium channel. The same increase in voltage that opens the activation gate also closes the inactivation gate. The inactivation gate, however, closes a few 10,000ths of a second after the activation gate opens. That is, the conformational change that flips the inactivation gate to the closed state is a slower process than the conformational change that opens the activation gate. Therefore, after the sodium channel has remained open for a few 10,000ths of a second, the inactivation gate closes, and sodium ions no longer can pour to the inside of the membrane. At this point, the membrane potential begins to return toward the resting membrane state, which is the repolarization process.

Another important characteristic of the sodium channel inactivation process is that the inactivation gate will not reopen until the membrane potential returns to or near the original resting membrane potential level. Therefore, it is usually not possible for the sodium channels to open again without first repolarizing the nerve fiber.

Voltage-Gated Potassium Channel and Its Activation

The lower panel of **Figure 5-7** shows the voltage-gated potassium channel in two states—during the resting state

Figure 5-8 Voltage clamp method for studying flow of ions through specific channels.

(left) and toward the end of the action potential (right). During the resting state, the gate of the potassium channel is closed, and potassium ions are prevented from passing through this channel to the exterior. When the membrane potential rises from -70 millivolts toward zero, this voltage change causes a conformational opening of the gate and allows increased potassium diffusion outward through the channel. However, because of the slight delay in opening of the potassium channels, they open, for the most part, at about the same time that the sodium channels are beginning to close because of inactivation. Thus, the decrease in sodium entry to the cell and the simultaneous increase in potassium exit from the cell combine to speed the repolarization process, leading to full recovery of the resting membrane potential within another few 10,000ths of a second.

The Voltage Clamp Method for Measuring the Effect of Voltage on Opening and Closing of Voltage-Gated Channels.

The original research that led to quantitative understanding of the sodium and potassium channels was so ingenious that it led to Nobel Prizes for the scientists responsible, Hodgkin and Huxley, in 1963. The essence of these studies is shown in [Figures 5-8 and 5-9](#).

[Figure 5-8](#) shows the *voltage clamp method*, which is used to measure the flow of ions through the different channels. In using this apparatus, two electrodes are inserted into the nerve fiber. One of these electrodes is used to measure the voltage of the membrane potential, and the other is used to conduct electrical current into or out of the nerve fiber.

This apparatus is used in the following way. The investigator decides which voltage to establish inside the nerve fiber. The electronic portion of the apparatus is then adjusted to the desired voltage, automatically injecting either positive or negative electricity through the current electrode at whatever rate is required to hold the voltage, as measured

Figure 5-9 Typical changes in conductance of sodium and potassium ion channels when the membrane potential is suddenly increased from the normal resting value of -70 millivolts to a positive value of $+10$ millivolts for 2 milliseconds. This figure shows that the sodium channels open (activate) and then close (inactivate) before the end of the 2 milliseconds, whereas the potassium channels only open (activate), and the rate of opening is much slower than that of the sodium channels.

by the voltage electrode, at the level set by the operator. When the membrane potential is suddenly increased by this voltage clamp from -70 millivolts to zero, the voltage-gated sodium and potassium channels open, and sodium and potassium ions begin to pour through the channels. To counterbalance the effect of these ion movements on the desired setting of the intracellular voltage, electrical current is injected automatically through the current electrode of the voltage clamp to maintain the intracellular voltage at the required steady zero level. To achieve this level, the current injected must be equal to but of opposite polarity to the net current flow through the membrane channels. To measure how much current flow is occurring at each instant, the current electrode is connected to an ammeter that records the current flow, as demonstrated in [Figure 5-8](#).

Finally, the investigator adjusts the concentrations of the ions to other than normal levels both inside and outside the nerve fiber and repeats the study. This experiment can be performed easily when using large nerve fibers removed from some invertebrates, especially the giant squid axon, which in some cases is as large as 1 millimeter in diameter. When sodium is the only permeant ion in the solutions inside and outside the squid axon, the voltage clamp measures current flow only through the sodium channels. When potassium is the only permeant ion, current flow only through the potassium channels is measured.

Another means for studying the flow of ions through an individual type of channel is to block one type of channel at a time. For example, the sodium channels can be blocked by a toxin called tetrodotoxin when it is applied to the outside of the cell membrane where the sodium activation gates are located. Conversely, tetraethylammonium ion blocks the potassium channels when it is applied to the interior of the nerve fiber.

[Figure 5-9](#) shows typical changes in conductance of the voltage-gated sodium and potassium channels when the membrane potential is suddenly changed through use of the voltage clamp, from -70 millivolts to $+10$ millivolts and then, 2 milliseconds later, back to -70 millivolts. Note

the sudden opening of the sodium channels (the activation stage) within a small fraction of a millisecond after the membrane potential is increased to the positive value. However, during the next millisecond or so, the sodium channels automatically close (the inactivation stage).

Note the opening (activation) of the potassium channels, which open less rapidly and reach their full open state only after the sodium channels have almost completely closed. Furthermore, once the potassium channels open, they remain open for the entire duration of the positive membrane potential and do not close again until after the membrane potential is decreased back to a negative value.

SUMMARY OF EVENTS THAT CAUSE THE ACTION POTENTIAL

Figure 5-10 summarizes the sequential events that occur during and shortly after the action potential. The bottom of the figure shows the changes in membrane conductance for sodium and potassium ions. During the resting state, before the action potential begins, the conductance for potassium ions is 50 to 100 times as great as the conductance for sodium ions. This disparity is caused by much greater leakage of potassium ions than sodium ions through the leak channels. However, at the onset of the action potential, the sodium channels almost instantaneously become activated and allow up to a 5000-fold increase in sodium conductance. The inactivation process then closes the sodium channels

Figure 5-10 Changes in sodium and potassium conductance during the course of the action potential. Sodium conductance increases several thousand-fold during the early stages of the action potential, whereas potassium conductance increases only about 30-fold during the latter stages of the action potential and for a short period thereafter. (These curves were constructed from theory presented in papers by Hodgkin and Huxley but transposed from a squid axon to apply to the membrane potentials of large mammalian nerve fibers.)

within another fraction of a millisecond. The onset of the action potential also initiates voltage gating of the potassium channels, causing them to begin opening more slowly, a fraction of a millisecond after the sodium channels open. At the end of the action potential, the return of the membrane potential to the negative state causes the potassium channels to close back to their original status but, again, only after an additional millisecond or more delay.

The middle portion of **Figure 5-10** shows the ratio of sodium to potassium conductance at each instant during the action potential, and above this depiction is the action potential itself. During the early portion of the action potential, the ratio of sodium to potassium conductance increases more than 1000-fold. Therefore, far more sodium ions flow to the interior of the fiber than potassium ions to the exterior. This is what causes the membrane potential to become positive at the action potential onset. Then, the sodium channels begin to close, and the potassium channels begin to open; thus, the ratio of conductance shifts far in favor of high potassium conductance but low sodium conductance. This shift allows for a very rapid loss of potassium ions to the exterior but virtually zero flow of sodium ions to the interior. Consequently, the action potential quickly returns to its baseline level.

Roles of Other Ions During the Action Potential

Thus far, we have considered only the roles of sodium and potassium ions in generating the action potential. At least two other types of ions must be considered, negative anions and calcium ions.

Impermeant Negatively Charged Ions (Anions) Inside the Nerve Axon. Inside the axon are many negatively charged ions that cannot go through the membrane channels. They include the anions of protein molecules and of many organic phosphate compounds and sulfate compounds, among others. Because these ions cannot leave the interior of the axon, any deficit of positive ions inside the membrane leaves an excess of these impermeant negative anions. Therefore, these impermeant negative ions are responsible for the negative charge inside the fiber when there is a net deficit of positively charged potassium ions and other positive ions.

Calcium Ions. The membranes of almost all cells of the body have a calcium pump similar to the sodium pump, and calcium serves along with (or instead of) sodium in some cells to cause most of the action potential. Like the sodium pump, the calcium pump transports calcium ions from the interior to the exterior of the cell membrane (or into the endoplasmic reticulum of the cell), creating a calcium ion gradient of about 10,000-fold. This process leaves an internal cell concentration of calcium ions of about 10^{-7} molar, in contrast to an external concentration of about 10^{-3} molar.

In addition, there are *voltage-gated calcium channels*. Because the calcium ion concentration is more than 10,000 times greater in the extracellular fluid than in the intracellular fluid, there is a tremendous diffusion gradient and elec-

trochemical driving force for the passive flow of calcium ions into the cells. These channels are slightly permeable to sodium ions and calcium ions, but their permeability to calcium is about 1000-fold greater than to sodium under normal physiological conditions. When the channels open in response to a stimulus that depolarizes the cell membrane, calcium ions flow to the interior of the cell.

A major function of the voltage-gated calcium ion channels is to contribute to the depolarizing phase on the action potential in some cells. The gating of calcium channels, however, is relatively slow, requiring 10 to 20 times as long for activation as for the sodium channels. For this reason, they are often called *slow channels*, in contrast to the sodium channels, which are called *fast channels*. Therefore, the opening of calcium channels provides a more sustained depolarization, whereas the sodium channels play a key role in initiating action potentials.

Calcium channels are numerous in cardiac muscle and smooth muscle. In fact, in some types of smooth muscle, the fast sodium channels are hardly present; therefore, the action potentials are caused almost entirely by the activation of slow calcium channels.

Increased Permeability of the Sodium Channels When There Is a Deficit of Calcium Ions. The concentration of calcium ions in the extracellular fluid also has a profound effect on the voltage level at which the sodium channels become activated. When there is a deficit of calcium ions, the sodium channels become activated (opened) by a small increase of the membrane potential from its normal, very negative level. Therefore, the nerve fiber becomes highly excitable, sometimes discharging repetitively without provocation, rather than remaining in the resting state. In fact, the calcium ion concentration needs to fall only 50% below normal before spontaneous discharge occurs in some peripheral nerves, often causing *muscle tetany*. Muscle tetany is sometimes lethal because of tetanic contraction of the respiratory muscles.

The probable way in which calcium ions affect the sodium channels is as follows. These ions appear to bind to the exterior surfaces of the sodium channel protein. The positive charges of these calcium ions, in turn, alter the electrical state of the sodium channel protein, thus altering the voltage level required to open the sodium gate.

INITIATION OF THE ACTION POTENTIAL

Thus far, we have explained the changing sodium and potassium permeability of the membrane, as well as the development of the action potential, but we have not explained what initiates the action potential.

A Positive-Feedback Cycle Opens the Sodium Channels. As long as the membrane of the nerve fiber remains undisturbed, no action potential occurs in the normal nerve. However, if any event causes enough initial rise in the membrane potential from -70 millivolts toward the zero level, the rising voltage will cause many voltage-gated sodium channels to begin opening. This occurrence allows for the rapid inflow of sodium ions, which causes a further

rise in the membrane potential, thus opening still more voltage-gated sodium channels and allowing more streaming of sodium ions to the interior of the fiber. This process is a positive feedback cycle that, once the feedback is strong enough, continues until all the voltage-gated sodium channels have become activated (opened). Then, within another fraction of a millisecond, the rising membrane potential causes closure of the sodium channels and opening of potassium channels, and the action potential soon terminates.

Initiation of the Action Potential Occurs Only After the Threshold Potential Is Reached. An action potential will not occur until the initial rise in membrane potential is great enough to create the positive feedback described in the preceding paragraph. This occurs when the number of sodium ions entering the fiber is greater than the number of potassium ions leaving the fiber. A sudden rise in membrane potential of 15 to 30 millivolts is usually required. Therefore, a sudden increase in the membrane potential in a large nerve fiber, from -70 millivolts up to about -55 millivolts, usually causes the explosive development of an action potential. This level of -55 millivolts is said to be the *threshold* for stimulation.

PROPAGATION OF THE ACTION POTENTIAL

In the preceding paragraphs, we discussed the action potential as though it occurs at one spot on the membrane. However, an action potential elicited at any one point on an excitable membrane usually excites adjacent portions of the membrane, resulting in propagation of the action potential along the membrane. This mechanism is demonstrated in [Figure 5-11](#).

[Figure 5-11A](#) shows a normal resting nerve fiber, and [Figure 5-11B](#) shows a nerve fiber that has been excited in its midportion, which suddenly develops increased permeability to sodium. The *arrows* show a local circuit of current flow from the depolarized areas of the membrane to the adjacent resting membrane areas. That is, positive electrical charges are carried by the inward-diffusing sodium ions through the depolarized membrane and then for several millimeters in both directions along the core of the axon. These positive charges increase the voltage for a distance of 1 to 3 millimeters inside the large myelinated fiber to above the threshold voltage value for initiating an action potential. Therefore, the sodium channels in these new areas immediately open, as shown in [Figure 5-11C and D](#), and the explosive action potential spreads. These newly depolarized areas produce still more local circuits of current flow farther along the membrane, causing progressively more and more depolarization. Thus, the depolarization process travels along the entire length of the fiber. This transmission of the depolarization process along a nerve or muscle fiber is called a *nerve* or *muscle impulse*.

Direction of Propagation. As demonstrated in **Figure 5-11**, an excitable membrane has no single direction of propagation, but the action potential travels in all directions away from the stimulus—even along all branches of a nerve fiber—until the entire membrane has become depolarized.

All-or-Nothing Principle. Once an action potential has been elicited at any point on the membrane of a normal fiber, the depolarization process travels over the entire membrane if conditions are right, but it does not travel at all if conditions are not right. This principle is called the *all-or-nothing principle*, and it applies to all normal excitable tissues. Occasionally, the action potential reaches a point on the membrane at which it does not generate sufficient voltage to stimulate the next area of the membrane. When this situation occurs, the spread of depolarization stops. Therefore, for continued propagation of an impulse to occur, the ratio of action potential to threshold for excitation must at all times be greater than 1. This “greater than 1” requirement is called the *safety factor* for propagation.

RE-ESTABLISHING SODIUM AND POTASSIUM IONIC GRADIENTS AFTER ACTION POTENTIALS ARE COMPLETED—IMPORTANCE OF ENERGY METABOLISM

Transmission of each action potential along a nerve fiber slightly reduces the concentration differences of sodium and potassium inside and outside the membrane because sodium ions diffuse to the inside during depolarization, and potassium ions diffuse to the outside during

Figure 5-11 A–D, Propagation of action potentials in both directions along a conductive fiber.

repolarization. For a single action potential, this effect is so minute that it cannot be measured. Indeed, 100,000 to 50 million impulses can be transmitted by large nerve fibers before the concentration differences reach the point that action potential conduction ceases. With time, however, it becomes necessary to re-establish the sodium and potassium membrane concentration differences, which is achieved by action of the $\text{Na}^+\text{-K}^+$ pump in the same way as described previously for the original establishment of the resting potential. That is, sodium ions that have diffused to the interior of the cell during the action potentials and potassium ions that have diffused to the exterior must be returned to their original state by the $\text{Na}^+\text{-K}^+$ pump. Because this pump requires energy for operation, this “recharging” of the nerve fiber is an active metabolic process, using energy derived from the adenosine triphosphate (ATP) energy system of the cell. **Figure 5-12** shows that the nerve fiber produces increased heat during recharging, which is a measure of energy expenditure when the nerve impulse frequency increases.

A special feature of the $\text{Na}^+\text{-K}^+$ ATP pump is that its degree of activity is strongly stimulated when excess sodium ions accumulate inside the cell membrane. In fact, the pumping activity increases approximately in proportion to the third power of this intracellular sodium concentration. As the internal sodium concentration rises from 10 to 20 mEq/L, the activity of the pump does not merely double but increases about eightfold. Therefore, it is easy to understand how the recharging process of the nerve fiber can be set rapidly into motion whenever the concentration differences of sodium and potassium ions across the membrane begin to run down.

PLATEAU IN SOME ACTION POTENTIALS

In some cases, the excited membrane does not repolarize immediately after depolarization; instead, the potential remains on a plateau near the peak of the spike potential for many milliseconds before repolarization begins. Such a plateau is shown in **Figure 5-13**; one can readily see that

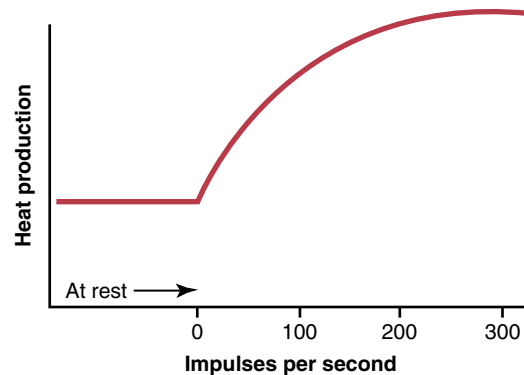

Figure 5-12 Heat production in a nerve fiber at rest and at progressively increasing rates of stimulation.

the plateau greatly prolongs the period of depolarization. This type of action potential occurs in heart muscle fibers, where the plateau lasts for as long as 0.2 to 0.3 second and causes contraction of heart muscle to last for this same long period.

The cause of the plateau is a combination of several factors. First, in heart muscle, two types of channels contribute to the depolarization process: (1) the usual voltage-activated sodium channels, called *fast channels*; and (2) voltage-activated calcium-sodium channels (*L-type calcium channels*), which are slow to open and therefore are called *slow channels*. Opening of fast channels causes the spike portion of the action potential, whereas the prolonged opening of the slow calcium-sodium channels mainly allows calcium ions to enter the fiber, which is largely responsible for the plateau portion of the action potential.

Another factor that may be partly responsible for the plateau is that the voltage-gated potassium channels are slower to open than usual, often not opening much until the end of the plateau. This factor delays the return of the membrane potential toward its normal negative value of -70 millivolts. The plateau ends when the calcium-sodium channels close, and permeability to potassium ions increases.

RHYTHMICITY OF SOME EXCITABLE TISSUES—REPETITIVE DISCHARGE

Repetitive self-induced discharges occur normally in the heart, in most smooth muscle, and in many of the neurons of the central nervous system. These rhythmic discharges cause the following: (1) rhythmic beat of the heart; (2) rhythmic peristalsis of the intestines; and (3) neuronal events such as the rhythmic control of breathing.

In addition, almost all other excitable tissues can discharge repetitively if the threshold for stimulation of the tissue cells is reduced to a low enough level. For example, even large nerve fibers and skeletal muscle fibers, which normally are highly stable, discharge repetitively when they

are placed in a solution that contains the drug *veratridine*, which activates sodium ion channels, or when the calcium ion concentration decreases below a critical value, which increases the sodium permeability of the membrane.

Re-Excitation Process Necessary for Spontaneous Rhythmicity. For spontaneous rhythmicity to occur, the membrane—even in its natural state—must be permeable enough to sodium ions (or to calcium and sodium ions through the slow calcium-sodium channels) to allow automatic membrane depolarization. Thus, **Figure 5-14** shows that the resting membrane potential in the rhythmical control center of the heart is only -60 to -70 millivolts, which is not enough negative voltage to keep the sodium and calcium channels totally closed. Therefore, the following sequence occurs: (1) some sodium and calcium ions flow inward; (2) this activity increases the membrane voltage in the positive direction, which further increases membrane permeability; (3) still more ions flow inward; and (4) the permeability increases more, and so on, until an action potential is generated. Then, at the end of the action potential, the membrane repolarizes. After another delay of milliseconds or seconds, spontaneous excitability causes depolarization again, and a new action potential occurs spontaneously. This cycle continues over and over and causes self-induced rhythmic excitation of the excitable tissue.

Why does the membrane of the heart control center not depolarize immediately after it has become repolarized, rather than delaying for nearly 1 second before the onset of the next action potential? The answer can be found by observing the curve labeled “potassium conductance” in **Figure 5-14**. This curve shows that toward the end of each action potential, and continuing for a short period thereafter, the membrane becomes more permeable to potassium ions. The increased outflow of potassium ions carries tremendous numbers of positive charges to the outside of the membrane, leaving considerably more negativity inside the fiber than would otherwise occur. This continues for nearly 1 second after the preceding action potential is over, thus drawing the membrane potential

Figure 5-13 Action potential (in millivolts) from a Purkinje fiber of the heart, showing a plateau.

Figure 5-14 Rhythmical action potentials (in millivolts) similar to those recorded in the rhythmical control center of the heart. Note their relationship to potassium conductance and to the state of hyperpolarization.

nearer to the potassium Nernst potential. This state, called *hyperpolarization*, is also shown in **Figure 5-14**. As long as this state exists, self-re-excitation will not occur. However, the increased potassium conductance (and the state of hyperpolarization) gradually disappears, as shown after each action potential is completed in the figure, thereby again allowing the membrane potential to increase up to the *threshold* for excitation. Then, suddenly, a new action potential results and the process occurs again and again.

SPECIAL CHARACTERISTICS OF SIGNAL TRANSMISSION IN NERVE TRUNKS

Myelinated and Unmyelinated Nerve Fibers. **Figure 5-15** shows a cross section of a typical small nerve, revealing many large nerve fibers that constitute most of the cross-sectional area. However, a more careful look reveals many more small fibers lying between the large ones. The large fibers are *myelinated*, and the small ones are *unmyelinated*. The average nerve trunk contains about twice as many unmyelinated fibers as myelinated fibers.

Figure 5-16 illustrates schematically the features of a typical myelinated fiber. The central core of the fiber is the *axon*, and the membrane of the axon is the membrane that actually conducts the action potential. The axon is filled in its center with *axoplasm*, which is a viscid intracellular fluid. Surrounding the axon is a *myelin sheath* that is often much thicker than the axon itself. About once every 1 to 3 millimeters along the length of the myelin sheath is a *node of Ranvier*.

The myelin sheath is deposited around the axon by *Schwann cells* in the following manner. The membrane of a Schwann cell first envelops the axon. The Schwann cell then rotates around the axon many times, laying down multiple layers of Schwann cell membrane containing the lipid substance *sphingomyelin*. This substance is an excellent

Figure 5-15 Cross section of a small nerve trunk containing both myelinated and unmyelinated fibers.

electrical insulator that decreases ion flow through the membrane about 5000-fold. At the juncture between each two successive Schwann cells along the axon, a small unmyelinated area only 2 to 3 micrometers in length remains where ions still can flow with ease through the axon membrane between the extracellular fluid and intracellular fluid inside the axon. This area is called the *node of Ranvier*.

Saltatory Conduction in Myelinated Fibers from Node to Node. Even though almost no ions can flow through the thick myelin sheaths of myelinated nerves, they can flow with ease through the nodes of Ranvier. Therefore, action potentials occur *only at the nodes*. Yet, the action potentials are conducted from node to node by *saltatory conduction*, as shown in **Figure 5-17**. That is, electrical current flows through the surrounding extracellular fluid outside the myelin sheath, as well as through the axoplasm inside the axon from node to node, exciting successive nodes one after another. Thus, the nerve impulse jumps along the fiber, which is the origin of the term *saltatory*.

Saltatory conduction is of value for two reasons:

1. First, by causing the depolarization process to jump long intervals along the axis of the nerve fiber, this mechanism increases the velocity of nerve transmission in myelinated fibers as much as 5- to 50-fold.

Figure 5-16 Function of the Schwann cell to insulate nerve fibers. **A**, Wrapping of a Schwann cell membrane around a large axon to form the myelin sheath of the myelinated nerve fiber. **B**, Partial wrapping of the membrane and cytoplasm of a Schwann cell around multiple unmyelinated nerve fibers (shown in cross section). (A, Modified from Leeson TS, Leeson R: *Histology*. Philadelphia: WB Saunders, 1979.)

2. Second, saltatory conduction conserves energy for the axon because only the nodes depolarize, allowing perhaps 100 times less loss of ions than would otherwise be necessary, and therefore requiring much less energy expenditure for re-establishing the sodium and potassium concentration differences across the membrane after a series of nerve impulses.

The excellent insulation afforded by the myelin membrane and the 50-fold decrease in membrane capacitance also allow repolarization to occur with little transfer of ions.

Velocity of Conduction in Nerve Fibers. The velocity of action potential conduction in nerve fibers varies from as little as 0.25 m/sec in small unmyelinated fibers to as much as 100 m/sec—more than the length of a football field in 1 second—in large myelinated fibers.

EXCITATION—THE PROCESS OF ELICITING THE ACTION POTENTIAL

Basically, any factor that causes sodium ions to begin to diffuse inward through the membrane in sufficient numbers can set off automatic regenerative opening of the sodium channels. This automatic regenerative opening can result from *mechanical* disturbance of the membrane, *chemical* effects on the membrane, or passage of *electricity* through the membrane. All these approaches are used at different points in the body to elicit nerve or muscle

action potentials: mechanical pressure to excite sensory nerve endings in the skin, chemical neurotransmitters to transmit signals from one neuron to the next in the brain, and electrical current to transmit signals between successive muscle cells in the heart and intestine.

Excitation of a Nerve Fiber by a Negatively Charged Metal Electrode. The usual means for exciting a nerve or muscle in the experimental laboratory is to apply electricity to the nerve or muscle surface through two small electrodes, one of which is negatively charged and the other positively charged. When electricity is applied in this manner, the excitable membrane becomes stimulated at the negative electrode.

Remember that the action potential is initiated by the opening of voltage-gated sodium channels. Furthermore, these channels are opened by a decrease in the normal resting electrical voltage across the membrane—that is, negative current from the electrode decreases the voltage on the outside of the membrane to a negative value nearer to the voltage of the negative potential inside the fiber. This effect decreases the electrical voltage across the membrane and allows the sodium channels to open, resulting in an action potential. Conversely, at the positive electrode, the injection of positive charges on the outside of the nerve membrane heightens the voltage difference across the membrane, rather than lessening it. This effect causes a state of hyperpolarization, which actually decreases the excitability of the fiber rather than causing an action potential.

Figure 5-17 Saltatory conduction along a myelinated axon. The flow of electrical current from node to node is illustrated by the arrows.

Threshold for Excitation and Acute Local Potentials.

A weak negative electrical stimulus may not be able to excite a fiber. However, when the voltage of the stimulus is increased, there comes a point at which excitation does take place. **Figure 5-18** shows the effects of successively applied stimuli of progressing strength. A weak stimulus at point A causes the membrane potential to change from -70 to -65 millivolts, but this change is not sufficient for the automatic regenerative processes of the action potential to develop. At point B, the stimulus is greater, but the intensity is still not enough. The stimulus does, however, disturb the membrane potential locally for as long as 1 millisecond or more after both of these weak stimuli. These local potential changes are called *acute local potentials* and, when they fail to elicit an action potential, they are called *acute subthreshold potentials*.

At point C in **Figure 5-18**, the stimulus is even stronger. Now, the local potential has barely reached the *threshold level* required to elicit an action potential, but this occurs only after a short “latent period.” At point D, the stimulus is still stronger, the acute local potential is also stronger, and the action potential occurs after less of a latent period.

Thus, this figure shows that even a weak stimulus causes a local potential change at the membrane, but the intensity of the local potential must rise to a threshold level before the action potential is set off.

REFRACTORY PERIOD AFTER AN ACTION POTENTIAL, DURING WHICH A NEW STIMULUS CANNOT BE ELICITED

A new action potential cannot occur in an excitable fiber as long as the membrane is still depolarized from the preceding action potential. The reason for this restriction is that shortly after the action potential is initiated, the sodium channels (or calcium channels, or both) become inactivated, and no amount of excitatory signal applied to these channels at this point will open the inactivation gates. The only condition that will allow them to reopen is for the membrane potential to return to or near the original

Figure 5-18 Effect of stimuli of increasing voltages to elicit an action potential. Note the development of acute subthreshold potentials when the stimuli are below the threshold value required for eliciting an action potential.

resting membrane potential level. Then, within another small fraction of a second, the inactivation gates of the channels open, and a new action potential can be initiated.

The period during which a second action potential cannot be elicited, even with a strong stimulus, is called the *absolute refractory period*. This period for large myelinated nerve fibers is about $1/2500$ second. Therefore, one can readily calculate that such a fiber can transmit a maximum of about 2500 impulses per second.

Inhibition of Excitability—Stabilizers and Local Anesthetics

In contrast to the factors that increase nerve excitability, *membrane-stabilizing factors* can decrease excitability. For example, a high *extracellular fluid calcium ion concentration* decreases membrane permeability to sodium ions and simultaneously reduces excitability. Therefore, calcium ions are said to be what is called a *stabilizer*.

Local Anesthetics. Among the most important stabilizers are the many substances used clinically as local anesthetics, including *procaine* and *tetracaine*. Most of these agents act directly on the activation gates of the sodium channels, making it much more difficult for these gates to open and thereby reducing membrane excitability. When excitability has been reduced so low that the ratio of *action potential strength to excitability threshold* (called the *safety factor*) is reduced below 1.0, nerve impulses fail to pass along the anesthetized nerves.

Contraction of Skeletal Muscle

About 40% of the body is skeletal muscle, and perhaps another 10% is smooth and cardiac muscle. Some of the same basic principles of contraction apply to all these muscle types. In this chapter, we mainly consider skeletal muscle function; the specialized functions of smooth muscle are discussed in [Chapter 8](#), and cardiac muscle is discussed in [Chapter 9](#).

PHYSIOLOGICAL ANATOMY OF SKELETAL MUSCLE

[Figure 6-1](#) shows that skeletal muscles are composed of numerous fibers ranging from 10 to 80 micrometers in diameter. Each of these fibers is made up of successively smaller subunits, also shown in [Figure 6-1](#), and described in subsequent paragraphs.

In most skeletal muscles, each fiber extends the entire length of the muscle. Except for about 2% of the fibers, each fiber is usually innervated by only one nerve ending, located near the middle of the fiber.

The Sarcolemma Is a Thin Membrane Enclosing a Skeletal Muscle Fiber. The sarcolemma consists of a true cell membrane, called the plasma membrane, and an outer coat made up of a thin layer of polysaccharide material that contains numerous thin collagen fibrils. At each end of the muscle fiber, this surface layer of the sarcolemma fuses with a tendon fiber. The tendon fibers, in turn, collect into bundles to form the muscle tendons that then connect the muscles to the bones.

Myofibrils Are Composed of Actin and Myosin Filaments. Each muscle fiber contains several hundred to several thousand *myofibrils*, which are illustrated in the cross-sectional view of [Figure 6-1C](#). Each myofibril ([Figure 6-1D and E](#)) is composed of about 1500 adjacent *myosin filaments* and 3000 *actin filaments*, which are large polymerized protein molecules that are responsible for the muscle contraction. These filaments can be seen in longitudinal view in the electron micrograph of [Figure 6-2](#) and are represented diagrammatically in [Figure 6-1E through L](#). The thick filaments in the diagrams are *myosin*, and the thin filaments are *actin*.

Note in [Figure 6-1E](#) that the myosin and actin filaments partially interdigitate and thus cause the myofibrils to have alternate light and dark bands, as illustrated in [Figure 6-2](#). The light bands contain only actin filaments and are called *I bands* because they are *isotropic* to polarized light. The dark bands contain myosin filaments, as well as the ends of the actin filaments, where they overlap the myosin, and are called *A bands* because they are *anisotropic* to polarized light. Note also the small projections from the sides of the myosin filaments in [Figure 6-1E and L](#). These projections are *cross-bridges*. It is the interaction between these cross-bridges and the actin filaments that causes contraction (Video 6-1).

[Figure 6-1E](#) also shows that the ends of the actin filaments are attached to a *Z disk*. From this disk, these filaments extend in both directions to interdigitate with the myosin filaments. The Z disk, which is composed of filamentous proteins different from the actin and myosin filaments, passes crosswise across the myofibril and also crosswise from myofibril to myofibril, attaching the myofibrils to one another all the way across the muscle fiber. Therefore, the entire muscle fiber has light and dark bands, as do the individual myofibrils. These bands give skeletal and cardiac muscle their striated appearance.

The portion of the myofibril (or of the whole muscle fiber) that lies between two successive Z disks is called a *sarcomere*. When the muscle fiber is contracted, as shown at the bottom of [Figure 6-5](#), the length of the sarcomere is about 2 micrometers. At this length, the actin filaments completely overlap the myosin filaments, and the tips of the actin filaments are just beginning to overlap one another. As discussed later, at this length, the muscle is capable of generating its greatest force of contraction.

Titin Filamentous Molecules Keep the Myosin and Actin Filaments in Place. The side-by-side relationship between the myosin and actin filaments is maintained by a large number of filamentous molecules of a protein called *titin* ([Figure 6-3](#)). Each titin molecule has a molecular weight of about 3 million, which makes it one of the largest protein molecules in the body. Also, because it is filamentous, it is very *springy*. These springy titin molecules act as a framework that holds the myosin and actin filaments in place so that the contractile machinery of

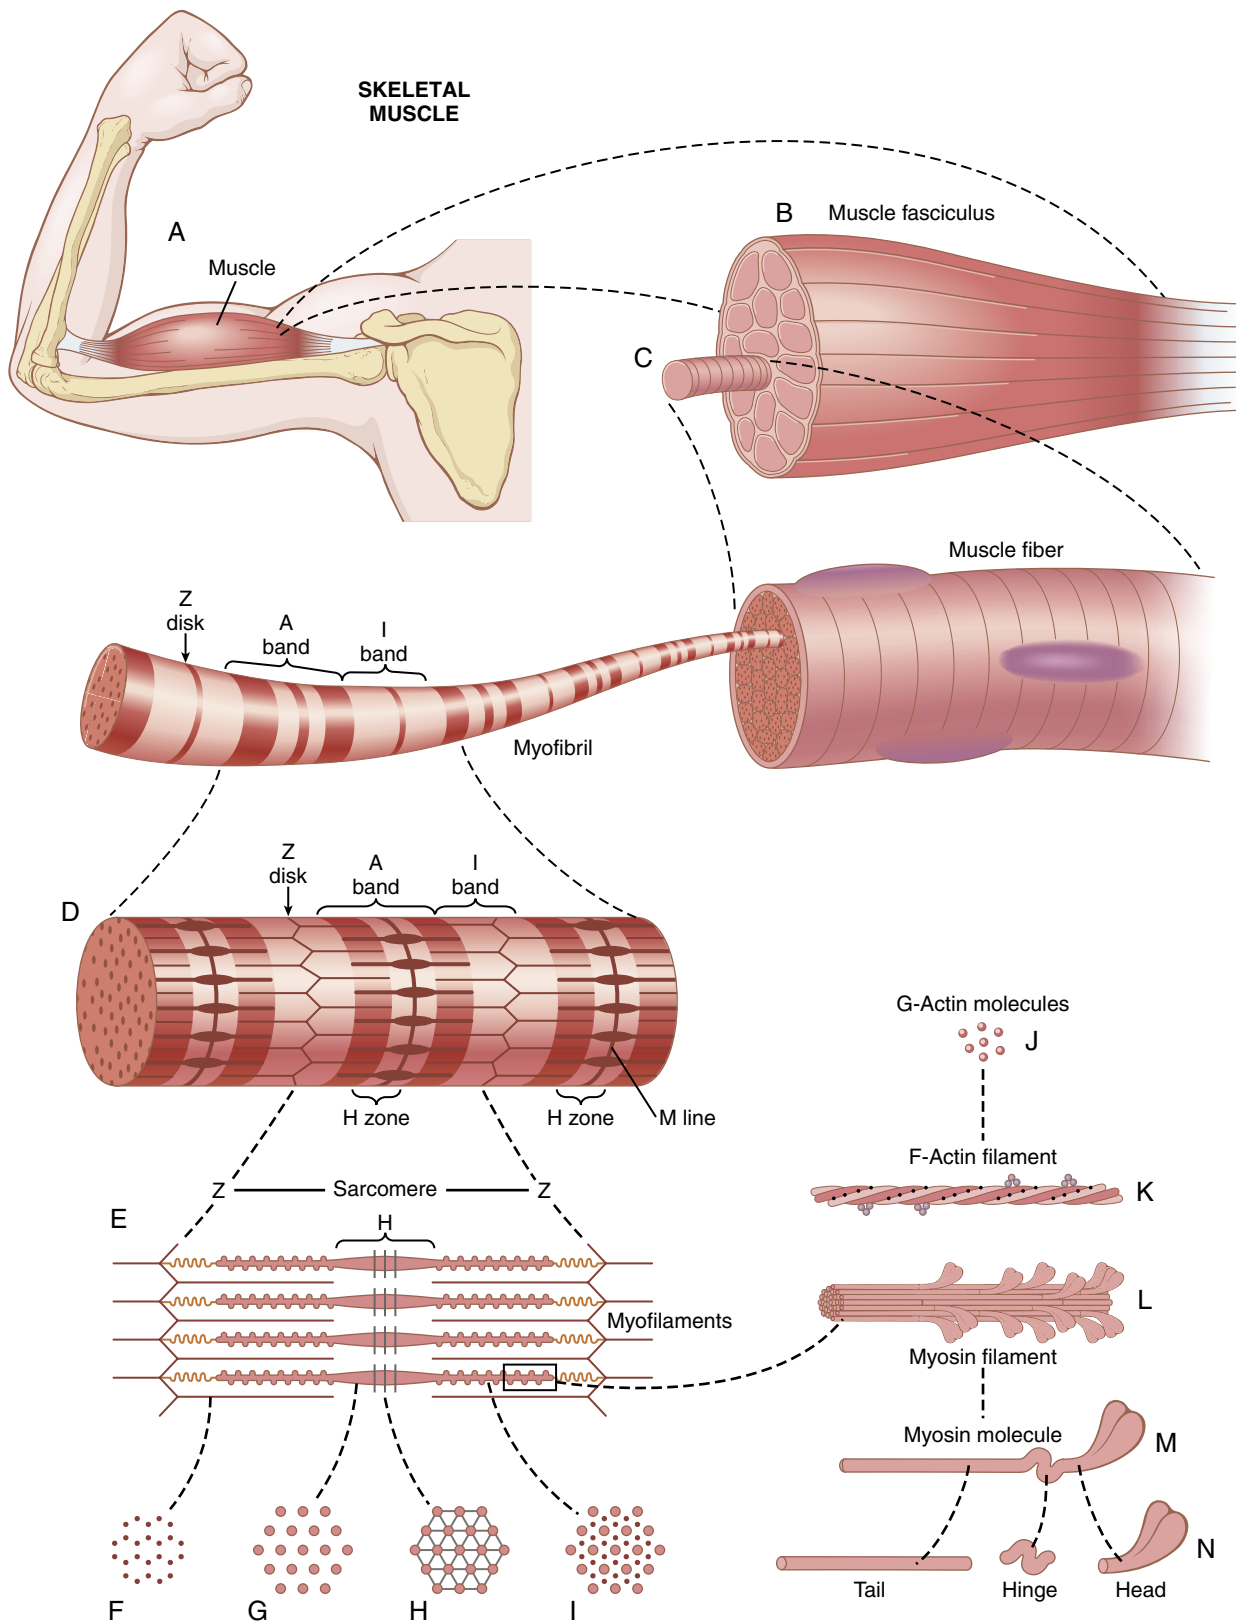

Figure 6-1 A-E, Organization of skeletal muscle, from the gross to the molecular level. F-I, Cross sections at the levels indicated.

Figure 6-3 Organization of proteins in a sarcomere. Each titin molecule extends from the Z disk to the M line. Part of the titin molecule is closely associated with the myosin thick filament, whereas the rest of the molecule is springy and changes length as the sarcomere contracts and relaxes.

the sarcomere will work. One end of the titin molecule is elastic and is attached to the Z disk, acting as a spring and changing length as the sarcomere contracts and relaxes. The other part of the titin molecule tethers it to the myosin thick filament. The titin molecule may also act as a template for the initial formation of portions of the contractile filaments of the sarcomere, especially the myosin filaments.

Sarcoplasm Is the Intracellular Fluid Between Myofibrils. Many myofibrils are suspended side by side in each muscle fiber. The spaces between the myofibrils are filled with intracellular fluid called *sarcoplasm*, containing large quantities of potassium, magnesium, and phosphate, plus multiple protein enzymes. Also present are tremendous numbers of *mitochondria* that lie parallel to the myofibrils. These mitochondria supply the contracting myofibrils with large amounts of energy in the form of adenosine triphosphate (ATP) formed by the mitochondria.

Sarcoplasmic Reticulum Is a Specialized Endoplasmic Reticulum of Skeletal Muscle. Also, in the sarcoplasm surrounding the myofibrils of each muscle fiber, is an extensive reticulum (Figure 6-4), called the *sarcoplas-*

Figure 6-4 Sarcoplasmic reticulum in the spaces between the myofibrils, showing a longitudinal system paralleling the myofibrils. Also shown in cross section are T tubules (arrows) that lead to the exterior of the fiber membrane and are important for conducting the electrical signal into the center of the muscle fiber. (From Fawcett DW: *The Cell*. Philadelphia: WB Saunders, 1981.)

mic reticulum. This reticulum has a special organization that is extremely important in regulating calcium storage, release, reuptake and therefore muscle contraction, as discussed in Chapter 7. The rapidly contracting types of muscle fibers have especially extensive sarcoplasmic reticula.

GENERAL MECHANISM OF MUSCLE CONTRACTION

The initiation and execution of muscle contraction occur in the following sequential steps.

1. An action potential travels along a motor nerve to its endings on muscle fibers.
2. At each ending, the nerve secretes a small amount of the neurotransmitter *acetylcholine*.
3. Acetylcholine acts on a local area of the muscle fiber membrane to open acetylcholine-gated cation channels through protein molecules floating in the membrane.
4. The opening of acetylcholine-gated channels allows large quantities of sodium ions to diffuse to the interior of the muscle fiber membrane. This action causes a local depolarization that in turn leads to the opening of voltage-gated sodium channels, which initiates an action potential at the membrane.
5. The action potential travels along the muscle fiber membrane in the same way that action potentials travel along nerve fiber membranes.
6. The action potential depolarizes the muscle membrane, and much of the action potential electricity flows through the center of the muscle fiber. Here it causes the sarcoplasmic reticulum to release large quantities of calcium ions that have been stored within this reticulum.

Figure 6-5 Relaxed and contracted states of a myofibril showing (top) sliding of the actin filaments (pink) into the spaces between the myosin filaments (red) and (bottom) pulling of the Z membranes toward each other.

- The calcium ions initiate attractive forces between the actin and myosin filaments, causing them to slide alongside each other, which is the contractile process.
- After a fraction of a second, the calcium ions are pumped back into the sarcoplasmic reticulum by a Ca^{2+} membrane pump and remain stored in the reticulum until a new muscle action potential comes along; this removal of calcium ions from the myofibrils causes the muscle contraction to cease.

We now describe the molecular machinery of the muscle contractile process.

MOLECULAR MECHANISM OF MUSCLE CONTRACTION

Muscle Contraction Occurs by a Sliding Filament Mechanism. Figure 6-5 demonstrates the basic mechanism of muscle contraction. It shows the relaxed state of a sarcomere (top) and the contracted state (bottom). In the relaxed state, the ends of the actin filaments extending from two successive Z disks barely overlap one another. Conversely, in the contracted state, these actin filaments have been pulled inward among the myosin filaments, so their ends overlap one another to their maximum extent. Also, the Z disks have been pulled by the actin filaments up to the ends of the myosin filaments. Thus, muscle contraction occurs by a *sliding filament mechanism*.

But what causes the actin filaments to slide inward among the myosin filaments? This action is caused by forces generated by interaction of the cross-bridges from the myosin filaments with the actin filaments. Under resting conditions, these forces are inactive, but when an action potential travels along the muscle fiber, this causes the sarcoplasmic reticulum to release large quantities of calcium ions that rapidly surround the myofibrils. The

Figure 6-6 A, Myosin molecule. B, Combination of many myosin molecules to form a myosin filament. Also shown are thousands of myosin *cross-bridges* and interaction between the *heads* of the cross-bridges with adjacent actin filaments.

calcium ions, in turn, activate the forces between the myosin and actin filaments, and contraction begins. However, energy is needed for the contractile process to proceed. This energy comes from high-energy bonds in the ATP molecule, which is degraded to adenosine diphosphate (ADP) to liberate the energy. In the next few sections, we describe these molecular processes of contraction.

Molecular Characteristics of the Contractile Filaments

Myosin Filaments Are Composed of Multiple Myosin Molecules. Each of the myosin molecules, shown in Figure 6-6A, has a molecular weight of about 480,000. Figure 6-6B shows the organization of many molecules to form a myosin filament, as well as interaction of this filament on one side with the ends of two actin filaments.

The *myosin molecule* (see Figure 6-6A) is composed of six polypeptide chains—two *heavy chains*, each with a molecular weight of about 200,000; and four *light chains*, with molecular weights of about 20,000 each. The two heavy chains wrap spirally around each other to form a double helix, which is called the *tail* of the myosin molecule. One end of each of these chains is folded bilaterally into a globular polypeptide structure called a *myosin head*. Thus, there are two free heads at one end of the double-helix myosin molecule. The four light chains are also part of the myosin head, two to each head. These light chains help control the function of the head during muscle contraction.

The *myosin filament* is made up of 200 or more individual myosin molecules. The central portion of one of these filaments is shown in Figure 6-6B, displaying the tails of the myosin molecules bundled together to form the *body* of the filament, while many heads of the molecules hang outward to the sides of the body. Also, part of the body

Figure 6-7 Actin filament composed of two helical strands of *F-actin* molecules and two strands of *tropomyosin* molecules that fit in the grooves between the actin strands. Attached to one end of each tropomyosin molecule is a *troponin* complex that initiates contraction.

of each myosin molecule hangs to the side along with the head, thus providing an *arm* that extends the head outward from the body, as shown in the figure. The protruding arms and heads together are called *cross-bridges*. Each cross-bridge is flexible at two points called *hinges*—one where the arm leaves the body of the myosin filament and the other where the head attaches to the arm. The hinged arms allow the heads either to be extended far outward from the body of the myosin filament or brought close to the body. The hinged heads, in turn, participate in the contraction process, as discussed in the following sections.

The total length of each myosin filament is uniform, almost exactly 1.6 micrometers. Note, however, that there are no cross-bridge heads in the center of the myosin filament for a distance of about 0.2 micrometer because the hinged arms extend away from the center.

Now, to complete the picture, the myosin filament is twisted so that each successive pair of cross-bridges is axially displaced from the previous pair by 120 degrees. This twisting ensures that the cross-bridges extend in all directions around the filament.

Adenosine Triphosphatase Activity of the Myosin Head. Another feature of the myosin head that is essential for muscle contraction is that it functions as an *adenosine triphosphatase (ATPase) enzyme*. As explained later, this property allows the head to cleave ATP and use the energy derived from the ATP's high-energy phosphate bond to energize the contraction process.

Actin Filaments Are Composed of Actin, Tropomyosin, and Troponin. The backbone of the actin filament is a double-stranded *F-actin protein molecule*, represented by the two lighter-colored strands in [Figure 6-7](#). The two strands are wound in a helix in the same manner as the myosin molecule.

Each strand of the double F-actin helix is composed of polymerized *G-actin molecules*, each having a molecular weight of about 42,000. Attached to each one of the G-actin molecules is one molecule of ADP. These ADP molecules are believed to be the active sites on the actin filaments with which the cross-bridges of the myosin filaments interact to cause muscle contraction. The active sites on the two F-actin strands of the double helix are staggered, giving one active site on the overall actin filament about every 2.7 nanometers.

Each actin filament is about 1 micrometer long. The bases of the actin filaments are inserted strongly into the Z disks; the ends of the filaments protrude in both directions to lie in the spaces between the myosin molecules, as shown in [Figure 6-5](#).

Tropomyosin Molecules. The actin filament also contains another protein, tropomyosin. Each molecule of tropomyosin has a molecular weight of 70,000 and a length of 40 nanometers. These molecules are wrapped spirally around the sides of the F-actin helix. In the resting state, the tropomyosin molecules lie on top of the active sites of the actin strands so that attraction cannot occur between the actin and myosin filaments to cause contraction. Contraction occurs only when an appropriate signal causes a conformation change in tropomyosin that “uncover” active sites on the actin molecule and initiates contraction, as explained later.

Troponin and Its Role in Muscle Contraction. Attached intermittently along the sides of the tropomyosin molecules are additional protein molecules called *troponin*. These protein molecules are actually complexes of three loosely bound protein subunits, each of which plays a specific role in controlling muscle contraction. One of the subunits (troponin I) has a strong affinity for actin, another (troponin T) for tropomyosin, and a third (troponin C) for calcium ions. This complex is believed to attach the tropomyosin to the actin. The strong affinity of the troponin for calcium ions is believed to initiate the contraction process, as explained in the next section.

Interaction of One Myosin Filament, Two Actin Filaments, and Calcium Ions to Cause Contraction

Inhibition of the Actin Filament by the Troponin-Tropomyosin Complex. A pure actin filament without the presence of the troponin-tropomyosin complex (but in the presence of magnesium ions and ATP) binds instantly and strongly with the heads of the myosin molecules. Then, if the troponin-tropomyosin complex is added to the actin filament, the binding between myosin and actin does not take place. Therefore, it is believed that the active sites on the normal actin filament of the relaxed muscle are inhibited or physically covered by the troponin-tropomyosin complex. Consequently, the sites cannot attach to the heads of the myosin filaments to cause contraction. Before contraction can take place, the inhibitory effect of the troponin-tropomyosin complex must itself be inhibited.

Activation of the Actin Filament by Calcium Ions. In the presence of large amounts of calcium ions, the inhibitory effect of the troponin-tropomyosin on the actin filaments is itself inhibited. The mechanism of this inhibition is not known, but one suggestion has been presented. When calcium ions combine with

Figure 6-8 The walk-along mechanism for contraction of the muscle.

troponin C, each molecule of which can bind strongly with up to four calcium ions, the troponin complex then undergoes a conformational change that in some way tugs on the tropomyosin molecule and moves it deeper into the groove between the two actin strands. This action uncovers the active sites of the actin, thus allowing these active sites to attract the myosin cross-bridge heads and allow contraction to proceed. Although this mechanism is hypothetical, it emphasizes that the normal relationship between the troponin-tropomyosin complex and actin is altered by calcium ions, producing a new condition that leads to contraction.

Interaction of the Activated Actin Filament and the Myosin Cross-Bridges—The Walk-Along Theory of Contraction. As soon as the actin filament is activated by the calcium ions, the heads of the cross-bridges from the myosin filaments become attracted to the active sites of the actin filament and initiate contraction. Although the precise manner in which this interaction between the cross-bridges and the actin causes contraction is still partly theoretical, one hypothesis for which considerable evidence exists is the walk-along (or *ratchet*) theory of contraction.

Figure 6-8 demonstrates this postulated walk-along mechanism for contraction. The figure shows the heads of two cross-bridges attaching to and disengaging from active sites of an actin filament. When a head attaches to an active site, this attachment simultaneously causes profound changes in the intramolecular forces between the head and arm of its cross-bridge. The new alignment of forces causes the head to tilt toward the arm and to drag the actin filament along with it. This tilt of the head is called the *power stroke*. Immediately after tilting, the head then automatically breaks away from the active site. Next, the head returns to its extended direction. In this position, it combines with a new active site farther down along the actin filament; the head then tilts again to cause a new power stroke, and the actin filament moves another step. Thus, the heads of the cross-bridges bend back and forth and, step by step, walk along the actin filament, pulling the ends of two successive actin filaments toward the center of the myosin filament.

Each of the cross-bridges is believed to operate independently of all the others, with each attaching and pulling in a continuous repeated cycle. Therefore, the greater the number of cross-bridges in contact with the actin filament at any given time, the greater the force of contraction.

ATP Is the Energy Source for Contraction—Chemical Events in the Motion of the Myosin Heads. When a muscle contracts, work is performed, and energy is required. Large amounts of ATP are cleaved to form ADP during the contraction process, and the more work performed by the muscle, the more ATP that is cleaved; this phenomenon is called the *Fenn effect*. The following sequence of events is believed to be the means whereby this effect occurs:

1. Before contraction begins, the heads of the cross-bridges bind with ATP. The ATPase activity of the myosin head immediately cleaves the ATP but leaves the cleavage products, ADP plus phosphate ion, bound to the head. In this state, the conformation of the head is such that it extends perpendicularly toward the actin filament but is not yet attached to the actin.
2. When the troponin-tropomyosin complex binds with calcium ions, active sites on the actin filament are uncovered, and the myosin heads then bind with these sites, as shown in **Figure 6-8**.
3. The bond between the head of the cross-bridge and the active site of the actin filament causes a conformational change in the head, prompting the head to tilt toward the arm of the cross-bridge and providing the *power stroke* for pulling the actin filament. The energy that activates the power stroke is the energy already stored, like a cocked spring, by the conformational change that occurred in the head when the ATP molecule was cleaved earlier.
4. Once the head of the cross-bridge tilts, release of the ADP and phosphate ion that were previously attached to the head is allowed. At the site of release of the ADP, a new molecule of ATP binds. This binding of new ATP causes detachment of the head from the actin.
5. After the head has detached from the actin, the new molecule of ATP is cleaved to begin the next cycle, leading to a new power stroke. That is, the energy again cocks the head back to its perpendicular condition, ready to begin the new power stroke cycle.
6. When the cocked head (with its stored energy derived from the cleaved ATP) binds with a new active site on the actin filament, it becomes uncocked and once again provides a new power stroke.

Thus, the process proceeds again and again until the actin filaments pull the Z membrane up against the ends of the myosin filaments or until the load on the muscle becomes too great for further pulling to occur.

Figure 6-9 Length-tension diagram for a single fully contracted sarcomere showing the maximum strength of contraction when the sarcomere is 2.0 to 2.2 micrometers in length. At the *upper right* are the relative positions of the actin and myosin filaments at different sarcomere lengths from point A to point D. (Modified from Gordon AM, Huxley AF, Julian FJ: *The length-tension diagram of single vertebrate striated muscle fibers. J Physiol* 171:28P, 1964.)

Amount of Actin and Myosin Filament Overlap Determines Tension Developed by the Contracting Muscle

Figure 6-9 shows the effect of sarcomere length and the amount of myosin-actin filament overlap on the active tension developed by a contracting muscle fiber. To the right are different degrees of overlap of the myosin and actin filaments at different sarcomere lengths. At point D on the diagram, the actin filament has pulled all the way out to the end of the myosin filament, with no actin-myosin overlap. At this point, the tension developed by the activated muscle is zero. Then, as the sarcomere shortens, and the actin filament begins to overlap the myosin filament, the tension increases progressively until the sarcomere length decreases to about 2.2 micrometers. At this point, the actin filament has already overlapped all the cross-bridges of the myosin filament but has not yet reached the center of the myosin filament. With further shortening, the sarcomere maintains full tension until point B is reached, at a sarcomere length of about 2 micrometers. At this point, the ends of the two actin filaments begin to overlap each other in addition to overlapping the myosin filaments. As the sarcomere length decreases from 2 micrometers to about 1.65 micrometers at point A, the strength of contraction decreases rapidly. At this point, the two Z disks of the sarcomere abut the ends of the myosin filaments. Then, as contraction proceeds to still shorter sarcomere lengths, the ends of the myosin filaments are crumpled and, as shown in the figure, the strength of contraction approaches zero, but the sarcomere has now contracted to its shortest length.

Effect of Muscle Length on Force of Contraction in the Whole Intact Muscle. The top curve of **Figure 6-10** is similar to that in **Figure 6-9**, but the curve in **Figure 6-10** depicts tension of the intact whole muscle rather than of a single muscle fiber. The whole muscle

Figure 6-10 Relationship of muscle length to tension in the muscle both before and during muscle contraction.

has a large amount of connective tissue in it; in addition, the sarcomeres in different parts of the muscle do not always contract the same amount. Therefore, the curve has somewhat different dimensions from those shown for the individual muscle fiber, but it exhibits the same general form for the slope *in the normal range of contraction*, as shown in **Figure 6-10**.

Note in **Figure 6-10** that when the muscle is at its normal *resting* length, which is at a sarcomere length of about 2 micrometers, it contracts on activation with the approximate maximum force of contraction. However, the *increase* in tension that occurs during contraction, called *active tension*, decreases as the muscle is stretched beyond its normal length—that is, to a sarcomere length greater than about 2.2 micrometers. This phenomenon is demonstrated by the decreased length of the arrow in the figure at greater than normal muscle length.

Relation of Velocity of Contraction to Load

A skeletal muscle contracts rapidly when it contracts against no load to a state of full contraction in about 0.1 second for the average muscle. When loads are applied, the velocity of contraction decreases progressively as the load increases, as shown in **Figure 6-11**. When the load has been increased to equal the maximum force that the muscle can exert, the velocity of contraction becomes zero, and no contraction results, despite activation of the muscle fiber.

This decreasing velocity of contraction with load occurs because a load on a contracting muscle is a reverse force that opposes the contractile force caused by muscle contraction. Therefore, the net force that is available to cause the velocity of shortening is correspondingly reduced.

ENERGETICS OF MUSCLE CONTRACTION

Work Output During Muscle Contraction

When a muscle contracts against a load, it performs *work*. To perform work means that *energy* is transferred from

Figure 6-11 Relationship of load to velocity of contraction in a skeletal muscle with a cross section of 1 square centimeter and a length of 8 centimeters.

the muscle to the external load to lift an object to a greater height or to overcome resistance to movement.

In mathematical terms, work is defined by the following equation:

$$W = L \times D$$

in which W is the work output, L is the load, and D is the distance of movement against the load. The energy required to perform the work is derived from the chemical reactions in the muscle cells during contraction, as described in the following sections.

Three Sources of Energy for Muscle Contraction

Most of the energy required for muscle contraction is used to trigger the walk-along mechanism whereby the cross-bridges pull the actin filaments, but small amounts are required for the following: (1) pumping calcium ions from the sarcoplasm into the sarcoplasmic reticulum after the contraction is over; and (2) pumping sodium and potassium ions through the muscle fiber membrane to maintain an appropriate ionic environment for the propagation of muscle fiber action potentials.

The concentration of ATP in the muscle fiber, about 4 millimolar, is sufficient to maintain full contraction for only 1 to 2 seconds at most. The ATP is split to form ADP, which transfers energy from the ATP molecule to the contracting machinery of the muscle fiber. Then, as described in [Chapter 2](#), the ADP is rephosphorylated to form new ATP within another fraction of a second, which allows the muscle to continue its contraction. There are three sources of the energy for this rephosphorylation.

The first source of energy that is used to reconstitute the ATP is the substance *phosphocreatine*, which carries a high-energy phosphate bond similar to the bonds of ATP. The high-energy phosphate bond of phosphocreatine has a slightly higher amount of free energy than that of each ATP bond, as discussed in more detail in [Chapters 68 and 73](#). Therefore, phosphocreatine is instantly cleaved, and its released energy causes bonding of a new phosphate ion to

ADP to reconstitute the ATP. However, the total amount of phosphocreatine in the muscle fiber is also small, only about 5 times as great as the ATP. Therefore, the combined energy of both the stored ATP and the phosphocreatine in the muscle is capable of causing maximal muscle contraction for only 5 to 8 seconds.

The second important source of energy, which is used to reconstitute both ATP and phosphocreatine, is a process called *glycolysis*—the breakdown of *glycogen* previously stored in the muscle cells. Rapid enzymatic breakdown of the glycogen to pyruvic acid and lactic acid liberates energy that is used to convert ADP to ATP; the ATP can then be used directly to energize additional muscle contraction and also to re-form the stores of phosphocreatine.

The importance of this glycolysis mechanism is twofold. First, glycolytic reactions can occur even in the absence of oxygen, so muscle contraction can be sustained for many seconds and sometimes up to more than 1 minute, even when oxygen delivery from the blood is not available. Second, the rate of ATP formation by glycolysis is about 2.5 times as rapid as ATP formation in response to cellular foodstuffs reacting with oxygen. However, so many end products of glycolysis accumulate in the muscle cells that glycolysis also loses its capability to sustain maximum muscle contraction after about 1 minute.

The third and final source of energy is *oxidative metabolism*, which means combining oxygen with the end products of glycolysis and with various other cellular foodstuffs to liberate ATP. *More than 95% of all energy used by the muscles for sustained long-term contraction is derived from oxidative metabolism.* The foodstuffs that are consumed are carbohydrates, fats, and protein. For extremely long-term maximal muscle activity—over a period of many hours—the greatest proportion of energy comes from fats but, for periods of 2 to 4 hours, as much as one half of the energy can come from stored carbohydrates.

The detailed mechanisms of these energetic processes are discussed in [Chapters 68 through 73](#). In addition, the importance of the different mechanisms of energy release during performance of different sports is discussed in [Chapter 85](#).

Efficiency of Muscle Contraction. The efficiency of an engine or a motor is calculated as the percentage of energy input that is converted into work instead of heat. The percentage of the input energy to muscle (the chemical energy in nutrients) that can be converted into work, even under the best conditions, is less than 25%, with the remainder becoming heat. The reason for this low efficiency is that about one-half of the energy in foodstuffs is lost during the formation of ATP and, even then, only 40% to 45% of the energy in ATP itself can later be converted into work.

Maximum efficiency can be realized only when the muscle contracts at a moderate velocity. If the muscle contracts slowly or without any movement, small amounts of *maintenance heat* are released during contraction, even though little or no work is performed, thereby decreasing

the conversion efficiency to as little as zero. Conversely, if contraction is too rapid, much of the energy is used to overcome viscous friction within the muscle itself, and this too reduces the efficiency of contraction. Ordinarily, maximum efficiency occurs when the velocity of contraction is about 30% of maximum.

CHARACTERISTICS OF WHOLE MUSCLE CONTRACTION

Many features of muscle contraction can be demonstrated by eliciting single *muscle twitches*. This can be accomplished by electrical excitation of the nerve to a muscle or by passing a short electrical stimulus through the muscle itself, giving rise to a single sudden contraction lasting a fraction of a second.

Isometric Contractions Do Not Shorten Muscle, Whereas Isotonic Contractions Shorten Muscle at a Constant Tension. Muscle contraction is said to be *isometric* when the muscle does not shorten during contraction and *isotonic* when it shortens but the tension on the muscle remains constant throughout the contraction. Systems for recording the two types of muscle contraction are shown in **Figure 6-12**.

In the isometric system, the muscle contracts against a force transducer without decreasing the muscle length, as shown in the bottom panel of **Figure 6-12**. In the isotonic system, the muscle shortens against a fixed load, which is illustrated in the top panel of the figure, showing a muscle lifting a weight. The characteristics of isotonic contraction depend on the load against which the muscle contracts, as well as the inertia of the load. However, the isometric system records changes in force of muscle contraction independently of load inertia. Therefore, the isometric system is often used when comparing the functional characteristics of different muscle types.

Characteristics of Isometric Twitches Recorded from Different Muscles. The human body has many sizes of skeletal muscles—from the small stapedius muscle in the middle ear, measuring only a few millimeters long and 1 millimeter or so in diameter, up to the large quadriceps muscle, a half-million times as large as the stapedius. Furthermore, the fibers may be as small as 10 micrometers in diameter or as large as 80 micrometers. Finally, the energetics of muscle contraction vary considerably from one muscle to another. Therefore, it is no wonder that the mechanical characteristics of muscle contraction differ among muscles.

Figure 6-13 shows records of isometric contractions of three types of skeletal muscle—an ocular muscle, which has a duration of *isometric* contraction of less than 1/50 second; the gastrocnemius muscle, which has a duration of contraction of about 1/15 second; and the soleus muscle, which has a duration of contraction of about 1/5

Figure 6-12 Isotonic and isometric systems for recording muscle contractions. Isotonic contraction occurs when the force of the muscle contraction is greater than the load, and the tension on the muscle remains constant during the contraction. When the muscle contracts, it shortens and moves the load. Isometric contraction occurs when the load is greater than the force of the muscle contraction; the muscle creates tension when it contracts, but the overall length of the muscle does not change.

Figure 6-13 Duration of isometric contractions for different types of mammalian skeletal muscles showing a latent period between the action potential (depolarization) and muscle contraction.

second. These durations of contraction are highly adapted to the functions of the respective muscles. Ocular movements must be extremely rapid to maintain fixation of the eyes on specific objects to provide accuracy of vision. The gastrocnemius muscle must contract moderately rapidly to provide sufficient velocity of limb movement for running and jumping, and the soleus muscle is concerned principally with slow contraction for continual, long-term support of the body against gravity.

Fast Versus Slow Muscle Fibers. As will be discussed more fully in [Chapter 85](#) on sports physiology, every muscle of the body is composed of a mixture of so-called *fast* and *slow* muscle fibers, with still other fibers gradated between these two extremes. Muscles that react rapidly, including the anterior tibialis, are composed mainly of fast fibers, with only small numbers of the slow variety. Conversely, muscles such as soleus that respond slowly but with prolonged contraction are composed mainly of slow fibers. The differences between these two types of fibers are described in the following sections.

Slow Fibers (Type 1, Red Muscle). The following are characteristics of slow fibers:

1. Slow fibers are smaller than fast fibers.
2. Slow fibers are also innervated by smaller nerve fibers.
3. Slow fibers have a more extensive blood vessel system and more capillaries to supply extra amounts of oxygen compared with fast fibers,
4. Slow fibers have greatly increased numbers of mitochondria to support high levels of oxidative metabolism.
5. Slow fibers contain large amounts of myoglobin, an iron-containing protein similar to hemoglobin in red blood cells. Myoglobin combines with oxygen and stores it until needed, which also greatly speeds oxygen transport to the mitochondria. The myoglobin gives the slow muscle a reddish appearance—hence, the name *red muscle*.

Fast Fibers (Type II, White Muscle). The following are characteristics of fast fibers:

1. Fast fibers are large for great strength of contraction.
2. Fast fibers have an extensive sarcoplasmic reticulum for rapid release of calcium ions to initiate contraction.
3. Large amounts of glycolytic enzymes are present in fast fibers for rapid release of energy by the glycolytic process.
4. Fast fibers have a less extensive blood supply than slow fibers because oxidative metabolism is of secondary importance.
5. Fast fibers have fewer mitochondria than slow fibers, also because oxidative metabolism is secondary. A deficit of red myoglobin in fast muscle gives it the name *white muscle*.

Figure 6-14 A motor unit consists of a motor neuron and the group of skeletal muscle fibers it innervates. A single motor axon may branch to innervate several muscle fibers that function together as a group. Although each muscle fiber is innervated by a single motor neuron, an entire muscle may receive input from hundreds of different motor neurons.

MECHANICS OF SKELETAL MUSCLE CONTRACTION

Motor Unit—All the Muscle Fibers Innervated by a Single Nerve Fiber. Each motoneuron that leaves the spinal cord innervates multiple muscle fibers, with the number of fibers innervated depending on the type of muscle. All the muscle fibers innervated by a single nerve fiber are called a *motor unit* ([Figure 6-14](#)). In general, small muscles that react rapidly and whose control must be exact have more nerve fibers for fewer muscle fibers (e.g., as few as two or three muscle fibers per motor unit in some of the laryngeal muscles). Conversely, large muscles that do not require fine control, such as the soleus muscle, may have several hundred muscle fibers in a motor unit. An average figure for all the muscles of the body is questionable, but a reasonable guess would be about 80 to 100 muscle fibers to a motor unit.

The muscle fibers in each motor unit are not all bunched together in the muscle but overlap other motor units in microbundles of 3 to 15 fibers. This interdigitation allows the separate motor units to contract in support of one another rather than entirely as individual segments.

Muscle Contractions of Different Force—Force Summation. *Summation* means the adding together of individual twitch contractions to increase the intensity

Figure 6-15 Frequency summation and tetanization.

of overall muscle contraction. Summation occurs in two ways: (1) by increasing the number of motor units contracting simultaneously, which is called *multiple fiber summation*; and (2) by increasing the frequency of contraction, which is called *frequency summation* and can lead to *tetanus*.

Multiple Fiber Summation. When the central nervous system sends a weak signal to contract a muscle, the smaller motor units of the muscle may be stimulated in preference to the larger motor units. Then, as the strength of the signal increases, larger and larger motor units begin to be excited, with the largest motor units often having as much as 50 times the contractile force of the smallest units. This phenomenon, called the *size principle*, is important because it allows the gradations of muscle force during weak contraction to occur in small steps, whereas the steps become progressively greater when large amounts of force are required. This size principle occurs because the smaller motor units are driven by small motor nerve fibers, and the small motoneurons in the spinal cord are more excitable than the larger ones, so naturally they are excited first.

Another important feature of multiple fiber summation is that the different motor units are driven asynchronously by the spinal cord; as a result, contraction alternates among motor units one after the other, thus providing smooth contraction, even at low frequencies of nerve signals.

Frequency Summation and Tetanization. Figure 6-15 shows the principles of frequency summation and tetanization. Individual twitch contractions occurring one after another at low frequency of stimulation are displayed on the left. Then, as the frequency increases, there comes a point when each new contraction occurs before the preceding one is over. As a result, the second contraction is added partially to the first, and thus the total strength of contraction rises progressively with increasing frequency. When the frequency reaches a critical level, the successive contractions eventually become so rapid that they fuse together, and the whole muscle contraction appears to be

completely smooth and continuous, as shown in the figure. This process is called *tetanus*. At a slightly higher frequency, the strength of contraction reaches its maximum, so any additional increase in frequency beyond that point has no further effect in increasing contractile force. Tetanus occurs because enough calcium ions are maintained in the muscle sarcoplasm, even between action potentials, so that a full contractile state is sustained without allowing any relaxation between the action potentials.

Maximum Strength of Contraction. The maximum strength of tetanic contraction of a muscle operating at a normal muscle length averages between 3 and 4 kg/cm² of muscle, or 50 pounds/inch². Because a quadriceps muscle can have up to 16 square inches of muscle belly, as much as 800 pounds of tension may be applied to the patellar tendon. Thus, one can readily understand how it is possible for muscles to pull their tendons out of their insertions in bone.

Changes in Muscle Strength at the Onset of Contraction—the Staircase Effect (Treppe). When a muscle begins to contract after a long period of rest, its initial strength of contraction may be as little as one-half its strength 10 to 50 muscle twitches later. That is, the strength of contraction increases to a plateau, a phenomenon called the *staircase effect*, or *treppe*.

Although all the possible causes of the staircase effect are not known, it is believed to be caused primarily by increasing calcium ions in the cytosol because of the release of more and more ions from the sarcoplasmic reticulum with each successive muscle action potential and failure of the sarcoplasm to recapture the ions immediately.

Skeletal Muscle Tone. Even when muscles are at rest, a certain amount of tautness usually remains, called *muscle tone*. Because normal skeletal muscle fibers do not contract without an action potential to stimulate the fibers, skeletal muscle tone results entirely from a low rate of nerve impulses coming from the spinal cord. These nerve impulses, in turn, are controlled partly by signals transmitted from the brain to the appropriate spinal cord anterior motoneurons and partly by signals that originate in *muscle spindles* located in the muscle. Both these signals are discussed in relationship to muscle spindle and spinal cord function in Chapter 55.

Muscle Fatigue. Prolonged strong contraction of a muscle leads to the well-known state of muscle fatigue. Studies in athletes have shown that muscle fatigue increases in almost direct proportion to the rate of depletion of muscle glycogen. Therefore, fatigue results mainly from the inability of the contractile and metabolic processes of the muscle fibers to continue supplying the same work output. However, experiments have also shown that transmission of the nerve signal through the neuromuscular

Figure 6-16 Lever system activated by the biceps muscle.

junction, discussed in [Chapter 7](#), can diminish at least a small amount after intense prolonged muscle activity, thus further diminishing muscle contraction. Interruption of blood flow through a contracting muscle leads to almost complete muscle fatigue within 1 or 2 minutes because of the loss of nutrient supply, especially the loss of oxygen.

Lever Systems of the Body. Muscles operate by applying tension to their points of insertion into bones, and the bones in turn form various types of lever systems. [Figure 6-16](#) shows the lever system activated by the biceps muscle to lift the forearm against a load. If we assume that a large biceps muscle has a cross-sectional area of 6 square inches, the maximum force of contraction would be about 300 pounds. When the forearm is at right angles with the upper arm, the tendon attachment of the biceps is about 2 inches anterior to the fulcrum at the elbow, and the total length of the forearm lever is about 14 inches. Therefore, the amount of lifting power of the biceps at the hand would be only one-seventh of the 300 pounds of muscle force, or about 43 pounds. When the arm is fully extended, the attachment of the biceps is much less than 2 inches anterior to the fulcrum, and the force with which the hand can be brought forward is also much less than 43 pounds.

In short, an analysis of the lever systems of the body depends on knowledge of the following: (1) the point of muscle insertion; (2) its distance from the fulcrum of the lever; (3) the length of the lever arm; and (4) the position of the lever. Many types of movement are required in the body, some of which need great strength and others that need large distances of movement. For this reason, there are many different types of muscle; some are long and contract a long distance, and some are short but have large cross-sectional areas and can provide extreme strength of contraction over short distances. The study of different types of muscles, lever systems, and their movements is called *kinesiology* and is an important scientific component of human physiology.

Positioning of a Body Part by Contraction of Agonist and Antagonist Muscles on Opposite Sides of a Joint. Virtually all body movements are caused by simultaneous contraction of agonist and antagonist muscles on opposite sides of joints. This process is called *coactivation of the agonist and antagonist muscles*, and it is controlled by the motor control centers of the brain and spinal cord.

The position of each separate part of the body, such as an arm or a leg, is determined by the relative degrees of contraction of the agonist and antagonist sets of muscles. For example, let us assume that an arm or a leg is to be placed in a midrange position. To achieve this position, agonist and antagonist muscles are excited to about an equal degree. Remember that an elongated muscle contracts with more force than does a shortened muscle, which was illustrated in [Figure 6-10](#), showing maximum strength of contraction at full functional muscle length and almost no strength of contraction at half-normal length. Therefore, the elongated muscle on one side of a joint can contract with far greater force than the shorter muscle on the opposite side. As an arm or leg moves toward its midposition, the strength of the longer muscle decreases, but the strength of the shorter muscle increases until the two strengths equal each other. At this point, movement of the arm or leg stops. Thus, by varying the ratios of the degree of activation of the agonist and antagonist muscles, the nervous system directs the positioning of the arm or leg.

We discuss in [Chapter 55](#) that the motor nervous system has additional important mechanisms to compensate for different muscle loads when directing this positioning process.

REMODELING OF MUSCLE TO MATCH FUNCTION

The muscles of the body continually remodel to match the functions required of them. Their diameters, lengths, strengths, and vascular supplies are altered, and even the types of muscle fibers are altered, at least slightly. This remodeling process is often quite rapid, occurring within a few weeks. Experiments in animals have shown that muscle contractile proteins in some smaller, more active muscles can be replaced in as little as 2 weeks.

Muscle Hypertrophy and Muscle Atrophy. The increase of the total mass of a muscle is called *muscle hypertrophy*. When the total mass decreases, the process is called *muscle atrophy*.

Virtually all muscle hypertrophy results from an increase in the number of actin and myosin filaments in each muscle fiber, causing enlargement of the individual muscle fibers; this condition is called simply *fiber hypertrophy*. Hypertrophy occurs to a much greater extent when the muscle is loaded during the contractile process. Only a few strong contractions each day are required to cause significant hypertrophy within 6 to 10 weeks.

The manner in which forceful contraction leads to hypertrophy is poorly understood. It is known, however, that the rate of synthesis of muscle contractile proteins is

far greater when hypertrophy is developing, leading also to progressively greater numbers of both actin and myosin filaments in the myofibrils, often increasing as much as 50%. Some of the myofibrils have been observed to split within hypertrophying muscle to form new myofibrils, but the importance of this process in the usual enlargement of skeletal muscle is still unknown.

Along with the increasing size of myofibrils, the enzyme systems that provide energy also increase, especially the enzymes for glycolysis, allowing for a rapid supply of energy during short-term forceful muscle contraction.

When a muscle remains unused for many weeks, the rate of degradation of the contractile proteins is more rapid than the rate of replacement. Therefore, muscle atrophy occurs. The pathway that appears to account for much of the protein degradation in a muscle undergoing atrophy is the *ATP-dependent ubiquitin-proteasome pathway*. Proteasomes are large protein complexes that degrade damaged or unneeded proteins by *proteolysis*, a chemical reaction that breaks peptide bonds. Ubiquitin is a regulatory protein that basically labels which cells will be targeted for proteosomal degradation.

Adjustment of Muscle Length. Another type of hypertrophy occurs when muscles are stretched to greater than normal length. This stretching causes new sarcomeres to be added at the ends of the muscle fibers, where they attach to the tendons. In fact, new sarcomeres can be added as rapidly as several per minute in newly developing muscle, illustrating the rapidity of this type of hypertrophy.

Conversely, when a muscle continually remains shortened to less than its normal length, sarcomeres at the ends of the muscle fibers can actually disappear. It is by these processes that muscles are continually remodeled so they have the appropriate length for proper muscle contraction.

Hyperplasia of Muscle Fibers. Under rare conditions of extreme muscle force generation, the actual number of muscle fibers has been observed to increase (but only by a few percent), in addition to the fiber hypertrophy process. This increase in fiber number is called *fiber hyperplasia*. When it does occur, the mechanism is linear splitting of previously enlarged fibers.

Muscle Denervation Causes Rapid Atrophy. When a muscle loses its nerve supply, it no longer receives the contractile signals that are required to maintain normal muscle size. Therefore, atrophy begins almost immediately. After about 2 months, degenerative changes also begin to appear in the muscle fibers. If the nerve supply to the muscle grows back rapidly, full return of function can occur in as little as 3 months but, from then onward, the capability of functional return becomes less and less, with no further return of function after 1 to 2 years.

In the final stage of denervation atrophy, most of the muscle fibers are destroyed and replaced by fibrous and

fatty tissue. The fibers that do remain are composed of a long cell membrane with a lineup of muscle cell nuclei but with few or no contractile properties and little or no capability of regenerating myofibrils if a nerve does regrow.

The fibrous tissue that replaces the muscle fibers during denervation atrophy also has a tendency to continue shortening for many months, a process called *contracture*. Therefore, one of the most important problems in the practice of physical therapy is to keep atrophying muscles from developing debilitating and disfiguring contractures. This goal is achieved by daily stretching of the muscles or use of appliances that keep the muscles stretched during the atrophying process.

Recovery of Muscle Contraction in Poliomyelitis: Development of Macromotor Units.

When some but not all nerve fibers to a muscle are destroyed, as occurs in poliomyelitis, the remaining nerve fibers branch off to form new axons that then innervate many of the paralyzed muscle fibers. This process results in large motor units called *macromotor units*, which can contain as many as five times the normal number of muscle fibers for each motoneuron coming from the spinal cord. The formation of large motor units decreases the fineness of control one has over the muscles but allows the muscles to regain varying degrees of strength.

Rigor Mortis. Several hours after death, all the muscles of the body go into a state of *contracture* called *rigor mortis*; that is, the muscles contract and become rigid, even without action potentials. This rigidity results from loss of all the ATP, which is required to cause separation of the cross-bridges from the actin filaments during the relaxation process. The muscles remain in rigor until the muscle proteins deteriorate about 15 to 25 hours later, which presumably results from autolysis caused by enzymes released from lysosomes. All these events occur more rapidly at higher temperatures.

Muscular Dystrophy. The muscular dystrophies include several inherited disorders that cause progressive weakness and degeneration of muscle fibers, which are replaced by fatty tissue and collagen.

One of the most common forms of muscular dystrophy is *Duchenne muscular dystrophy* (DMD). This disease affects only males because it is transmitted as an X-linked recessive trait and is caused by mutation of the gene that encodes for a protein called *dystrophin*, which links actins to proteins in the muscle cell membrane. Dystrophin and associated proteins form an interface between the intracellular contractile apparatus and extracellular connective matrix.

Although the precise functions of dystrophin are not completely understood, lack of dystrophin or mutated forms of the protein cause muscle cell membrane destabilization and activation of multiple pathophysiological processes, including altered intracellular calcium handling and impaired membrane repair after injury. One important effect of abnormal dystrophin is an increase in membrane permeability to calcium, thus allowing extracellular calcium ions to enter the muscle fiber and initiate changes in intracellular enzymes that ultimately lead to proteolysis and muscle fiber breakdown.

Symptoms of DMD include muscle weakness that begins in early childhood and rapidly progresses, so that the patient is usually in wheelchairs by age 12 years and often dies of respiratory failure before age 30 years. A milder form of this disease, called *Becker muscular dystrophy* (BMD), is also caused by mutations of the gene that encodes for dystrophin but has a later onset and longer survival. It is estimated that DMD and BMD affect 1 of every 5,600 to 7,700 males between the ages of 5 through 24 years. Currently, no effective treatment exists for DMD or BMD, although characterization of the genetic basis for these diseases has provided the potential for gene therapy in the future.

Excitation of Skeletal Muscle: Neuromuscular Transmission and Excitation-Contraction Coupling

NEUROMUSCULAR JUNCTION AND TRANSMISSION OF IMPULSES FROM NERVE ENDINGS TO SKELETAL MUSCLE FIBERS

Skeletal muscle fibers are innervated by large myelinated nerve fibers that originate from large motoneurons in the anterior horns of the spinal cord. As discussed in [Chapter 6](#), each nerve fiber, after entering the muscle belly, normally branches and stimulates from three to several hundred skeletal muscle fibers. Each nerve ending makes a junction, called the *neuromuscular junction*, with the muscle fiber near its midpoint. The action potential initiated in the muscle fiber by the nerve signal travels in both directions toward the muscle fiber ends. With the exception of about 2% of the muscle fibers, there is only one such junction per muscle fiber.

PHYSIOLOGIC ANATOMY OF THE NEUROMUSCULAR JUNCTION—THE MOTOR END PLATE

[Figure 7-1A and B](#) shows the neuromuscular junction from a large myelinated nerve fiber to a skeletal muscle fiber. The nerve fiber forms a complex of *branching nerve terminals* that invaginate into the surface of the muscle fiber but lie outside the muscle fiber plasma membrane. The entire structure is called the *motor end plate*. It is covered by one or more Schwann cells that insulate it from the surrounding fluids.

[Figure 7-1C](#) shows the junction between a single axon terminal and the muscle fiber membrane. The invaginated membrane is called the *synaptic gutter* or *synaptic trough*, and the space between the terminal and the fiber membrane is called the *synaptic space* or *synaptic cleft*, which is 20 to 30 nanometers wide. At the bottom of the gutter are numerous smaller *folds* of the muscle membrane called *subneural clefts*, which greatly increase the surface area at which the synaptic transmitter can act.

In the axon terminal are many mitochondria that supply adenosine triphosphate (ATP), the energy source used for synthesis of a transmitter, *acetylcholine*, which excites the muscle fiber membrane. Acetylcholine is synthesized

in the cytoplasm of the terminal but is absorbed rapidly into many small *synaptic vesicles*, about 300,000 of which are normally in the terminals of a single end plate. In the synaptic space are large quantities of the enzyme *acetylcholinesterase*, which destroys acetylcholine a few milliseconds after it has been released from the synaptic vesicles.

SECRETION OF ACETYLCHOLINE BY THE NERVE TERMINALS

When a nerve impulse reaches the neuromuscular junction, about 125 vesicles of acetylcholine are released from the terminals into the synaptic space. Some of the details of this mechanism can be seen in [Figure 7-2](#), which shows an expanded view of a synaptic space with the neural membrane above and the muscle membrane and its subneural clefts below.

On the inside surface of the neural membrane are linear *dense bars*, shown in cross section in [Figure 7-2](#). To each side of each dense bar are protein particles that penetrate the neural membrane; these are *voltage-gated calcium channels*. When an action potential spreads over the terminal, these channels open and allow calcium ions to diffuse from the synaptic space to the interior of the nerve terminal. The calcium ions, in turn, are believed to activate *Ca²⁺-calmodulin-dependent protein kinase*, which, in turn, phosphorylates *synapsin* proteins that anchor the acetylcholine vesicles to the cytoskeleton of the presynaptic terminal. This process frees the acetylcholine vesicles from the cytoskeleton and allows them to move to the *active zone* of the presynaptic neural membrane adjacent to the dense bars. The vesicles then dock at the release sites, fuse with the neural membrane, and empty their acetylcholine into the synaptic space by the process of *exocytosis*.

Although some of the aforementioned details are speculative, it is known that the effective stimulus for causing acetylcholine release from the vesicles is entry of calcium ions and that acetylcholine from the vesicles is then emptied through the neural membrane adjacent to the dense bars.

Figure 7-1. Different views of the motor end plate. **A**, Longitudinal section through the end plate. **B**, Surface view of the end plate. **C**, Electron micrographic appearance of the contact point between a single axon terminal and the muscle fiber membrane.

Figure 7-2. Release of acetylcholine from synaptic vesicles at the neural membrane of the neuromuscular junction. Note the proximity of the release sites in the neural membrane to the acetylcholine receptors in the muscle membrane at the mouths of the subneural clefts.

Acetylcholine Opens Ion Channels on Postsynaptic Membranes. **Figure 7-2** also shows many small *acetylcholine receptors* and *voltage-gated sodium channels* in the muscle fiber membrane. The *acetylcholine-gated ion channels* are located almost entirely near the mouths of

the subneural clefts lying immediately below the dense bar areas, where the acetylcholine is emptied into the synaptic space. The voltage-gated sodium channels also line the subneural clefts.

Each acetylcholine receptor is a protein complex that has a total molecular weight of approximately 275,000. The fetal acetylcholine receptor complex is composed of five subunit proteins, two *alpha* proteins and one each of *beta*, *delta*, and *gamma* proteins. In the adult, an *epsilon* protein substitutes for the gamma protein in this receptor complex. These protein molecules penetrate all the way through the membrane, lying side by side in a circle to form a tubular channel, illustrated in **Figure 7-3**. The channel remains constricted, as shown in part A of the figure, until two acetylcholine molecules attach respectively to the two *alpha* subunit proteins. This attachment causes a conformational change that opens the channel, as shown in part B of the figure.

The acetylcholine-gated channel has a diameter of about 0.65 nanometer, which is large enough to allow the important positive ions—sodium (Na^+), potassium (K^+), and calcium (Ca^{2+})—to move easily through the opening. Patch clamp studies have shown that one of these channels, when opened by acetylcholine, can transmit 15,000 to 30,000 sodium ions in 1 millisecond. Conversely, negative ions, such as chloride ions, do not pass through because of strong negative charges in the mouth of the channel that repel these negative ions.

Figure 7-3. Acetylcholine-gated channel. **A**, Closed state. **B**, After acetylcholine (Ach) has become attached and a conformational change has opened the channel, allowing sodium ions to enter the muscle fiber and excite contraction. Note the negative charges at the channel mouth that prevent passage of negative ions such as chloride ions.

In practice, far more sodium ions flow through the acetylcholine-gated channels than any other ions for two reasons. First, there are only two positive ions present in large concentrations—sodium ions in the extracellular fluid and potassium ions in the intracellular fluid. Second, the negative potential on the inside of the muscle membrane, -80 to -90 millivolts, pulls the positively charged sodium ions to the inside of the fiber while simultaneously preventing efflux of the positively charged potassium ions when they attempt to pass outward.

As shown in **Figure 7-3B**, the principal effect of opening the acetylcholine-gated channels is to allow sodium ions to flow to the inside of the fiber, carrying positive charges with them. This action creates a local positive potential change inside the muscle fiber membrane, called the *end plate potential*. This end plate potential normally causes sufficient depolarization to open neighboring voltage-gated sodium channels, allowing even greater sodium ion inflow and initiating an action potential that

Figure 7-4. End plate potentials (in millivolts). **A**, Weakened end plate potential recorded in a curarized muscle that is too weak to elicit an action potential. **B**, Normal end plate potential eliciting a muscle action potential. **C**, Weakened end plate potential caused by botulinum toxin that decreases end plate release of acetylcholine, again too weak to elicit a muscle action potential.

spreads along the muscle membrane and causes muscle contraction.

Destruction of the Released Acetylcholine by Acetylcholinesterase. The acetylcholine, once released into the synaptic space, continues to activate acetylcholine receptors as long as the acetylcholine persists in the space. However, it is rapidly destroyed by the enzyme *acetylcholinesterase*, which is attached mainly to the spongy layer of fine connective tissue that fills the synaptic space between the presynaptic nerve terminal and the postsynaptic muscle membrane. A small amount of acetylcholine diffuses out of the synaptic space and is then no longer available to act on the muscle fiber membrane.

The short time that the acetylcholine remains in the synaptic space—a few milliseconds at most—normally is sufficient to excite the muscle fiber. Then the rapid removal of the acetylcholine prevents continued muscle re-excitation after the muscle fiber has recovered from its initial action potential.

End Plate Potential and Excitation of the Skeletal Muscle Fiber. The sudden insurgence of sodium ions into the muscle fiber when the acetylcholine-gated channels open causes the electrical potential inside the fiber at the *local area of the end plate* to increase in the positive direction as much as 50 to 75 millivolts, creating a *local potential* called the *end plate potential*. Recall from **Chapter 5** that a sudden increase in nerve membrane potential of more than 20 to 30 millivolts is normally sufficient to initiate more and more sodium channel opening, thus initiating an action potential at the muscle fiber membrane.

Figure 7-4 illustrates an end plate potential initiating the action potential. This figure shows three separate end plate potentials. End plate potentials A and C are too weak to elicit an action potential, but they do produce weak local end plate voltage changes, as recorded in the figure. By contrast, end plate potential B is much stronger and causes enough sodium channels to open

so that the self-regenerative effect of more and more sodium ions flowing to the interior of the fiber initiates an action potential. The weakness of the end plate potential at point A was caused by poisoning of the muscle fiber with *curare*, a drug that blocks the gating action of acetylcholine on the acetylcholine channels by competing for the acetylcholine receptor sites. The weakness of the end plate potential at point C resulted from the effect of *botulinum toxin*, a bacterial poison that decreases the quantity of acetylcholine release by the nerve terminals.

Safety Factor for Transmission at the Neuromuscular Junction—Fatigue of the Junction. Ordinarily, each impulse that arrives at the neuromuscular junction causes about three times as much end plate potential as that required to stimulate the muscle fiber. Therefore, the normal neuromuscular junction is said to have a high *safety factor*. However, stimulation of the nerve fiber at rates greater than 100 times per second for several minutes may diminish the number of acetylcholine vesicles so much that impulses fail to pass into the muscle fiber. This situation is called *fatigue* of the neuromuscular junction, and it is the same effect that causes fatigue of synapses in the central nervous system when the synapses are overexcited. Under normal functioning conditions, measurable fatigue of the neuromuscular junction occurs rarely and, even then, only at the most exhausting levels of muscle activity.

Acetylcholine Formation and Release

Acetylcholine formation and release at the neuromuscular junction occur in the following stages:

1. Small vesicles, about 40 nanometers in size, are formed by the Golgi apparatus in the cell body of the motoneuron in the spinal cord. These vesicles are then transported by axoplasm that streams through the core of the axon from the central cell body in the spinal cord all the way to the neuromuscular junction at the tips of the peripheral nerve fibers. About 300,000 of these small vesicles collect in the nerve terminals of a single skeletal muscle end plate.
2. Acetylcholine is synthesized in the cytosol of the nerve fiber terminal but is immediately transported through the membranes of the vesicles to their interior, where it is stored in highly concentrated form—about 10,000 molecules of acetylcholine in each vesicle.
3. When an action potential arrives at the nerve terminal, it opens many *calcium channels* in the membrane of the nerve terminal because this terminal has an abundance of voltage-gated calcium channels. As a result, the calcium ion concentration inside the terminal membrane increases about 100-fold, which in turn increases the rate of fusion of the acetylcholine vesicles with the terminal membrane about 10,000-fold. This fusion makes many of the vesicles rupture, allowing *exocytosis* of acetylcholine into the synaptic space. About 125 vesicles usually rupture with each action potential. Then, after a few milliseconds, the acetylcholine is split by acetylcholinesterase into acetate ion and choline, and the choline

is actively reabsorbed into the neural terminal to be re-used to form new acetylcholine. This sequence of events occurs within a period of 5 to 10 milliseconds.

4. The number of vesicles available in the nerve ending is sufficient to allow transmission of only a few thousand nerve to muscle impulses. Therefore, for continued function of the neuromuscular junction, new vesicles need to be re-formed rapidly. Within a few seconds after each action potential is over, coated pits appear in the terminal nerve membrane, caused by contractile proteins in the nerve ending, especially the protein *clathrin*, which is attached to the membrane in the areas of the original vesicles. Within about 20 seconds, the proteins contract and cause the pits to break away to the interior of the membrane, thus forming new vesicles. Within another few seconds, acetylcholine is transported to the interior of these vesicles, and they are then ready for a new cycle of acetylcholine release.

Drugs That Enhance or Block Transmission at the Neuromuscular Junction

Drugs That Stimulate the Muscle Fiber by Acetylcholine-Like Action. Several compounds, including *methacholine*, *carbachol*, and *nicotine*, have nearly the same effect on the muscle fiber as acetylcholine. The main differences between these drugs and acetylcholine are that the drugs are not destroyed by cholinesterase or are destroyed so slowly that their action often persists for many minutes to several hours. The drugs work by causing localized areas of depolarization of the muscle fiber membrane at the motor end plate where the acetylcholine receptors are located. Then, every time the muscle fiber recovers from a previous contraction, these depolarized areas, by virtue of leaking ions, initiate a new action potential, thereby causing a state of muscle spasm.

Drugs That Stimulate the Neuromuscular Junction by Inactivating Acetylcholinesterase. Three particularly well-known drugs—*neostigmine*, *physostigmine*, and *diisopropyl fluorophosphate*—inactivate acetylcholinesterase in the synapses so that it no longer hydrolyzes acetylcholine. Therefore, with each successive nerve impulse, additional acetylcholine accumulates and stimulates the muscle fiber repetitively. This activity causes *muscle spasm* when even a few nerve impulses reach the muscle. Unfortunately, it can also cause death as a result of laryngeal spasm, which smothers a person.

Neostigmine and physostigmine combine with acetylcholinesterase to inactivate the acetylcholinesterase for up to several hours, after which these drugs are displaced from the acetylcholinesterase so that the esterase once again becomes active. Conversely, diisopropyl fluorophosphate, which is a powerful nerve gas poison, inactivates acetylcholinesterase for weeks, which makes this poison particularly lethal.

Drugs That Block Transmission at the Neuromuscular Junction. A group of drugs known as *curariform drugs* can prevent the passage of impulses from the nerve ending into the muscle. For example, D-tubocurarine blocks the action of acetylcholine on the muscle fiber acetylcholine receptors, thus preventing sufficient increase in permeability of the muscle membrane channels to initiate an action potential.

Myasthenia Gravis Causes Muscle Weakness

Myasthenia gravis, which occurs in about 1 in every 20,000 persons, causes muscle weakness because of the inability of the neuromuscular junctions to transmit enough signals from the nerve fibers to the muscle fibers. Antibodies that attack the acetylcholine receptors have been demonstrated in the blood of most patients with myasthenia gravis. Therefore, myasthenia gravis is believed to be an autoimmune disease in which the patients have developed antibodies that block or destroy their own acetylcholine receptors at the postsynaptic neuromuscular junction.

Regardless of the cause, the end plate potentials that occur in the muscle fibers are mostly too weak to initiate opening of the voltage-gated sodium channels, and muscle fiber depolarization does not occur. If the disease is intense enough, the patient may die of respiratory failure as a result of severe weakness of the respiratory muscles. The disease can usually be ameliorated for several hours by administering *neostigmine* or some other anticholinesterase drug, which allows larger than normal amounts of acetylcholine to accumulate in the synaptic space. Within minutes, some of those affected can begin to function almost normally until a new dose of neostigmine is required a few hours later.

MUSCLE ACTION POTENTIAL

Almost everything discussed in Chapter 5 regarding the initiation and conduction of action potentials in nerve fibers applies equally to skeletal muscle fibers, except for quantitative differences. Some of the quantitative aspects of muscle potentials are as follows:

1. The resting membrane potential is about -80 to -90 millivolts in skeletal fibers, about 10 to 20 millivolts more negative than in neurons.
2. The duration of the action potential is 1 to 5 milliseconds in skeletal muscle, about five times as long as in large myelinated nerves.
3. The velocity of conduction is 3 to 5 m/sec, about $1/13$ the velocity of conduction in the large myelinated nerve fibers that excite skeletal muscle.

Action Potentials Spread to the Interior of the Muscle Fiber by Way of Transverse Tubules

The skeletal muscle fiber is so large that action potentials spreading along its surface membrane cause almost no current flow deep within the fiber. Maximum muscle contraction, however, requires the current to penetrate deeply into the muscle fiber to the vicinity of the separate myofibrils. This penetration is achieved by transmission of action potentials along *transverse tubules* (T tubules) that penetrate all the way through the muscle fiber, from one side of the fiber to the other, as illustrated in Figure 7-5. The T tubule action potentials cause release of calcium ions inside the muscle fiber in the immediate vicinity of the myofibrils, and these calcium ions then cause contraction. The overall process is called *excitation-contraction* coupling.

EXCITATION-CONTRACTION COUPLING**Transverse Tubule–Sarcoplasmic Reticulum System**

Figure 7-5 shows myofibrils surrounded by the T tubule–sarcoplasmic reticulum system. The T tubules are small and run transverse to the myofibrils. They begin at the cell membrane and penetrate all the way from one side of the muscle fiber to the opposite side. Not shown in the figure is that these tubules branch among themselves and form entire *planes* of T tubules interlacing among all the separate myofibrils. Also, where the T tubules originate from the cell membrane, they are open to the exterior of the muscle fiber. Therefore, they communicate with the extracellular fluid surrounding the muscle fiber and contain extracellular fluid in their lumens. In other words, the T tubules are actually internal extensions of the cell membrane. Therefore, when an action potential spreads over a muscle fiber membrane, a potential change also spreads along the T tubules to the deep interior of the muscle fiber. The electrical currents surrounding these T tubules then elicit the muscle contraction.

Figure 7-5 also shows a sarcoplasmic reticulum, in yellow. This sarcoplasmic reticulum is composed of two major parts: (1) large chambers called *terminal cisternae* that abut the T tubules; and (2) long longitudinal tubules that surround all surfaces of the contracting myofibrils.

Release of Calcium Ions by the Sarcoplasmic Reticulum

One of the special features of the sarcoplasmic reticulum is that within its vesicular tubules is an excess of calcium ions in high concentration. Many of these ions are released from each vesicle when an action potential occurs in the adjacent T tubule.

Figures 7-6 and 7-7 show that the action potential of the T tubule causes current flow into the sarcoplasmic reticular cisternae where they abut the T tubule. As the action potential reaches the T tubule, the voltage change is sensed by dihydropyridine receptors linked to calcium release channels, also called ryanodine receptor channels, in the adjacent sarcoplasmic reticular cisternae (see Figure 7-6). Activation of dihydropyridine receptors triggers the opening of the calcium release channels in the cisternae, as well as in their attached longitudinal tubules. These channels remain open for a few milliseconds, releasing calcium ions into the sarcoplasm surrounding the myofibrils and causing contraction, as discussed in Chapter 6.

Calcium Pump Removes Calcium Ions from the Myofibrillar Fluid After Contraction Occurs.

Once the calcium ions have been released from the sarcoplasmic tubules and have diffused among the myofibrils, muscle contraction continues as long as the calcium ion concentration remains high. However, a continually active calcium pump located in the walls of the sarcoplasmic reticulum

Figure 7-5. Transverse (T) tubule–sarcoplasmic reticulum system. Note that the T tubules communicate with the outside of the cell membrane and, deep in the muscle fiber, each T tubule lies adjacent to the ends of longitudinal sarcoplasmic reticulum tubules that surround all sides of the actual myofibrils that contract. This illustration was drawn from frog muscle, which has one T tubule per sarcomere, located at the Z disk. A similar arrangement is found in mammalian heart muscle, but mammalian skeletal muscle has two T tubules per sarcomere, located at the A-I band junctions.

pumps calcium ions away from the myofibrils back into the sarcoplasmic tubules (see [Figure 7-6](#)). This pump, called SERCA (sarcoplasmic reticulum Ca^{2+} -ATPase), can concentrate the calcium ions about 10,000-fold inside the tubules. In addition, inside the reticulum is a *calcium-binding protein* called *calsequestrin*, which can bind up to 40 calcium ions for each molecule of calsequestrin.

Excitatory Pulse of Calcium Ions. The normal resting state concentration ($<10^{-7}$ molar) of calcium ions in the cytosol that bathes the myofibrils is too little to elicit contraction. Therefore, the troponin-tropomyosin complex keeps the actin filaments inhibited and maintains a relaxed state of the muscle.

Conversely, full excitation of the T tubule and sarcoplasmic reticulum system causes enough release of calcium ions to increase the concentration in the myofibrillar fluid to as high as 2×10^{-4} molar concentration, a 500-fold increase, which is about 10 times the level required to cause maximum muscle contraction. Immediately thereafter, the calcium pump depletes the calcium

ions again. The total duration of this calcium pulse in the usual skeletal muscle fiber lasts about 1/20 of a second, although it may last several times as long in some fibers and several times less in others. In heart muscle, the calcium pulse lasts about one-third of a second because of the long duration of the cardiac action potential.

During this calcium pulse, muscle contraction occurs. If the contraction is to continue without interruption for long intervals, a series of calcium pulses must be initiated by a continuous series of repetitive action potentials, as discussed in [Chapter 6](#).

Malignant Hyperthermia

In susceptible individuals, *malignant hyperthermia* and a *hypermetabolic crisis* may be triggered by exposure to certain types of anesthetics, including halothane and isoflurane, or succinylcholine. At least six genetic mutations, especially of the ryanodine receptor or dihydropyridine receptor genes, have been shown to increase susceptibility greatly to developing malignant hyperthermia during anesthesia. Little is known about the specific mechanisms

Figure 7-6. Excitation-contraction coupling in skeletal muscle. The *top panel* shows an action potential in the transverse tubule that causes a conformational change in the voltage-sensing dihydropyridine (DHP) receptors, opening the ryanodine (RyR) Ca²⁺ release channels in the terminal cisternae of the sarcoplasmic reticulum and permitting Ca²⁺ to diffuse rapidly into the sarcoplasm and initiate muscle contraction. During repolarization (*bottom panel*), the conformational change in the DHP receptor closes the Ca²⁺ release channels, and Ca²⁺ is transported from the sarcoplasm into the sarcoplasmic reticulum by an adenosine triphosphate-dependent calcium pump, called SERCA (sarcoplasmic reticulum Ca²⁺-ATPase).

Figure 7-7. Excitation-contraction coupling in the muscle, showing (1) an action potential that causes release of calcium ions from the sarcoplasmic reticulum and then (2) re-uptake of the calcium ions by a calcium pump. ATP, Adenosine triphosphate.

whereby anesthetics interact with these abnormal receptors to trigger malignant hyperthermia. It is known, however, that these mutations cause unregulated passage of calcium from the sarcoplasmic reticulum into the intracellular spaces, which in turn causes the muscle fibers to contract excessively. These sustained muscled contractions greatly increase metabolic rate, generating large amounts of heat and causing cellular acidosis, as well as depletion of energy stores.

Symptoms of malignant include muscle rigidity, high fever, and rapid heart rate. Additional complications in severe cases may include rapid breakdown of skeletal muscle (*rhabdomyolysis*) and a high plasma potassium level due to release of large amounts of potassium from damaged muscle cells. Treatment of malignant hyperthermia generally involves rapid cooling and the administration of *dantrolene*, a drug that antagonizes ryanodine receptors, which inhibits calcium ion release for the sarcoplasmic reticulum and thereby attenuating muscle contraction.

Excitation and Contraction of Smooth Muscle

CONTRACTION OF SMOOTH MUSCLE

Smooth muscle is composed of small fibers that are usually 1 to 5 micrometers in diameter and only 20 to 500 micrometers in length. In contrast, skeletal muscle fibers are as much as 30 times greater in diameter and hundreds of times as long. Many of the same principles of contraction apply to smooth muscle as to skeletal muscle. Most important, essentially the same attractive forces between myosin and actin filaments cause contraction in smooth muscle as in skeletal muscle, but the internal physical arrangement of smooth muscle fibers is different.

TYPES OF SMOOTH MUSCLE

The smooth muscle of each organ is distinctive from that of most other organs in several ways: (1) physical dimensions; (2) organization into bundles or sheets; (3) response to different types of stimuli; (4) characteristics of innervation; and (5) function. Yet, for the sake of simplicity, smooth muscle can generally be divided into two major types, which are shown in **Figure 8-1**, *multi-unit smooth muscle* and *unitary* (or *single-unit*) *smooth muscle*.

Multi-Unit Smooth Muscle. Multi-unit smooth muscle is composed of discrete, separate, smooth muscle fibers. Each fiber operates independently of the others and often is innervated by a single nerve ending, as occurs for skeletal muscle fibers. Furthermore, the outer surfaces of these fibers, like those of skeletal muscle fibers, are covered by a thin layer of basement membrane–like substance, a mixture of fine collagen and glycoprotein that helps insulate the separate fibers from one another.

Important characteristics of multi-unit smooth muscle fibers are that each fiber can contract independently of the others, and their control is exerted mainly by nerve signals. In contrast, a major share of control of unitary smooth muscle is exerted by non-nervous stimuli. Some examples of multi-unit smooth muscle are the ciliary muscle of the eye, the iris muscle of the eye, and the piloerector muscles that cause erection of the hairs when stimulated by the sympathetic nervous system.

Unitary Smooth Muscle. Unitary smooth muscle is also called *syncytial smooth muscle* or *visceral smooth muscle*. The term *unitary* does not mean single muscle fibers. Instead, it means a mass of hundreds to thousands of smooth muscle fibers that contract together as a single unit. The fibers usually are arranged in sheets or bundles, and their cell membranes are adherent to one another at multiple points so that force generated in one muscle fiber can be transmitted to the next. In addition, the cell membranes are joined by many *gap junctions* through which ions can flow freely from one muscle cell to the next so that action potentials, or ion flow without action potentials, can travel from one fiber to the next and cause the muscle fibers to contract together. This type of smooth muscle is also known as *syncytial smooth muscle* because of its syncytial interconnections among fibers. It is also called *visceral smooth muscle* because it is found in the walls of most viscera of the body, including the gastrointestinal tract, bile ducts, ureters, uterus, and many blood vessels.

CONTRACTILE MECHANISM IN SMOOTH MUSCLE

Chemical Basis for Smooth Muscle Contraction

Smooth muscle contains both *actin* and *myosin filaments*, having chemical characteristics similar to those of the actin and myosin filaments in skeletal muscle. It does not contain the troponin complex that is required for the control of skeletal muscle contraction, and thus the mechanism for controlling contraction is different. This topic is discussed in more detail later in this chapter.

Chemical studies have shown that actin and myosin filaments derived from smooth muscle interact with each other in much the same way that they do in skeletal muscle. Furthermore, the contractile process is activated by calcium ions, and adenosine triphosphate (ATP) is degraded to adenosine diphosphate (ADP) to provide the energy for contraction.

There are, however, major differences between the physical organization of smooth muscle and that of

skeletal muscle, as well as differences in excitation-contraction coupling, control of the contractile process by calcium ions, duration of contraction, and the amount of energy required for contraction.

Physical Basis for Smooth Muscle Contraction

Smooth muscle does not have the same striated arrangement of actin and myosin filaments as is found in skeletal muscle. Instead, electron micrographic techniques suggest the physical organization shown in **Figure 8-2**, which illustrates large numbers of actin filaments attached to *dense bodies*. Some of these bodies are attached to the cell membrane, and others are dispersed inside the cell. Some of the membrane-dense bodies of adjacent cells are bonded together by intercellular protein bridges. It is mainly through these bonds that the force of contraction is transmitted from one cell to the next.

Interspersed among the actin filaments in the muscle fiber are myosin filaments. These filaments have a diameter more than twice that of the actin filaments. In electron micrographs, 5 to 10 times as many actin filaments as myosin filaments are usually found.

To the right in **Figure 8-2** is a postulated structure of an individual contractile unit in a smooth muscle cell, showing large numbers of actin filaments radiating from two dense bodies; the ends of these filaments overlap a myosin filament located midway between the dense bodies. This contractile unit is similar to the contractile unit of skeletal muscle, but without the regularity of the skeletal muscle structure. In fact, the dense bodies of smooth muscle serve the same role as the Z disks in skeletal muscle.

Another difference is that most of the myosin filaments have “side polar” cross-bridges arranged so that the bridges on one side hinge in one direction, and those on the other side hinge in the opposite direction. This configuration allows the myosin to pull an actin filament in one direction

Figure 8-2 Physical structure of smooth muscle. The fiber on the upper left shows actin filaments radiating from dense bodies. The fiber on the lower left and at right demonstrate the relation of myosin filaments to actin filaments.

on one side while simultaneously pulling another actin filament in the opposite direction on the other side. The value of this organization is that it allows smooth muscle cells to contract as much as 80% of their length instead of being limited to less than 30%, as occurs in skeletal muscle.

Comparison of Smooth Muscle Contraction and Skeletal Muscle Contraction

Although most skeletal muscles contract and relax rapidly, most smooth muscle contraction is prolonged tonic contraction, sometimes lasting hours or even days. Therefore, it is to be expected that both the physical and chemical characteristics of smooth muscle versus skeletal muscle contraction would differ. Some of the differences are noted in the following sections.

Slow Cycling of the Myosin Cross-Bridges. The rapidity of cycling of the myosin cross-bridges in smooth muscle—that is, their attachment to actin, then release from the actin, and reattachment for the next cycle—is much slower than in skeletal muscle. The frequency is as little as 1/10 to 1/300 that in skeletal muscle. Yet, the *fraction of time* that the cross-bridges remain attached to the actin filaments, which is a major factor that determines the force of contraction, is believed to be greatly increased in smooth muscle. A possible reason for the slow cycling is that the cross-bridge heads have far less ATPase activity than in skeletal muscle; thus, degradation of the ATP that energizes the movements of the cross-bridge heads is greatly reduced, with corresponding slowing of the rate of cycling.

Low Energy Requirement to Sustain Smooth Muscle Contraction. Only 1/10 to 1/300 as much energy is required to sustain the same tension of contraction in smooth muscle as in skeletal muscle. This, too, is believed to result from the slow attachment and detachment cycling of the cross-bridges, and because only one molecule of ATP is required for each cycle, regardless of its duration.

This low energy utilization by smooth muscle is important to the overall energy economy of the body because organs such as the intestines, urinary bladder, gallbladder, and other viscera often maintain tonic muscle contraction almost indefinitely.

Slowness of Onset of Contraction and Relaxation of the Total Smooth Muscle Tissue. A typical smooth muscle tissue begins to contract 50 to 100 milliseconds after it is excited, reaches full contraction about 0.5 second later, and then declines in contractile force in another 1 to 2 seconds, giving a total contraction time of 1 to 3 seconds. This is about 30 times as long as a single contraction of an average skeletal muscle fiber. However, because there are so many types of smooth muscle, contraction of some types can be as short as 0.2 second or as long as 30 seconds.

The slow onset of contraction of smooth muscle, as well as its prolonged contraction, is caused by the slowness of attachment and detachment of the cross-bridges with the actin filaments. In addition, the initiation of contraction in response to calcium ions is much slower than in skeletal muscle, as will be discussed later.

Maximum Force of Contraction Is Often Greater in Smooth Muscle Than in Skeletal Muscle. Despite the relatively few myosin filaments in smooth muscle, and despite the slow cycling time of the cross-bridges, the maximum force of contraction of smooth muscle is often greater than that of skeletal muscle, as much as 4 to 6 kg/cm² cross-sectional area for smooth muscle in comparison with 3 to 4 kilograms for skeletal muscle. This great force of smooth muscle contraction results from the pro-

longed period of attachment of the myosin cross-bridges to the actin filaments.

Latch Mechanism Facilitates Prolonged Holding of Contractions of Smooth Muscle. Once smooth muscle has developed full contraction, the amount of continuing excitation can usually be reduced to far less than the initial level, even though the muscle maintains its full force of contraction. Furthermore, the energy consumed to maintain contraction is often minuscule, sometimes as little as 1/300 of the energy required for comparable sustained skeletal muscle contraction. This mechanism is called the *latch mechanism*.

The importance of the latch mechanism is that it can maintain prolonged tonic contraction in smooth muscle for hours, with little use of energy. Little continued excitatory signal is required from nerve fibers or hormonal sources.

Stress-Relaxation of Smooth Muscle. Another important characteristic of smooth muscle, especially the visceral unitary type of smooth muscle of many hollow organs, is its ability to return to nearly its original *force* of contraction seconds or minutes after it has been elongated or shortened. For example, a sudden increase in fluid volume in the urinary bladder, thus stretching the smooth muscle in the bladder wall, causes an immediate large increase in pressure in the bladder. However, during about the next 15 to 60 seconds, despite continued stretch of the bladder wall, the pressure returns almost exactly back to the original level. Then, when the volume is increased by another step, the same effect occurs again.

Conversely, when the volume is suddenly decreased, the pressure falls drastically at first but then rises in another few seconds or minutes to or near the original level. These phenomena are called *stress-relaxation* and *reverse stress-relaxation*. Their importance is that except for short periods, they allow a hollow organ to maintain about the same amount of pressure inside its lumen despite sustained large changes in volume.

REGULATION OF CONTRACTION BY CALCIUM IONS

As is true for skeletal muscle, the initiating stimulus for most smooth muscle contraction is an increase in intracellular calcium ions. This increase can be caused in different types of smooth muscle by nerve stimulation of the smooth muscle fiber, hormonal stimulation, stretch of the fiber, or even changes in the chemical environment of the fiber.

Smooth muscle does not contain troponin, the regulatory protein that is activated by calcium ions to cause skeletal muscle contraction. Instead, smooth muscle contraction is activated by an entirely different mechanism, as described in the next section.

Figure 8-3 Intracellular calcium ion (Ca^{2+}) concentration increases when Ca^{2+} enters the cell through calcium channels in the cell membrane or is released from the sarcoplasmic reticulum. The Ca^{2+} binds to calmodulin (CaM) to form a Ca^{2+} -CaM complex, which then activates myosin light chain kinase (MLCK). The active MLCK phosphorylates the myosin light chain, leading to attachment of the myosin head with the actin filament and contraction of the smooth muscle. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; P, phosphate.

Calcium Ions Combine with Calmodulin to Cause Activation of Myosin Kinase and Phosphorylation of the Myosin Head. In place of troponin, smooth muscle cells contain a large amount of another regulatory protein called *calmodulin* (Figure 8-3). Although this protein is similar to troponin, it is different in the manner in which it initiates contraction. Calmodulin initiates contraction by activating the myosin cross-bridges. This activation and subsequent contraction occur in the following sequence:

1. The calcium concentration in the cytosolic fluid of the smooth muscle increases as a result of the influx of calcium from the extracellular fluid through calcium channels and/or release of calcium from the sarcoplasmic reticulum.
2. The calcium ions bind reversibly with calmodulin.
3. The calmodulin-calcium complex then joins with and activates *myosin light chain kinase*, a phosphorylating enzyme.
4. One of the light chains of each myosin head, called the *regulatory chain*, becomes phosphorylated in response to this myosin kinase. When this chain is not phosphorylated, the attachment-detachment

Figure 8-4 Sarcoplasmic tubules in a large smooth muscle fiber showing their relation to invaginations in the cell membrane called *caveolae*.

cycling of the myosin head with the actin filament does not occur. However, when the regulatory chain is phosphorylated, the head has the capability of binding repetitively with the actin filament and proceeding through the entire cycling process of intermittent pulls, the same as what occurs for skeletal muscle, thus causing muscle contraction.

Source of Calcium Ions That Cause Contraction

Although the contractile process in smooth muscle, as in skeletal muscle, is activated by calcium ions, the source of the calcium ions differs. An important difference is that the sarcoplasmic reticulum, which provides virtually all the calcium ions for skeletal muscle contraction, is only slightly developed in most smooth muscle. Instead, most of the calcium ions that cause contraction enter the muscle cell from the extracellular fluid at the time of the action potential or other stimulus. That is, the concentration of calcium ions in the extracellular fluid is greater than 10^{-3} molar, in comparison with less than 10^{-7} molar inside the smooth muscle cell; this causes rapid diffusion of the calcium ions into the cell from the extracellular fluid when the calcium channels open. The time required for this diffusion to occur averages 200 to 300 milliseconds and is called the *latent period* before contraction begins. This latent period is about 50 times as great for smooth muscle as for skeletal muscle contraction.

Role of the Smooth Muscle Sarcoplasmic Reticulum.

Figure 8-4 shows a few slightly developed sarcoplasmic tubules that lie near the cell membrane in some larger smooth muscle cells. Small invaginations of the cell membrane, called *caveolae*, abut the surfaces of these tubules. The caveolae suggest a rudimentary analog of the trans-

verse tubule system of skeletal muscle. When an action potential is transmitted into the caveolae, this is believed to excite calcium ion release from the abutting sarcoplasmic tubules in the same way that action potentials in skeletal muscle transverse tubules cause release of calcium ions from the skeletal muscle longitudinal sarcoplasmic tubules. In general, the more extensive the sarcoplasmic reticulum in the smooth muscle fiber, the more rapidly it contracts.

Smooth Muscle Contraction Is Dependent on Extracellular Calcium Ion Concentration. Whereas changing the extracellular fluid calcium ion concentration from normal has little effect on the force of contraction of skeletal muscle, this is not true for most smooth muscle. When the extracellular fluid calcium ion concentration decreases to about 1/3 to 1/10 normal, smooth muscle contraction usually ceases. Therefore, the force of contraction of smooth muscle is usually highly dependent on the extracellular fluid calcium ion concentration.

A Calcium Pump Is Required to Cause Smooth Muscle Relaxation. To cause relaxation of smooth muscle after it has contracted, the calcium ions must be removed from the intracellular fluids. This removal is achieved by a *calcium pump* that pumps calcium ions out of the smooth muscle fiber back into the extracellular fluid, or into a sarcoplasmic reticulum, if it is present (Figure 8-5). This pump requires ATP and is slow acting in comparison with the fast-acting sarcoplasmic reticulum pump in skeletal muscle. Therefore, a single smooth muscle contraction often lasts for seconds rather than hundredths to tenths of a second, as occurs for skeletal muscle.

Myosin Phosphatase Is Important in Cessation of Contraction. Relaxation of the smooth muscle occurs when the calcium channels close and the calcium pump transports calcium ions out of the cytosolic fluid of the cell. When the calcium ion concentration falls below a critical level, the aforementioned processes automatically reverse, except for the phosphorylation of the myosin head. Reversal of this situation requires another enzyme, *myosin phosphatase* (see Figure 8-5), located in the cytosol of the smooth muscle cell, which splits the phosphate from the regulatory light chain. Then the cycling stops, and contraction ceases. The time required for the relaxation of muscle contraction, therefore, is determined to a great extent by the amount of active myosin phosphatase in the cell.

Possible Mechanism for Regulating the Latch Phenomenon. Because of the importance of the latch phenomenon in smooth muscle, and because this phenomenon allows for the long-term maintenance of tone in many smooth muscle organs without much expenditure of energy, many attempts have been made to explain it. Among the many mechanisms that have been postulated, one of the simplest is the following.

Figure 8-5 Relaxation of smooth muscle occurs when the calcium ion (Ca^{2+}) concentration decreases below a critical level as Ca^{2+} is pumped out of the cell or into the sarcoplasmic reticulum. Ca^{2+} is then released from calmodulin (CaM), and myosin phosphatase removes phosphate from the myosin light chain, causing detachment of the myosin head from the actin filament and relaxation of the smooth muscle. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Na^+ , sodium; P, phosphate.

When the myosin kinase and myosin phosphatase enzymes are both strongly activated, the cycling frequency of the myosin heads and the velocity of contraction are great. Then, as activation of the enzymes decreases, the cycling frequency decreases but, at the same time, the deactivation of these enzymes allows the myosin heads to remain attached to the actin filament for a longer and longer proportion of the cycling period. Therefore, the number of heads attached to the actin filament at any given time remains large. Because the number of heads attached to the actin determines the static force of contraction, tension is maintained, or latched, yet little energy is used by the muscle because ATP is not degraded to ADP, except on the rare occasion when a head detaches.

NERVOUS AND HORMONAL CONTROL OF SMOOTH MUSCLE CONTRACTION

Although skeletal muscle fibers are stimulated exclusively by the nervous system, smooth muscle can be stimulated to contract by nervous signals, hormonal stimulation, stretch of the muscle, and several other ways. The principal reason for the difference is that the smooth muscle

Figure 8-6 Innervation of smooth muscle by autonomic nerve fibers that branch diffusely and secrete neurotransmitter from multiple varicosities. Unitary (visceral) smooth muscle cells are connected by gap junctions so that depolarization can rapidly spread from one cell to another, permitting the muscle cells to contract as a single unit. In multi-unit smooth muscle, each cell is stimulated independently by a neurotransmitter released from closely associated autonomic nerve varicosities.

membrane contains many types of receptor proteins that can initiate the contractile process. Still other receptor proteins inhibit smooth muscle contraction, which is another difference from skeletal muscle. Therefore, in this section, we discuss nervous control of smooth muscle contraction, followed by hormonal control and other means of control.

NEUROMUSCULAR JUNCTIONS OF SMOOTH MUSCLE

Physiologic Anatomy of Smooth Muscle Neuromuscular Junctions. Neuromuscular junctions of the highly structured type found on skeletal muscle fibers do not occur in smooth muscle. Instead, the *autonomic nerve fibers* that innervate smooth muscle generally branch diffusely on top of a sheet of muscle fibers, as shown in [Figure 8-6](#). In most cases, these fibers do not make direct contact with the smooth muscle fiber cell membranes but instead form *diffuse junctions* that secrete their transmitter substance into the matrix coating of the smooth muscle, often a few nanometers to a few micrometers away from the muscle cells. The transmitter substance then diffuses to the cells. Furthermore, where there are many layers of muscle cells, the nerve fibers often innervate only the outer layer. Muscle excitation travels from this outer layer to the inner layers by action potential conduction in the muscle mass or by additional diffusion of the transmitter substance.

The axons that innervate smooth muscle fibers do not have the typical branching end feet of the type found in the motor end plate on skeletal muscle fibers. Instead,

most of the fine terminal axons have multiple *varicosities* distributed along their axes. At these points, the *Schwann cells* that envelop the axons are interrupted so that transmitter substance can be secreted through the walls of the varicosities. In the varicosities are vesicles similar to those in the skeletal muscle end plate that contain transmitter substance. However, in contrast to the vesicles of skeletal muscle junctions, which always contain acetylcholine, the vesicles of the autonomic nerve fiber endings contain acetylcholine in some fibers and norepinephrine in others and occasionally other substances as well.

In a few cases, particularly in the multi-unit type of smooth muscle, the varicosities are separated from the muscle cell membrane by as little as 20 to 30 nanometers—the same width as the synaptic cleft that is found in the skeletal muscle junction. These are called *contact junctions*, and they function in much the same way as the skeletal muscle neuromuscular junction. The rapidity of contraction of these smooth muscle fibers is considerably faster than that of fibers stimulated by the diffuse junctions.

Excitatory and Inhibitory Transmitter Substances Secreted at the Smooth Muscle Neuromuscular Junction. The most important transmitter substances secreted by the autonomic nerves innervating smooth muscle are *acetylcholine* and *norepinephrine*, but they are never secreted by the same nerve fibers. Acetylcholine is an excitatory transmitter substance for smooth muscle fibers in some organs but an inhibitory transmitter for smooth muscle in other organs. When acetylcholine excites a muscle fiber, norepinephrine ordinarily inhibits it. Conversely, when acetylcholine inhibits a fiber, norepinephrine usually excites it.

Why are these responses different? The answer is that both acetylcholine and norepinephrine excite or inhibit smooth muscle by first binding with a *receptor protein* on the surface of the muscle cell membrane. Some of the receptor proteins are *excitatory receptors*, whereas others are *inhibitory receptors*. Thus, the type of receptor determines whether the smooth muscle is inhibited or excited and also determines which of the two transmitters, acetylcholine or norepinephrine, is effective in causing the excitation or inhibition. These receptors are discussed in more detail in [Chapter 61](#) in regard to function of the autonomic nervous system.

MEMBRANE POTENTIALS AND ACTION POTENTIALS IN SMOOTH MUSCLE

Membrane Potentials in Smooth Muscle. The quantitative voltage of the membrane potential of smooth muscle depends on the momentary condition of the muscle. In the normal resting state, the intracellular potential is usually about -50 to -60 millivolts, which is about 30 millivolts less negative than in skeletal muscle.

Figure 8-7 **A**, Typical smooth muscle action potential (spike potential) elicited by an external stimulus. **B**, Repetitive spike potentials, elicited by slow rhythmic electrical waves that occur spontaneously in the smooth muscle of the intestinal wall. **C**, Action potential with a plateau, recorded from a smooth muscle fiber of the uterus.

Action Potentials in Unitary Smooth Muscle. Action potentials occur in unitary smooth muscle (e.g., visceral muscle) in the same way that they occur in skeletal muscle. They do not normally occur in most multi-unit types of smooth muscle, as discussed in a subsequent section.

The action potentials of visceral smooth muscle occur in one of two forms—(1) spike potentials or (2) action potentials with plateaus.

Spike Potentials. Typical spike action potentials, such as those seen in skeletal muscle, occur in most types of unitary smooth muscle. The duration of this type of action potential is 10 to 50 milliseconds, as shown in [Figure 8-7A](#). Such action potentials can be elicited in many ways—for example, by electrical stimulation, by the action of hormones on the smooth muscle, by the action of transmitter substances from nerve fibers, by stretch, or as a result of spontaneous generation in the muscle fiber itself, as discussed subsequently.

Action Potentials with Plateaus. [Figure 8-7C](#) shows a smooth muscle action potential with a plateau. The onset of this action potential is similar to that of the typical spike potential. However, instead of rapid repolarization of the muscle fiber membrane, the repolarization is delayed for several hundred to as much as 1000 milliseconds (1 second). The importance of the plateau is that it can account for the prolonged contraction that occurs in some types of smooth muscle, such as the ureter, the uterus under

some conditions, and certain types of vascular smooth muscle. Also, this is the type of action potential seen in cardiac muscle fibers that have a prolonged period of contraction, as discussed in Chapters 9 and 10.

Calcium Channels Are Important in Generating the Smooth Muscle Action Potential. The smooth muscle cell membrane has far more voltage-gated calcium channels than skeletal muscle but few voltage-gated sodium channels. Therefore, sodium does not participate much in the generation of the action potential in most smooth muscle. Instead, the flow of calcium ions to the interior of the fiber is mainly responsible for the action potential. This flow occurs in the same self-regenerative way as occurs for the sodium channels in nerve fibers and in skeletal muscle fibers. However, the calcium channels open many times more slowly than sodium channels, and they also remain open much longer. These characteristics largely account for the prolonged plateau action potentials of some smooth muscle fibers.

Another important feature of calcium ion entry into the cells during the action potential is that the calcium ions act directly on the smooth muscle contractile mechanism to cause contraction. Thus, the calcium performs two tasks at once.

Slow Wave Potentials in Unitary Smooth Muscle Can Lead to Spontaneous Generation of Action Potentials. Some smooth muscle is self-excitatory—that is, action potentials arise within the smooth muscle cells without an extrinsic stimulus. This activity is often associated with a basic *slow wave rhythm* of the membrane potential. A typical slow wave in a visceral smooth muscle of the gut is shown in [Figure 8-7B](#). The slow wave is not the action potential. That is, it is not a self-regenerative process that spreads progressively over the membranes of the muscle fibers. Instead, it is a local property of the smooth muscle fibers that make up the muscle mass.

The cause of the slow wave rhythm is unknown. One suggestion is that the slow waves are caused by waxing and waning of the pumping of positive ions (presumably sodium ions) outward through the muscle fiber membrane. That is, the membrane potential becomes more negative when sodium is pumped rapidly and less negative when the sodium pump becomes less active. Another suggestion is that the conductances of the ion channels increase and decrease rhythmically.

The importance of the slow waves is that when they are strong enough, they can initiate action potentials. The slow waves themselves cannot cause muscle contraction. However, when the peak of the negative slow wave potential inside the cell membrane rises in the positive direction, from -60 to about -35 millivolts (the approximate threshold for eliciting action potentials in most visceral smooth muscle), an action potential develops and spreads over the muscle mass and contraction occurs. [Figure 8-7B](#) demonstrates this effect, showing that at

each peak of the slow wave, one or more action potentials occur. These repetitive sequences of action potentials elicit rhythmical contraction of the smooth muscle mass. Therefore, the slow waves are called *pacemaker waves*. In [Chapter 63](#), we see that this type of pacemaker activity controls the rhythmical contractions of the gut.

Excitation of Visceral Smooth Muscle by Muscle Stretch. When visceral (unitary) smooth muscle is stretched sufficiently, spontaneous action potentials are usually generated. They result from a combination of the following: (1) the normal slow wave potentials; and (2) a decrease in overall negativity of the membrane potential caused by the stretch. This response to stretch allows the gut wall, when excessively stretched, to contract automatically and rhythmically. For example, when the gut is overfilled by intestinal contents, local automatic contractions often set up peristaltic waves that move the contents away from the overfilled intestine, usually in the direction of the anus.

DEPOLARIZATION OF MULTI-UNIT SMOOTH MUSCLE WITHOUT ACTION POTENTIALS

The smooth muscle fibers of multi-unit smooth muscle (e.g., the muscle of the iris of the eye or the piloerector muscle of each hair) normally contract mainly in response to nerve stimuli. The nerve endings secrete acetylcholine in the case of some multi-unit smooth muscles and norepinephrine in the case of others. In both cases, the transmitter substances cause depolarization of the smooth muscle membrane, and this depolarization in turn elicits contraction. Action potentials usually do not develop because the fibers are too small to generate an action potential. (When action potentials are elicited in *visceral unitary smooth muscle*, 30 to 40 smooth muscle fibers must depolarize simultaneously before a self-propagating action potential ensues.) However, in small smooth muscle cells, even without an action potential, the local depolarization (called the *junctional potential*) caused by the nerve transmitter substance spreads “electrotonically” over the entire fiber and is all that is necessary to cause muscle contraction.

Local Tissue Factors and Hormones Can Cause Smooth Muscle Contraction Without Action Potentials

Approximately half of all smooth muscle contraction is likely initiated by stimulatory factors acting directly on the smooth muscle contractile machinery and without action potentials. Two types of non-nervous and nonaction potential stimulating factors often involved are (1) local tissue chemical factors and (2) various hormones.

Smooth Muscle Contraction in Response to Local Tissue Chemical Factors. In [Chapter 17](#), we discuss control of contraction of the arterioles, meta-arterioles, and precapillary sphincters. The smallest of these vessels have lit-

tle or no nervous supply. Yet, the smooth muscle is highly contractile, responding rapidly to changes in local chemical conditions in the surrounding interstitial fluid and to stretch caused by changes in blood pressure.

In the normal resting state, many of these small blood vessels remain contracted. However, when extra blood flow to the tissue is necessary, multiple factors can relax the vessel wall, thus allowing for increased flow. In this way, a powerful local feedback control system controls the blood flow to the local tissue area. Some of the specific control factors are as follows:

1. Lack of oxygen in the local tissues causes smooth muscle relaxation and, therefore, vasodilation.
2. Excess carbon dioxide causes vasodilation.
3. Increased hydrogen ion concentration causes vasodilation.

Adenosine, lactic acid, increased potassium ions, nitric oxide, and increased body temperature can all cause local vasodilation. Decreased blood pressure, by causing decreased stretch of the vascular smooth muscle, also causes these small blood vessels to dilate.

Effects of Hormones on Smooth Muscle Contraction.

Many circulating hormones in the blood affect smooth muscle contraction to some degree, and some have profound effects. Among the more important of these hormones are *norepinephrine*, *epinephrine*, *angiotensin II*, *endothelin*, *vasopressin*, *oxytocin*, *serotonin*, and *histamine*.

A hormone causes contraction of a smooth muscle when the muscle cell membrane contains *hormone-gated excitatory receptors* for the respective hormone. Conversely, the hormone causes inhibition if the membrane contains *inhibitory receptors* for the hormone rather than excitatory receptors.

Mechanisms of Smooth Muscle Excitation or Inhibition by Hormones or Local Tissue Factors. Some hormone receptors in the smooth muscle membrane open sodium or calcium ion channels and depolarize the membrane, the same as after nerve stimulation. Sometimes, action potentials result, or action potentials that are already occurring may be enhanced. In other cases, depolarization occurs without action potentials, and this depolarization allows for calcium ion entry into the cell, which promotes the contraction.

Inhibition, in contrast, occurs when the hormone (or other tissue factor) *closes the sodium and calcium channels* to prevent entry of these positive ions; inhibition also occurs if the normally closed potassium channels are opened, allowing positive potassium ions to diffuse out of the cell. Both these actions increase the degree of negativity inside the muscle cell, a state called *hyperpolarization*, which strongly inhibits muscle contraction.

Sometimes, smooth muscle contraction or inhibition is initiated by hormones without directly causing any change in the membrane potential. In these cases, the hormone may activate a membrane receptor that does not open

any ion channels but, instead, causes an internal change in the muscle fiber, such as release of calcium ions from the intracellular sarcoplasmic reticulum; the calcium then induces contraction. To inhibit contraction, other receptor mechanisms are known to activate the enzyme adenylyl cyclase or guanylyl cyclase in the cell membrane. The portions of the receptors that protrude to the interior of the cells are coupled to these enzymes, causing the formation of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP), so-called second messengers. cAMP or cGMP has many effects, one of which is to change the degree of phosphorylation of several enzymes that indirectly inhibit contraction. The pump that moves calcium ions from the sarcoplasm into the sarcoplasmic reticulum is activated, as well as the cell membrane pump that moves calcium ions out of the cell; these effects reduce the calcium ion concentration in the sarcoplasm, thereby inhibiting contraction.

Smooth muscles have considerable diversity in how they initiate contraction or relaxation in response to different hormones, neurotransmitters, and other substances. In some cases, the same substance may cause either relaxation or contraction of smooth muscles in different locations. For example, norepinephrine inhibits contraction of smooth muscle in the intestine but stimulates contraction of smooth muscle in blood vessels.

Cardiac Muscle; The Heart as a Pump and Function of the Heart Valves

The heart, shown in **Figure 9-1**, is actually two separate pumps, a *right heart* that pumps blood through the lungs and a *left heart* that pumps blood through the systemic circulation that provides blood flow to the other organs and tissues of the body. Each of these is a pulsatile, two-chamber pump composed of an *atrium* and a *ventricle*. Each atrium is a weak primer pump for the ventricle, helping to move blood into the ventricle. The ventricles then supply the main pumping force that propels the blood either (1) through the pulmonary circulation by the right ventricle or (2) through the systemic circulation by the left ventricle. The heart is surrounded by a two-layer sac called the *pericardium*, which protects the heart and holds it in place.

Special mechanisms in the heart cause a continuing succession of contractions called *cardiac rhythmicity*, transmitting action potentials throughout the cardiac muscle to cause the heart's rhythmical beat. This rhythmical control system is discussed in **Chapter 10**. In this chapter, we explain how the heart operates as a pump, beginning with the special features of cardiac muscle (Video 9-1).

PHYSIOLOGY OF CARDIAC MUSCLE

The heart is composed of three major types of cardiac muscle—*atrial muscle*, *ventricular muscle*, and specialized *excitatory* and *conductive muscle* fibers. The atrial and ventricular types of muscle contract in much the same way as skeletal muscle, except that the duration of contraction is much longer. The specialized excitatory and conductive fibers of the heart, however, contract feebly because they contain few contractile fibrils; instead, they exhibit automatic rhythmical electrical discharge in the form of action potentials or conduction of the action potentials through the heart, providing an excitatory system that controls the rhythmical beating of the heart.

CARDIAC MUSCLE ANATOMY

Figure 9-2 shows the cardiac muscle histology, demonstrating cardiac muscle fibers arranged in a latticework, with the fibers dividing, recombining, and then spreading

again. Note that cardiac muscle is *striated* in the same manner as in skeletal muscle. Furthermore, cardiac muscle has typical myofibrils that contain *actin* and *myosin filaments* almost identical to those found in skeletal muscle; these filaments lie side by side and slide during contraction in the same manner as occurs in skeletal muscle (see **Chapter 6**). In other ways, however, cardiac muscle is quite different from skeletal muscle, as we shall see.

Left Ventricular Rotation (Twist) Aids Left Ventricular Ejection and Relaxation. The left ventricle is organized into complex muscle fiber layers that run in different directions and allow the heart to contract in a twisting motion during systole. The subepicardial (outer) layer spirals in a leftward direction, and the subendocardial (inner) layer spirals in the opposite direction (rightward), causing clockwise rotation of the apex of the heart and counterclockwise rotation of the base of the left ventricle (**Figure 9-3**). This causes a wringing motion of the left ventricle, pulling the base downward toward the apex during systole (contraction). At the end of systole, the left ventricle is similar to a loaded spring and recoils or untwists during diastole (relaxation) to allow blood to enter the pumping chambers rapidly.

Cardiac Muscle Is a Syncytium. The dark areas crossing the cardiac muscle fibers in **Figure 9-2** are called *intercalated discs*; they are actually cell membranes that separate individual cardiac muscle cells from one another. That is, cardiac muscle fibers are made up of many individual cells connected in series and in parallel with one another.

At each intercalated disc, the cell membranes fuse with one another to form permeable communicating junctions (gap junctions) that allow rapid diffusion of ions. Therefore, from a functional point of view, ions move with ease in the intracellular fluid along the longitudinal axes of the cardiac muscle fibers so that action potentials travel easily from one cardiac muscle cell to the next, past the intercalated discs. Thus, cardiac muscle is a *syncytium* of many heart muscle cells in which the cardiac cells are so interconnected that when one cell becomes excited, the action potential rapidly spreads to all of them.

The heart actually is composed of two syncytia; the *atrial syncytium*, which constitutes the walls of the two

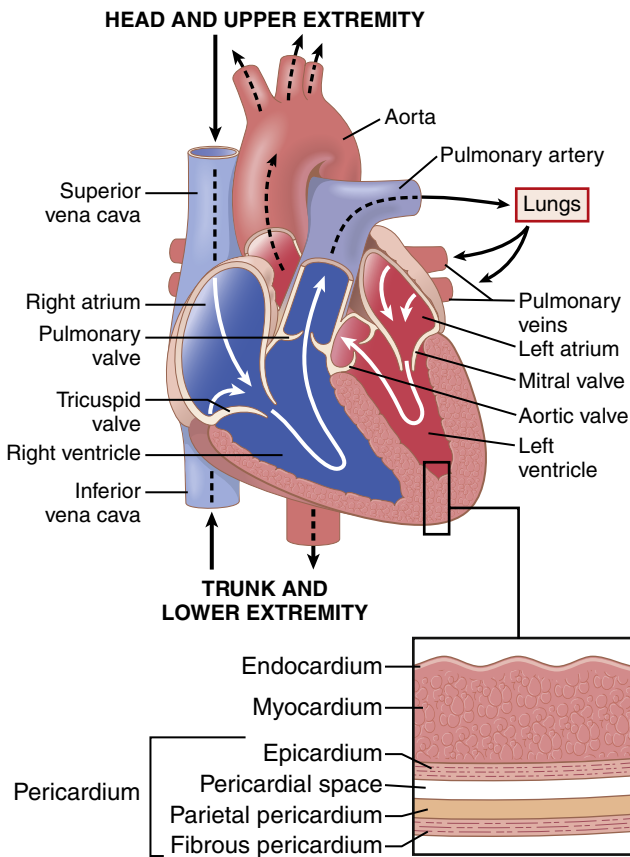

Figure 9-1. Structure of the heart and course of blood flow through the heart chambers and heart valves. The heart consists of multiple layers, including the inner endocardium, myocardium, and more outward epicardium and pericardium layers.

Figure 9-2. Syncytial interconnecting nature of cardiac muscle fibers.

atria; and the *ventricular syncytium*, which constitutes the walls of the two ventricles. The atria are separated from the ventricles by fibrous tissue that surrounds the atrioventricular (A-V) valvular openings between the atria and ventricles. Normally, potentials are not conducted from the atrial syncytium into the ventricular syncytium directly through this fibrous tissue. Instead, they are only conducted by way of a specialized conductive system called the *A-V bundle*, a bundle of conductive

Figure 9-3. **A**, The left ventricular inner subendocardial fibers (lavender shade) run obliquely to the outer subepicardial fibers (red shade). **B**, The subepicardial muscle fibers are wrapped in a left-handed helix and subendocardial fibers are arranged in a right-handed helix.

Figure 9-4. Rhythmic action potentials (in millivolts) from a Purkinje fiber and from a ventricular muscle fiber, recorded by microelectrodes.

fibers several millimeters in diameter that is discussed in [Chapter 10](#).

This division of the muscle of the heart into two functional syncytia allows the atria to contract a short time ahead of ventricular contraction, which is important for the effectiveness of heart pumping.

ACTION POTENTIALS IN CARDIAC MUSCLE

The *action potential* recorded in a ventricular muscle fiber, shown in [Figure 9-4](#), averages about 105 millivolts, which means that the intracellular potential rises from a very negative value between beats, about -85 millivolts, to a slightly positive value, about $+20$ millivolts, during each beat. After the initial *spike*, the membrane remains depolarized for about 0.2 second, exhibiting a *plateau*, followed at the end of the plateau by abrupt repolarization.

The presence of this plateau in the action potential causes ventricular contraction to last as much as 15 times longer in cardiac muscle than in skeletal muscle.

What Causes the Long Action Potential and Plateau in Cardiac Muscle? At least two major differences between the membrane properties of cardiac and skeletal muscle account for the prolonged action potential and the plateau in cardiac muscle. First, the *action potential of skeletal muscle* is caused almost entirely by the sudden opening of large numbers of *fast sodium channels* that allow tremendous numbers of sodium ions to enter the skeletal muscle fiber from the extracellular fluid. These channels are called *fast channels* because they remain open for only a few thousandths of a second and then abruptly close. At the end of this closure, repolarization occurs, and the action potential is over within about another thousandth of a second.

In cardiac muscle, the action potential is caused by opening of two types of channels: (1) the same *voltage-activated fast sodium channels* as those in skeletal muscle; and (2) another entirely different population of *L-type calcium channels* (*slow calcium channels*), which are also called *calcium-sodium channels*. This second population of channels differs from the fast sodium channels in that they are slower to open and, even more importantly, remain open for several tenths of a second. During this time, a large quantity of both calcium and sodium ions flows through these channels to the interior of the cardiac muscle fiber, and this activity maintains a prolonged period of depolarization, *causing the plateau* in the action potential. Furthermore, the calcium ions that enter during this plateau phase activate the muscle contractile process, whereas the calcium ions that cause skeletal muscle contraction are derived from the intracellular sarcoplasmic reticulum.

The second major functional difference between cardiac muscle and skeletal muscle that helps account for both the prolonged action potential and its plateau is that immediately after the onset of the action potential, the permeability of the cardiac muscle membrane for potassium ions *decreases* about fivefold, an effect that does not occur in skeletal muscle. This decreased potassium permeability may result from the excess calcium influx through the calcium channels just noted. Regardless of the cause, the decreased potassium permeability greatly decreases the efflux of positively charged potassium ions during the action potential plateau and thereby prevents early return of the action potential voltage to its resting level. When the slow calcium-sodium channels do close at the end of 0.2 to 0.3 second, and the influx of calcium and sodium ions ceases, the membrane permeability for potassium ions also increases rapidly. This rapid loss of potassium from the fiber immediately returns the membrane potential to its resting level, thus ending the action potential.

Phases of Cardiac Muscle Action Potential. Figure 9-5 summarizes the phases of the action potential in cardiac muscle and the ion flows that occur during each phase.

Figure 9-5. Phases of action potential of cardiac ventricular muscle cell and associated ionic currents for sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+).

Phase 0 (Depolarization): Fast Sodium Channels Open. When the cardiac cell is stimulated and depolarizes, the membrane potential becomes more positive. Voltage-gated sodium channels (fast sodium channels) open and permit sodium to rapidly flow into the cell and depolarize it. The membrane potential reaches about +20 millivolts before the sodium channels close.

Phase 1 (Initial Repolarization): Fast Sodium Channels Close. The sodium channels close, the cell begins to repolarize, and potassium ions leave the cell through open potassium channels.

Phase 2 (Plateau): Calcium Channels Open and Fast Potassium Channels Close. A brief initial repolarization occurs and the action potential then plateaus as a result of increased calcium ion permeability and decreased potassium ion permeability. The voltage-gated calcium ion channels open slowly during phases 1 and 0, and calcium enters the cell. Potassium channels then close, and the combination of decreased potassium ion efflux and increased calcium ion influx causes the action potential to plateau.

Phase 3 (Rapid Repolarization): Calcium Channels Close and Slow Potassium Channels Open. The closure of calcium ion channels and increased potassium ion permeability, permitting potassium ions to exit the cell rapidly, ends the plateau and returns the cell membrane potential to its resting level.

Figure 9-6. Force of ventricular heart muscle contraction, showing also the duration of the refractory period and relative refractory period, plus the effect of premature contraction. Note that premature contractions do not cause wave summation, as occurs in skeletal muscle.

Phase 4 (Resting Membrane Potential): This averages about -80 to -90 millivolts.

Velocity of Signal Conduction in Cardiac Muscle. The velocity of conduction of the excitatory action potential signal along both *atrial and ventricular muscle fibers* is about 0.3 to 0.5 m/sec, or about $1/250$ the velocity in very large nerve fibers and about $1/10$ the velocity in skeletal muscle fibers. The velocity of conduction in the specialized heart conductive system—in the *Purkinje fibers*—is as high as 4 m/sec in most parts of the system, allowing rapid conduction of the excitatory signal to the different parts of the heart, as explained in [Chapter 10](#).

Refractory Period of Cardiac Muscle. Cardiac muscle, like all excitable tissue, is refractory to restimulation during the action potential. Therefore, the refractory period of the heart is the interval of time, as shown to the left in [Figure 9-6](#), during which a normal cardiac impulse cannot re-excite an already excited area of cardiac muscle. The normal refractory period of the ventricle is 0.25 to 0.30 second, which is about the duration of the prolonged plateau action potential. There is an additional *relative refractory period* of about 0.05 second during which the muscle is more difficult to excite than normal but can be excited by a very strong excitatory signal, as demonstrated by the early premature contraction in the second example of [Figure 9-6](#). The refractory period of atrial muscle is much shorter than that for the ventricles (about 0.15 second for the atria compared with 0.25 to 0.30 second for the ventricles).

EXCITATION-CONTRACTION COUPLING— FUNCTION OF CALCIUM IONS AND THE TRANSVERSE TUBULES

The term *excitation-contraction coupling* refers to the mechanism whereby the action potential causes the myofibrils of muscle to contract. This mechanism was

discussed for skeletal muscle in [Chapter 7](#). Again, there are differences in this mechanism in cardiac muscle that have important effects on the characteristics of heart muscle contraction.

As is true for skeletal muscle, when an action potential passes over the cardiac muscle membrane, the action potential spreads to the interior of the cardiac muscle fiber along the membranes of the *transverse (T) tubules*. The T tubule action potentials then act on the membranes of the *longitudinal sarcoplasmic tubules* to cause release of calcium ions into the muscle sarcoplasm from the sarcoplasmic reticulum. In another few thousandths of a second, these calcium ions diffuse into the myofibrils and catalyze the chemical reactions that promote sliding of the actin and myosin filaments along one another, which produces the muscle contraction.

Thus far, this mechanism of excitation-contraction coupling is the same as that for skeletal muscle, but there is a second effect that is quite different. In addition to the calcium ions that are released into the sarcoplasm from the cisternae of the sarcoplasmic reticulum, calcium ions also diffuse into the sarcoplasm from the T tubules at the time of the action potential, which opens voltage-dependent calcium channels in the membrane of the T tubule ([Figure 9-7](#)). Calcium entering the cell then activates *calcium release channels*, also called *ryanodine receptor channels*, in the sarcoplasmic reticulum membrane, triggering the release of calcium into the sarcoplasm. Calcium ions in the sarcoplasm then interact with troponin to initiate cross-bridge formation and contraction by the same basic mechanism as that described for skeletal muscle in [Chapter 6](#).

Without the calcium from the T tubules, the strength of cardiac muscle contraction would be reduced considerably because the sarcoplasmic reticulum of cardiac muscle is less well developed than that of skeletal muscle and does not store enough calcium to provide full contraction. The T tubules of cardiac muscle, however, have a diameter five times as great as that of the skeletal muscle tubules, which means a volume 25 times as great. Also, inside the T tubules is a large quantity of mucopolysaccharides that are electronegatively charged and bind an abundant store of calcium ions, keeping them available for diffusion to the interior of the cardiac muscle fiber when a T tubule action potential appears.

The strength of contraction of cardiac muscle depends to a great extent on the concentration of calcium ions in the extracellular fluids. In fact, a heart placed in a calcium-free solution will quickly stop beating. The reason for this response is that the openings of the T tubules pass directly through the cardiac muscle cell membrane into the extracellular spaces surrounding the cells, allowing the same extracellular fluid that is in the cardiac muscle interstitium to percolate through the T tubules. Consequently, the quantity of calcium ions in the T tubule system (i.e., the availability of calcium ions to cause cardiac muscle

Figure 9-7. Mechanisms of excitation-contraction coupling and relaxation in cardiac muscle. ATP, Adenosine triphosphate. RyR, ryanodine receptor Ca²⁺ release channel; SERCA, sarcoplasmic reticulum Ca²⁺-ATPase

contraction) depends to a great extent on the extracellular fluid calcium ion concentration.

In contrast, the strength of skeletal muscle contraction is hardly affected by moderate changes in extracellular fluid calcium concentration. This is because skeletal muscle contraction is caused almost entirely by calcium ions released from the sarcoplasmic reticulum *inside* the skeletal muscle fiber.

At the end of the plateau of the cardiac action potential, the influx of calcium ions to the interior of the muscle fiber is suddenly cut off, and calcium ions in the sarcoplasm are rapidly pumped back out of the muscle fibers into the sarcoplasmic reticulum and T tubule–extracellular fluid space. Transport of calcium back into the sarcoplasmic reticulum is achieved with the help of a calcium–adenosine triphosphatase (ATPase) pump (the sarcoplasmic endoplasmic reticulum calcium ATPase, SERCA2; see [Figure 9-7](#)). Calcium ions are also removed from the cell by a sodium–calcium exchanger. The sodium that enters the cell during this exchange is then transported out of the cell by the sodium–potassium ATPase pump. As a result, the contraction ceases until a new action potential comes along.

Duration of Contraction. Cardiac muscle begins to contract a few milliseconds after the action potential begins

and continues to contract until a few milliseconds after the action potential ends. Therefore, the duration of contraction of cardiac muscle is mainly a function of the duration of the action potential, *including the plateau*—about 0.2 second in atrial muscle and 0.3 second in ventricular muscle.

CARDIAC CYCLE

The cardiac events that occur from the beginning of one heartbeat to the beginning of the next are called the *cardiac cycle*. Each cycle is initiated by the spontaneous generation of an action potential in the *sinus node*, as explained in [Chapter 10](#). This node is located in the superior lateral wall of the right atrium near the opening of the superior vena cava, and the action potential travels from here rapidly through both atria and then through the A-V bundle into the ventricles. Because of this special arrangement of the conducting system from the atria into the ventricles, there is a delay of more than 0.1 second during passage of the cardiac impulse from the atria into the ventricles. This delay allows the atria to contract ahead of ventricular contraction, thereby pumping blood into the ventricles before the strong ventricular contraction begins. Thus, the atria act as *primer pumps* for the ventricles, and the ventricles in turn

Figure 9-8. Events of the cardiac cycle for left ventricular function, showing changes in left atrial pressure, left ventricular pressure, aortic pressure, ventricular volume, the electrocardiogram, and the phonocardiogram. A-V, Atrioventricular.

provide the major source of power for moving blood through the body's vascular system.

Diastole and Systole

The total *duration of the cardiac cycle*, including systole and diastole, is the reciprocal of the heart rate. For example, if the heart rate is 72 beats/min, the duration of the cardiac cycle is $1/72$ min/beat—about 0.0139 min/beat, or 0.833 sec/beat.

Figure 9-8 shows the different events during the cardiac cycle for the left side of the heart. The top three curves show the pressure changes in the aorta, left ventricle, and left atrium, respectively. The fourth curve depicts the changes in left ventricular volume, the fifth depicts the *electrocardiogram*, and the sixth depicts a *phonocardiogram*, which is a recording of the sounds produced by the heart—mainly by the heart valves—as it pumps. It is especially important that the reader study this figure in detail and understand the causes of all the events shown.

Increasing Heart Rate Decreases Duration of Cardiac Cycle. When heart rate increases, the duration of each cardiac cycle decreases, including the contraction and relaxation phases. The duration of the action potential and systole also decrease, but not by as great a percentage as diastole. At a normal heart rate of 72 beats/min, systole comprises about 0.4 of the entire cardiac cycle. At three times the normal heart rate, systole is about 0.65 of the entire cardiac cycle. This means that the heart beating very rapidly does not remain relaxed long enough to allow complete filling of the cardiac chambers before the next contraction.

Relationship of the Electrocardiogram to the Cardiac Cycle

The electrocardiogram in **Figure 9-8** shows the *P*, *Q*, *R*, *S*, and *T* waves, discussed in **Chapters 11** and **12**. These are electrical voltages generated by the heart and recorded by the electrocardiogram from the surface of the body.

The *P* wave is caused by the *spread of depolarization* through the atria and is followed by atrial contraction, which causes a slight rise in the atrial pressure curve immediately after the electrocardiographic *P* wave.

About 0.16 second after the onset of the *P* wave, the *QRS* waves appear as a result of electrical depolarization of the ventricles, which initiates contraction of the ventricles and causes the ventricular pressure to begin rising. Therefore, the *QRS* complex begins slightly before the onset of ventricular systole.

Finally, the *ventricular T* wave represents the stage of repolarization of the ventricles when the ventricular muscle fibers begin to relax. Therefore, the *T* wave occurs slightly before the end of ventricular contraction.

The Atria Function as Primer Pumps for the Ventricles

Blood normally flows continually from the great veins into the atria; about 80% of the blood flows directly through the atria into the ventricles, even before the atria contract. Then, atrial contraction usually causes an additional 20% filling of the ventricles. Therefore, the atria function as primer pumps that increase the ventricular pumping effectiveness as much as 20%. However, the heart can continue to operate under most conditions even without this extra 20% effectiveness because

it normally has the capability of pumping 300% to 400% more blood than is required by the resting body. Therefore, when the atria fail to function, the difference is unlikely to be noticed unless a person exercises; then, symptoms of heart failure occasionally develop, especially shortness of breath.

Pressure Changes in the Atria—a, c, and v Waves. In the atrial pressure curve of **Figure 9-8**, three minor pressure elevations, called *a*, *c*, and *v* atrial pressure waves, are shown.

The *a* wave is caused by atrial contraction. Ordinarily, the *right* atrial pressure increases 4 to 6 mm Hg during atrial contraction, and the *left* atrial pressure increases about 7 to 8 mm Hg.

The *c* wave occurs when the ventricles begin to contract; it is caused partly by slight backflow of blood into the atria at the onset of ventricular contraction, but mainly by bulging of the A-V valves backward toward the atria because of increasing pressure in the ventricles.

The *v* wave occurs toward the end of ventricular contraction; it results from slow flow of blood into the atria from the veins while the A-V valves are closed during ventricular contraction. Then, when ventricular contraction is over, the A-V valves open, allowing this stored atrial blood to flow rapidly into the ventricles, causing the *v* wave to disappear.

FUNCTION OF THE VENTRICLES AS PUMPS

The Ventricles Fill with Blood During Diastole.

During ventricular systole, large amounts of blood accumulate in the right and left atria because of the closed A-V valves. Therefore, as soon as systole is over, and the ventricular pressures fall again to their low diastolic values, the moderately increased pressures that have developed in the atria during ventricular systole immediately push the A-V valves open and allow blood to flow rapidly into the ventricles, as shown by the rise of the left *ventricular volume curve* in **Figure 9-8**. This period is called the *period of rapid filling of the ventricles*.

In a healthy heart, the period of rapid filling lasts for about the first third of diastole. During the middle third of diastole, only a small amount of blood normally flows into the ventricles. This is blood that continues to empty into the atria from the veins and passes through the atria directly into the ventricles. During the last third of diastole, the atria contract and give an additional thrust to the inflow of blood into the ventricles. This mechanism accounts for about 20% of the filling of the ventricles during each heart cycle.

The ventricles stiffen with aging or diseases that cause cardiac fibrosis such as high blood pressure or diabetes mellitus. This causes less blood to fill the ventricles in the early portion of diastole and requires more volume (preload; discussed later) or more filling from the later atrial contraction to maintain adequate cardiac output.

Outflow of Blood from the Ventricles During Systole

Period of Isovolumic (Isometric) Contraction. Immediately after ventricular contraction begins, the ventricular pressure rises abruptly, as shown in **Figure 9-8**, causing the A-V valves to close. Then, an additional 0.02 to 0.03 second is required for the ventricle to build up sufficient pressure to push the semilunar (aortic and pulmonary) valves open against the pressures in the aorta and pulmonary artery. Therefore, during this period, contraction is occurring in the ventricles, but no emptying occurs. This period is called the period of *isovolumic* or *isometric contraction*, meaning that cardiac muscle tension is increasing but little or no shortening of the muscle fibers is occurring.

Period of Ejection. When the left ventricular pressure rises slightly above 80 mm Hg (and the right ventricular pressure rises slightly above 8 mm Hg), the ventricular pressures push the semilunar valves open. Immediately, blood is ejected out of the ventricles into the aorta and pulmonary artery. Approximately 60% of the blood in the ventricles at the end of diastole is ejected during systole; about 70% of this portion flows out during the first third of the ejection period, with the remaining 30% emptying during the next two thirds. Therefore, the first third is called the *period of rapid ejection*, and the last two thirds is called the *period of slow ejection*.

Period of Isovolumic (Isometric) Relaxation. At the end of systole, ventricular relaxation begins suddenly, allowing both the right and left *intraventricular pressures* to decrease rapidly. The elevated pressures in the distended large arteries that have just been filled with blood from the contracted ventricles immediately push blood back toward the ventricles, which snaps the aortic and pulmonary valves closed. For another 0.03 to 0.06 second, the ventricular muscle continues to relax, even though the ventricular volume does not change, giving rise to the period of *isovolumic* or *isometric relaxation*. During this period, the intraventricular pressures rapidly decrease back to their low diastolic levels. Then, the A-V valves open to begin a new cycle of ventricular pumping.

End-Diastolic Volume, End-Systolic Volume, and Stroke Volume Output.

During diastole, normal filling of the ventricles increases the volume of each ventricle to about 110 to 120 ml. This volume is called the *end-diastolic volume*. Then, as the ventricles empty during systole, the volume decreases by about 70 ml, which is called the *stroke volume output*. The remaining volume in each ventricle, about 40 to 50 ml, is called the *end-systolic volume*. The fraction of the end-diastolic volume that is ejected is called the *ejection fraction*, usually equal to about 0.6 (or 60%). The ejection fraction percentage is often used clinically to assess cardiac systolic (pumping) capability.

Figure 9-9. Mitral and aortic valves (the left ventricular valves).

When the heart contracts strongly, the end-systolic volume may decrease to as little as 10 to 20 ml. Conversely, when large amounts of blood flow into the ventricles during diastole, the ventricular end-diastolic volumes can become as much as 150 to 180 ml in the healthy heart. By both increasing the end-diastolic volume and decreasing the end-systolic volume, the stroke volume output can be increased to more than double that which is normal.

THE HEART VALVES PREVENT BACKFLOW OF BLOOD DURING SYSTOLE

Atrioventricular Valves. The *A-V valves* (i.e., the *tricuspid* and *mitral valves*) prevent backflow of blood from the ventricles to the atria during systole, and the *semilunar valves* (i.e., the *aortic* and *pulmonary artery valves*) prevent backflow from the aorta and pulmonary arteries into the ventricles during diastole. These valves, shown in [Figure 9-9](#) for the left ventricle, close and open *passively*. That is, they close when a backward pressure gradient pushes blood backward, and they open when a forward pressure gradient forces blood in the forward direction. For anatomical reasons, the thin A-V valves require almost no backflow to cause closure, whereas the much heavier semilunar valves require rather rapid backflow for a few milliseconds.

Function of the Papillary Muscles. [Figure 9-9](#) also shows papillary muscles that attach to the vanes of the A-V valves by the *chordae tendineae*. The papillary muscles contract when the ventricular walls contract but, contrary to what might be expected, they *do not* help the valves to close. Instead, they pull the vanes of the valves inward toward the ventricles to prevent their bulging too far backward toward the atria during ventricular contraction. If a chorda tendina becomes ruptured, or if one of the papillary muscles becomes paralyzed due to low blood

flow from a myocardial infarction, the valve bulges far backward during ventricular contraction, sometimes so far that it leaks severely and results in severe or even lethal cardiac incapacity.

Aortic and Pulmonary Artery Valves. The aortic and pulmonary artery semilunar valves function quite differently from the A-V valves. First, the high pressures in the arteries at the end of systole cause the semilunar valves to snap closed, in contrast to the much softer closure of the A-V valves. Second, because of smaller openings, the velocity of blood ejection through the aortic and pulmonary valves is much greater than that through the much larger A-V valves. Also, because of the rapid closure and rapid ejection, the edges of the aortic and pulmonary valves are subjected to much greater mechanical abrasion than the A-V valves. Finally, the A-V valves are supported by the chordae tendineae, which is not true for the semilunar valves. It is obvious from the anatomy of the aortic and pulmonary valves (as shown for the aortic valve at the bottom of [Figure 9-9](#)) that they must be constructed with an especially strong, yet very pliable, fibrous tissue to withstand the extra physical stresses.

AORTIC PRESSURE CURVE

When the left ventricle contracts, the ventricular pressure increases rapidly until the aortic valve opens. Then, after the valve opens, the pressure in the ventricle rises much less rapidly, as shown in [Figure 9-7](#), because blood immediately flows out of the ventricle into the aorta and then into the systemic distribution arteries.

The entry of blood into the arteries during systole causes the walls of these arteries to stretch and the pressure to increase to about 120 mm Hg. Next, at the end of systole, after the left ventricle stops ejecting blood and the aortic valve closes, the elastic walls of the arteries maintain a high pressure in the arteries, even during diastole.

An *incisura* occurs in the aortic pressure curve when the aortic valve closes. This is caused by a short period of backward flow of blood immediately before closure of the valve, followed by the sudden cessation of backflow.

After the aortic valve closes, pressure in the aorta decreases slowly throughout diastole because the blood stored in the distended elastic arteries flows continually through the peripheral vessels back to the veins. Before the ventricle contracts again, the aortic pressure usually has fallen to about 80 mm Hg (diastolic pressure), which is two thirds the maximal pressure of 120 mm Hg (systolic pressure) that occurs in the aorta during ventricular contraction.

The pressure curves in the *right ventricle* and *pulmonary artery* are similar to those in the aorta, except that the pressures are only about one-sixth as great, as discussed in [Chapter 14](#).

Relationship of the Heart Sounds to Heart Pumping

When listening to the heart with a stethoscope, one does not hear the opening of the valves because this is a relatively slow process that normally makes no noise. However, when the valves close, the vanes of the valves and the surrounding fluids vibrate under the influence of sudden pressure changes, giving off sound that travels in all directions through the chest.

When the ventricles contract, one first hears a sound caused by closure of the A-V valves. The vibration pitch is low and relatively long-lasting and is known as the *first heart sound (S1)*. When the aortic and pulmonary valves close at the end of systole, one hears a rapid snap because these valves close rapidly, and the surroundings vibrate for a short period. This sound is called the *second heart sound (S2)*. The precise causes of the heart sounds are discussed more fully in [Chapter 23](#) in relation to listening to the sounds with the stethoscope.

Work Output of the Heart

The *stroke work output* of the heart is the amount of energy that the heart converts to work during each heartbeat while pumping blood into the arteries. Work output of the heart is in two forms. First, the major proportion is used to move the blood from the low-pressure veins to the high-pressure arteries. This is called *volume-pressure work* or *external work*. Second, a minor proportion of the energy is used to accelerate the blood to its velocity of ejection through the aortic and pulmonary valves, which is the *kinetic energy of blood flow* component of the work output.

Right ventricular external work output is normally about one-sixth the work output of the left ventricle because of the sixfold difference in systolic pressures pumped by the two ventricles. The additional work output of each ventricle required to create kinetic energy of blood flow is proportional to the mass of blood ejected times the square of velocity of ejection.

Ordinarily, the work output of the left ventricle required to create kinetic energy of blood flow is only about 1% of the total work output of the ventricle and therefore is ignored in the calculation of the total stroke work output. In certain abnormal conditions, however, such as aortic stenosis, in which blood flows with great velocity through the stenosed valve, more than 50% of the total work output may be required to create kinetic energy of blood flow.

GRAPHIC ANALYSIS OF VENTRICULAR PUMPING

Figure 9-10 shows a diagram that is especially useful in explaining the pumping mechanics of the *left* ventricle. The most important components of the diagram are the two curves labeled “diastolic pressure” and “systolic pressure.” These curves are volume-pressure curves.

The diastolic pressure curve is determined by filling the heart with progressively greater volumes of blood and then measuring the diastolic pressure immediately before ventricular contraction occurs, which is the *end-diastolic pressure* of the ventricle.

The systolic pressure curve is determined by recording the systolic pressure achieved during ventricular contraction at each volume of filling.

Figure 9-10. Relationship between left ventricular volume and intraventricular pressure during diastole and systole. Also shown by the red lines is the “volume-pressure diagram,” demonstrating changes in intraventricular volume and pressure during the normal cardiac cycle. EW, Net external work; PE, potential energy.

Until the volume of the noncontracting ventricle rises above about 150 ml, the diastolic pressure does not increase much. Therefore, up to this volume, blood can flow easily into the ventricle from the atrium. Above 150 ml, the ventricular diastolic pressure increases rapidly, partly because of fibrous tissue in the heart that will stretch no more, and partly because the pericardium that surrounds the heart becomes filled nearly to its limit.

During ventricular contraction, the systolic pressure increases, even at low ventricular volumes, and reaches a maximum at a ventricular volume of 150 to 170 ml. Then, as the volume increases further, the systolic pressure actually decreases under some conditions, as demonstrated by the falling systolic pressure curve in **Figure 9-10**. This occurs because at these great volumes, the actin and myosin filaments of the cardiac muscle fibers are pulled apart far enough that the strength of each cardiac fiber contraction becomes less than optimal.

Note especially in the figure that the maximum systolic pressure for the normal *left* ventricle is between 250 and 300 mm Hg, but this varies widely with each person’s heart strength and degree of heart stimulation by cardiac nerves. For the normal *right* ventricle, the maximum systolic pressure is between 60 and 80 mm Hg.

Volume-Pressure Diagram During the Cardiac Cycle; Cardiac Work Output. The red lines in **Figure 9-10** form a loop called the *volume-pressure diagram* of the cardiac cycle for normal function of the *left* ventricle. A more detailed version of this loop is shown in **Figure 9-11**. It is divided into four phases.

Phase I: Period of Filling. Phase I in the volume-pressure diagram begins at a ventricular volume of about 50 ml and a diastolic pressure of 2 to 3 mm Hg. The amount of blood that remains in the ventricle after the previous heartbeat, 50 ml, is called the *end-systolic volume*. As venous blood flows into the ventricle from the

Figure 9-11. The volume-pressure diagram demonstrating changes in intraventricular volume and pressure during a single cardiac cycle (red line). The shaded area represents the net external work (EW) output by the left ventricle during the cardiac cycle.

left atrium, the ventricular volume normally increases to about 120 ml, called the *end-diastolic volume*, an increase of 70 ml. Therefore, the volume-pressure diagram during phase I extends along the line in [Figure 9-10](#) labeled “I” and from point A to point B in [Figure 9-11](#), with the volume increasing to 120 ml and the diastolic pressure rising to about 5 to 7 mm Hg.

Phase II: Period of Isovolumic Contraction. During isovolumic contraction, the volume of the ventricle does not change because all valves are closed. However, the pressure inside the ventricle increases to equal the pressure in the aorta, at a pressure value of about 80 mm Hg, as depicted by point C (see [Figure 9-11](#)).

Phase III: Period of Ejection. During ejection, the systolic pressure rises even higher because of still more contraction of the ventricle. At the same time, the volume of the ventricle decreases because the aortic valve has now opened, and blood flows out of the ventricle into the aorta. Therefore, in [Figure 9-10](#), the curve labeled “III,” or “period of ejection,” traces the changes in volume and systolic pressure during this period of ejection.

Phase IV: Period of Isovolumic Relaxation. At the end of the period of ejection (point D, [Figure 9-11](#)), the aortic valve closes, and the ventricular pressure falls back to the diastolic pressure level. The line labeled “IV” ([Figure 9-10](#)) traces this decrease in intraventricular pressure without any change in volume. Thus, the ventricle returns to its starting point, with about 50 ml of blood left in the ventricle at an atrial pressure of 2 to 3 mm Hg.

The area subtended by this functional volume-pressure diagram (the shaded area, labeled “EW”) represents the *net external work output* of the ventricle during its contraction cycle. In experimental studies of cardiac

contraction, this diagram is used for calculating cardiac work output.

When the heart pumps large quantities of blood, the area of the work diagram becomes much larger. That is, it extends far to the right because the ventricle fills with more blood during diastole, it rises much higher because the ventricle contracts with greater pressure, and it usually extends farther to the left because the ventricle contracts to a smaller volume—especially if the ventricle is stimulated to increased activity by the sympathetic nervous system.

Concepts of Preload and Afterload. In assessing the contractile properties of muscle, it is important to specify the degree of tension on the muscle when it begins to contract, called the *preload*, and to specify the load against which the muscle exerts its contractile force, called the *afterload*.

For cardiac contraction, the *preload* is usually considered to be the end-diastolic pressure when the ventricle has become filled. The *afterload* of the ventricle is the pressure in the aorta leading from the ventricle. In [Figure 9-10](#), this corresponds to the systolic pressure described by the phase III curve of the volume-pressure diagram. (Sometimes the afterload is loosely considered to be the resistance in the circulation rather than the pressure.)

The importance of the concepts of preload and afterload is that in many abnormal functional states of the heart or circulation, the pressure during filling of the ventricle (the preload), the arterial pressure against which the ventricle must contract (the afterload), or both are altered from normal to a severe degree.

Chemical Energy Required for Cardiac Contraction: Oxygen Utilization by the Heart

Heart muscle, like skeletal muscle, uses chemical energy to provide the work of contraction. Approximately 70% to 90% of this energy is normally derived from oxidative metabolism of fatty acids, with about 10% to 30% coming from other nutrients, especially glucose and lactate. Therefore, the rate of oxygen consumption by the heart is an excellent measure of the chemical energy liberated while the heart performs its work. The different chemical reactions that liberate this energy are discussed in Chapters 68 and 69.

Experimental studies have shown that oxygen consumption of the heart and the chemical energy expended during contraction are directly related to the total shaded area in **Figure 9-10**. This shaded portion consists of the *external work* (EW), as explained earlier, and an additional portion called the *potential energy*, labeled “PE.” The potential energy represents additional work that could be accomplished by contraction of the ventricle if the ventricle could completely empty all the blood in its chamber with each contraction.

Oxygen consumption has also been shown to be nearly proportional to the *tension* that occurs in the heart muscle during contraction multiplied by the *duration of time* that the contraction persists; this is called the *tension-time index*. According to the law of Laplace, ventricular wall tension (T) is related to the left ventricular pressure (P) and the radius (r): $T = P \times r$.

Because tension is high when systolic pressure (and therefore left ventricular pressure) is high, correspondingly more oxygen is used. When systolic pressure is chronically elevated, wall stress and cardiac workload are also increased, inducing thickening of the left ventricular walls, which can reduce the ventricular chamber radius (concentric hypertrophy) and at least partially relieve the increased wall tension. Also, much more chemical energy is expended, even at normal systolic pressures, when the ventricle is abnormally dilated (eccentric hypertrophy) because the heart muscle tension during contraction is proportional to pressure times the radius of the ventricle. This becomes especially important in heart failure when the heart ventricle is dilated and, paradoxically, the amount of chemical energy required for a given amount of work output is greater than normal, even though the heart is already failing.

Cardiac Efficiency. During heart muscle contraction, most of the expended chemical energy is converted into *heat*, and a much smaller portion is converted into *work output*. *Cardiac efficiency* is the ratio of work output to total chemical energy used to perform the work. Maximum efficiency of the normal heart is between 20% and 25%. In persons with heart failure, this efficiency can decrease to as low as 5%.

REGULATION OF HEART PUMPING

When a person is at rest, the heart pumps only 4 to 6 liters of blood each minute. During strenuous exercise, the heart may pump four to seven times this amount. The basic mechanisms for regulating heart pumping are as follows: (1) intrinsic cardiac pumping regulation in response to changes in volume of blood flowing into the heart; and

(2) control of heart rate and heart strength by the autonomic nervous system.

INTRINSIC REGULATION OF HEART PUMPING—THE FRANK-STARLING MECHANISM

In **Chapter 20**, we will learn that under most conditions, the amount of blood pumped by the heart each minute is normally determined almost entirely by the rate of blood flow into the heart from the veins, which is called *venous return*. That is, each peripheral tissue of the body controls its own local blood flow, and all the local tissue flows combine and return by way of the veins to the right atrium. The heart, in turn, automatically pumps this incoming blood into the arteries so that it can flow around the circuit again.

This intrinsic ability of the heart to adapt to increasing volumes of inflowing blood is called the *Frank-Starling mechanism of the heart*, named in honor of Otto Frank and Ernest Starling, two great physiologists. Basically, the Frank-Starling mechanism means that the more the heart muscle is stretched during filling, the greater is the force of contraction, and the greater is the quantity of blood pumped into the aorta. Or, stated another way—*within physiological limits, the heart pumps all the blood that returns to it by way of the veins*.

What Is the Explanation of the Frank-Starling Mechanism? When an extra amount of blood flows into the ventricles, the cardiac muscle is stretched to a greater length. This stretching causes the muscle to contract with increased force because the actin and myosin filaments are brought to a more nearly optimal degree of overlap for force generation. Therefore, the ventricle, because of its increased pumping, automatically pumps the extra blood into the arteries. This ability of stretched muscle, up to an optimal length, to contract with increased work output is characteristic of all striated muscle, as explained in **Chapter 6**, and is not simply a characteristic of cardiac muscle.

In addition to the important effect of lengthening the heart muscle, another factor increases heart pumping when its volume is increased. Stretch of the right atrial wall directly increases the heart rate by 10% to 20%, which also helps increase the amount of blood pumped each minute, although its contribution is much less than that of the Frank-Starling mechanism. As discussed in **Chapter 18**, stretch of the atrium also activates stretch receptors and a nervous reflex, the *Bainbridge reflex*, that is transmitted by the vagus nerve and may increase heart rate an additional 40% to 60%.

Ventricular Function Curves

One of the best ways to express the functional ability of the ventricles to pump blood is by *ventricular function curves*. **Figure 9-12** shows a type of ventricular function

Figure 9-12. Left and right ventricular function curves recorded from dogs, depicting *ventricular stroke work output* as a function of left and right mean atrial pressures. (Data from Sarnoff SJ: *Myocardial contractility as described by ventricular function curves*. *Physiol Rev* 35:107, 1955.)

Figure 9-13. Approximate normal right and left *ventricular volume output* curves for the normal resting human heart as extrapolated from data obtained in dogs and data from humans.

curve called the *stroke work output curve*. Note that as atrial pressure for each side of the heart increases, stroke work output for that side increases until it reaches the limit of the ventricle's pumping ability.

Figure 9-13 shows another type of ventricular function curve called the *ventricular volume output curve*. The two curves of this figure represent function of the two ventricles of the human heart based on data extrapolated from experimental animal studies. As the right and left atrial pressures increase, the respective ventricular volume outputs per minute also increase.

Thus, *ventricular function curves* are another way of expressing the Frank-Starling mechanism of the heart. That is, as the ventricles fill in response to higher atrial pressures, each ventricular volume and strength of cardiac muscle contraction increase, causing the heart to pump increased quantities of blood into the arteries.

Control of the Heart by the Sympathetic and Parasympathetic Nerves

The pumping effectiveness of the heart also is controlled by the *sympathetic* and *parasympathetic* (*vagus*) nerves, which abundantly supply the heart, as shown in **Figure 9-14**. For given levels of atrial pressure, the amount of blood pumped each minute (*cardiac output*) often can be

Figure 9-14. Cardiac *sympathetic* and *parasympathetic* nerves. (The vagus nerves to the heart are parasympathetic nerves.) A-V, Atrioventricular; S-A, sinoatrial.

increased more than 100% by sympathetic stimulation. By contrast, the output can be decreased to almost zero by vagal (parasympathetic) stimulation.

Mechanisms of Excitation of the Heart by the Sympathetic Nerves. Strong sympathetic stimulation can increase the heart rate in young adult humans from the normal rate of 70 beats/min up to 180 to 200 beats/min and, rarely, even 250 beats/min. Also, sympathetic stimulation may double the force of heart contraction, thereby increasing the volume of blood pumped and increasing the ejection pressure. Thus, sympathetic stimulation often can increase the maximum cardiac output as much as twofold to threefold, in addition to the increased output caused by the Frank-Starling mechanism already discussed.

Conversely, *inhibition* of the sympathetic nerves to the heart can decrease cardiac pumping to a moderate extent. Under normal conditions, the sympathetic nerve fibers to the heart discharge continuously at a slow rate that maintains pumping at about 30% above that with no sympathetic stimulation. Therefore, when sympathetic nervous system activity is depressed below normal, both the heart rate and strength of ventricular muscle contraction decrease, thereby decreasing the level of cardiac pumping by as much as 30% below normal.

Parasympathetic (Vagal) Stimulation Reduces Heart Rate and Strength of Contraction. Strong stimulation of the parasympathetic nerve fibers in the vagus nerves to the heart can stop the heartbeat for a few seconds, but then the heart usually “escapes” and beats at a rate of 20 to 40 beats/min as long as the parasympathetic stimulation continues. In addition, strong vagal stimulation can decrease the strength of heart muscle contraction by 20% to 30%.

Figure 9-15. Effect on the cardiac output curve of different degrees of sympathetic or parasympathetic stimulation.

The vagal fibers are distributed mainly to the atria and not much to the ventricles, where the power contraction of the heart occurs. This distribution explains why the effect of vagal stimulation is mainly to decrease the heart rate rather than to decrease greatly the strength of heart contraction. Nevertheless, the great decrease in heart rate, combined with a slight decrease in heart contraction strength, can decrease ventricular pumping by 50% or more.

Effect of Sympathetic or Parasympathetic Stimulation on the Cardiac Function Curve. Figure 9-15 shows four cardiac function curves. These curves are similar to the ventricular function curves of Figure 9-13. However, they represent function of the entire heart rather than that of a single ventricle. They show the relationship between right atrial pressure at the input of the right heart and cardiac output from the left ventricle into the aorta.

The curves of Figure 9-15 demonstrate that at any given right atrial pressure, the cardiac output increases during increased sympathetic stimulation and decreases during increased parasympathetic stimulation. These changes in output caused by autonomic nervous system stimulation result from *changes in heart rate* and from *changes in contractile strength of the heart*.

EFFECT OF POTASSIUM AND CALCIUM IONS ON HEART FUNCTION

In our discussion of membrane potentials in Chapter 5, we pointed out that potassium ions have a marked effect on membrane potentials, and in Chapter 6 we noted that calcium ions play an especially important role in activating the muscle contractile process. Therefore, it is not surprising that the concentrations of each of these two

ions in the extracellular fluids have important effects on cardiac pumping.

Effect of Potassium Ions. Excess potassium in the extracellular fluids causes the heart to become dilated and flaccid and also slows the heart rate. Large quantities of potassium also can block conduction of the cardiac impulse from the atria to the ventricles through the A-V bundle. Elevation of potassium concentration to only 8 to 12 mEq/L—two to three times the normal value—can cause severe weakness of the heart, abnormal rhythm, and death.

These effects result partially from the fact that a high potassium concentration in the extracellular fluids decreases the resting membrane potential in the cardiac muscle fibers, as explained in Chapter 5. That is, a high extracellular fluid potassium concentration partially depolarizes the cell membrane, causing the membrane potential to be less negative. As the membrane potential decreases, the intensity of the action potential also decreases, which makes contraction of the heart progressively weaker.

Effect of Calcium Ions. Excess calcium ions cause effects almost exactly opposite to those of potassium ions, causing the heart to move toward spastic contraction. This effect is caused by a direct effect of calcium ions to initiate the cardiac contractile process, as explained earlier in this chapter.

Conversely, deficiency of calcium ions causes cardiac weakness, similar to the effect of high potassium. Fortunately, calcium ion levels in the blood normally are regulated within a very narrow range. Therefore, cardiac effects of abnormal calcium concentrations are seldom of clinical concern.

EFFECT OF TEMPERATURE ON HEART FUNCTION

Increased body temperature, such as that which occurs during fever, greatly increases the heart rate, sometimes to double the normal rate. Decreased temperature greatly decreases the heart rate, which may fall to as low as a few beats per minute when a person is near death from hypothermia in the body temperature range of 60° to 70°F (15.5°–21°C). These effects presumably result from the fact that heat increases the permeability of the cardiac muscle membrane to ions that control heart rate, resulting in acceleration of the self-excitation process.

Contractile strength of the heart often is enhanced temporarily by a moderate increase in temperature, such as that which occurs during body exercise, but prolonged temperature elevation exhausts the metabolic systems of the heart and eventually causes weakness. Therefore, optimal heart function depends greatly on proper control of body temperature by the control mechanisms explained in Chapter 74.

Figure 9-16. Constancy of cardiac output up to a pressure level of 160 mm Hg. Only when the arterial pressure rises above this normal limit does the increasing pressure load cause the cardiac output to fall significantly.

INCREASING THE ARTERIAL PRESSURE LOAD (UP TO A LIMIT) DOES NOT DECREASE CARDIAC OUTPUT

Note in [Figure 9-16](#) that increasing the arterial pressure in the aorta does not decrease cardiac output until the mean arterial pressure rises above about 160 mm Hg. In other words, during normal heart function at normal systolic arterial pressures (80–140 mm Hg), cardiac output is determined almost entirely by the ease of blood flow through the body’s tissues, which in turn controls *venous return* of blood to the heart. This mechanism is the principal subject of [Chapter 20](#).

Rhythmical Excitation of the Heart

The human heart has a special system for rhythmic self-excitation and repetitive contraction approximately 100,000 times each day or 3 billion times in the average human lifetime. This impressive feat is performed by a system that does the following: (1) generates electrical impulses to initiate rhythmical contraction of the heart muscle; and (2) conducts these impulses rapidly through the heart. When this system functions normally, the atria contract about one-sixth of a second ahead of ventricular contraction, which allows filling of the ventricles before they pump blood through the lungs and peripheral circulation. Another especially important feature of the system is that it allows all portions of the ventricles to contract almost simultaneously, which is essential for the most effective pressure generation in the ventricular chambers.

This rhythmical and conductive system of the heart is susceptible to damage by heart disease, especially by ischemia resulting from inadequate coronary blood flow. The effect is often a bizarre heart rhythm or an abnormal sequence of contraction of the heart chambers, and the pumping effectiveness of the heart can be affected severely, even to the extent of causing death.

SPECIALIZED EXCITATORY AND CONDUCTIVE SYSTEM OF THE HEART

Figure 10-1 shows the specialized excitatory and conductive system of the heart that controls cardiac contractions. The figure shows the sinus node (also called sinoatrial [S-A] node), in which the normal rhythmical impulses are generated; the internodal pathways that conduct impulses from the sinus node to the atrioventricular (A-V) node; the A-V node in which impulses from the atria are delayed before passing into the ventricles; the A-V bundle, which conducts impulses from the atria into the ventricles; and the left and right bundle branches of Purkinje fibers, which conduct the cardiac impulses to all parts of the ventricles.

SINUS (SINOATRIAL) NODE

The sinus node is a small, flattened, ellipsoid strip of specialized cardiac muscle about 3 mm wide, 15 mm long,

and 1 mm thick. It is located in the superior posterolateral wall of the right atrium immediately below and slightly lateral to the opening of the superior vena cava. The fibers of this node have almost no contractile muscle filaments and are each only 3 to 5 micrometers (μm) in diameter, in contrast to a diameter of 10 to 15 μm for the surrounding atrial muscle fibers. However, the sinus nodal fibers connect directly with the atrial muscle fibers, so that any action potential that begins in the sinus node spreads immediately into the atrial muscle wall.

AUTOMATIC ELECTRICAL RHYTHMICITY OF THE SINUS FIBERS

Some cardiac fibers have the capability of *self-excitation*, a process that can cause automatic rhythmical discharge and contraction. This capability is especially true of the heart's specialized conducting system, including fibers of the sinus node. For this reason, the sinus node ordinarily controls the beat rate of the entire heart, as discussed in detail later in this chapter. First, let us describe this automatic rhythmicity.

Mechanism of Sinus Nodal Rhythmicity. **Figure 10-2** shows action potentials recorded from inside a sinus nodal fiber for three heartbeats and, by comparison, a single ventricular muscle fiber action potential. Note that the resting membrane potential of the sinus nodal fiber between discharges is about -55 to -60 millivolts, in comparison with -85 to -90 millivolts for the ventricular muscle fiber. The cause of this lower negativity is that the cell membranes of the sinus fibers are naturally leaky to sodium and calcium ions, and positive charges of the entering sodium and calcium ions neutralize some of the intracellular negativity.

Before we explain the rhythmicity of the sinus nodal fibers, first recall from the discussions of **Chapters 5 and 9** that cardiac muscle has three main types of membrane ion channels that play important roles in causing the voltage changes of the action potential. They are (1) *fast sodium channels*, (2) *calcium channels* (particularly *L-type* or "slow" calcium channels), and (3) *potassium channels* (see **Figure 9-5**).

Figure 10-1 Sinus node and the Purkinje system of the heart, showing also the atrioventricular (A-V) node, atrial internodal pathways, and ventricular bundle branches.

Figure 10-2 Rhythmical discharge of a sinus nodal fiber. Also, the sinus nodal action potential is compared with that of a ventricular muscle fiber.

Opening of the fast sodium channels for a few 10,000ths of a second is responsible for the rapid upstroke spike of the action potential observed in ventricular muscle because of rapid influx of positive sodium ions to the interior of the fiber. Then, the plateau of the ventricular action potential is caused primarily by slower opening of the slow sodium-calcium channels, which lasts for about 0.3 second. Finally, opening of potassium channels allows for the diffusion of large amounts of positive potassium ions in the outward direction through the fiber membrane and returns the membrane potential to its resting level.

However, there is a difference in the function of these channels in the sinus nodal fiber because the resting potential is much less negative—only -55 millivolts in the nodal fiber instead of the -90 millivolts in the ventricular muscle fiber. At this level of -55 millivolts, the fast sodium channels mainly have already become inactivated, or blocked. This is because any time the membrane potential remains less negative than about -55 millivolts

for more than a few milliseconds, the inactivation gates on the inside of the cell membrane that close the fast sodium channels become closed and remain so. Therefore, only the slow sodium-calcium channels can open (i.e., can become activated) and thereby cause the action potential. As a result, the atrial nodal action potential is slower to develop than the action potential of the ventricular muscle. Also, after the action potential does occur, return of the potential to its negative state occurs slowly as well, rather than the abrupt return that occurs for the ventricular fiber.

Leakiness of Sinus Nodal Fibers to Sodium and Calcium Causes Self-Excitation. Because of the high sodium ion concentration in the extracellular fluid outside the nodal fiber, as well as a moderate number of already open sodium channels, positive sodium ions from outside the fibers normally tend to leak to the inside through inward, “funny” currents. Therefore, between heartbeats, the influx of positively charged sodium ions causes a slow rise in the resting membrane potential in the positive direction. Thus, as shown in **Figure 10-2**, the resting potential gradually rises and becomes less negative between each two heartbeats. When the potential reaches a threshold voltage of about -40 millivolts, the L-type calcium channels become activated, thus causing the action potential. Therefore, basically, the inherent leakiness of the sinus nodal fibers to sodium and calcium ions causes their self-excitation.

Why does this leakiness to sodium and calcium ions not cause the sinus nodal fibers to remain depolarized all the time? Two events occur during the course of the action potential to prevent such a constant state of depolarization. First, the L-type calcium channels become inactivated (i.e., they close) within about 100 to 150 milliseconds after opening; and second, at about the same time, greatly increased numbers of potassium channels open. Therefore, influx of positive calcium and sodium ions through the L-type calcium channels ceases, while at the same time large quantities of positive potassium ions diffuse out of the fiber. Both these effects reduce the intracellular potential back to its negative resting level and therefore terminate the action potential. Furthermore, the potassium channels remain open for another few tenths of a second, temporarily continuing movement of positive charges out of the cell, with resultant excess negativity inside the fiber; this process is called *hyperpolarization*. The hyperpolarization state initially carries the resting membrane potential down to about -55 to -60 millivolts at the termination of the action potential.

Why is this new state of hyperpolarization not maintained forever? The reason is that during the next few tenths of a second after the action potential is over, progressively more and more potassium channels close. The inward-leaking sodium (“funny” current) and calcium ions once again overbalance the outward flux of potassium ions, which causes the resting potential to drift

Figure 10-3 Organization of the atrioventricular (A-V) node. The numbers represent the interval of time from the origin of the impulse in the sinus node. The values have been extrapolated to humans.

upward once more, finally reaching the threshold level for discharge at a potential of about -40 millivolts. Then, the entire process begins again: self-excitation to cause the action potential, recovery from the action potential, hyperpolarization after the action potential is over, drift of the resting potential to threshold, and finally re-excitation to elicit another cycle. This process continues throughout a person's life.

INTERNODAL AND INTERATRIAL PATHWAYS TRANSMIT CARDIAC IMPULSES THROUGH THE ATRIA

The ends of the sinus nodal fibers connect directly with the surrounding atrial muscle fibers. Therefore, action potentials originating in the sinus node travel outward into these atrial muscle fibers. In this way, the action potential spreads through the entire atrial muscle mass and, eventually, to the A-V node. The velocity of conduction in most atrial muscle is about 0.3 m/sec, but conduction is more rapid, about 1 m/sec, in several small bands of atrial fibers. One of these bands, called the *anterior interatrial band* (also called *Bachman's bundle*), passes through the anterior walls of the atria to the left atrium. In addition, three other small bands curve through the anterior, lateral, and posterior atrial walls and terminate in the A-V node, shown in **Figure 10-1** and **Figure 10-3**; these are called, respectively, the *anterior*, *middle*, and *posterior internodal pathways*. The cause of more rapid velocity of conduction in these bands is the presence of specialized conduction fibers. These fibers are similar to even more

rapidly conducting Purkinje fibers of the ventricles, discussed below.

THE ATRIOVENTRICULAR NODE DELAYS IMPULSE CONDUCTION FROM THE ATRIA TO THE VENTRICLES

The atrial conductive system is organized so that the cardiac impulse does not travel from the atria into the ventricles too rapidly; this delay allows time for the atria to empty their blood into the ventricles before ventricular contraction begins. It is primarily the A-V node and its adjacent conductive fibers that delay this transmission into the ventricles.

The A-V node is located in the posterior wall of the right atrium, immediately behind the tricuspid valve, as shown in **Figure 10-1**. **Figure 10-3** diagrams the different parts of this node, plus its connections with the entering atrial internodal pathway fibers and the exiting A-V bundle. This figure also shows the approximate intervals of time (in fractions of a second) between the initial onset of the cardiac impulse in the sinus node and its subsequent appearance in the A-V nodal system. Note that the impulse, after traveling through the internodal pathways, reaches the A-V node about 0.03 second after its origin in the sinus node. Then, there is a delay of another 0.09 second in the A-V node itself before the impulse enters the penetrating portion of the A-V bundle, where it passes into the ventricles. A final delay of another 0.04 second occurs mainly in this penetrating A-V bundle, which is composed of multiple small fascicles passing through the fibrous tissue separating the atria from the ventricles.

Thus, the total delay in the A-V nodal and A-V bundle system is about 0.13 second. This delay, in addition to the initial conduction delay of 0.03 second from the sinus node to the A-V node, makes a total delay of 0.16 second before the excitatory signal finally reaches the contracting muscle of the ventricles.

Cause of the Slow Conduction. The slow conduction in the transitional, nodal, and penetrating A-V bundle fibers is caused mainly by diminished numbers of gap junctions between successive cells in the conducting pathways, so there is great resistance to conduction of excitatory ions from one conducting fiber to the next. Therefore, it is easy to see why each succeeding cell is slow to be excited.

RAPID TRANSMISSION OF THE CARDIAC IMPULSE IN THE VENTRICULAR PURKINJE SYSTEM

Special Purkinje fibers lead from the A-V node through the A-V bundle into the ventricles. Except for the initial portion of these fibers, where they penetrate the A-V fibrous barrier, they have functional characteristics that are the opposite of those of the A-V nodal fibers. They are very large fibers, even larger than the normal ventricular muscle fibers, and they transmit action potentials at a

velocity of 1.5 to 4.0 m/sec, a velocity about six times that in the usual ventricular muscle and 150 times that in some of the A-V nodal fibers. This velocity allows almost instantaneous transmission of the cardiac impulse throughout the entire remainder of the ventricular muscle.

The rapid transmission of action potentials by Purkinje fibers is believed to be caused by a very high level of permeability of the gap junctions at the intercalated discs between the successive cells that make up the Purkinje fibers. Therefore, ions are transmitted easily from one cell to the next, thus enhancing the velocity of transmission. The Purkinje fibers also have very few myofibrils, which means that they contract little or not at all during the course of impulse transmission.

The A-V Bundle Is Normally a One-Way Conduction Path. A special characteristic of the A-V bundle is the inability, except in abnormal states, of action potentials to travel backward from the ventricles to the atria. This characteristic prevents re-entry of cardiac impulses by this route from the ventricles to the atria, allowing only forward conduction from the atria to the ventricles.

Furthermore, it should be recalled that everywhere, except at the A-V bundle, the atrial muscle is separated from the ventricular muscle by a continuous fibrous barrier, a portion of which is shown in [Figure 10-3](#). This barrier normally acts as an insulator to prevent passage of the cardiac impulse between atrial and ventricular muscle through any other route besides forward conduction through the A-V bundle. In rare cases, an abnormal muscle bridge, or accessory pathway, does penetrate the fibrous barrier elsewhere besides at the A-V bundle. Under such conditions, the cardiac impulse can re-enter the atria from the ventricles and cause serious cardiac arrhythmias.

Distribution of the Purkinje Fibers in the Ventricles—Left and Right Bundle Branches. After penetrating the fibrous tissue between the atrial and ventricular muscle, the distal portion of the A-V bundle passes downward in the ventricular septum for 5 to 15 mm toward the apex of the heart, as shown in [Figures 10-1 and 10-3](#). Then, the bundle divides into left and right bundle branches that lie beneath the endocardium on the two respective sides of the ventricular septum. Each branch spreads downward toward the apex of the ventricle, progressively dividing into smaller branches. These branches, in turn, course sidewise around each ventricular chamber and back toward the base of the heart. The ends of the Purkinje fibers penetrate about one-third of the way into the muscle mass and finally become continuous with the cardiac muscle fibers.

The total elapsed time averages only 0.03 second from the time the cardiac impulse enters the bundle branches in the ventricular septum until it reaches the terminations of the Purkinje fibers. Therefore, once the cardiac impulse enters the ventricular Purkinje conductive system, it spreads almost immediately to the entire ventricular muscle mass.

TRANSMISSION OF THE CARDIAC IMPULSE IN THE VENTRICULAR MUSCLE

Once the impulse reaches the ends of the Purkinje fibers, it is transmitted through the ventricular muscle mass by the ventricular muscle fibers themselves. The velocity of transmission is now only 0.3 to 0.5 m/sec, one-sixth that in the Purkinje fibers.

The cardiac muscle wraps around the heart in a double spiral, with fibrous septa between the spiraling layers; therefore, the cardiac impulse does not necessarily travel directly outward toward the surface of the heart but, instead, angulates toward the surface along the directions of the spirals. Because of this angulation, transmission from the endocardial surface to the epicardial surface of the ventricle requires as much as another 0.03 second, approximately equal to the time required for transmission through the entire ventricular portion of the Purkinje system. Thus, the total time for transmission of the cardiac impulse from the initial bundle branches to the last of the ventricular muscle fibers in the normal heart is about 0.06 second.

SUMMARY OF THE SPREAD OF THE CARDIAC IMPULSE THROUGH THE HEART

[Figure 10-4](#) summarizes the transmission of the cardiac impulse through the human heart. The numbers on the

Figure 10-4 Transmission of the cardiac impulse through the heart, showing the time of appearance (in fractions of a second after initial appearance at the sinoatrial node) in different parts of the heart. A-V, Atrioventricular; S-A, sinoatrial.

figure represent the intervals of time, in fractions of a second, that lapse between the origin of the cardiac impulse in the sinus node and its appearance at each respective point in the heart. Note that the impulse spreads at moderate velocity through the atria but is delayed more than 0.1 second in the A-V nodal region before appearing in the ventricular septal A-V bundle. Once it has entered this bundle, it spreads very rapidly through the Purkinje fibers to the entire endocardial surfaces of the ventricles. Then, the impulse once again spreads slightly less rapidly through the ventricular muscle to the epicardial surfaces.

It is important that the student learn in detail the course of the cardiac impulse through the heart and the precise times of its appearance in each separate part of the heart. A thorough quantitative knowledge of this process is essential for understanding electrocardiography, which is discussed in [Chapters 11 through 13](#).

CONTROL OF EXCITATION AND CONDUCTION IN THE HEART

THE SINUS NODE IS THE NORMAL PACEMAKER OF THE HEART

In discussing the genesis and transmission of the cardiac impulse through the heart, we have noted that the impulse normally arises in the sinus node. In some abnormal conditions, this is not the case. Other parts of the heart can also exhibit intrinsic rhythmical excitation in the same way as the sinus nodal fibers; this is particularly true of the A-V nodal and Purkinje fibers.

The A-V nodal fibers, when not stimulated from some outside source, discharge at an intrinsic rhythmical rate of 40 to 60 times per minute, and the Purkinje fibers discharge at a rate somewhere between 15 and 40 times per minute. These rates are in contrast to the normal rate of the sinus node of 70 to 80 times per minute.

Why then does the sinus node rather than the A-V node or the Purkinje fibers control the heart's rhythmicity? The answer derives from the fact that the discharge rate of the sinus node is considerably faster than the natural self-excitatory discharge rate of either the A-V node or the Purkinje fibers. Each time the sinus node discharges, its impulse is conducted into both the A-V node and Purkinje fibers, also discharging their excitable membranes. However, the sinus node discharges again before either the A-V node or Purkinje fibers can reach their own thresholds for self-excitation. Therefore, the new impulse from the sinus node discharges both the A-V node and Purkinje fibers before self-excitation can occur in either of these sites.

Thus, the sinus node controls the beat of the heart because its rate of rhythmical discharge is faster than that of any other part of the heart. Therefore, the sinus node is almost always the pacemaker of the normal heart.

Abnormal Pacemakers—Ectopic Pacemaker. Occasionally, some other part of the heart develops a rhythmical

discharge rate that is more rapid than that of the sinus node. For example, this development sometimes occurs in the A-V node or in the Purkinje fibers when one of these becomes abnormal. In either case, the pacemaker of the heart shifts from the sinus node to the A-V node or to the excited Purkinje fibers. Under rarer conditions, a place in the atrial or ventricular muscle develops excessive excitability and becomes the pacemaker.

A pacemaker elsewhere than the sinus node is called an *ectopic pacemaker*. An ectopic pacemaker causes an abnormal sequence of contraction of the different parts of the heart and can cause significant weakening of heart pumping.

Another cause of shift of the pacemaker is blockage of transmission of the cardiac impulse from the sinus node to the other parts of the heart. The new pacemaker then usually occurs at the A-V node or in the penetrating portion of the A-V bundle on the way to the ventricles.

When A-V block occurs—that is, when the cardiac impulse fails to pass from the atria into the ventricles through the A-V nodal and bundle system—the atria continue to beat at the normal rate of rhythm of the sinus node while a new pacemaker usually develops in the Purkinje system of the ventricles and drives the ventricular muscle at a new rate, somewhere between 15 and 40 beats per minute. After sudden A-V bundle block, the Purkinje system does not begin to emit its intrinsic rhythmical impulses until 5 to 20 seconds later because, before the blockage, the Purkinje fibers had been “overdriven” by the rapid sinus impulses and, consequently, are in a suppressed state. During these 5 to 20 seconds, the ventricles fail to pump blood, and the person faints after the first 4 to 5 seconds because of lack of blood flow to the brain. This delayed pickup of the heartbeat is called *Stokes-Adams syndrome*. If the delay period is too long, it can lead to death.

ROLE OF THE PURKINJE SYSTEM IN CAUSING SYNCHRONOUS CONTRACTION OF THE VENTRICULAR MUSCLE

The rapid conduction of the Purkinje system normally permits the cardiac impulse to arrive at almost all portions of the ventricles within a narrow span of time, exciting the first ventricular muscle fiber only 0.03 to 0.06 second ahead of excitation of the last ventricular muscle fiber. This timing causes all portions of the ventricular muscle in both ventricles to begin contracting at almost the same time and then to continue contracting for about another 0.3 second.

Effective pumping by the two ventricular chambers requires this synchronous type of contraction. If the cardiac impulse should travel through the ventricles slowly, much of the ventricular mass would contract before contraction of the remainder, in which case the overall pumping effect would be greatly depressed. Indeed, in some types of cardiac dysfunction, several of which are

discussed in [Chapters 12 and 13](#), slow transmission does occur, and the pumping effectiveness of the ventricles is decreased as much as 20% to 30%. Implantable cardiac resynchronization devices are types of pacemakers using electrical wires or leads that can be inserted into the cardiac chambers to restore appropriate timing between the atria and both ventricles to improve pumping effectiveness in patients with enlarged and weakened hearts.

SYMPATHETIC AND PARASYMPATHETIC NERVES CONTROL HEART RHYTHMICITY AND IMPULSE CONDUCTION BY THE CARDIAC NERVES

The heart is supplied with both sympathetic and parasympathetic nerves, as shown in [Figure 9-14](#) of [Chapter 9](#). The parasympathetic nerves (the vagi) are distributed mainly to the S-A and A-V nodes, to a lesser extent to the muscle of the two atria, and very little directly to the ventricular muscle. The sympathetic nerves, conversely, are distributed to all parts of the heart, with strong representation in the ventricular muscle, as well as in all the other areas.

Parasympathetic (Vagal) Stimulation Slows the Cardiac Rhythm and Conduction. Stimulation of the parasympathetic nerves to the heart (the vagi) causes *acetylcholine* to be released at the vagal endings. This neurotransmitter has two major effects on the heart. First, it decreases the rate of rhythm of the sinus node, and second, it decreases the excitability of the A-V junctional fibers between the atrial musculature and the A-V node, thereby slowing transmission of the cardiac impulse into the ventricles.

Weak to moderate vagal stimulation slows the rate of heart pumping, often to as little as one-half normal. Furthermore, strong stimulation of the vagi can completely stop the rhythmical excitation by the sinus node or completely block transmission of the cardiac impulse from the atria into the ventricles through the A-V node. In either case, rhythmical excitatory signals are no longer transmitted into the ventricles. The ventricles may stop beating for 5 to 20 seconds, but then some small area in the Purkinje fibers, usually in the ventricular septal portion of the A-V bundle, develops a rhythm of its own and causes ventricular contraction at a rate of 15 to 40 beats per minute. This phenomenon is called *ventricular escape*.

Mechanism of the Vagal Effects. The acetylcholine released at the vagal nerve endings greatly increases the permeability of the fiber membranes to potassium ions, which allows rapid leakage of potassium out of the conductive fibers. This process causes increased negativity inside the fibers, an effect called *hyperpolarization*, which makes this excitable tissue much less excitable, as explained in [Chapter 5](#).

In the sinus node, the state of hyperpolarization makes the resting membrane potential of the sinus nodal fibers considerably more negative than usual—that is, -65 to

-75 millivolts rather than the normal level of -55 to -60 millivolts. Therefore, the initial rise of the sinus nodal membrane potential caused by inward sodium and calcium leakage requires much longer to reach the threshold potential for excitation. This requirement greatly slows the rate of rhythmicity of these nodal fibers. If the vagal stimulation is strong enough, it is possible to stop the rhythmical self-excitation of this node entirely.

In the A-V node, a state of hyperpolarization caused by vagal stimulation makes it difficult for the small atrial fibers entering the node to generate enough electricity to excite the nodal fibers. Therefore, the safety factor for transmission of the cardiac impulse through the transitional fibers into the A-V nodal fibers decreases. A moderate decrease simply delays conduction of the impulse, but a large decrease blocks conduction entirely.

Sympathetic Stimulation Increases the Cardiac Rhythm and Conduction. Sympathetic stimulation causes essentially the opposite effects on the heart as those caused by vagal stimulation, as follows.

1. It increases the rate of sinus nodal discharge.
2. It increases the rate of conduction, as well as the level of excitability in all portions of the heart.
3. It increases greatly the force of contraction of all the cardiac musculature, both atrial and ventricular, as discussed in [Chapter 9](#).

In short, sympathetic stimulation increases the overall activity of the heart. Maximal stimulation can almost triple the heartbeat frequency and can increase the strength of heart contraction as much as twofold.

Mechanism of the Sympathetic Effect. Stimulation of the sympathetic nerves releases *norepinephrine* at the sympathetic nerve endings. Norepinephrine, in turn, stimulates *beta-1 adrenergic receptors*, which mediate the effects on heart rate. The precise mechanism whereby beta-1 adrenergic stimulation acts on cardiac muscle fibers is somewhat unclear, but is thought to increase the permeability of the fiber membrane to sodium and calcium ions. In the sinus node, an increase of sodium-calcium permeability causes a more positive resting potential. It also causes an increased rate of upward drift of the diastolic membrane potential toward the threshold level for self-excitation, thus accelerating self-excitation and, therefore, increasing the heart rate.

In the A-V node and A-V bundles, increased sodium-calcium permeability makes it easier for the action potential to excite each succeeding portion of the conducting fiber bundles, thereby decreasing the conduction time from the atria to the ventricles.

The increase in permeability to calcium ions is at least partially responsible for the increase in contractile strength of the cardiac muscle under the influence of sympathetic stimulation. This is because calcium ions play a powerful role in exciting the contractile process of the myofibrils.

Fundamentals of Electrocardiography

When a cardiac impulse passes through the heart, electrical current also spreads from the heart into the adjacent tissues surrounding the heart. A small portion of the current spreads all the way to the surface of the body. If electrodes are placed on the skin on opposite sides of the heart, electrical potentials generated by the current can be recorded; the recording is known as an *electrocardiogram* (ECG). A normal ECG for two beats of the heart is shown in [Figure 11-1](#).

WAVEFORMS OF THE NORMAL ELECTROCARDIOGRAM

The normal ECG (see [Figure 11-1](#)) is composed of a P wave, a QRS complex, and a T wave. The QRS complex is often, but not always, three separate waves: the Q wave, the R wave, and the S wave.

The *P wave* is caused by electrical potentials generated when the atria depolarize before atrial contraction begins. The *QRS complex* is caused by potentials generated when the ventricles depolarize before contraction—that is, as the depolarization wave spreads through the ventricles. Therefore, both the P wave and the components of the QRS complex are *depolarization waves*.

The *T wave* is caused by potentials generated as the ventricles recover from depolarization. This process normally occurs in ventricular muscle 0.25 to 0.35 second after depolarization. The T wave is known as a *repolarization wave*.

Thus, the ECG is composed of both depolarization and repolarization waves. The principles of depolarization and repolarization are discussed in [Chapter 5](#). The distinction between depolarization waves and repolarization waves is so important in electrocardiography that further clarification is necessary.

CARDIAC DEPOLARIZATION WAVES VERSUS REPOLARIZATION WAVES

[Figure 11-2](#) shows a single cardiac muscle fiber in four stages of depolarization and repolarization, with the color red designating depolarization. During depolarization, the normal negative potential inside the fiber reverses and becomes slightly positive inside and negative outside.

In [Figure 11-2A](#), depolarization, demonstrated by red positive charges inside and red negative charges outside, is traveling from left to right. The first half of the fiber has already depolarized while the remaining half is still polarized. Therefore, the left electrode on the outside of the fiber is in an area of negativity, and the right electrode is in an area of positivity, which causes the meter to record positively. To the right of the muscle fiber is shown a record of changes in potential between the two electrodes, as recorded by a high-speed recording meter. Note that when depolarization has reached the halfway mark in [Figure 11-2A](#), the recording on the right has risen to a maximum positive value.

In [Figure 11-2B](#), depolarization has extended over the entire muscle fiber, and the recording to the right has returned to the zero baseline because both electrodes are now in areas of equal negativity. The completed wave is a depolarization wave because it results from the spread of depolarization along the muscle fiber membrane.

[Figure 11-2C](#) shows halfway repolarization of the same muscle fiber, with positivity returning to the outside of the fiber. At this point, the left electrode is in an area of positivity, and the right electrode is in an area of negativity. This polarity is opposite to the polarity in [Figure 11-2A](#). Consequently, the recording, as shown to the right, becomes negative.

In [Figure 11-2D](#), the muscle fiber has completely repolarized, and both electrodes are now in areas of positivity so that no potential difference is recorded between them. Thus, in the recording on the right, the potential returns once more to zero. This completed negative wave is a repolarization wave because it results from the spread of repolarization along the muscle fiber membrane.

Relation of the Monophasic Action Potential of Ventricular Muscle to the QRS and T Waves in the Standard Electrocardiogram. The monophasic action potential of ventricular muscle, discussed in [Chapter 10](#), normally lasts between 0.25 and 0.35 second. The top part of [Figure 11-3](#) shows a monophasic action potential recorded from a microelectrode inserted into the inside of a single ventricular muscle fiber. The upswing of this action potential is caused by depolarization, and the return of the potential to the baseline is caused by repolarization.

Figure 11-1. Normal electrocardiogram.

Figure 11-2. Recording the depolarization wave (A and B) and the repolarization wave (C and D) from a cardiac muscle fiber.

Figure 11-3. Top, Monophasic action potential from a ventricular muscle fiber during normal cardiac function showing rapid depolarization and then repolarization occurring slowly during the plateau stage but rapidly toward the end. Bottom, Electrocardiogram recorded simultaneously.

The lower half of **Figure 11-3** shows a simultaneous recording of the ECG from this same ventricle. Note that the QRS waves appear at the beginning of the monophasic action potential, and the T wave appears at the end. Note especially that *no potential is recorded in the ECG when the ventricular muscle is either completely polarized or completely depolarized*. Only when the muscle is partly polarized and partly depolarized does current flow from one part of the ventricles to another part, and therefore current also flows to the surface of the body to produce the ECG.

RELATIONSHIP OF ATRIAL AND VENTRICULAR CONTRACTION TO THE WAVES OF THE ELECTROCARDIOGRAM

Before contraction of muscle can occur, depolarization must spread through the muscle to initiate the chemical processes of contraction. Refer again to **Figure 11-1**; the P wave occurs at the beginning of contraction of the atria, and the QRS complex of waves occurs at the beginning of contraction of the ventricles. The ventricles remain contracted until after repolarization has occurred—that is, until after the end of the T wave.

The atria repolarize about 0.15 to 0.20 second after termination of the P wave, which is also approximately when the QRS complex is being recorded in the ECG. Therefore, the atrial repolarization wave, known as the *atrial T wave*, is usually obscured by the much larger QRS complex. For this reason, an atrial T wave is seldom observed on the ECG.

The ventricular repolarization wave is the T wave of the normal ECG. Ordinarily, ventricular muscle begins to repolarize in some fibers about 0.20 second after the beginning of the depolarization wave (the QRS complex), but in many other fibers, it takes as long as 0.35 second. Thus, the process of ventricular repolarization extends over a long period, about 0.15 second. For this reason, the T wave in the normal ECG is a prolonged wave, but the voltage of the T wave is considerably less than the voltage of the QRS complex, partly because of its prolonged length.

ELECTROCARDIOGRAPHIC CALIBRATION AND DISPLAY

All recordings of ECGs are made with appropriate calibration lines on the display grid. Historically, ECGs were recorded electronically and printed onto paper; ECGs are now usually displayed digitally. As shown in **Figure 11-1**, the horizontal calibration lines are arranged so that 10 of the small line divisions upward or downward in the standard ECG represent 1 millivolt, with positivity in the upward direction and negativity in the downward direction.

The vertical lines on the ECG are time calibration lines. A typical ECG is run at a speed of 25 millimeters per second, although faster speeds are sometimes used. Therefore, each 25 millimeters in the horizontal direction is 1 second, and each 5-millimeter segment, indicated by the dark vertical lines, represents 0.20 second. The 0.20-second intervals are then broken into five smaller intervals by thin lines, each of which represents 0.04 second.

Normal Voltages in the Electrocardiogram. The recorded voltages of the waves in the normal ECG depend on the manner in which the electrodes are applied to the surface of the body and how close the electrodes are to the heart. When one electrode is placed directly over the ventricles, and a second electrode is placed elsewhere on the body remote from the heart, the voltage of the QRS complex may be as high as 3 to 4 millivolts. Even this voltage is small in comparison with the monophasic action potential of 110 millivolts recorded directly at the heart muscle membrane. When ECGs are recorded from electrodes on the two arms or on one arm and one leg, the voltage of the QRS complex usually is 1.0 to 1.5 millivolts from the top of the R wave to the bottom of the S wave, the voltage of the P wave is between 0.1 and 0.3 millivolts, and the voltage of the T wave is between 0.2 and 0.3 millivolts.

P-Q or P-R Interval. The time between the beginning of the P wave and the beginning of the QRS complex is the interval between the beginning of electrical excitation of the atria and the beginning of excitation of the ventricles. This period is called the *P-Q interval*. The normal P-Q interval is about 0.16 second. (Often, this interval is called the *P-R interval* because the Q wave is likely to be absent.) The P-R interval shortens at faster heart rates due to increased sympathetic or decreased parasympathetic activity, which increase atrioventricular node conduction speed. Conversely, the P-R interval lengthens with slower heart rates as a consequence of slower atrioventricular nodal conduction caused by increased parasympathetic tone or withdrawal of sympathetic activity.

Q-T Interval. Contraction of the ventricle lasts almost from the beginning of the Q wave (or R wave, if the Q wave is absent) to the end of the T wave. This interval is called the *Q-T interval* and ordinarily is about 0.35 second.

Figure 11-4. Instantaneous potentials develop on the surface of a cardiac muscle mass that has been depolarized in its center.

Heart Rate as Determined from the Electrocardiogram. The rate of the heartbeat can be determined easily from an ECG because the heart rate is the reciprocal of the time interval between two successive heartbeats (the R-R interval). If the interval between two beats as determined from the time calibration lines is 1 second, the heart rate is 60 beats/min. The normal interval between two successive QRS complexes in an adult is about 0.83 second, which is a heart rate of $60/0.83$ times/min, or 72 beats/min.

FLOW OF CURRENT AROUND THE HEART DURING THE CARDIAC CYCLE

Recording Electrical Potentials from a Partially Depolarized Mass of Syncytial Cardiac Muscle

Figure 11-4 shows a syncytial mass of cardiac muscle that has been stimulated at its most central point. Before stimulation, all the exteriors of the muscle cells had been positive, and the interiors had been negative. For reasons presented in **Chapter 5** in the discussion of membrane potentials, as soon as an area of cardiac syncytium becomes depolarized, negative charges leak to the outsides of the depolarized muscle fibers, making this part of the surface electronegative, as represented by the minus signs in **Figure 11-4**. The remaining surface of the heart, which is still polarized, is represented by the plus signs. Therefore, a meter connected with its negative terminal on the area of depolarization and its positive terminal on one of the still polarized areas, as shown to the right in the figure, records positively.

Two other electrode placements and meter readings are also demonstrated in **Figure 11-4**. These placements and readings should be studied carefully, and the reader should be able to explain the causes of the respective meter readings. Because the depolarization spreads in all directions through the heart, the potential differences shown in the figure persist for only a few thousandths of a second, and the actual voltage measurements can be accomplished only with a high-speed recording apparatus.

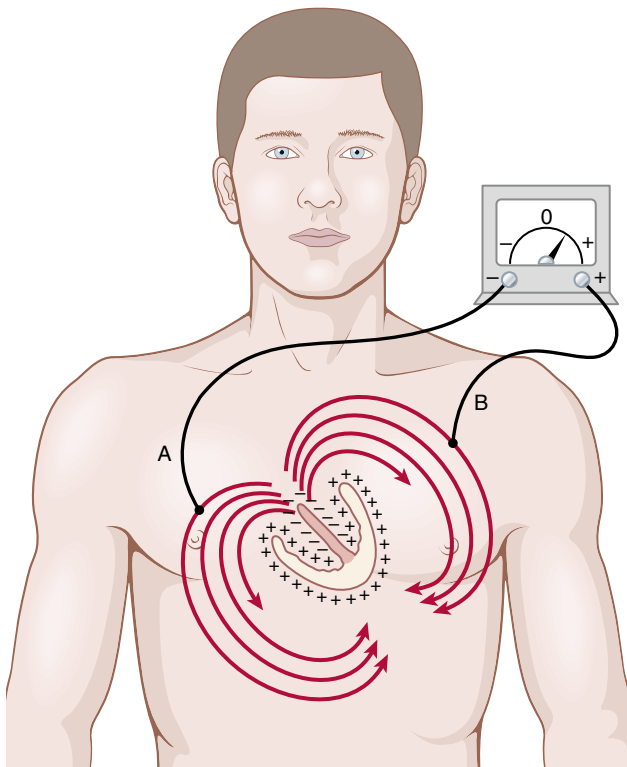

Figure 11-5. Flow of current in the chest around partially depolarized ventricles. *A* and *B* are electrodes.

Flow of Electrical Currents in the Chest Around the Heart

Figure 11-5 shows the ventricular muscle lying within the chest. Even the lungs, although mostly filled with air, conduct electricity to a surprising extent, and fluids in other tissues surrounding the heart conduct electricity even more easily. Therefore, the heart is actually suspended in a conductive medium. When one portion of the ventricles depolarizes and therefore becomes electronegative with respect to the remainder, electrical current flows from the depolarized area to the polarized area in large circuitous routes, as noted in the figure.

It should be recalled from the discussion of the Purkinje system in **Chapter 10** that the cardiac impulse first arrives in the ventricles in the septum and shortly thereafter spreads to the inside surfaces of the remainder of the ventricles, as shown by the red areas and the negative signs in **Figure 11-5**. This process provides electronegativity on the insides of the ventricles and electropositivity on the outer walls of the ventricles, with electrical current flowing through the fluids surrounding the ventricles along elliptical paths, as demonstrated by the curving arrows in the figure. If one algebraically averages all the lines of current flow (the elliptical lines), *the average current flow occurs with negativity toward the base of the heart and with positivity toward the apex.*

During most of the remainder of the depolarization process, current also continues to flow in this same direction, whereas depolarization spreads from the endocardial

Figure 11-6. Conventional arrangement of electrodes for recording the standard electrocardiographic leads. Einthoven's triangle is superimposed on the chest.

surface outward through the ventricular muscle mass. Then, immediately before depolarization has completed its course through the ventricles, the average direction of current flow reverses for about 0.01 second, flowing from the ventricular apex toward the base, because the last part of the heart to become depolarized is the outer walls of the ventricles near the base of the heart.

*Thus, in normal heart ventricles, current flows from negative to positive primarily in the direction from the base of the heart toward the apex during almost the entire cycle of depolarization, except at the very end. If a meter is connected to electrodes on the surface of the body, as shown in **Figure 11-5**, the electrode nearer the base will be negative, whereas the electrode nearer the apex will be positive, and the recording meter will show a positive recording in the ECG.*

ELECTROCARDIOGRAPHIC LEADS

Three Standard Bipolar Limb Leads

Figure 11-6 shows electrical connections between the patient's limbs and the electrocardiograph for recording

ECGs from the so-called *standard bipolar limb leads*. The term *bipolar* means that the ECG is recorded from two electrodes located on different sides of the heart—in this case, on the limbs. Thus, a lead is not a single wire connecting from the body but a combination of two wires and their electrodes to make a complete circuit between the body and the electrocardiograph. The electrocardiograph in each case is represented by an electrical meter in the diagram, although the actual electrocardiograph is a high-speed, computer-based system with an electronic display.

Lead I. In recording limb lead I, the negative terminal of the electrocardiograph is connected to the right arm, and the positive terminal is connected to the left arm. Therefore, when the point where the right arm connects to the chest is electronegative with respect to the point where the left arm connects, the electrocardiograph records positively—that is, above the zero-voltage line in the ECG. When the opposite is true, the electrocardiograph records below the line.

Lead II. To record limb lead II, the negative terminal of the electrocardiograph is connected to the right arm and the positive terminal is connected to the left leg. Therefore, when the right arm is negative with respect to the left leg, the electrocardiograph records positively.

Lead III. To record limb lead III, the negative terminal of the electrocardiograph is connected to the left arm, and the positive terminal is connected to the left leg. This configuration means that the electrocardiograph records positively when the left arm is negative with respect to the left leg.

Einthoven's Triangle. In [Figure 11-6](#), the triangle, called *Einthoven's triangle*, is drawn around the area of the heart. This triangle illustrates that the two arms and left leg form apices of a triangle surrounding the heart. The two apices at the upper part of the triangle represent the points at which the two arms connect electrically with the fluids around the heart, and the lower apex is the point at which the left leg connects with the fluids.

Einthoven's Law. Einthoven's law states that if the ECGs are recorded simultaneously with the three limb leads, the sum of the potentials recorded in leads I and III will equal the potential in lead II:

$$\text{Lead I potential} + \text{Lead III potential} = \text{Lead II potential}$$

In other words, if the electrical potentials of any two of the three bipolar limb electrocardiographic leads are known at any given instant, the third one can be determined by simply summing the first two. Note, however, that the positive and negative signs of the different leads must be observed when making this summation.

For instance, let us assume that momentarily, as noted in [Figure 11-6](#), the right arm is -0.2 millivolts (negative)

Figure 11-7. Normal electrocardiograms recorded from the three standard electrocardiographic leads (I–III).

with respect to the average potential in the body, the left arm is $+0.3$ millivolts (positive), and the left leg is $+1.0$ millivolts (positive). Observing the meters in the figure, one can see that lead I records a positive potential of $+0.5$ millivolts because this is the difference between the -0.2 millivolts on the right arm and the $+0.3$ millivolts on the left arm. Similarly, lead III records a positive potential of $+0.7$ millivolts, and lead II records a positive potential of $+1.2$ millivolts because these are the instantaneous potential differences between the respective pairs of limbs.

Now, note that the sum of the voltages in leads I and III equals the voltage in lead II; that is, 0.5 plus 0.7 equals 1.2 . Mathematically, this principle, called Einthoven's law, holds true at any given instant while the three "standard" bipolar ECGs are being recorded.

Normal Electrocardiograms Recorded from the Three Standard Bipolar Limb Leads. [Figure 11-7](#) shows recordings of the ECGs in leads I, II, and III. It is obvious that the ECGs in these three leads are similar to one another because they all record positive P waves and positive T waves, and the major portion of the QRS complex is also positive in each ECG. On analysis of the three ECGs, it can be shown, with careful measurements and proper observance of polarities, that at any given instant, the sum of the potentials in leads I and III equals the potential in lead II, thus illustrating the validity of Einthoven's law.

Because the recordings from all the bipolar limb leads are similar to one another, it does not matter greatly which lead is recorded when one wants to diagnose different cardiac arrhythmias, because diagnosis of arrhythmias depends mainly on the time

Figure 11-8. Connections of the body with the electrocardiograph for recording chest leads. LA, Left arm; RA, right arm.

relationships between the different waves of the cardiac cycle. However, when one wants to diagnose damage in the ventricular or atrial muscle or in the Purkinje conducting system, it matters greatly which leads are recorded, because abnormalities of cardiac muscle contraction or cardiac impulse conduction change the patterns of the ECGs markedly in some leads yet may not affect other leads. Electrocardiographic interpretation of these two types of conditions—cardiac myopathies and cardiac arrhythmias—is discussed separately in [Chapters 12 and 13](#).

Precordial Leads

Often ECGs are recorded with one electrode placed on the anterior surface of the chest directly over the heart at one of the points shown in [Figure 11-8](#). This electrode is connected to the positive terminal of the electrocardiograph, and the negative electrode, called the *indifferent electrode* or *Wilson central terminal*, is connected through equal electrical resistances to the right arm, left arm, and left leg all at the same time, as also shown in the figure. Usually, six standard chest leads are recorded, one at a time, from the anterior chest wall, with the chest electrode being placed sequentially at the six points shown in the diagram. The different recordings are known as leads V_1 , V_2 , V_3 , V_4 , V_5 , and V_6 .

Figure 11-9. Normal electrocardiograms recorded from the six standard chest leads.

Figure 11-10. Normal electrocardiograms recorded from the three augmented unipolar limb leads.

[Figure 11-9](#) illustrates the ECGs of the healthy heart as recorded from these six standard chest leads. Because the heart surfaces are close to the chest wall, each chest lead records mainly the electrical potential of the cardiac musculature immediately beneath the electrode. Therefore, relatively minute abnormalities in the ventricles, particularly in the anterior ventricular wall, can cause marked changes in the ECGs recorded from individual chest leads.

In leads V_1 and V_2 , the QRS recordings of the normal heart are mainly negative because, as shown in [Figure 11-8](#), the chest electrode in these leads is closer to the base of the heart than to the apex, and the base of the heart is the direction of electronegativity during most of the ventricular depolarization process. Conversely, the QRS complexes in leads V_4 , V_5 , and V_6 are mainly positive because the chest electrode in these leads is closer to the heart apex, which is the direction of electropositivity during most of depolarization.

Augmented Limb Leads

Another system of leads in wide use is the *augmented limb leads*. In this type of recording, two of the limbs are connected through electrical resistances to the negative terminal of the electrocardiograph, and the third limb is connected to the positive terminal. When the positive terminal is on the right arm, the lead is known as the aVR lead; when on the left arm, it is known as the aVL lead; and when on the left leg, it is known as the aVF lead.

Normal recordings of the augmented limb leads are shown in [Figure 11-10](#). They are all similar to the standard limb lead recordings, except that the recording from

Figure 11-11. Normal 12-lead electrocardiogram.

the aVR lead is inverted. (Why does this inversion occur? Study the polarity connections to the electrocardiograph to determine the answer to this question.)

Electrocardiographic Display

Leads are typically displayed into three groupings as in [Figure 11-11](#): the standard bipolar limb leads (I, II, III) followed by the augmented leads (aVR, aVL, and aVF) and then the precordial leads (V₁–V₆).

Ambulatory Electrocardiography

Standard ECGs provide an assessment of cardiac electrical events over a brief duration, usually while the patient is resting. In conditions associated with infrequent but important abnormalities of cardiac rhythms, it may be useful to examine the ECG over a longer period, thereby permitting evaluation of changing cardiac electrical phenomena that are transient and may be missed with a standard resting ECG. Extending the ECG to allow assessment of cardiac electrical events while the patient is ambulating during normal daily activities is called *ambulatory electrocardiography*.

Ambulatory electrocardiographic monitoring is typically used when a patient demonstrates symptoms that are thought to be caused by transient arrhythmias or other transient cardiac abnormalities. These symptoms may include chest pain, syncope (fainting) or near syncope, dizziness, and irregular heartbeats (palpitations). The crucial information needed to diagnose serious transient arrhythmias or other cardiac conditions is a recording of an ECG during the precise time that the symptom is occurring. These devices can also be used to detect asymptomatic cardiac arrhythmias such as atrial fibrillation that may increase the risk of embolus formation, which can, in turn,

cause strokes. Because the daily variability in the frequency of arrhythmias is substantial, detection often requires ambulatory electrocardiographic monitoring throughout the day.

There are several categories of ambulatory electrocardiographic recorders. Continuous recorders (Holter monitors), are typically used for 24 to 48 hours to investigate the relationship of symptoms and electrocardiographic events that are likely to occur within that time frame. Intermittent recorders are used for longer periods (weeks to months) to provide brief intermittent recordings for detection of events that occur infrequently; these recordings are usually initiated by the patient when experiencing symptoms. In some cases, a small device, about the size of a large paper clip and called an *implantable loop recorder*, is implanted just under the skin in the chest to monitor the heart's electrical activity continuously for as long as 2 to 3 years. The device can be programmed to initiate a recording when the heart rate falls below, or rises above, a predetermined level, or it can be activated manually by the patient when a symptom such as dizziness occurs. Improvements in solid-state digital technology and recorders equipped with microprocessors now permit continuous or intermittent transmission of digital electrocardiographic data over telephone lines, and sophisticated software systems provide rapid online computerized analysis of the data as they are acquired. Newer wearable devices, including watches or hand-held electrocardiographic monitoring devices, are also being developed for home-based heart rhythm monitoring.

See the bibliography for [Chapter 13](#).

Electrocardiographic Interpretation of Cardiac Muscle and Coronary Blood Flow Abnormalities: Vectorial Analysis

From the discussion in [Chapter 10](#) of impulse transmission through the heart, it is obvious that any change in the pattern of this transmission can cause abnormal electrical potentials around the heart and, consequently, alter the shapes of the waves in the electrocardiogram (ECG). For this reason, most serious abnormalities of the heart muscle can be diagnosed by analyzing the contours of the waves in the different electrocardiographic leads.

VECTORIAL ANALYSIS OF ELECTROCARDIOGRAMS

VECTORS CAN REPRESENT ELECTRICAL POTENTIALS

To understand how cardiac abnormalities affect the contours of the ECG, one must first become familiar with the concept of *vectors* and *vectorial analysis* as applied to electrical potentials in and around the heart. In [Chapter 11](#), we pointed out that heart current flows in a particular direction in the heart at a given instant during the cardiac cycle. A vector is an arrow that points in the direction of the electrical potential generated by the current flow, *with the arrowhead in the positive direction*. Also, by convention, the length of the arrow is drawn *proportional to the voltage of the potential*.

Resultant Vector in the Heart at Any Given Instant.

The shaded area and the minus signs in [Figure 12-1](#) show depolarization of the ventricular septum and of parts of the apical endocardial walls of the two ventricles. At the instant of heart excitation, electrical current flows between the depolarized areas inside the heart and the nondepolarized areas on the outside of the heart, as indicated by the long elliptical arrows. Some current also flows inside the heart chambers directly from the depolarized areas toward the still polarized areas. Overall, considerably more current flows downward from the base of the ventricles toward the apex than in the upward direction. Therefore, the summated vector of the generated potential at this particular instant, called the *instantaneous mean vector*, is represented by the long *black arrow* drawn through the center of the ventricles in a direction from the base toward the apex. Furthermore, because the summated current is quite large, the potential is large, and the vector is long.

THE DIRECTION OF A VECTOR IS DENOTED IN TERMS OF DEGREES

When a vector is exactly horizontal and directed toward the person's left side, the vector is said to extend in the direction of 0 degrees, as shown in [Figure 12-2](#). From this zero reference point, the scale of vectors rotates clockwise; when the vector extends from above and straight downward, it has a direction of +90 degrees, when it extends from the person's left to right, it has a direction of +180 degrees, and when it extends straight upward, it has a direction of -90 (or +270) degrees.

In a normal heart, the average direction of the vector during spread of the depolarization wave through the ventricles, called the *mean QRS vector*, is about +59 degrees, which is shown by vector *A* drawn through the center of [Figure 12-2](#) in the +59-degree direction. This means that during most of the depolarization wave, the apex of the heart remains positive with respect to the base of the heart, as discussed later in this chapter.

AXIS FOR EACH STANDARD BIPOLAR LEAD AND EACH UNIPOLAR LIMB LEAD

In [Chapter 11](#), the three standard bipolar and the three unipolar limb leads are described. Each lead is actually a pair of electrodes connected to the body on opposite sides of the heart, and the direction from negative electrode to positive electrode is called the *axis* of the lead. Lead I is recorded from two electrodes placed respectively on the two arms. Because the electrodes lie exactly in the horizontal direction, with the positive electrode to the left, the axis of lead I is 0 degrees.

In recording lead II, electrodes are placed on the right arm and left leg. The right arm connects to the torso in the upper right-hand corner, and the left leg connects in the lower left-hand corner. Therefore, the direction of this lead is about +60 degrees.

By similar analysis, it can be seen that lead III has an axis of about +120 degrees, lead aVR, +210 degrees, lead aVF, +90 degrees, and lead aVL, -30 degrees. The directions of the axes of all these leads are shown in [Figure 12-3](#), which is known as the *hexagonal reference system*. The polarities of the electrodes are shown by the plus

Figure 12-1 Mean vector through the partially depolarized ventricles goes from the base of the left ventricle towards the apex.

Figure 12-2 Vectors drawn to represent potentials for several different hearts and the axis of the potential (expressed in degrees) for each heart.

Figure 12-3 Axes of the three bipolar and three unipolar leads.

Figure 12-4 Determination of a projected vector B along the axis of lead I when vector A represents the instantaneous potential in the ventricles.

and minus signs in the figure. *The reader must learn these axes and their polarities, particularly for the bipolar limb leads I, II, and III, to understand the remainder of this chapter.*

VECTORIAL ANALYSIS OF POTENTIALS RECORDED IN DIFFERENT LEADS

Figure 12-4 shows a partially depolarized heart, with vector A representing the instantaneous mean direction of current flow in the ventricles. In this case, the direction of the vector is +55 degrees, and the voltage of the potential, represented by the length of vector A, is 2 millivolts. In the diagram below the heart, vector A is shown again, and a line is drawn to represent the axis of lead I in the 0-degree direction. To determine how much of the voltage in vector A will be recorded in lead I, a line perpendicular to the axis of lead I is drawn from the tip of vector A to the lead I axis, and a so-called *projected vector (B)* is drawn along the lead I axis. The arrow of this projected vector points toward the positive end of the lead I axis, which means that the record momentarily being recorded in the ECG of lead I is positive. The instantaneous recorded voltage will be equal to the length of B divided by the length of A times 2 millivolts, or about 1 millivolt.

Figure 12-5 shows another example of vectorial analysis. In this example, vector A represents the electrical potential and its axis at a given instant during ventricular depolarization in a heart in which the left side of the heart depolarizes more rapidly than the right side. In this case, the instantaneous vector has a direction of 100 degrees, and its voltage is again 2 millivolts. To determine the potential actually recorded in lead I, we draw a perpendicular line from the tip of vector A to the lead I axis and find projected vector B. Vector B is very short, and this time it is in the negative direction, indicating that at this particular instant, the recording in lead I will be negative (below the zero line in the ECG), and the voltage recorded will be small, about -0.3 millivolts. This figure demonstrates that *when the vector in the heart is in a direction almost perpendicular to the axis of the lead, the voltage recorded in the ECG of this lead is very low.* Conversely,

Figure 12-5 Determination of the projected vector B along the axis of lead I when vector A represents the instantaneous potential in the ventricles.

Figure 12-6 Determination of projected vectors in leads I, II, and III when vector A represents the instantaneous potential in the ventricles.

when the heart vector has almost exactly the same axis as the lead axis, essentially the entire voltage of the vector will be recorded.

Vectorial Analysis of Potentials in the Three Standard Bipolar Limb Leads. In **Figure 12-6**, vector A depicts the instantaneous electrical potential of a partially depolarized heart. To determine the potential recorded at this instant in the ECG for each one of the three standard bipolar limb leads, perpendicular lines (the *dashed lines*) are drawn from the tip of vector A to the three lines representing the axes of the three different standard leads, as shown in the figure. The projected vector B depicts the potential recorded at that instant in lead I, projected vector C depicts the potential in lead II, and projected vector D depicts the potential in lead III. In each of these, the record in the ECG is positive—that is, above the zero line—because the projected vectors point in the positive directions along the axes of all the leads. The potential in lead I (vector B) is about half of that of the actual potential in the heart (vector A), in lead II (vector C), it is almost

equal to that in the heart and, in lead III (vector D), it is about one-third that in the heart.

An identical analysis can be used to determine potentials recorded in augmented limb leads, except that the respective axes of the augmented leads (see **Figure 12-3**) are used in place of the standard bipolar limb lead axes used for **Figure 12-6**.

VECTORIAL ANALYSIS OF THE NORMAL ELECTROCARDIOGRAM

VECTORS THAT OCCUR AT SUCCESSIVE INTERVALS DURING DEPOLARIZATION OF THE VENTRICLES—THE QRS COMPLEX

When the cardiac impulse enters the ventricles through the atrioventricular bundle, the first part of the ventricles to become depolarized is the left endocardial surface of the septum. Then, depolarization spreads rapidly to involve both endocardial surfaces of the septum, as shown by the darker shaded portion of the ventricle in **Figure 12-7A**. Next, depolarization spreads along the endocardial surfaces of the remainder of the two ventricles, as shown in **Figure 12-7B and C**. Finally, it spreads through the ventricular muscle to the outside of the heart, as shown progressively in **Figure 12-7C to E**.

At each stage in **Figure 12-7, A to E**, the instantaneous mean electrical potential of the ventricles is represented by a red vector superimposed on the ventricle in each figure. Each of these vectors is then analyzed by the method described in the preceding section to determine the voltages that will be recorded at each instant in each of the three standard electrocardiographic leads. To the right in each Figure is shown progressive development of the electrocardiographic QRS complex. *Keep in mind that a positive vector in a lead will cause recording in the ECG above the zero line, whereas a negative vector will cause recording below the zero line.*

Before proceeding with further consideration of vectorial analysis, it is essential that this analysis of the successive normal vectors presented in **Figure 12-7** be understood. Each of these analyses should be studied in detail by the procedure given here. A short summary of this sequence follows.

In **Figure 12-7A**, the ventricular muscle has just begun to be depolarized, representing an instant about 0.01 second after the onset of depolarization. At this time, the vector is short because only a small portion of the ventricles—the septum—is depolarized. Therefore, all electrocardiographic voltages are low, as recorded to the right of the ventricular muscle for each of the leads. The voltage in lead II is greater than the voltages in leads I and III because the heart vector extends mainly in the same direction as the axis of lead II.

In **Figure 12-7B**, which represents about 0.02 second after onset of depolarization, the heart vector is long because much of the ventricular muscle mass has become depolarized. Therefore, the voltages in all electrocardiographic leads have increased.

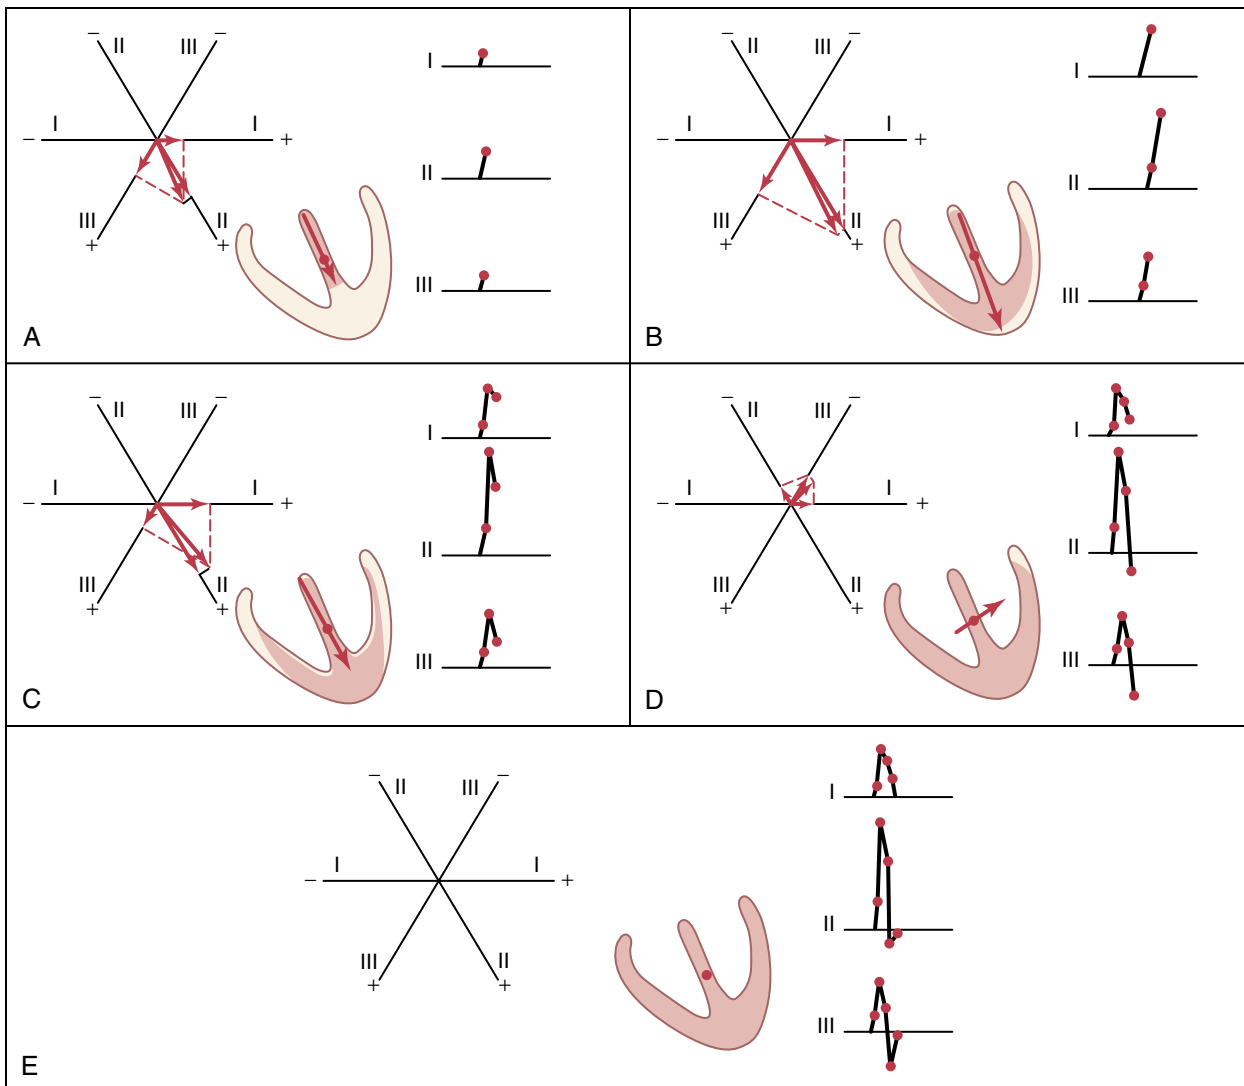

Figure 12-7 Shaded areas of the ventricles are depolarized (–); nonshaded areas are still polarized (+). Shown are the ventricular vectors and QRS complexes 0.01 second after onset of ventricular depolarization (**A**), 0.02 second after onset of depolarization (**B**), 0.035 second after onset of depolarization (**C**), 0.05 second after onset of depolarization (**D**), and after depolarization of the ventricles is complete, 0.06 second after onset (**E**).

In **Figure 12-7C**, about 0.035 second after onset of depolarization, the heart vector is becoming shorter, and the recorded electrocardiographic voltages are lower, because the outside of the heart apex is now electronegative, neutralizing much of the positivity on the other epicardial surfaces of the heart. Also, the axis of the vector is beginning to shift toward the left side of the chest because the left ventricle is slightly slower to depolarize than the right ventricle. Therefore, the ratio of the voltage in lead I to that in lead III is increasing.

In **Figure 12-7D**, about 0.05 second after onset of depolarization, the heart vector points toward the base of the left ventricle, and it is short because only a minute portion of the ventricular muscle is still polarized positive. Because of the direction of the vector at this time, the voltages recorded in leads II and III are both negative—that is, below the line—whereas the voltage of lead I is still positive.

In **Figure 12-7E**, about 0.06 second after onset of depolarization, the entire ventricular muscle mass is depolarized so that no current flows around the heart and no electrical potential is generated. The vector becomes zero, and the voltages in all leads become zero.

Thus, the QRS complexes are completed in the three standard bipolar limb leads.

Sometimes the QRS complex has a slight negative deflection at its beginning in one or more of the leads, which is not shown in **Figure 12-7**; this deflection is the Q wave. When it occurs, it is caused by initial depolarization of the left side of the septum before the right side, which creates a weak vector from left to right for a fraction of a second before the usual base to apex vector occurs. The major positive deflection shown in **Figure 12-7** is the R wave, and the final negative deflection is the S wave.

Figure 12-8 Generation of the T wave during repolarization of the ventricles, also showing vectorial analysis of the first stage of repolarization. The total time from the beginning of the T wave to its end is approximately 0.15 second.

ELECTROCARDIOGRAM DURING VENTRICULAR REPOLARIZATION—THE T WAVE

After the ventricular muscle has become depolarized, about 0.15 second later, repolarization begins and proceeds until complete, at about 0.35 second. This repolarization causes the T wave in the ECG.

Because the septum and endocardial areas of the ventricular muscle depolarize first, it seems logical that these areas should repolarize first as well. However, this is not the usual case, because the septum and other endocardial areas have a longer period of contraction than most of the external surfaces of the heart. Therefore, *the greatest portion of ventricular muscle mass to repolarize first is the entire outer surface of the ventricles, especially near the apex of the heart.* The endocardial areas, conversely, normally repolarize last. This sequence of repolarization is postulated to be caused by the high blood pressure inside the ventricles during contraction, which greatly reduces coronary blood flow to the endocardium, thereby slowing repolarization in the endocardial areas.

Because the outer apical surfaces of the ventricles repolarize before the inner surfaces, the positive end of the overall ventricular vector during repolarization is toward the apex of the heart. *As a result, the normal T wave in all three bipolar limb leads is positive, which is also the polarity of most of the normal QRS complex.*

In **Figure 12-8**, five stages of repolarization of the ventricles are denoted by progressive increase of the light tan areas—the repolarized areas. At each stage, the vector extends from the base of the heart toward the apex until it disappears in the last stage. At first, the vector is relatively small because the area of repolarization is small. Later, the vector becomes stronger because of greater degrees

Figure 12-9 Depolarization of the atria and generation of the P wave showing the maximum vector through the atria and the resultant vectors in the three standard leads. At the right are the atrial P and T waves. SA, Sinoatrial node.

of repolarization. Finally, the vector becomes weaker again because the areas of depolarization still persisting become so slight that the total quantity of current flow decreases. These changes also demonstrate that the vector is greatest when about half the heart is in the polarized state and about half is depolarized.

The changes in the ECGs of the three standard limb leads during repolarization are noted under each of the ventricles, depicting the progressive stages of repolarization. Thus, over about 0.15 second, the period of time required for the entire process to take place, the T wave of the ECG is generated.

ATRIAL DEPOLARIZATION—THE P WAVE

Depolarization of the atria begins in the sinus node and spreads in all directions over the atria. Therefore, the point of original electronegativity in the atria is at about the point of entry of the superior vena cava where the sinus node lies, and the direction of initial depolarization is denoted by the black vector in **Figure 12-9**. Furthermore, the vector remains generally in this direction throughout the process of normal atrial depolarization. Because this direction is generally in the positive directions of the axes of the three standard bipolar limb leads I, II, and III, the ECGs recorded from the atria during depolarization are also usually positive in all three of these leads, as shown in **Figure 12-9**. This record of atrial depolarization is known as the atrial P wave.

Repolarization of the Atria—the Atrial T Wave. Spread of depolarization through the atrial muscle is *much slower than in the ventricles* because the atria have no Purkinje system for fast conduction of the depolarization signal. Therefore, the musculature around the sinus node becomes depolarized a long time before the musculature in distal parts of the atria. Consequently, *the area in the atria that also becomes repolarized first is the sinus nodal region, the area that had originally become depolarized first.*

Thus, when repolarization begins, the region around the sinus node becomes positive with respect to the remainder of the atria. Therefore, the atrial repolarization vector is *backward to the vector of depolarization*. (Note that this is opposite to the effect that occurs in the ventricles.) Therefore, as shown to the right in **Figure 12-9**, the so-called atrial T wave follows about 0.15 second after the atrial P wave, but this T wave is on the opposite side of the zero reference line from the P wave; that is, it is normally negative rather than positive in the three standard bipolar limb leads.

In a normal ECG, the *atrial T wave* appears at about the same time that the QRS complex of the ventricles appears. Therefore, it is almost always totally obscured by the large *ventricular QRS complex*, although in some very abnormal states it does appear in the recorded ECG.

Figure 12-10 QRS and T vectorcardiograms.

Vectorcardiogram

As noted previously, the vector of current flow through the heart changes rapidly as the impulse spreads through the myocardium. It changes in two aspects. First, the vector increases and decreases in length because of increasing and decreasing voltage of the vector. Second, the vector changes direction because of changes in the average direction of the electrical potential from the heart. The *vectorcardiogram* depicts these changes at different times during the cardiac cycle, as shown in **Figure 12-10**.

In the large vectorcardiogram of **Figure 12-10**, point 5 is the *zero reference point*, and this point is the negative end of all the successive vectors. While the heart muscle is polarized between heartbeats, the positive end of the vector remains at the zero point because there is no vectorial electrical potential. However, as soon as current begins to flow through the ventricles at the beginning of ventricular depolarization, the positive end of the vector leaves the zero reference point.

When the septum first becomes depolarized, the vector extends downward toward the apex of the ventricles, but it is relatively weak, thus generating the first portion of the ventricular vectorcardiogram, as shown by the positive end of vector 1. As more of the ventricular muscle becomes depolarized, the vector becomes stronger and stronger, usually swinging slightly to one side. Thus, vector 2 of **Figure 12-10** represents the state of depolarization of the ventricles about 0.02 second after vector 1. After another 0.02 second, vector 3 represents the potential, and vector 4 occurs in another 0.01 second. Finally, the ventricles become totally depolarized, and the vector becomes zero once again, as shown at point 5.

The elliptical figure generated by the positive ends of the vectors is called the *QRS vectorcardiogram*.

MEAN ELECTRICAL AXIS OF THE VENTRICULAR QRS AND ITS SIGNIFICANCE

The vectorcardiogram during ventricular depolarization (the QRS vectorcardiogram) shown in **Figure 12-10** is that of a normal heart. Note that during most of the cycle

Figure 12-11 Plotting the mean electrical axis of the ventricles from two electrocardiographic leads (leads I and III).

of ventricular depolarization, the direction of the electrical potential (negative to positive) is from the base of the ventricles toward the apex. This preponderant direction of the potential during depolarization from the base to the apex of the heart is called the *mean electrical axis of the ventricles*. The mean electrical axis of the normal ventricles is 59 degrees. In many pathological conditions of the heart, this direction changes markedly, sometimes even to opposite poles of the heart.

DETERMINING THE ELECTRICAL AXIS FROM STANDARD LEAD ELECTROCARDIOGRAMS

Clinically, the electrical axis of the heart is usually estimated from the standard bipolar limb lead ECGs rather than from the vectorcardiogram. **Figure 12-11** shows a method for performing this estimation. After recording the standard leads, one determines the net potential and polarity of the recordings in leads I and III. In lead I of **Figure 12-11**, the recording is positive, and in lead III, the recording is mainly positive but negative during part of the cycle. If any part of a recording is negative, *this negative potential is subtracted from the positive part of*

the potential to determine the net potential for that lead, as shown by the arrow to the right of the QRS complex for lead III. Then, each net potential for leads I and III is plotted on the axes of the respective leads, with the base of the potential at the point of intersection of the axes, as shown in Figure 12-11.

To determine the vector of the total QRS ventricular mean electrical potential, one draws perpendicular lines (the dashed lines in the figure) from the apices of leads I and III, respectively. The point of intersection of these two perpendicular (dashed) lines represents, by vectorial analysis, the apex of the mean QRS vector in the ventricles, and the point of intersection of the lead I and lead III axes represents the negative end of the mean vector. Therefore, the mean QRS vector is drawn between these two points. The approximate average potential generated by the ventricles during depolarization is represented by the length of this mean QRS vector, and the mean electrical axis is represented by the direction of the mean vector. Thus, the orientation of the mean electrical axis of the normal ventricles, as determined in Figure 12-11, is 59 degrees positive (+59 degrees).

ABNORMAL VENTRICULAR CONDITIONS THAT CAUSE AXIS DEVIATION

Although the mean electrical axis of the ventricles averages about 59 degrees, this axis can swing, even in a normal heart, from about 20 degrees to about 100 degrees. The causes of the normal variations are mainly anatomical differences in the Purkinje distribution system or in the musculature itself of different hearts. However, a number of abnormal conditions of the heart can cause axis deviation beyond the normal limits, as described below.

Change in the Position of the Heart in the Chest. If the heart is angulated to the left, the mean electrical axis of the heart also shifts to the left. Such shift occurs (1) at the end of deep expiration, (2) when a person lies down, because the abdominal contents press upward against the diaphragm, and (3) quite frequently in obese people, whose diaphragms normally press upward against the heart all the time as a result of increased visceral adiposity.

Likewise, angulation of the heart to the right causes the mean electrical axis of the ventricles to shift to the right. This shift occurs (1) at the end of deep inspiration, (2) when a person stands up, and (3) normally in tall lanky people whose hearts hang downward.

Hypertrophy of One Ventricle. When one ventricle hypertrophies greatly, the axis of the heart shifts toward the hypertrophied ventricle for two reasons. First, there is more muscle on the hypertrophied side of the heart than on the other side, which allows for the generation of greater electrical potential on that side. Second, more time is required for the depolarization wave to travel

Figure 12-12 Left axis deviation in a hypertensive heart (hypertrophic left ventricle). Note the slightly prolonged QRS complex as well.

through the hypertrophied ventricle than through the normal ventricle. Consequently, the normal ventricle becomes depolarized considerably in advance of the hypertrophied ventricle, and this situation causes a strong vector from the normal side of the heart toward the hypertrophied side, which remains strongly positively charged. Thus, the axis deviates toward the hypertrophied ventricle.

Vectorial Analysis of Left Axis Deviation Resulting from Hypertrophy of the Left Ventricle. Figure 12-12 shows the three standard bipolar limb lead ECGs. Vectorial analysis demonstrates left axis deviation, with the mean electrical axis pointing in the -15 -degree direction. This is a typical ECG caused by increased muscle mass of the left ventricle. In this case, the axis deviation was caused by hypertension (high arterial blood pressure), which caused the left ventricle to hypertrophy so that it could pump blood against elevated systemic arterial pressure. A similar picture of left axis deviation occurs when the left ventricle hypertrophies as a result of aortic valvular stenosis, aortic valvular regurgitation, or congenital heart conditions in which the left ventricle enlarges while the right ventricle remains relatively normal in size.

Vectorial Analysis of Right Axis Deviation Resulting from Hypertrophy of the Right Ventricle. The ECG of Figure 12-13 shows intense right axis deviation, to an electrical axis of 170 degrees, which is 111 degrees to the right of the normal 59-degree mean ventricular QRS axis. The right axis deviation demonstrated in this figure was caused by hypertrophy of the right ventricle as a result of congenital pulmonary valve stenosis. Right axis deviation also can occur in other congenital heart conditions that cause hypertrophy of the right ventricle, such as tetralogy of Fallot and interventricular septal defect.

Figure 12-13 A high-voltage electrocardiogram for a person with congenital pulmonary valve stenosis with right ventricular hypertrophy. Intense right axis deviation and a slightly prolonged QRS complex are also seen.

Bundle Branch Block Causes Axis Deviation. Ordinarily, the lateral walls of the two ventricles depolarize at almost the same instant because both the left and right bundle branches of the Purkinje system transmit the cardiac impulse to the two ventricular walls at almost the same time. As a result, the potentials generated by the two ventricles (on the two opposite sides of the heart) almost neutralize each other. However, if only one of the major bundle branches is blocked, the cardiac impulse spreads through the normal ventricle before it spreads through the other ventricle. Therefore, depolarization of the two ventricles does not occur, even nearly at the same time, and the depolarization potentials do not neutralize each other. As a result, axis deviation occurs as follows.

Vectorial Analysis of Left Axis Deviation in Left Bundle Branch Block. When the left bundle branch is blocked, cardiac depolarization spreads through the right ventricle two to three times as rapidly as through the left ventricle. Consequently, much of the left ventricle remains polarized for as long as 0.1 second after the right ventricle has become totally depolarized. Thus, the right ventricle becomes electronegative, whereas the left ventricle remains electropositive during most of the depolarization process, and a strong vector projects from the right ventricle toward the left ventricle. In other words, intense left axis deviation of about -50 degrees occurs because the positive end of the vector points toward the left ventricle. This situation is demonstrated in [Figure 12-14](#), which shows typical left axis deviation resulting from left bundle branch block.

Figure 12-14 Left axis deviation caused by left bundle branch block. Note also the greatly prolonged QRS complex.

Because of slowness of impulse conduction when the Purkinje system is blocked, in addition to axis deviation, the duration of the QRS complex is greatly prolonged as a result of extreme slowness of depolarization in the affected side of the heart. One can see this effect by observing the excessive widths of the QRS waves in [Figure 12-14](#) (discussed in greater detail later in this chapter). This extremely prolonged QRS complex differentiates bundle branch block from axis deviation caused by hypertrophy.

Vectorial Analysis of Right Axis Deviation in Right Bundle Branch Block. When the right bundle branch is blocked, the left ventricle depolarizes far more rapidly than the right ventricle, and thus the left side of the ventricles becomes electronegative as long as 0.1 second before the right. Therefore, a strong vector develops, with its negative end toward the left ventricle and its positive end toward the right ventricle. In other words, intense right axis deviation occurs. In [Figure 12-15](#), right axis deviation caused by right bundle branch block is demonstrated, and its vector is analyzed; this analysis shows an axis of about 105 degrees instead of the normal 59 degrees and a prolonged QRS complex because of slow conduction.

CONDITIONS THAT CAUSE ABNORMAL VOLTAGES OF THE QRS COMPLEX

INCREASED VOLTAGE IN THE STANDARD BIPOLAR LIMB LEADS

Normally, the voltages in the three standard bipolar limb leads, as measured from the peak of the R wave to the bottom of the S wave, vary between 0.5 and 2.0 millivolts, with lead III usually recording the lowest

Figure 12-15 Right axis deviation caused by *right bundle branch block*. Note also the greatly prolonged QRS complex.

voltage and lead II the highest voltage. However, these relationships are not invariable, even for the normal heart. In general, when the sum of the voltages of all the QRS complexes of the three standard leads is greater than 4 millivolts, the patient is considered to have a high-voltage ECG.

The cause of high-voltage QRS complexes is usually increased muscle mass of the heart, which ordinarily results from *hypertrophy of the muscle* in response to excessive load on one part of the heart or the other. For example, the right ventricle hypertrophies when it must pump blood through a stenotic pulmonary valve or when the pulmonary arterial pressure is elevated, and the left ventricle hypertrophies when a person has high systemic arterial blood pressure. The increased quantity of muscle generates increased electricity around the heart. As a result, the electrical potentials recorded in the electrocardiographic leads are considerably greater than normal, as shown in **Figures 12-12 and 12-13**.

DECREASED VOLTAGE OF THE ELECTROCARDIOGRAM

Decreased Voltage Caused by Cardiac Myopathies.

One of the most common causes of decreased voltage of the QRS complex is a series of *old myocardial infarctions* with resultant *diminished muscle mass*. This condition also causes the depolarization wave to move through the ventricles slowly and prevents major portions of the heart from becoming massively depolarized all at once. Consequently, this condition causes some prolongation of the QRS complex, along with the decreased voltage. **Figure 12-16** shows a typical low-voltage ECG with prolongation of the QRS complex, which is common after multiple small infarctions of the heart have caused local delays of impulse conduction and reduced voltages due to loss of muscle mass throughout the ventricles. Infiltrative myocardial diseases also cause low ECG voltage. For example, in cardiac amyloidosis, abnormal proteins infiltrate the myocardium, leading to reduced voltages, particularly in the limb leads.

Figure 12-16 A low-voltage electrocardiogram following local damage throughout the ventricles caused by a *previous myocardial infarction*.

Decreased Voltage Caused by Conditions Surrounding the Heart.

One of the most important causes of decreased voltage in electrocardiographic leads is excessive *fluid in the pericardium* (*pericardial effusion*). Because extracellular fluid easily conducts electrical currents, a large portion of the electricity flowing out of the heart is conducted from one part of the heart to another through the pericardial fluid. Thus, this effusion effectively “short-circuits” the electrical potentials generated by the heart, decreasing the electrocardiographic voltages that reach the outside surfaces of the body. *Pleural effusion*, to a lesser extent, also can short-circuit the electricity around the heart so that the voltages at the surface of the body and in the ECGs are decreased.

Pulmonary emphysema can decrease the electrocardiographic potentials, but for a different reason than that of pericardial effusion. In persons with pulmonary emphysema, conduction of electrical current through the lungs is depressed considerably because of an excessive quantity of air in the lungs. Also, the chest cavity enlarges, and the lungs tend to envelop the heart to a greater extent than normal. Therefore, the lungs act as an insulator to prevent the spread of electrical voltage from the heart to the surface of the body, which results in decreased electrocardiographic potentials in the various leads.

PROLONGED AND BIZARRE PATTERNS OF THE QRS COMPLEX

CARDIAC HYPERTROPHY OR DILATION PROLONG THE QRS COMPLEX

The QRS complex lasts as long as depolarization continues to spread through the ventricles—that is, as long as part of the ventricles is depolarized and part is still polarized. Therefore, *prolonged conduction* of the impulse through the ventricles always causes a prolonged QRS complex. Such prolongation often occurs when one or both ventricles are hypertrophied or dilated because of the longer pathway that the impulse must then travel. The normal QRS complex lasts 0.06 to 0.08 second, whereas in hypertrophy or dilation of the left or right ventricle, the QRS complex may be prolonged to 0.09 to 0.12 second.

PURKINJE SYSTEM BLOCK PROLONGS THE QRS COMPLEX

When the Purkinje fibers are blocked, the cardiac impulse must then be conducted by the ventricular muscle instead of through the Purkinje system. This action decreases the velocity of impulse conduction to about one-third of normal. Therefore, if complete block of one of the bundle branches occurs, the duration of the QRS complex is usually increased to 0.14 second or longer.

In general, a QRS complex is considered to be abnormally long when it lasts more than 0.09 second. When it lasts more than 0.12 second, the prolongation is almost certainly caused by a pathological block somewhere in the ventricular conduction system, as shown by the ECGs for bundle branch block in [Figures 12-14 and 12-15](#).

CONDITIONS THAT CAUSE BIZARRE QRS COMPLEXES

Bizarre patterns of the QRS complex are usually caused by two conditions: (1) destruction of cardiac muscle in various areas throughout the ventricular system, with replacement of this muscle by scar tissue; and (2) multiple small local blocks in the conduction of impulses at many points in the Purkinje system. As a result, cardiac impulse conduction becomes irregular, causing rapid shifts in voltages and axis deviations. This irregularity often causes double or even triple peaks in some of the electrocardiographic leads, such as those shown in [Figure 12-14](#).

CURRENT OF INJURY

Many different cardiac abnormalities, especially those that damage the heart muscle, may cause part of the heart to remain partially or totally *depolarized all the time*. When this condition occurs, current flows between the pathologically depolarized and normally polarized areas, even between heartbeats. This condition is called a *current of injury*. Note especially that *the injured part of the heart is negative, because this is the part that is depolarized and emits negative charges into the surrounding fluids, whereas the remainder of the heart is neutral or in positive polarity*.

Some abnormalities that can cause a current of injury are as follows: (1) *mechanical trauma*, which sometimes makes the membranes remain so permeable that full repolarization cannot take place; (2) *infectious processes* that damage the muscle membranes; and (3) *ischemia of local areas of heart muscle caused by local coronary occlusions*, which is the most common cause of a current of injury in the heart. During ischemia, not enough nutrients from the coronary blood supply are available to the heart muscle to maintain normal membrane polarization.

EFFECT OF CURRENT OF INJURY ON THE QRS COMPLEX

In [Figure 12-17](#), a small area in the base of the left ventricle is newly infarcted (i.e., there is loss of coronary blood flow). Therefore, during the T-P interval—that is, when the normal ventricular muscle is totally polarized—abnormal *negative* current still flows from the infarcted area at the base of the left ventricle and spreads toward the rest of the ventricles.

Figure 12-17 Effect of a current of injury on the electrocardiogram.

The vector of this current of injury, as shown in the first heart in **Figure 12-17**, is in a direction of about 125 degrees, with the base of the vector, the *negative end*, toward the injured muscle. As shown in the lower portions of the figure, even before the QRS complex begins, *this vector causes an initial record in lead I below the zero potential line*, because the projected vector of the current of injury in lead I points toward the negative end of the lead I axis. In lead II, the record is above the line because the projected vector points more toward the positive terminal of the lead. In lead III, the projected vector points in the same direction as the positive terminal of lead III so that the record is positive. Furthermore, because the vector lies almost exactly in the direction of the axis of lead III, the voltage of the current of injury in lead III is much greater than in either lead I or lead II.

As the heart then proceeds through its normal process of depolarization, the septum first becomes depolarized; then the depolarization spreads down to the apex and back toward the bases of the ventricles. The last portion of the ventricles to become totally depolarized is the base of the right ventricle because the base of the left ventricle is already totally and permanently depolarized. By vectorial analysis, the successive stages of electrocardiographic generation by the depolarization wave traveling through the ventricles can be constructed graphically, as demonstrated in the lower part of **Figure 12-17**.

When the heart becomes totally depolarized, at the end of the depolarization process (as noted by the next to last stage in **Figure 12-17**), all the ventricular muscle is in a negative state. Therefore, at this instant in the ECG, no current flows from the ventricles to the electrocardiographic electrodes because now both the injured heart muscle and the contracting muscle are depolarized.

Next, as repolarization takes place, all the heart finally repolarizes, except the area of permanent depolarization in the injured base of the left ventricle. Thus, repolarization causes a return of the current of injury in each lead, as noted at the far right in **Figure 12-17**.

THE J POINT IS THE ZERO REFERENCE POTENTIAL FOR ANALYZING CURRENT OF INJURY

One might think that the ECG machines could determine when no current is flowing around the heart. However, many stray currents exist in the body, such as currents resulting from skin potentials and from differences in ionic concentrations in different fluids of the body. Therefore, when two electrodes are connected between the arms or between an arm and a leg, these stray currents make it impossible to predetermine the exact zero reference level in the ECG.

For these reasons, the following procedure must be used to determine the zero potential level: First, one notes *the exact point at which the wave of depolarization just completes its passage through the heart*, which occurs at

the end of the QRS complex. At exactly this point, all parts of the ventricles have become depolarized, including both the damaged parts and the normal parts, so no current is flowing around the heart. Even the current of injury disappears at this point. Therefore, the potential of the electrocardiogram at this instant is at zero voltage. This point is known as the *J point* in the ECG, as shown in **Figure 12-18**.

Then, for analysis of the electrical axis of the injury potential caused by a current of injury, a horizontal line is drawn in the ECG for each lead at the level of the J point. This horizontal line is then the *zero potential level* in the ECG from which all potentials caused by currents of injury must be measured.

Use of the J Point in Plotting Axis of Injury Potential.

Figure 12-18 shows ECGs (leads I and III) from an injured heart. Both records show injury potentials. In other words, the J point of each of these two ECGs is not on the same line as the T-P segment. In the figure, a horizontal line has been drawn through the J point to represent the zero voltage level in each of the two recordings. The injury potential in each lead is the difference between the voltage of the ECG immediately before onset of the P wave and the zero voltage level determined from the J point. In lead I, the recorded voltage of the injury potential is above the zero potential level and is therefore positive. Conversely, in lead III, the injury potential is below the zero voltage level and therefore is negative.

At the bottom in **Figure 12-18**, the respective injury potentials in leads I and III are plotted on the coordinates of these leads, and the resultant vector of the injury potential for the whole ventricular muscle mass is determined by vectorial analysis as described. In this case, the

Figure 12-18 J point as the zero reference potential of the electrocardiograms for leads I and III. Also, the method for plotting the axis of the injury potential is shown in the *bottom panel*.

resultant vector extends from the right side of the ventricles toward the left and slightly upward, with an axis of about -30 degrees. If one places this vector for the injury potential directly over the ventricles, the negative end of the vector points toward the permanently depolarized, "injured" area of the ventricles. In the example shown in **Figure 12-18**, the injured area would be in the lateral wall of the right ventricle.

This analysis is obviously complex. However, it is essential that the student review it again and again until it is thoroughly understood. *No other aspect of electrocardiographic analysis is more important.*

CORONARY ISCHEMIA AS A CAUSE OF INJURY POTENTIAL

Insufficient blood flow to the cardiac muscle depresses the metabolism of the muscle for at least three reasons: (1) lack of oxygen; (2) excess accumulation of carbon dioxide; and (3) lack of sufficient food nutrients. Consequently, repolarization of the muscle membrane cannot occur in areas of severe myocardial ischemia. Often, the heart muscle does not die because the blood flow is sufficient to maintain life of the muscle, even though it is not sufficient to cause normal repolarization of the membranes. As long as this state exists, an injury potential continues to flow during the diastolic portion (the T-P portion) of each heart cycle.

Extreme ischemia of the cardiac muscle occurs after coronary occlusion, and a strong current of injury flows from the infarcted area of the ventricles during the T-P interval between heartbeats, as shown in **Figs. 12-19** and

12-20. Therefore, one of the most important diagnostic features of ECGs recorded after acute coronary thrombosis is the current of injury.

Acute Anterior Wall Infarction. **Figure 12-19** shows the ECG in the three standard bipolar limb leads and in one chest lead (lead V_2) recorded from a patient with acute anterior wall cardiac infarction. The most important diagnostic feature of this ECG is the intense injury potential in chest lead V_2 . If one draws a zero horizontal potential line through the J point of this ECG, a strong negative injury potential during the T-P interval is found, which means that the chest electrode over the front of the heart is in an area of strongly negative potential. In other words, the negative end of the injury potential vector in this heart is against the anterior chest wall. This means that the current of injury is emanating from the anterior wall of the ventricles, which diagnoses this condition as an *anterior wall infarction*.

When analyzing the injury potentials in leads I and III, one finds a negative potential in lead I and a positive potential in lead III. This finding means that the resultant vector of the injury potential in the heart is about $+150$ degrees, with the negative end pointing toward the left ventricle and the positive end pointing toward the right ventricle. Thus, in this ECG, the current of injury is coming mainly from the left ventricle, as well as from the anterior wall of the heart. Therefore, one would conclude that this anterior wall infarction almost certainly is caused by thrombosis of the anterior descending branch of the left coronary artery.

Figure 12-19 Current of injury in acute anterior wall infarction. Note the intense injury potential in lead V_2 .

Figure 12-20 Injury potential in an acute posterior wall, apical infarction.

Posterior Wall Infarction. Figure 12-20 shows the three standard bipolar limb leads and one chest lead (lead V₂) from a patient with a posterior wall infarction. The major diagnostic feature of this ECG is also in the chest lead. If a zero potential reference line is drawn through the J point of this lead, it is readily apparent that during the T-P interval, the potential of the current of injury is positive. This means that the positive end of the vector is in the direction of the anterior chest wall, and the negative end (the injured end of the vector) points away from the chest wall. In other words, the current of injury is coming from the back of the heart opposite to the anterior chest wall, which is the reason this type of ECG is the basis for diagnosing posterior wall infarction.

If one analyzes the injury potentials from leads II and III of Figure 12-20, it is readily apparent that the injury potential is negative in both leads. By vectorial analysis, as shown in the figure, one finds that the resultant vector of the injury potential is about -95 degrees, with the negative end pointing downward and the positive end pointing upward. Thus, because the infarct, as indicated by the chest lead, is on the posterior wall of the heart and, as indicated by the injury potentials in leads II and III, it is in the apical portion of the heart, one would suspect that this infarct is near the apex on the posterior wall of the left ventricle.

Infarction in Other Parts of the Heart. Using the same procedures demonstrated in the preceding discussions of anterior and posterior wall infarctions, it is often possible to determine the locus of an infarcted area emitting a current of injury. In making such vectorial analyses, it should be remembered that *the positive end of the injury potential vector points toward the normal cardiac muscle, and the negative end points toward the injured portion of the heart that is emitting the current of injury.*

ECG Progression During and After Acute Coronary Thrombosis. Figure 12-21 shows a V₃ chest lead from a patient with an acute anterior wall infarction, demonstrating changes in the ECG from the day of the attack to 1 week later, 3 weeks later and, finally, 1 year later. From this ECG, one can see that the injury potential is strong immediately after the acute attack (the T-P segment is displaced positively from the S-T segment). However, af-

Figure 12-21 Recovery of the myocardium after *anterior wall infarction*, demonstrating the disappearance of the injury potential that is present on the first day after the infarction.

ter about 1 week, the injury potential has diminished considerably and, after 3 weeks, it is gone. After that, the ECG does not change greatly during the next year. This is the usual recovery pattern after an acute myocardial infarction of moderate degree, showing that the *new collateral coronary blood flow* develops enough to re-establish appropriate nutrition to most of the infarcted area.

In some patients who experience myocardial infarction, the infarcted area never redevelops adequate coronary blood supply. Often, some of the heart muscle dies but, if the muscle does not die, it will continue to show an injury potential as long as the ischemia exists, particularly during bouts of exercise when the heart is overloaded.

Q Waves on an ECG Represent Old Myocardial Infarction. Figure 12-22 shows leads I and III after *anterior and posterior infarctions* about 1 year after the acute heart attacks. Usually, a Q wave has developed at the beginning of the QRS complex in lead I in anterior infarction because of the loss of muscle mass in the anterior wall of the left ventricle but, in a posterior infarction, a Q wave has developed at the beginning of the QRS complex in lead III because of loss of muscle in the posterior apical part of the ventricle.

These configurations are certainly not found in all cases of old myocardial infarction. Local loss of muscle and local points of cardiac signal conduction block can cause very bizarre QRS patterns (e.g., especially prominent Q waves), decreased voltage, and QRS prolongation.

Current of Injury in Angina Pectoris. The term *angina pectoris* means pain from the heart felt in the pectoral regions of the chest. This pain usually also radiates into the left neck area and down the left arm. The pain is typically caused by moderate ischemia of the heart. Usually, no pain is felt as long as the person is quiet, but as soon as the heart is overworked, the pain appears.

An injury potential sometimes appears on the ECG during an attack of severe angina pectoris because the coronary insufficiency becomes great enough to prevent adequate repolarization of some areas of the heart during diastole.

Figure 12-22 Electrocardiograms of anterior and posterior wall infarctions that occurred about 1 year previously, showing a Q wave in lead I in an anterior wall infarction and a Q wave in lead III in a posterior wall infarction.

ABNORMALITIES IN THE T WAVE

Earlier in the chapter, we noted that the T wave is normally positive in all the standard bipolar limb leads, and that this is caused by repolarization of the apex and outer surfaces of the ventricles ahead of the intraventricular surfaces. That is, the T wave becomes abnormal when the normal sequence of repolarization does not occur. Several factors, including myocardial ischemia, can change this sequence of repolarization.

EFFECT OF SLOW CONDUCTION OF THE DEPOLARIZATION WAVE ON THE CHARACTERISTICS OF THE T WAVE

Referring to [Figure 12-14](#), note that the QRS complex is considerably prolonged. The reason for this prolongation is *delayed conduction in the left ventricle* resulting from left bundle branch block. This delayed conduction causes the left ventricle to become depolarized about 0.08 second after depolarization of the right ventricle, which gives a strong mean QRS vector *to the left*. However, the refractory periods of the right and left ventricular muscle masses are not greatly different from each other. Therefore, the right ventricle begins to repolarize long before the left ventricle, which causes strong positivity in the right ventricle and negativity in the left ventricle when the T wave is developing. In other words, the mean axis of the T wave is now deviated *to the right*, which is opposite to the mean electrical axis of the QRS complex in the same ECG. Thus, when conduction of the depolarization impulse through the ventricles is greatly delayed, the T wave is almost always of opposite polarity to that of the QRS complex.

SHORTENED DEPOLARIZATION IN PORTIONS OF THE VENTRICULAR MUSCLE CAN CAUSE T-WAVE ABNORMALITIES

If the base of the ventricles should exhibit an abnormally short period of depolarization—that is, a shortened action potential—repolarization of the ventricles would not begin at the apex, as it normally does. Instead, the base of the ventricles would repolarize ahead of the apex, and the vector of repolarization would point from the apex toward the base of the heart, opposite to the standard vector of repolarization. Consequently, the T wave in all three standard leads would be negative rather than the usual positive. Thus, the simple fact that the base of the ventricles has a shortened period of depolarization is sufficient to cause marked changes in the T wave, even to the extent of changing the entire T-wave polarity, as shown in [Figure 12-23](#).

Figure 12-23 An inverted T wave resulting from mild *ischemia* at the base of the ventricles.

Figure 12-24 A biphasic T wave caused by *digitalis* toxicity.

Mild ischemia is the most common cause of shortening of depolarization of cardiac muscle because this condition increases current flow through the potassium channels. When the ischemia occurs in only one area of the heart, the depolarization period of this area decreases out of proportion to that in other portions. As a result, changes in the T-wave morphology, such as inversion or biphasic waveforms, can be evidence of myocardial ischemia. The ischemia might result from chronic, progressive coronary stenosis (narrowing), acute coronary occlusion, coronary artery spasm, or relative coronary insufficiency that occurs during exercise or severe anemia.

Effect of Digitalis on the T Wave. As discussed in [Chapter 22](#), digitalis is a drug that can be used during heart failure to increase the strength of cardiac muscle contraction. However, when an overdose of digitalis is given, depolarization duration in one part of the ventricles may be increased out of proportion to that of other parts. As a result, nonspecific changes, such as T-wave inversion or biphasic T waves, may occur in one or more of the electrocardiographic leads. A biphasic T wave caused by excessive administration of digitalis is shown in [Figure 12-24](#). Therefore, changes in the T wave during digitalis administration are often the earliest signs of digitalis toxicity.

Bibliography

See the bibliography for [Chapter 13](#).

Cardiac Arrhythmias and Their Electrocardiographic Interpretation

Some of the most distressing types of heart malfunction occur because of abnormal rhythm of the heart. For example, sometimes the beat of the atria is not coordinated with the beat of the ventricles, so the atria no longer function to optimize ventricular filling.

The purpose of this chapter is to discuss the physiology of common cardiac arrhythmias and their effects on heart pumping, as well as their diagnosis by electrocardiography. The causes of the cardiac arrhythmias are usually one or a combination of the following abnormalities in the rhythmicity-conduction system of the heart:

- Abnormal rhythmicity of the pacemaker
- Shift of the pacemaker from the sinus node to another place in the heart
- Blocks at different points in the spread of the impulse through the heart
- Abnormal pathways of impulse transmission through the heart
- Spontaneous generation of spurious impulses in almost any part of the heart

ABNORMAL SINUS RHYTHMS

TACHYCARDIA

The term *tachycardia* means *fast heart rate*, which usually is defined as faster than 100 beats/min in an adult. An electrocardiogram (ECG) recorded from a patient with tachycardia is shown in [Figure 13-1](#). This ECG is normal except that the heart rate, as determined from the time intervals between QRS complexes, is about 150 beats/min instead of the normal 72 beats/min. Some causes of tachycardia include increased body temperature, dehydration, blood loss anemia, stimulation of the heart by the sympathetic nerves, and toxic conditions of the heart.

The heart rate usually increases about 10 beats/min for each degree Fahrenheit increase in body temperature (with an increase of 18 beats/min for each degree Celsius), up to a body temperature of about 105°F (40.5°C). Beyond this, the heart rate may decrease because of progressive debility of the heart muscle as a result of the fever. Fever causes tachycardia because an increased temperature increases the rate of metabolism of the sinus node, which in turn directly increases its excitability and rate of rhythm.

Many factors can cause the sympathetic nervous system to excite the heart, as discussed in this text. For example, when a patient sustains severe blood loss, sympathetic reflex stimulation of the heart may increase the heart rate to 150 to 180 beats/min. Simple weakening of the myocardium usually increases the heart rate because the weakened heart does not pump blood into the arterial tree to a normal extent, causing reductions in blood pressure and eliciting sympathetic reflexes to increase the heart rate.

BRADYCARDIA

The term *bradycardia* means a slow heart rate, usually defined as fewer than 60 beats/min. Bradycardia is shown by the ECG in [Figure 13-2](#).

Bradycardia in Athletes. The well-trained athlete's heart is often larger and considerably stronger than that of a normal person, which allows the athlete's heart to pump a large stroke volume output per beat, even during periods of rest. When the athlete is at rest, increased quantities of blood pumped into the arterial tree with each beat initiate feedback circulatory reflexes or other effects that cause bradycardia.

Vagal Stimulation Causes Bradycardia. Any circulatory reflex that stimulates the vagus nerves causes release of acetylcholine at the vagal endings in the heart, resulting in a parasympathetic effect. Perhaps the most striking example of this phenomenon occurs in patients with *carotid sinus syndrome*. In these patients, the pressure receptors (baroreceptors) in the carotid sinus region of the carotid artery walls are excessively sensitive. Therefore, even mild external pressure on the neck elicits a strong baroreceptor reflex, causing intense vagal-acetylcholine effects on the heart, including extreme bradycardia. Sometimes this reflex is so powerful that it actually stops the heart for 5 to 10 seconds, leading to loss of consciousness (syncope).

SINUS ARRHYTHMIA

[Figure 13-3](#) shows a *cardiotachometer* recording of the heart rate, at first during normal respiration and then, in the second half of the record, during deep

Figure 13-1. Sinus tachycardia (lead I).

Figure 13-2. Sinus bradycardia (lead III).

Figure 13-3. Sinus arrhythmia as recorded by a cardiometer. To the left is the record when the subject was breathing normally; to the right, when the subject was breathing deeply.

respiration. A cardiometer is an instrument that records the duration of the interval between the successive QRS complexes in the ECG by the height of successive spikes. Note from this record that the heart rate increased and decreased no more than 5% during quiet respiration (shown on the left half of the record). Then, during deep respiration, the heart rate increased and decreased with each respiratory cycle by as much as 30%.

Sinus arrhythmia can result from any one of many circulatory conditions that alter the strengths of the sympathetic and parasympathetic nerve signals to the heart sinus node. The respiratory type of sinus arrhythmia results mainly from the spillover of signals from the medullary respiratory center into the adjacent vasomotor center during inspiratory and expiratory cycles of respiration. The spillover signals cause alternate increases and decreases in the number of impulses transmitted through the sympathetic and vagus nerves to the heart.

HEART BLOCK WITHIN THE INTRACARDIAC CONDUCTION PATHWAYS

SINOATRIAL BLOCK

In rare cases, the impulse from the sinus node is blocked before it enters the atrial muscle. This phenomenon is demonstrated in Figure 13-4, which shows sudden cessation of P waves, with resultant standstill of the atria. However, the ventricles pick up a new rhythm, with the impulse usually originating spontaneously in the atrioventricular (A-V) node, so the rate of the ventricular QRS-T complex is slowed but not otherwise altered. Sinoatrial block can be due to myocardial ischemia affecting the

Figure 13-4. Sinoatrial (SA) nodal block, with atrioventricular nodal rhythm during the block period (lead III).

sinus node, inflammation or infection of the heart, or side effects from certain medications, and it can be observed in well-trained athletes.

ATRIOVENTRICULAR BLOCK

The only means whereby impulses ordinarily can pass from the atria into the ventricles is through the *A-V bundle*, also known as the *bundle of His*. Conditions that can either decrease the rate of impulse conduction in this bundle or block the impulse entirely are as follows:

1. *Ischemia of the A-V node or A-V bundle fibers* often delays or blocks conduction from the atria to the ventricles. Coronary insufficiency can cause ischemia of the A-V node and bundle in the same way that it can cause ischemia of the myocardium.
2. *Compression of the A-V bundle* by scar tissue or by calcified portions of the heart can depress or block conduction from the atria to the ventricles.
3. *Inflammation of the A-V node or A-V bundle* can depress conduction from the atria to the ventricles. Inflammation results frequently from different types of myocarditis that are caused, for example, by diphtheria or rheumatic fever.
4. *Extreme stimulation of the heart by the vagus nerves* in rare cases blocks impulse conduction through the A-V node. Such vagal excitation occasionally results from strong stimulation of the baroreceptors in people with *carotid sinus syndrome*, discussed earlier in relationship to bradycardia.
5. *Degeneration of the A-V conduction system*, which is sometimes seen in older patients.
6. *Medications such as digitalis or beta-adrenergic antagonists* can, in some cases, impair A-V conduction.

INCOMPLETE ATRIOVENTRICULAR BLOCK

First-Degree Block—Prolonged P-R Interval. The usual lapse of time between the *beginning* of the P wave and the *beginning* of the QRS complex is about 0.16 second when the heart is beating at a normal rate. This so-called *P-R interval* usually decreases in length with a faster heartbeat and increases with a slower heartbeat. In general, when the P-R interval increases to more than 0.20 second, the P-R interval is said to be prolonged, and the patient is said to have *first-degree incomplete heart block*.

Figure 13-5 shows an ECG with a prolonged P-R interval; the interval in this case is about 0.30 second instead of the normal 0.20 second or less. Thus, first-degree block

Figure 13-5. Prolonged P-R interval caused by first-degree atrioventricular heart block (lead II).

is defined as a *delay* of conduction from the atria to the ventricles but not actual blockage of conduction. The P-R interval seldom increases above 0.35 to 0.45 second because, by that time, conduction through the A-V bundle is depressed so much that conduction stops entirely. One means for determining the severity of some heart diseases, such as *acute rheumatic heart disease*, for example, is to measure the P-R interval.

Second-Degree Block. When conduction through the A-V bundle is slowed enough to increase the P-R interval to 0.25 to 0.45 second, the action potential is sometimes strong enough to pass through the bundle into the ventricles and sometimes not strong enough to do so. In this case, there will be an atrial P wave but no QRS-T wave, and it is said that there are “dropped beats” of the ventricles. This condition is called *second-degree heart block*.

There are two types of second-degree A-V block—*Mobitz type I* (also known as *Wenckebach periodicity*) and *Mobitz type II*. Type I block is characterized by progressive prolongation of the P-R interval until a ventricular beat is dropped and is then followed by resetting of the P-R interval and repeating of the abnormal cycle. A type I block is almost always caused by abnormality of the A-V node. In most cases, this type of block is benign, and no specific treatment is needed.

In type II block, there is usually a fixed number of non-conducted P waves for every QRS complex. For example, a 2:1 block implies that there are two P waves for every QRS complex. At other times, rhythms of 3:2 or 3:1 may develop. In contrast to type I block, with type II block the P-R interval does not change before the dropped beat; it remains fixed. Type II block is generally caused by an abnormality of the bundle of His–Purkinje system and may require implantation of a pacemaker to prevent progression to complete heart block and cardiac arrest.

Figure 13-6 shows progressive P-R interval prolongation typical of type I (Wenckebach) block. Note prolongation of the P-R interval preceding the dropped beat, followed by a shortened P-R interval after the dropped beat.

Complete A-V Block (Third-Degree Block). When the condition causing poor conduction in the A-V node or A-V bundle becomes severe, complete block of the impulse from the atria into the ventricles occurs. In this case, the ventricles spontaneously establish their own signal, usually originating in the A-V node or A-V bundle distal to the block. Therefore, the P waves become dissociated from the QRS-T complexes, as shown in **Figure 13-7**. Note

Figure 13-6. Type I second-degree atrioventricular block showing progressive P-R prolongation prior to the dropped beat.

Figure 13-7. Complete atrioventricular block (lead II).

that the *rate of rhythm of the atria* in this ECG is about 100 beats/min, whereas the *rate of ventricular beat* is less than 40 beats/min. Furthermore, there is no relationship between the rhythm of the P waves and that of the QRS-T complexes because the ventricles have “escaped” from control by the atria and are beating at their own natural rate, controlled most often by rhythmical signals generated distal to the A-V node or A-V bundle where the block occurs.

Stokes-Adams Syndrome—Ventricular Escape. In some patients with A-V block, the total block comes and goes; that is, impulses are conducted from the atria into the ventricles for a period of time and then, suddenly, impulses are not conducted. The duration of block may be a few seconds, a few minutes, a few hours, or even weeks or longer before conduction returns. This condition occurs in hearts with borderline ischemia of the conductive system.

Each time A-V conduction ceases, the ventricles often do not start their own beating until after a delay of 5 to 30 seconds. This delay results from the phenomenon called *overdrive suppression*. Overdrive suppression means that ventricular excitability is at first suppressed because the ventricles have been driven by the atria at a rate greater than their natural rate of rhythm. However, after a few seconds, some part of the Purkinje system beyond the block, usually in the distal part of the A-V node beyond the blocked point in the node, or in the A-V bundle, begins discharging rhythmically at a rate of 15 to 40 times/min, acting as the pacemaker of the ventricles. This phenomenon is called *ventricular escape*.

Because the brain cannot remain active for more than 4 to 7 seconds without blood supply, most people faint a few seconds after complete block occurs because the heart does not pump any blood for 5 to 30 seconds, until the ventricles “escape.” After escape, however, the slowly beating ventricles (typically beating less than 40 beats/min) usually pump enough blood to allow rapid recovery from the faint and then to sustain the person. These

Figure 13-8. Partial intraventricular block—electrical alternans (lead I).

periodic fainting spells (syncope) are known as the *Stokes-Adams syndrome*.

Occasionally, the interval of ventricular standstill at the onset of complete block is so long that it becomes detrimental to the patient's health or even causes death. Consequently, most of these patients are provided with an *artificial pacemaker*, a small battery-operated electrical stimulator planted beneath the skin, with electrodes usually connected to the right ventricle. The pacemaker provides continued rhythmical impulses to the ventricles.

INCOMPLETE INTRAVENTRICULAR BLOCK—ELECTRICAL ALTERNANS

Most of the same factors that can cause A-V block can also block impulse conduction in the peripheral ventricular Purkinje system. Figure 13-8 shows the condition known as *electrical alternans*, which results from partial intraventricular block every other heartbeat. This ECG also shows *tachycardia* (rapid heart rate), which is probably the reason the block has occurred. This is because when the rate of the heart is rapid, it may be impossible for some portions of the Purkinje system to recover from the previous refractory period quickly enough to respond during every succeeding heartbeat. Also, many conditions that depress the heart, such as ischemia, myocarditis, or digitalis toxicity, can cause incomplete intraventricular block, resulting in electrical alternans.

PREMATURE CONTRACTIONS

A premature contraction is a contraction of the heart before the time that normal contraction would have been expected. This condition is also called *extrasystole*, *premature beat*, or *ectopic beat*.

CAUSES OF PREMATURE CONTRACTIONS

Most premature contractions result from *ectopic foci* in the heart, which emit abnormal impulses at odd times during the cardiac rhythm. Possible causes of ectopic foci are as follows: (1) local areas of ischemia; (2) small calcified plaques at different points in the heart, which press against the adjacent cardiac muscle so that some of the fibers are irritated; and (3) toxic irritation of the A-V node, Purkinje system, or myocardium caused by infection, drugs, nicotine, or caffeine. The mechanical initiation of premature contractions is also frequent during cardiac catheterization; large numbers of premature contractions often occur when the catheter enters the ventricle and presses against the endocardium.

Figure 13-9. Atrial premature beat (lead I).

Figure 13-10. Atrioventricular nodal premature contraction (lead III).

PREMATURE ATRIAL CONTRACTIONS

Figure 13-9 shows a single premature atrial contraction (PAC). The P wave of this beat occurred too soon in the heart cycle; the P-R interval is shortened, indicating that the ectopic origin of the beat is in the atria near the A-V node. Also, the interval between the premature contraction and the next succeeding contraction is slightly prolonged, which is called a *compensatory pause*. One of the reasons for this compensatory pause is that the premature contraction originated in the atrium some distance from the sinus node, and the impulse had to travel through a considerable amount of atrial muscle before it discharged the sinus node. Consequently, the sinus node discharged late in the premature cycle, which made the succeeding sinus node discharge also late in appearing.

PACs occur frequently in otherwise healthy people. They often occur in athletes whose hearts are in a very healthy condition. Mild toxic conditions resulting from such factors as smoking, lack of sleep, ingestion of too much coffee, alcoholism, and use of various drugs can also initiate such contractions.

Pulse Deficit. When the heart contracts ahead of schedule, the ventricles will not have filled with blood normally, and the stroke volume output during that contraction is depressed or is almost absent. Therefore, the pulse wave passing to the peripheral arteries after a premature contraction may be so weak that it cannot be felt in the radial artery. Thus, a deficit in the number of radial pulses occurs when compared with the actual number of contractions of the heart.

A-V NODAL OR A-V BUNDLE PREMATURE CONTRACTIONS

Figure 13-10 shows a premature contraction that originated in the A-V node or A-V bundle. The P wave is missing from the electrocardiographic record of the premature contraction. Instead, the P wave is superimposed

Figure 13-11. Premature ventricular contractions (PVCs) demonstrated by the large abnormal QRS-T complexes (leads II and III). The axis of the premature contractions is plotted in accordance with the principles of vectorial analysis explained in Chapter 12 and shows the origin of the PVC to be near the base of the ventricles.

onto the QRS-T complex because the cardiac impulse traveled backward into the atria at the same time that it traveled forward into the ventricles. This P wave slightly distorts the QRS-T complex, but the P wave itself cannot be discerned as such. In general, A-V nodal premature contractions have the same significance and causes as atrial premature contractions.

PREMATURE VENTRICULAR CONTRACTIONS

The ECG in Figure 13-11 shows a series of premature ventricular contractions (PVCs) alternating with normal contractions in a pattern known as *bigeminy*. PVCs cause specific effects in the ECG, as follows:

1. *The QRS complex is usually considerably prolonged.*
The reason for this prolongation is that the impulse is conducted mainly through slowly conducting muscle of the ventricles rather than through the Purkinje system.
2. *The QRS complex has a high voltage.* When the normal impulse passes through the heart, it passes through both ventricles nearly simultaneously. Consequently, in the normal heart, the depolarization waves of the two sides of the heart—mainly of opposite polarity to each other—partially neutralize each other in the ECG. When a PVC occurs, the impulse almost always travels in only one direction, so there is no such neutralization effect, and one entire side or end of the ventricles is depolarized ahead of the other, which causes large electrical potentials, as shown for the PVCs in Figure 13-11.

3. After almost all PVCs, the *T wave has an electrical potential polarity exactly opposite to that of the QRS complex* because the *slow conduction of the impulse* through the cardiac muscle causes the muscle fibers that depolarize first also to repolarize first.

Some PVCs are relatively benign in their effects on overall pumping by the heart; they can result from such factors as cigarettes, excessive intake of coffee, lack of sleep, various mild toxic states, and even emotional irritability. Conversely, many other PVCs result from stray impulses or re-entrant signals that originate around the borders of infarcted or ischemic areas of the heart. The presence of such PVCs is not to be taken lightly. People with significant numbers of PVCs often have a much higher than normal risk of developing spontaneous lethal ventricular fibrillation, presumably initiated by one of the PVCs. This development is especially true when the PVCs occur during the vulnerable period for causing fibrillation, just at the end of the T wave, when the ventricles are coming out of refractoriness, as explained later in this chapter.

Vector Analysis of the Origin of an Ectopic Premature Ventricular Contraction. In Chapter 12, the principles of vectorial analysis are explained. By applying these principles, one can determine from the ECG in Figure 13-11 the point of origin of the PVC, as follows. Note that the potentials of the premature contractions in leads II and III are both strongly positive. On plotting these potentials on the axes of leads II and III and solving by vectorial analysis for the mean QRS vector in the heart, one finds that the vector of this premature contraction has its negative end (origin) at the base of the heart and its positive end toward the apex. Thus, the first portion of the heart to become depolarized during this premature contraction is near the base of the ventricles, which therefore is the origin of the ectopic focus.

Disorders of Cardiac Repolarization—the Long QT Syndromes. Recall that the Q wave corresponds to ventricular depolarization, whereas the T wave corresponds to ventricular repolarization. The Q-T interval is the time from the Q point to the end of the T wave. Disorders that delay repolarization of ventricular muscle after the action potential cause prolonged ventricular action potentials and therefore excessively long Q-T intervals on the ECG, a condition called *long QT syndrome* (LQTS).

The major reason that LQTS is of concern is that delayed repolarization of ventricular muscle increases a person's susceptibility to developing ventricular arrhythmias called *torsades de pointes*, which literally means "twisting of the points." This type of arrhythmia has the features shown in Figure 13-12. The shape of the QRS complex may change over time, with the onset of arrhythmia usually following a premature beat, a pause, and then another beat with a long Q-T interval, which may trigger arrhythmias, tachycardia and, in some cases, ventricular fibrillation.

Figure 13-12. Development of arrhythmias in long QT syndrome (LQTS). When the ventricular muscle fiber action potential is prolonged as a result of delayed repolarization, a premature depolarization (*dashed line in top left figure*) may occur before complete repolarization. Repetitive premature depolarizations (*top right figure*) may lead to multiple depolarizations under certain conditions. In torsades de pointes (*bottom figure*), premature ventricular beats lead pauses, postpause prolongation of the Q-T interval, and arrhythmias. (Modified from Murray KT, Roden DM: *Disorders of cardiac repolarization: the long QT syndromes*. In: Crawford MG, DiMarco JP [eds]: *Cardiology*. London: Mosby, 2001.)

Disorders of cardiac repolarization that lead to LQTS may be inherited or acquired. The congenital forms of LQTS are rare disorders caused by mutations of sodium or potassium channel genes. At least 17 different mutations of these genes causing variable degrees of Q-T prolongation have been identified.

More common are the acquired forms of LQTS that are associated with plasma electrolyte disturbances, such as hypomagnesemia, hypokalemia, or hypocalcemia, or with the administration of excess amounts of antiarrhythmic drugs such as quinidine or some antibiotics such as fluoroquinolones or erythromycin, which prolong the Q-T interval.

Although some people with LQTS exhibit no major symptoms (other than the prolonged Q-T interval), other people exhibit fainting and experience ventricular arrhythmias that may be precipitated by physical exercise, intense emotions such as fright or anger, or being startled by a noise. The ventricular arrhythmias associated with LQTS can, in some cases, deteriorate into ventricular fibrillation and sudden death.

Treatment may include magnesium sulfate for acute LQTS and antiarrhythmic medications such as beta-adrenergic blockers or surgical implantation of a cardiac defibrillator for long-term LQTS.

PAROXYSMAL TACHYCARDIA

Some abnormalities in different portions of the heart, including the atria, Purkinje system, or ventricles, can occasionally cause rapid rhythmical discharge of impulses

that spread in all directions throughout the heart. This phenomenon is believed to be caused most frequently by re-entrant *circus movement* feedback pathways that set up local repeated self-re-excitation. Because of the rapid rhythm in the irritable focus, this focus becomes the pacemaker of the heart.

The term *paroxysmal* means that the heart rate becomes rapid in paroxysms, with the paroxysm beginning suddenly and lasting for a few seconds, a few minutes, a few hours, or much longer. The paroxysm usually ends as suddenly as it began, with the pacemaker of the heart instantly shifting back to the sinus node.

Paroxysmal tachycardia often can be stopped by eliciting a vagal reflex. A type of vagal reflex sometimes elicited for this purpose is to press on the neck in the regions of the carotid sinuses, which may cause enough of a vagal reflex to stop the paroxysm. Antiarrhythmic drugs may also be used to slow conduction or prolong the refractory period in cardiac tissues.

PAROXYSMAL ATRIAL TACHYCARDIA

Figure 13-13 demonstrates a sudden increase in the heart rate from about 95 to about 150 beats/min in the middle of the record. On close study of the ECG, an inverted P wave is seen during the rapid heartbeat before each QRS-T complex, and this P wave is partially superimposed onto the normal T wave of the preceding beat. This finding indicates that the origin of this paroxysmal tachycardia is in the atrium but, because the P wave is abnormal in shape, the origin is not near the sinus node.

Figure 13-13. Paroxysmal atrial tachycardia—onset in the middle of the record (lead I).

Figure 13-14. Ventricular paroxysmal tachycardia (lead III).

A-V Nodal Paroxysmal Tachycardia. Paroxysmal tachycardia often results from an aberrant rhythm involving the A-V node that usually causes almost normal QRS-T complexes but totally missing or obscured P waves.

Atrial or A-V nodal paroxysmal tachycardia, both of which are referred to as *supraventricular tachycardias*, usually occur in young, otherwise healthy people, and they generally grow out of the predisposition to tachycardia after adolescence. In general, supraventricular tachycardia frightens a person tremendously and may cause weakness during the paroxysm, but it usually does not cause permanent harm from the attack.

VENTRICULAR TACHYCARDIA

Figure 13-14 shows a typical short paroxysm of ventricular tachycardia. The ECG of ventricular tachycardia has the appearance of a series of ventricular premature beats occurring one after another, without any normal beats interspersed.

Ventricular tachycardia is usually a serious condition for two reasons. First, this type of tachycardia usually does not occur unless considerable ischemic damage is present in the ventricles. Second, *ventricular tachycardia frequently initiates the lethal condition of ventricular fibrillation* because of rapid repeated stimulation of the ventricular muscle, as discussed in the next section.

Sometimes, intoxication from the heart failure treatment drug *digitalis* causes irritable foci that lead to ventricular tachycardia. Antiarrhythmic drugs such as *amiodarone* or *lidocaine* can be used to treat ventricular tachycardia. Lidocaine depresses the normal increase in sodium permeability of the cardiac muscle membrane during generation of the action potential, thereby often blocking the rhythmical discharge of the focal point that has been causing the paroxysmal attack. Amiodarone has multiple actions, such as prolonging the action potential and refractory period in cardiac muscle and slowing A-V conduction. In some cases, *cardioversion* with an electric

shock to the heart is needed for restoration of normal heart rhythm.

VENTRICULAR FIBRILLATION

The most serious of all cardiac arrhythmias is ventricular fibrillation, which, if not stopped within 1 to 3 minutes, is almost invariably fatal. Ventricular fibrillation results from cardiac impulses that have gone berserk within the ventricular muscle mass, stimulating first one portion of the ventricular muscle, then another portion, then another, and eventually feeding back onto itself to re-excite the same ventricular muscle over and over, never stopping. When this phenomenon occurs, many small portions of the ventricular muscle will be contracting at the same time, while equally as many other portions will be relaxing. Thus, there is never a coordinated contraction of all the ventricular muscle at once, which is required for a pumping cycle of the heart. Despite massive movement of stimulatory signals throughout the ventricles, the ventricular chambers neither enlarge nor contract but remain in an indeterminate stage of partial contraction, pumping either no blood or negligible amounts. Therefore, after fibrillation begins, unconsciousness occurs within 4 to 5 seconds because of lack of blood flow to the brain, and irretrievable death of tissues begins to occur throughout the body within a few minutes.

Multiple factors can spark the beginning of ventricular fibrillation; a person may have a normal heartbeat one moment, but 1 second later, the ventricles are in fibrillation. Especially likely to initiate fibrillation are sudden electrical shock of the heart, ischemia of the heart muscle, or ischemia of the specialized conducting system.

PHENOMENON OF RE-ENTRY—CIRCUS MOVEMENTS AS THE BASIS FOR VENTRICULAR FIBRILLATION

When the *normal* cardiac impulse in the normal heart has traveled through the extent of the ventricles, it has no place to go because all the ventricular muscle is refractory and cannot conduct the impulse farther. Therefore, that impulse dies, and the heart awaits a new action potential to begin in the sinus node.

Under some circumstances, however, this normal sequence of events does not occur. Therefore, the following is a more complete explanation of the background conditions that can initiate re-entry and lead to what is referred to as *circus movements*, which in turn cause ventricular fibrillation.

Figure 13-15 shows several small cardiac muscle strips cut in the form of circles. If such a strip is stimulated at the 12 o'clock position so that the impulse travels in only one direction, the impulse spreads progressively around the circle until it returns to the 12 o'clock position. If the originally stimulated muscle fibers are still in a refractory state, the impulse then dies out because refractory muscle

Figure 13-15. Circus movement, showing annihilation of the impulse in the short pathway and continued propagation of the impulse in the long pathway.

cannot transmit a second impulse. However, three different conditions can cause this impulse to continue to travel around the circle—that is, cause re-entry of the impulse into muscle that has already been excited (circus movement):

1. If the *pathway around the circle is much longer than normal*, by the time the impulse returns to the 12 o'clock position, the originally stimulated muscle will no longer be refractory, and the impulse will continue around the circle again and again.
2. If the length of the pathway remains constant but the *velocity of conduction becomes decreased* enough, an increased interval of time will elapse before the impulse returns to the 12 o'clock position. By this time, the originally stimulated muscle might be out of the refractory state, and the impulse can continue around the circle again and again.
3. *The refractory period of the muscle might become greatly shortened.* In this case, the impulse could also continue around and around the circle.

All these conditions occur in different pathological states of the human heart: (1) a long pathway typically occurs in dilated hearts; (2) a decreased rate of conduction frequently results from blockage of the Purkinje system, ischemia of the muscle, high blood potassium levels, or many other factors; and (3) a shortened refractory period commonly occurs in response to various drugs, such as epinephrine, or after repetitive electrical stimulation. Thus, in many cardiac disturbances, re-entry can cause abnormal patterns of cardiac contraction or abnormal cardiac rhythms that ignore the pace-setting effects of the sinus node.

CHAIN REACTION MECHANISM OF FIBRILLATION

In ventricular fibrillation, one sees many separate and small contractile waves spreading at the same time in different directions over the cardiac muscle. The re-entrant impulses in fibrillation are not simply a single impulse

Figure 13-16. **A**, Initiation of fibrillation in a heart when patches of refractory musculature are present. **B**, Continued propagation of fibrillatory impulses in the fibrillating ventricle.

moving in a circle, as shown in [Figure 13-15](#). Instead, they have degenerated into a series of multiple wave fronts that have the appearance of a chain reaction. One of the best ways to explain this process in fibrillation is to describe the initiation of fibrillation by electric shock with a 60-cycle alternating electric current.

Fibrillation Caused by 60-Cycle Alternating Current.

At a central point in the ventricles of heart A in [Figure 13-16](#), a 60-cycle electrical stimulus is applied through a stimulating electrode. The first cycle of the electrical stimulus causes a depolarization wave to spread in all directions, leaving all the muscle beneath the electrode in a refractory state. After about 0.25 second, part of this muscle begins to come out of the refractory state. Some portions come out of refractoriness before other portions. This state of events is depicted in heart A by many lighter patches, which represent excitable cardiac muscle, and dark patches, which represent muscle that is still refractory. Now, continuing 60-cycle stimuli from the electrode can cause impulses to travel only in certain directions through the heart but not in all directions. Thus, in heart A, certain impulses travel for short distances until they reach refractory areas of the heart, and then they are blocked. However, other impulses pass between the refractory areas and continue to travel in the excitable areas. Then, several events transpire in rapid succession, all occurring simultaneously and eventuating in a state of fibrillation.

First, block of the impulses in some directions but successful transmission in other directions creates one of the necessary conditions for a re-entrant signal to develop—that is, *transmission of some of the depolarization waves around the heart in only some directions but not in other directions.*

Second, the rapid stimulation of the heart causes two changes in the cardiac muscle, both of which predispose to circus movement: (1) the *velocity of conduction through the heart muscle decreases*, which allows a longer time

Figure 13-17. Ventricular fibrillation (lead II).

interval for the impulses to travel around the heart; and (2) the *refractory period of the muscle is shortened*, allowing re-entry of the impulse into previously excited heart muscle within a much shorter time than normal.

Third, one of the most important features of ventricular fibrillation is the *division of impulses*, as demonstrated in heart A in Figure 13-16. When a depolarization wave reaches a refractory area in the heart, it travels to both sides around the refractory area. Thus, a single impulse becomes two impulses. Then, when each of these impulses reaches another refractory area, it divides to form two more impulses. In this way, many new wave fronts are continually being formed in the heart by progressive *chain reactions* until, finally, many small depolarization waves are traveling in many directions at the same time. Furthermore, this irregular pattern of impulse travel causes *many circuitous routes for the impulses to travel, greatly lengthening the conductive pathway, which is one of the conditions that sustains the fibrillation*. It also results in a continual irregular pattern of patchy refractory areas in the heart.

One can readily see when a vicious circle has been initiated. More and more impulses are formed; these impulses cause more and more patches of refractory muscle, and the refractory patches cause more and more division of the impulses. Therefore, whenever a single area of cardiac muscle comes out of refractoriness, an impulse is close at hand to re-enter the area.

Heart B in Figure 13-16 demonstrates the final state that develops in ventricular fibrillation. Here, one can see many impulses traveling in all directions, with some dividing and increasing the number of impulses and others blocked by refractory areas. A single electric shock during this vulnerable period frequently can lead to an odd pattern of impulses spreading multidirectionally around refractory areas of muscle, which will lead to ventricular fibrillation.

ELECTROCARDIOGRAM IN VENTRICULAR FIBRILLATION

In ventricular fibrillation, the ECG is bizarre (Figure 13-17) and ordinarily shows no tendency toward a regular rhythm of any type. During the first few seconds of ventricular fibrillation, relatively large masses of muscle contract simultaneously, which causes coarse irregular waves in the ECG. After another few seconds, the coarse contractions of the ventricles disappear, and the ECG changes into a new pattern of low-voltage, very irregular waves. Thus, no repetitive electrocardiographic pattern can be ascribed to ventricular fibrillation. Instead, the

ventricular muscle contracts at as many as 30 to 50 small patches of muscle at a time, and electrocardiographic potentials change constantly and spasmodically because the electrical currents in the heart flow first in one direction and then in another and seldom repeat any specific cycle.

The voltages of the waves in the ECG in ventricular fibrillation are usually about 0.5 millivolt when ventricular fibrillation first begins, but they decay rapidly; thus, after 20 to 30 seconds, they are usually only 0.2 to 0.3 millivolt. Minute voltages of 0.1 millivolt or less may be recorded for 10 minutes or longer after ventricular fibrillation begins. As already noted, because no pumping of blood occurs during ventricular fibrillation, this state is lethal unless stopped by successful therapy, such as an immediate electroshock (defibrillation) through the heart, as explained in the next section.

VENTRICULAR DEFIBRILLATION

Although a moderate alternating current voltage applied directly to the ventricles almost invariably throws the ventricles into fibrillation, a strong high-voltage electrical current passed through the ventricles for a fraction of a second can stop fibrillation by throwing all the ventricular muscle into refractoriness simultaneously. This is accomplished by passing intense current through large electrodes placed on two sides of the heart. The current penetrates most of the fibers of the ventricles at the same time, thus stimulating essentially all parts of the ventricles simultaneously and causing them all to become refractory. All action potentials stop, and the heart remains quiescent for 3 to 5 seconds, after which it begins to beat again, usually with the sinus node or some other part of the heart becoming the pacemaker. However, if the same re-entrant focus that had originally thrown the ventricles into fibrillation is still present, fibrillation may begin again immediately.

When electrodes are applied directly to the two sides of the heart, fibrillation can usually be stopped using 1000 volts of direct current applied for a few thousandths of a second. When applied through two electrodes on the chest wall, as shown in Figure 13-18, the usual procedure is to charge a large electrical capacitor up to several thousand volts and then to cause the capacitor to discharge for a few thousandths of a second through the electrodes and through the heart.

In most cases, defibrillation current is delivered to the heart in biphasic waveforms, alternating the direction of the current pulse through the heart. This form of delivery substantially reduces the energy needed for successful defibrillation, thereby decreasing the risk for burns and cardiac damage.

In patients with a high risk for ventricular fibrillation, a small, battery-powered, implantable cardioverter-defibrillator (ICD) with electrode wires lodged in the right ventricle may be implanted. The device is programmed to detect ventricular fibrillation and revert

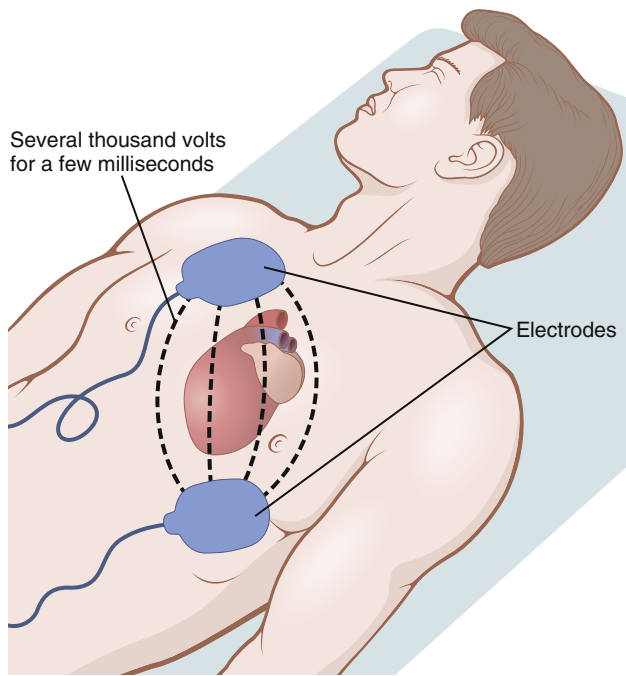

Figure 13-18. Application of electrical current to the chest to stop ventricular fibrillation.

it by delivering a brief electrical impulse to the heart. Advances in electronics and batteries have permitted the development of ICDs that can deliver enough electrical current to defibrillate the heart through electrode wires implanted subcutaneously, outside the rib cage near the heart rather than in or on the heart itself. These devices can be implanted with a minor surgical procedure.

HAND PUMPING OF THE HEART (CARDIOPULMONARY RESUSCITATION) AS AN AID TO DEFIBRILLATION

Unless defibrillated within 1 minute after ventricular fibrillation begins, the heart is usually too weak to be revived by defibrillation because of the lack of nutrition from coronary blood flow. However, it is still possible to revive the heart by preliminarily pumping the heart by hand (intermittent hand squeezing) and then defibrillating the heart later. In this way, small quantities of blood are delivered into the aorta, and a renewed coronary blood supply develops. Then, after a few minutes of hand pumping, electrical defibrillation often becomes possible. Fibrillating hearts have been pumped by hand for as long as 90 minutes followed by successful defibrillation.

A technique for pumping the heart without opening the chest consists of intermittent thrusts of pressure on the chest wall along with artificial respiration. This process, plus defibrillation, is called *cardiopulmonary resuscitation* (CPR).

Lack of blood flow to the brain for more than 5 to 8 minutes usually causes permanent mental impairment or even destruction of brain tissue. Even if the heart is revived, the person may die from the effects of brain damage or may live with permanent mental impairment.

Figure 13-19. Atrial fibrillation (lead II). The waves that can be seen are ventricular QRS and T waves.

ATRIAL FIBRILLATION

Remember that except for the conducting pathway through the A-V bundle, the atrial muscle mass is separated from the ventricular muscle mass by fibrous tissue. Therefore, ventricular fibrillation often occurs without atrial fibrillation. Likewise, fibrillation often occurs in the atria without ventricular fibrillation (shown on the right in [Figure 13-20](#)).

The mechanism of atrial fibrillation is identical to that of ventricular fibrillation, except that the process occurs only in the atrial muscle mass instead of the ventricular mass. A frequent cause of atrial fibrillation is atrial enlargement, which can result, for example, from heart valve lesions that prevent the atria from emptying adequately into the ventricles or from ventricular failure with excess damming of blood in the atria. The dilated atrial walls provide ideal conditions of a long conductive pathway, as well as slow conduction, both of which predispose to atrial fibrillation.

Impaired Pumping of the Atria During Atrial Fibrillation. For the same reasons that the ventricles will not pump blood during ventricular fibrillation, neither do the atria pump blood in atrial fibrillation. Therefore, the atria become useless as primer pumps for the ventricles. Even so, blood flows passively through the atria into the ventricles, and the efficiency of ventricular pumping is decreased by only 20% to 30%. Therefore, in contrast to the lethality of ventricular fibrillation, a person can live for years with atrial fibrillation, although at reduced efficiency of overall heart pumping. However, due to the reduced atrial contractile function, blood can stagnate, allowing blood clots to form in the atrial appendage. These blood clots can dislodge and travel to the brain, causing stroke, or to other parts of the body. Therefore, patients with atrial fibrillation are often placed on blood thinner medications (anticoagulants) to reduce the risk of embolism.

ELECTROCARDIOGRAM IN ATRIAL FIBRILLATION

[Figure 13-19](#) shows the ECG during atrial fibrillation. Numerous small depolarization waves spread in all directions through the atria during atrial fibrillation. Because the waves are weak, and many of them are of opposite polarity at any given time, they usually almost completely electrically neutralize one another. Therefore, in the ECG, one can see either no P waves from the atria or only a fine, high-frequency, very

Figure 13-20. Pathways of impulses in atrial flutter and atrial fibrillation.

low voltage wave record. Conversely, the QRS-T complexes are normal unless there is some pathology of the ventricles, but their timing is irregular, as explained next.

IRREGULARITY OF VENTRICULAR RHYTHM DURING ATRIAL FIBRILLATION

When the atria are fibrillating, impulses arrive from the atrial muscle at the A-V node rapidly but also irregularly. Because the A-V node will not pass a second impulse for about 0.35 second after a previous one, at least 0.35 second must elapse between one ventricular contraction and the next. Then, an additional but variable interval of 0 to 0.6 second occurs before one of the irregular atrial fibrillatory impulses happens to arrive at the A-V node. Thus, the interval between successive ventricular contractions varies from a minimum of about 0.35 second to a maximum of about 0.95 second, causing a very irregular heartbeat. In fact, this irregularity, demonstrated by the variable spacing of the heartbeats in the ECG shown in [Figure 13-19](#), is one of the clinical findings used to diagnose the condition. Also, because of the rapid rate of the fibrillatory impulses in the atria, the ventricle is driven at a fast heart rate, usually between 125 and 150 beats/min.

ELECTROSHOCK TREATMENT OF ATRIAL FIBRILLATION

Similar to ventricular fibrillation being converted back to a normal rhythm by electroshock, so can atrial fibrillation be converted by electroshock. The procedure is similar as that for ventricular fibrillation conversion, except the single electric shock is programmed (or synchronized) to fire only during the QRS complex when the ventricles are refractory to stimulation. A normal rhythm often follows *if the heart is capable of generating a normal rhythm*. This procedure is called *synchronized cardioversion* instead of *defibrillation* in the setting of ventricular fibrillation.

ATRIAL FLUTTER

Atrial flutter is another condition caused by a circus movement in the atria. Atrial flutter is different from atrial

Figure 13-21. Atrial flutter at 250 beats/min with a 2:1 atrial to ventricular rhythm at 125 beats/min (lead II).

fibrillation in that the electrical signal travels as a single large wave, always in one direction, around and around the atrial muscle mass, as shown to the left in [Figure 13-20](#). Atrial flutter causes a rapid rate of contraction of the atria, usually between 200 and 350 beats/min. However, because one side of the atria is contracting while the other side is relaxing, the amount of blood pumped by the atria is reduced. Furthermore, the signals reach the A-V node too rapidly for all of them to be passed into the ventricles because the refractory periods of the A-V node and A-V bundle are too long to pass more than a fraction of the atrial signals. Therefore, there are usually two to three beats of the atria for every single beat of the ventricles.

[Figure 13-21](#) shows a typical ECG in atrial flutter. The P waves are strong because of the contraction of semicoordinated masses of muscle. However, note that a QRS-T complex follows an atrial P wave only once for every two beats of the atria, giving a 2:1 rhythm.

CARDIAC ARREST

A final serious abnormality of the cardiac rhythmicity-conduction system is *cardiac arrest*, which results from cessation of all electrical control signals in the heart. That is, no spontaneous rhythm remains.

Cardiac arrest may occur *during deep anesthesia*, when severe hypoxia may develop because of inadequate respiration. The hypoxia prevents the muscle fibers and conductive fibers from maintaining normal electrolyte concentration differentials across their membranes, and their excitability may be so affected that the automatic rhythmicity disappears.

In many cases of cardiac arrest from anesthesia, prolonged CPR (for many minutes or even hours) is quite successful in re-establishing a normal heart rhythm. In some patients, severe myocardial disease can cause permanent or semipermanent cardiac arrest, which can cause death. To treat the condition, rhythmical electrical impulses from an *implanted electronic cardiac pacemaker* have been used successfully to keep patients alive for months to years.

Overview of the Circulation: Pressure, Flow, and Resistance

The function of the circulation is to serve the needs of the body tissues—to transport nutrients to the tissues, to transport waste products away, transport hormones from one part of the body to another and, in general, to maintain an appropriate environment in all the tissue fluids for survival and optimal function of the cells.

The rate of blood flow through many tissues is controlled mainly in response to their need for nutrients and removal of waste products of metabolism. In some organs, such as the kidneys, the circulation serves additional functions. Blood flow to the kidney, for example, is far in excess of its metabolic requirements and is related to its excretory function, which requires that a large volume of blood be filtered each minute.

The heart and blood vessels, in turn, are controlled to provide the cardiac output and arterial pressure needed to supply adequate tissue blood flow. What are the mechanisms for controlling blood volume and blood flow, and how does this process relate to the other functions of the circulation? These are some of the topics and questions that we discuss in this section on the circulation.

PHYSICAL CHARACTERISTICS OF THE CIRCULATION

The circulation, shown in **Figure 14-1**, is divided into the *systemic circulation* and the *pulmonary circulation*. Because the systemic circulation supplies blood flow to all the tissues of the body except the lungs, it is also called the *greater circulation* or *peripheral circulation*.

Functional Parts of the Circulation. Before discussing the details of circulatory function, it is important to understand the role of each part of the circulation.

The function of the *arteries* is to transport blood *under high pressure* to the tissues. For this reason, the arteries have strong vascular walls, and blood flows at a high velocity in the arteries.

The *arterioles* are the last small branches of the arterial system; they act as *control conduits* through which blood is released into the capillaries. Arterioles have strong muscular walls that can close the arterioles completely or, by relaxing, can dilate the vessels severalfold; thus, the arterioles can vastly alter blood flow in each tissue in response to its needs.

The function of the *capillaries* is to exchange fluid, nutrients, electrolytes, hormones, and other substances between the blood and interstitial fluid. To serve this role, the capillary walls are thin and have numerous minute *capillary pores* permeable to water and other small molecular substances.

The *venules* collect blood from the capillaries and gradually coalesce into progressively larger veins.

The *veins* function as conduits for transport of blood from the venules back to the heart. The veins also serve as a major reservoir of extra blood. Because the pressure in the venous system is low, the venous walls are thin. Even so, they are muscular enough to contract or expand and thereby serve as

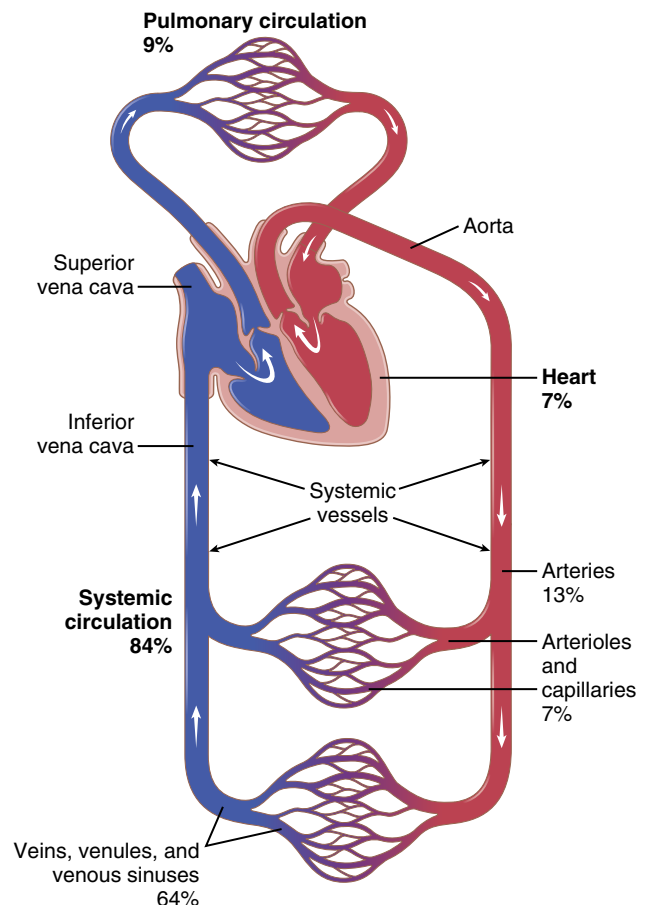

Figure 14-1. Distribution of blood (in percentage of total blood) in the different parts of the circulatory system.

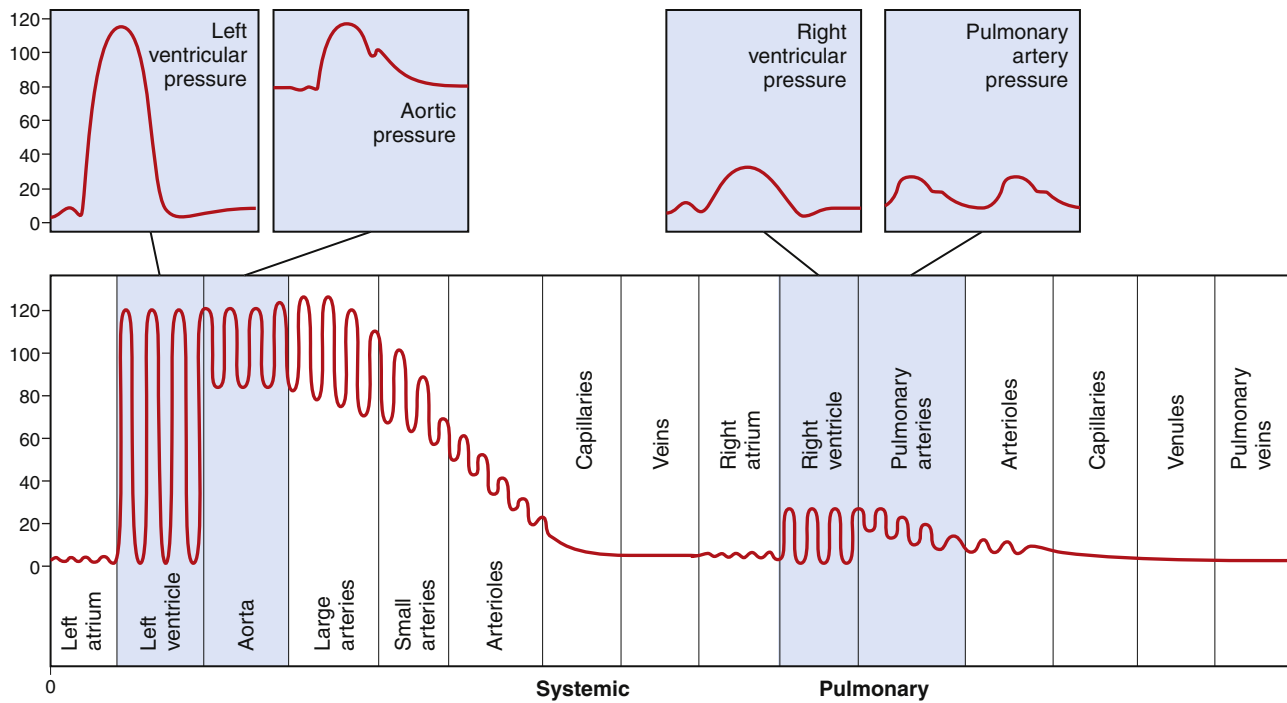

Figure 14-2. Normal blood pressures (in mm Hg) in the different portions of the circulatory system when a person is lying in the horizontal position.

a controllable reservoir for the extra blood, either a small or a large amount, depending on the needs of the circulation.

Volumes of Blood in the Different Parts of the Circulation. Figure 14-1 provides an overview of the circulation and lists the percentages of total blood volume in major segments of the circulation. For example, about 84% of the entire blood volume of the body is in the systemic circulation, and 16% is in the heart and lungs. Of the 84% in the systemic circulation, approximately 64% is in the veins, 13% is in the arteries, and 7% is in the systemic arterioles and capillaries. The heart contains 7% of the blood, and the pulmonary vessels contain 9%.

Most surprising is the low blood volume in the capillaries. It is here, however, that the most important function of the circulation occurs—diffusion of substances back and forth between the blood and tissues, as discussed in Chapter 16.

Cross-Sectional Areas and Velocities of Blood Flow. If all the *systemic vessels* of each type were put side by side, their approximate total cross-sectional areas for the average human would be as follows:

Vessel	Cross-Sectional Area (cm ²)
Aorta	2.5
Small arteries	20
Arterioles	40
Capillaries	2500
Venules	250
Small veins	80
Venae cavae	8

Note particularly that the cross-sectional areas of the veins are much larger than those of the arteries, averaging about four times those of the corresponding arteries. This difference explains the large blood storage capacity of the venous system in comparison with the arterial system.

Because the same volume of blood flow (*F*) must pass through each segment of the circulation each minute, the velocity of blood flow (*v*) is inversely proportional to the vascular cross-sectional area (*A*):

$$v = F/A$$

Thus, under resting conditions, the velocity averages about 33 cm/sec in the aorta but is only 1/1000 as rapid in the capillaries—about 0.3 mm/sec. However, because the capillaries have a typical length of only 0.3 to 1 millimeter, the blood remains in the capillaries for only 1 to 3 seconds, which is surprising because all diffusion of nutrient food substances and electrolytes that occurs through the capillary walls must be performed in this short time.

Pressures in the Various Portions of the Circulation. Because the heart pumps blood continually into the aorta, the mean pressure in the aorta is high, averaging about 100 mm Hg. Also, because heart pumping is pulsatile, the arterial pressure normally alternates between an average *systolic pressure level* of 120 mm Hg and a *diastolic pressure level* of 80 mm Hg under resting conditions, as shown on the left side of Figure 14-2.

As the blood flows through the *systemic circulation*, its mean pressure falls progressively to about 0 mm Hg by the time it reaches the termination of the superior and inferior venae cavae where they empty into the right atrium of the heart.

The pressure in many of the systemic capillaries varies from as high as 35 mm Hg near the arteriolar ends to as low as 10 mm Hg near the venous ends, but their average functional pressure in most vascular beds is about 17 mm Hg, a pressure low enough that little of the plasma leaks through the minute *pores* of the capillary walls, even though nutrients can *diffuse* easily through these same pores to the outlying tissue cells. In some capillaries, such as the glomerular capillaries of the kidneys, the pressure is considerably higher, averaging about 60 mm Hg and causing much higher rates of fluid filtration.

At the far-right side of **Figure 14-2**, note the respective pressures in the different parts of the *pulmonary circulation*. In the pulmonary arteries, the pressure is pulsatile, just as in the aorta, but the pressure is far less; *pulmonary artery systolic pressure* averages about 25 mm Hg and *diastolic pressure* averages about 8 mm Hg, with a mean pulmonary arterial pressure of only 16 mm Hg. The mean pulmonary capillary pressure averages only 7 mm Hg. Yet, the total blood flow through the lungs each minute is the same as through the systemic circulation. The low pressures of the pulmonary system are in accord with the needs of the lungs because all that is required is to expose the blood in the pulmonary capillaries to oxygen and other gases in the pulmonary alveoli.

BASIC PRINCIPLES OF CIRCULATORY FUNCTION

Although the details of circulatory function are complex, three basic principles underlie all functions of the system.

1. *Blood flow to most tissues is controlled according to the tissue needs.* When tissues are active, they need an increased supply of nutrients and therefore more blood flow than when at rest, occasionally as much as 20 to 30 times the resting level. However, the heart normally cannot increase its cardiac output more than four to seven times higher than resting levels. Therefore, it is not possible simply to increase blood flow everywhere in the body when a particular tissue demands increased flow. Instead, the microvessels of each tissue, especially the arterioles, continuously monitor tissue needs, such as the availability of oxygen and other nutrients and the accumulation of carbon dioxide and other tissue waste products. These microvessels, in turn, dilate or constrict to control local blood flow at the level required for the tissue activity. Also, nervous control of the circulation from the central nervous system and hormones provides additional help in controlling tissue blood flow.

Figure 14-3. Interrelationships of pressure, resistance, and blood flow. P_1 , Pressure at the origin of the vessel; P_2 , pressure at the other end of the vessel.

2. *Cardiac output is the sum of all the local tissue flows.* When blood flows through a tissue, it immediately returns by way of the veins to the heart. The heart responds automatically to this increased inflow of blood by pumping it immediately back into the arteries. Thus, as long as the heart is functioning normally, it acts as an automaton, responding to the demands of the tissues. The heart, however, often needs help in the form of special nerve signals to make it pump the required amounts of blood flow.
3. *Arterial pressure regulation is generally independent of either local blood flow control or cardiac output control.* The circulatory system is provided with an extensive system for controlling the arterial blood pressure. For example, if at any time the pressure falls significantly below the normal level of about 100 mm Hg, a barrage of nervous reflexes elicits a series of circulatory changes to raise the pressure back toward normal within seconds. The nervous signals especially do the following: (a) increase the force of heart pumping; (b) cause contraction of the large venous reservoirs to provide more blood to the heart; and (c) cause generalized constriction of the arterioles in many tissues so that more blood accumulates in the large arteries to increase the arterial pressure. Then, over more prolonged periods—hours and days—the kidneys play an additional major role in pressure control by secreting pressure-controlling hormones and regulating blood volume.

Thus, the needs of the individual tissues are served specifically by the circulation. In the remainder of this chapter, we begin to discuss the basic control of tissue blood flow, cardiac output, and arterial pressure.

INTERRELATIONSHIPS OF PRESSURE, FLOW, AND RESISTANCE

Blood flow through a blood vessel is determined by two factors: (1) *pressure difference* of the blood between the two ends of the vessel, also sometimes called the *pressure gradient* along the vessel, which pushes the blood through the vessel; and (2) the impediment to blood flow through the vessel, which is called *vascular resistance*. **Figure 14-3** demonstrates these relationships, showing a blood vessel segment located anywhere in the circulatory system.

Figure 14-4. **A,** Electromagnetic flowmeter showing generation of an electrical voltage in a wire as it passes through an electromagnetic field. **B,** Generation of an electrical voltage in electrodes on a blood vessel when the vessel is placed in a strong magnetic field, and blood flows through the vessel. **C,** Modern electromagnetic flowmeter probe for chronic implantation around blood vessels. N and S refer to the magnet's north and south poles.

P_1 represents the pressure at the origin of the vessel and P_2 is the pressure at the other end. Resistance occurs as a result of friction between the flowing blood and the intravascular endothelium all along the inside of the vessel. The flow through the vessel can be calculated by the following formula, which is called *Ohm's law*:

$$F = \frac{\Delta P}{R}$$

in which F is blood flow, ΔP is the pressure difference ($P_1 - P_2$) between the two ends of the vessel, and R is the resistance. This formula states that the blood flow is directly proportional to the pressure difference but inversely proportional to the resistance.

Note that it is the *difference* in pressure between the two ends of the vessel, not the absolute pressure in the vessel, that determines flow rate. For example, if the pressure at both ends of a vessel is 100 mm Hg and no difference exists between the two ends, there will be no flow, despite the presence of 100 mm Hg pressure.

Ohm's law, illustrated in the preceding formula, expresses one of the most important of all the relationships that the reader needs to understand to comprehend the hemodynamics of the circulation. Because of the extreme importance of this formula, the reader should also become familiar with its other algebraic forms:

$$\Delta P = F \times R$$

$$R = \frac{\Delta P}{F}$$

BLOOD FLOW

Blood flow rate means the quantity of blood that passes a given point in the circulation in a given period of time.

Ordinarily, blood flow is expressed in *milliliters per minute* or *liters per minute*, but it can be expressed in milliliters per second or in any other units of flow and time.

The overall blood flow in the total circulation of an adult person at rest is about 5000 ml/min. This is called the *cardiac output* because it is the amount of blood pumped into the aorta by the heart each minute.

Methods for Measuring Blood Flow. Many mechanical and mechano-electrical *flowmeter* devices can be inserted in series with a blood vessel or, in some cases, applied to the outside of the vessel to measure blood flow.

Electromagnetic Flowmeter. An electromagnetic flowmeter, the principles of which are illustrated in [Figure 14-4](#), can be used to measure blood flow experimentally without opening the blood vessel. [Figure 14-4A](#) shows the generation of electromotive force (electrical voltage) in a wire that is moved rapidly in a cross-wise direction through a magnetic field. This is the well-known principle for production of electricity by the electric generator. [Figure 14-4B](#) shows that the same principle applies for generation of electromotive force in blood that is moving through a magnetic field. In this case, a blood vessel is placed between the poles of a strong magnet, and electrodes are placed on the two sides of the vessel perpendicular to the magnetic lines of force. When blood flows through the vessel, an electrical voltage proportional to the rate of blood flow is generated between the two electrodes, and this voltage is recorded using an appropriate voltmeter or electronic recording apparatus. [Figure 14-4C](#) shows an actual probe that is placed on a large blood vessel to record its blood flow. The probe contains both the strong magnet and the electrodes.

A special advantage of the electromagnetic flowmeter is that it can record changes in flow in less than 1/100 of a second, allowing for the accurate recording of pulsatile changes in flow, as well as steady flow.

Ultrasonic Doppler Flowmeter. Another type of flowmeter that can be applied to the outside of the vessel and that has many of the same advantages as the electromagnetic flowmeter is the *ultrasonic Doppler flowmeter*, shown in **Figure 14-5**. A minute piezoelectric crystal is mounted at one end in the wall of the device. This crystal, when energized with an appropriate electronic apparatus, transmits ultrasound at a frequency of several hundred thousand cycles per second downstream along the flowing blood. A portion of the sound is reflected by the red blood cells in the flowing blood. The reflected ultrasound waves then travel backward from the blood cells toward the crystal. These reflected waves have a lower frequency than the transmitted wave because the red blood cells are moving away from the transmitter crystal. This effect is called the *Doppler effect*. (It is the same effect that one experiences when a train approaches and passes by while blowing its whistle. Once the whistle has passed by the person, the pitch of the sound from the whistle suddenly becomes much lower than when the train is approaching.)

For the flowmeter shown in **Figure 14-5**, the high-frequency ultrasound wave is intermittently cut off, and the reflected wave is received back onto the crystal and greatly amplified by the electronic apparatus. Another portion of the electronic apparatus determines the frequency difference between the transmitted wave and the reflected wave, thus determining the velocity of blood flow. As long as the diameter of a blood vessel does not change, changes in blood flow in the vessel are directly related to changes in flow velocity.

Like the electromagnetic flowmeter, the ultrasonic Doppler flowmeter is capable of recording rapid pulsatile changes in flow, as well as steady flow.

Laminar Flow of Blood in Vessels. When blood flows at a steady rate through a long smooth blood vessel, it flows in *streamlines*, with each layer of blood remaining the same distance from the vessel wall. Also, the centralmost portion of the blood stays in the center of the vessel. This type of flow is called *laminar flow* or *streamline flow*, in contrast to *turbulent flow*, which is blood flowing in all directions in the vessel and continually mixing in the vessel, as discussed subsequently.

Parabolic Velocity Profile During Laminar Flow.

When laminar flow occurs, the velocity of flow in the center of the vessel is far greater than that toward the outer edges. This phenomenon is demonstrated in **Figure 14-6**. In **Figure 14-6A**, a vessel contains two fluids, the one at the left colored by a dye and the one

Figure 14-6. A, Two fluids (one dyed red, and the other clear) before flow begins. B, The same fluids 1 second after flow begins. C, Turbulent flow, with elements of the fluid moving in a disorderly pattern.

at the right a clear fluid, but there is no flow in the vessel. When the fluids are made to flow, a parabolic interface develops between them, as shown 1 second later in **Figure 14-6B**. The portion of fluid adjacent to the vessel wall has hardly moved, the portion slightly away from the wall has moved a small distance, and the portion in the center of the vessel has moved a long distance. This effect is called the *parabolic profile for velocity of blood flow*.

The cause of the parabolic profile is as follows. The fluid molecules touching the wall move slowly because of adherence to the vessel wall. The next layer of molecules slips over these, the third layer over the second, the fourth layer over the third, and so forth. Therefore, the fluid in the middle of the vessel can move rapidly because many layers of slipping molecules exist between the middle of the vessel and the vessel wall. Thus, each layer toward the center flows progressively more rapidly than the outer layers.

Turbulent Flow of Blood Under Some Conditions.

When the rate of blood flow becomes too great, when it passes by an obstruction in a vessel, when it makes a sharp turn, or when it passes over a rough surface, the flow may then become *turbulent*, or disorderly, rather than streamlined (**Figure 14-6C**). Turbulent flow means that the blood flows crosswise in the vessel and along the vessel, usually forming whorls in the blood, called *eddy currents*. These eddy currents are similar to the whirlpools that can be seen in a rapidly flowing river at a point of obstruction. When eddy currents are present, the blood flows with much greater resistance than when the flow is streamlined because eddies add to the overall friction of flow in the vessel tremendously.

The tendency for turbulent flow increases in direct proportion to the velocity of blood flow, the diameter of the blood vessel, and the density of the blood and is inversely proportional to the viscosity of the blood, in accordance with the following equation:

$$Re = \frac{v \cdot d \cdot \rho}{\eta}$$

Figure 14-5. Ultrasonic Doppler flowmeter.

where Re is *Reynolds' number*, the measure of the tendency for turbulence to occur, v is the mean velocity of blood flow (in cm/sec), d is the vessel diameter (in centimeters), ρ is density (in grams/ml), and η is the viscosity (in poise). The viscosity of blood is normally about 1/30 poise, and the density is only slightly greater than 1. When Reynolds' number rises above 200 to 400, turbulent flow will occur at some branches of vessels but will die out along the smooth portions of the vessels. However, when Reynolds' number rises above approximately 2000, turbulence will usually occur, even in a straight, smooth vessel.

Reynolds' number for flow in the vascular system normally rises to 200 to 400, even in large arteries. As a result, there is almost always some flow turbulence at the branches of these vessels. In the proximal portions of the aorta and pulmonary artery, Reynolds' number can rise to several thousand during the rapid phase of ejection by the ventricles, which causes considerable turbulence in the proximal aorta and pulmonary artery, where many conditions are appropriate for turbulence, such as the following: (1) high velocity of blood flow; (2) pulsatile nature of the flow; (3) sudden change in vessel diameter; and (4) large vessel diameter. However, in small vessels, Reynolds' number is almost never high enough to cause turbulence.

BLOOD PRESSURE

Standard Units of Pressure. Blood pressure almost always is measured in millimeters of mercury (mm Hg) because the mercury manometer has been used as the standard reference for measuring pressure since its invention in 1846 by Poiseuille. Actually, blood pressure means the *force exerted by the blood against any unit area of the vessel wall*. If the pressure in a vessel is 100 mm Hg, this means that the force exerted is sufficient to push a column of mercury against gravity up to a level 50 millimeters high.

Occasionally, pressure is measured in *centimeters of water* (cm H₂O). A pressure of 10 cm H₂O means a pressure sufficient to raise a column of water against gravity to a height of 10 centimeters. *One millimeter of mercury pressure equals 1.36 centimeters of water pressure* because the specific gravity of mercury is 13.6 times that of water, and 1 centimeter is 10 times as great as 1 millimeter.

High-Fidelity Methods for Measuring Blood Pressure.

The mercury in a manometer has so much inertia that it cannot rise and fall rapidly. For this reason, the mercury manometer, although excellent for recording steady pressures, cannot respond to pressure changes that occur more rapidly than about one cycle every 2 to 3 seconds. Whenever it is desired to record rapidly changing pressures, some other type of pressure recorder is necessary. **Figure 14-7** demonstrates the basic principles of three electronic pressure *transducers* commonly used for converting blood pressure and/or rapid changes in pressure into electrical signals and then

recording the electrical signals on a high-speed electrical recorder. Each of these transducers uses a very thin, highly stretched metal membrane that forms one wall of the fluid chamber. The fluid chamber, in turn, is connected through a needle or catheter inserted into the blood vessel in which the pressure is to be measured. When the pressure is high, the membrane bulges slightly and, when it is low, it returns toward its resting position.

In **Figure 14-7A**, a simple metal plate is placed a few hundredths of a centimeter above the membrane. When the membrane bulges, the membrane comes closer to the plate, which increases the *electrical capacitance* between these two, and this change in capacitance can be recorded using an appropriate electronic system.

In **Figure 14-7B**, a small iron slug rests on the membrane, and this slug can be displaced upward into a center space inside an electrical wire coil. Movement of the iron into the coil increases the *inductance* of the coil, and this too can be recorded electronically.

Finally, in **Figure 14-7C**, a very thin, stretched resistance wire is connected to the membrane. When this wire is stretched greatly, its resistance increases; when it is stretched less, its resistance decreases. These changes can also be recorded by an electronic system.

The electrical signals from the transducer are sent to an amplifier and then to an appropriate recording device. With some of these high-fidelity types of recording systems, pressure cycles up to 500 cycles/sec have been recorded accurately. In common use are recorders capable of registering pressure changes that occur as rapidly as 20 to 100 cycles/sec in the manner shown on the recorder in **Figure 14-7C**.

Figure 14-7. A–C, Principles of three types of electronic transducers for recording rapidly changing blood pressures (see text).

RESISTANCE TO BLOOD FLOW

Units of Resistance. Resistance is the impediment to blood flow in a vessel, but it cannot be measured by any direct means. Instead, resistance must be calculated from measurements of blood flow and pressure difference between two points in the vessel. If the pressure difference between two points is 1 mm Hg and the flow is 1 ml/sec, the resistance is said to be *1 peripheral resistance unit*, usually abbreviated *PRU*.

Expression of Resistance in CGS Units. Occasionally, a basic physical unit called the CGS (centimeters, grams, seconds) unit is used to express resistance. This unit is dyne sec/cm^5 . Resistance in these units can be calculated by the following formula:

$$R \left(\text{in } \frac{\text{dyne sec}}{\text{cm}^5} \right) = \frac{1333 \times \text{mm Hg}}{\text{ml/sec}}$$

Total Peripheral Vascular Resistance and Total Pulmonary Vascular Resistance. The rate of blood flow through the entire circulatory system is equal to the rate of blood pumping by the heart—that is, it is equal to the cardiac output. In an adult human, this averages approximately 100 ml/sec. The pressure difference from the systemic arteries to the systemic veins is about 100 mm Hg. Therefore, the resistance of the entire systemic circulation, called the *total peripheral resistance*, is about $100/100$, or 1 PRU.

In conditions in which all the blood vessels throughout the body become strongly constricted, the total peripheral resistance occasionally rises to as high as 4 PRU. Conversely, when the vessels become greatly dilated, the resistance can fall to as little as 0.2 PRU.

In the pulmonary system, the mean pulmonary arterial pressure averages 16 mm Hg and the mean left atrial pressure averages 2 mm Hg, giving a net pressure difference of 14 mm. Therefore, when the cardiac output is normal at about 100 ml/sec, the *total pulmonary vascular resistance* calculates to be about 0.14 PRU (about one seventh that in the systemic circulation).

Conductance of Blood in a Vessel Is the Reciprocal of Resistance. Conductance is a measure of the blood flow through a vessel for a given pressure difference. This measurement is generally expressed in terms of ml/sec per mm Hg pressure, but it can also be expressed in terms of L/sec per mm Hg or in any other units of blood flow and pressure.

It is evident that conductance is the exact reciprocal of resistance in accord with the following equation:

$$\text{Conductance} = \frac{1}{\text{Resistance}}$$

Figure 14-8. **A**, Demonstration of the effect of vessel diameter on blood flow. **B**, Concentric rings of blood flowing at different velocities; the farther away from the vessel wall, the faster the flow. *d*, diameter; *P*, pressure difference between the two ends of the vessels.

Small Changes in Vessel Diameter Markedly Change Its Conductance. Slight changes in the diameter of a vessel cause tremendous changes in the vessel's ability to conduct blood when the blood flow is streamlined. This phenomenon is illustrated in [Figure 14-8A](#), which shows three vessels with relative diameters of 1, 2, and 4 but with the same pressure difference of 100 mm Hg between the two ends of the vessels. Although the diameters of these vessels increase only fourfold, the respective flows are 1, 16, and 256 ml/min, which is a 256-fold increase in flow. Thus, the conductance of the vessel increases in proportion to the *fourth power of the diameter*, in accordance with the following formula:

$$\text{Conductance} \propto \text{Diameter}^4$$

Poiseuille's Law. The cause of this great increase in conductance when the diameter increases can be explained by referring to [Figure 14-8B](#), which shows cross sections of a large and small vessel. The concentric rings inside the vessels indicate that the velocity of flow in each ring is different from that in the adjacent rings because of *laminar* flow, which was discussed earlier in the chapter. That is, the blood in the ring touching the wall of the vessel is barely flowing because of its adherence to the vascular endothelium. The next ring of blood toward the center of the vessel slips past the first ring and, therefore, flows more rapidly. Likewise, the third, fourth, fifth, and sixth rings flow at progressively increasing velocities. Thus, the blood that is near the wall of the vessel flows slowly, whereas that in the middle of the vessel flows much more rapidly.

In the small vessel, essentially all the blood is near the wall, so the extremely rapidly flowing central stream of blood simply does not exist. By integrating the velocities of all the concentric rings of flowing blood and multiplying them by the areas of the rings, one can derive the following formula, known as *Poiseuille's law*:

$$F = \frac{\pi \Delta P r^4}{8 \eta l}$$

in which F is the rate of blood flow, ΔP is the pressure difference between the ends of the vessel, r is the radius of the vessel, l is length of the vessel, and η is viscosity of the blood.

Note particularly in this equation that the rate of blood flow is directly proportional to the *fourth power of the radius* of the vessel, which demonstrates once again that the diameter of a blood vessel (which is equal to twice the radius) plays the greatest role of all factors in determining the rate of blood flow through a vessel.

Importance of the Vessel Diameter Fourth Power Law in Determining Arteriolar Resistance. In the systemic circulation, about two thirds of the total systemic resistance to blood flow is resistance in the small arterioles. The internal diameters of the arterioles range from as little as 4 micrometers to as much as 25 micrometers. However, their strong vascular walls allow the internal diameters to change tremendously, often as much as fourfold. From the fourth power law discussed earlier, which relates blood flow to diameter of the vessel, one can see that a fourfold increase in vessel diameter can increase the flow as much as 256-fold. Thus, this fourth power law makes it possible for the arterioles, responding with only small changes in diameter to nervous signals or local tissue chemical signals, either to turn off the blood flow to the tissue almost completely or, at the other extreme, to cause a vast increase in flow. Ranges of blood flow of more than 100-fold in separate tissue areas have been recorded between the limits of maximum arteriolar constriction and maximum arteriolar dilation.

Resistance to Blood Flow in Series and Parallel Vascular Circuits. Blood pumped by the heart flows from the high-pressure part of the systemic circulation (i.e., aorta) to the low-pressure side (i.e., vena cava) through many miles of blood vessels arranged in series and in parallel. The arteries, arterioles, capillaries, venules, and veins are collectively arranged in series. When blood vessels are arranged in series, flow through each blood vessel is the same, and the total resistance to blood flow (R_{total}) is equal to the sum of the resistances of each vessel:

$$R_{\text{total}} = R_1 + R_2 + R_3 + R_4 \dots$$

The total peripheral vascular resistance is therefore equal to the sum of resistances of the arteries, arterioles, capillaries, venules, and veins. In the example shown in [Figure 14-9A](#), the total vascular resistance is equal to the sum of R_1 and R_2 .

Blood vessels branch extensively to form parallel circuits that supply blood to the many organs and tissues of the body. This parallel arrangement permits each tissue to regulate its own blood flow, to a great extent, independently of flow to other tissues.

For blood vessels arranged in parallel ([Figure 14-9B](#)), the total resistance to blood flow is expressed as follows:

Figure 14-9. Vascular resistance (R). **A**, In series. **B**, In parallel.

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} \dots$$

It is obvious that for a given pressure gradient, far greater amounts of blood will flow through this parallel system than through any of the individual blood vessels. Therefore, the total resistance is far less than the resistance of any single blood vessel. Flow through each of the parallel vessels in [Figure 14-9B](#) is determined by the pressure gradient and its own resistance, not the resistance of the other parallel blood vessels. However, increasing the resistance of any of the blood vessels increases the total vascular resistance.

It may seem paradoxical that adding more blood vessels to a circuit reduces the total vascular resistance. Many parallel blood vessels, however, make it easier for blood to flow through the circuit because each parallel vessel provides another pathway, or *conductance*, for blood flow. The total conductance (C_{total}) for blood flow is the sum of the conductance of each parallel pathway:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 \dots$$

For example, brain, kidney, muscle, gastrointestinal, skin, and coronary circulations are arranged in parallel, and each tissue contributes to the overall conductance of the systemic circulation. Blood flow through each tissue is a fraction of the total blood flow (cardiac output) and is determined by the resistance (the reciprocal of conductance) for blood flow in the tissue, as well as the pressure gradient. Therefore, amputation of a limb or surgical removal of a kidney also removes a parallel circuit and reduces the total vascular conductance and total blood flow (i.e., cardiac output) while increasing the total peripheral vascular resistance.

Effect of Blood Hematocrit and Blood Viscosity on Vascular Resistance and Blood Flow

Note that another important factor in Poiseuille's equation is the viscosity of the blood. The greater the viscosity, the lower the flow in a vessel if all other factors are constant. Furthermore, *the viscosity of normal blood is about three times as great as the viscosity of water.*

What makes the blood so viscous? It is mainly the large numbers of suspended red cells in the blood, each

Figure 14-10. Hematocrit values in a healthy (normal) person and in patients with anemia and polycythemia. The numbers refer to the percentage of the blood composed of red blood cells.

of which exerts frictional drag against adjacent cells and against the wall of the blood vessel.

Hematocrit—the Proportion of Blood That Is Red Blood Cells. If a person has a hematocrit of 40, this means that 40% of the blood volume is cells, and the remainder is plasma. The hematocrit of adult men averages about 42, whereas that of women averages about 38. These values can vary greatly, depending on whether the person has anemia, the degree of bodily activity, and the altitude at which the person resides. These changes in hematocrit are discussed in relationship to the red blood cells and their oxygen transport function in [Chapter 33](#).

Hematocrit is determined by centrifuging blood in a calibrated tube, as shown in [Figure 14-10](#). The calibration allows direct reading of the percentage of cells.

Increasing Hematocrit Markedly Increases Blood Viscosity. The viscosity of blood increases markedly as the hematocrit increases, as shown in [Figure 14-11](#). The viscosity of whole blood at a normal hematocrit is about 3 to 4, which means that three to four times as much pressure is required to force whole blood as to force water through the same blood vessel. When the hematocrit rises to 60 or 70, which it often does in persons with *polycythemia*, the blood viscosity can become as great as 10 times that of water, and its flow through blood vessels is greatly retarded.

Other factors that affect blood viscosity are the plasma protein concentration and types of proteins in the plasma, but these effects are so much less than the effect

Figure 14-11. Effect of hematocrit on blood viscosity (water viscosity = 1).

Figure 14-12. Effect of changes in arterial pressure over a period of several minutes on blood flow in a tissue such as skeletal muscle. Note that between pressures of 70 and 175 mm Hg, blood flow is autoregulated. The *blue line* shows the effect of sympathetic nerve stimulation or vasoconstriction by hormones such as norepinephrine, angiotensin II, vasopressin, or endothelin on this relationship. Reduced tissue blood flow is rarely maintained for more than a few hours because of the activation of local autoregulatory mechanisms that eventually return blood flow toward normal.

of hematocrit that they are not significant considerations in most hemodynamic studies. The viscosity of blood plasma is about 1.5 times that of water.

EFFECTS OF PRESSURE ON VASCULAR RESISTANCE AND TISSUE BLOOD FLOW

Autoregulation Attenuates the Effect of Arterial Pressure on Tissue Blood Flow. From the discussion thus far, one might expect an increase in arterial pressure to cause a proportionate increase in blood flow through the body's tissues. However, the effect of arterial pressure on blood flow in many tissues is usually far less than one might expect, as shown in [Figure 14-12](#). This is because an increase in arterial pressure not only increases the force that pushes blood through the vessels, but also initiates compensatory increases in vascular resistance within a few seconds through activation of the local control mechanisms, discussed in [Chapter 17](#). Conversely, with reductions in arterial pressure, vascular

Figure 14-13. Effect of arterial pressure on blood flow through a passive blood vessel at different degrees of vascular tone caused by increased or decreased sympathetic stimulation of the vessel.

resistance is promptly reduced in most tissues, and blood flow is maintained at a relatively constant rate. The ability of each tissue to adjust its vascular resistance and to maintain normal blood flow during changes in arterial pressure between approximately 70 and 175 mm Hg is called *blood flow autoregulation*.

Note in [Figure 14-12](#) that changes in blood flow can be caused by strong sympathetic stimulation, which *constricts* the blood vessels. Likewise, hormonal vasoconstrictors, such as *norepinephrine*, *angiotensin II*, *vasopressin*, or *endothelin*, can also reduce blood flow, at least transiently.

Blood flow changes rarely last for more than a few hours in most tissues, even when increases in arterial pressure or increased levels of vasoconstrictors are sustained. The reason for the relative constancy of blood flow is that each tissue's local autoregulatory mechanisms eventually override most of the effects of vasoconstrictors to provide a blood flow that is appropriate for the needs of the tissue.

Pressure-Flow Relationship in Passive Vascular Beds.

In isolated blood vessels or in tissues that do not exhibit autoregulation, changes in arterial pressure may have important effects on blood flow. The effect of pressure on blood flow may be greater than that predicted by Poiseuille's equation, as shown by the upward curving lines in [Figure 14-13](#). The reason for this is that increased arterial pressure not only increases the force that pushes blood through the vessels, but also distends the elastic vessels, actually *decreasing* vascular resistance. Conversely, decreased arterial pressure in passive blood vessels increases resistance as the elastic vessels gradually collapse due to reduced distending pressure. When pressure falls below a critical level, called the *critical closing pressure*, flow ceases because the blood vessels are completely collapsed.

Sympathetic stimulation and other vasoconstrictors can alter the passive pressure-flow relationship shown in [Figure 14-13](#). Thus, *inhibition* of sympathetic activity *greatly dilates* the vessels and can increase the blood flow

Figure 14-14. Illustration of the effects of vessel wall tension and shear stress on blood vessels. Wall tension develops in response to transmembrane pressure gradients and causes stretch of endothelial and vascular smooth muscle cells in all directions. Shear stress is the frictional force or drag on endothelial cells caused by flowing blood. Shear stress results in unidirectional endothelial cell deformation.

twofold or more. Conversely, very strong sympathetic stimulation *can constrict* the vessels so much that blood flow occasionally decreases to as low as zero for a few seconds, despite high arterial pressure.

In reality, there are few physiological conditions in which tissues display the passive pressure-flow relationship shown in [Figure 14-13](#). Even in tissues that do not effectively autoregulate blood flow during acute changes in arterial pressure, blood flow is regulated according to the needs of the tissue when the pressure changes are sustained, as discussed in [Chapter 17](#).

Vascular Wall Tension. Tension on the blood vessel wall develops in response to transmembrane pressure gradients and causes vascular smooth muscle and endothelial cells to stretch in all directions ([Figure 14-14A](#)). According to the *law of Laplace*, wall tension (T) for a thin-walled tube is proportional to the transmembrane pressure gradient (ΔP) times the radius (r) of the blood vessel divided by its wall thickness (h):

$$T = \Delta P \times (r/h)$$

Thus, larger blood vessels exposed to high pressures, such as the aorta, must have stronger walls to withstand higher levels of tension and are generally reinforced with fibrous bands of collagen. In contrast, capillaries have a much smaller radii and therefore are exposed to much lower wall tension, permitting them to withstand pressures as high as 65 to 70 mm Hg in some organs such as the kidneys. As discussed in [Chapter 17](#), chronic changes in blood pressure lead to remodeling of blood vessels to accommodate the associated changes in wall tension.

Vascular Shear Stress. As blood flows it creates a frictional force, or drag, on the endothelial cells lining the blood vessels (see [Figure 14-14B](#)). This force, called *shear stress*, is proportional to the flow velocity and viscosity of the blood, inversely related to the radius cubed, and generally is expressed in force/unit area (e.g., dynes/cm²). In clinical practice, there is no single commonly used method for measuring shear stress. However, despite its relatively low magnitude compared to contractile forces or wall stretch from blood pressure, shear stress is important in the development and adaptation of the vascular system

to accommodate the blood flow requirements of the tissues. Endothelial cells contain multiple proteins that together serve as mechanical sensors and regulate signaling pathways that shape the vasculature during embryonic development and continue altering blood vessel morphology to optimize delivery of blood to tissues in adult life, as discussed further in [Chapter 17](#).

Bibliography

See the bibliography for [Chapter 15](#).

Vascular Distensibility and Functions of the Arterial and Venous Systems

VASCULAR DISTENSIBILITY

A valuable characteristic of the vascular system is that all blood vessels are *distensible*. The distensible nature of the arteries allows them to accommodate the pulsatile output of the heart and to average out the pressure pulsations. This capability provides smooth continuous flow of blood through the very small blood vessels of the tissues.

The most distensible of all the vessels are the veins. Even slight increases in venous pressure cause the veins to store 0.5 to 1.0 liter of extra blood. Therefore, *the veins provide a reservoir* for storing large quantities of extra blood that can be called into use whenever blood is required elsewhere in the circulation.

Units of Vascular Distensibility. Vascular distensibility normally is expressed as the fractional increase in volume for each millimeter of mercury rise in pressure, in accordance with the following formula:

$$\text{Vascular distensibility} = \frac{\text{Increase in volume}}{\text{Increase in pressure} \times \text{Original volume}}$$

That is, if 1 mm Hg causes a vessel that originally contained 10 ml of blood to increase its volume by 1 ml, the distensibility would be 0.1 per mm Hg, or 10% per mm Hg.

The Veins Are Much More Distensible Than the Arteries. The walls of the arteries are thicker and far stronger than those of the veins. Consequently, the veins, on average, are about eight times more distensible than the arteries. That is, a given increase in pressure causes about eight times as much increase in blood in a vein as in an artery of comparable size.

In the pulmonary circulation, the pulmonary vein distensibilities are similar to those of the systemic circulation. However, the pulmonary arteries normally operate under pressures about one sixth of those in the systemic arterial system, and their distensibilities are correspondingly greater—about six times the distensibility of systemic arteries.

VASCULAR COMPLIANCE (OR VASCULAR CAPACITANCE)

In hemodynamic studies, it usually is much more important to know the *total quantity of blood* that can be stored in a given portion of the circulation for each mm Hg pressure rise than to know the distensibilities of the individual vessels. This value is called the *compliance* or *capacitance* of the respective vascular bed; that is:

$$\text{Vascular compliance} = \frac{\text{Increase in volume}}{\text{Increase in pressure}}$$

Compliance and distensibility are quite different. A highly distensible vessel that has a small volume may have far less compliance than a much less distensible vessel that has a large volume because *compliance is equal to distensibility times volume*.

The compliance of a systemic vein is about 24 times that of its corresponding artery because it is about 8 times as distensible and has a volume about 3 times as great ($8 \times 3 = 24$).

VOLUME-PRESSURE CURVES OF THE ARTERIAL AND VENOUS CIRCULATIONS

A convenient method for expressing the relationship of pressure to volume in a vessel or in any portion of the circulation is to use a *volume-pressure curve*. The red and blue solid curves in **Figure 15-1** represent, respectively, the volume-pressure curves of the normal systemic arterial system and venous system, showing that when the arterial system of the average adult person (including all the large arteries, small arteries, and arterioles) is filled with about 700 ml of blood, the mean arterial pressure is 100 mm Hg but, when it is filled with only 400 ml of blood, the pressure falls to zero.

In the entire systemic venous system, the volume normally ranges from 2000 to 3500 ml, and a change of several hundred ml in this volume is required to change the venous pressure by only 3 to 5 mm Hg. This requirement mainly explains why as much as one-half liter of blood can be transfused into a healthy person in only a few minutes without greatly altering the function of the circulation.

Figure 15-1. Volume-pressure curves of the systemic arterial and venous systems, showing the effects of stimulation or inhibition of the sympathetic nerves to the circulatory system.

Effect of Sympathetic Stimulation or Sympathetic Inhibition on the Volume-Pressure Relationships of the Arterial and Venous Systems. Also shown in [Figure 15-1](#) are the effects on the volume-pressure curves when the vascular sympathetic nerves are excited or inhibited. It is evident that an increase in vascular smooth muscle tone caused by sympathetic stimulation increases the pressure at each volume of the arteries or veins, whereas sympathetic inhibition decreases the pressure at each volume. Control of the vessels by the sympathetics in this manner is a valuable means for diminishing the dimensions of one segment of the circulation, thus transferring blood to other segments. For example, an increase in vascular tone throughout the systemic circulation can cause large volumes of blood to shift into the heart, which is one of the principal methods that the body uses to rapidly increase heart pumping.

Sympathetic control of vascular capacitance is also highly important during hemorrhage. Enhancement of sympathetic tone, especially to the veins, reduces the vessel sizes enough that the circulation continues to operate almost normally, even when as much as 25% of the total blood volume has been lost.

Delayed Compliance (Stress-Relaxation) of Vessels.

The term *delayed compliance* means that a vessel exposed to increased volume at first exhibits a large increase in pressure, but progressive delayed stretching of smooth muscle in the vessel wall allows the pressure to return toward normal over a period of minutes to hours. This effect is shown in [Figure 15-2](#). In this figure, the pressure is recorded in a small segment of a vein that is occluded at both ends. An extra volume of blood is suddenly injected until the pressure rises from 5 to 12 mm Hg. Even though none of the blood is removed after it is injected, the pressure begins to decrease immediately and approaches about 9 mm Hg after several minutes. Thus, the volume of blood injected causes immediate *elastic* distention of the vein, but then the smooth muscle fibers of the

Figure 15-2. Effect on the intravascular pressure of injecting a volume of blood into a venous segment and later removing the excess blood, demonstrating the principle of *delayed compliance*.

vein begin to creep to longer lengths, and their tensions correspondingly decrease. This effect is a characteristic of all smooth muscle and is called *stress-relaxation*, as explained in [Chapter 8](#).

Delayed compliance is a valuable mechanism whereby the circulation can accommodate extra blood when necessary, such as after a large transfusion. Delayed compliance in the reverse direction is one way in which the circulation automatically adjusts itself over a period of minutes or hours to diminished blood volume after serious hemorrhage.

ARTERIAL PRESSURE PULSATATIONS

With each beat of the heart, a new surge of blood fills the arteries. Were it not for distensibility of the arterial system, all this new blood would have to flow through the peripheral blood vessels almost instantaneously, only during cardiac systole, and no flow would occur during diastole. However, the compliance of the arterial tree normally reduces the pressure pulsations to almost no pulsations by the time the blood reaches the capillaries; therefore, tissue blood flow is mainly continuous with very little pulsation.

The *pressure pulsations* at the root of the aorta are illustrated in [Figure 15-3](#). In a healthy young adult, the pressure at the top of each pulse, called the *systolic pressure*, is about 120 mm Hg. At the lowest point of each pulse, called the *diastolic pressure*, it is about 80 mm Hg. The difference between these two pressures, about 40 mm Hg, is called the *pulse pressure*.

Two major factors affect the pulse pressure: (1) the *stroke volume output* of the heart; and (2) the *compliance (total distensibility)* of the arterial tree. A third less important factor is the character of ejection from the heart during systole.

In general, the greater the stroke volume output, the greater the amount of blood that must be accommodated in the arterial tree with each heartbeat and, therefore, the greater the pressure rise and fall during systole and diastole, thus causing a greater pulse pressure. Conversely, the less the compliance of the arterial system, the greater

Figure 15-3. Pressure pulse contour in the ascending aorta.

Figure 15-4. Aortic pressure pulse contours in arteriosclerosis, aortic stenosis, patent ductus arteriosus, and aortic regurgitation.

the rise in pressure for a given stroke volume of blood pumped into the arteries. For example, as demonstrated by the middle top curves in Figure 15-4, the pulse pressure in old age sometimes rises to twice normal because the arteries have stiffened with *arteriosclerosis* and therefore are relatively noncompliant.

In effect, pulse pressure is determined approximately by the *ratio of stroke volume output to compliance of the arterial tree*. Any condition of the circulation that affects either of these two factors also affects the pulse pressure:

$$\text{Pulse pressure} \approx \text{Stroke volume} / \text{arterial compliance}$$

ABNORMAL PRESSURE PULSE CONTOURS

Some pathophysiological conditions of the circulation cause *abnormal contours of the pressure pulse wave* in addition to altering the pulse pressure. Especially distinctive among these conditions are aortic stenosis, patent ductus arteriosus, and aortic regurgitation, each of which is shown in Figure 15-4.

In persons with *aortic valve stenosis*, the diameter of the aortic valve opening is reduced significantly, and the aortic

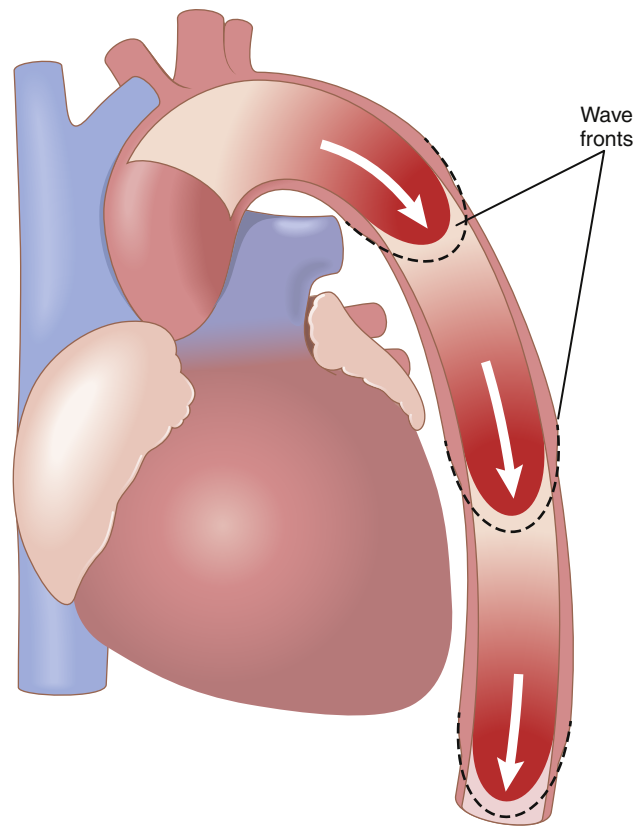

Figure 15-5. Progressive stages in transmission of the pressure pulse along the aorta.

pressure pulse is decreased significantly because of diminished blood flow outward through the stenotic valve.

In persons with *patent ductus arteriosus*, 50% or more of the blood pumped into the aorta by the left ventricle flows immediately backward through the wide open ductus into the pulmonary artery and lung blood vessels, thus allowing the diastolic pressure to fall very low before the next heartbeat and increasing the pulse pressure.

In persons with *aortic regurgitation*, the aortic valve is absent or does not close completely. Therefore, after each heartbeat, the blood that has just been pumped into the aorta flows immediately backward into the left ventricle. As a result, the aortic pressure can fall all the way to zero between heartbeats. Also, there is no incisura in the aortic pulse contour because there is no aortic valve to close.

TRANSMISSION OF PRESSURE PULSES TO THE PERIPHERAL ARTERIES

When the heart ejects blood into the aorta during systole, only the proximal portion of the aorta initially becomes distended because the inertia of the blood prevents sudden blood movement all the way to the periphery. However, the rising pressure in the proximal aorta rapidly overcomes this inertia, and the wavefront of distention spreads farther and farther along the aorta, as shown in Figure 15-5. This phenomenon is called *transmission of the pressure pulse* in the arteries.

Figure 15-6. Changes in the pulse pressure contour as the pulse wave travels toward the smaller vessels.

The velocity of pressure pulse transmission is 3 to 5 m/sec in the normal aorta, 7 to 10 m/sec in the large arterial branches, and 15 to 35 m/sec in the small arteries. In general, the greater the compliance of each vascular segment, the slower the velocity, which explains the slow transmission in the aorta and the much faster transmission in the much less compliant small distal arteries. In the aorta, the velocity of transmission of the pressure pulse is 15 or more times the velocity of blood flow because the pressure pulse is simply a moving wave of *pressure* that involves little forward total movement of blood volume.

Pressure Pulses Are Damped in the Smaller Arteries, Arterioles, and Capillaries. Figure 15-6 shows typical changes in the pressure pulse contours as the pulse travels into the peripheral vessels. Note especially in the three lower curves that the intensity of pulsation becomes progressively less in the smaller arteries, arterioles and, especially, capillaries. In fact, only when the aortic pulsations are extremely large or the arterioles are greatly dilated can pulsations be observed in the capillaries.

This progressive diminution of the pulsations in the periphery is called *damping of the pressure pulses*. The cause of this damping is twofold: (1) resistance to blood movement in the vessels; and (2) compliance of the vessels. The resistance damps the pulsations because a small amount of blood must flow forward at the pulse wave front to distend the next segment of the vessel; the greater the resistance, the more difficult it is for this to occur. The compliance damps the pulsations because the more compliant a vessel, the greater the quantity of blood required at the pulse wave front to cause an increase in pressure.

Therefore, *the degree of damping is almost directly proportional to the product of resistance times compliance*.

CLINICAL METHODS FOR MEASURING SYSTOLIC AND DIASTOLIC PRESSURES

It is not practical to use pressure recorders that require needle insertion into an artery for making routine arterial pressure measurements in human patients, although these types of recorders are used on occasion when special studies are necessary. Instead, the clinician determines systolic and diastolic pressures through indirect means, usually by the *auscultatory method*.

Auscultatory Method. Figure 15-7 shows the auscultatory method for determining systolic and diastolic arterial pressures. A stethoscope is placed over the antecubital artery, and a blood pressure cuff is inflated around the upper arm. As long as the cuff continues to compress the arm with too little pressure to close the brachial artery, no sounds are heard from the antecubital artery with the stethoscope. However, when the cuff pressure is great enough to close the artery during part of the arterial pressure cycle, a sound is then heard with each pulsation. These sounds are called *Korotkoff sounds*, named after Nikolai Korotkoff, a Russian physician, who described them in 1905.

Korotkoff sounds are believed to be caused mainly by blood jetting through the partly occluded vessel and by vibrations of the vessel wall. The jet causes turbulence in the vessel beyond the cuff, and this turbulence sets up the vibrations heard through the stethoscope.

In determining blood pressure by the auscultatory method, the pressure in the cuff is first elevated well above arterial systolic pressure. As long as this cuff pressure is higher than systolic pressure, the brachial artery remains collapsed so that no blood jets into the lower artery during any part of the pressure cycle. Therefore, no Korotkoff sounds are heard in the lower artery. Then the cuff pressure gradually is reduced. Just as soon as the pressure in the cuff falls below systolic pressure (point B, Figure 15-7), blood begins to flow through the artery beneath the cuff during the peak of systolic pressure, and one begins to hear *tapping* sounds from the antecubital artery in synchrony with the heartbeat. As soon as these sounds begin to be heard, the pressure level indicated by the manometer connected to the cuff is about equal to the systolic pressure.

As the pressure in the cuff is lowered still more, the Korotkoff sounds change in quality, having less of the tapping quality and more of a rhythmical and harsher quality. Then, finally, when the pressure in the cuff falls near diastolic pressure, the sounds suddenly change to a muffled quality (point C, Figure 15-7). One notes the manometer pressure when the Korotkoff sounds change to the muffled quality, and this pressure is about equal to the diastolic pressure, although it slightly overestimates

Figure 15-7. Auscultatory method for measuring systolic and diastolic arterial pressures.

the diastolic pressure determined by direct intra-arterial catheter. As the cuff pressure falls a few mm Hg further, the artery no longer closes during diastole, which means that the basic factor causing the sounds (the jetting of blood through a squeezed artery) is no longer present. Therefore, the sounds disappear entirely. Many clinicians believe that the pressure at which the Korotkoff sounds completely disappear should be used as the diastolic pressure, except in situations in which the disappearance of sounds cannot reliably be determined because sounds are audible, even after complete deflation of the cuff. For example, in patients with arteriovenous fistulas for hemodialysis or with aortic insufficiency, Korotkoff sounds may be heard after complete deflation of the cuff.

The auscultatory method for determining systolic and diastolic pressures is not entirely accurate, but it usually

gives values within 10% of those determined by direct catheter measurement from inside the arteries.

Automated Oscillometric Method. Systolic and diastolic arterial pressures are often measured using automated oscillometric devices. These devices use a sphygmomanometer cuff, like the auscultatory method, but with an electronic pressure sensor to detect cuff pressure oscillations that occur when blood flows through an artery, often the brachial artery. Oscillometric arterial pressure devices use specific electronic algorithms to inflate and deflate the cuff automatically and interpret the cuff pressure oscillations. When the cuff is inflated, and its pressure exceeds systolic pressure, there is no blood flow in the artery and no oscillation of the cuff pressure. As the cuff is slowly deflated, blood begins to spurt through the artery, and the cuff pressure then oscillates in synchrony with the cyclic expansion and contraction of the artery. As the cuff pressure declines, the oscillations increase in amplitude to a maximum, which corresponds to the mean arterial pressure. The oscillation amplitude then declines as the cuff pressure falls below the patient's diastolic pressure and blood flows smoothly through the artery. Using device-specific algorithms, the cuff pressure oscillations are automatically converted into digital systolic and diastolic pressures signals, as well as heart rate, and displayed.

Oscillometric arterial pressure monitors require less skill than the auscultatory technique and can be used by the patient at home, avoiding the so-called white-coat effect that raises blood pressure in some patients when a health care professional is present. These devices, however, must be calibrated for accuracy and can yield unreliable measurements in patients when the cuff size is inappropriate or in some abnormal circulatory conditions, such as severe arteriosclerosis, which increases stiffness of the artery wall.

Normal Arterial Pressures as Measured by the Auscultatory and Oscillatory Methods. Figure 15-8 shows the approximate normal systolic and diastolic arterial pressures at different ages. The progressive increase in pressure with age results from the effects of aging on the blood pressure control mechanisms. We shall see in Chapter 19 that the kidneys are primarily responsible for this long-term regulation of arterial pressure; it is well known that the kidneys exhibit definitive changes with age, especially after the age of 50 years.

A slight extra increase in *systolic* pressure usually occurs beyond the age of 60 years. This increase results from decreasing distensibility, or hardening, of the arteries, which is often a result of *atherosclerosis*. The final effect is a higher systolic pressure with considerable increase in pulse pressure, as previously explained.

Mean Arterial Pressure. The mean arterial pressure is the average of the arterial pressures measured millisecond by millisecond over a period of time. It is not equal to the average of the systolic and diastolic pressures because at

Figure 15-8. Changes in systolic, diastolic, and mean arterial pressures with age. The shaded areas show the approximate normal ranges.

normal heart rates, a greater fraction of the cardiac cycle is spent in diastole than in systole. Thus, the arterial pressure remains closer to diastolic pressure than to systolic pressure during the greater part of the cardiac cycle. The mean arterial pressure is therefore determined about 60% by the diastolic pressure and 40% by the systolic pressure. Note in [Figure 15-8](#) that the mean pressure (*solid green line*) at all ages is nearer to the diastolic pressure than to the systolic pressure. However, at very high heart rates, diastole comprises a smaller fraction of the cardiac cycle, and the mean arterial pressure is more closely approximated as the average of systolic and diastolic pressures.

VEINS AND THEIR FUNCTIONS

The veins provide passageways for flow of blood to the heart, but they also perform other special functions that are necessary for operation of the circulation. Of special importance is that they are capable of constricting and enlarging and thereby storing small or large quantities of blood and making this blood available when required by the remainder of the circulation. The peripheral veins can also propel blood forward by means of a so-called *venous pump*, and they even help regulate cardiac output, an exceedingly important function described in detail in [Chapter 20](#).

VENOUS PRESSURES—RIGHT ATRIAL PRESSURE (CENTRAL VENOUS PRESSURE) AND PERIPHERAL VENOUS PRESSURES

Blood from all the systemic veins flows into the right atrium of the heart. Therefore, the pressure in the right atrium is called the *central venous pressure*.

Right atrial pressure is regulated by a balance between (1) the ability of the heart to pump blood out of the right atrium and ventricle into the lungs and (2) the tendency for blood to flow from the peripheral veins into the right atrium. If the right heart is pumping strongly, the right atrial pressure decreases. Conversely, weakness of the heart elevates the right atrial pressure. Also, any effect

that causes rapid inflow of blood into the right atrium from the peripheral veins elevates the right atrial pressure. Some factors that can increase this venous return and thereby increase the right atrial pressure are as follows: (1) increased blood volume; (2) increased large vessel tone throughout the body with resultant increased peripheral venous pressures; and (3) dilation of the arterioles, which decreases the peripheral resistance and allows rapid flow of blood from the arteries into the veins.

The same factors that regulate right atrial pressure also contribute to the regulation of cardiac output because the amount of blood pumped by the heart depends on both the ability of the heart to pump and the tendency for blood to flow into the heart from the peripheral vessels. Therefore, we discuss regulation of right atrial pressure in much more depth in [Chapter 20](#) in connection with cardiac output regulation.

The *normal right atrial pressure* is about 0 mm Hg, which is equal to the atmospheric pressure around the body. It can increase to 20 to 30 mm Hg under very abnormal conditions, such as the following: (1) serious heart failure; or (2) after massive transfusion of blood, which greatly increases the total blood volume and causes excessive quantities of blood to attempt to flow into the heart from the peripheral vessels.

The lower limit to the right atrial pressure is usually about -3 to -5 mm Hg below atmospheric pressure, which is also the pressure in the chest cavity that surrounds the heart. The right atrial pressure approaches these low values when the heart pumps with exceptional vigor or when blood flow into the heart from the peripheral vessels is greatly depressed, such as after severe hemorrhage.

Venous Resistance and Peripheral Venous Pressure

Large veins have so little resistance to blood flow *when they are distended* that the resistance then is almost zero. However, as shown in [Figure 15-9](#), most of the large veins that enter the thorax are compressed at many points by the surrounding tissues, so that blood flow is impeded at these points. For example, the veins from the arms are compressed by their sharp angulations over the first rib. Also, the pressure in the neck veins often falls so low that the atmospheric pressure on the outside of the neck causes these veins to collapse. Finally, veins coursing through the abdomen are often compressed by different organs and by the intra-abdominal pressure, so they usually are at least partially collapsed to an ovoid or slitlike state. For these reasons, the *large veins do usually offer some resistance to blood flow*, and thus the pressure in the more peripheral small veins in a person lying down is usually $+4$ to $+6$ mm Hg greater than the right atrial pressure.

Effect of High Right Atrial Pressure on Peripheral Venous Pressure. When the right atrial pressure rises above its normal value of 0 mm Hg, blood begins to back

Figure 15-9. Compression points that tend to collapse the veins entering the thorax.

up in the large veins. This backup of blood enlarges the veins, and even the collapse points in the veins open up when the right atrial pressure rises above +4 to +6 mm Hg. Then, as the right atrial pressure rises further, the additional increase causes a corresponding rise in peripheral venous pressure in the limbs and elsewhere. Because heart function must be impaired significantly to cause a rise in right atrial pressure as high as +4 to +6 mm Hg, the peripheral venous pressure is not noticeably elevated, even in the early stages of heart failure, as long as the person is at rest.

Effect of Intra-abdominal Pressure on Venous Pressures of the Leg. The pressure in the abdominal cavity of a recumbent person normally averages about +6 mm Hg, but it can rise to +15 to +30 mm Hg as a result of pregnancy, large tumors, abdominal obesity, or excessive fluid (called *ascites*) in the abdominal cavity. When the intra-abdominal pressure rises, the pressure in the veins of the legs must rise *above* the abdominal pressure before the abdominal veins will open and allow the blood to flow from the legs to the heart. Thus, if the intra-abdominal pressure is +20 mm Hg, the lowest possible pressure in the femoral veins is also about +20 mm Hg.

Effect of Gravitational Pressure on Venous Pressure

In any body of water that is exposed to air, the pressure at the surface of the water is equal to atmospheric pressure, but the pressure rises 1 mm Hg for each 13.6 millimeters of distance below the surface. This pressure results from the weight of the water and therefore is called *gravitational pressure* or *hydrostatic pressure*.

Figure 15-10. Effect of gravitational pressure on the venous pressures throughout the body in the standing person.

Gravitational pressure also occurs in the vascular system because of the weight of the blood in the vessels, as shown in **Figure 15-10**. When a person is standing, the pressure in the right atrium remains about 0 mm Hg because the heart pumps any excess blood that attempts to accumulate at this point into the arteries. However, in an adult *who is standing absolutely still*, the pressure in the veins of the feet is about +90 mm Hg simply because of the gravitational weight of the blood in the veins between the heart and the feet. The venous pressures at other levels of the body are proportionately between 0 and 90 mm Hg.

In the arm veins, the pressure at the level of the top rib is usually about +6 mm Hg because of compression of the subclavian vein as it passes over this rib. The gravitational pressure down the length of the arm is then determined by the distance below the level of this rib. Thus, if the gravitational difference between the level of the rib and the hand is +29 mm Hg, this gravitational pressure is added to the +6 mm Hg pressure caused by compression of the vein as it crosses the rib, making a total of +35 mm Hg pressure in the veins of the hand.

The neck veins of a person standing upright collapse almost completely all the way to the skull because of

atmospheric pressure on the outside of the neck. This collapse causes the pressure in these veins to remain at zero along their entire extent. Any tendency for the pressure to rise above this level opens the veins and allows the pressure to fall back to zero because of flow of the blood. Conversely, any tendency for the neck vein pressure to fall below zero collapses the veins still more, which further increases their resistance and again returns the pressure back to zero.

The veins inside the skull, on the other hand, are in a chamber (the skull cavity) that cannot collapse. Consequently, *negative pressure can exist in the dural sinuses of the head*; in the standing position, the venous pressure in the sagittal sinus at the top of the brain is about -10 mm Hg because of the hydrostatic “suction” between the top of the skull and the base of the skull. Therefore, if the sagittal sinus is opened during surgery, air can be sucked immediately into the venous system; the air may even pass downward to cause air embolism in the heart and death.

Effect of the Gravitational Factor on Arterial and Other Pressures. The gravitational factor also affects pressures in the peripheral arteries and capillaries. For example, a standing person who has a mean arterial pressure of 100 mm Hg at the level of the heart has an arterial pressure in the feet of about 190 mm Hg. Therefore, when the arterial pressure is stated to be 100 mm Hg, this generally means that 100 mm Hg is the pressure at the gravitational level of the heart but not necessarily elsewhere in the arterial vessels.

Venous Valves and the Venous Pump: Their Effects on Venous Pressure

Were it not for valves in the veins, the gravitational pressure effect would cause the venous pressure in the feet always to be about $+90$ mm Hg in a standing adult. However, every time the legs move, the muscles tighten and compress the veins in or adjacent to the muscles, which squeezes the blood out of the veins. However, the valves in the veins, shown in **Figure 15-11**, are arranged so that the direction of venous blood flow can only be toward the heart. Consequently, every time a person moves the legs or even tenses the leg muscles, a certain amount of venous blood is propelled toward the heart. This pumping system is known as the *venous pump* or *muscle pump*, and it is efficient enough that under ordinary circumstances, the venous pressure in the feet of a walking adult remains less than $+20$ mm Hg.

If a person stands perfectly still, the venous pump does not work, and the venous pressures in the lower legs increase to the full gravitational value of 90 mm Hg in about 30 seconds. The pressures in the capillaries also increase greatly, causing fluid to leak from the circulatory system into the tissue spaces. As a result, the legs swell, and the blood volume diminishes; 10% to 20% of the blood volume can be lost from the circulatory system

Figure 15-11. Venous valves of the leg.

within the 15 to 30 minutes of standing absolutely still, which may lead to fainting, as sometimes occurs when a soldier is made to stand at attention. This situation can be avoided by simply flexing the leg muscles periodically and slightly bending the knees, thus permitting the venous pump to work.

Venous Valve Incompetence Causes Varicose Veins.

The valves of the venous system may become incompetent or even be destroyed when the veins have been overstretched by excess venous pressure lasting weeks or months, which can occur in pregnancy or when a person stands most of the time. Stretching the veins increases their cross-sectional areas, but the leaflets of the valves do not increase in size. Therefore, the leaflets of the valves no longer close completely. With this lack of complete closure, the pressure in the veins of the legs increases greatly because of failure of the venous pump, which further increases the sizes of the veins and finally destroys the function of the valves entirely. Thus, the person develops what are called *varicose veins*, which are characterized by large bulbous protrusions of the veins beneath the skin of the entire leg, particularly the lower leg.

Whenever people with varicose veins stand for more than a few minutes, the venous and capillary pressures become very high, and leakage of fluid from the capillaries causes constant edema in the legs. The edema, in turn, prevents adequate diffusion of nutritional materials from the capillaries to the muscle and skin cells, so the muscles become painful and weak, and the skin may even become gangrenous and ulcerate. The best treatment for such a condition is continual elevation of the legs to a level at least as high as the heart. Tight binders or long compression stockings on the legs also can be of considerable assistance in preventing the edema and its sequelae.

Clinical Estimation of Venous Pressure Venous pressure often can be estimated by simply observing the degree of distention of the peripheral veins, especially of the neck veins. For example, in the sitting position, the neck veins are never distended in the normal, quietly resting person. However, when the right atrial pressure becomes increased to as much as +10 mm Hg, the lower veins of the neck begin to protrude and, at +15 mm Hg atrial pressure, essentially all the veins in the neck become distended.

Direct Measurement of Venous Pressure and Right Atrial Pressure Venous pressure can be measured easily by inserting a needle directly into a vein and connecting it to a pressure recorder. The only means whereby *right atrial pressure* can be measured accurately is by inserting a catheter through the peripheral veins and into the right atrium. Pressures measured through such *central venous catheters* are often used in some types of hospitalized cardiac patients to provide a constant assessment of the heart-pumping ability.

Pressure Reference Level for Measuring Venous and Other Circulatory Pressures Although we have spoken of right atrial pressure as being 0 mm Hg and arterial pressure as being 100 mm Hg, we have not stated the gravitational level in the circulatory system to which this pressure is referred. There is one point in the circulatory system at which gravitational pressure factors caused by changes in body position of a healthy person usually do not affect the pressure measurement by more than 1 to 2 mm Hg. This is at or near the level of the tricuspid valve, as shown by the crossed axes in [Figure 15-12](#). Therefore, all circulatory pressure measurements discussed in this text are referred to this level, which is called the *reference level for pressure measurement*.

The reason for the lack of gravitational effects at the tricuspid valve is that the heart automatically prevents significant gravitational changes in pressure at this point in the following way. If the pressure at the tricuspid valve rises slightly above normal, the right ventricle fills to a greater extent than usual, causing the heart to pump blood more rapidly and therefore decreasing the pressure at the tricuspid valve back toward the normal mean value. Conversely, if the pressure falls, the right ventricle fails to fill adequately, its pumping decreases, and blood dams up in the venous system until the pressure at the tricuspid level again rises to the normal value. In other words, *the heart acts as a feedback regulator of pressure* at the tricuspid valve.

When a person is lying on his or her back, the tricuspid valve is located at almost exactly 60% of the chest thickness in front of the back. This is the *zero pressure reference level* for a person lying down.

BLOOD RESERVOIR FUNCTION OF THE VEINS

We indicated in [Chapter 14](#) that more than 60% of all the blood in the circulatory system is usually in the veins. For this reason, and also because the veins are so compliant, the venous system serves as a *blood reservoir* for the circulation.

When blood is lost from the body, and the arterial pressure begins to fall, nervous signals are elicited from the carotid sinuses and other pressure-sensitive areas of the

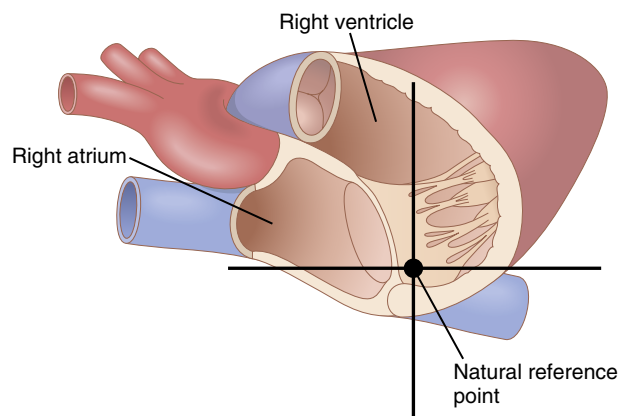

Figure 15-12. Reference point for circulatory pressure measurement (located near the tricuspid valve).

circulation, as discussed in [Chapter 18](#). These signals, in turn, elicit nerve signals from the brain and spinal cord, mainly through sympathetic nerves to the veins, causing them to constrict. This process takes up much of the slack in the circulatory system caused by the lost blood. Even after as much as 20% of the total blood volume has been lost, the circulatory system often functions almost normally because of this variable reservoir function of the veins.

SPECIFIC BLOOD RESERVOIRS

Certain portions of the circulatory system are so extensive and/or so compliant that they are called *specific blood reservoirs*. These reservoirs include the following: (1) the *spleen*, which sometimes can decrease in size sufficiently to release as much as 100 ml of blood into other areas of the circulation; (2) the *liver*, the sinuses of which can release several hundred milliliters of blood into the remainder of the circulation; (3) the *large abdominal veins*, which can contribute as much as 300 ml; and (4) the *venous plexus beneath the skin*, which also can contribute several hundred milliliters. The *heart* and *lungs*, although not parts of the systemic venous reservoir system, may also be considered blood reservoirs. The heart, for example, shrinks during sympathetic stimulation and in this way can contribute some 50 to 100 ml of blood; the lungs can contribute another 100 to 200 ml when the pulmonary pressures decrease to low values.

THE SPLEEN IS A RESERVOIR FOR RED BLOOD CELLS

[Figure 15-13](#) shows that the spleen has two separate areas for storing blood, the *venous sinuses* and the *pulp*. The sinuses can swell in the same way as any other part of the venous system and store whole blood.

In the splenic pulp, the capillaries are so permeable that whole blood, including the red blood cells, oozes through the capillary walls into a trabecular mesh, forming the *red pulp*. The red cells are trapped by the trabeculae while the plasma flows on into the venous sinuses and then into the general circulation. As a consequence, the

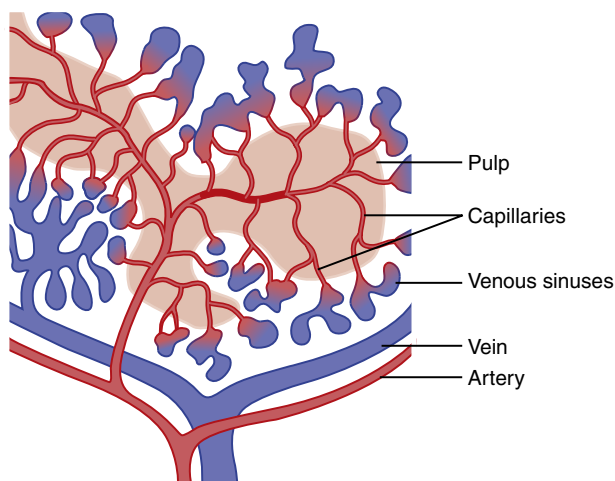

Figure 15-13. Functional structures of the spleen.

red pulp of the spleen is a *special reservoir that contains large quantities of concentrated red blood cells*. These concentrated red blood cells can then be expelled into the general circulation whenever the sympathetic nervous system becomes excited and causes the spleen and its vessels to contract. As much as 50 ml of concentrated red blood cells can be released into the circulation, raising the hematocrit by 1% to 2%.

In other areas of the splenic pulp are islands of white blood cells, which collectively are called the *white pulp*. Here, lymphoid cells are manufactured that are similar to those manufactured in the lymph nodes. They are part of the body's immune system, described in [Chapter 35](#).

Blood-Cleansing Function of the Spleen—Removal of Old Cells Blood cells passing through the splenic pulp before entering the sinuses undergo thorough squeezing. Therefore, it is to be expected that fragile red blood cells would not withstand the trauma. For this reason, many of the red blood cells are destroyed in the spleen. After the cells rupture, the released hemoglobin and cell stroma are digested by the reticuloendothelial cells of the spleen, and the products of digestion are mainly reused by the body as nutrients, often used for making new blood cells.

Reticuloendothelial Cells of the Spleen. The pulp of the spleen contains many large phagocytic reticuloendothelial cells, and the venous sinuses are lined with similar cells. These cells function as part of a cleansing system for the blood, acting in concert with a similar system of reticuloendothelial cells in the venous sinuses of the liver. When the blood is invaded by infectious agents, the reticuloendothelial cells of the spleen rapidly remove substances such as debris, bacteria, and parasites. Also, in many chronic infections, the spleen enlarges in the same manner as lymph nodes and then performs its cleansing function even more avidly.

The Microcirculation and Lymphatic System: Capillary Fluid Exchange, Interstitial Fluid, and Lymph Flow

The most purposeful functions of the microcirculation are the *transport of nutrients to the tissues* and *removal of cell excreta*. The small arterioles control blood flow to each tissue, and local conditions in the tissues, in turn, control the diameters of the arterioles. Thus, each tissue, in most cases, controls its own blood flow in relationship to its individual needs as discussed in [Chapter 17](#).

The walls of the capillaries are thin and constructed of single-layer, highly permeable endothelial cells. Therefore, water, cell nutrients, and cell excreta can all interchange quickly and easily between the tissues and circulating blood.

The peripheral circulation of the entire body has about 10 billion capillaries, with a total surface area estimated to be 500 to 700 square meters (about one eighth the surface area of a football field). It is rare that any single functional cell of the body is more than 20 to 30 micrometers away from a capillary.

STRUCTURE OF THE MICROCIRCULATION AND CAPILLARY SYSTEM

The microcirculation of each organ is organized to serve that organ's specific needs. In general, each nutrient artery entering an organ branches six to eight times before the arteries become small enough to be called *arterioles*, which generally have internal diameters of only 10 to 15 micrometers. Then, the arterioles branch two to five times, reaching diameters of 5 to 9 micrometers at their ends, where they supply blood to the capillaries.

The arterioles are highly muscular, and their diameters can change by many times. The metarterioles (the terminal arterioles) do not have a continuous muscular coat, but smooth muscle fibers encircle the vessel at intermittent points, as shown in [Figure 16-1](#).

At the point where each true capillary originates from a metarteriole, a smooth muscle fiber usually encircles the capillary. This structure is called the *precapillary sphincter*. This sphincter can open and close the entrance to the capillary.

The venules are larger than the arterioles and have a much weaker muscular coat. Yet, the pressure in the venules is much less than that in the arterioles, so the

venules can still contract considerably, despite the weak muscle.

This typical arrangement of the capillary bed is not found in all parts of the body, although a similar arrangement may serve the same purposes. Most importantly, the metarterioles and precapillary sphincters are in close contact with the tissues they serve. Therefore, the local conditions of the tissues—such as the concentrations of nutrients, end products of metabolism, and hydrogen ions—can cause direct effects on the vessels to control local blood flow in each small tissue area.

Structure of the Capillary Wall. [Figure 16-2](#) shows the ultramicroscopic structure of typical endothelial cells in the capillary wall as found in most organs of the body, especially in muscles and connective tissue. Note that the wall is composed of a unicellular layer of endothelial cells and is surrounded by a thin basement membrane on the outside of the capillary. The total thickness of the capillary wall is only about 0.5 micrometer. The internal diameter of the capillary is 4 to 9 micrometers, barely large enough for red blood cells and other blood cells to squeeze through.

Pores in the Capillary Membrane. [Figure 16-2](#) shows two small passageways connecting the interior of the capillary with the exterior. One of these passageways is an *intercellular cleft*, which is the thin-slitted, curving channel that lies at the top of the figure between adjacent endothelial cells. Each cleft is interrupted periodically by short ridges of protein attachments that hold the endothelial cells together but, between these ridges, fluid can percolate freely through the cleft. The cleft normally has a uniform spacing, with a width of about 6 to 7 nanometers (60 to 70 angstroms [\AA]), which is slightly smaller than the diameter of an albumin protein molecule.

Because the intercellular clefts are located only at the edges of the endothelial cells, they usually represent no more than 1/1000 of the total surface area of the capillary wall. Nevertheless, the rate of thermal motion of water molecules, as well as most water-soluble ions and small solutes, is so rapid that all these substances diffuse with ease between the interior and exterior of the capillaries through these *slit pores*, the intercellular clefts.

Figure 16-1. Components of the microcirculation.

Present in the endothelial cells are many minute *plasmalemmal vesicles*, also called *caveolae* (small caves). These plasmalemmal vesicles form from oligomers of proteins called *caveolins* that are associated with molecules of *cholesterol* and *sphingolipids*. Although the precise functions of caveolae are still unclear, they are believed to play a role in *endocytosis* (the process whereby the cell engulfs material from outside the cell) and *transcytosis* of macromolecules across the interior of the endothelial cells. The caveolae at the surface of the cell appear to imbibe small packets of plasma or extracellular fluid that contain plasma proteins. These vesicles can then move slowly through the endothelial cell. Some of these vesicles may coalesce to form *vesicular channels* all the way through the endothelial cell, as shown in [Figure 16-2](#).

Special Types of Pores in Capillaries of Certain Organs. The pores in capillaries of some organs have special characteristics to meet the specific needs of the organs. Some of these characteristics are as follows:

1. In the *brain*, the junctions between the capillary endothelial cells are mainly *tight junctions* that allow only extremely small molecules such as water, oxygen, and carbon dioxide to pass into or out of the brain tissues.
2. In the *liver*, the clefts between the capillary endothelial cells are nearly wide open so that almost all dissolved substances of the plasma, including the plasma proteins, can pass from the blood into the liver tissues.
3. The pores of the *gastrointestinal capillary membranes* are midway in size between those of the muscles and those of the liver.

Figure 16-2. Structure of the capillary wall. Note especially the *intercellular cleft* at the junction between adjacent endothelial cells. It is believed that most water-soluble substances diffuse through the capillary membrane along the clefts. Small membrane invaginations, called *caveolae*, are believed to play a role in transporting macromolecules across the cell membrane. Caveolae contain caveolins, which are proteins that interact with cholesterol and polymerize to form the caveolae.

4. In the *glomerular capillaries of the kidney*, numerous small oval windows called *fenestrae* penetrate all the way through the middle of the endothelial cells so that tremendous amounts of small molecular and ionic substances (but not the large molecules of the plasma proteins) can filter through the glomeruli without having to pass through the clefts between the endothelial cells.

FLOW OF BLOOD IN THE CAPILLARIES—VASOMOTION

Blood usually does not flow continuously through the capillaries. Instead, it flows intermittently, turning on and off every few seconds or minutes. The cause of this intermittency is the phenomenon called *vasomotion*, which means intermittent contraction of the metarterioles and precapillary sphincters (and sometimes even the very small arterioles).

Regulation of Vasomotion. The most important factor affecting the degree of opening and closing of the metarterioles and precapillary sphincters that has been found thus far is the concentration of *oxygen* in the tissues. When the rate of oxygen usage by the tissue is great—so that tissue oxygen concentration decreases below

Figure 16-3. Diffusion of fluid molecules and dissolved substances between the capillary and interstitial fluid spaces.

normal—the intermittent periods of capillary blood flow occur more often, and the duration of each period of flow lasts longer, thereby allowing the capillary blood to carry increased quantities of oxygen (as well as other nutrients) to the tissues. This effect, along with multiple other factors that control local tissue blood flow, is discussed in [Chapter 17](#).

Average Function of the Capillary System. Despite the fact that blood flow through each capillary is intermittent, so many capillaries are present in the tissues that their overall function becomes averaged. That is, there is an *average rate of blood flow* through each tissue capillary bed, an *average capillary pressure* within the capillaries, and an *average rate of transfer of substances* between the blood of the capillaries and the surrounding interstitial fluid. In the remainder of this chapter, we are concerned with these averages, although it should be remembered that the average functions are, in reality, the functions of billions of individual capillaries, each operating intermittently in response to local conditions in the tissues.

EXCHANGE OF WATER, NUTRIENTS, AND OTHER SUBSTANCES BETWEEN THE BLOOD AND INTERSTITIAL FLUID

Diffusion Through the Capillary Membrane Is the Most Important Means of Transferring Substances Between Plasma and Interstitial Fluid. [Figure 16-3](#) illustrates that as the blood flows along the lumen of the capillary, tremendous numbers of water molecules and dissolved particles diffuse back and forth through the capillary wall, providing continual mixing between the interstitial fluid and plasma. Electrolytes, nutrients, and waste products of metabolism all diffuse easily through the capillary membrane. The proteins are the only dissolved con-

stituents in the plasma and interstitial fluids that do not readily pass through the capillary membrane.

Lipid-Soluble Substances Diffuse Directly Through the Cell Membranes of the Capillary Endothelium. If a substance is lipid-soluble, it can diffuse directly through the cell membranes of the capillary without having to go through the pores. Such substances include *oxygen* and *carbon dioxide*. Because these substances can permeate all areas of the capillary membrane, their rates of transport through the capillary membrane are many times faster than the rates for lipid-insoluble substances, such as sodium ions and glucose, which can go only through the pores.

Water-Soluble, Non-Lipid-Soluble Substances Diffuse Through Intercellular Pores in the Capillary Membrane. Many substances needed by the tissues are soluble in water but cannot pass through the lipid membranes of the endothelial cells; these include *water molecules*, *sodium ions*, *chloride ions*, and *glucose*. Although only 1/1000 of the surface area of the capillaries is represented by the intercellular clefts between the endothelial cells, the velocity of thermal molecular motion in the clefts is so great that even this small area is sufficient to allow tremendous diffusion of water and water-soluble substances through these cleft pores. To give an idea of the rapidity with which these substances diffuse, *the rate at which water molecules diffuse through the capillary membrane is about 80 times greater than the rate at which plasma itself flows linearly along the capillary*. That is, the water of the plasma is exchanged with the water of the interstitial fluid 80 times before the plasma can flow the entire distance through the capillary.

Effect of Molecular Size on Passage Through the Pores. The width of the capillary intercellular cleft pores, 6 to 7 nanometers, is about 20 times the diameter of the water molecule, which is the smallest molecule that normally passes through the capillary pores. The diameters of plasma protein molecules, however, are slightly greater than the width of the pores. Other substances, such as sodium ions, chloride ions, glucose, and urea, have intermediate diameters. Therefore, the permeability of the capillary pores for different substances varies according to their molecular diameters.

[Table 16-1](#) lists the relative permeabilities of the capillary pores in skeletal muscle for various substances, demonstrating, for example, that the permeability for glucose molecules is 0.6 times that for water molecules, whereas the permeability for albumin molecules is very slight—only one 1/1000 that for water molecules.

A word of caution must be stated at this point. The capillaries in various tissues have extreme differences in their permeabilities. For example, the membranes of the liver capillary sinusoids are so permeable that even plasma proteins pass through these walls, almost as easily

Table 16-1 Relative Permeability of Skeletal Muscle Capillary Pores to Different-Sized Molecules

Substance	Molecular Weight	Permeability
Water	18	1.00
NaCl	58.5	0.96
Urea	60	0.8
Glucose	180	0.6
Sucrose	342	0.4
Inulin	5000	0.2
Myoglobin	17,600	0.03
Hemoglobin	68,000	0.01
Albumin	69,000	0.001

Data from Pappenheimer JR: Passage of molecules through capillary walls. *Physiol Rev* 33:387, 1953.

as water and other substances. Also, the permeability of the renal glomerular membrane for water and electrolytes is about 500 times the permeability of the muscle capillaries, but this is not true for the plasma proteins. For these proteins, the capillary permeabilities are very slight, as in other tissues and organs. When we study these different organs later in this text, it should become clear why some tissues require greater degrees of capillary permeability than other tissues. For example, greater degrees of capillary permeability are required for the liver to transfer tremendous amounts of nutrients between the blood and liver parenchymal cells and for the kidneys to allow filtration of large quantities of fluid for the formation of urine.

Diffusion Through the Capillary Membrane Is Proportional to the Concentration Difference Between the Two Sides of the Membrane. The greater the difference between the concentrations of any given substance on the two sides of the capillary membrane, the greater the net movement of the substance in one direction through the membrane. For example, the concentration of oxygen in capillary blood is normally greater than in the interstitial fluid. Therefore, large quantities of oxygen normally move from the blood toward the tissues. Conversely, the concentration of carbon dioxide is greater in the tissues than in the blood, which causes excess carbon dioxide to move into the blood and to be carried away from the tissues.

The rates of diffusion through the capillary membranes of most nutritionally important substances are so great that only slight concentration differences cause more than adequate transport between the plasma and interstitial fluid. For example, the concentration of oxygen in the interstitial fluid immediately outside the capillary is no more than a few percent less than its concentration in the plasma of the blood, yet this slight difference causes enough oxygen to move from the blood into the interstitial spaces to provide all the oxygen required for tissue metabolism—often as much as several liters of oxygen per minute during very active states of the body.

Figure 16-4. Structure of the interstitium. Proteoglycan filaments are everywhere in the spaces between the collagen fiber bundles. Free fluid vesicles and small amounts of free fluid in the form of rivulets occasionally also occur.

INTERSTITIUM AND INTERSTITIAL FLUID

About one sixth of the total volume of the body consists of spaces between cells, which collectively are called the *interstitium*. The fluid in these spaces is called the *interstitial fluid*.

The structure of the interstitium is shown in **Figure 16-4**. It contains two major types of solid structures: (1) *collagen fiber bundles*; and (2) *proteoglycan filaments*. The collagen fiber bundles extend long distances in the interstitium. They are extremely strong and provide most of the tensional strength of the tissues. The proteoglycan filaments, however, are extremely thin, coiled or twisted molecules composed of about 98% *hyaluronic acid* and 2% protein. These molecules are so thin that they cannot be seen with a light microscope and are difficult to demonstrate, even with the electron microscope. Nevertheless, they form a mat of very fine reticular filaments aptly described as a *brush pile*.

Gel in the Interstitium. The fluid in the interstitium is derived by filtration and diffusion from the capillaries. It contains almost the same constituents as plasma except for much lower concentrations of proteins because proteins do not easily pass outward through the pores of the capillaries. The interstitial fluid is entrapped mainly in the minute spaces among the proteoglycan filaments. This combination of proteoglycan filaments and fluid entrapped within them has the characteristics of a *gel*; it is therefore called *tissue gel*.

Because of the large number of proteoglycan filaments, it is *difficult for fluid to flow easily* through the tissue gel. Instead, *fluid mainly diffuses* through the gel; that is, it moves molecule by molecule from one place to another by kinetic thermal motion rather than by large numbers of molecules moving together.

Diffusion through the gel occurs about 95% to 99% as rapidly as it does through free fluid. For the short distances between the capillaries and tissue cells, this diffusion allows for rapid transport through the interstitium, not only of water molecules but also of substances such as electrolytes, low-molecular-weight nutrients, cellular excreta, oxygen, and carbon dioxide.

Free Fluid in the Interstitium. Although almost all the fluid in the interstitium normally is entrapped within the tissue gel, occasionally small *rivulets of free fluid* and *small free fluid vesicles* are also present, which means fluid that is free of the proteoglycan molecules and therefore can flow freely. When a dye is injected into the circulating blood, it often can be seen to flow through the interstitium in the small rivulets, usually coursing along the surfaces of collagen fibers or surfaces of cells.

The amount of free fluid present in most *normal* tissues is slight, usually less than 1%. Conversely, when the tissues develop *edema*, these *small pockets and rivulets of free fluid expand tremendously* until one half or more of the edema fluid becomes free-flowing fluid, independent of the proteoglycan filaments.

FLUID FILTRATION ACROSS CAPILLARIES

The hydrostatic pressure in the capillaries tends to force fluid and its dissolved substances through the capillary pores into the interstitial spaces. Conversely, osmotic pressure caused by the plasma proteins (called *colloid osmotic pressure*) tends to cause fluid movement by osmosis from the interstitial spaces into the blood. This osmotic pressure exerted by the plasma proteins normally prevents significant loss of fluid volume from the blood into the interstitial spaces.

Also important is the *lymphatic system*, which returns to the circulation the small amounts of excess protein and fluid that leak from the blood into the interstitial spaces. In the remainder of this chapter, we discuss the mechanisms that control capillary filtration and lymph flow function together to regulate the respective volumes of the plasma and interstitial fluid.

Hydrostatic and Colloid Osmotic Forces Determine Fluid Movement Through the Capillary Membrane.

Figure 16-5 shows the four primary forces that determine whether fluid will move out of the blood into the interstitial fluid or in the opposite direction. These forces, called *Starling forces*, were named after the physiologist Ernest Starling who first demonstrated their importance:

1. The *capillary hydrostatic pressure* (P_c), which tends to force fluid *outward* through the capillary membrane
2. The *interstitial fluid hydrostatic pressure* (P_{if}), which tends to force fluid *inward* through the capillary membrane when P_{if} is positive but outward when P_{if} is negative

Figure 16-5. Fluid pressure and colloid osmotic pressure forces operate at the capillary membrane and tend to move fluid outward or inward through the membrane pores.

3. The *capillary plasma colloid osmotic pressure* (Π_p), which tends to cause osmosis of fluid *inward* through the capillary membrane
4. The *interstitial fluid colloid osmotic pressure* (Π_{if}), which tends to cause osmosis of fluid *outward* through the capillary membrane

If the sum of these forces—the *net filtration pressure*—is positive, there will be a net *fluid filtration* across the capillaries. If the sum of the Starling forces is negative, there will be a net *fluid absorption* from the interstitial spaces into the capillaries. The net filtration pressure (NFP) is calculated as follows:

$$NFP = P_c - P_{if} - \Pi_p + \Pi_{if}$$

As discussed later, the NFP is slightly positive under normal conditions, resulting in a net filtration of fluid across the capillaries into the interstitial space in most organs. The rate of fluid filtration in a tissue is also determined by the number and size of the pores in each capillary, as well as the number of capillaries in which blood is flowing. These factors are usually expressed together as the *capillary filtration coefficient* (K_f). The K_f is therefore a measure of the capacity of the capillary membranes to filter water for a given NFP and is usually expressed as ml/min per mm Hg NFP.

The rate of capillary fluid filtration is therefore determined as follows:

$$\text{Filtration} = K_f \times NFP$$

In the following sections, we discuss each of the forces that determine the rate of capillary fluid filtration.

CAPILLARY HYDROSTATIC PRESSURE

Various methods have been used to estimate the capillary hydrostatic pressure: (1) *direct micropipette cannulation of the capillaries*, which gives an average capillary pressure of about 25 mm Hg in some tissues, such as the skeletal muscle and gut, and (2) *indirect functional measurement of the capillary pressure*, which gives a capillary pressure averaging about 17 mm Hg in these tissues.

Micropipette Method for Measuring Capillary Pressure.

To measure pressure in a capillary by cannulation, a microscopic glass pipette is thrust directly into the capillary, and the pressure is measured by an appropriate micromanometer system. Using this method, capillary pressures have been measured in exposed tissues of animals and in large capillary loops of the eponychium at the base of the fingernail in humans. These measurements have given pressures of 30 to 40 mm Hg in the arterial ends of the capillaries, 10 to 15 mm Hg in the venous ends, and about 25 mm Hg in the middle.

In some capillaries, such as the *glomerular capillaries* of the kidneys, the pressures measured by the micropipette method are much higher, averaging about 60 mm Hg. The *peritubular capillaries* of the kidneys, in contrast, have a hydrostatic pressure that averages only about 13 mm Hg. Thus, the capillary hydrostatic pressures in different tissues are highly variable, depending on the particular tissue and the physiological condition.

INTERSTITIAL FLUID HYDROSTATIC PRESSURE

There are several methods for measuring interstitial fluid hydrostatic pressure, each of which gives slightly different values, depending on the method used and the tissue in which the pressure is measured. In loose subcutaneous tissue, interstitial fluid pressure measured by the different methods is usually a few millimeters of mercury less than atmospheric pressure; that is, the values are called *negative interstitial fluid pressure*. In other tissues that are surrounded by capsules, such as the kidneys, the interstitial pressure is generally *positive* (i.e., greater than atmospheric pressure). The methods most widely used have been: (1) measurement of the pressure with a micropipette inserted into the tissues; (2) measurement of the pressure from implanted perforated capsules; and (3) measurement of the pressure from a cotton wick inserted into the tissue. These different methods provide different values for interstitial hydrostatic pressure, even in the same tissues.

Measurement of Interstitial Fluid Pressure Using Micropipettes. The same type of micropipette used for measuring capillary pressure can also be used in some tissues for measuring interstitial fluid pressure. The tip of the micropipette is about 1 micrometer in diameter, but even this is 20 or more times larger than the sizes of the spaces between the proteoglycan filaments of the interstitium. Therefore, the pressure that is measured is probably the pressure in a free fluid pocket.

Pressures measured using the micropipette method range from -2 to $+2$ mm Hg in *loose* tissues, such as skin but, in most cases, they average slightly less than atmospheric pressure.

Measurement of Interstitial Free Fluid Pressure in Implanted Perforated Hollow Capsules. Interstitial free fluid pressure measured when using 2-centimeter diameter capsules in normal *loose* subcutaneous tissue averages about -6 mm Hg but, with smaller capsules, the values are not greatly different from the -2 mm Hg measured by the micropipette.

Interstitial Fluid Pressures in Tightly Encased Tissues.

Some tissues of the body are surrounded by tight encasements, such as the cranial vault around the brain, the strong fibrous capsule around the kidney, the fibrous sheaths around the muscles, and the sclera around the eye. In most of these tissues, regardless of the method used for measurement, the interstitial fluid pressures are positive. However, these interstitial fluid pressures almost invariably are still less than the pressures exerted on the outsides of the tissues by their encasements. For example, the cerebrospinal fluid pressure surrounding the brain of an animal lying on its side averages about $+10$ mm Hg, whereas the *brain interstitial fluid pressure* averages about $+4$ to $+6$ mm Hg. In the kidneys, the capsular pressure surrounding the kidney averages about $+13$ mm Hg, whereas the reported *renal interstitial fluid pressures* have averaged about $+6$ mm Hg. Thus, if one remembers that the pressure exerted on the skin is atmospheric pressure, which is considered to be zero pressure, one might formulate a general rule that the normal interstitial fluid pressure is usually several millimeters of mercury negative with respect to the pressure that surrounds each tissue.

In most natural cavities of the body, where there is free fluid in dynamic equilibrium with the surrounding interstitial fluids, the pressures that have been measured have been negative. Some of these cavities and pressure measurements are as follows:

- Intrapleural space: -8 mm Hg
- Joint synovial spaces: -4 to -6 mm Hg
- Epidural space: -4 to -6 mm Hg

Summary: Interstitial Fluid Pressure in Loose Subcutaneous Tissue Usually Subatmospheric. Although the aforementioned different methods give slightly different values for interstitial fluid pressure, most physiologists believe that the interstitial fluid pressure in *loose* subcutaneous tissue is, in normal conditions, slightly less subatmospheric, averaging about -3 mm Hg.

Pumping by the Lymphatic System—Basic Cause of the Negative Interstitial Fluid Pressure. The lymphatic system is discussed later in the chapter, but first we need to understand the basic role that this system plays in determining interstitial fluid pressure. The lymphatic system is a kind of scavenger system that removes excess fluid, excess protein molecules, debris, and other matter from the tissue spaces. Normally, when fluid enters the terminal lymphatic capillaries, the lymph vessel walls automatically contract for a few seconds and pump the fluid into the blood circulation. This overall process creates the slight negative pressure that has been measured for fluid in the interstitial spaces.

PLASMA COLLOID OSMOTIC PRESSURE

Plasma Proteins Cause Colloid Osmotic Pressure. As discussed in [Chapter 4](#), only the molecules or ions that fail

to pass through the pores of a semipermeable membrane exert osmotic pressure. Because the proteins are the only dissolved constituents in the plasma and interstitial fluids that do not readily pass through the capillary pores, it is the proteins of the plasma and interstitial fluids that are responsible for the osmotic pressures on the two sides of the capillary membrane. To distinguish this osmotic pressure from that which occurs at the cell membrane, it is called *colloid osmotic pressure* or *oncotic pressure*. The term *colloid osmotic pressure* is derived from the fact that a protein solution resembles a colloidal solution, despite the fact that it is actually a true molecular solution.

Normal Values for Plasma Colloid Osmotic Pressure.

The colloid osmotic pressure of normal human plasma averages about 28 mm Hg; 19 mm of this pressure is caused by molecular effects of the dissolved protein, and 9 mm is caused by the *Donnan effect*—that is, extra osmotic pressure caused by sodium, potassium, and the other cations bound to the plasma proteins.

Effect of the Different Plasma Proteins on Colloid Osmotic

Pressure. The plasma proteins are a mixture that contains albumin, globulins, and fibrinogen, with an average molecular weight of 69,000, 140,000, and 400,000, respectively. Thus, 1 gram of globulin contains only half as many molecules as 1 gram of albumin, and 1 gram of fibrinogen contains only one sixth as many molecules as 1 gram of albumin. It should be recalled from the discussion of osmotic pressure in Chapter 4 that osmotic pressure is determined by the *number of molecules* dissolved in a fluid rather than by the mass of these molecules. The following chart gives both the relative mass concentrations (g/dl) of the different types of proteins in normal plasma and their respective contributions to the total plasma colloid osmotic pressure (Π_p). These values include the Donnan effect of ions bound to the plasma proteins:

	g/dl	Π_p (mm Hg)
Albumin	4.5	21.8
Globulins	2.5	6.0
Fibrinogen	0.3	0.2
Total	7.3	28.0

Thus, about 80% of the total colloid osmotic pressure of the plasma results from the albumin, 20% from the globulins, and almost none from fibrinogen. Therefore, from the point of view of capillary and tissue fluid dynamics, it is mainly albumin that is important.

INTERSTITIAL FLUID COLLOID OSMOTIC PRESSURE

Although the size of the usual capillary pore is smaller than the molecular sizes of the plasma proteins, this is not true of all the pores. Therefore, small amounts of plasma proteins do leak into the interstitial spaces through pores and by transcytosis in small vesicles.

The total quantity of protein in the entire 12 liters of interstitial fluid of the body is slightly greater than the

total quantity of protein in the plasma but, because this volume is four times the volume of plasma, the average protein *concentration* of the interstitial fluid of most tissues is usually only 40% of that in plasma, or about 3 g/dl. Quantitatively, the average interstitial fluid colloid osmotic pressure for this concentration of proteins is about 8 mm Hg.

FLUID VOLUME EXCHANGE THROUGH THE CAPILLARY MEMBRANE

The different factors affecting fluid movement through the capillary membrane have been discussed, so we can put all these factors together to see how the capillary system maintains normal fluid volume distribution between the plasma and interstitial fluid.

The average capillary pressure at the arterial ends of the capillaries is 15 to 25 mm Hg greater than at the venous ends. Because of this difference, fluid filters out of the capillaries at their arterial ends but, at their venous ends, fluid is reabsorbed back into the capillaries (see Figure 16-3). Thus, a small amount of fluid actually “flows” through the tissues from the arterial ends of the capillaries to the venous ends. The dynamics of this flow are as follows.

Analysis of the Forces Causing Filtration at the Arterial End of the Capillary. The approximate average forces operative at the *arterial end* of the capillary that cause movement through the capillary membrane are shown as follows:

	mm Hg
Forces Tending to Move Fluid Outward	
Capillary hydrostatic pressure (arterial end of capillary)	30
Negative interstitial fluid hydrostatic pressure	3
Interstitial fluid colloid osmotic pressure	8
TOTAL OUTWARD FORCE	41
Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	28
TOTAL INWARD FORCE	28
Summation of Forces	
Outward	41
Inward	28
NET OUTWARD FORCE (AT ARTERIAL END)	13

Thus, the summation of forces at the arterial end of the capillary shows a net *filtration pressure* of 13 mm Hg, tending to move fluid outward through the capillary pores. This 13 mm Hg filtration pressure causes, on average, about 1/200 of the plasma in the flowing blood to filter out of the arterial ends of the capillaries into the interstitial spaces each time the blood passes through the capillaries.

Analysis of Reabsorption at the Venous End of the Capillary. The low blood pressure at the venous end of the capillary changes the balance of forces in favor of absorption as follows:

	mm Hg
Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	<u>28</u>
TOTAL INWARD FORCE	28
Forces Tending to Move Fluid Outward	
Capillary hydrostatic pressure (venous end of capillary)	10
Negative interstitial fluid hydrostatic pressure	3
Interstitial fluid colloid osmotic pressure	<u>8</u>
TOTAL OUTWARD FORCE	21
Summation of Forces	
Inward	28
Outward	<u>21</u>
NET INWARD FORCE	7

Thus, there is a *net reabsorption pressure* of 7 mm Hg at the venous ends of the capillaries. This reabsorption pressure is considerably less than the filtration pressure at the capillary arterial ends, but remember that the venous capillaries are more numerous and more permeable than the arterial capillaries. Thus less reabsorption pressure is required to cause inward movement of fluid.

The reabsorption pressure causes about nine tenths of the fluid that has filtered out of the arterial ends of the capillaries to be reabsorbed at the venous ends. The remaining one tenth flows into the lymph vessels and returns to the circulating blood.

STARLING EQUILIBRIUM FOR CAPILLARY EXCHANGE

Ernest Starling pointed out more than a century ago that under normal conditions, a state of near-equilibrium exists in most capillaries. That is, the amount of fluid filtering outward from the arterial ends of capillaries almost exactly equals the fluid returned to the circulation by absorption. The slight disequilibrium that does occur accounts for the fluid that is eventually returned to the circulation by way of the lymphatics.

The following chart shows the principles of the Starling equilibrium. For this chart, the pressures in the arterial and venous capillaries are averaged to calculate mean the *functional* capillary pressure for the entire length of the capillary. This mean functional capillary pressure is calculated to be 17.3 mm Hg.

	mm Hg
Mean Forces Tending to Move Fluid Outward	
Mean capillary pressure	17.3
Negative interstitial fluid hydrostatic pressure	3.0

	mm Hg
Interstitial fluid colloid osmotic pressure	<u>8.0</u>
TOTAL OUTWARD FORCE	28.3
Mean Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	<u>28.0</u>
TOTAL INWARD FORCE	28.0
Summation of Mean Forces	
Outward	28.3
Inward	<u>28.0</u>
NET OUTWARD FORCE	0.3

Thus, for the total capillary circulation, we find a near-equilibrium between the total outward forces, 28.3 mm Hg, and the total inward force, 28.0 mm Hg. This slight imbalance of forces, 0.3 mm Hg, causes slightly more filtration of fluid into the interstitial spaces than reabsorption. This slight excess of filtration is called *net filtration*, and it is the fluid that must be returned to the circulation through the lymphatics. The normal rate of net filtration *in the entire body*, not including the kidneys, is only about 2 ml/min.

CAPILLARY FILTRATION COEFFICIENT

In the previous example, an average net imbalance of forces at the capillary membranes of 0.3 mm Hg causes net fluid filtration in the entire body of 2 ml/min. Expressing the net fluid filtration rate for each mm Hg imbalance, one finds a net filtration rate of 6.67 ml/min of fluid per mm Hg for the entire body. This value is called the whole body *capillary filtration coefficient*.

The filtration coefficient can also be expressed for separate parts of the body in terms of the rate of filtration per minute per mm Hg per 100 grams of tissue. On this basis, the capillary filtration coefficient of the average tissue is about 0.01 ml/min per mm Hg per 100 g of tissue. However, because of extreme differences in permeabilities and surface areas of the capillary systems in different tissues, this coefficient varies more than 100-fold among the different tissues. It is very small in brain and muscle, moderately large in subcutaneous tissue, large in the intestine, and extremely large in the liver and glomerulus of the kidney, where the capillary surface is large, and the pores are numerous or wide open. By the same token, the permeation of proteins through the capillary membranes also varies greatly. The concentration of protein in the interstitial fluid of muscles is about 1.5 g/dl; in subcutaneous tissue, it is 2 g/dl; in the intestine, it is 4 g/dl; and, in the liver, it is 6 g/dl.

Effect of Abnormal Imbalance of Forces at the Capillary Membrane. If the mean capillary pressure rises significantly above the average value of 17 mm Hg, the net force tending to cause filtration of fluid into the tissue spaces rises. Thus, a 20-mm Hg rise in mean capillary pressure causes an increase in net filtration pressure from 0.3 to 20.3 mm Hg,

Figure 16-6. The lymphatic system.

which results in 68 times as much net filtration of fluid into the interstitial spaces as normally occurs. To prevent accumulation of excess fluid in these spaces would require 68 times the normal flow of fluid into the lymphatic system, an amount that is 2 to 5 times too much for the lymphatics to carry away. As a result, fluid will begin to accumulate in the interstitial spaces and edema will result.

Conversely, if the capillary pressure falls very low, net reabsorption of fluid into the capillaries will occur instead of net filtration, and the blood volume will increase at the expense of the interstitial fluid volume. These effects of imbalance at the capillary membrane in relationship to the development of the different types of edema are discussed in [Chapter 25](#).

LYMPHATIC SYSTEM

The lymphatic system represents an accessory route through which fluid can flow from the interstitial spaces into the blood. Most importantly, the lymphatics can carry proteins and large particulate matter away from the tissue spaces, neither of which can be removed by absorption directly into the blood capillaries. This return of proteins to the blood from the interstitial spaces is an essential function, without which we would die within about 24 hours.

LYMPH CHANNELS OF THE BODY

Almost all tissues of the body have special lymph channels that drain excess fluid directly from the interstitial spaces. The exceptions include the superficial portions of the skin, central nervous system, endomysium of muscles, and bones. However, even these tissues have minute interstitial channels called *prelymphatics* through which interstitial fluid can flow; this fluid eventually empties into lymphatic vessels or, in the case of the brain, into the cerebrospinal fluid and then directly back into the blood.

Essentially all the lymph vessels from the lower part of the body eventually empty into the *thoracic duct*, which in turn empties into the blood venous system at the juncture of the *left* internal jugular vein and left subclavian vein, as shown in [Figure 16-6](#).

Lymph from the left side of the head, left arm, and parts of the chest region also enters the thoracic duct before it empties into the veins.

Lymph from the right side of the neck and head, right arm, and parts of the right thorax enters the *right lymph duct* (much smaller than the thoracic duct), which empties into the blood venous system at the juncture of the *right* subclavian vein and internal jugular vein.

Figure 16-7. Special structure of the lymphatic capillaries that permits passage of substances of high molecular weight into the lymph.

Terminal Lymphatic Capillaries and Their Permeability. Most of the fluid filtering from the *arterial ends* of *blood capillaries* flows among the cells and finally is reabsorbed back into the *venous ends* of the *blood capillaries* but, on average, about one tenth of the fluid instead enters the *lymphatic capillaries* and returns to the blood through the lymphatic system rather than through the venous capillaries. The total quantity of all this lymph is normally only 2 to 3 L/day.

The fluid that returns to the circulation by way of the lymphatics is extremely important because substances of high molecular weight, such as proteins, cannot be absorbed from the tissues in any other way, although they can enter the lymphatic capillaries almost unimpeded. The reason for this mechanism is a special structure of the lymphatic capillaries, demonstrated in [Figure 16-7](#). This figure shows the endothelial cells of the lymphatic capillary attached by *anchoring filaments* to the surrounding connective tissue. At the junctions of adjacent endothelial cells, the edge of one endothelial cell overlaps the edge of the adjacent cell in such a way that the overlapping edge is free to flap inward, thus forming a minute valve that opens to the interior of the lymphatic capillary. Interstitial fluid, along with its suspended particles, can push the valve open and flow directly into the lymphatic capillary. However, this fluid has difficulty leaving the capillary once it has entered because any backflow closes the flap valve. Thus, the lymphatics have valves at the very tips of the terminal lymphatic capillaries, as well as valves along their larger vessels, up to the point where they empty into the blood circulation.

FORMATION OF LYMPH

Lymph is derived from interstitial fluid that flows into the lymphatics. Therefore, lymph as it first enters the terminal lymphatics has almost the same composition as the interstitial fluid.

Figure 16-8. Relationship between interstitial fluid pressure and lymph flow in the leg of a dog. Note that lymph flow reaches a maximum when the interstitial pressure (P_{if}) rises slightly above atmospheric pressure (0 mm Hg). (Courtesy Dr. Harry Gibson and Dr. Aubrey Taylor.)

The protein concentration in the interstitial fluid of most tissues averages about 2 g/dl, and the protein concentration of lymph flowing from these tissues is near this value. Lymph formed in the liver has a protein concentration as high as 6 g/dl, and lymph formed in the intestines has a protein concentration as high as 3 to 4 g/dl. Because about two thirds of all lymph normally is derived from the liver and intestines, the thoracic duct lymph, which is a mixture of lymph from all areas of the body, usually has a protein concentration of 3 to 5 g/dl.

The lymphatic system is also one of the major routes for absorption of nutrients from the gastrointestinal tract, especially for absorption of virtually all fats in food, as discussed in [Chapter 66](#). After a fatty meal, thoracic duct lymph sometimes contains as much as 1% to 2% fat.

Finally, even large particles, such as bacteria, can push their way between the endothelial cells of the lymphatic capillaries and in this way enter the lymph. As the lymph passes through the lymph nodes, these particles are almost entirely removed and destroyed, as discussed in [Chapter 34](#).

RATE OF LYMPH FLOW

About 100 ml/hr of lymph flows through the *thoracic duct* of a resting human, and approximately another 20 ml flows into the circulation each hour through other channels, making a total estimated lymph flow of about 120 ml/hr or 2 to 3 L/day.

Effect of Interstitial Fluid Pressure on Lymph Flow.

[Figure 16-8](#) shows the effect of different levels of interstitial fluid hydrostatic pressure on lymph flow, as measured in animals. Note that normal lymph flow is very little at interstitial fluid pressures more negative than the normal

Figure 16-9. Structure of lymphatic capillaries and a collecting lymphatic, with the lymphatic valves also shown.

value of -6 mm Hg. Then, as the pressure rises to 0 mm Hg (atmospheric pressure), flow increases more than 20-fold. Therefore, any factor that increases interstitial fluid pressure also increases lymph flow if the lymph vessels are functioning normally. Such factors include the following:

- Elevated capillary hydrostatic pressure
- Decreased plasma colloid osmotic pressure
- Increased interstitial fluid colloid osmotic pressure
- Increased permeability of the capillaries

All these factors favor net fluid movement into the interstitium, thus increasing interstitial fluid volume, interstitial fluid pressure, and lymph flow all at the same time.

However, note in [Figure 16-8](#) that when the interstitial fluid hydrostatic pressure becomes 1 or 2 mm Hg greater than atmospheric pressure (>0 mm Hg), lymph flow fails to rise any further at still higher pressures. This results from the fact that the increasing tissue pressure not only increases entry of fluid into the lymphatic capillaries, but also compresses the outside surfaces of the larger lymphatics, thus impeding lymph flow. At the higher pressures, these two factors balance each other, so lymph flow reaches a maximum flow rate. This maximum flow rate is illustrated by the upper level plateau in [Figure 16-8](#).

Lymphatic Pump Increases Lymph Flow. Valves exist in all lymph channels. [Figure 16-9](#) shows typical valves for collecting lymphatics into which the lymphatic capillaries empty.

Videos of exposed lymph vessels in animals and in humans have shown that when a collecting lymphatic or larger lymph vessel becomes stretched with fluid, the smooth muscle in the wall of the vessel automatically contracts. Furthermore, each segment of the lymph vessel between successive valves functions as a separate automatic pump. That is, even slight filling of a segment causes it to contract, and the fluid is pumped through the next valve into the next lymphatic segment. This fluid fills the subsequent segment and a few seconds later it also contracts, with the process continuing all along the lymph vessel until the fluid is finally emptied into the blood circulation. In a very large lymph vessel, such as the thoracic

duct, this lymphatic pump can generate pressure as high as 50 to 100 mm Hg.

Pumping Caused by External Intermittent Compression of the Lymphatics. In addition to the pumping caused by intrinsic intermittent contraction of the lymph vessel walls, any external factor that intermittently compresses the lymph vessel can also cause pumping. In order of their importance, such factors are as follows:

- Contraction of surrounding skeletal muscles
- Movement of the parts of the body
- Pulsations of arteries adjacent to the lymphatics
- Compression of the tissues by objects outside the body

The lymphatic pump becomes very active during exercise, often increasing lymph flow 10- to 30-fold. Conversely, during periods of rest, lymph flow is sluggish (almost zero).

Lymphatic Capillary Pump. The terminal lymphatic capillary is also capable of pumping lymph, in addition to the pumping by the larger lymph vessels. As explained earlier in the chapter, the anchoring filaments on the walls of the lymphatic capillaries tightly adhere to the surrounding tissue cells. Therefore, each time excess fluid enters the tissue and causes the tissue to swell, the anchoring filaments pull on the wall of the lymphatic capillary, and fluid flows into the terminal lymphatic capillary through the junctions between the endothelial cells. Then, when the tissue is compressed, the pressure inside the capillary increases and causes the overlapping edges of the endothelial cells to close like valves. Therefore, the pressure pushes the lymph forward into the collecting lymphatic instead of backward through the cell junctions.

The lymphatic capillary endothelial cells also contain a few contractile actomyosin filaments. In some animal tissues (e.g., a bat wing), these filaments have been observed to cause rhythmical contraction of the lymphatic capillaries in the same rhythmic way that many of the small blood vessels and larger lymphatic vessels contract. Therefore, it is probable that at least part of lymph pumping results from lymph capillary endothelial cell contraction in addition to contraction of the larger muscular lymphatics.

Summary of Factors That Determine Lymph Flow.

From the previous discussion, one can see that the two primary factors that determine lymph flow are (1) the interstitial fluid pressure and (2) the activity of the lymphatic pump. Therefore, one can state that, roughly, *the rate of lymph flow is determined by the product of interstitial fluid pressure times the activity of the lymphatic pump.*

Lymphatic System Plays a Key Role in Controlling Interstitial Fluid Protein Concentration, Volume, and Pressure

It is already clear that the lymphatic system functions as an overflow mechanism to return excess proteins and excess fluid volume from the tissue spaces to the circulation. Therefore, the lymphatic system also plays a central role in controlling the following: (1) concentration of proteins in the interstitial fluids; (2) volume of interstitial fluid; and (3) interstitial fluid pressure. Here is an explanation of how these factors interact.

1. Remember that small amounts of proteins leak continuously out of the blood capillaries into the interstitium. Only minute amounts, if any, of the leaked proteins return to the circulation by way of the venous ends of the blood capillaries. Therefore, these proteins tend to accumulate in the interstitial fluid, which in turn increases the colloid osmotic pressure of the interstitial fluids.
2. The increasing colloid osmotic pressure in the interstitial fluid shifts the balance of forces at the blood capillary membranes in favor of fluid filtration into the interstitium. Therefore, in effect, fluid is translocated osmotically outward through the capillary wall by the proteins and into the interstitium, thus increasing both interstitial fluid volume and interstitial fluid pressure.
3. The increasing interstitial fluid pressure greatly increases the rate of lymph flow, which carries away the excess interstitial fluid volume and excess protein that has accumulated in the spaces.

Thus, once the interstitial fluid protein concentration reaches a certain level and causes comparable increases in interstitial fluid volume and pressure, the return of protein and fluid by way of the lymphatic system becomes great enough to balance the rate of leakage of these into the interstitium from the blood capillaries. Therefore, the quantitative values of all these factors reach a steady state, and they remain balanced at these steady state levels until some factor changes the rate of leakage of proteins and fluid from the blood capillaries.

Significance of Negative Interstitial Fluid Pressure for Holding Body Tissues Together

Traditionally, it has been assumed that the different tissues of the body are held together entirely by connective tissue fibers. However, connective tissue fibers are very weak or even absent at many places in the body, particularly at points where tissues slide over one another (e.g., skin sliding over the back of the hand or over the face). Yet, even at these places, the tissues are held together by the negative interstitial fluid pressure, which is actually a partial vacuum. When the tissues lose their negative pressure, fluid accumulates in the spaces, and the condition known as *edema* occurs. This condition is discussed in [Chapter 25](#).

Local and Humoral Control of Tissue Blood Flow

LOCAL CONTROL OF BLOOD FLOW IN RESPONSE TO TISSUE NEEDS

A fundamental principle of circulatory function is that most tissues have the ability to control their own local blood flow in proportion to their specific metabolic needs. Some of the specific needs of the tissues for blood flow include the following:

1. Delivery of oxygen to the tissues
2. Delivery of other nutrients such as glucose, amino acids, and fatty acids
3. Removal of carbon dioxide from the tissues
4. Removal of hydrogen ions from the tissues
5. Maintenance of proper concentrations of ions in the tissues
6. Transport of various hormones and other substances to the different tissue.

Certain organs have special requirements. For example, blood flow to the skin determines heat loss from the body and, in this way, helps control body temperature. Also, delivery of adequate quantities of blood plasma to the kidneys allows the kidneys to filter and excrete the waste products of the body and to regulate body fluid volumes and electrolytes.

We shall see that these factors exert extreme degrees of local blood flow control and that different tissues place different levels of importance on these factors in controlling blood flow.

Variations in Blood Flow in Different Tissues and Organs. Note the very large blood flows listed in [Table 17-1](#) for some organs—for example, several hundred milliliters per minute per 100 grams of thyroid or adrenal gland tissue and a total blood flow of 1350 ml/min in the liver, which is 95 ml/min/100 g of liver tissue.

Also note the extremely large blood flow through the kidneys—1100 ml/min. This extreme amount of flow is required for the kidneys to perform their function of cleansing the blood of waste products and regulating composition of the body fluids precisely.

Conversely, most surprising is the low blood flow to all the *inactive* muscles of the body—only a total of 750 ml/min—even though the muscles constitute between 30% and 40% of the total body mass. In the resting state, the

metabolic activity of the muscles is low, as is the blood flow—only 4 ml/min/100 g. Yet, during heavy exercise, muscle metabolic activity can increase more than 60-fold and the blood flow as much as 20-fold, increasing to as high as 16,000 ml/min in the body's total muscle vascular bed (or 80 ml/min/100 g of muscle).

Importance of Blood Flow Control by the Local Tissues. The following question might be asked: Why not continuously provide a very large blood flow through every tissue of the body that would always be enough to supply the tissue's needs, regardless of whether the activity of the tissue is small or large? The answer is equally simple; such a mechanism would require many times more blood flow than the heart can pump.

Experiments have shown that the blood flow to each tissue usually is regulated at the minimal level that will supply the tissue's requirements—no more, no less. For example, in tissues for which the most important requirement is delivery of oxygen, the blood flow is always controlled at a level only slightly more than that required to maintain full tissue oxygenation but no more than this. By controlling local blood flow in such an exact way, the tissues almost never experience oxygen nutritional deficiency, and the workload on the heart is kept at a minimum.

MECHANISMS OF BLOOD FLOW CONTROL

Local blood flow control can be divided into two phases, acute control and long-term control. *Acute control* is achieved by rapid changes in local vasodilation or vasoconstriction of the arterioles, metarterioles, and precapillary sphincters that occur within seconds to minutes to provide rapid maintenance of appropriate local tissue blood flow. *Long-term control* means slow, controlled changes in flow over a period of days, weeks, or even months. In general, these long-term changes provide even better control of the flow in proportion to the needs of the tissues. These changes come about as a result of an increase or decrease in the physical sizes and numbers of blood vessels supplying the tissues.

Table 17-1 Blood Flow to Different Organs and Tissues Under Basal Conditions

	Percentage of Cardiac Output	ml/min	ml/min/100 g of Tissue Weight
Brain	14	700	50
Heart	4	200	70
Bronchi	2	100	25
Kidneys	22	1100	360
Liver	27	1350	95
• Portal	(21)	(1050)	
• Arterial	(6)	(300)	
Muscle (inactive state)	15	750	4
Bone	5	250	3
Skin (cool weather)	6	300	3
Thyroid gland	1	50	160
Adrenal glands	0.5	25	300
Other tissues	3.5	175	1.3
Total	100.0	5000	

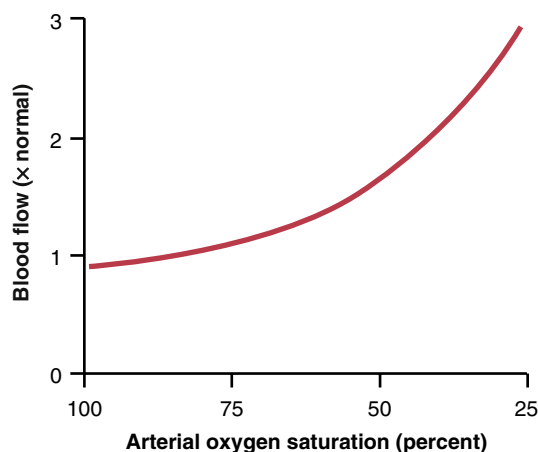

Figure 17-1. Effect of increasing rate of metabolism on tissue blood flow.

ACUTE CONTROL OF LOCAL BLOOD FLOW

Increases in Tissue Metabolism Increase Tissue Blood Flow

Figure 17-1 shows the approximate acute effect on blood flow of increasing the rate of metabolism in a local tissue, such as in a skeletal muscle. Note that an increase in metabolism up to eight times normal increases the blood flow acutely about fourfold.

Reduced Oxygen Availability Increases Tissue Blood Flow. One of the most necessary of the metabolic nutrients is oxygen. Whenever the availability of oxygen to

Figure 17-2. Effect of decreasing arterial oxygen saturation on blood flow through an isolated dog leg.

the tissues decreases, such as during the following: (1) at a high altitude at the top of a high mountain; (2) in pneumonia; (3) in carbon monoxide poisoning (which poisons the ability of hemoglobin to transport oxygen); or (4) in cyanide poisoning (which poisons the ability of the tissues to use oxygen), the blood flow through the tissues increases markedly. **Figure 17-2** shows that as the arterial oxygen saturation decreases to about 25% of normal, the blood flow through an isolated leg increases about threefold; that is, the blood flow increases almost enough, but not quite enough, to make up for the decreased amount of oxygen in the blood, thus almost maintaining a relatively constant supply of oxygen to the tissues.

Total cyanide poisoning of oxygen usage by a local tissue area can cause local blood flow to increase as much as sevenfold, thus demonstrating the extreme effect of oxygen deficiency to increase blood flow. The mechanisms whereby changes in tissue metabolism or oxygen availability alter tissue blood flow are not fully understood, but two main theories have been proposed, the *vasodilator theory* and the *oxygen demand theory*.

Vasodilator Theory for Acute Local Blood Flow Regulation—Possible Special Role of Adenosine.

According to the vasodilator theory, the greater the rate of metabolism or the less the availability of oxygen or some other nutrients to a tissue, the greater the rate of formation of *vasodilator substances* in the tissue cells. The vasodilator substances are then believed to diffuse through the tissues to the precapillary sphincters, metarterioles, and arterioles to cause dilation. Some of the different vasodilator substances that have been suggested are *adenosine*, *carbon dioxide*, *adenosine phosphate compounds*, *histamine*, *potassium ions*, and *hydrogen ions*.

Vasodilator substances may be released from the tissue in response to oxygen deficiency. For example, experiments have shown that decreased oxygen availability can cause adenosine and lactic acid (containing hydrogen ions) to be released into the spaces between the tissue cells; these substances then cause intense acute vasodilation

and therefore are responsible, or partially responsible, for the local blood flow regulation. Other vasodilator substances, such as carbon dioxide, lactic acid, and potassium ions, also tend to increase in the tissues when blood flow is reduced and cell metabolism continues at the same rate, or when cell metabolism is suddenly increased. An increase in the concentration of vasodilator metabolites causes vasodilation of the arterioles, thus increasing the tissue blood flow and returning the tissue concentration of the metabolites toward normal.

Many physiologists believe that *adenosine* is an important local vasodilator for controlling local blood flow. For example, minute quantities of adenosine are released from heart muscle cells when coronary blood flow becomes too little, and this release of adenosine causes enough local vasodilation in the heart to return coronary blood flow to normal. Also, whenever the heart becomes more active than normal, the heart's metabolism increases, causing increased utilization of oxygen, followed by (1) decreased oxygen concentration in the heart muscle cells with (2) consequent degradation of adenosine triphosphate (ATP), which (3) increases the release of adenosine. It is believed that much of this adenosine leaks out of the heart muscle cells to cause coronary vasodilation, providing increased coronary blood flow to supply the increased nutrient demands of the active heart.

Although research evidence is less clear, many physiologists also have suggested that the same adenosine mechanism is an important controller of blood flow in skeletal muscle and many other tissues, as well as in the heart. However, it has been difficult to prove that sufficient quantities of any single vasodilator substance, including adenosine, are formed in the tissues to cause all the measured increase in blood flow. It is likely that a combination of several different vasodilators released by the tissues contributes to blood flow regulation.

Oxygen Demand Theory for Local Blood Flow Control.

Although the vasodilator theory is widely accepted, several critical facts have made other physiologists favor another theory, which can be called the *oxygen demand theory* or, more accurately, the *nutrient demand theory* (because other nutrients besides oxygen are involved). Oxygen is one of the metabolic nutrients required to cause vascular muscle contraction, with other nutrients required as well. Therefore, in the absence of adequate oxygen, it is reasonable to believe that the blood vessels would relax and therefore dilate. Also, increased utilization of oxygen in the tissues as a result of increased metabolism theoretically could decrease the availability of oxygen to the smooth muscle fibers in the local blood vessels, causing local vasodilation.

A mechanism whereby oxygen availability could operate is shown in [Figure 17-3](#). This figure shows a tissue vascular unit, consisting of a metarteriole with a single sidearm capillary and its surrounding tissue. At the origin of the capillary is a *precapillary sphincter* and around

Figure 17-3. Diagram of a tissue unit area for an explanation of acute local feedback control of blood flow, showing a *metarteriole* passing through the tissue and a *sidearm capillary* with its *precapillary sphincter* for controlling capillary blood flow.

the metarteriole are several other smooth muscle fibers. When observing such a tissue under a microscope, the precapillary sphincters are normally completely open or completely closed. The number of precapillary sphincters that are open at any given time is roughly proportional to the requirements of the tissue for nutrition. The precapillary sphincters and metarterioles open and close cyclically several times per minute, with the duration of the open phases being proportional to the metabolic needs of the tissues for oxygen. The cyclical opening and closing is called *vasomotion*.

Because smooth muscle requires oxygen to remain contracted, one might assume that the strength of contraction of the sphincters would increase with an increase in oxygen concentration. Consequently, when the oxygen concentration in the tissue rises above a certain level, the precapillary and metarteriole sphincters presumably would close until the tissue cells consume the excess oxygen. However, when the excess oxygen is gone and the oxygen concentration falls low enough, the sphincters open once more to begin the cycle again.

Thus, on the basis of available data, either the *vasodilator substance theory* or *oxygen demand theory* could explain acute local blood flow regulation in response to the metabolic needs of the tissues. It is probably a combination of the two mechanisms.

Possible Role of Other Nutrients Besides Oxygen in Control of Local Blood Flow.

Under special conditions, it has been shown that the lack of glucose in the perfusing blood can cause local tissue vasodilation. It also is possible that this same effect occurs when other nutrients, such as amino acids or fatty acids, are deficient, although

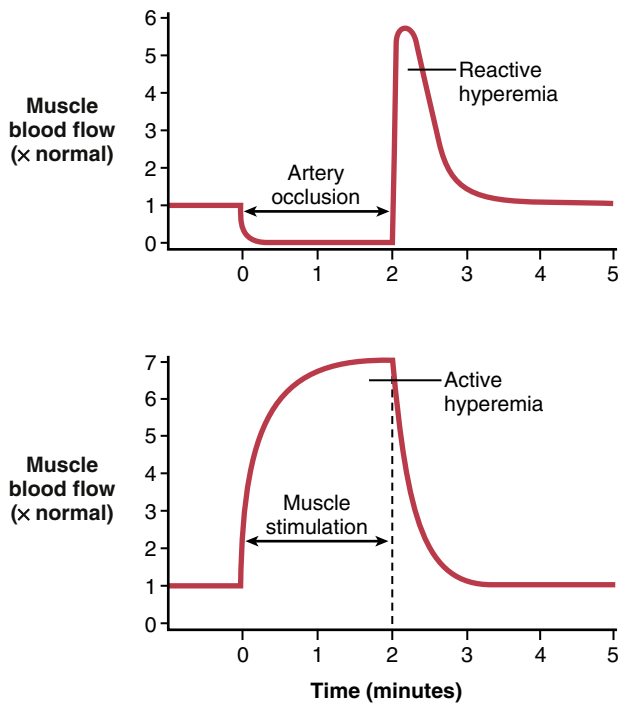

Figure 17-4. Reactive hyperemia in a tissue after temporary occlusion of the artery supplying blood flow and active hyperemia following increased tissue metabolic activity.

this is still uncertain. In addition, vasodilation occurs in the vitamin deficiency disease *beriberi*, in which the patient has deficiencies of the vitamin B substances *thiamine*, *niacin*, and *riboflavin*. In this disease, the peripheral vascular blood flow almost everywhere in the body often increases twofold to threefold. Because all these vitamins are necessary for oxygen-induced phosphorylation, which is required to produce ATP in the tissue cells, one can understand how deficiency of these vitamins might lead to diminished smooth muscle contractile ability and therefore local vasodilation as well.

Special Examples of Acute Metabolic Control of Local Blood Flow

The mechanisms we have described thus far for local blood flow control are called *metabolic mechanisms* because they all function in response to the metabolic needs of the tissues. Two additional special examples of metabolic control of local blood flow are *reactive hyperemia* and *active hyperemia* (Figure 17-4).

Reactive Hyperemia Occurs After Tissue Blood Supply Is Blocked for a Short Time. When the blood supply to a tissue is blocked for a few seconds to as long as 1 hour or more and then is unblocked, blood flow through the tissue usually increases immediately to four to seven times normal. This increased flow will continue for a few seconds if the block has lasted only a few seconds but sometimes continues for as long as many hours if the blood flow has been stopped for an hour or more. This phenomenon is called *reactive hyperemia*.

Figure 17-5. Effect of different levels of arterial pressure on blood flow through a muscle. The solid red curve shows the effect if the arterial pressure is raised over a period of a few minutes. The dashed green curve shows the effect if the arterial pressure is raised slowly over many weeks.

Reactive hyperemia is another manifestation of the local metabolic blood flow regulation mechanism—that is, lack of flow sets into motion all the factors that cause vasodilation. After short periods of vascular occlusion, the extra blood flow during the reactive hyperemia phase lasts long enough to repay almost exactly the tissue oxygen deficit that has accrued during the period of occlusion. This mechanism emphasizes the close connection between local blood flow regulation and delivery of oxygen and other nutrients to the tissues.

Active Hyperemia Occurs When Tissue Metabolic Rate Increases. When a tissue becomes highly active, such as an exercising muscle, a gastrointestinal gland during a hypersecretory period, or even the brain during increased mental activity, the rate of blood flow through the tissue increases (see Figure 17-4). The increase in local metabolism causes the cells to devour tissue fluid nutrients rapidly and release large quantities of vasodilator substances. The result is dilation of local blood vessels and increased local blood flow. In this way, the active tissue receives the additional nutrients required to sustain its new level of function. As noted earlier, active hyperemia in skeletal muscle can increase local muscle blood flow as much as 20-fold during intense exercise.

Autoregulation of Blood Flow During Changes in Arterial Pressure—Metabolic and Myogenic Mechanisms

In any tissue of the body, a rapid increase in arterial pressure causes an immediate rise in blood flow. However, within less than 1 minute, the blood flow in most tissues returns almost to the normal level, even though the arterial pressure is kept elevated. This return of flow toward normal is called *autoregulation*. After autoregulation has occurred, the local blood flow in most tissues will be related to arterial pressure approximately in accord with the solid acute curve in Figure 17-5. Note that between

arterial pressures of about 70 and 175 mm Hg, the blood flow increases only 20% to 30%, even though the arterial pressure increases 150%. In some tissues, such as the brain and heart, this autoregulation is even more precise.

For almost a century, two views have been proposed to explain this acute autoregulation mechanism. They have been called the metabolic theory and the myogenic theory.

The *metabolic theory* can be understood easily by applying the basic principles of local blood flow regulation discussed in previous sections. Thus, when the arterial pressure becomes too great, the excess flow provides too much oxygen and too many other nutrients to the tissues and washes out the vasodilators released by the tissues. These nutrients (especially oxygen) and decreased tissue levels of vasodilators then cause the blood vessels to constrict and return flow to nearly normal, despite the increased pressure.

The *myogenic theory*, however, suggests that another mechanism not related to tissue metabolism explains the phenomenon of autoregulation. This theory is based on the observation that a sudden stretch of small blood vessels causes the smooth muscle of the vessel wall to contract. Therefore, it has been proposed that when high arterial pressure stretches the vessel, reactive vascular constriction results, which reduces blood flow nearly back to normal. Conversely, at low pressures, the degree of stretch of the vessel is less, so the smooth muscle relaxes, reducing vascular resistance and helping to return flow toward normal.

The myogenic response is inherent to vascular smooth muscle and can occur in the absence of neural or hormonal influences. It is most pronounced in arterioles but can also be observed in arteries, venules, veins, and even lymphatic vessels. Myogenic contraction is initiated by *stretch-induced vascular depolarization*, which then rapidly increases calcium ion entry from the extracellular fluid into the cells, causing them to contract. Changes in vascular pressure may also open or close other ion channels that influence vascular contraction. The precise mechanisms whereby changes in pressure cause opening or closing of vascular ion channels are still uncertain but likely involve mechanical effects of pressure on extracellular proteins that are tethered to cytoskeleton elements of the vascular wall or to the ion channels themselves.

The myogenic mechanism appears to be important in preventing excessive stretching of blood vessels when blood pressure is increased. However, the role of the myogenic mechanism in blood flow regulation is unclear because this pressure-sensing mechanism cannot detect changes in blood flow in the tissue directly. Metabolic factors appear to override the myogenic mechanism in circumstances in which the metabolic demands of the tissues are significantly increased, such as during vigorous muscle exercise, which causes dramatic increases in skeletal muscle blood flow.

Special Mechanisms for Acute Blood Flow Control in Specific Tissues

Although the general mechanisms for local blood flow control discussed thus far are present in almost all tissues of the body, distinctly different mechanisms operate in a few special areas. All mechanisms are discussed throughout this text in relation to specific organs, but two notable mechanisms are as follows:

1. In the *kidneys*, blood flow control is significantly vested in a mechanism called *tubuloglomerular feedback*, in which the composition of the fluid in the early distal tubule is detected by an epithelial structure of the distal tubule, called the *macula densa*. This structure is located where the distal tubule lies adjacent to the afferent and efferent arterioles at the nephron *juxtaglomerular apparatus*. When too much fluid filters from the blood through the glomerulus into the tubular system, feedback signals from the macula densa cause constriction of the afferent arterioles, thereby reducing renal blood flow and glomerular filtration rate back to nearly normal. The details of this mechanism are discussed in [Chapter 27](#).
2. In the *brain*, in addition to control of blood flow by tissue oxygen concentration, the concentrations of carbon dioxide and hydrogen ions play prominent roles. An increase of either or both of these substances dilates the cerebral vessels and allows rapid washout of the excess carbon dioxide or hydrogen ions from the brain tissues. This mechanism is important because the *level of excitability of the brain is highly dependent on exact control of both carbon dioxide concentration and hydrogen ion concentration*. This special mechanism for cerebral blood flow control is presented in [Chapter 62](#).
3. In the *skin*, blood flow control is closely linked to body temperature regulation. Cutaneous and subcutaneous flow regulates heat loss from the body by metering the flow of heat from the core to the surface of the body, where heat is lost to the environment. Skin blood flow is controlled largely by the central nervous system through the sympathetic nerves, as discussed in [Chapter 74](#). Although skin blood flow is only about 3 ml/min/100 g of tissue in cool weather, large changes from that value can occur as needed. When humans are exposed to body heating, skin blood flow may increase greatly, to as high as 7 to 8 L/min for the entire body. When body temperature is reduced, skin blood flow decreases, falling to barely above zero at very low temperatures. Even with severe vasoconstriction, skin blood flow is usually great enough to meet the basic metabolic demands of the skin.

Figure 17-6. Nitric oxide synthase (eNOS) enzyme in endothelial cells synthesizes nitric oxide (NO) from arginine and oxygen. NO activates soluble guanylate cyclases in vascular smooth muscle cells, resulting in conversion of cyclic guanosine triphosphate (cGTP) to cyclic guanosine monophosphate (cGMP), which ultimately causes the blood vessels to relax.

Control of Tissue Blood Flow: Endothelium-Derived Relaxing or Constricting Factors

The endothelial cells lining the blood vessels synthesize several substances that when released, can affect the degree of relaxation or contraction of the vascular wall. For many of these endothelium-derived relaxing or constrictor factors, the physiological roles are just beginning to be understood.

Nitric Oxide Is a Vasodilator Released from Healthy Endothelial Cells. The most important of the endothelium-derived relaxing factors is *nitric oxide* (NO), a lipophilic gas that is released from endothelial cells in response to a variety of chemical and physical stimuli. *Endothelium-derived nitric oxide synthase* (eNOS) enzymes synthesize NO from *arginine* and oxygen and by reduction of inorganic nitrate. After diffusing out of the endothelial cell, NO has a half-life in the blood of only about 6 seconds and acts mainly in the local tissues, where it is released. NO activates *soluble guanylate cyclases* in vascular smooth muscle cells (Figure 17-6), resulting in the conversion of cyclic guanosine triphosphate (cGTP) to cyclic guanosine monophosphate (cGMP) and activation of *cGMP-dependent protein kinase* (PKG), which has several actions that cause the blood vessels to relax.

The flow of blood through the arteries and arterioles causes *shear stress* on the endothelial cells because of viscous drag of the blood against the vascular walls. This stress contorts the endothelial cells in the direction of flow and causes significant increase in NO release. The NO then relaxes the blood vessels, fortunately, because the local metabolic mechanisms for controlling tissue blood flow mainly dilate the very small arteries and arterioles in each tissue. Yet, when blood flow through a microvascular portion of the circulation increases, this action secondarily stimulates the release of NO from

larger vessels as a result of increased flow and shear stress in these vessels. The released NO increases the diameters of the larger upstream blood vessels whenever microvascular blood flow increases downstream. Without such a response, the effectiveness of local blood flow control would be decreased because a significant part of the resistance to blood flow is in the upstream small arteries.

NO synthesis and release from endothelial cells are also stimulated by some vasoconstrictors, such as *angiotensin II*, which bind to specific receptors on endothelial cells. The increased NO release protects against excessive vasoconstriction.

When endothelial cells are damaged by chronic hypertension or atherosclerosis, impaired NO synthesis may contribute to excessive vasoconstriction and worsening of the hypertension and endothelial damage. If untreated, this may eventually cause vascular injury and damage to vulnerable tissues such as the heart, kidneys, and brain.

Even before NO was discovered, clinicians used nitroglycerin, amyl nitrate, and other nitrate derivatives to treat patients who had *angina pectoris*—that is, severe chest pain caused by ischemia of the heart muscle. These drugs, when broken down chemically, release NO and cause dilation of blood vessels throughout the body, including the coronary blood vessels.

Other important applications of NO physiology and pharmacology are the development and clinical use of drugs (e.g., sildenafil) that inhibit *cGMP-specific phosphodiesterase-5* (PDE-5), an enzyme that degrades cGMP. By preventing the degradation of cGMP, the PDE-5 inhibitors effectively prolong the actions of NO to cause vasodilation. The primary clinical use of the PDE-5 inhibitors is to treat *erectile dysfunction*. Penile erection is caused by parasympathetic nerve impulses through the pelvic nerves to the penis, where the neurotransmitters acetylcholine and NO are released. By preventing the degradation of NO, the PDE-5 inhibitors enhance the dilation of the blood vessels in the penis and aid in erection, as discussed in Chapter 81.

Endothelin Is a Powerful Vasoconstrictor Released From Damaged Endothelium. Endothelial cells also release vasoconstrictor substances. The most important of these is *endothelin*, a large, 27–amino acid peptide that requires only minute amounts (nanograms) to cause powerful vasoconstriction. This substance is present in the endothelial cells of all or most blood vessels but greatly increases when the vessels are injured. The usual stimulus for release is damage to the endothelium, such as that caused by crushing the tissues or injecting a traumatizing chemical into the blood vessel. After severe blood vessel damage, local release of endothelin and subsequent vasoconstriction helps prevent extensive bleeding from arteries as large as 5 millimeters in diameter that might have been torn open by crushing injury.

Increased endothelin release is also believed to contribute to vasoconstriction when the endothelium is

damaged by hypertension. Drugs that block endothelin receptors have been used to treat *pulmonary hypertension* but generally have not been used for lowering blood pressure in patients with systemic arterial hypertension.

LONG-TERM BLOOD FLOW REGULATION

Thus far, most of the mechanisms for local blood flow regulation that we have discussed act within a few seconds to a few minutes after the local tissue conditions have changed. Yet, even after full activation of these acute mechanisms, the blood flow usually is adjusted only about three quarters of the way to the exact additional requirements of the tissues. For example, when the arterial pressure suddenly increases from 100 to 150 mm Hg, the blood flow increases almost instantaneously, by about 100%. Then, within 30 seconds to 2 minutes, the flow decreases back to about 10% to 15% above the original control value. This example illustrates the rapidity of the acute mechanisms for local blood flow regulation, but also demonstrates that the regulation is still incomplete because a 10% to 15% excess blood flow remains in some tissues.

However, over a period of hours, days, and weeks, a long-term type of local blood flow regulation develops in addition to the acute control. This long-term regulation gives far more complete control of blood flow. In the aforementioned example, if the arterial pressure remains at 150 mm Hg indefinitely, the blood flow through the tissues gradually approaches almost exactly the normal flow level within a few weeks. **Figure 17-5** shows (*dashed green curve*) the extreme effectiveness of this long-term local blood flow regulation. Note that once the long-term regulation has had time to occur, long-term changes in arterial pressure between 50 and 200 mm Hg have little effect on the rate of local blood flow.

Long-term regulation of blood flow is especially important when the metabolic demands of a tissue change. Thus, if a tissue becomes chronically overactive and requires increased quantities of oxygen and other nutrients, the arterioles and capillary vessels usually increase both in number and size within a few weeks to match the needs of the tissue, unless the circulatory system has become pathological or too old to respond.

Blood Flow Regulation by Changes in Tissue Vascularity

A key mechanism for long-term local blood flow regulation is to change the amount of vascularity of the tissues. For example, if the metabolism in a tissue is increased for a prolonged period, vascularity increases, a process generally called *angiogenesis*; if the metabolism is decreased, vascularity decreases. **Figure 17-7** shows the large increase in the number of capillaries in a rat anterior tibialis muscle that was stimulated electrically to contract for short periods each day for 30 days, compared with the unstimulated muscle in the other leg of the animal.

Figure 17-7. A large increase in the number of capillaries (*white dots*) in a rat anterior tibialis muscle that was stimulated electrically to contract for short periods each day for 30 days (**B**), compared with the unstimulated muscle (**A**). The 30 days of intermittent electrical stimulation converted the predominantly fast-twitch, glycolytic anterior tibialis muscle to a predominantly slow-twitch, oxidative muscle with increased numbers of capillaries and decreased fiber diameter, as shown. (Courtesy Dr. Thomas Adair.)

Thus, actual physical reconstruction of the tissue vasculature occurs to meet the needs of the tissues. This reconstruction occurs rapidly (within days) in young animals. It also occurs rapidly in new growth tissue, such as in cancerous tissue, but occurs much more slowly in old, well-established tissues. Therefore, the time required for long-term regulation to take place may be only a few days in the neonate or as long as months in older adults. Furthermore, the final degree of response is much better in younger than in older tissues; thus, in the neonate, the vascularity will adjust to match almost exactly the needs of the tissue for blood flow, whereas in older tissues, vascularity frequently lags far behind the needs of the tissues.

Role of Oxygen in Long-Term Regulation. Oxygen is important not only for acute control of local blood flow but also for long-term control. One example of this is

increased vascularity in tissues of animals that live at high altitudes, where the atmospheric oxygen is low. In premature babies who are put into oxygen tents for therapeutic purposes, the excess oxygen causes almost immediate cessation of new vascular growth in the retina of the premature baby's eyes and even causes degeneration of some of the small vessels that already have formed. When the infant is taken out of the oxygen tent, explosive overgrowth of new vessels then occurs to make up for the sudden decrease in available oxygen. Often, so much overgrowth occurs that the retinal vessels grow out from the retina into the eye's vitreous humor, eventually causing blindness, a condition called *retrolental fibroplasia*.

Importance of Vascular Growth Factors in Formation of New Blood Vessels. A dozen or more factors that increase growth of new blood vessels have been found, almost all of which are small peptides. The four factors that have been best characterized are *vascular endothelial growth factor* (VEGF), *fibroblast growth factor*, *platelet-derived growth factor* (PDGF), and *angiogenin*, each of which has been isolated from tissues that have inadequate blood supply. Deficiency of tissue oxygen induces expression of *hypoxia inducible factors* (HIFs), transcription factors that in turn upregulate gene expression and the formation of vascular growth factors (also called *angiogenic factors*).

Angiogenesis begins with new vessels sprouting from other small vessels. The first step is dissolution of the basement membrane of the endothelial cells at the point of sprouting. This step is followed by rapid reproduction of new endothelial cells, which stream outward through the vessel wall in extended cords directed toward the source of the angiogenic factor. The cells in each cord continue to divide and rapidly fold over into a tube. Next, the tube connects with another tube budding from another donor vessel (another arteriole or venule) and forms a capillary loop through which blood begins to flow. If the flow is great enough, smooth muscle cells eventually invade the wall, so some of the new vessels eventually grow to be new arterioles or venules or perhaps even larger vessels. Thus, angiogenesis explains how metabolic factors in local tissues can cause growth of new vessels.

Certain other substances, such as some steroid hormones, have the opposite effect on small blood vessels, occasionally even causing dissolution of vascular cells and disappearance of vessels. Therefore, blood vessels can also be made to disappear when they are not needed. Peptides produced in the tissues can also block the growth of new blood vessels. For example, *angiostatin*, a fragment of the protein plasminogen, is a naturally occurring inhibitor of angiogenesis. *Endostatin* is another antiangiogenic peptide derived from the breakdown of collagen type XVII. Although the precise physiological functions of these antiangiogenic substances are still unknown, there is great interest in their potential use in arresting blood

vessel growth in cancerous tumors and therefore preventing the large increases in blood flow needed to sustain the nutrient supply of rapidly growing tumors.

Vascularity Determined by Maximum Blood Flow Need, Not by Average Need. An especially valuable characteristic of long-term vascular control is that vascularity is determined mainly by the *maximum* level of blood flow required by the tissue rather than by average need. For example, during heavy exercise, the need for whole-body blood flow often increases to six to eight times the resting blood flow. This great excess of flow may not be required for more than a few minutes each day. Nevertheless, even this short time of need can cause enough angiogenic factors to be formed by the muscles to increase their vascularity as required. Were it not for this capability, every time a person attempted heavy exercise, the muscles would fail to receive the required nutrients, especially the required oxygen, and thus the muscles would fail to contract.

However, after extra vascularity does develop, the extra blood vessels normally remain mainly vasoconstricted, opening to allow extra flow only when appropriate local stimuli such as a lack of oxygen, nerve vasodilatory stimuli, or other stimuli call forth the required extra flow.

Blood Flow Regulation by Development of Collateral Circulation

In most tissues of the body, when an artery or a vein is blocked, a new vascular channel usually develops around the blockage and allows at least partial resupply of blood to the affected tissue. The first stage in this process is dilation of small vascular loops that already connect the vessel above the blockage to the vessel below. This dilation occurs within the first minute or two, indicating that the dilation is likely mediated by metabolic factors. After this initial opening of collateral vessels, the blood flow often is still less than 25% of that required to supply all the tissue needs. However, further opening occurs within the ensuing hours, so that within 1 day as much as half the tissue needs may be met and, within a few days, the blood flow is usually sufficient to meet the tissue needs.

The collateral vessels continue to grow for many months thereafter, usually forming multiple small collateral channels rather than one single large vessel. Under resting conditions, the blood flow may return to nearly normal, but the new channels seldom become large enough to supply the blood flow needed during strenuous tissue activity. Thus, development of collateral vessels follows the usual principles of acute and long-term local blood flow control; the acute control is rapid metabolic dilation, followed chronically by growth and enlargement of new vessels over a period of weeks and months.

An important example of the development of collateral blood vessels occurs after thrombosis of one of the coronary arteries. By the age of 60 years, many people

have experienced closure or at least partial occlusion of at least one of the smaller branch coronary vessels, but they are not aware of it because collateral blood vessels have developed rapidly enough to prevent myocardial damage. When collateral blood vessels are unable to develop quickly enough to maintain blood flow because of the rapidity or severity of the coronary insufficiency, serious heart attacks can occur.

Vascular Remodeling in Response to Chronic Changes in Blood Flow or Blood Pressure

Vascular growth and remodeling are critical components of tissue development and growth and occur as an adaptive response to long-term changes in blood pressure or blood flow. For example, after several months of chronic exercise training, vascularity of the trained muscles increases to accommodate their higher blood flow requirements. In addition to changes in capillary density, there may also be changes in the structure of large blood vessels in response to long-term changes in blood pressure and blood flow. When blood pressure is chronically elevated above normal, for example, the large and small arteries and arterioles remodel to accommodate the increased mechanical wall stress of the higher blood pressure. In most tissues, the small arteries and arterioles rapidly respond (within seconds) to increased arterial pressure with vasoconstriction, which helps autoregulate tissue blood flow, as discussed previously. The vasoconstriction decreases lumen diameter, which in turn tends to normalize the vascular wall tension (T), which, according to *Laplace's equation*, is the product of the radius (r) of the blood vessel and its pressure (P): $T = r \times P$

In small blood vessels that constrict in response to increased blood pressure, the vascular smooth muscle cells and endothelial cells gradually—over a period of several days or weeks—rearrange themselves around the smaller lumen diameter, a process called *inward eutrophic remodeling*, with no change in the total cross-sectional area of the vascular wall (Figure 17-8). In larger arteries that do not constrict in response to the increased pressure, the vessel wall is exposed to increased wall tension that stimulates a *hypertrophic remodeling* response and an increase in the cross-sectional area of the vascular wall. The hypertrophic response increases the size of vascular smooth muscle cells and stimulates formation of additional extracellular matrix proteins, such as collagen and fibronectin, that reinforce the strength of the vascular wall to withstand the higher blood pressures. However, this hypertrophic response also makes the large blood vessels stiffer, which is a hallmark of chronic hypertension.

Another example of vascular remodeling is the change that occurs when a large vein (often the saphenous vein) is implanted in a patient for a coronary artery bypass graft procedure. Veins are normally exposed to much lower

Figure 17-8. Vascular remodeling in response to a chronic increase in blood pressure or blood flow. In small arteries and arterioles that constrict in response to increased blood pressure, *inward eutrophic remodeling* typically occurs because the lumen diameter is smaller and the vascular wall is thicker, but the total cross-sectional area of the vessel wall is hardly changed. In large blood vessels that do not constrict in response to increased blood pressure, there may be *hypertrophic remodeling*, with increases in thickness and total cross-sectional area of the vascular wall. If blood vessels are exposed to chronic increases in blood flow, there is typically *outward remodeling*, with increases in lumen diameter, little change in wall thickness, and increased total cross-sectional area of the vascular wall. If the blood vessel is exposed to long-term increases in blood pressure and blood flow, there is usually *outward hypertrophic remodeling*, with increases in lumen diameter, wall thickness, and total cross-sectional area of the vascular wall. Chronic reductions in blood pressure and blood flow have the opposite effects, as previously described.

pressures than arteries and have much thinner walls, but when a vein is sewn onto the aorta and connected to a coronary artery, it is exposed to increases in intraluminal pressure and wall tension. The increased wall tension initiates hypertrophy of vascular smooth muscle cells and increased extracellular matrix formation, which thicken and strengthen the wall of the vein; as a result, several months after implantation into the arterial system, the vein will typically have a wall thickness similar to that of an artery.

Vascular remodeling also occurs when a blood vessel is exposed chronically to increased or decreased blood flow. The creation of a fistula connecting a large artery and large vein, thereby completely bypassing high-resistance small vessels and capillaries, provides an especially interesting example of remodeling in the affected artery and vein. In patients with renal failure who undergo dialysis, an

arteriovenous (A-V) fistula directly from the radial artery to the antecubital vein of the forearm is created to permit vascular access for dialysis. The blood flow rate in the radial artery may increase as much as 10 to 50 times the normal flow rate, depending on the patency of the fistula. As a result of the high flow rate and high shear stress on the vessel wall, the luminal diameter of the radial artery increases progressively (*outward remodeling*), whereas the thickness of the vessel wall may remain unchanged, resulting in an increase in cross-sectional area of the vascular wall. In contrast, wall thickness, lumen diameter, and cross-sectional area of the vascular wall on the venous side of the fistula increase in response to increases in pressure and blood flow (*outward hypertrophic remodeling*). This pattern of remodeling is consistent with the idea that long-term increases in vascular wall tension cause hypertrophy and increased wall thickness in large blood vessels, whereas increased blood flow rate and shear stress cause outward remodeling and increased luminal diameter to accommodate the increased blood flow.

Chronic reductions in blood pressure and blood flow have effects opposite to those previously described. When blood flow is greatly reduced, the diameter of the vascular lumen is also reduced and, when blood pressure is reduced, the thickness of the vascular wall usually decreases. Thus, vascular remodeling is an important adaptive response of the blood vessels to tissue growth and development, as well as to physiological and pathological changes in blood pressure and blood flow to the tissues.

HUMORAL CONTROL OF THE CIRCULATION

Humoral control of the circulation means control by substances secreted or absorbed into the body fluids, such as hormones and locally produced factors. Some of these substances are formed by special glands and transported in the blood throughout the entire body. Others are formed in local tissue areas and cause only local circulatory effects. Among the most important of the humoral factors that affect circulatory function are those described in the following sections.

VASOCONSTRICTORS

Norepinephrine and Epinephrine. *Norepinephrine* is an especially powerful vasoconstrictor hormone; *epinephrine* is less powerful as a vasoconstrictor and, in some tissues, even causes mild vasodilation. (A special example of vasodilation caused by epinephrine is that which occurs to dilate the coronary arteries during increased heart activity.)

When the sympathetic nervous system is stimulated in most parts of the body during stress or exercise, the sympathetic nerve endings in the individual tissues release norepinephrine, which excites the heart and constricts the veins and arterioles. In addition, the sympathetic nerves to the adrenal medullae cause these glands to

secrete norepinephrine and epinephrine into the blood. These hormones then circulate to all areas of the body and cause almost the same effects on the circulation as direct sympathetic stimulation, thus providing a dual system of control: (1) direct nerve stimulation; and (2) indirect effects of norepinephrine and/or epinephrine in the circulating blood.

Angiotensin II. Angiotensin II is another powerful vasoconstrictor substance. As little as *one millionth* of a gram can increase the arterial pressure of a person by 50 mm Hg or more.

The effect of angiotensin II is to constrict the small arterioles powerfully. If this constriction occurs in an isolated tissue area, the blood flow to that area can be severely depressed. However, the real importance of angiotensin II is that it normally acts on many arterioles of the body at the same time to increase the *total peripheral resistance* and decrease sodium and water excretion by the kidneys, thereby increasing the arterial pressure. Thus, this hormone plays an integral role in the regulation of arterial pressure, as is discussed in detail in [Chapter 19](#).

Vasopressin. *Vasopressin*, also called *antidiuretic hormone*, is even more powerful than angiotensin II as a vasoconstrictor, thus making it one of the body's most potent vascular constrictor substances. It is formed in nerve cells in the hypothalamus of the brain (see [Chapters 29](#) and [76](#)) but is then transported downward by nerve axons to the posterior pituitary gland, where it is finally secreted into the blood.

It is clear that vasopressin could have enormous effects on circulatory function. Yet, because only minute amounts of vasopressin are secreted in most physiological conditions, most physiologists have thought that vasopressin plays little role in vascular control. However, experiments have shown that the concentration of circulating blood vasopressin after severe hemorrhage can increase enough to attenuate reductions in arterial pressure markedly. In some cases, this action can, by itself, bring the arterial pressure almost back up to normal.

Vasopressin has the major function of greatly increasing water reabsorption from the renal tubules back into the blood (discussed in [Chapter 29](#)) and therefore helps control body fluid volume. That is why this hormone is also called *antidiuretic hormone*.

VASODILATORS

Bradykinin. Several substances called *kinins* cause powerful vasodilation when formed in the blood and tissue fluids of some organs. The kinins are small polypeptides that are split away by proteolytic enzymes from α_2 -globulins in the plasma or tissue fluids. A proteolytic enzyme of particular importance for this purpose is *kallikrein*, which is present in the blood and tissue fluids in an inactive form. This inactive kallikrein is activated by

maceration of the blood, tissue inflammation, or other similar chemical or physical effects on the blood or tissues. As kallikrein becomes activated, it acts immediately on α_2 -globulin to release a kinin called *kallidin*, which is then converted by tissue enzymes into *bradykinin*. Once formed, bradykinin persists for only a few minutes because it is inactivated by the enzyme *carboxypeptidase* or by *converting enzyme*, the same enzyme that also plays an essential role in activating angiotensin, as discussed in [Chapter 19](#). The activated kallikrein enzyme is destroyed by a *kallikrein inhibitor* that is also present in body fluids.

Bradykinin causes both powerful *arteriolar dilation* and *increased capillary permeability*. For example, injection of 1 microgram of bradykinin into the brachial artery of a person increases blood flow through the arm as much as sixfold, and even smaller amounts injected locally into tissues can cause marked local edema resulting from an increase in capillary pore size.

Kinins appear to play special roles in regulating blood flow and capillary leakage of fluids in inflamed tissues. It is also believed that bradykinin plays a normal role to help regulate blood flow in the skin, as well as in the salivary and gastrointestinal glands.

Histamine. Histamine is released in almost every tissue of the body if the tissue becomes damaged or inflamed or is the subject of an allergic reaction. Most of the histamine is derived from *mast cells* in the damaged tissues and from *basophils* in the blood.

Histamine has a powerful vasodilator effect on the arterioles and, like bradykinin, has the ability to increase capillary porosity greatly, allowing leakage of fluid and plasma protein into the tissues. In many pathological conditions, the intense arteriolar dilation and increased capillary porosity produced by histamine cause large quantities of fluid to leak out of the circulation into the tissues, inducing edema. The local vasodilatory and edema-producing effects of histamine are especially prominent during allergic reactions and are discussed in [Chapter 35](#).

VASCULAR CONTROL BY IONS AND OTHER CHEMICAL FACTORS

Many different ions and other chemical factors can dilate or constrict local blood vessels. The following list details some of their specific effects:

1. An increase in intracellular *calcium ion* concentration causes *vasoconstriction* because of the general effect of calcium to stimulate smooth muscle contraction, as discussed in [Chapter 8](#).
2. An increase in *potassium ion* concentration, within the physiological range, causes *vasodilation*. This effect results from the ability of potassium ions to inhibit smooth muscle contraction.
3. An increase in *magnesium ion* concentration causes *powerful vasodilation* because magnesium ions inhibit smooth muscle contraction.

4. An *increase in hydrogen ion* concentration (decrease in pH) causes dilation of the arterioles. Conversely, a *slight decrease in hydrogen ion concentration* causes arteriolar constriction.
5. *Anions* that have significant effects on blood vessels are *acetate* and *citrate*, both of which cause mild degrees of vasodilation.
6. An *increase in carbon dioxide concentration* causes moderate vasodilation in most tissues but marked vasodilation in the brain. Also, carbon dioxide in the blood, acting on the brain vasomotor center, has an extremely powerful indirect effect, transmitted through the sympathetic nervous vasoconstrictor system, that causes widespread vasoconstriction throughout the body.

Most Vasodilators or Vasoconstrictors Have Little Effect on Long-Term Blood Flow Unless They Alter the Metabolic Rate of the Tissues.

In most experimental studies, tissue blood flow and cardiac output (the sum of flow to all the body's tissues) are not substantially altered, except for 1 or 2 days, when large amounts of powerful vasoconstrictors such as angiotensin II or vasodilators such as bradykinin are chronically infused. Why is blood flow not significantly altered in most tissues, even in the presence of very large amounts of these vasoactive agents?

To answer this question, we must return to one of the fundamental principles of circulatory function that was previously discussed—the ability of each tissue to *autoregulate* its own blood flow according to the metabolic needs and other functions of the tissue. Administration of a powerful vasoconstrictor, such as angiotensin II, may cause transient decreases in tissue blood flow and cardiac output but usually has little long-term effect if it does not alter metabolic rate of the tissues. Likewise, most vasodilators cause only short-term changes in tissue blood flow and cardiac output if they do not alter tissue metabolism. Therefore, blood flow is generally regulated according to the specific needs of the tissues, as long as the arterial pressure is adequate to perfuse the tissues.

Nervous Regulation of the Circulation and Rapid Control of Arterial Pressure

NERVOUS REGULATION OF THE CIRCULATION

As discussed in [Chapter 17](#), adjustment of blood flow in the tissues and organs of the body is mainly the function of local tissue control mechanisms. In this chapter, we discuss how nervous control of the circulation has more global functions, such as redistributing blood flow to different areas of the body, increasing or decreasing pumping activity by the heart, and providing rapid control of systemic arterial pressure.

The nervous system controls the circulation almost entirely through the *autonomic nervous system*. The total function of this system is presented in [Chapter 61](#), and this subject was also introduced in [Chapter 17](#). In this chapter, we consider additional specific anatomical and functional characteristics.

AUTONOMIC NERVOUS SYSTEM

The most important part of the autonomic nervous system for regulating the circulation is the *sympathetic nervous system*. The *parasympathetic nervous system*, however, contributes importantly to regulation of heart function, as described later in the chapter.

Sympathetic Nervous System. [Figure 18-1](#) shows the anatomy of sympathetic nervous control of the circulation. Sympathetic vasomotor nerve fibers leave the spinal cord through all the thoracic spinal nerves and through the first one or two lumbar spinal nerves. They then pass immediately into a *sympathetic chain*, one of which lies on each side of the vertebral column. Next, they pass by two routes to the circulation: (1) through specific *sympathetic nerves* that innervate mainly the vasculature of the internal viscera and the heart, as shown on the right side of [Figure 18-1](#); and (2) almost immediately into peripheral portions of the *spinal nerves* distributed to the vasculature of the peripheral areas. The precise pathways of these fibers in the spinal cord and in the sympathetic chains are discussed in [Chapter 61](#).

Sympathetic Innervation of the Blood Vessels. [Figure 18-2](#) shows the distribution of sympathetic nerve fibers to the blood vessels, demonstrating that in most tissues, all the vessels *except* the capillaries are innervated. Precapillary sphincters and metarterioles are innervated in some tissues, such as the mesenteric blood vessels, although their sympathetic innervation is usually not as dense as in the small arteries, arterioles, and veins.

The innervation of the *small arteries* and *arterioles* allows sympathetic stimulation to increase *resistance* to blood flow and thereby *decrease* the rate of blood flow through the tissues.

The innervation of the large vessels, particularly of the *veins*, makes it possible for sympathetic stimulation to *decrease* the volume of these vessels. This decrease in volume can push blood into the heart and thereby plays a major role in regulation of heart pumping, as we explain later in this and subsequent chapters.

Sympathetic Stimulation Increases Heart Rate and Contractility. Sympathetic fibers also go directly to the heart, as shown in [Figure 18-1](#). As discussed in [Chapter 9](#), sympathetic stimulation markedly increases the activity of the heart, both increasing the heart rate and enhancing its strength and volume of pumping.

Parasympathetic Stimulation Decreases Heart Rate and Contractility. Although the parasympathetic nervous system is exceedingly important for many other autonomic functions of the body, such as control of multiple gastrointestinal actions, it plays only a minor role in regulating vascular function in most tissues. Its most important circulatory effect is to control heart rate by way of *parasympathetic nerve fibers* to the heart in the *vagus nerves*, shown in [Figure 18-1](#) by the dashed red line from the brain medulla directly to the heart.

The effects of parasympathetic stimulation on heart function were discussed in detail in [Chapter 9](#). Principally, parasympathetic stimulation causes a marked *decrease* in heart rate and a slight decrease in heart muscle contractility.

Figure 18-1. Anatomy of *sympathetic nervous control* of the circulation. Also, shown by the *dashed red line*, is a *vagus nerve* that carries *parasympathetic signals* to the heart.

Sympathetic Vasoconstrictor System and Its Control by the Central Nervous System

The sympathetic nerves carry large numbers of *vasoconstrictor nerve fibers* and only a few *vasodilator fibers*. The vasoconstrictor fibers are distributed to essentially all segments of the circulation, but more to some tissues than to others. This sympathetic vasoconstrictor effect is especially powerful in the kidneys, intestines, spleen, and skin

Figure 18-2. Sympathetic innervation of the systemic circulation.

Figure 18-3. Areas of the brain that play important roles in the nervous regulation of the circulation. The *dashed lines* represent *inhibitory pathways*.

but is much less potent in skeletal muscle, heart, and the brain.

Vasomotor Center in the Brain and Its Control of the Vasoconstrictor System.

Located bilaterally mainly in the reticular substance of the medulla and lower third of the pons is an area called the *vasomotor center*, shown in **Figure 18-1** and **Figure 18-3**. This center transmits parasympathetic impulses through the vagus nerves to the heart and sympathetic impulses through the spinal cord and peripheral sympathetic nerves to virtually all arteries, arterioles, and veins of the body.

Although the total organization of the vasomotor center is still unclear, experiments have made it possible to identify certain important areas in this center:

1. A *vasoconstrictor area* located bilaterally in the anterolateral portions of the upper medulla. The neurons originating in this area distribute their fibers

Figure 18-4. Effect of total spinal anesthesia on the arterial pressure, showing a marked decrease in pressure resulting from loss of vasomotor tone.

to all levels of the spinal cord, where they excite preganglionic vasoconstrictor neurons of the sympathetic nervous system.

2. A *vasodilator area* located bilaterally in the anterolateral portions of the lower half of the medulla. The fibers from these neurons project upward to the vasoconstrictor area just described, inhibiting the vasoconstrictor activity of this area and causing vasodilation.
3. A *sensory area* located bilaterally in the *nucleus tractus solitarius* in the posterolateral portions of the medulla and lower pons. The neurons of this area receive sensory nerve signals from the circulatory system mainly through the *vagus* and *glossopharyngeal nerves*, and output signals from this sensory area then help control activities of the vasoconstrictor and vasodilator areas of the vasomotor center, thus providing reflex control of many circulatory functions. An example is the *baroreceptor reflex* for controlling arterial pressure, described later in this chapter.

Continuous Partial Constriction of Blood Vessels by Sympathetic Vasoconstrictor Tone. Under normal conditions, the vasoconstrictor area of the vasomotor center transmits signals continuously to the sympathetic vasoconstrictor nerve fibers over the entire body, causing slow firing of these fibers at a rate of about 0.5 to 2 impulses per second. This continual firing is called *sympathetic vasoconstrictor tone*. These impulses normally maintain a partial state of constriction in the blood vessels, called *vasomotor tone*.

Figure 18-4 demonstrates the significance of vasoconstrictor tone. In the experiment shown in this figure, a spinal anesthetic was administered to an animal. This anesthetic blocked all transmission of sympathetic nerve impulses from the spinal cord to the periphery. As a result, the arterial pressure fell from 100 to 50 mm Hg, demonstrating the effect of the loss of vasoconstrictor

tone throughout the body. A few minutes later, a small amount of the hormone norepinephrine was injected into the blood (norepinephrine is the principal vasoconstrictor hormonal substance secreted at the endings of the sympathetic vasoconstrictor nerve fibers). As this injected hormone was transported in the blood to blood vessels, the vessels once again became constricted, and the arterial pressure rose to a level even greater than normal for 1 to 3 minutes until the norepinephrine was destroyed.

Control of Heart Activity by the Vasomotor Center.

At the same time that the vasomotor center regulates the amount of vascular constriction, it also controls heart activity. The *lateral* portions of the vasomotor center transmit excitatory impulses through the sympathetic nerve fibers to the heart when there is a need to increase heart rate and contractility. Conversely, when there is a need to decrease heart pumping, the *medial* portion of the vasomotor center sends signals to the adjacent *dorsal motor nuclei of the vagus nerves*, which then transmit parasympathetic impulses through the vagus nerves to the heart to decrease heart rate and heart contractility. Therefore, the vasomotor center can increase or decrease heart activity. Heart rate and the strength of heart contractions ordinarily increase when vasoconstriction occurs and ordinarily decrease when vasoconstriction is inhibited.

Control of the Vasomotor Center by Higher Nervous Centers.

Large numbers of small neurons located throughout the *reticular substance* of the *pons*, *mesencephalon*, and *diencephalon* can excite or inhibit the vasomotor center. This reticular substance is shown in **Figure 18-3**. In general, the neurons in the more lateral and superior portions of the reticular substance cause excitation, whereas the more medial and inferior portions cause inhibition.

The *hypothalamus* plays a special role in controlling the vasoconstrictor system because it can exert powerful excitatory or inhibitory effects on the vasomotor center. The *posterolateral portions* of the hypothalamus cause mainly excitation, whereas the *anterior portion* can cause mild excitation or inhibition, depending on the precise part of the anterior hypothalamus that is stimulated.

Many parts of the *cerebral cortex* can also excite or inhibit the vasomotor center. Stimulation of the *motor cortex*, for example, excites the vasomotor center because of impulses transmitted downward into the hypothalamus and then to the vasomotor center. Also, stimulation of the *anterior temporal lobe*, *orbital areas of the frontal cortex*, *anterior part of the cingulate gyrus*, *amygdala*, *septum*, and *hippocampus* can all excite or inhibit the vasomotor center, depending on the precise portions of these areas that are stimulated and the intensity of the stimulus. Thus, widespread basal areas of the brain can have profound effects on cardiovascular function.

Norepinephrine Is the Sympathetic Vasoconstrictor Neurotransmitter. The substance secreted at the endings

of the vasoconstrictor nerves is almost entirely norepinephrine, which acts directly on the *alpha-adrenergic receptors* of the vascular smooth muscle to cause vasoconstriction, as discussed in [Chapter 61](#).

Adrenal Medullae and Their Relationship to the Sympathetic Vasoconstrictor System. Sympathetic impulses are transmitted to the adrenal medullae at the same time that they are transmitted to the blood vessels. These impulses cause the medullae to *secrete epinephrine and norepinephrine into the circulating blood*. These two hormones are carried in the blood stream to all parts of the body, where they act directly on all blood vessels and usually cause vasoconstriction. In a few tissues, *epinephrine* causes vasodilation because it also stimulates *beta-adrenergic receptors*, which dilates rather than constricts certain vessels, as discussed in [Chapter 61](#).

Sympathetic Vasodilator System and Its Control by the Central Nervous System. The sympathetic nerves to skeletal muscles carry sympathetic *vasodilator* fibers, as well as constrictor fibers. In some animals, such as the cat, these dilator fibers release *acetylcholine*, not norepinephrine, at their endings. However, in primates, the vasodilator effect is believed to be caused by epinephrine exciting specific beta-adrenergic receptors in the muscle vasculature.

The pathway for central nervous system (CNS) control of the vasodilator system is shown by the dashed lines in [Figure 18-3](#). The principal area of the brain controlling this system is the *anterior hypothalamus*.

Possible Role of the Sympathetic Vasodilator System.

The sympathetic vasodilator system does not appear to play a major role in the control of the circulation in humans because complete block of the sympathetic nerves to the muscles hardly affects the ability of these muscles to control their own blood flow in many physiological conditions. Yet, some experiments have suggested that at the onset of exercise, the sympathetic system might cause initial vasodilation in skeletal muscles to allow an *anticipatory increase in blood flow*, even before the muscles require increased nutrients. There is evidence in humans that this sympathetic vasodilator response in skeletal muscles may be mediated by circulating epinephrine, which stimulates beta-adrenergic receptors, or by nitric oxide released from the vascular endothelium in response to stimulation by acetylcholine.

Emotional Fainting—Vasovagal Syncope. An interesting vasodilatory reaction occurs in people who experience intense emotional disturbances that cause fainting. In this case, the muscle vasodilator system becomes activated and, at the same time, the vagal cardioinhibitory center transmits strong signals to the heart to slow the heart rate markedly. The arterial pressure falls rapidly, which reduces blood flow to the brain and causes the person to lose consciousness. This overall effect is called *vasovagal syncope*. Emotional fainting begins with disturbing thoughts in the cerebral cortex. The pathway probably then goes to the vasodilatory center of the anterior hypothalamus next to the vagal centers of the medulla, to the heart through the vagus nerves, and also through the spinal cord to the *sympathetic vasodilator* nerves of the muscles.

Role of the Nervous System in Rapid Control of Arterial Pressure

One of the most important functions of nervous control of the circulation is its capability to cause rapid increases in arterial pressure. For this purpose, the entire vasoconstrictor and cardioaccelerator functions of the sympathetic nervous system are stimulated together. At the same time, there is reciprocal inhibition of parasympathetic vagal inhibitory signals to the heart. Thus, the following three major changes occur simultaneously, each of which helps increase arterial pressure:

1. *Most arterioles of the systemic circulation are constricted*, which greatly increases the total peripheral resistance, thereby increasing the arterial pressure.
2. *The veins especially (but the other large vessels of the circulation as well) are strongly constricted*. This constriction displaces blood out of the large peripheral blood vessels toward the heart, thus increasing the volume of blood in the heart chambers. The stretch of the heart then causes the heart to beat with greater force and therefore to pump increased quantities of blood. This also increases the arterial pressure.
3. Finally, *the heart is directly stimulated by the autonomic nervous system, further enhancing cardiac pumping*. Much of this enhanced cardiac pumping is caused by an increase in the heart rate, which sometimes increases to as much as three times normal. In addition, sympathetic nervous signals directly increase the contractile force of the heart muscle, increasing the capability of the heart to pump larger volumes of blood. During strong sympathetic stimulation, the heart can pump about two times as much blood as under normal conditions, which contributes still more to the acute rise in arterial pressure.

Nervous Control of Arterial Pressure Is Rapid. An especially important characteristic of nervous control of arterial pressure is its rapidity of response, beginning within seconds and often increasing the pressure to two times normal within 5 to 10 seconds. Conversely, sudden inhibition of nervous cardiovascular stimulation can decrease the arterial pressure to as little as half-normal within 10 to 40 seconds. Therefore, nervous control is the most rapid mechanism for arterial pressure regulation.

INCREASES IN ARTERIAL PRESSURE DURING MUSCLE EXERCISE AND OTHER STRESSES

An important example of the nervous system's ability to increase arterial pressure is the rise in pressure that occurs during muscle exercise. During heavy exercise, the muscles require greatly increased blood flow. Part of this increase results from local vasodilation of the muscle vasculature caused by increased metabolism of the muscle cells, as explained in [Chapter 17](#). An additional increase results from simultaneous elevation of arterial pressure

caused by sympathetic stimulation of the overall circulation during exercise. In heavy exercise, the arterial pressure rises by about 30% to 40%, which further increases blood flow by almost 2-fold.

The increase in arterial pressure during exercise results mainly from effects of the nervous system. At the same time that the motor areas of the brain become activated to cause exercise, most of the reticular activating system of the brain stem is also activated, which includes greatly increased stimulation of the vasoconstrictor and cardio-acceleratory areas of the vasomotor center. These effects rapidly increase the arterial pressure to keep pace with the increase in muscle activity.

In many other types of stress besides muscle exercise, a similar rise in pressure can also occur. For example, during extreme fright, the arterial pressure sometimes rises by as much as 75 to 100 mm Hg within a few seconds. This response is called the *alarm reaction*, and it provides an elevated arterial pressure that can immediately supply blood to the muscles of the body that might be needed to respond instantly to enable flight from danger.

REFLEX MECHANISMS FOR MAINTAINING NORMAL ARTERIAL PRESSURE

Aside from the exercise and stress functions of the autonomic nervous system to increase arterial pressure,

multiple subconscious special nervous control mechanisms operate all the time to maintain the arterial pressure at or near normal. Almost all these are *negative feedback reflex mechanisms*, described in the following sections.

Baroreceptor Arterial Pressure Control System—Baroreceptor Reflexes

The best known of the nervous mechanisms for arterial pressure control is the *baroreceptor reflex*. Basically, this reflex is initiated by stretch receptors, called *baroreceptors* or *pressoreceptors*, located at specific points in the walls of several large systemic arteries. A rise in arterial pressure stretches the baroreceptors and causes them to transmit signals into the CNS. Feedback signals are then sent back through the autonomic nervous system to the circulation to reduce arterial pressure down toward the normal level.

Physiologic Anatomy of the Baroreceptors and Their Innervation. Baroreceptors are spray-type nerve endings that lie in the walls of the arteries and are stimulated when stretched. A few baroreceptors are located in the wall of almost every large artery of the thoracic and neck regions but, as shown in [Figure 18-5](#), baroreceptors are extremely abundant in the following regions: (1) the wall of each internal carotid artery, slightly above the carotid bifurcation, an area known as the *carotid sinus*; and (2) the wall of the aortic arch.

Figure 18-5. Baroreceptor system for controlling arterial pressure.

Figure 18-6. Activation of the baroreceptors at different levels of arterial pressure. ΔI , Change in carotid sinus nerve impulses per second; ΔP , change in arterial blood pressure (in mm Hg).

Figure 18-5 shows that signals from the carotid baroreceptors are transmitted through small *Hering's nerves* to the *glossopharyngeal nerves* in the high neck and then to the *nucleus tractus solitarius* in the medullary area of the brain stem. Signals from the aortic baroreceptors in the arch of the aorta are transmitted through the *vagus nerves* to the same nucleus tractus solitarius of the medulla.

Response of the Baroreceptors to Changes in Arterial Pressure. **Figure 18-6** shows the effects of different arterial pressure levels on the rate of impulse transmission in a Hering's carotid sinus nerve. Note that the carotid sinus baroreceptors are not stimulated at all by pressures between 0 and 50 to 60 mm Hg but, above these levels, they respond progressively more rapidly and reach a maximum at about 180 mm Hg. The responses of the aortic baroreceptors are similar to those of the carotid receptors except that they operate, in general, at arterial pressure levels about 30 mm Hg higher.

Note especially that in the normal operating range of arterial pressure, around 100 mm Hg, even a slight change in pressure causes a strong change in the baroreflex signal to readjust arterial pressure back toward normal. Thus, the baroreceptor feedback mechanism functions most effectively in the pressure range where it is most needed.

The baroreceptors respond rapidly to changes in arterial pressure; the rate of impulse firing increases in the fraction of a second during each systole and decreases again during diastole. Furthermore, the baroreceptors *respond much more to a rapidly changing pressure* than to a stationary pressure. That is, if the mean arterial pressure is 150 mm Hg but at that moment is rising rapidly, the rate of impulse transmission may be as much as twice that when the pressure is stationary at 150 mm Hg.

Circulatory Reflex Initiated by the Baroreceptors. After the baroreceptor signals have entered the nucleus tractus solitarius of the medulla, secondary signals *inhibit*

Figure 18-7. Typical carotid sinus reflex effect on aortic arterial pressure caused by clamping both common carotids (after the two vagus nerves have been cut).

the vasoconstrictor center of the medulla and *excite the vagal parasympathetic center*. The net effects are as follows: (1) *vasodilation* of the veins and arterioles throughout the peripheral circulatory system; and (2) *decreased heart rate* and *strength of heart contraction*. Therefore, excitation of the baroreceptors by high pressure in the arteries reflexly *causes the arterial pressure to decrease* because of a decrease in peripheral resistance and a decrease in cardiac output. Conversely, low pressure has the opposite effects, reflexly causing the pressure to rise back toward normal.

Figure 18-7 shows a typical reflex change in arterial pressure caused by occluding the two common carotid arteries. This reduces the carotid sinus pressure; as a result, signals from the baroreceptors decrease and cause less inhibitory effect on the vasomotor center. The vasomotor center then becomes much more active than usual, causing the aortic arterial pressure to rise and remain elevated during the 10 minutes that the carotids are occluded. Removal of the occlusion allows the pressure in the carotid sinuses to rise, and the carotid sinus reflex now causes the aortic pressure to fall almost immediately to slightly below normal as a momentary overcompensation and then return to normal in another minute.

Baroreceptors Attenuate Blood Pressure Changes During Changes in Body Posture. The ability of the baroreceptors to maintain relatively constant arterial pressure in the upper body is important when a person stands up after lying down. Immediately on standing, the arterial pressure in the head and upper part of the body tends to fall, and marked reduction of this pressure could cause loss of consciousness. However, the falling pressure at the baroreceptors elicits an immediate reflex, resulting in strong sympathetic discharge throughout the body that minimizes the decrease in pressure in the head and upper body.

Figure 18-8. Two-hour records of arterial pressure in a normal dog (top) and in the same dog (bottom) several weeks after the baroreceptors had been denervated. (Modified from Cowley AW Jr, Liard JF, Guyton AC: Role of baroreceptor reflex in daily control of arterial blood pressure and other variables in dogs. *Circ Res* 32:564, 1973.)

Pressure Buffer Function of the Baroreceptor Control System. Because the baroreceptor system opposes increases or decreases in arterial pressure, it is called a *pressure buffer system*, and the nerves from the baroreceptors are called *buffer nerves*.

Figure 18-8 shows the importance of this buffer function of the baroreceptors. The upper panel in this figure shows an arterial pressure recording for 2 hours from a normal dog, and the lower panel shows an arterial pressure recording from a dog whose baroreceptor nerves from the carotid sinuses and the aorta had been removed. Note the extreme variability of pressure in the denervated dog caused by simple events of the day, such as lying down, standing, excitement, eating, defecation, and noises.

Figure 18-9 shows the frequency distributions of the mean arterial pressures recorded for a 24-hour day in the normal dog and the denervated dog. Note that when the baroreceptors were functioning normally, the mean arterial pressure remained within a narrow range of between 85 and 115 mm Hg throughout the day and, for most of the day, it remained at about 100 mm Hg. After denervation of the baroreceptors, however, the frequency distribution curve flattened, showing that the pressure range increased 2.5-fold, frequently falling to as low as 50 mm Hg or rising to more than 160 mm Hg. Thus, one can see the extreme variability of pressure in the absence of the arterial baroreceptor system.

Figure 18-9. Frequency distribution curves of the arterial pressure for a 24-hour period in a normal dog and in the same dog several weeks after the baroreceptors had been denervated. (Modified from Cowley AW Jr, Liard JF, Guyton AC: Role of baroreceptor reflex in daily control of arterial blood pressure and other variables in dogs. *Circ Res* 32:564, 1973.)

A primary purpose of the arterial baroreceptor system is therefore to reduce the minute by minute variation in arterial pressure to about one-third that which would occur if the baroreceptor system were not present.

Are the Baroreceptors Important in Long-Term Regulation of Arterial Pressure? Although the arterial baroreceptors provide powerful moment to moment control of arterial pressure, their importance in long-term blood pressure regulation has been controversial. One reason that the baroreceptors have been considered by some physiologists to be relatively unimportant in chronic regulation of arterial pressure is that they tend to *reset* in 1 to 2 days to the pressure level to which they are exposed. That is, if the arterial pressure rises from the normal value of 100 to 160 mm Hg, a very high rate of baroreceptor impulses is at first transmitted. During the next few minutes, the rate of firing diminishes considerably. Then, it diminishes much more slowly during the next 1 to 2 days, at the end of which time the rate of firing will have returned to nearly normal, despite the fact that the mean arterial pressure still remains at 160 mm Hg. Conversely, when the arterial pressure falls to a very low level, the baroreceptors at first transmit no impulses but gradually, over 1 to 2 days, the rate of baroreceptor firing returns toward the control level.

This resetting of the baroreceptors may attenuate their potency as a control system for correcting disturbances that tend to change arterial pressure for longer than a few days at a time. Experimental studies, however, have suggested that the baroreceptors do not completely reset and may therefore contribute to long-term blood pressure regulation, especially by influencing sympathetic nerve activity of the kidneys. For example, with prolonged increases in arterial pressure, the baroreceptor reflexes may mediate

decreases in renal sympathetic nerve activity that promote increased excretion of sodium and water by the kidneys. This action, in turn, causes a gradual decrease in blood volume, which helps restore arterial pressure toward normal. Thus, long-term regulation of mean arterial pressure by the baroreceptors requires interaction with additional systems, principally the renal–body fluid–pressure control system (along with its associated nervous and hormonal mechanisms), discussed in Chapters 19 and 30.

Experimental studies and clinical trials have shown that chronic electrical stimulation of carotid sinus afferent nerve fibers can cause sustained reductions in sympathetic nervous system activity and arterial pressure of at least 15 to 20 mm Hg. These observations suggest that most, if not all, the baroreceptor reflex resetting that occurs when increases in arterial pressure are sustained, as in chronic hypertension, is due to resetting of the carotid sinus nerve mechanoreceptors themselves rather than resetting in central nervous system vasomotor centers.

Control of Arterial Pressure by the Carotid and Aortic Chemoreceptors—Effect of Low Oxygen on Arterial Pressure. Closely associated with the baroreceptor pressure control system is a *chemoreceptor reflex* that operates in much the same way as the baroreceptor reflex except that *chemoreceptors*, instead of stretch receptors, initiate the response.

The chemoreceptor cells are sensitive to low oxygen or elevated carbon dioxide and hydrogen ion levels. They are located in several small *chemoreceptor organs* about 2 millimeters in size (two *carotid bodies*, one of which lies in the bifurcation of each common carotid artery, and usually one to three *aortic bodies* adjacent to the aorta). The chemoreceptors excite nerve fibers that along with the baroreceptor fibers, pass through Hering's nerves and the vagus nerves into the vasomotor center of the brain stem.

Each carotid or aortic body is supplied with an abundant blood flow through a small nutrient artery, so the chemoreceptors are always in close contact with arterial blood. Whenever the arterial pressure falls below a critical level, the chemoreceptors become stimulated because diminished blood flow causes decreased oxygen, as well as excess buildup of carbon dioxide and hydrogen ions that are not removed by the slowly flowing blood.

The signals transmitted from the chemoreceptors *excite* the vasomotor center, and this response elevates the arterial pressure back toward normal. However, this chemoreceptor reflex is not a powerful arterial pressure controller until the arterial pressure falls below 80 mm Hg. Therefore, it is at the lower pressures that this reflex becomes important to help prevent further decreases in arterial pressure.

The chemoreceptors are discussed in much more detail in [Chapter 42](#) in relation to *respiratory control*, in which they normally play a far more important role than in blood pressure control. However, activation of the chemoreceptors may also contribute to increases in arterial pressure

in conditions such as severe obesity and *obstructive sleep apnea*, a serious sleep disorder associated with repetitive episodes of nocturnal breathing cessation and hypoxia.

Atrial and Pulmonary Artery Reflexes Regulate Arterial Pressure. The atria and pulmonary arteries have stretch receptors in their walls called *low-pressure receptors*. Low-pressure receptors are similar to the baroreceptor stretch receptors of the large systemic arteries. These low-pressure receptors play an important role, especially in minimizing arterial pressure changes in response to changes in blood volume. For example, if 300 milliliters of blood suddenly are infused into a dog with all receptors intact, the arterial pressure rises only about 15 mm Hg. With the *arterial baroreceptors denervated*, the pressure rises about 40 mm Hg. If the *low-pressure receptors* also are denervated, the arterial pressure rises about 100 mm Hg.

Thus, one can see that even though the low-pressure receptors in the pulmonary artery and in the atria cannot detect the systemic arterial pressure, they do detect simultaneous increases in pressure in the low-pressure areas of the circulation caused by increase in volume. Also, they elicit reflexes parallel to the baroreceptor reflexes to make the total reflex system more potent for control of arterial pressure.

Atrial Reflexes That Activate the Kidneys—The Volume Reflex. Stretch of the atria and activation of low-pressure atrial receptors also causes reflex reductions in renal sympathetic nerve activity, decreased tubular reabsorption, and dilation of afferent arterioles in the kidneys ([Figure 18-10](#)). Signals are also transmitted simultaneously from the atria to the hypothalamus to decrease secretion of antidiuretic hormone (ADH). The decreased afferent arteriolar resistance in the kidneys causes the glomerular capillary pressure to rise, with a resultant increase in filtration of fluid into the kidney tubules. The decrease in ADH level diminishes the reabsorption of water from the tubules. The combination of these effects—an increase in glomerular filtration and a decrease in reabsorption of the fluid—increases fluid loss by the kidneys and attenuates the increased blood volume. Atrial stretch caused by increased blood volume also elicits release of *atrial natriuretic peptide*, a hormone that adds further to the excretion of sodium and water in the urine and return of blood volume toward normal (see [Figure 18-10](#)).

All these mechanisms that tend to return blood volume back toward normal after a volume overload act indirectly as pressure controllers, as well as blood volume controllers, because excess volume drives the heart to greater cardiac output and higher arterial pressure. This *volume reflex* mechanism is discussed again in [Chapter 30](#), along with other mechanisms of blood volume control.

Increased Atrial Pressure Raises Heart Rate—Bainbridge Reflex. Increases in atrial pressure sometimes increase the heart rate as much as 75%, particularly when the prevailing

Figure 18-10. Reflex responses to increased blood volume which increase arterial pressure and atrial stretch.

heart rate is slow. When the heart rate is rapid, atrial stretch cause by infusion of fluids may reduce the heart rate due to activation of arterial baroreceptors. Thus, the net effect of increased blood volume and atrial stretch on heart rate depends on the relative contributions of the baroreceptor reflexes (which tends to slow the heart rate) and the *Bainbridge reflex* which tends to accelerate the heart rate, as shown in [Figure 18-10](#). When blood volume is increased above normal, the *Bainbridge reflex* often increases heart rate despite the inhibitory actions of the baroreflexes.

A small part of the increased heart rate associated with increased blood volume and atrial stretch is caused by a direct effect of the increased atrial volume to stretch the sinus node; it was noted in [Chapter 10](#) that such direct stretch can increase the heart rate as much as 15%. An additional 40% to 60% increase in heart rate is caused by the *Bainbridge reflex*. The stretch receptors of the atria that elicit the *Bainbridge reflex* transmit their afferent signals through the vagus nerves to the medulla of the brain. Then efferent signals are transmitted back through vagal and sympathetic nerves to increase the heart rate and strength of heart contraction. Thus, this reflex helps prevent damming of blood in the veins, atria, and pulmonary circulation.

DECREASED BLOOD FLOW TO BRAIN VASOMOTOR CENTER ELICITS INCREASED BLOOD PRESSURE—CNS ISCHEMIC RESPONSE

Most nervous control of blood pressure is achieved by reflexes that originate in the baroreceptors, chemoreceptors,

and low-pressure receptors, all of which are located in the peripheral circulation outside the brain. However, when blood flow to the vasomotor center in the lower brain stem becomes decreased severely enough to cause nutritional deficiency—that is, to cause *cerebral ischemia*—the vasoconstrictor and cardioaccelerator neurons in the vasomotor center respond directly to the ischemia and become strongly excited. When this excitation occurs, the systemic arterial pressure often rises to a level as high as the heart can possibly pump. This effect is believed to be caused by failure of the slowly flowing blood to carry carbon dioxide away from the brain stem vasomotor center. At low levels of blood flow to the vasomotor center, the local concentration of carbon dioxide increases greatly and has an extremely potent effect in stimulating the sympathetic vasomotor nervous control areas in the brain's medulla.

It is possible that other factors, such as buildup of lactic acid and other acidic substances in the vasomotor center, also contribute to the marked stimulation and elevation in arterial pressure. This arterial pressure elevation in response to cerebral ischemia is known as the *CNS ischemic response*.

The ischemic effect on vasomotor activity can elevate the mean arterial pressure dramatically, sometimes to as high as 250 mm Hg for as long as 10 minutes. *The degree of sympathetic vasoconstriction caused by intense cerebral ischemia is often so great that some of the peripheral vessels become totally or almost totally occluded.* The kidneys, for example, often cease their production of urine entirely because of renal arteriolar constriction in response to the sympathetic discharge. Therefore, *the CNS ischemic*

response is one of the most powerful of all the activators of the sympathetic vasoconstrictor system.

Importance of CNS Ischemic Response as a Regulator of Arterial Pressure. Despite the powerful nature of the CNS ischemic response, it does not become significant until the arterial pressure falls far below normal, down to 60 mm Hg and below, reaching its greatest degree of stimulation at a pressure of 15 to 20 mm Hg. Therefore, the CNS ischemic response is not one of the normal mechanisms for regulating arterial pressure. Instead, it operates principally as an *emergency pressure control system that acts rapidly and powerfully to prevent further decrease in arterial pressure whenever blood flow to the brain decreases dangerously close to the lethal level*. It is sometimes called the *last-ditch stand pressure control mechanism*.

Cushing Reaction to Increased Pressure Around the Brain. The *Cushing reaction* is a special type of CNS ischemic response that results from increased pressure of the cerebrospinal fluid around the brain in the cranial vault. For example, when the cerebrospinal fluid pressure rises to equal the arterial pressure, it compresses the whole brain, as well as the arteries in the brain, and cuts off the blood supply to the brain. This action initiates a CNS ischemic response that causes the arterial pressure to rise. When the arterial pressure has risen to a level higher than the cerebrospinal fluid pressure, blood will flow once again into the vessels of the brain to relieve the brain ischemia. Ordinarily, the blood pressure reaches a new equilibrium level slightly higher than the cerebrospinal fluid pressure, thus allowing blood to begin to flow through the brain again. The Cushing reaction helps protect vital centers of the brain from loss of nutrition if the cerebrospinal fluid pressure ever rises high enough to compress the cerebral arteries.

SPECIAL FEATURES OF NERVOUS CONTROL OF ARTERIAL PRESSURE

ROLE OF THE SKELETAL NERVES AND SKELETAL MUSCLES IN INCREASING CARDIAC OUTPUT AND ARTERIAL PRESSURE

Although most rapidly acting nervous control of the circulation is affected through the autonomic nervous system, at least two conditions exist in which the skeletal nerves and muscles also play major roles in circulatory responses.

Abdominal Compression Reflex Increases Cardiac Output and Arterial Pressure. When a baroreceptor or chemoreceptor reflex is elicited, nerve signals are transmitted simultaneously through skeletal nerves to skeletal muscles of the body, particularly to the abdominal muscles. Muscle contraction then compresses all the

venous reservoirs of the abdomen, helping translocate blood out of the abdominal vascular reservoirs toward the heart. As a result, increased quantities of blood are made available for the heart to pump. This overall response is called the *abdominal compression reflex*. The resulting effect on the circulation is the same as that caused by sympathetic vasoconstrictor impulses when they constrict the veins—an increase in both cardiac output and arterial pressure. The abdominal compression reflex is probably much more important than was realized in the past because it is well known that people whose skeletal muscles have been paralyzed are considerably more prone to hypotensive episodes than people with normal skeletal muscles.

Skeletal Muscle Contraction Increases Cardiac Output and Arterial Pressure During Exercise.

When the skeletal muscles contract during exercise, they compress blood vessels throughout the body. Even anticipation of exercise tightens the muscles, thereby compressing the vessels in the muscles and in the abdomen. This compression translocates blood from the peripheral vessels into the heart and lungs and, therefore, increases cardiac output. This effect is essential in helping cause the fivefold to sevenfold increase in cardiac output that sometimes occurs during heavy exercise. The rise in cardiac output, in turn, is an essential ingredient in increasing the arterial pressure during exercise, from a normal mean of 100 mm Hg up to 130 to 160 mm Hg.

RESPIRATORY WAVES IN THE ARTERIAL PRESSURE

With each cycle of respiration, the arterial pressure usually rises and falls 4 to 6 mm Hg in a wavelike manner, causing *respiratory waves* in the arterial pressure. The waves result from several different effects, some of which are reflex in nature, as follows:

1. Many of the breathing signals that arise in the respiratory center of the medulla spill over into the vasomotor center with each respiratory cycle.
2. Every time a person inspires, the pressure in the thoracic cavity becomes more negative than usual, causing the blood vessels in the chest to expand. This reduces the quantity of blood returning to the left side of the heart and thereby momentarily decreases the cardiac output and arterial pressure.
3. The pressure changes caused in the thoracic vessels by respiration can excite vascular and atrial stretch receptors.

Although it is difficult to analyze the exact relations of all these factors in causing the respiratory pressure waves, the net result during normal respiration is usually an increase in arterial pressure during the early part of expiration and a decrease in pressure during the remainder of the respiratory cycle. During deep respiration, the blood

pressure can rise and fall as much as 20 mm Hg with each respiratory cycle.

Arterial Pressure Vasomotor Waves—Oscillation of Pressure Reflex Control Systems

Often while recording arterial pressure, in addition to the small pressure waves caused by respiration, some much larger waves are also noted—as high as 10 to 40 mm Hg at times—that rise and fall more slowly than the respiratory waves. The duration of each cycle varies from 26 seconds in the anesthetized dog to 7 to 10 seconds in the unanesthetized human. These waves are called *vasomotor waves* or *Mayer waves*. Such records are illustrated in **Figure 18-11**, showing the cyclical rise and fall in arterial pressure.

The cause of vasomotor waves is reflex oscillation of one or more nervous pressure control mechanisms, some of which are the following.

Oscillation of Baroreceptor and Chemoreceptor Reflexes. The vasomotor waves of **Figure 18-11B** are often seen in experimental pressure recordings, although they are usually much less intense than shown in the figure. They are caused mainly by oscillation of the *baroreceptor reflex*. That is, a high pressure excites the baroreceptors, which then inhibits the sympathetic nervous system and lowers the pressure a few seconds later. The decreased pressure, in turn, reduces the baroreceptor stimulation and allows the vasomotor center to become active once again, elevating the pressure to a high value. The response is not instantaneous, and it is delayed until a few seconds later. This high pressure then initiates another cycle, and the oscillation continues.

The *chemoreceptor reflex* can also oscillate to give the same type of waves. This reflex usually oscillates simultaneously with the baroreceptor reflex. It probably plays the major role in causing vasomotor waves when the arterial pressure is in the range of 40 to 80 mm Hg because, in this low range, chemoreceptor control of the circulation becomes powerful, whereas baroreceptor control becomes weaker.

Oscillation of CNS Ischemic Response. The record in **Figure 18-11A** resulted from oscillation of the CNS ischemic pressure control mechanism. In this experiment, the cerebrospinal fluid pressure increased to 160 mm Hg, which compressed the cerebral vessels and initiated a CNS ischemic pressure response up to 200 mm Hg. When the arterial pressure rose to such a high value, the brain ischemia was relieved, and the sympathetic nervous system became inactive. As a result, the arterial pressure fell rapidly back to a much lower value, causing brain ischemia once again. The ischemia then initiated another rise in pressure. Again, the ischemia was relieved, and again the pressure fell. This response repeated itself cycli-

Figure 18-11. **A**, Vasomotor waves caused by oscillation of the CNS ischemic response. **B**, Vasomotor waves caused by baroreceptor reflex oscillation.

cally as long as the cerebrospinal fluid pressure remained elevated.

Thus, any reflex pressure control mechanism can oscillate if the intensity of feedback is strong enough, and if there is a delay between excitation of the pressure receptor and the subsequent pressure response. The vasomotor waves illustrate that the nervous reflexes that control arterial pressure obey the same principles as those applicable to mechanical and electrical control systems. For example, if the feedback gain is too great in the guiding mechanism of an automatic pilot for an airplane, and there is also delay in the response time of the guiding mechanism, the plane will oscillate from side to side instead of following a straight course.

Role of the Kidneys in Long-Term Control of Arterial Pressure and in Hypertension: The Integrated System for Arterial Pressure Regulation

In addition to the rapidly acting mechanisms for regulation of arterial pressure discussed in Chapter 18, the body also has powerful mechanisms for regulating arterial pressure week after week and month after month. This long-term control of arterial pressure is closely intertwined with homeostasis of body fluid volume, which is determined by the balance between fluid intake and output. For long-term survival, fluid intake and output must be precisely balanced, a task that is performed by multiple nervous and hormonal controls and by local control systems in the kidneys that regulate their excretion of salt and water. In this chapter, we discuss these renal–body fluid systems that play a major role in long-term blood pressure regulation.

RENAL–BODY FLUID SYSTEM FOR ARTERIAL PRESSURE CONTROL

The renal–body fluid system for arterial pressure control acts slowly but powerfully, as follows. If blood volume increases and vascular capacitance is not altered, arterial pressure will also increase. The rising pressure, in turn, causes the kidneys to excrete the excess volume, thus returning the pressure back toward normal.

In the phylogenetic history of animal development, this renal–body fluid system for pressure control is a primitive one. It is fully operative in one of the lowest of vertebrates, the hagfish. This animal has a low arterial pressure, only 8 to 14 mm Hg, and this pressure increases almost directly in proportion to its blood volume. The hagfish continually drinks sea water, which is absorbed into its blood, increasing the blood volume and blood pressure. However, when the pressure rises too high, the kidney excretes the excess volume into the urine and relieves the pressure. At low pressure, the kidney excretes less fluid than is ingested. Therefore, because the hagfish continues to drink, extracellular fluid volume, blood volume, and pressure all build up again to the higher levels.

This primitive mechanism of pressure control has survived throughout the ages, but with the addition of multiple nervous system, hormones, and local control systems that also contribute to the regulation of salt and water excretion. In humans, kidney output of water and salt is

just as sensitive—if not more so—to pressure changes as in the hagfish. Indeed, an increase in arterial pressure in the human of only a few millimeters of Hg can double the renal output of water, a phenomenon called *pressure diuresis*, as well as double the output of salt, called *pressure natriuresis*.

In humans, just as in the hagfish, the renal–body fluid system for arterial pressure control is a fundamental mechanism for long-term arterial pressure control. However, through the stages of evolution, multiple refinements have been added to make this system much more precise in its control. An especially important refinement, as discussed later, has been the addition of the renin-angiotensin mechanism.

QUANTITATION OF PRESSURE DIURESIS AS A BASIS FOR ARTERIAL PRESSURE CONTROL

Figure 19-1 shows the approximate average effect of different arterial pressure levels on the renal output of salt and water by an isolated kidney, demonstrating markedly increased urine output as the pressure rises. This increased urinary output is the phenomenon of *pressure diuresis*. The curve in this figure is called a *renal urinary output curve* or a *renal function curve*. In humans, at an arterial pressure of 50 mm Hg, the urine output is essentially zero. At 100 mm Hg, it is normal and, at 200 mm Hg, it is 4 to 6 times normal. Furthermore, not only does increasing the arterial pressure increase urine volume output, but it also causes an approximately equal increase in sodium output, which is the phenomenon of *pressure natriuresis*.

Experiment Demonstrating the Renal–Body Fluid System for Arterial Pressure Control. Figure 19-2 shows the results of an experiment in dogs in which all the nervous reflex mechanisms for blood pressure control were first blocked. Then, the arterial pressure was suddenly elevated by infusing about 400 ml of blood intravenously. Note the rapid increase in cardiac output to about double normal and the increase in mean arterial pressure to 205 mm Hg, 115 mm Hg above its

Figure 19-1. A typical arterial pressure–renal urinary output curve measured in a perfused isolated kidney, showing pressure diuresis when the arterial pressure rises above normal (point A) to approximately 150 mm Hg (point B). The equilibrium point A describes the level to which the arterial pressure will be regulated if intake is not altered. (Note that the small portion of the salt and water intake that is lost from the body through nonrenal routes is ignored in this and similar figures in this chapter.)

resting level. Shown by the middle curve is the effect of this increased arterial pressure on urine output, which increased 12-fold. Along with this tremendous loss of fluid in the urine, both the cardiac output and arterial pressure returned to normal during the subsequent hour. Thus, one sees an extreme capability of the kidneys to eliminate excess fluid volume from the body in response to high arterial pressure and, in so doing, to return the arterial pressure back to normal.

Renal–Body Fluid Mechanism Provides Nearly Infinite Feedback Gain for Long-term Arterial Pressure Control.

Figure 19-1 shows the relationship of the following: (1) the renal output curve for water and salt in response to rising arterial pressure; and (2) the line that represents the net water and salt intake. Over a long period, the water and salt output must equal the intake. Furthermore, the only point on the graph in **Figure 19-1** at which output equals intake is where the two curves intersect, called the *equilibrium point* (point A). Let us see what happens if the arterial pressure increases above or decreases below the equilibrium point.

First, assume that the arterial pressure rises to 150 mm Hg (point B). At this level, the renal output of water and salt is almost three times as great as intake. Therefore, the body loses fluid, the blood volume decreases, and the arterial pressure decreases. Furthermore, this negative balance of fluid will not cease until the pressure falls *all the way* back exactly to the equilibrium level. Even when the arterial pressure is only a few mm Hg greater than the equilibrium level, there still is slightly more loss of water and salt than intake, so the pressure continues to fall that last few mm Hg *until the pressure eventually returns to the equilibrium point*.

If the arterial pressure falls below the equilibrium point, the intake of water and salt is greater than the

Figure 19-2. Increases in cardiac output, urinary output, and arterial pressure caused by increased blood volume in dogs whose nervous pressure control mechanisms had been blocked. This figure shows return of arterial pressure to normal after about 1 hour of fluid loss into the urine. (Courtesy Dr. William Dobbs.)

output. Therefore, body fluid volume increases, blood volume increases, and the arterial pressure rises until once again it returns to the equilibrium point. This return of the arterial pressure *always back to the equilibrium point* is known as the *near-infinite feedback gain principle* for control of arterial pressure by the renal–body fluid mechanism.

Two Key Determinants of Long-Term Arterial Pressure.

In **Figure 19-1**, one can also see that two basic long-term factors determine the long-term arterial pressure level. As long as the two curves representing the renal output of salt and water and the intake of salt and water remain exactly as they are shown in **Figure 19-1**, the mean arterial pressure level will eventually readjust to 100 mm Hg, which is the pressure level depicted by the equilibrium point of this figure. Furthermore, there are only two ways in which the pressure of this equilibrium point can be changed from the 100 mm Hg level. One is by shifting the pressure level of the renal output curve for salt and water, and the other is by changing the level of the water and salt intake. Therefore, expressed simply, the two primary determinants of the long-term arterial pressure level are as follows:

1. The degree of pressure shift of the renal output curve for water and salt
2. The level of the water and salt intake

Operation of these two determinants in the control of arterial pressure is demonstrated in **Figure 19-3**. In **Figure 19-3A**, some abnormality of the kidneys has caused

Figure 19-3. Two ways in which the arterial pressure can be increased. **A**, By shifting the renal output curve in the right-hand direction toward a higher pressure level or by increasing the intake level of salt and water (**B**).

the renal output curve to shift 50 mm Hg in the high-pressure direction (to the right). Note that the equilibrium point has also shifted to 50 mm Hg higher than normal. Therefore, one can state that if the renal output curve shifts to a new pressure level, the arterial pressure will follow to this new pressure level within a few days.

Figure 19-3B shows how a change in the level of salt and water intake also can change the arterial pressure. In this case, the intake level has increased fourfold, and the equilibrium point has shifted to a pressure level of 160 mm Hg, 60 mm Hg above the normal level. Conversely, a decrease in the intake level would reduce the arterial pressure.

Thus, it is *impossible to change the long-term mean arterial pressure level* to a new value without changing one or both of the two basic determinants of long-term arterial pressure, either (1) the level of salt and water intake or (2) the degree of shift of the renal function curve along the pressure axis. However, if either of these is changed, one finds the arterial pressure thereafter to be regulated at a new pressure level, the arterial pressure at which the two new curves intersect.

In most people, however, the renal function curve is much steeper than that shown in **Figure 19-3**, and changes in salt intake have only a modest effect on arterial pressure, as discussed in the next section.

Chronic Renal Output Curve Much Steeper Than the Acute Curve. An important characteristic of pressure natriuresis (and pressure diuresis) is that chronic changes in arterial pressure, lasting for days or months, have a

Figure 19-4. Acute and chronic renal output curves. Under steady-state conditions, the renal output of salt and water is equal to intake of salt and water. Points A and B represent the equilibrium points for long-term regulation of arterial pressure when salt intake is normal or six times normal, respectively. Because of the steepness of the chronic renal output curve, increased salt intake normally causes only small changes in arterial pressure. In persons with impaired kidney function, the steepness of the renal output curve may be reduced, similar to the acute curve, resulting in increased sensitivity of arterial pressure to changes in salt intake.

much greater effect on the renal output of salt and water than that observed during acute changes in pressure (**Figure 19-4**). Thus, when the kidneys are functioning normally, the *chronic renal output curve* is much steeper than the acute curve.

The powerful effects of chronic increases in arterial pressure on urine output occur because increased pressure not only has direct hemodynamic effects on the kidney to increase excretion, but also has indirect effects mediated by nervous and hormonal changes that occur when blood pressure is increased. For example, increased arterial pressure decreases activity of the sympathetic nervous system, partly through the baroreceptor reflex mechanisms discussed in **Chapter 18**, and by reducing formation of various hormones such as angiotensin II and aldosterone that tend to reduce salt and water excretion by the kidneys. Reduced activity of these *antinatriuretic* systems therefore amplifies the effectiveness of pressure natriuresis and diuresis in raising salt and water excretion during chronic increases in arterial pressure (see **Chapters 28** and **30** for further discussion).

Conversely, when blood pressure is reduced, the sympathetic nervous system is activated, and formation of antinatriuretic hormones is increased, adding to the direct effects of reduced pressure to decrease renal output of salt and water. This combination of direct effects of pressure on the kidneys and indirect effects of pressure on the sympathetic nervous system and various hormone systems make pressure natriuresis and diuresis extremely powerful factors for long-term control of arterial pressure and body fluid volumes.

The importance of neural and hormonal influences on pressure natriuresis is especially evident during chronic changes in sodium intake. If the kidneys and nervous and hormonal mechanisms are functioning

normally, chronic increases in intakes of salt and water to as high as six times normal are usually associated with little effect on arterial pressure. Note that the blood pressure equilibrium point B on the curve is nearly the same as point A, the equilibrium point at normal salt intake. Conversely, decreases in salt and water intake to as low as one-sixth normal typically have little effect on arterial pressure. Thus, many persons are said to be *salt-insensitive* because large variations in salt intake do not change blood pressure more than a few mm Hg.

Persons with kidney injury or excessive secretion of antinatriuretic hormones such as angiotensin II or aldosterone, however, may be *salt-sensitive*, with an attenuated renal output curve similar to the acute curve shown in [Figure 19-4](#). In these cases, even moderate increases in salt intake may cause significant increases in arterial pressure.

Some of the factors that cause blood pressure to be salt-sensitive include loss of functional nephrons due to kidney injury and excessive formation of antinatriuretic hormones such as angiotensin II or aldosterone. For example, surgical reduction of kidney mass or injury to the kidney due to hypertension, diabetes, or various kidney diseases all cause blood pressure to be more sensitive to changes in salt intake. In these cases, greater than normal increases in arterial pressure are required to raise renal output sufficiently to maintain a balance between the intake and output of salt and water.

There is evidence that long-term high salt intake, lasting for several years, may actually damage the kidneys and eventually makes blood pressure more salt-sensitive. We will discuss salt sensitivity of blood pressure in patients with hypertension later in this chapter.

Failure of Increased Total Peripheral Resistance to Elevate Long-Term Level of Arterial Pressure if Fluid Intake and Renal Function Do Not Change

Recalling the basic equation for arterial pressure—*arterial pressure equals cardiac output times total peripheral resistance*—it is clear that an increase in total peripheral resistance should elevate the arterial pressure. Indeed, *when the total peripheral resistance is acutely increased*, the arterial pressure does rise immediately. Yet, if the kidneys continue to function normally, the acute rise in arterial pressure usually is not maintained. Instead, the arterial pressure returns all the way to normal within about 1 or 2 days. Why?

The reason for this phenomenon is that increasing vascular resistance everywhere else in the body *besides in the kidneys* does not change the equilibrium point for blood pressure control as dictated by the kidneys (see [Figures 19-1 and 19-3](#)). Instead, the kidneys immediately begin to respond to the high arterial pressure, causing pressure diuresis and pressure natriuresis. Within hours, large

Figure 19-5. Relationships of total peripheral resistance to the long-term levels of arterial pressure and cardiac output in different clinical abnormalities. In these conditions, the kidneys were functioning normally. Note that changing the whole-body total peripheral resistance caused equal and opposite changes in cardiac output but, in all cases, had no effect on arterial pressure. AV, Arteriovenous. (Modified from Guyton AC: *Arterial Pressure and Hypertension*. Philadelphia: WB Saunders, 1980.)

amounts of salt and water are lost from the body; this process continues until the arterial pressure returns to the equilibrium pressure level. At this point, blood pressure is normalized, and extracellular fluid volume and blood volume are decreased to levels below normal.

[Figure 19-5](#) shows the approximate cardiac outputs and arterial pressures in different clinical conditions in which the *long-term total peripheral resistance* is much less than or much greater than normal, but kidney excretion of salt and water is normal. Note in all these different clinical conditions that the arterial pressure is also normal.

A word of caution is necessary at this point in our discussion. Often, when the total peripheral resistance increases, *this also increases the intrarenal vascular resistance at the same time*, which alters the function of the kidney and can cause hypertension by shifting the renal function curve to a higher pressure level, as shown in [Figure 19-3A](#). We will see an example of this mechanism later in this chapter when we discuss hypertension caused by vasoconstrictor mechanisms. However, *it is the increase in renal resistance that is the culprit, not the increased total peripheral resistance*—an important distinction.

Increased Fluid Volume Can Elevate Arterial Pressure by Increasing Cardiac Output or Total Peripheral Resistance

The overall mechanism whereby increased extracellular fluid volume may elevate arterial pressure, *if vascular capacity is not simultaneously increased*, is shown in [Figure 19-6](#). The

Figure 19-6. Sequential steps whereby increased extracellular fluid volume increases the arterial pressure. Note especially that increased cardiac output has both a *direct effect* to increase arterial pressure and an *indirect effect* by first increasing the total peripheral resistance.

sequential events are as follows: (1) increased extracellular fluid volume, which (2) increases the blood volume, which (3) increases the mean circulatory filling pressure, which (4) increases venous return of blood to the heart, which (5) increases cardiac output, which (6) increases arterial pressure. The increased arterial pressure, in turn, increases the renal excretion of salt and water and may return extracellular fluid volume to nearly normal if kidney function is normal and vascular capacity is unaltered.

Note especially in this case the two ways in which an increase in cardiac output can increase the arterial pressure. One of these is the direct effect of increased cardiac output to increase the pressure, and the other is an indirect effect to raise total peripheral vascular resistance through *autoregulation* of blood flow. The second effect can be explained as follows.

Referring to [Chapter 17](#), let us recall that whenever an excess amount of blood flows through a tissue, the local tissue vasculature constricts and decreases the blood flow back toward normal. This phenomenon is called *autoregulation*, which simply means regulation of blood flow by the tissue itself. When increased blood volume raises the cardiac output, blood flow tends to increase in all tissues of the body; if the increased blood flow exceeds the metabolic needs of the tissues, the autoregulation mechanisms constricts blood vessels all over the body, which in turn increases the total peripheral resistance.

Finally, because arterial pressure is equal to *cardiac output* times *total peripheral resistance*, the secondary increase in total peripheral resistance that results from the autoregulation mechanism helps increase the arterial pressure. For example, only a 5% to 10% increase in cardiac output can increase the arterial pressure from the normal mean arterial pressure of 100 mm Hg up to 150 mm Hg when accompanied by an increase in total peripheral resistance due to tissue blood flow autoregulation or other factors that cause vasoconstriction. The slight increase in cardiac output is often not measurable.

Importance of Salt (NaCl) in the Renal-Body Fluid Schema for Arterial Pressure Regulation

Although the discussions thus far have emphasized the importance of volume in regulation of arterial pressure, experimental studies have shown that an increase in salt intake is far more likely to elevate the arterial pressure, especially in people who are salt-sensitive, than is an increase in water intake. The reason for this finding is that pure water is normally excreted by the kidneys almost as rapidly as it is ingested, but salt is not excreted so easily. As salt accumulates in the body, it also indirectly increases the extracellular fluid volume for two basic reasons:

1. Although some additional sodium may be stored in the tissues when salt accumulates in the body, excess salt in the extracellular fluid increases the fluid osmolality. The increased osmolality stimulates the thirst center in the brain, making the person drink extra amounts of water to return the extracellular salt concentration to normal and increasing the extracellular fluid volume.
2. The increase in osmolality caused by the excess salt in the extracellular fluid also stimulates the hypothalamic–posterior pituitary gland secretory mechanism to secrete increased quantities of *antidiuretic hormone* (discussed in [Chapter 29](#)). The antidiuretic hormone then causes the kidneys to reabsorb greatly increased quantities of water from the renal tubular fluid, thereby diminishing the excreted volume of urine but increasing the extracellular fluid volume.

Thus, the amount of salt that accumulates in the body is an important determinant of the extracellular fluid volume. Relatively small increases in extracellular fluid and blood volume can often increase the arterial pressure substantially. This is true, however, only if the excess salt accumulation leads to an increase in blood volume and if vascular capacity is not simultaneously increased. As discussed previously, increasing salt intake in the absence of impaired kidney function or excessive formation of antinatriuretic hormones usually does not increase arterial pressure much because the kidneys rapidly eliminate the excess salt, and blood volume is hardly altered.

CHRONIC HYPERTENSION (HIGH BLOOD PRESSURE) CAUSED BY IMPAIRED RENAL FUNCTION

When a person is said to have chronic *hypertension* (or high blood pressure), this means that his or her *mean arterial pressure* is greater than the upper range of the accepted normal measure. A *mean* arterial pressure greater than 110 mm Hg (normal is ≈ 90 mm Hg) is considered to be hypertensive. (This level of *mean* pressure occurs when the *diastolic* blood pressure is greater than ≈ 90 mm Hg and the *systolic* pressure is greater than ≈ 135 mm Hg.) In persons with severe hypertension, the *mean* arterial pressure can rise to 150 to 170 mm Hg, with *diastolic* pressure as high as 130 mm Hg and *systolic* pressure occasionally as high as 250 mm Hg.

Even moderate elevation of arterial pressure leads to shortened life expectancy. At severely high pressures—that is, mean arterial pressures 50% or more above normal—a person can expect to live no more than a few more years unless appropriately treated. The lethal effects of hypertension are caused mainly in three ways:

1. Excess workload on the heart leads to early heart failure and coronary heart disease, often causing death as a result of a heart attack.
2. The high pressure frequently damages a major blood vessel in the brain, followed by death of major portions of the brain; this occurrence is a *cerebral infarct*. Clinically, it is called a *stroke*. Depending on which part of the brain is involved, a stroke can be fatal or cause paralysis, dementia, blindness, or multiple other serious brain disorders.
3. High pressure almost always causes injury in the kidneys, producing many areas of renal destruction and, eventually, kidney failure, uremia, and death.

Lessons learned from the type of hypertension called *volume-loading hypertension* have been crucial in

understanding the role of the renal–body fluid volume mechanism for arterial pressure regulation. Volume-loading hypertension means hypertension caused by excess accumulation of extracellular fluid in the body, some examples of which follow.

Experimental Volume-Loading Hypertension Caused by Reduced Kidney Mass and Increased Salt Intake.

Figure 19-7 shows a typical experiment demonstrating volume-loading hypertension in a group of dogs with 70% of their kidney mass removed. At the first circled point on the curve, the two poles of one of the kidneys were removed, and at the second circled point, the entire opposite kidney was removed, leaving the animals with only 30% of their normal renal mass. Note that removal of this amount of kidney mass increased the arterial pressure by an average of only 6 mm Hg. Then, the dogs were given salt solution to drink instead of water. Because salt solution fails to quench the thirst, the dogs drank two to four times the normal amounts of volume, and within a few days, their average arterial pressure rose to about 40 mm Hg above normal. After 2 weeks, the dogs were given tap water again instead of salt solution; the pressure returned to normal within 2 days. Finally, at the end of the experiment, the dogs were given salt solution again, and this time the pressure rose much more rapidly to a high level, again demonstrating volume-loading hypertension.

If one considers again the basic determinants of long-term arterial pressure regulation, it is apparent why hypertension occurred in the volume-loading experiment illustrated in **Figure 19-7**. First, reduction of the kidney mass to 30% of normal greatly reduced the ability of the kidneys to excrete salt and water. Therefore, salt and water accumulated in the body and, in a few days, raised the arterial pressure high enough to excrete the excess salt and water intake.

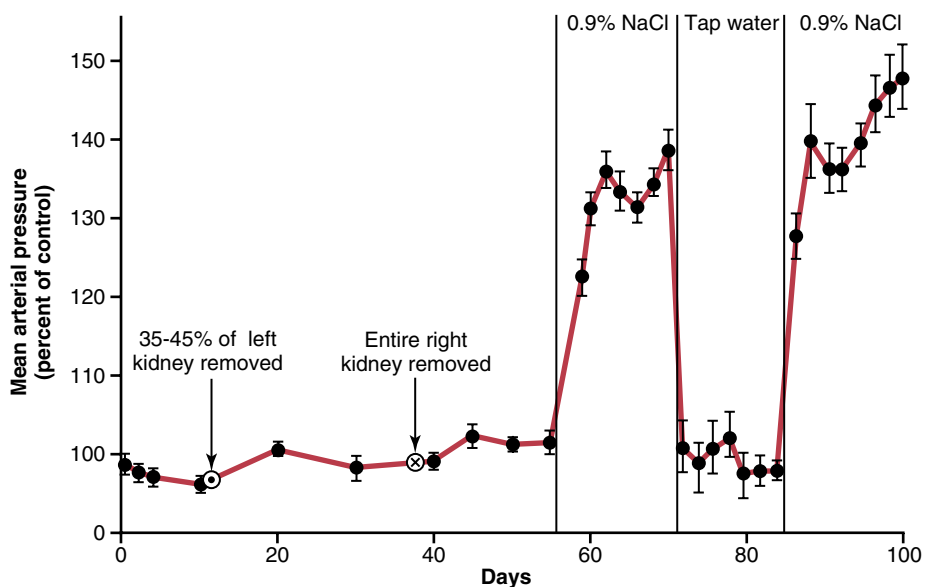

Figure 19-7. The average effect on arterial pressure of drinking 0.9% saline solution (0.9% NaCl) instead of water in dogs with 70% of their renal tissue removed. (Modified from Langston JB, Guyton AC, Douglas BH, et al: *Effect of changes in salt intake on arterial pressure and renal function in partially nephrectomized dogs. Circ Res* 12:508, 1963.)

Sequential Changes in Circulatory Function During Development of Volume-Loading Hypertension.

It is especially instructive to study the sequential changes in circulatory function during progressive development of volume-loading hypertension (Figure 19-8). A week or so before the point labeled "0" days, the kidney mass had already been decreased to only 30% of normal. Then, at this point, the intake of salt and water was increased to about six times normal and kept at this high intake thereafter. The acute effect was to increase extracellular fluid volume, blood volume, and cardiac output to 20% to 40% above normal. Simultaneously, the arterial pressure began to rise but not nearly so much at first as the fluid volumes and cardiac output. The reason for this slower rise in pressure can be discerned by studying the total peripheral resistance curve, which shows an initial decrease in total peripheral resistance. This decrease was caused by the baroreceptor mechanism discussed in Chapter 18, which transiently attenuated the rise in pressure. However, after 2 to 4 days, the baroreceptors adapted (reset) and were no longer able to prevent the rise in pressure. At this time, the arterial pressure had risen almost to its full height because of the increase in cardiac output, even though the total peripheral resistance was still almost at the normal level.

Figure 19-8. Progressive changes in important circulatory system variables during the first few weeks of volume-loading hypertension. Note especially the initial increase in cardiac output as the basic cause of the hypertension. Subsequently, the autoregulation mechanism returns the cardiac output almost to normal while simultaneously causing a secondary increase in total peripheral resistance. (Modified from Guyton AC: *Arterial Pressure and Hypertension*. Philadelphia: WB Saunders, 1980.)

After these early acute changes in the circulatory variables had occurred, more prolonged secondary changes occurred during the next few weeks. Especially important was a progressive increase in total peripheral resistance, while at the same time the cardiac output decreased back toward normal, at least partly as a result of the long-term blood flow autoregulation mechanism discussed in Chapter 17 and earlier in this chapter. That is, after the cardiac output had risen to a high level and had initiated the hypertension, the excess blood flow through the tissues then caused progressive constriction of the local arterioles, thus returning the local blood flow in the body tissues and also the cardiac output toward normal while simultaneously causing a secondary increase in total peripheral resistance.

Note that the extracellular fluid volume and blood volume also returned toward normal along with the decrease in cardiac output. This outcome resulted from two factors. First, the increase in arteriolar resistance decreased the capillary pressure, which allowed the fluid in the tissue spaces to be absorbed back into the blood. Second, the elevated arterial pressure now caused the kidneys to excrete the excess volume of fluid that had initially accumulated in the body.

Several weeks after the initial onset of volume loading, the following effects were found:

1. Hypertension
2. Marked increase in total peripheral resistance
3. Almost complete return of the extracellular fluid volume, blood volume, and cardiac output back to normal

Therefore, we can divide volume-loading hypertension into two sequential stages. The first stage results from increased fluid volume causing increased cardiac output. This increase in cardiac output mediates the hypertension. The second stage in volume-loading hypertension is characterized by high blood pressure and high total peripheral resistance but return of the cardiac output so close to normal that the usual measuring techniques frequently cannot detect an abnormally elevated cardiac output.

Thus, the increased total peripheral resistance in volume-loading hypertension occurs after the hypertension has developed and, therefore, is secondary to the hypertension rather than being the cause of the hypertension.

Volume-Loading Hypertension in Patients Who Have No Kidneys but Are Being Maintained With an Artificial Kidney

When a patient is maintained with an artificial kidney, it is especially important to keep the patient's body fluid volume at a normal level by removing the appropriate amount of water and salt each time the patient undergoes dialysis. If this step is not performed, and extracellular fluid volume is allowed to increase, hypertension almost invariably develops in exactly the same way as shown

in **Figure 19-8**. That is, the cardiac output increases at first and causes hypertension. Then, the autoregulation mechanism returns the cardiac output back toward normal while causing a secondary increase in total peripheral resistance. Therefore, in the end, the hypertension appears to be a high peripheral resistance type of hypertension, although the initial cause is excess volume accumulation.

Hypertension Caused by Excess Aldosterone

Another type of volume-loading hypertension is caused by excess aldosterone in the body or, occasionally, by excesses of other types of steroids. A small tumor in one of the adrenal glands occasionally secretes large quantities of aldosterone, which is the condition called *primary aldosteronism*. As discussed in **Chapters 28** and **30**, aldosterone increases the rate of salt and water reabsorption by the tubules of the kidneys, thereby increasing blood volume, extracellular fluid volume, and arterial pressure. If salt intake is increased at the same time, the hypertension becomes even greater. Furthermore, if the condition persists for months or years, the excess arterial pressure often causes pathological changes in the kidneys that make the kidneys retain even more salt and water in addition to that caused directly by the aldosterone. Therefore, the hypertension often finally becomes severe to the point of being lethal.

Here again, in the early stages of this type of hypertension, cardiac output is often increased but, in later stages, the cardiac output generally returns almost to normal while total peripheral resistance becomes secondarily elevated, as explained earlier in the chapter for primary volume-loading hypertension.

ROLE OF THE RENIN-ANGIOTENSIN SYSTEM IN ARTERIAL PRESSURE CONTROL

Aside from the capability of the kidneys to control arterial pressure through changes in extracellular fluid volume, the kidneys also have another powerful mechanism for controlling pressure, the *renin-angiotensin system*.

Renin is a protein enzyme released by the kidneys when the arterial pressure falls too low. In turn, it raises the arterial pressure in several ways, thus helping correct the initial fall in pressure.

COMPONENTS OF THE RENIN-ANGIOTENSIN SYSTEM

Figure 19-9 shows the main functional steps whereby the renin-angiotensin system helps regulate arterial pressure. Renin is synthesized and stored in the *juxtaglomerular cells* (JG cells) of the kidneys. The JG cells are modified smooth muscle cells located mainly *in the walls of the afferent arterioles immediately proximal to the glomeruli*. Multiple factors control renin secretion, including the

sympathetic nervous system, various hormones, and local autacoids such as prostaglandins, nitric oxide, and endothelin. When the arterial pressure falls, the JG cells release renin by at least three major mechanisms:

1. *Pressure-sensitive baroreceptors* in the JG cells respond to decreased arterial pressure with increased release of renin.
2. *Decreased sodium chloride delivery to the macula densa cells* in the early distal tubule stimulates renin release (discussed further in **Chapter 27**)
3. *Increased sympathetic nervous system activity* stimulates renin release by activating beta-adrenergic receptors in the JG cells. Sympathetic stimulation also activates alpha-adrenergic receptors, which can increase renal sodium chloride reabsorption and reduce the glomerular filtration rate in cases of strong sympathetic activation. Increased renal sympathetic activity also enhances the sensitivity of renal baroreceptor and macula densa mechanisms for renin release.

Most of the renin enters the renal blood and then passes out of the kidneys to circulate throughout the entire body. However, small amounts of the renin do remain in the local fluids of the kidney and initiate several intrarenal functions.

Renin itself is an enzyme, not a vasoactive substance. As shown in **Figure 19-9**, renin acts enzymatically on another plasma protein, a globulin called *renin substrate* (or *angiotensinogen*), to release a 10–amino acid peptide, *angiotensin I*. Angiotensin I has mild vasoconstrictor

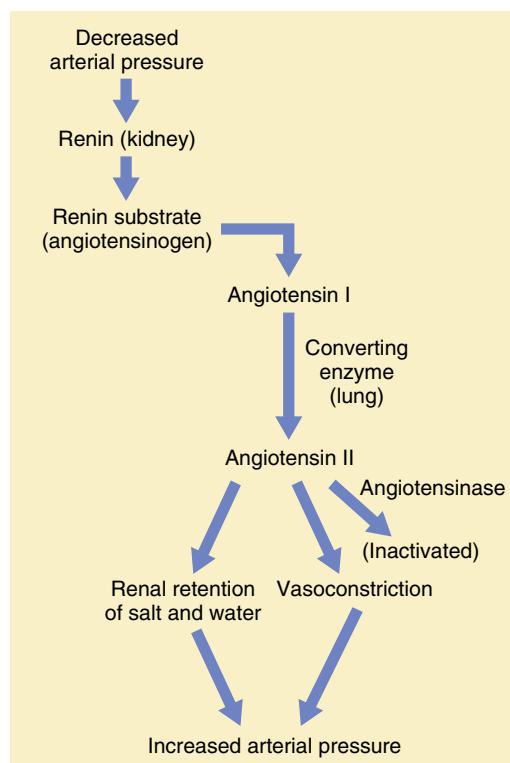

Figure 19-9. The renin-angiotensin vasoconstrictor mechanism for arterial pressure control.

properties but not enough to cause significant changes in circulatory function. The renin persists in the blood for 30 to 60 minutes and continues to cause formation of still more angiotensin I during this entire time.

Within a few seconds to minutes after the formation of angiotensin I, two additional amino acids are split from the angiotensin I to form the 8-amino acid peptide *angiotensin II*. This conversion occurs to a great extent in the lungs while the blood flows through the small vessels of the lungs, catalyzed by an enzyme called *angiotensin-converting enzyme* (ACE) that is present in the endothelium of the lung vessels. Other tissues such as the kidneys and blood vessels also contain ACE and therefore form angiotensin II locally.

Angiotensin II is an extremely powerful vasoconstrictor, and it affects circulatory function in other ways as well. However, it persists in the blood only for 1 or 2 minutes because it is rapidly inactivated by multiple blood and tissue enzymes collectively called *angiotensinases*.

Angiotensin II has two principal effects that can elevate arterial pressure. The first of these, *vasoconstriction in many areas of the body*, occurs rapidly. Vasoconstriction occurs intensely in the arterioles and less so in the veins. Constriction of the arterioles increases the total peripheral resistance, thereby raising the arterial pressure, as demonstrated at the bottom of [Figure 19-9](#). Also, the mild constriction of the veins promotes increased venous return of blood to the heart, thereby helping the heart pump against the increasing pressure.

The second principal means whereby angiotensin II increases the arterial pressure is *decreased excretion of salt and water* by the kidneys due to stimulation of aldosterone secretion, as well as direct effects on the kidneys. The salt and water retention by the kidneys slowly increases the extracellular fluid volume, which then increases the arterial pressure during subsequent hours and days. This long-term effect, through the direct and indirect actions of angiotensin II on the kidneys, is even more powerful than the acute vasoconstrictor mechanism in eventually raising the arterial pressure.

Rapidity and Intensity of the Vasoconstrictor Pressure Response to the Renin-Angiotensin System

[Figure 19-10](#) shows an experiment demonstrating the effect of hemorrhage on the arterial pressure under two separate conditions: (1) with the renin-angiotensin system functioning; and (2) after blocking the system with a renin-blocking antibody. Note that after hemorrhage—enough to cause acute decrease of the arterial pressure to 50 mm Hg—the arterial pressure rose back to 83 mm Hg when the renin-angiotensin system was functional. Conversely, it rose to only 60 mm Hg when the renin-angiotensin system was blocked. This phenomenon shows that the renin-angiotensin system is powerful enough to return the arterial pressure at least halfway back to normal within a few minutes after severe hemorrhage. Therefore,

Figure 19-10. The pressure-compensating effect of the renin-angiotensin vasoconstrictor system after severe hemorrhage. (Drawn from experiments by Dr. Royce Brough.)

this system can be of lifesaving service to the body, especially in circulatory shock.

Note also that the renin-angiotensin vasoconstrictor system requires about 20 minutes to become fully active. Therefore, it is somewhat slower for blood pressure control than the nervous reflexes and sympathetic norepinephrine-epinephrine system.

Angiotensin II Causes Renal Retention of Salt and Water—An Important Means for Long-Term Control of Arterial Pressure

Angiotensin II causes the kidneys to retain both salt and water in two major ways:

1. Angiotensin II acts directly on the kidneys to cause salt and water retention.
2. Angiotensin II stimulates the adrenal glands to secrete aldosterone, and the aldosterone in turn increases salt and water reabsorption by the kidney tubules.

Thus, whenever excess amounts of angiotensin II circulate in the blood, the entire long-term renal-body fluid mechanism for arterial pressure control automatically becomes set to a higher arterial pressure level than normal.

Mechanisms of the Direct Renal Effects of Angiotensin II to Cause Renal Retention of Salt and Water.

Angiotensin has several direct renal effects that make the kidneys retain salt and water. One major effect is to constrict the renal arterioles, especially the glomerular *efferent arterioles*, thereby diminishing blood flow through the kidneys. The slow flow of blood reduces the pressure in the peritubular capillaries, which increases reabsorption of fluid from the tubules. Angiotensin II also has important direct actions on the tubular cells to increase tubular reabsorption of sodium and water, as discussed in [Chapter 28](#). The combined effects of angiotensin II can sometimes decrease urine output to less than one-fifth normal.

Angiotensin II Increases Kidney Salt and Water Retention by Stimulating Aldosterone.

Angiotensin II is also one of the most powerful stimulators of aldosterone secretion by the adrenal glands, as we shall discuss in relation to body fluid regulation in [Chapter 30](#)

and in relation to adrenal gland function in [Chapter 78](#). Therefore, when the renin-angiotensin system becomes activated, the rate of aldosterone secretion usually also increases; an important subsequent function of aldosterone is to cause marked increase in sodium reabsorption by the kidney tubules, thus increasing the total body extracellular fluid sodium and, as already explained, extracellular fluid volume. Thus, both the direct effect of angiotensin II on the kidneys and its effect acting through aldosterone are important in long-term arterial pressure control.

Quantitative Analysis of Arterial Pressure Changes

Caused by Angiotensin II. [Figure 19-11](#) shows a quantitative analysis of the effect of angiotensin in arterial pressure control. This figure shows two renal function curves, as well as a line depicting a normal level of sodium intake. The left-hand renal function curve is that measured in dogs whose renin-angiotensin system had been blocked by an ACE inhibitor drug that blocks the conversion of angiotensin I to angiotensin II. The right-hand curve was measured in dogs infused continuously with angiotensin II at a level about 2.5 times the normal rate of angiotensin formation in the blood. Note the shift of the renal output curve toward higher pressure levels under the influence of angiotensin II. This shift is caused by the direct effects of angiotensin II on the kidney and the indirect effect acting through aldosterone secretion, as explained earlier.

Finally, note the two equilibrium points, one for zero angiotensin showing an arterial pressure level of 75 mm Hg, and one for elevated angiotensin showing a pressure level of 115 mm Hg. Therefore, the effect of angiotensin to cause renal retention of salt and water can have a powerful effect in promoting chronic elevation of the arterial pressure.

Figure 19-11. The effect of two angiotensin II levels in the blood on the renal output curve showing regulation of the arterial pressure at an equilibrium point of 75 mm Hg, when the angiotensin II level is low, and at 115 mm Hg, when the angiotensin II level is high.

Role of the Renin-Angiotensin System in Maintaining a Normal Arterial Pressure Despite Large Variations in Salt Intake

One of the most important functions of the renin-angiotensin system is to allow a person to ingest very small or very large amounts of salt without causing major changes in extracellular fluid volume or arterial pressure. This function is explained by [Figure 19-12](#), which shows that the initial effect of increased salt intake is to elevate the extracellular fluid volume, which tends to elevate the arterial pressure. Multiple effects of increased salt intake, including small increases in arterial pressure and pressure-independent effects, reduce the rate of renin secretion and angiotensin II formation, which then helps eliminate the additional salt with minimal increases in extracellular fluid volume or arterial pressure. Thus, the renin-angiotensin system is an automatic feedback mechanism that helps maintain the arterial pressure at or near the normal level, even when salt intake is increased. When salt intake is decreased below normal, exactly opposite effects take place.

To emphasize the efficacy of the renin-angiotensin system in controlling arterial pressure, when the system functions normally, the pressure usually rises no more than 4 to 6 mm Hg in response to as much as a 100-fold increase in salt intake ([Figure 19-13](#)). Conversely, when the usual suppression of angiotensin formation is prevented due to continuous infusion of small amounts of angiotensin II so that blood levels cannot decrease, the same increase in salt intake may cause the pressure to rise by 40 mm Hg or more (see [Figure 19-13](#)). When salt intake is reduced to as low as one-tenth normal, arterial pressure barely changes as long as the renin-angiotensin system functions normally. However, when angiotensin II

Figure 19-12. Sequential events whereby increased salt intake increases the arterial pressure, but feedback decrease in activity of the renin-angiotensin system returns the arterial pressure almost to the normal level.

Figure 19-13. Changes in mean arterial pressure during chronic changes in sodium intake in normal control dogs and in dogs treated with an angiotensin-converting enzyme (ACE) inhibitor to block angiotensin II (Ang II) formation or infused with Ang II to prevent Ang II from being suppressed. Sodium intake was raised in steps from a low level of 5 mmol/day to 80, 240, and 500 mmol/day for 8 days at each level. (Modified from Hall JE, Guyton AC, Smith MJ Jr, et al: *Blood pressure and renal function during chronic changes in sodium intake: role of angiotensin*. *Am J Physiol* 239:F271, 1980.)

formation is blocked with an ACE inhibitor, blood pressure decreases markedly as salt intake is reduced (see [Figure 19-13](#)). Thus, the renin-angiotensin system is perhaps the body's most powerful system for accommodating wide variations in salt intake with minimal changes in arterial pressure.

HYPERTENSION CAUSED BY RENIN-SECRETING TUMOR OR RENAL ISCHEMIA

Occasionally, a tumor of the renin-secreting JG cells occurs and secretes large quantities of renin, causing formation of large amounts of angiotensin II. In all patients in whom this phenomenon has occurred, severe hypertension has developed. Also, when large amounts of angiotensin II are infused continuously for days or weeks into animals, similar severe long-term hypertension develops.

We have already noted that angiotensin II can increase the arterial pressure in two ways:

1. By constricting the arterioles throughout the entire body, thereby increasing the total peripheral resistance and arterial pressure; this effect occurs within seconds after one begins to infuse large amounts of angiotensin II.
2. By causing the kidneys to retain salt and water; over a period of days, even moderate amounts of angiotensin II can cause hypertension through its renal actions, the principal cause of the long-term elevation of arterial pressure.

Figure 19-14. Effect of placing a constricting clamp on the renal artery of one kidney after the other kidney has been removed. Note the changes in systemic arterial pressure, renal artery pressure distal to the clamp, and rate of renin secretion. The resulting hypertension is called *one-kidney Goldblatt hypertension*.

One-Kidney Goldblatt Hypertension. When one kidney is removed, and a constrictor is placed on the renal artery of the remaining kidney, as shown in [Figure 19-14](#), the immediate effect is greatly reduced pressure in the renal artery beyond the constrictor, as demonstrated by the dashed curve in the figure. Then, within seconds or minutes, the systemic arterial pressure begins to rise and continues to rise for several days. The pressure usually rises rapidly for the first hour or so, and this effect is followed by a slower additional rise during the next several days. When the *systemic* arterial pressure reaches its new stable pressure level, the *renal arterial pressure* distal to the constriction (the dashed curve in the figure) will have returned almost all the way back to normal. The hypertension produced in this way is called *one-kidney Goldblatt hypertension* in honor of Harry Goldblatt, who first studied the important quantitative features of hypertension caused by renal artery constriction.

The early rise in arterial pressure in Goldblatt hypertension is caused by the renin-angiotensin vasoconstrictor

mechanism. That is, because of poor blood flow through the kidney after acute constriction of the renal artery, large quantities of renin are secreted by the kidney, as demonstrated by the lowermost curve in **Figure 19-14**, and this action increases angiotensin II and aldosterone levels in the blood. The angiotensin II, in turn, raises the arterial pressure acutely. The secretion of renin rises to a peak in about 1 or 2 hours but returns nearly to normal in 5 to 7 days because the *renal* arterial pressure by that time has also risen back to normal, so the kidney is no longer ischemic.

The second rise in arterial pressure is caused by retention of salt and water by the constricted kidney, which is also stimulated by angiotensin II and aldosterone. In 5 to 7 days, the body fluid volume increases enough to raise the arterial pressure to its new sustained level. The quantitative value of this sustained pressure level is determined by the degree of constriction of the renal artery. That is, the aortic pressure must rise enough so that renal arterial pressure distal to the constrictor is high enough to cause normal urine output.

A similar scenario occurs in patients with stenosis of the renal artery of a single remaining kidney, as sometimes occurs after a person receives a kidney transplant. Also, functional or pathological increases in resistance of the renal arterioles, due to atherosclerosis or excessive levels of vasoconstrictors, can cause hypertension through the same mechanisms as constriction of the main renal artery.

Two-Kidney Goldblatt Hypertension. Hypertension also can result when the artery to only one kidney is constricted while the artery to the other kidney is normal. The constricted kidney secretes renin and also retains salt and water because of decreased renal arterial pressure in this kidney. Then, the “normal” opposite kidney retains salt and water because of the renin produced by the ischemic kidney. This renin causes increased formation of angiotensin II and aldosterone, both of which circulate to the opposite kidney and cause it also to retain salt and water. Thus, both kidneys—but for different reasons—become salt and water retainers. Consequently, hypertension develops.

The clinical counterpart of two-kidney Goldblatt hypertension occurs when there is stenosis of a single renal artery—for example, caused by atherosclerosis—in a person who has two kidneys.

Hypertension Caused by Diseased Kidneys That Secrete Renin Chronically. Often, patchy areas of one or both kidneys are diseased and become ischemic because of local vascular constrictions or infarctions, whereas other areas of the kidneys are normal. When this situation occurs, almost identical effects occur as in the two-kidney type of Goldblatt hypertension. That is, the patchy ischemic kidney tissue secretes renin, which, in turn—by acting through the formation of angiotensin II—causes

the remaining kidney mass also to retain salt and water. One of the most common causes of renal hypertension, especially in older persons, is this patchy ischemic kidney disease.

Other Types of Hypertension Caused by Combinations of Volume Loading and Vasoconstriction

Hypertension in the Upper Part of the Body Caused by Coarctation of the Aorta. One out of every few thousand babies is born with pathological constriction or blockage of the aorta at a point beyond the aortic branches to the head and arms but proximal to the renal arteries, a condition called *coarctation of the aorta*. When this occurs, blood flow to the lower body is carried by multiple small collateral arteries in the body wall, with much vascular resistance between the upper aorta and lower aorta. As a consequence, the arterial pressure in the upper part of the body may be 40% to 50% higher than that in the lower body.

The mechanism of this upper body hypertension is almost identical to that of one-kidney Goldblatt hypertension. That is, when a constrictor is placed on the aorta above the renal arteries, the blood pressure in both kidneys falls at first, renin is secreted, angiotensin and aldosterone are formed, and hypertension occurs in the upper body. The arterial pressure in the lower body at the level of the kidneys rises approximately to normal, but high pressure persists in the upper body. The kidneys are no longer ischemic, and thus secretion of renin and formation of angiotensin and aldosterone return to nearly normal. Likewise, in coarctation of the aorta, the arterial pressure in the lower body is usually almost normal, whereas the pressure in the upper body is far higher than normal.

Role of Autoregulation in Hypertension Caused by Aortic Coarctation. A significant feature of hypertension caused by aortic coarctation is that blood flow in the arms, where the pressure may be 40% to 60% above normal, is almost exactly normal. Also, blood flow in the legs, where the pressure is not elevated, is almost exactly normal. How could this be, with the pressure in the upper body 40% to 60% greater than in the lower body? There are no differences in vasoconstrictor substances in the blood of the upper and lower body because the same blood flows to both areas. Likewise, the nervous system innervates both areas of the circulation similarly, so there is no reason to believe that there is a difference in nervous control of the blood vessels. The main reason is that *long-term autoregulation develops so nearly completely* that the local blood flow control mechanisms have compensated almost 100% for the differences in pressure. The result is that in both the high-pressure area and low-pressure area, the local blood flow is controlled by local autoregulatory mechanisms almost exactly in accord with the needs of the tissue and not in accord with the level of the pressure.

Hypertension in Preeclampsia (Toxemia of Pregnancy).

A syndrome called *preeclampsia* (also called *toxemia of pregnancy*) develops in approximately 5% to 10% of expectant mothers. One of the manifestations of preeclampsia is hypertension that usually subsides after delivery of the baby. Although the precise causes of preeclampsia are not completely understood, ischemia of the placenta and subsequent release by the placenta of toxic factors are believed

to play a role in causing many of the manifestations of this disorder, including hypertension in the mother. Substances released by the ischemic placenta, in turn, cause dysfunction of vascular endothelial cells throughout the body, including the blood vessels of the kidneys. This *endothelial dysfunction decreases release of nitric oxide* and other vasodilator substances, causing vasoconstriction, decreased rate of fluid filtration from the glomeruli into the renal tubules, impaired renal pressure natriuresis, and the development of hypertension.

Another pathological abnormality that may contribute to hypertension in preeclampsia is thickening of the kidney glomerular membranes (perhaps caused by an autoimmune process), which also reduces the glomerular fluid filtration rate. For obvious reasons, the arterial pressure level required to cause normal formation of urine becomes elevated, and the long-term level of arterial pressure becomes correspondingly elevated. These patients are especially prone to extra degrees of hypertension when they have excess salt intake.

Neurogenic Hypertension. *Acute neurogenic hypertension* can be caused by strong *stimulation of the sympathetic nervous system*. For example, when a person becomes excited for any reason or during states of anxiety, the sympathetic system becomes excessively stimulated, peripheral vasoconstriction occurs everywhere in the body, and *acute hypertension* ensues.

Another type of *acute neurogenic hypertension* occurs when the nerves leading from the baroreceptors are cut or when the tractus solitarius is destroyed in each side of the medulla oblongata. These are the areas where the nerves from the carotid and aortic baroreceptors connect in the brain stem. The sudden cessation of normal nerve signals from the baroreceptors has the same effect on the nervous pressure control mechanisms as a sudden reduction of the arterial pressure in the aorta and carotid arteries. That is, loss of the normal inhibitory effect on the vasomotor center caused by normal baroreceptor nervous signals allows the vasomotor center suddenly to become extremely active and the mean arterial pressure to increase from 100 mm Hg to as high as 160 mm Hg. The pressure returns to nearly normal within about 2 days because the response of the vasomotor center to the absent baroreceptor signal fades away, which is called *central resetting of the baroreceptor pressure control mechanism*. Therefore, the neurogenic hypertension caused by sectioning the baroreceptor nerves is mainly an acute type of hypertension, not a chronic type.

The sympathetic nervous system also plays an important role in some forms of chronic hypertension, in large part by activation of the renal sympathetic nerves. For example, excess weight gain and obesity often lead to activation of the sympathetic nervous system, which in turn stimulates the renal sympathetic nerves, impairs renal pressure natriuresis, and causes chronic hypertension. These abnormalities appear to play a major role in a large percentage of patients with *primary (essential) hypertension*, as discussed later.

Genetic Causes of Hypertension. Spontaneous hereditary hypertension has been observed in several strains of animals, including different strains of rats and rabbits and at least one strain of dogs. In the strain of rats that has been studied to the greatest extent, the Okamoto *spontaneously hypertensive rat*, there is evidence that in early develop-

ment of the hypertension, the sympathetic nervous system is considerably more active than in normal rats. In the later stages of this type of hypertension, structural changes have been observed in the nephrons of the kidneys: (1) increased preglomerular renal arterial resistance; and (2) decreased permeability of the glomerular membranes. These structural changes could also contribute to the long-term continuance of the hypertension. In other strains of hypertensive rats, impaired renal function also has been observed.

In humans, several different gene mutations have been identified that can cause hypertension. These forms of hypertension are called *monogenic hypertension* because they are caused by mutation of a single gene. An interesting feature of these genetic disorders is that they all cause impaired kidney function, either by increased resistance of the renal arterioles or by excessive salt and water reabsorption by the renal tubules. In some cases, the increased reabsorption is due to gene mutations that directly increase the transport of sodium or chloride in the renal tubular epithelial cells. In other cases, the gene mutations cause increased synthesis or activity of hormones that stimulate renal tubular salt and water reabsorption. Thus, in all monogenic hypertensive disorders discovered thus far, the final common pathway to hypertension appears to be impaired kidney function. Monogenic hypertension, however, is rare, and all the known forms together account for less than 1% of cases of human hypertension.

PRIMARY (ESSENTIAL) HYPERTENSION

About 90% to 95% of all people who have hypertension are said to have primary hypertension, also referred to as *essential hypertension* by many clinicians. These terms simply mean that *the hypertension is of unknown origin*, in contrast to the forms of hypertension that are *secondary* to known causes, such as renal artery stenosis or monogenic forms of hypertension.

In most patients, *excess weight gain* and a *sedentary lifestyle* appear to play a major role in causing primary hypertension. Most patients with hypertension are overweight, and studies of different populations have suggested that excess adiposity may account for as much as 65% to 75% of the risk for developing primary hypertension. Clinical studies have clearly shown the value of weight loss for reducing blood pressure in most patients with hypertension, and clinical guidelines for treating hypertension recommend increased physical activity and weight loss as a first step in treating most patients with hypertension.

The following characteristics of primary hypertension, among others, are caused by excess weight gain and obesity:

1. *Cardiac output is increased* in part because of the additional blood flow required for the extra adipose tissue. However, blood flow in the heart, kidneys, gastrointestinal tract, and skeletal muscle also increases with weight gain because of increased metabolic rate and growth of the organs and tissues in response to their increased metabolic demands. As the hypertension is sustained for many months and

years, total peripheral vascular resistance may be increased.

2. *Sympathetic nerve activity, especially in the kidneys, is increased in overweight patients.* The causes of increased sympathetic activity in obese persons are not fully understood, but studies have suggested that hormones such as *leptin* that are released from fat cells may directly stimulate multiple regions of the hypothalamus, which in turn have an excitatory influence on the vasomotor centers of the brain medulla. There is also evidence for reduced sensitivity of arterial baroreceptors in buffering increases in arterial pressure, as well as activation of chemoreceptors in obese persons, especially in those who also have obstructive sleep apnea.
3. *Angiotensin II and aldosterone levels are increased in many obese patients.* This increase may be caused partly by increased sympathetic nerve stimulation, which increases renin release by the kidneys and therefore formation of angiotensin II, which in turn stimulates the adrenal gland to secrete aldosterone.
4. *The renal-pressure natriuresis mechanism is impaired, and the kidneys will not excrete adequate amounts of salt and water unless the arterial pressure is high or kidney function is somehow improved.* If mean arterial pressure in the essential hypertensive person is 150 mm Hg, acute reduction of mean arterial pressure to the normal value of 100 mm Hg (but without otherwise altering renal function except for the decreased pressure) will cause almost total anuria. The person will then retain salt and water until the pressure rises back to the elevated value of 150 mm Hg. Chronic reductions in arterial pressure with effective antihypertensive therapies, however, usually do not cause marked salt and water retention by the kidneys because these therapies also improve renal pressure natriuresis, as discussed later.

Experimental studies in obese animals and obese patients have suggested that impaired renal pressure natriuresis in obesity hypertension is caused mainly by increased renal tubular reabsorption of salt and water due to increased sympathetic nerve activity and increased levels of angiotensin II and aldosterone. However, if hypertension is not effectively treated, there may also be vascular damage in the kidneys that can reduce glomerular filtration rate and increase the severity of hypertension. Eventually, uncontrolled hypertension associated with obesity and associated metabolic disorders can lead to severe vascular injury and complete loss of kidney function.

Graphic Analysis of Arterial Pressure Control in Essential Hypertension. Figure 19-15 is a graphic analysis of essential hypertension. The curves of this figure are called

Figure 19-15. Analysis of arterial pressure regulation in (1) salt-insensitive essential hypertension and (2) salt-sensitive essential hypertension. (Modified from Guyton AC, Coleman TG, Young DB, et al: Salt balance and long-term blood pressure control. *Annu Rev Med* 31:15, 1980.)

sodium-loading renal function curves because the arterial pressure in each case is increased very slowly, over many days or weeks, by gradually increasing the level of sodium intake. The sodium-loading type of curve can be determined by increasing the level of sodium intake to a new level every few days and then waiting for the renal output of sodium to come into balance with the intake and, at the same time, recording the changes in arterial pressure.

When this procedure is used in patients with essential hypertension, two types of curves, shown at the right in Figure 19-15, can be recorded; one is called (1) *salt-insensitive* hypertension and the other (2) *salt-sensitive* hypertension. Note in both cases that the curves are shifted to the right, to a higher pressure level than for people with normal arterial pressure. In the case of the person with salt-insensitive essential hypertension, the arterial pressure does not increase significantly when changing from a normal salt intake to a high salt intake. However, in patients who have salt-sensitive essential hypertension, the high salt intake significantly exacerbates the hypertension.

Two additional points should be emphasized. First, salt sensitivity of blood pressure is not an all-or-none finding—it is quantitative, with some individuals being more salt-sensitive than others. Second, salt sensitivity of blood pressure is not a fixed characteristic; instead, blood pressure usually becomes more salt sensitive as a person ages, especially after 50 or 60 years of age, when the number of functional units (*nephrons*) in the kidneys begins to decrease gradually.

The reason for the difference between salt-insensitive essential hypertension and salt-sensitive hypertension is presumably related to structural or functional differences in the kidneys of these two types of hypertensive patients. For example, salt-sensitive hypertension may occur with different types of chronic renal disease because of the

gradual loss of nephrons or because of normal aging, as discussed in Chapter 32. Abnormal function of the renin-angiotensin system can also cause arterial pressure to become salt-sensitive, as discussed previously in this chapter.

Treatment of Essential Hypertension. As a first step, current guidelines for treating hypertension recommend lifestyle modifications aimed at increasing physical activity and weight loss in most patients. Unfortunately, many patients are unable to lose weight, and pharmacological treatment with antihypertensive drugs must be initiated. Two general classes of drugs are used to treat hypertension: (1) *vasodilator drugs*, which increase renal blood flow and glomerular filtration rate; and (2) *natriuretic or diuretic drugs*, which decrease tubular reabsorption of salt and water.

Vasodilator drugs usually cause vasodilation in many other tissues of the body, as well as in the kidneys. Different vasodilators act in one of the following ways: (1) by inhibiting sympathetic nervous signals to the kidneys or by blocking the action of the sympathetic transmitter substance on the renal vasculature and renal tubules; (2) by directly relaxing the smooth muscle of the renal vasculature; or (3) by blocking the action of the renin-angiotensin-aldosterone system on the renal vasculature or renal tubules.

Drugs that reduce the reabsorption of salt and water by the renal tubules include, in particular, drugs that block active transport of sodium through the tubular wall; this blockage in turn also prevents the reabsorption of water, as explained earlier in the chapter. These natriuretic or diuretic drugs are discussed in greater detail in Chapter 32.

SUMMARY OF INTEGRATED MULTIFACETED SYSTEMS FOR ARTERIAL PRESSURE REGULATION

It is clear that arterial pressure is regulated not by a single pressure controlling system but instead by several inter-related systems, each of which performs a specific function. For example, when a person bleeds so severely that the pressure falls suddenly, two problems confront the pressure control system. The first is survival; the arterial pressure must be rapidly returned to a high enough level that the person can live through the acute episode. The second is to return the blood volume and arterial pressure eventually to their normal levels so that the circulatory system can reestablish full normality, not merely back to the levels required for survival.

In Chapter 18, we saw that the first line of defense against acute changes in arterial pressure is the nervous control system. In this chapter, we have emphasized a second line of defense achieved mainly by kidney mechanisms for the long-term control of arterial pressure. However, there are other pieces to the puzzle. Figure 19-16 helps put these pieces together.

Figure 19-16. Approximate potency of various arterial pressure control mechanisms at different time intervals after the onset of a disturbance to the arterial pressure. Note especially the near-infinite gain (∞) of the renal body fluid pressure control mechanism that occurs after a few weeks' time. CNS, Central nervous system. (Modified from Guyton AC: *Arterial Pressure and Hypertension*. Philadelphia: WB Saunders, 1980.)

Figure 19-16 shows the approximate immediate (seconds and minutes) and long-term (hours and days) control responses, expressed as feedback gain, of eight arterial pressure control mechanisms. These mechanisms can be divided into three groups: (1) those that react rapidly, within seconds or minutes; (2) those that respond over an intermediate time period—that is, minutes or hours; and (3) those that provide long-term arterial pressure regulation for days, months, and years.

Arterial Pressure Control Mechanisms That Act Within Seconds or Minutes. The rapidly acting pressure control mechanisms are almost entirely acute nervous reflexes or other autonomic nervous system responses. Note in Figure 19-16 the three mechanisms that show responses within seconds: (1) the baroreceptor feedback mechanism; (2) the central nervous system ischemic mechanism; and (3) the chemoreceptor mechanism. Not only do these mechanisms begin to react within seconds, but they are also powerful. After any acute fall in pressure, as might be caused by severe hemorrhage, the nervous mechanisms combine to cause the following: (1) constriction of the veins and transfer of blood into the heart; (2) increased heart rate and contractility of the heart to provide greater pumping capability by the heart; and (3) constriction of most peripheral arterioles. All these effects occur almost instantly to raise the arterial pressure back into a survival range.

When the pressure suddenly rises too high, as might occur in response to a rapid transfusion of excess blood, the same control mechanisms operate in the reverse direction, again returning the pressure back toward normal.

Arterial Pressure Control Mechanisms That Act After Many Minutes. Several pressure control mechanisms exhibit significant responses only after a few minutes following an acute arterial pressure change. Three of these mechanisms, shown in [Figure 19-16](#), are as follows: (1) the renin-angiotensin vasoconstrictor mechanism; (2) stress relaxation of the vasculature; and (3) shift of fluid through the tissue capillary walls in and out of the circulation to readjust the blood volume as needed.

We have already described at length the role of the renin-angiotensin vasoconstrictor system to provide a semiacute means for increasing the arterial pressure when necessary. The *stress relaxation mechanism* is demonstrated by the following example. When the pressure in the blood vessels becomes too high, they become stretched more and more for minutes or hours; as a result, the pressure in the vessels falls toward normal. This continuing stretch of the vessels, called *stress relaxation*, can serve as an intermediate-term pressure “buffer.”

The *capillary fluid shift mechanism* means simply that whenever capillary pressure falls too low, fluid is absorbed from the tissues through the capillary membranes and into the circulation, thus building up the blood volume and increasing the pressure in the circulation. Conversely, when the capillary pressure rises too high, fluid is lost out of the circulation into the tissues, thus reducing the blood volume, as well as virtually all the pressures throughout the circulation.

These three intermediate mechanisms mostly become activated within 30 minutes to several hours. During this time, the nervous mechanisms usually become less and less effective, illustrating the importance of these non-nervous, intermediate-term pressure control measures.

Long-Term Mechanisms for Arterial Pressure Regulation. The goal of this chapter has been to explain the role of the kidneys in long-term control of arterial pressure. To the far right in [Figure 19-16](#) is shown the renal–blood volume pressure control mechanism, which is the same as the renal–body fluid pressure control mechanism, demonstrating that it takes a few hours to begin showing significant response. Yet, it eventually develops a feedback gain for control of arterial pressure that is nearly equal to infinity. This means that this mechanism can eventually return the arterial pressure nearly *all the way* back, not merely partway back, to the pressure level that provides normal output of salt and water by the kidneys.

Many factors can affect the pressure-regulating level of the renal–body fluid mechanism. One of these, shown in [Figure 19-16](#), is aldosterone. A decrease in arterial pressure leads within minutes to an increase in aldosterone secretion and, over the next hour or days, this effect plays an important role in modifying the pressure control characteristics of the renal–body fluid mechanism.

Especially important is the interaction of the renin-angiotensin system with the aldosterone and renal fluid mechanisms. For example, a person’s salt intake varies tremendously from one day to another. We have seen in this chapter that salt intake can decrease to as little as one-tenth normal or can increase to 10 to 15 times normal and yet the regulated level of the mean arterial pressure will change only a few mm Hg if the renin-angiotensin-aldosterone system is fully operative. However, without a functional renin-angiotensin-aldosterone system, blood pressure becomes very sensitive to changes in salt intake.

Thus, arterial pressure control begins with the life-saving measures of the nervous pressure controls, then continues with the sustaining characteristics of the intermediate pressure controls and, finally, is stabilized at the long-term pressure level by the renal–body fluid mechanism. This long-term mechanism, in turn, has multiple interactions with the renin-angiotensin-aldosterone system, the nervous system, and several other factors that provide special blood pressure control capabilities for special purposes.

Cardiac Output, Venous Return, and Their Regulation

Cardiac output is the quantity of blood pumped into the aorta each minute by the heart. This is also the quantity of blood that flows through the circulation. Because cardiac output is the sum of the blood flow to all the tissues of the body, it is one of the most important factors to consider in relation to function of the cardiovascular system.

Venous return is equally important because it is the quantity of blood flowing from the veins into the right atrium each minute. The venous return and the cardiac output must equal each other except for a few heartbeats when blood is temporarily stored in or removed from the heart and lungs.

NORMAL VALUES FOR CARDIAC OUTPUT AT REST AND DURING ACTIVITY

Cardiac output varies widely with the level of activity of the body. The following factors, among others, directly affect cardiac output: (1) the basic level of body metabolism; (2) whether the person is exercising; (3) the person's age; and (4) the size of the body.

For *young healthy men*, resting cardiac output averages about 5.6 L/min. For *women*, this value is about 4.9 L/min. When one considers the factor of age as well—because with increasing age, body activity and mass of some tissues (e.g., skeletal muscle) diminish—the average cardiac output for the resting adult, in round numbers, is often stated to be about 5 L/min. However, cardiac output varies considerably among healthy men and women depending on muscle mass, adiposity, physical activity, and other factors that influence metabolic rate and nutritional needs of the tissues.

Cardiac Index

Experiments have shown that the cardiac output increases approximately in proportion to the surface area of the body. Therefore, cardiac output is frequently stated in terms of the *cardiac index*, which is the *cardiac output per square meter of body surface area*. The average person who weighs 70 kilograms has a body surface area of about 1.7 square meters, which means that the normal average cardiac index for adults is about 3 L/min/m² of body surface area.

Effect of Age on Cardiac Output. Figure 20-1 shows the cardiac output, expressed as cardiac index, at different ages. The cardiac index rises rapidly to a level greater than 4 L/min/m² at age 10 years and declines to about 2.4 L/min/m² at age 80 years. We explain later in this chapter that the cardiac output is regulated throughout life almost directly in proportion to overall metabolic activity. Therefore, the declining cardiac index is indicative of declining activity and/or declining muscle mass with age.

CONTROL OF CARDIAC OUTPUT BY VENOUS RETURN—FRANK-STARLING MECHANISM OF THE HEART

Although heart function is obviously crucial in determining cardiac output, the various factors of the peripheral circulation that affect flow of blood into the heart from the veins, called *venous return*, are normally the primary controllers of cardiac output.

The main reason why peripheral factors are usually so important in controlling cardiac output is that the heart has a built-in mechanism that normally allows it to pump automatically the amount of blood that flows from the veins into the right atrium. This mechanism, called the *Frank-Starling law of the heart*, was discussed in Chapter 9. Basically, this law states that when increased quantities of blood flow into the heart, the increased volume of blood stretches the walls of the heart chambers. As a result of the stretch, the cardiac muscle contracts with increased force, and this action ejects the extra blood that has entered from the systemic circulation. Therefore, the blood that flows into the heart is automatically pumped without delay into the aorta and flows again through the circulation.

Another important factor, discussed in Chapters 10 and 18, is that stretching the heart causes an increased heart rate. Stretch of the *sinus node* in the wall of the right atrium has a direct effect on the rhythmicity of the node to increase the heart rate as much as 10% to 15%. In addition, the stretched right atrium initiates a nervous reflex called the *Bainbridge reflex*, passing first to the vasomotor center of the brain and then back to the heart by way of the sympathetic nerves and vagi, which also increases the heart rate.

Figure 20-1. Cardiac index for a person—cardiac output per square meter of surface area—at different ages. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Under most normal unstressed conditions, the cardiac output is controlled mainly by peripheral factors that determine venous return. However, as we discuss later in the chapter, if the returning blood does become more than the heart can pump, then the heart becomes the limiting factor that determines cardiac output.

Cardiac Output Is the Sum of All Tissue Blood Flows—Tissue Metabolism Regulates Most Local Blood Flow

The venous return to the heart is the sum of all the local blood flow through all the individual tissue segments of the peripheral circulation (Figure 20-2). Therefore, it follows that cardiac output regulation is normally the sum of all the local blood flow regulations.

The mechanisms of local blood flow regulation were discussed in Chapter 17. In most tissues, blood flow increases mainly in proportion to each tissue’s metabolism. For example, local blood flow almost always increases when tissue oxygen consumption increases; this effect is demonstrated in Figure 20-3 for different levels of exercise. Note that at each increasing level of work output during exercise, oxygen consumption and cardiac output increase in parallel to each other.

To summarize, cardiac output is usually determined by the sum of all the various factors throughout the body that control local blood flow. All the local blood flows summate to form the venous return, and the heart automatically pumps this returning blood back into the arteries to flow around the system again.

Cardiac Output Varies Inversely With Total Peripheral Resistance When Arterial Pressure Is Unchanged. Figure 20-3 is the same as Figure 19-5. It is repeated here to illustrate an extremely important principle in cardiac

Figure 20-2. Cardiac output is equal to venous return and is the sum of tissue and organ blood flows. Except when the heart is severely weakened and unable to pump the venous return adequately, cardiac output (total tissue blood flow) is determined mainly by the metabolic needs of the tissues and organs of the body.

Figure 20-3. Effect of increasing levels of exercise to increase cardiac output (red solid line) and oxygen consumption (blue dashed line). (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

output control: Under many conditions, the long-term cardiac output level varies reciprocally with changes in total peripheral vascular resistance as long as the arterial pressure is unchanged. Note in Figure 20-4 that when the total peripheral resistance is exactly normal (at the 100% mark in the figure), the cardiac output is also normal. Then, when the total peripheral resistance increases above normal, the cardiac output falls; conversely, when the total peripheral resistance decreases, the cardiac output increases. One can easily understand this phenomenon by reconsidering one of the forms of Ohm’s law, as expressed in Chapter 14:

Figure 20-4. Chronic effect of different levels of total peripheral resistance on cardiac output, showing a reciprocal relationship between total peripheral resistance and cardiac output. AV, Atrioventricular. (Modified from Guyton AC: *Arterial Pressure and Hypertension*. Philadelphia: WB Saunders, 1980.)

$$\text{Cardiac output} = \frac{\text{Arterial pressure}}{\text{Total peripheral resistance}}$$

Thus, any time the long-term level of total peripheral resistance changes (but no other functions of the circulation change), the cardiac output changes quantitatively in exactly the opposite direction.

Limits for the Cardiac Output

There are definite limits to the amount of blood that the heart can pump, which can be expressed quantitatively in the form of *cardiac output curves*.

Figure 20-5 demonstrates the *normal cardiac output curve*, showing the cardiac output per minute at each level of right atrial pressure. This is one type of *cardiac function curve*, which was discussed in **Chapter 9**. Note that the plateau level of this normal cardiac output curve is about 13 L/min, 2.5 times the normal cardiac output of about 5 L/min. This means that the normal human heart, functioning without any special stimulation, can pump a venous return up to about 2.5 times the normal venous return before the heart becomes a limiting factor in the control of cardiac output.

Shown in **Figure 20-5** are several other cardiac output curves for hearts that are not pumping normally. The uppermost curves are for *hypereffective hearts* that are pumping better than normal. The lowermost curves are for *hypoeffective hearts* that are pumping at levels below normal.

Factors That Cause a Hypereffective Heart

Two general types of factors that can make the heart a stronger pump than normal are nervous stimulation and hypertrophy of the heart muscle.

Figure 20-5. Cardiac output curves for the normal heart and for hypoeffective and hypereffective hearts. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Nervous Excitation Can Increase Heart Pumping.

In **Chapter 9**, we saw that a combination of sympathetic *stimulation* and parasympathetic *inhibition* does two things to increase the pumping effectiveness of the heart: (1) it greatly increases the heart rate—sometimes, in young people, from the normal level of 72 beats/min up to 180 to 200 beats/min—and (2) it increases the strength of heart contraction (called *increased contractility*) to twice its normal strength. Combining these two effects, maximal nervous excitation of the heart can raise the plateau level of the cardiac output curve to almost twice the plateau of the normal curve, as shown by the 25-L/min level of the uppermost curve in **Figure 20-5**.

Heart Hypertrophy Can Increase Pumping Effectiveness.

A long-term increased workload, but not so much excess load that it damages the heart, causes the heart muscle to increase in mass and contractile strength in the same way that heavy exercise causes skeletal muscles to hypertrophy. For example, the hearts of marathon runners may be increased in mass by 50% to 75%. This factor increases the plateau level of the cardiac output curve, sometimes 60% to 100%, and therefore allows the heart to pump much greater than the usual amounts of cardiac output.

When one combines nervous excitation of the heart and hypertrophy, as occurs in marathon runners, the total effect can allow the heart to pump as much 30 to 40 L/min, about 2.5 times the level that can be achieved in the average person. This increased level of pumping is one of the most important factors in determining the runner's running time.

Factors That Cause a Hypoeffective Heart

Any factor that decreases the heart's ability to pump blood causes hypoeffectiveness. Some of the factors that

can decrease the heart's ability to pump blood are the following:

- Increased arterial pressure against which the heart must pump, such as in severe hypertension
- Inhibition of nervous excitation of the heart
- Pathological factors that cause abnormal heart rhythm or rate of heartbeat
- Coronary artery blockage, causing a heart attack
- Valvular heart disease
- Congenital heart disease
- Myocarditis, an inflammation of the heart muscle
- Cardiac hypoxia

NERVOUS SYSTEM REGULATION OF CARDIAC OUTPUT

Importance of Nervous System For Maintaining Arterial Pressure When Peripheral Blood Vessels Are Dilated and Venous Return and Cardiac Output Increase. Figure 20-6 shows an important difference in cardiac output control with and without a functioning autonomic nervous system. The solid curves demonstrate the effect in the normal dog of intense dilation of the peripheral blood vessels caused by administering the drug dinitrophenol, which increased the metabolism of virtually all tissues of the body about fourfold. With nervous control mechanisms intact, dilating all the peripheral blood vessels caused almost no change in arterial pressure but increased the cardiac output almost fourfold. However, after autonomic control of the nervous system was blocked, vasodilation of the blood vessels with dinitrophenol (dashed curves) then caused a profound fall in arterial pressure to about one-half normal, and the cardiac output increased only 1.6-fold instead of fourfold.

Thus, maintenance of a normal arterial pressure by the nervous system reflexes, by mechanisms explained in

Figure 20-6. Experiment in a dog to demonstrate the importance of nervous maintenance of the arterial pressure as a prerequisite for cardiac output control. Note that with pressure control, the metabolic stimulant *dinitrophenol* increased cardiac output greatly; without pressure control, the arterial pressure fell, and the cardiac output increased very little. (Drawn from experiments by Dr. M. Banet.)

Chapter 18, is essential to achieve high cardiac outputs when the peripheral tissues dilate their blood vessels to increase the venous return.

Effect of Nervous System to Increase Arterial Pressure During Exercise.

During exercise, intense increases in metabolism in active skeletal muscles cause relaxation of muscle arterioles to allow adequate oxygen and other nutrients needed to sustain muscle contraction. This greatly decreases the total peripheral resistance, which normally would decrease the arterial pressure as well. However, the nervous system immediately compensates. The same brain activity that sends motor signals to the muscles sends simultaneous signals into the autonomic nervous centers of the brain to excite circulatory activity, causing large vein constriction, increased heart rate, and increased contractility of the heart. All these changes acting together increase the arterial pressure above normal, which in turn forces still more blood flow through the active muscles.

In summary, when local tissue blood vessels dilate and increase venous return and cardiac output above normal, the nervous system plays a key role in preventing the arterial pressure from falling to disastrously low levels. During exercise, the nervous system goes even further, providing additional signals to raise the arterial pressure above normal, which serves to increase the cardiac output an extra 30% to 100%.

Pathologically High or Low Cardiac Outputs

Multiple clinical abnormalities can cause either high or low cardiac outputs. Some of the more important of these abnormal cardiac outputs are shown in Figure 20-7.

High Cardiac Output Caused by Reduced Total Peripheral Resistance

The left side of Figure 20-7 identifies conditions that cause abnormally high cardiac outputs. One of the distinguishing features of these conditions is that *they all result from chronically reduced total peripheral resistance*. None of them result from excessive excitation of the heart itself, which we will explain subsequently. Let us consider some of the conditions that can decrease the peripheral resistance and at the same time increase the cardiac output to above normal.

1. *Beriberi*. This disease is caused by insufficient quantity of the vitamin *thiamine* (vitamin B₁) in the diet. Lack of this vitamin causes diminished ability of the tissues to use some cellular nutrients, and the local tissue blood flow control mechanisms in turn cause marked compensatory peripheral vasodilation. Sometimes the total peripheral resistance decreases to as little as half-normal. Consequently, the long-term levels of venous return and cardiac output also may increase to twice the normal value.
2. *Arteriovenous (AV) fistula (shunt)*. Earlier, we pointed out that whenever a fistula (also called an *AV shunt*) occurs between a major artery and major vein, large amounts

of blood flow directly from the artery into the vein. This also greatly decreases the total peripheral resistance and, likewise, increases the venous return and cardiac output.

3. **Hyperthyroidism.** In hyperthyroidism, the metabolism of most tissues of the body becomes greatly increased. Oxygen usage increases, and vasodilator products are released from the tissues. Therefore, total peripheral resistance decreases markedly because of local tissue blood flow control reactions throughout the body; consequently, venous return and cardiac output often increase to 40% to 80% above normal.
4. **Anemia.** In anemia, two peripheral effects greatly decrease total peripheral resistance. One of these effects is reduced viscosity of the blood, resulting from the decreased concentration of red blood cells. The other effect is diminished delivery of oxygen to the tissues, which causes local vasodilation. As a consequence, cardiac output increases greatly.

Any other factor that decreases total peripheral resistance chronically also increases cardiac output if arterial pressure does not decrease too much.

Low Cardiac Output

Figure 20-7 shows at the far right several conditions that cause abnormally low cardiac output. These conditions fall into two categories: (1) abnormalities that decrease pumping effectiveness of the heart; and (2) those that decrease venous return.

Decreased Cardiac Output Caused by Cardiac Factors.

Whenever the heart becomes severely damaged, regardless of the cause, its limited level of pumping may fall below that needed for adequate blood flow to the tissues. Some examples of this condition include the following: (1) *severe coronary blood vessel blockage and consequent myocardial infarction*; (2) *severe valvular heart disease*; (3) *myocarditis*;

(4) *cardiac tamponade*; and (5) *cardiac metabolic derangements*. The effects of several of these conditions are shown on the right in Figure 20-7, demonstrating the low cardiac outputs that result.

When the cardiac output falls so low that the tissues throughout the body begin to suffer nutritional deficiency, the condition is called *cardiac shock*. This condition is discussed in Chapter 22 in relationship to cardiac failure.

Decreased Cardiac Output Caused by Noncardiac Peripheral Factors—Decreased Venous Return. Anything that interferes with venous return also can lead to decreased cardiac output. Some of these factors are as follows:

1. **Decreased blood volume.** The most common noncardiac peripheral factor that leads to decreased cardiac output is decreased blood volume, often from hemorrhage. Loss of blood may decrease the filling of the vascular system to such a low level that there is not enough blood in the peripheral vessels to create peripheral vascular pressures high enough to push the blood back to the heart.
2. **Acute venous dilation.** Acute venous dilation results most often when the sympathetic nervous system suddenly becomes inactive. For example, fainting often results from sudden loss of sympathetic nervous system activity, which causes the peripheral capacitance vessels, especially the veins, to dilate markedly. This dilation decreases the filling pressure of the vascular system because the blood volume can no longer create adequate pressure in the now flaccid peripheral blood vessels. As a result, the blood pools in the vessels and does not return to the heart as rapidly as normal.
3. **Obstruction of the large veins.** On rare occasions, the large veins leading into the heart become obstructed, and the blood in the peripheral vessels cannot flow back into the heart. Consequently, the cardiac output falls markedly.

Figure 20-7. Cardiac output in different pathological conditions. The numbers in parentheses indicate the number of patients studied in each condition. AV, Atrioventricular. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

4. *Decreased tissue mass, especially decreased skeletal muscle mass.* With normal aging or with prolonged periods of physical inactivity, a reduction in the size of the skeletal muscles usually occurs. This reduction, in turn, decreases the total oxygen consumption and blood flow needs of the muscles, resulting in decreases in skeletal muscle blood flow and cardiac output.
5. *Decreased metabolic rate of the tissues.* If the tissue metabolic rate is reduced, as occurs in skeletal muscle during prolonged bed rest, the oxygen consumption and nutrition needs of the tissues will also be lower, which decreases blood flow to the tissues, resulting in reduced cardiac output. Other conditions, such as *hypothyroidism*, may also reduce metabolic rate and therefore tissue blood flow and cardiac output.

Regardless of the cause of low cardiac output, whether it is a peripheral factor or a cardiac factor, if the cardiac output ever falls below the level required for adequate nutrition of the tissues, the person is said to experience *circulatory shock*. This condition can be lethal within a few minutes to a few hours. Circulatory shock is such an important clinical problem that it is discussed in detail in [Chapter 24](#).

CARDIAC OUTPUT CURVES USED IN QUANTITATIVE ANALYSIS OF CARDIAC OUTPUT REGULATION

Our discussion of cardiac output regulation thus far is adequate for understanding the factors that control cardiac output in most simple conditions. However, to understand cardiac output regulation in especially stressful situations, such as the extremes of exercise, cardiac failure, and circulatory shock, a more complex quantitative analysis is presented in the following sections.

To perform the more quantitative analysis, it is necessary to distinguish separately the two primary factors concerned with cardiac output regulation: (1) the pumping ability of the heart, as represented by *cardiac output curves*; and (2) the peripheral factors that affect flow of blood from the veins into the heart, as represented by *venous return curves*. Then we can put these curves together in a quantitative way to show how they interact with each other to determine cardiac output, venous return, and right atrial pressure at the same time.

Some of the cardiac output curves used to depict quantitative heart pumping effectiveness have already been shown in [Figure 20-5](#). However, an additional set of curves is required to show the effect on cardiac output caused by changing external pressures on the outside of the heart, as explained in the next section.

Effect of External Pressure Outside the Heart on Cardiac Output Curves. [Figure 20-8](#) shows the effect of changes in external cardiac pressure on the cardiac output curve. The normal external pressure is equal to the normal intrapleural pressure (the pressure in the chest cavity), which is about -4 mm Hg. Note in the figure that a rise in intrapleural pressure, to -2 mm Hg,

shifts the entire cardiac output curve to the right by the same amount. This shift occurs because filling the cardiac chambers with blood requires an extra 2 mm Hg of right atrial pressure to overcome the increased pressure on the outside of the heart. Likewise, an increase in intrapleural pressure to $+2$ mm Hg requires a 6 mm Hg increase in right atrial pressure from the normal -4 mm Hg, which shifts the entire cardiac output curve 6 mm Hg to the right.

Some factors that can alter the external pressure on the heart and thereby shift the cardiac output curve are the following:

1. *Cyclical changes of intrapleural pressure during respiration*, which are about ± 2 mm Hg during normal breathing but can be as much as ± 50 mm Hg during strenuous breathing
2. *Breathing against a negative pressure*, which shifts the curve to a more negative right atrial pressure (to the left).
3. *Positive-pressure breathing*, which shifts the curve to the right
4. *Opening the thoracic cage*, which increases the intrapleural pressure to 0 mm Hg and shifts the cardiac output curve to the right by 4 mm Hg
5. *Cardiac tamponade*, which means accumulation of a large quantity of fluid in the pericardial cavity around the heart with a resultant increase in external cardiac pressure and shifting of the curve to the right

Note in [Figure 20-8](#) that cardiac tamponade shifts the upper parts of the curves farther to the right than the lower parts because the external tamponade pressure rises to higher values as the chambers of the heart fill to increased volumes during high cardiac output.

Combinations of Different Patterns of Cardiac Output Curves. [Figure 20-9](#) shows that the final cardiac output curve can change as a result of simultaneous changes in the following: (1) external cardiac pressure; and (2) effectiveness of the heart as a pump. For example, the

Figure 20-8. Cardiac output curves at different levels of intrapleural pressure and different degrees of cardiac tamponade. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Figure 20-9. Combinations of two major patterns of cardiac output curves showing the effect of alterations in both extracardiac pressure and effectiveness of the heart as a pump. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

combination of a hypereffective heart and increased intrapleural pressure would lead to an increased maximum level of cardiac output due to the increased pumping capability of the heart, but the cardiac output curve would be shifted to the right (to higher atrial pressures) because of the increased intrapleural pressure. Thus, by knowing what is happening to the external pressure, and to the capability of the heart as a pump, one can express the momentary ability of the heart to pump blood by a single cardiac output curve.

VENOUS RETURN CURVES

The entire systemic circulation must be considered before complete analysis of cardiac regulation can be achieved. To analyze the function of the systemic circulation experimentally, the heart and lungs were removed from the circulation of an animal and replaced with a pump and artificial oxygenator system. Then, different factors, such as blood volume, vascular resistances, and central venous pressure in the right atrium, were altered to determine how the systemic circulation operates in different circulatory states. From these studies, one finds the following three principal factors that affect venous return to the heart from the systemic circulation:

1. *Right atrial pressure*, which exerts a backward force on the veins to impede flow of blood from the veins into the right atrium.
2. Degree of filling of the systemic circulation (measured by the *mean systemic filling pressure*), which forces the systemic blood toward the heart (this is the pressure measured everywhere in the systemic circulation when all flow of blood is stopped, discussed in detail later).
3. *Resistance to blood flow* between the peripheral vessels and the right atrium.

These factors can all be expressed quantitatively by the *venous return curve*, as we explain in the next sections.

Figure 20-10. Normal *venous return curve*. The plateau is caused by *collapse* of the large veins entering the chest when the right atrial pressure falls below atmospheric pressure. Note also that venous return becomes zero when the right atrial pressure rises to equal the mean systemic filling pressure.

Normal Venous Return Curve

In the same way that the cardiac output curve relates pumping of blood by the heart to right atrial pressure, the *venous return curve relates venous return also to right atrial pressure*—that is, the venous flow of blood into the heart from the systemic circulation at different levels of right atrial pressure.

The curve in **Figure 20-10** is the *normal venous return curve*. This curve shows that when heart pumping capability becomes diminished and causes the right atrial pressure to rise, the backward force of the rising atrial pressure on the veins of the systemic circulation decreases venous return of blood to the heart. *If all nervous circulatory reflexes are prevented from acting*, venous return decreases to zero when the right atrial pressure rises to about +7 mm Hg. Such a slight rise in right atrial pressure causes a drastic decrease in venous return because any increase in back pressure causes blood to dam up in the systemic circulation instead of returning to the heart.

At the same time that the right atrial pressure is rising and causing venous stasis, pumping by the heart also approaches zero because of decreasing venous return. Both the arterial and venous pressures reach equilibrium when all flow in the systemic circulation ceases at a pressure of 7 mm Hg, which, by definition, is the *mean systemic filling pressure*.

Plateau in Venous Return Curve at Negative Atrial Pressures Caused by Collapse of the Large Veins.

When the right atrial pressure falls *below zero*—that is, below atmospheric pressure—any further increase in venous return almost ceases, and by the time the right atrial pressure has fallen to about -2 mm Hg, the venous return reaches a plateau. It remains at this plateau level, even though the right atrial pressure falls to -20 mm Hg, -50 mm Hg or even further. This plateau is caused by *collapse of the veins* entering the chest. Negative pressure in the right atrium sucks the walls of the veins together where they enter the chest, which prevents any additional flow of blood from the peripheral veins. Consequently, even very negative pressures in the right atrium cannot increase

venous return significantly above that which exists at a normal atrial pressure of 0 mm Hg.

Mean Circulatory Filling Pressure, Mean Systemic Filling Pressure—Effects on Venous Return

When heart pumping is stopped by shocking the heart with electricity to cause ventricular fibrillation or is stopped in any other way, flow of blood everywhere in the circulation ceases a few seconds later. Without blood flow, the pressures everywhere in the circulation become equal. This equilibrated pressure level is called the *mean circulatory filling pressure*.

Increased Blood Volume Raises Mean Circulatory Filling Pressure. The greater the volume of blood in the circulation, the greater is the mean circulatory filling pressure because extra blood volume stretches the walls of the vasculature. The *red curve* in **Figure 20-11** shows the approximate normal effect of different levels of blood volume on the mean circulatory filling pressure. Note that at a blood volume of about 4000 ml, the mean circulatory filling pressure is close to zero because this is the unstressed volume of the circulation but, at a volume of 5000 ml, the filling pressure is the normal value of 7 mm Hg. Similarly, at still higher volumes, the mean circulatory filling pressure increases almost linearly.

Sympathetic Nervous Stimulation Increases Mean Circulatory Filling Pressure. The *green curve* and *blue curve* in **Figure 20-11** show the effects, respectively, of high and low levels of sympathetic nervous activity on the mean circulatory filling pressure. Strong sympathetic stimulation constricts all the systemic blood vessels, as well as the larger pulmonary blood vessels and even the

Figure 20-11. Effect of changes in total blood volume on the *mean circulatory filling pressure* (volume–pressure curve for the entire circulatory system). These curves also show the effects of strong sympathetic stimulation and complete sympathetic inhibition.

chambers of the heart. Therefore, the capacity of the system decreases so that at each level of blood volume, the mean circulatory filling pressure is increased. At normal blood volume, maximal sympathetic stimulation increases the mean circulatory filling pressure from 7 mm Hg to about twice that value or about 14 mm Hg.

Conversely, complete inhibition of the sympathetic nervous system relaxes both the blood vessels and heart, decreasing the mean circulatory filling pressure from the normal value of 7 mm Hg down to about 4 mm Hg. Note in **Figure 20-11** how steep the curves are, which means that even slight changes in blood volume or capacity of the system caused by various levels of sympathetic activity can have large effects on the mean circulatory filling pressure.

Mean Systemic Filling Pressure and Relationship to Mean Circulatory Filling Pressure. The *mean systemic filling pressure* (P_{sf}) is slightly different from the mean circulatory filling pressure. It is the pressure measured everywhere *in the systemic circulation* after blood flow has been stopped by clamping the large blood vessels at the heart, so the pressures in the systemic circulation can be measured independently from those in the pulmonary circulation. The *mean systemic filling pressure*, although almost impossible to measure in a live animal, is *almost always nearly equal to the mean circulatory filling pressure*, because the pulmonary circulation has less than one-eighth as much capacitance as the systemic circulation and only about one-tenth as much blood volume.

Effect on Venous Return Curve of Changes in Mean Systemic Filling Pressure. **Figure 20-12** shows the effects on the venous return curve caused by increasing or decreasing P_{sf} . Note that the normal P_{sf} is about 7 mm Hg. Then, for the uppermost curve in the figure, P_{sf} has been increased to 14 mm Hg and, for the lowermost curve, it has decreased to 3.5 mm Hg. These curves demonstrate that the higher the P_{sf} (which also means the greater the “tightness” with which the circulatory system is filled with blood), the more the venous return curve shifts *upward* and *to the right*. Conversely, the lower the P_{sf} , the more the curve shifts *downward* and *to the left*.

Figure 20-12. Venous return curves showing the normal curve when the mean *systemic filling pressure* (P_{sf}) is 7 mm Hg and the effect of altering the P_{sf} to 3.5, 7, or 14 mm Hg. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Expressing this another way, the greater the degree to which the system is filled, the easier it is for blood to flow into the heart. The lesser the degree to which the system is filled, the more difficult it is for blood to flow into the heart.

When Pressure Gradient for Venous Return Is Zero There Is No Venous Return. When the right atrial pressure rises to equal the Psf, there is no longer any pressure difference between the peripheral vessels and right atrium. Consequently, there can no longer be any blood flow from peripheral vessels back to the right atrium. However, when the right atrial pressure falls progressively lower than the Psf, blood flow to the heart increases proportionately, as can be seen by studying any of the venous return curves in **Figure 20-12**. That is, *the greater the difference between the Psf and right atrial pressure, the greater becomes the venous return*. Therefore, the difference between these two pressures is called the *pressure gradient for venous return*.

Resistance to Venous Return

In the same way that Psf represents a pressure pushing venous blood from the periphery toward the heart, there is also resistance to this venous flow of blood. This is called the *resistance to venous return*. Most of the resistance to venous return occurs in the veins, although some occurs in the arterioles and small arteries as well.

Why is venous resistance so important in determining the resistance to venous return? The answer is that when the resistance in the veins increases, blood begins to be dammed up, mainly in the veins themselves. However, the venous pressure rises very little because the veins are highly distensible. Therefore, this rise in venous pressure is not very effective in overcoming the resistance, and blood flow into the right atrium decreases drastically. Conversely, when arteriolar and small artery resistances increase, blood accumulates in the arteries, which have a capacitance only one thirtieth as great as that of the veins. Therefore, even slight accumulation of blood in the arteries raises the pressure greatly—30 times as much as in the veins—and this high pressure overcomes much of the increased resistance. Mathematically, it turns out that about two-thirds of the so-called resistance to venous return is determined by venous resistance, and about one-third is determined by the arteriolar and small artery resistance.

Venous return can be calculated by the following formula:

$$VR = \frac{Psf - PRA}{RVR}$$

in which VR is venous return, Psf is mean systemic filling pressure, PRA is right atrial pressure, and RVR is resistance to venous return. In the healthy adult, the approximate values for these are as follows: venous return = 5 L/min, Psf = 7 mm Hg, right atrial pressure = 0 mm Hg, and resistance to venous return = 1.4 mm Hg/L/min of blood flow.

Figure 20-13. Venous return curves depicting the effect of altering the resistance to venous return. Psf, Mean systemic filling pressure. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Effect of Resistance to Venous Return on the Venous Return Curve. **Figure 20-13** demonstrates the effect of different levels of resistance to venous return on the venous return curve, showing that a *decrease* in this resistance to half-normal allows twice as much flow of blood and, therefore, *rotates the curve upward* to twice as great a slope. Conversely, an *increase* in resistance to twice normal *rotates the curve downward* to half as great a slope.

Note also that when the right atrial pressure rises to equal the Psf, venous return becomes zero at all levels of resistance to venous return because there is no pressure gradient to cause flow of blood. Therefore, *the highest level to which the right atrial pressure can rise*, regardless of how much the heart might fail, is equal to the Psf.

Combinations of Venous Return Curve Patterns. **Figure 20-14** shows the effects on the venous return curve caused by simultaneous changes in Psf and resistance to venous return, demonstrating that both these factors can operate simultaneously.

ANALYSIS OF CARDIAC OUTPUT AND RIGHT ATRIAL PRESSURE BY SIMULTANEOUS CARDIAC OUTPUT AND VENOUS RETURN CURVES

In the complete circulation, the heart and the systemic circulation must operate together. This requirement means that (1) the venous return from the systemic circulation must equal the cardiac output from the heart and (2) the right atrial pressure is the same for the heart and systemic circulation.

Therefore, one can predict the cardiac output and right atrial pressure in the following way:

Figure 20-14. Combinations of the major patterns of venous return curves showing the effects of simultaneous changes in the mean systemic filling pressure (Psf) and in resistance to venous return. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

Figure 20-15. The two solid curves demonstrate an analysis of cardiac output and right atrial pressure when the cardiac output (red line) and venous return (blue line) curves are normal. Transfusion of blood equal to 20% of the blood volume causes the venous return curve to become the dashed curve. As a result, the cardiac output and right atrial pressure shift from point A to point B. Psf, Mean systemic filling pressure.

1. Determine the momentary pumping ability of the heart, and depict this ability in the form of a cardiac output curve.
2. Determine the momentary state of flow from the systemic circulation into the heart, and depict this state of flow in the form of a venous return curve.
3. Equate these curves against each other, as shown in **Figure 20-15**.

Two curves in the figure depict the *normal cardiac output curve* (red line) and the *normal venous return curve* (blue line). There is only one point on the graph, point A, at which the venous return equals the cardiac output and at which the right atrial pressure is the same for both the

heart and systemic circulation. Therefore, in the normal circulation, the right atrial pressure, cardiac output, and venous return are all depicted by point A, called the *equilibrium point*, giving a normal value for cardiac output of 5 L/min and a right atrial pressure of 0 mm Hg.

Effect of Increased Blood Volume on Cardiac Output.

A sudden increase in blood volume of about 20% increases the cardiac output to about 2.5 to 3 times normal. An analysis of this effect is shown in **Figure 20-15**. Immediately on infusing the large quantity of extra blood, the increased filling of the system causes the Psf to increase to 16 mm Hg, which shifts the venous return curve to the right. At the same time, the increased blood volume distends the blood vessels, reducing their resistance and thereby reducing the resistance to venous return, which rotates the curve upward. As a result of these two effects, the venous return curve of **Figure 20-15** is shifted to the right. This new curve equates with the cardiac output curve at point B, showing that the cardiac output and venous return increase 2.5 to 3 times and that the right atrial pressure rises to about +8 mm Hg.

Compensatory Effects Initiated in Response to Increased Blood Volume. The greatly increased cardiac output caused by increased blood volume lasts for only a few minutes because several compensatory effects immediately begin to occur:

1. The increased cardiac output *increases the capillary pressure* so that fluid begins to transude out of the capillaries into the tissues, thereby returning the blood volume toward normal.
2. The increased pressure in the veins causes the veins to continue distending gradually by the mechanism called *stress-relaxation*, especially causing the venous blood reservoirs, such as the liver and spleen, to distend, thus *reducing the Psf*.
3. The excess blood flow through the peripheral tissues causes an autoregulatory increase in the peripheral vascular resistance, thus increasing the *resistance to venous return*.

These factors cause the Psf to return toward normal and the resistance vessels of the systemic circulation to constrict. Therefore, gradually, over a period of 10 to 40 minutes, the cardiac output returns almost to normal.

Effect of Sympathetic Stimulation on Cardiac Output.

Sympathetic stimulation affects the heart and systemic circulation: (1) it *makes the heart a stronger pump*; and (2) in the systemic circulation, it *increases the Psf* because of contraction of the peripheral vessels, especially the veins, and it *increases the resistance to venous return*.

In **Figure 20-16**, the *normal cardiac output and venous return curves* are depicted; these equate with each other at point A, which represents a normal venous return, cardiac output of 5 L/min, and right atrial pressure of 0 mm Hg. Note in the figure that maximal sympathetic

Figure 20-16. Analysis of the effect on cardiac output of (1) moderate sympathetic stimulation (from point A to point C), (2) maximal sympathetic stimulation (point D), and (3) sympathetic inhibition caused by total spinal anesthesia (point B). (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

stimulation (green curves) increases the P_{sf} to 17 mm Hg (depicted by the point at which the venous return curve reaches the zero venous return level). Sympathetic stimulation also increases pumping effectiveness of the heart by nearly 100%. As a result, the cardiac output rises from the normal value at equilibrium point A to about double normal at equilibrium point D, and yet the right atrial pressure hardly changes. Thus, different degrees of sympathetic stimulation can increase the cardiac output progressively to about twice normal for short periods, until other compensatory effects occur within seconds or minutes to return cardiac output to nearly normal.

Effect of Sympathetic Inhibition on Cardiac Output.

The sympathetic nervous system can be blocked by inducing total spinal anesthesia or by using a drug, such as hexamethonium, that blocks transmission of nerve signals through the autonomic ganglia. The lowermost curves in Figure 20-16 show the effect of sympathetic inhibition caused by total spinal anesthesia, demonstrating the following: (1) the P_{sf} falls to about 4 mm Hg; and (2) the effectiveness of the heart as a pump decreases to about 80% of normal. The cardiac output falls from point A to point B, which is a decrease to about 60% of normal.

Effect of Opening a Large Arteriovenous Fistula. Figure 20-17 shows various stages of circulatory changes that occur after opening a large AV fistula—that is, after making an opening directly between a large artery and a large vein.

1. The two red curves crossing at point A show the normal condition.
2. The curves crossing at point B show the circulatory condition immediately after opening the large fistula.

Figure 20-17. Analysis of successive changes in cardiac output and right atrial pressure in a human after a large arteriovenous (AV) fistula is suddenly opened. The stages of the analysis, as shown by the equilibrium points, are as follows: A, normal conditions; B, immediately after opening the AV fistula; C, 1 minute or so after the sympathetic reflexes have become active; and D, several weeks after the blood volume has increased and the heart has begun to hypertrophy. (Modified from Guyton AC, Jones CE, Coleman TG: *Circulatory Physiology: Cardiac Output and Its Regulation*, 2nd ed. Philadelphia: WB Saunders, 1973.)

The principal effects are as follows: (a) a sudden and precipitous rotation of the venous return curve upward caused by the large decrease in resistance to venous return when blood is allowed to flow with almost no impediment directly from the large arteries into the venous system, bypassing most of the resistance elements of the peripheral circulation; and (b) a slight increase in the level of the cardiac output curve because opening the fistula decreases the peripheral resistance and allows an acute fall in arterial pressure against which the heart can pump more easily. The net result, depicted by point B, is an increase in cardiac output from 5 L/min up to 13 L/min and an increase in right atrial pressure to about +3 mm Hg.

3. Point C represents the effects about 1 minute later, after the sympathetic nerve reflexes have restored the arterial pressure almost to normal and caused two other effects: (a) an increase in the P_{sf} (because of constriction of all veins and arteries) from 7 to 9 mm Hg, thus shifting the venous return curve 2 mm Hg to the right; and (b) further elevation of the cardiac output curve because of sympathetic nervous excitation of the heart. The cardiac output now rises to almost 16 L/min, and the right atrial pressure rises to about 4 mm Hg.
4. Point D shows the effect after several more weeks. By this time, the blood volume has increased because the slight reduction in arterial pressure and the sympathetic stimulation have both transiently

reduced the kidney output of urine, causing salt and water retention. The Psf has now risen to +12 mm Hg, shifting the venous return curve another 3 mm Hg to the right. Also, the prolonged increased workload on the heart has caused the heart muscle to hypertrophy slightly, raising the level of the cardiac output curve still further. Therefore, point D shows a cardiac output that is now almost 20 L/min and a right atrial pressure of about 6 mm Hg.

Other Analyses of Cardiac Output Regulation. In Chapter 21, analysis of cardiac output regulation during exercise is presented. In Chapter 22, analyses of cardiac output regulation at various stages of congestive heart failure are discussed.

METHODS FOR MEASURING CARDIAC OUTPUT

Accurate assessment of cardiac output is vitally important in modern medical practice, especially in critically ill patients or in high-risk patients undergoing surgery. In animal experiments, one can measure the cardiac output using an electromagnetic or ultrasonic flowmeter placed on the aorta or pulmonary artery to measure cardiac output. In humans, however, cardiac output is usually measured by indirect methods that do not require surgery.

Pulsatile Output of the Heart Measured by Electromagnetic or Ultrasonic Flowmeter

Figure 20-18 shows a recording in a dog of blood flow in the root of the aorta; this recording was made using an electromagnetic flowmeter. It demonstrates that the blood flow rises rapidly to a peak during systole and then, at the end of systole, it reverses for a fraction of a second. This reverse flow causes the aortic valve to close and the flow to return to zero.

Measurement of Cardiac Output Using the Oxygen Fick Principle

The Fick principle is explained by Figure 20-19. This figure shows that 200 ml of oxygen are being absorbed from the lungs into the pulmonary blood each minute. It also shows that the blood entering the right heart has an

Figure 20-18. Pulsatile blood flow in the root of the aorta recorded using an electromagnetic flowmeter.

oxygen concentration of 160 ml/L of blood, whereas that leaving the left heart has an oxygen concentration of 200 ml/L of blood. From these data, one can calculate that each liter of blood passing through the lungs absorbs 40 ml of oxygen.

Because the total quantity of oxygen absorbed into the blood from the lungs each minute is 200 ml, dividing 200 by 40 calculates to a total of 5 liters of blood that must pass through the pulmonary circulation each minute to absorb this amount of oxygen. Therefore, the quantity of blood flowing through the lungs each minute is 5 liters, which is also a measure of the cardiac output. Thus, the cardiac output can be calculated by the following formula:

$$\begin{aligned} \text{Cardiac output (L/min)} \\ &= \frac{\text{O}_2 \text{ absorbed per minute by the lungs (ml/min)}}{\text{Arteriovenous O}_2 \text{ difference (ml/L of blood)}} \end{aligned}$$

In applying this Fick procedure for measuring cardiac output in humans, *mixed venous blood* is usually obtained through a catheter inserted up the brachial vein of the forearm, through the subclavian vein, down to the right atrium and, finally, into the right ventricle or pulmonary artery. *Systemic arterial blood* can then be obtained from any systemic artery in the body. The *rate of oxygen absorption* by the lungs is measured by the rate of disappearance of oxygen from the respired air, using any type of oxygen meter.

Indicator Dilution Method

To measure cardiac output by the indicator dilution method, a small amount of indicator, such as a dye, is injected into a large systemic vein or, preferably, into the right atrium. This indicator passes rapidly through the right side of the heart, then through the blood vessels of the lungs, through the left side of the heart, and finally into the systemic arterial system. The concentration of the dye is recorded as the dye passes through one of the peripheral arteries, giving a curve as shown in Figure 20-20. In each of these cases, 5 milligrams of Cardiogreen dye were injected at zero time. In the top recording, none of the dye passed into the arterial tree until about 3 seconds after the injection, but then the arterial concentration of the dye

Figure 20-19. Fick principle for determining cardiac output.

Figure 20-20. Extrapolated dye concentration curves used to calculate two separate cardiac outputs by the dilution method. The rectangular areas are the calculated average concentrations of dye in the arterial blood for the durations of the respective extrapolated curves.

rose rapidly to a maximum in about 6 to 7 seconds. After that, the concentration fell rapidly, but before the concentration reached zero, some of the dye had already circulated all the way through some of the peripheral systemic vessels and returned through the heart for a second time. Consequently, the dye concentration in the artery began to rise again. For the purpose of calculation, it is necessary to *extrapolate* the early downslope of the curve to the zero point, as shown by the dashed portion of each curve. In this way, the *extrapolated time-concentration curve* of the dye in the systemic artery without recirculation can be measured in its first portion and estimated reasonably accurately in its latter portion.

Once the extrapolated time-concentration curve has been determined, the mean concentration of dye in the arterial blood for the duration of the curve can then be calculated. For example, in the top example of **Figure 20-20**, this calculation was done by measuring the area under the entire initial and extrapolated curve and then averaging the concentration of dye for the duration of the curve. One can see from the shaded rectangle straddling the curve in the upper figure that the average concentration of dye was 0.25 mg/dl of blood and that the duration of this average value was 12 seconds. A total of 5 milligrams of dye had been injected at the beginning of the experiment. For blood carrying only 0.25 milligram of dye in each 100 milliliters to carry the entire 5 milligrams of dye through the heart and lungs in 12 seconds, a total of 20 portions, each with 100 milliliters of blood, would have passed through the heart during the 12 seconds, which would be the same as a cardiac output of 2 L/12 sec, or 10 L/min. We leave it to the reader to calculate the cardiac output from the bottom *extrapolated* curve of **Figure 20-20**. To summarize, the cardiac output can be determined using the following formula:

$$\text{Cardiac output (ml/min)} = \frac{\text{Milligrams of dye injected} \times 60}{\left(\begin{array}{l} \text{Average concentration of dye} \\ \text{in each milliliter of blood} \\ \text{for the duration of the curve} \end{array} \right) \times \left(\begin{array}{l} \text{Duration of} \\ \text{the curve} \\ \text{in seconds} \end{array} \right)}$$

Echocardiography

Cardiac output can also be estimated by *echocardiography*, a method that uses ultrasound waves from a transducer placed on the chest wall or passed into the patient's esophagus to measure the size of the heart's chambers and the velocity of blood flowing from the left ventricle into the aorta. Stroke volume is calculated from the velocity of blood flowing into the aorta, and the aorta cross-sectional area is determined from the aorta diameter measured by ultrasound imaging. Cardiac output is then calculated from the product of the stroke volume and heart rate.

Thoracic Electrical Bioimpedance Method

Impedance cardiography, also known as *thoracic electrical bioimpedance*, is a noninvasive technology used to measure changes in total electrical conductivity of the thorax as an indirect assessment of hemodynamic parameters such as cardiac output. This method detects the *impedance* changes caused by a high-frequency, low-magnitude current flowing through the thorax between additional two pairs of electrodes located outside the measured segment. Electrical impedance is the opposition that a circuit presents to a current when a voltage is applied. With each heartbeat, blood volume and velocity in the aorta change, and the corresponding change in impedance and its timing are measured and used to estimate cardiac output.

Although some studies have suggested that impedance cardiography may provide reasonable assessments of cardiac output under some conditions, this method is also subject to several potential sources of error, including electrical interferences, motion artifacts, fluid accumulation around the heart and in the lungs, and arrhythmias. Some studies have suggested that the average error with this method may be as high as 20% to 40%.

Accurate assessment of cardiac output provides insight into heart function and tissue perfusion because cardiac output represents the sum of blood flows to all the organs and tissues of the body. Thus, noninvasive methods for more accurate measurements of cardiac output are continuously being developed for managing patients with circulatory distress.

Muscle Blood Flow and Cardiac Output During Exercise; the Coronary Circulation and Ischemic Heart Disease

In this chapter we consider the following: (1) blood flow to the skeletal muscles; and (2) coronary artery blood flow to the heart. Regulation of each of these types of blood flow is achieved mainly by local control of vascular resistance in response to muscle tissue metabolic needs.

We also discuss the physiology of related subjects, including the following: (1) cardiac output control during exercise; (2) characteristics of heart attacks; and (3) the pain of angina pectoris.

BLOOD FLOW REGULATION IN SKELETAL MUSCLE AT REST AND DURING EXERCISE

Strenuous exercise is one of the most stressful conditions that the normal circulatory system faces because there is such a large mass of skeletal muscle in the body, all of it requiring large amounts of blood flow. Also, the cardiac output often must increase to four to five times normal in the nonathlete or to six to seven times normal in the well-trained athlete to satisfy the metabolic needs of the exercising muscles.

SKELETAL MUSCLE BLOOD FLOW RATE

During rest, skeletal muscle blood flow averages 3 to 4 ml/min/100 g of muscle. During extreme exercise in the well-conditioned athlete, this blood flow can increase 25- to 50-fold, rising to 100 to 200 ml/min/100 g of muscle. Peak blood flows as high as 400 ml/min/100 g of muscle have been reported for thigh muscles of endurance-trained athletes.

Blood Flow During Muscle Contractions. Figure 21-1 shows a record of blood flow changes in a calf muscle of a leg during strong rhythmic muscular exercise. Note that the flow increases and decreases with each muscle contraction. At the end of the contractions, the blood flow remains high for a few seconds but then returns to normal during the next few minutes.

The cause of the lower flow during the muscle contraction phase of exercise is compression of the blood vessels by the contracted muscle. During strong tetanic contraction, which causes sustained compression of the blood

vessels, the blood flow can be almost stopped, but this also causes rapid weakening of the contraction.

Increased Blood Flow in Muscle Capillaries During Exercise. During rest, some muscle capillaries have little or no flowing blood, but during strenuous exercise, all the capillaries open. This opening of dormant capillaries diminishes the distance that oxygen and other nutrients must diffuse from the capillaries to the contracting muscle fibers; it sometimes contributes a twofold to threefold increased capillary surface area through which oxygen and nutrients can diffuse from the blood to the tissues.

CONTROL OF SKELETAL MUSCLE BLOOD FLOW

Decreased Oxygen in Muscle Greatly Enhances Flow. The large increase in muscle blood flow that occurs during skeletal muscle activity is caused mainly by chemicals released locally that act directly on the muscle arterioles to cause dilation. One of the most important chemical effects is reduction of the oxygen level in the muscle tissues. When muscles are active, they use oxygen rapidly, thereby decreasing the oxygen concentration in the tissue fluids. This in turn causes local arteriolar vasodilation because

Figure 21-1. Effects of muscle exercise on blood flow in the calf of a leg during strong rhythmic contraction. The blood flow was much less during contractions than between contractions. (Modified from Barcroft H, Dornhorst AC: *The blood flow through the human calf during rhythmic exercise.* *J Physiol* 109:402, 1949.)

low oxygen levels cause the blood vessels to relax and because oxygen deficiency causes release of vasodilator substances. Adenosine may be an important vasodilator substance, but experiments have shown that even large amounts of adenosine infused directly into a muscle artery cannot increase blood flow to the same extent as during intense exercise, and it cannot sustain vasodilation in skeletal muscle for more than about 2 hours.

Fortunately, even after the muscle blood vessels have become insensitive to the vasodilator effects of adenosine, other vasodilator factors continue to maintain increased capillary blood flow as long as the exercise continues. These factors include the following: (1) potassium ions; (2) adenosine triphosphate (ATP); (3) lactic acid; and (4) carbon dioxide. We still do not know quantitatively how much of a role each of these factors plays in increasing muscle blood flow during muscle activity; this subject was discussed in additional detail in [Chapter 17](#).

Nervous Control of Muscle Blood Flow. In addition to local tissue vasodilator mechanisms, skeletal muscles are provided with sympathetic vasoconstrictor nerves and, in some species of animals, sympathetic vasodilator nerves as well.

The sympathetic vasoconstrictor nerve fibers secrete norepinephrine at their nerve endings. When maximally activated, this mechanism can decrease blood flow through resting muscles to as little as one-half to one-third normal. This vasoconstriction is of physiologic importance in attenuating decreases of arterial pressure in circulatory shock and during other periods of stress, when it may even be necessary to increase blood pressure.

In addition to the norepinephrine secreted at the sympathetic vasoconstrictor nerve endings, the medullae of the two adrenal glands also secrete increased amounts of norepinephrine plus even more epinephrine into the circulating blood during strenuous exercise. The circulating norepinephrine acts on the muscle vessels to cause a vasoconstrictor effect similar to that caused by direct sympathetic nerve stimulation. The epinephrine, however, often has a slight vasodilator effect because epinephrine excites more of the beta-adrenergic receptors of the vessels, which are vasodilator receptors, in contrast to the alpha vasoconstrictor receptors excited especially by norepinephrine. These receptors are discussed in [Chapter 61](#).

CIRCULATORY READJUSTMENTS DURING EXERCISE

Three major effects occur during exercise that are essential for the circulatory system to supply the tremendous blood flow required by the muscles: (1) sympathetic nervous system activation in many tissues with consequent stimulatory effects on the circulation; (2) increase in arterial pressure; and (3) increase in cardiac output.

Effects of Sympathetic Activation

At the onset of exercise, signals are transmitted not only from the brain to the muscles to cause muscle contraction but also into the vasomotor center to initiate sympathetic discharge in many other tissues. Simultaneously, the parasympathetic signals to the heart are attenuated. Therefore, three major circulatory effects result:

1. The heart is stimulated to a greatly increased heart rate and increased pumping strength as a result of the sympathetic drive to the heart plus release of the heart from normal parasympathetic inhibition.
2. Many of the arterioles of the peripheral circulation are strongly contracted, except for the arterioles in the active muscles, which are strongly vasodilated by the local vasodilator effects in the muscles, as noted earlier. Thus, the heart is stimulated to supply the increased blood flow required by the muscles, while at the same time blood flow through most nonmuscular areas of the body is temporarily reduced, thereby “lending” blood supply to the muscles. This process accounts for as much as 2 L/min of extra blood flow to the muscles, which is exceedingly important when considering a person running for his or her life, when even a fractional increase in running speed may make the difference between life and death. Two of the peripheral circulatory systems, the coronary and cerebral systems, are spared this vasoconstrictor effect because both these circulatory areas have poor vasoconstrictor innervation—fortunately so, because both the heart and brain are as essential to exercise as the skeletal muscles.
3. The muscle walls of the veins and other capacitative areas of the circulation are contracted powerfully, which greatly increases the mean systemic filling pressure. As we learned in [Chapter 20](#), this effect is one of the most important factors in promoting the increase in venous return of blood to the heart and, therefore, in increasing the cardiac output.

Sympathetic Stimulation May Increase Arterial Pressure During Exercise

An important effect of increased sympathetic stimulation in exercise is to increase the arterial pressure. This increased arterial pressure results from multiple stimulatory effects, including the following: (1) vasoconstriction of the arterioles and small arteries in most tissues of the body except the brain and active muscles, including the heart; (2) increased pumping activity by the heart; and (3) a great increase in mean systemic filling pressure caused mainly by venous contraction. These effects, working together, almost always increase the arterial pressure during exercise. This increase can be as little as 20 mm Hg or as much as 80 mm Hg, depending on the conditions

under which the exercise is performed. When a person performs exercise under tense conditions but uses only a few muscles, the sympathetic nervous response still occurs. In the few active muscles, vasodilation occurs, but elsewhere in the body the effect is mainly vasoconstriction, often increasing the mean arterial pressure to as high as 170 mm Hg. Such a condition might occur in a person standing on a ladder and nailing with a hammer on the ceiling above. The tenseness of the situation is obvious.

Conversely, when a person performs massive whole-body exercise, such as running or swimming, the increase in arterial pressure is often only 20 to 40 mm Hg. This lack of a large increase in pressure results from the extreme vasodilation that occurs simultaneously in large masses of active muscle.

Why Is Increased Arterial Pressure During Exercise Important? When muscles are stimulated maximally in a laboratory experiment, but without allowing the arterial pressure to rise, muscle blood flow seldom rises more than about eightfold. Yet, we know from studies of marathon runners that muscle blood flow can increase from as little as 1 L/min for the whole body during rest to more than 20 L/min during maximal activity. Therefore, it is clear that muscle blood flow can increase much more than that which occurs in this simple laboratory experiment. What is the difference? Mainly, the arterial pressure rises during normal exercise. Let us assume, for example, that the arterial pressure rises by 30% during heavy exercise. This 30% increase causes 30% more force to push blood through the muscle tissue vessels. However, this is not the only important effect—the extra pressure also stretches the walls of the vessels, and this effect, along with the locally released vasodilators and higher blood pressure, may increase muscle total flow to more than 20 times normal.

Importance of Increased Cardiac Output During Exercise

Many different physiologic effects occur at the same time during exercise to increase cardiac output approximately in proportion to the degree of exercise. In fact, the ability of the circulatory system to provide increased cardiac output for delivery of oxygen and other nutrients to the muscles during exercise is equally as important as the strength of the muscles themselves in setting the limit for continued muscle work. For example, marathon runners who can increase their cardiac outputs the most are generally the ones who have record-breaking running times.

Graphic Analysis of Changes in Cardiac Output During Heavy Exercise. Figure 21-2 shows a graphic analysis of the large increase in cardiac output that occurs during heavy exercise. The cardiac output and venous return curves crossing at point A represent the normal circulation, and the curves crossing at point B represent heavy exercise. Note that the great increase in cardiac output requires significant changes in both the cardiac output curve and the venous return curve, as follows.

Figure 21-2. Graphic analysis of change in cardiac output, venous return, and right atrial pressure with the onset of strenuous exercise. *Black curves*, Normal circulation. *Red curves*, heavy exercise.

The increased level of the cardiac output curve is easy to understand. It results almost entirely from sympathetic stimulation of the heart, which causes the following: (1) increased heart rate, up to as high as 170 to 190 beats/min; and (2) increased strength of contraction of the heart to as much as twice normal. Without this increased level of cardiac function, the increase in cardiac output would be limited to the plateau level of the normal heart, which would be a maximum increase of cardiac output of only about 2.5-fold rather than the 4-fold increase that can commonly be achieved by the untrained runner and the 7-fold increase that can be achieved in some marathon runners.

Now study the venous return curves. If no change occurred from the normal venous return curve, the cardiac output could hardly rise at all in exercise because the upper plateau level of the normal venous return curve is only 6 L/min. Yet, two important changes do occur:

1. The mean systemic filling pressure rises at the onset of heavy exercise. This effect results partly from the sympathetic stimulation that contracts the veins and other capacitative parts of the circulation. In addition, tensing of the abdominal and other skeletal muscles of the body compresses many of the internal vessels, thus providing more compression of the entire capacitative vascular system and causing a still greater increase in the mean systemic filling pressure. During maximal exercise, these two effects together can increase the mean systemic filling pressure from a normal level of 7 mm Hg to as high as 30 mm Hg.
2. The slope of the venous return curve rotates upward. This upward rotation is caused by decreased resistance in virtually all the blood vessels in active muscle tissue, which also causes resistance to venous return to decrease, thus increasing the upward slope of the venous return curve.

Therefore, the combination of increased mean systemic filling pressure and decreased resistance to venous return raises the entire level of the venous return curve.

Figure 21-3. Coronary arteries.

In response to the changes in both the venous return curve and cardiac output curve, the new equilibrium point in Figure 21-2 for cardiac output and right atrial pressure is now point B, in contrast to the normal level at point A. Note especially that the right atrial pressure has hardly changed, having risen only 1.5 mm Hg. In fact, in a person with a strong heart, the right atrial pressure often falls below normal during very heavy exercise because of the greatly increased sympathetic stimulation of the heart. In contrast, even a moderate level of exercise may cause marked increases in right atrial pressure in patients with weakened hearts.

CORONARY CIRCULATION

About one-third of all deaths in industrialized countries of the Western world result from coronary artery disease, and most older adults have at least some impairment of the coronary artery circulation. For this reason, understanding normal and pathological physiology of the coronary circulation is one of the most important subjects in medicine.

PHYSIOLOGIC ANATOMY OF THE CORONARY BLOOD SUPPLY

Figure 21-3 shows the heart and its coronary blood supply. Note that the main coronary arteries lie on the surface of the heart, and smaller arteries then penetrate from the surface into the cardiac muscle mass. It is almost entirely through these arteries that the heart receives its nutritive blood supply. Only the inner one-tenth millimeter of the endocardial surface can obtain significant nutrition directly from the blood inside the cardiac chambers, so this source of muscle nutrition is minuscule.

The *left coronary artery* supplies mainly the anterior and left lateral portions of the left ventricle, whereas the *right coronary artery* supplies most of the right ventricle, as well as the posterior part of the left ventricle in 80% to 90% of people.

Figure 21-4. Phasic flow of blood through the coronary capillaries of the human left ventricle during cardiac systole and diastole (as extrapolated from measured flows in dogs).

Most of the coronary venous blood flow from the left ventricular muscle returns to the right atrium of the heart by way of the *coronary sinus*, which is about 75% of the total coronary blood flow. On the other hand, most of the coronary venous blood from the right ventricular muscle returns through small *anterior cardiac veins* that flow directly into the right atrium, not by way of the coronary sinus. A very small amount of coronary venous blood also flows back into the heart through very minute *thebesian veins*, which empty directly into all chambers of the heart.

NORMAL CORONARY BLOOD FLOW AVERAGES 5% OF CARDIAC OUTPUT

The normal coronary blood flow in the resting person averages 70 ml/min/100 g of heart weight, or about 225 ml/min, which is about 4% to 5% of the total cardiac output.

During strenuous exercise, the heart in the young adult increases its cardiac output fourfold to sevenfold, and it pumps this blood against a higher than normal arterial pressure. Consequently, the work output of the heart under severe conditions may increase 6-fold to 9-fold. At the same time, the coronary blood flow increases 3-fold to 4-fold to supply the extra nutrients needed by the heart. This increase is not as much as the increase in workload, which means that the ratio of energy expenditure by the heart to coronary blood flow increases. Thus, the efficiency of cardiac utilization of energy increases to make up for the relative deficiency of coronary blood supply.

Cardiac Muscle Compression Causes Phasic Changes in Coronary Blood Flow During Systole and Diastole.

Figure 21-4 shows the changes in blood flow through the nutrient capillaries of the left ventricular coronary system in ml/min in the heart during systole and diastole, as extrapolated from studies in experimental animals. Note from this diagram that the coronary capillary blood flow in the left ventricle muscle falls to a low

Figure 21-5. Diagram of the epicardial, intramuscular, and subendocardial coronary vasculature.

value during systole, which is opposite to flow in vascular beds elsewhere in the body. The reason for this phenomenon is strong compression of the intramuscular blood vessels by the left ventricular muscle during systolic contraction.

During diastole, the cardiac muscle relaxes and no longer obstructs blood flow through the left ventricular muscle capillaries, so blood flows rapidly during all of diastole.

Blood flow through the coronary capillaries of the right ventricle also undergoes phasic changes during the cardiac cycle but, because the force of contraction of the right ventricular muscle is far less than that of the left ventricular muscle, the inverse phasic changes are only partial, in contrast to those in the left ventricular muscle.

Epicardial Versus Subendocardial Coronary Blood Flow—Effect of Intramyocardial Pressure. **Figure 21-5** demonstrates the special arrangement of the coronary vessels at different depths in the heart muscle, showing on the outer surface *epicardial coronary arteries* which supply most of the muscle. Smaller intramuscular arteries derived from the epicardial arteries penetrate the muscle, supplying the needed nutrients. Lying immediately beneath the endocardium is a plexus of *subendocardial arteries*. During systole, blood flow through the subendocardial plexus of the left ventricle, where the intramuscular coronary vessels are compressed greatly by ventricular muscle contraction, tends to be reduced. However, the extra vessels of the subendocardial plexus normally compensate for this reduction. Later in the chapter, we explain how this peculiar difference between blood flow in the epicardial and subendocardial arteries plays an important role in certain types of coronary ischemia.

CONTROL OF CORONARY BLOOD FLOW

Local Muscle Metabolism Is the Primary Controller of Coronary Flow

Blood flow through the coronary system is regulated mostly by local arteriolar vasodilation in response to the nutritional needs of cardiac muscle. That is, whenever the vigor of cardiac contraction is increased, the rate of coronary blood flow also increases. Conversely, decreased heart activity is accompanied by decreased coronary flow. This local regulation of coronary blood flow is similar to that which occurs in many other tissues of the body, especially in the skeletal muscles.

Oxygen Demand Is a Major Factor in Local Coronary Blood Flow Regulation. Blood flow in the coronary arteries usually is regulated almost exactly in proportion to the need of the cardiac musculature for oxygen. Normally, about 70% of the oxygen in the coronary arterial blood is removed as the blood flows through the heart muscle. Because not much oxygen is left, little additional oxygen can be supplied to the heart musculature unless the coronary blood flow increases. Fortunately, the coronary blood flow increases almost in direct proportion to any additional metabolic consumption of oxygen by the heart.

The exact means whereby increased oxygen consumption causes coronary dilation has not been determined. Many researchers have speculated that a decrease in oxygen concentration in the heart causes vasodilator substances to be released from the muscle cells and that these substances dilate the arterioles. A substance with great vasodilator propensity is adenosine. In the presence of very low concentrations of oxygen in the muscle cells, a large proportion of the cell's ATP degrades to adenosine monophosphate (AMP). Small portions of this substance are then further degraded and release adenosine to the tissue fluids of the heart muscle, with a resultant increase in local coronary blood flow. After adenosine causes vasodilation, much of it is reabsorbed into the cardiac cells to be reused for production of ATP.

Adenosine is not the only vasodilator product that has been identified; others include adenosine phosphate compounds, potassium ions, hydrogen ions, carbon dioxide, prostaglandins, and nitric oxide. The mechanisms of coronary vasodilation during increased cardiac activity have not been fully explained by adenosine. Pharmacologic agents that block or partially block the vasodilator effect of adenosine do not completely prevent coronary vasodilation caused by increased heart muscle activity. Studies in skeletal muscle have also shown that the continued infusion of adenosine maintains vascular dilation for only 1 to 3 hours, yet muscle activity still dilates the local blood vessels, even when the adenosine can no longer dilate them. Therefore, the other vasodilator mechanisms listed earlier should be remembered.

Nervous Control of Coronary Blood Flow

Stimulation of the autonomic nerves to the heart can affect coronary blood flow directly and indirectly. The direct effects result from action of the nervous transmitter substances acetylcholine from the vagus nerves and norepinephrine from the sympathetic nerves on the coronary vessels. The indirect effects result from secondary changes in coronary blood flow caused by increased or decreased activity of the heart.

The indirect effects, which are mostly opposite to the direct effects, play a far more important role in the normal control of coronary blood flow. Thus, sympathetic stimulation, which releases norepinephrine from the sympathetic nerves and epinephrine, as well as norepinephrine from the adrenal medullae, increases both heart rate and

heart contractility and increases the rate of metabolism of the heart. In turn, the increased metabolism of the heart sets off local blood flow regulatory mechanisms for dilating the coronary vessels and blood flow increases approximately in proportion to the metabolic needs of the heart muscle. In contrast, vagal stimulation, with its release of acetylcholine, slows the heart and has a slightly depressive effect on heart contractility. These effects decrease cardiac oxygen consumption and, therefore, indirectly constrict the coronary arteries.

Direct Effects of Nervous Stimuli on Coronary Vasculature. The distribution of parasympathetic (vagal) nerve fibers to the ventricular coronary system is not very great. However, the acetylcholine released by parasympathetic stimulation has a direct effect to dilate the coronary arteries.

Much more extensive sympathetic innervation of the coronary vessels occurs. In [Chapter 61](#), we see that the sympathetic transmitter substances norepinephrine and epinephrine can have vascular constrictor or vascular dilator effects, depending on the presence or absence of constrictor or dilator receptors in the blood vessel walls. The constrictor receptors are called *alpha receptors*, and the dilator receptors are called *beta receptors*. Both alpha and beta receptors exist in the coronary vessels. In general, the epicardial coronary vessels have a preponderance of alpha receptors, whereas the intramuscular arteries may have a preponderance of beta receptors. Therefore, sympathetic stimulation can, at least theoretically, cause slight overall coronary constriction or dilation, but usually constriction. In some people, the alpha vasoconstrictor effects seem to be disproportionately severe, and these people can have vasospastic myocardial ischemia during periods of excess sympathetic drive, often with resultant anginal pain.

Metabolic factors, especially myocardial oxygen consumption, are the major controllers of myocardial blood flow. Whenever the direct effects of nervous stimulation reduce coronary blood flow, the metabolic control of coronary flow usually overrides the direct coronary nervous effects within seconds.

SPECIAL FEATURES OF CARDIAC MUSCLE METABOLISM

The basic principles of cellular metabolism, discussed in [Chapters 68](#) through [73](#), apply to cardiac muscle the same as for other tissues, but some quantitative differences exist. Most importantly, under resting conditions, cardiac muscle normally consumes more fatty acids than carbohydrates to supply its energy ($\approx 70\%$ of the energy is derived from fatty acids). However, as is also true of other tissues, under anaerobic or ischemic conditions, cardiac metabolism must call on anaerobic glycolysis mechanisms for energy. However, glycolysis consumes large quantities of the blood glucose and, at the same time, forms large

amounts of lactic acid in the cardiac tissue. This is probably one of the causes of cardiac pain in cardiac ischemic conditions, as discussed later in this chapter.

As is true in other tissues, more than 95% of the metabolic energy liberated from foods is used to form ATP in the mitochondria. This ATP in turn acts as the conveyor of energy for cardiac muscular contraction and other cellular functions. In severe coronary ischemia, the ATP degrades first to adenosine diphosphate and then to AMP and adenosine. Because the cardiac muscle cell membrane is slightly permeable to adenosine, much of this agent can diffuse from the muscle cells into the circulating blood.

The released adenosine is believed to be one of the substances that causes dilation of the coronary arterioles during coronary hypoxia, as discussed earlier. However, loss of adenosine also has a serious cellular consequence. Within as little as 30 minutes of severe coronary ischemia, as occurs after a myocardial infarct, about half of the adenine base can be lost from the affected cardiac muscle cells. Furthermore, this loss can be replaced by new synthesis of adenine at a rate of only 2%/hour. Therefore, once a serious bout of coronary ischemia has persisted for 30 minutes or longer, relief of the ischemia may be too late to prevent injury and death of the cardiac cells. This is almost certainly one of the major causes of cardiac cellular death during myocardial ischemia.

ISCHEMIC HEART DISEASE

The most common cause of death in the Western countries is ischemic heart disease, which results from insufficient coronary blood flow. About 35% of people in the United States aged 65 years and older die of this cause. Some deaths occur suddenly as a result of acute coronary occlusion or fibrillation of the heart, whereas other deaths occur slowly over a period of weeks to years as a result of progressive weakening of the heart pumping process. In this chapter, we discuss acute coronary ischemia caused by acute coronary occlusion and myocardial infarction. In [Chapter 22](#), we discuss congestive heart failure, which is frequently caused by slowly increasing coronary ischemia and weakening of the cardiac muscle.

Atherosclerosis Is a Major Cause of Ischemic Heart Disease. A frequent cause of diminished coronary blood flow is atherosclerosis. The atherosclerotic process is discussed in connection with lipid metabolism in [Chapter 69](#). Briefly, in people who have a genetic predisposition to atherosclerosis, who are overweight or obese and have a sedentary lifestyle, or who have high blood pressure and damage to the endothelial cells of the coronary blood vessels, large quantities of cholesterol gradually become deposited beneath the endothelium at many points in arteries throughout the body. Gradually, these areas of deposit are invaded by fibrous tissue and frequently become calcified. The net result is the development of atherosclerotic plaques, which actually protrude into the vessel lumens

and block or partially block blood flow. A common site for development of atherosclerotic plaques is the first few centimeters of the major coronary arteries.

Acute Coronary Artery Occlusion

Acute occlusion of a coronary artery usually occurs in a person who already has underlying atherosclerotic coronary heart disease but almost never occurs in a person with a normal coronary circulation. Acute occlusion can have various causes, two of which are the following:

1. The atherosclerotic plaque can cause a local blood clot called a *thrombus* that occludes the artery. The thrombus usually occurs where the arteriosclerotic plaque has broken through the endothelium, thus coming into direct contact with the flowing blood. Because the plaque presents an unsmooth surface, blood platelets adhere to it, fibrin is deposited, and red blood cells become trapped to form a blood clot that grows until it occludes the vessel. Occasionally, the clot breaks away from its attachment on the atherosclerotic plaque and flows to a more peripheral branch of the coronary arterial tree, where it blocks the artery at that point. A thrombus that flows along the artery in this way and occludes the vessel more distally is called a *coronary embolus*.
2. Many clinicians believe that local muscular spasm of a coronary artery also can occur. The spasm might result from direct irritation of the smooth muscle of the arterial wall by the edges of an arteriosclerotic plaque, or it might result from local nervous reflexes that cause excess coronary vascular wall contraction. The spasm may then lead to *secondary thrombosis* of the vessel.

Lifesaving Value of Collateral Circulation in the Heart. The degree of damage to the heart muscle caused by slowly developing atherosclerotic constriction of the coronary arteries or by sudden coronary occlusion is determined to a great extent by the degree of collateral circulation that has already developed or that can open within minutes after the occlusion. In a normal heart, almost no large communications exist among the larger coronary arteries. However, many anastomoses do exist among the smaller arteries of 20 to 250 micrometers in diameter, as shown in [Figure 21-6](#).

When a sudden occlusion occurs in one of the larger coronary arteries, the small anastomoses begin to dilate within seconds. However, the blood flow through these minute collaterals is usually less than half of that needed to keep most of the cardiac muscle alive that they now supply. The diameters of the collateral vessels do not enlarge much more for the next 8 to 24 hours. Then, however, collateral flow begins to increase, doubling by the second or third day and often reaching normal or almost normal coronary flow within about 1 month. Because of these developing collateral channels, many patients recover almost completely from various degrees

Figure 21-6. Minute anastomoses in the normal coronary arterial system.

of coronary occlusion when the area of muscle involved is not too large.

When atherosclerosis constricts the coronary arteries slowly over a period of many years, rather than suddenly, collateral vessels can develop at the same time, while the atherosclerosis becomes more and more severe. Therefore, the person may never experience an acute episode of cardiac dysfunction. Eventually, however, the sclerotic process develops beyond the limits of even the collateral blood supply to provide the needed blood flow, and sometimes, the collateral blood vessels themselves develop atherosclerosis. When this occurs, the heart muscle becomes severely limited in its work output, and the heart cannot pump even normally required amounts of blood flow. This is one of the most common causes of cardiac failure in older people.

Myocardial Infarction

Immediately after an acute coronary occlusion, blood flow ceases in the coronary vessels beyond the occlusion, except for small amounts of collateral flow from surrounding vessels. The area of muscle that has zero flow or so little flow that it cannot sustain cardiac muscle function is said to be *infarcted*. The overall process is called a *myocardial infarction*.

Soon after the onset of the infarction, small amounts of collateral blood begin to infiltrate the infarcted area, which, combined with progressive dilation of local blood vessels, causes the area to become overfilled with stagnant blood. Simultaneously the muscle fibers use the last bits of the oxygen in the blood, causing the hemoglobin to become totally deoxygenated. Therefore, the infarcted area takes on a bluish-brown hue, and the blood vessels of the area appear to be engorged, despite lack of blood flow. In later stages, the vessel walls become highly permeable

and leak fluid, the local muscle tissue becomes edematous, and the cardiac muscle cells begin to swell because of diminished cellular metabolism. Within a few hours of almost no blood supply, the cardiac muscle cells die.

Cardiac muscle requires about 1.3 ml of oxygen/100 g of muscle tissue/min just to remain alive. In comparison, about 8 ml oxygen/100 g are delivered to the normal resting left ventricle each minute. Therefore, if there is even 15% to 30% of normal resting coronary blood flow, the muscle will not die. In the central portion of a large infarct, however, where there is almost no collateral blood flow, the muscle does die.

Subendocardial Infarction. The subendocardial muscle frequently becomes infarcted, even when there is no evidence of infarction in the outer surface portions of the heart. This occurs because the subendocardial muscle has a higher oxygen consumption and extra difficulty obtaining adequate blood flow because the blood vessels in the subendocardium are intensely compressed by systolic contraction of the heart, as explained earlier. Therefore, any condition that compromises blood flow to any area of the heart usually causes damage first in the subendocardial regions, and the damage then spreads outward toward the epicardium.

CAUSES OF DEATH AFTER ACUTE CORONARY OCCLUSION

The most common causes of death after acute myocardial infarction are the following: (1) decreased cardiac output; (2) damming of blood in the pulmonary blood vessels and then death resulting from pulmonary edema; (3) fibrillation of the heart; and, occasionally (4) rupture of the heart.

Decreased Cardiac Output—Systolic Stretch and Cardiac Shock. When some of the cardiac muscle fibers are not functioning and others are too weak to contract with great force, the overall pumping ability of the affected ventricle is proportionately depressed. The overall pumping strength of the infarcted heart is often decreased more than one might expect because of a phenomenon called *systolic stretch*, shown in [Figure 21-7](#). That is, when the normal portions of the ventricular muscle contract, the ischemic portion of the muscle, whether it is dead or simply nonfunctional, instead of contracting is forced outward by the pressure that develops inside the ventricle. Therefore, much of the pumping force of the ventricle is dissipated by bulging of the area of nonfunctional cardiac muscle.

When the heart becomes incapable of contracting with sufficient force to pump enough blood into the peripheral arterial tree, cardiac failure and death of peripheral tissues ensue as a result of peripheral ischemia. This condition, called *coronary shock*, *cardiogenic shock*, *cardiac shock*, or *low cardiac output failure*, is discussed more fully in the next chapter. Cardiac shock almost always occurs when

Figure 21-7. Systolic stretch in an area of ischemic cardiac muscle.

more than 40% of the left ventricle is infarcted, and death occurs in more than 70% of patients once cardiac shock develops.

Damming of Blood in the Body's Venous System.

When the heart is not pumping blood forward, it must be damming blood in the atria and in the blood vessels of the lungs or in the systemic circulation. This leads to increased capillary pressures, particularly in the lungs.

Damming of blood in the veins often causes little difficulty during the first few hours after a myocardial infarction. Instead, symptoms develop a few days later because the acutely diminished cardiac output leads to diminished blood flow to the kidneys. Then, for reasons discussed in [Chapter 22](#), the kidneys fail to excrete enough urine. This adds progressively to the total blood volume and, therefore, leads to congestive symptoms. Consequently, many patients who seemingly are getting along well during the first few days after the onset of heart failure will suddenly experience acute pulmonary edema and often will die within a few hours after the appearance of the initial pulmonary symptoms.

Fibrillation of the Ventricles After Myocardial Infarction.

In many people who die of coronary occlusion, death occurs because of sudden ventricular fibrillation. The tendency for fibrillation to develop is especially great after a large infarction, but fibrillation can sometimes occur after small occlusions as well. Some patients with chronic coronary insufficiency die suddenly of fibrillation without having any acute infarction.

Fibrillation is most likely to occur during two especially dangerous periods after coronary infarction. The first period is during the first 10 minutes after the infarction occurs. Then, there is a short period of relative safety, followed by a second period of cardiac irritability beginning 1 hour or so later and lasting for another few hours. Fibrillation can also occur many days after the infarct but is less likely to occur then.

At least four factors are involved in the tendency for the heart to fibrillate, as follows:

1. Acute loss of blood supply to the cardiac muscle causes rapid depletion of potassium from the ischemic musculature. This also increases the potassium concentration in the extracellular fluids surrounding the cardiac muscle fibers. Experiments in which potassium has been injected into the coronary system have demonstrated that an elevated extracellular potassium concentration increases the irritability of the cardiac musculature and, therefore, its likelihood of fibrillating.
2. Ischemia of the muscle causes an *injury current*, described in Chapter 12 in relation to electrocardiograms in patients with acute myocardial infarction. That is, the ischemic musculature often cannot completely repolarize its membranes after a heartbeat, and thus the external surface of this muscle remains negative with respect to normal cardiac muscle membrane potential elsewhere in the heart. Therefore, electric current flows from this ischemic area of the heart to the normal area and can elicit abnormal impulses, which can cause fibrillation.
3. Powerful sympathetic reflexes often develop after massive infarction, principally because the heart does not pump an adequate volume of blood into the arterial tree, which leads to reduced blood pressure. The sympathetic stimulation also increases irritability of the cardiac muscle and thereby predisposes to fibrillation.
4. Cardiac muscle weakness caused by the myocardial infarction often causes the ventricle to dilate excessively. This excessive dilation increases the pathway length for impulse conduction in the heart and frequently causes abnormal conduction pathways all the way around the infarcted area of the cardiac muscle. Both of these effects predispose to the development of *circus movements* because, as discussed in Chapter 13, excess prolongation of conduction pathways in the ventricles allows impulses to re-enter muscle that is already recovering from refractoriness, thereby initiating a circus movement cycle of new excitation and resulting in continuation of the process.

Rupture of Infarcted Area. During the first day or so after an acute infarct, there is little danger of rupture of the ischemic portion of the heart, but a few days later, the dead muscle fibers begin to degenerate, and the heart

Figure 21-8. Top, Small and large areas of coronary ischemia. Bottom, Stages of recovery from myocardial infarction.

will become stretched very thin. When this happens, the dead muscle bulges outward to a severe degree with each heart contraction, and this systolic stretch becomes greater and greater until finally the heart ruptures. One of the methods used to assess the progress of severe myocardial infarction is to record by cardiac imaging, with echocardiography, magnetic resonance imaging (MRI), or computed tomography (CT), whether the degree of systolic stretch is worsening.

When a ventricle does rupture, loss of blood into the pericardial space causes rapid development of *cardiac tamponade*—that is, compression of the heart from the outside by blood collecting in the pericardial cavity. Because of this compression of the heart, blood cannot flow into the right atrium, and the patient dies of suddenly decreased cardiac output.

STAGES OF RECOVERY FROM ACUTE MYOCARDIAL INFARCTION

The upper left part of Figure 21-8 shows the effects of acute coronary occlusion in a patient with a small area of muscle ischemia; to the right is shown a heart with a large area of ischemia. When the area of ischemia is small, little or no death of the muscle cells may occur, but part of the muscle often does become temporarily nonfunctional because of inadequate nutrition to support muscle contraction.

When the area of ischemia is large, some of the muscle fibers in the center of the area die rapidly, within 1 to 3 hours, where there is total cessation of coronary blood supply. Immediately around the dead area is a nonfunctional area, with failure of contraction and usually failure of impulse conduction. Then, extending circumferentially around the nonfunctional area, is an area that is still contracting but only weakly because of mild ischemia.

Replacement of Dead Muscle by Scar Tissue. In the lower part of Figure 21-8, the various stages of recovery after a large myocardial infarction are shown. Shortly af-

ter the occlusion, the muscle fibers in the center of the ischemic area die. Then, during the ensuing days, this area of dead fibers enlarges because many of the marginal fibers finally succumb to the prolonged ischemia. At the same time, because of the enlargement of collateral arterial channels supplying the outer rim of the infarcted area, much of the nonfunctional muscle recovers. After a few days to 3 weeks, most of the nonfunctional muscle becomes functional again or dies. In the meantime, fibrous tissue begins developing among the dead fibers because ischemia can stimulate growth of fibroblasts and promote development of greater than normal quantities of fibrous tissue. Therefore, the dead muscle tissue is gradually replaced by fibrous tissue. Then, because it is a general property of fibrous tissue to undergo progressive contraction and dissolution, the fibrous scar may grow smaller over a period of several months to a year.

Finally, the normal areas of the heart gradually hypertrophy to compensate, at least partially, for the lost dead cardiac musculature. By these means, the heart recovers partially or almost completely within a few months, depending on the severity of the infarction and cardiac tissue death.

Value of Rest in Treating Myocardial Infarction. The degree of cardiac cellular death is determined by the degree of ischemia and workload on the heart muscle. When the workload is greatly increased, such as during exercise, in severe emotional strain, or as a result of fatigue, the heart needs increased oxygen and other nutrients for sustaining its life. Furthermore, anastomotic blood vessels that supply blood to ischemic areas of the heart must also still supply the areas of the heart that they normally supply. When the heart becomes excessively active, the vessels of the normal musculature become greatly dilated. This dilation allows most of the blood flowing into the coronary vessels to flow through the normal muscle tissue, thus leaving little blood to flow through the small anastomotic channels into the ischemic area. As a result, the ischemic condition worsens, a condition called the *coronary steal syndrome*. Consequently, an important factor in the treatment of a patient with myocardial infarction is observance of absolute body rest during the recovery process.

HEART FUNCTION AFTER RECOVERY FROM MYOCARDIAL INFARCTION

Occasionally, a heart that has recovered from a large myocardial infarction returns almost to full functional capability, but more frequently, its pumping capability is permanently decreased below that of a healthy heart. This does not mean that the person is necessarily a cardiac invalid or that the resting cardiac output is depressed below normal because the normal heart is capable of pumping 300% to 400% more blood per minute than the body requires during rest—that is, a normal person has a

cardiac reserve of 300% to 400%. Even when the cardiac reserve is reduced to as little as 100%, the person can still perform most normal daily activities but not strenuous exercise, which would overload the heart.

PAIN IN CORONARY HEART DISEASE

Normally, a person cannot “feel” the heart, but ischemic cardiac muscle often does cause a pain sensation that is sometimes severe. Exactly what causes this pain is not known, but it is believed that ischemia causes the muscle to release acidic substances such as lactic acid or other pain-promoting products, such as histamine, kinins, or cellular proteolytic enzymes, which are not removed rapidly enough by the slowly moving coronary blood flow. The high concentrations of these abnormal products then stimulate pain nerve endings in the cardiac muscle, sending pain impulses through sensory afferent nerve fibers into the central nervous system.

Angina Pectoris (Cardiac Pain). In most people who sustain progressive constriction of their coronary arteries, cardiac pain, called *angina pectoris*, begins to appear whenever the load on the heart becomes too great in relation to the available coronary blood flow. This pain is usually felt beneath the upper sternum over the heart. In addition, the pain is often referred to distant surface areas of the body, usually to the left arm and left shoulder but also frequently to the neck and even to the side of the face. The reason for this distribution of pain is that during embryonic life, the heart originates in the neck, as do the arms. Therefore, both the heart and these surface areas of the body receive pain nerve fibers from the same spinal cord segments.

Most people who have chronic angina pectoris feel pain when they exercise or when they experience emotions that increase metabolism of the heart or temporarily constrict the coronary vessels because of sympathetic vasoconstrictor nerve signals. Anginal pain is also exacerbated by cold temperatures or by having a full stomach, both of which increase the workload of the heart. The pain usually lasts for only a few minutes. However, some patients have such severe and lasting ischemia that the pain is present all the time. The pain is frequently described as hot, pressing, and constricting and is of such quality that it usually makes the patient stop all unnecessary body activity.

Drug Treatment. Several vasodilator drugs, when administered during an acute anginal attack, can often provide immediate relief from the pain. Commonly used short-acting vasodilators are *nitroglycerin* and other *nitrate drugs*. Other drugs, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, and *ranolazine*, may be beneficial in treating chronic stable angina pectoris.

Another class of drugs used for the prolonged treatment of angina pectoris is the *beta blockers*, such as *propranolol*. These drugs block sympathetic beta-adrenergic receptors, which prevents sympathetic enhancement of heart rate and cardiac metabolism during exercise or emotional episodes. Therefore, therapy with a beta blocker decreases the need of the heart for extra metabolic oxygen during stressful conditions. For obvious reasons, this therapy can also reduce the number of anginal attacks, as well as their severity.

SURGICAL TREATMENT OF CORONARY ARTERY DISEASE

Aortic-Coronary Bypass Surgery. In many patients with coronary ischemia, the constricted areas of the coronary arteries are located at only a few discrete points blocked by atherosclerotic disease, and the coronary vessels elsewhere are normal or almost normal. In the 1960s, a surgical procedure called *aortic-coronary bypass* or *coronary artery bypass grafting* (CABG) was developed, in which a section of a subcutaneous vein is removed from an arm or leg and then grafted from the root of the aorta to the side of a peripheral coronary artery beyond the atherosclerotic blockage point. One to five such grafts are usually performed, each of which supplies a peripheral coronary artery beyond a block.

Anginal pain is relieved in most patients after coronary bypass surgery. Also, in patients whose hearts have not become too severely damaged before the operation, the coronary bypass procedure may provide the patient with normal life expectancy. If the heart has already been severely damaged, however, the bypass procedure may be of little value.

Coronary Angioplasty. Since the 1980s, a procedure has been used to open partially blocked coronary vessels before they become totally occluded. This procedure, called *coronary artery angioplasty*, is performed as follows. A small balloon-tipped catheter, about 1 millimeter in diameter, is passed under radiographic guidance into the coronary system and pushed through the partially occluded artery until the balloon portion of the catheter straddles the partially occluded point. The balloon is then inflated with high pressure, which stretches the diseased artery markedly. After this procedure is performed, the blood flow through the vessel often increases 3-fold to 4-fold, and more than 75% of patients who undergo the procedure are relieved of the coronary ischemic symptoms for at least several years, although many of the patients still eventually require coronary bypass surgery.

Small stainless steel mesh tubes called *stents* are sometimes placed inside a coronary artery dilated by angioplasty to hold the artery open, thus preventing its restenosis. Within a few weeks after the stent is placed in the coronary artery, the endothelium usually grows over the metal surface of the stent, allowing blood to flow smoothly through the stent. However, reclosure

(restenosis) of the blocked coronary artery occurs in about 25% to 40% of patients treated with angioplasty, often within 6 months of the initial procedure. Restenosis is usually due to the excessive formation of scar tissue that develops underneath the healthy new endothelium that has grown over the stent. Stents that slowly release drugs (drug-eluting stents) may help prevent the excessive growth of scar tissue.

Newer procedures for opening atherosclerotic coronary arteries are constantly in experimental development. One of these procedures uses a laser beam from the tip of a coronary artery catheter aimed at the atherosclerotic lesion. The laser literally dissolves the lesion without substantially damaging the remainder of the arterial wall.

Cardiac Failure

One of the most important ailments treated by the physician is cardiac failure (heart failure). This ailment can result from any heart condition that reduces the ability of the heart to pump enough blood to meet the body's needs. The cause is often decreased contractility of the myocardium resulting from diminished coronary blood flow. However, cardiac failure can also be caused by damaged heart valves, external pressure around the heart, vitamin B deficiency, primary cardiac muscle disease, or any other abnormality that makes the heart a hypoeffective pump.

In this chapter, we mainly discuss cardiac failure caused by ischemic heart disease resulting from partial blockage of the coronary blood vessels, which is the most common cause of heart failure. In [Chapter 23](#), we discuss valvular and congenital heart disease.

CIRCULATORY DYNAMICS IN CARDIAC FAILURE

ACUTE EFFECTS OF MODERATE CARDIAC FAILURE

If a heart suddenly becomes severely damaged, such as by myocardial infarction, the pumping ability of the heart is immediately depressed. As a result, two main effects occur: (1) reduced cardiac output; and (2) damming of blood in the veins, resulting in increased venous pressure.

The progressive changes in heart pumping effectiveness at different times after an acute myocardial infarction are shown graphically in [Figure 22-1](#). The top curve of this figure shows a normal cardiac output curve. Point A on this curve is the normal operating point, showing a normal cardiac output under resting conditions of 5 L/min and a right atrial pressure of 0 mm Hg.

Immediately after the heart becomes damaged, the cardiac output curve becomes greatly depressed, falling to the lowest curve at the bottom of the graph. Within a few seconds, a new circulatory state is established at point B, illustrating that the cardiac output has fallen to 2 L/min, about two-fifths normal, whereas the right atrial pressure has risen to +4 mm Hg because venous blood returning to

the heart from the body is dammed up in the right atrium. This low cardiac output is still sufficient to sustain life for perhaps a few hours, but it is likely to be associated with fainting. Fortunately, this acute stage usually lasts for only a few seconds because sympathetic nervous reflexes occur almost immediately and compensate, to a great extent, for the damaged heart, as follows.

Compensation for Acute Cardiac Failure by Sympathetic Nervous Reflexes. When the cardiac output falls precariously low, many of the circulatory reflexes discussed in [Chapter 18](#) are rapidly activated. The best known of these is the *baroreceptor reflex*, which is activated by diminished arterial pressure. The *chemoreceptor reflex*, the *central nervous system ischemic response*, and even *reflexes that originate in the damaged heart* also likely contribute to activation of the sympathetic nervous system. The sympathetics therefore become strongly stimulated within a few seconds, and the parasympathetic nervous signals to the heart become inhibited at the same time.

Strong sympathetic stimulation has major effects on the heart and peripheral vasculature. If all the ventricular musculature is diffusely damaged but is still functional, sympathetic stimulation strengthens this damaged musculature. If part of the muscle is nonfunctional, and part of it is still normal, the normal muscle is strongly stimulated by sympathetic stimulation, in this way partially compensating for the nonfunctional muscle. Thus, *the heart becomes a stronger pump* as a result of sympathetic stimulation. This effect is illustrated in [Figure 22-1](#), which shows about a twofold elevation of the very low cardiac output curve after sympathetic compensation.

Sympathetic stimulation also increases venous return because it increases the tone of most of the blood vessels of the circulation, especially the veins, *raising the mean systemic filling pressure* to 12 to 14 mm Hg, almost 100% above normal. As discussed in [Chapter 20](#), this increased filling pressure greatly increases the tendency for blood to flow from the veins back into the heart. Therefore, the damaged heart becomes primed with more inflowing blood than usual, and the right atrial pressure rises still further, which helps the heart pump still larger quantities

Figure 22-1 Progressive changes in the cardiac output curve after acute myocardial infarction. Both the cardiac output and right atrial pressure change progressively from point A to point D (illustrated by the black line) over a period of seconds, minutes, days, and weeks.

of blood. Thus, in **Figure 22-1**, the new circulatory state is depicted by point C, showing a cardiac output of 4.2 L/min and a right atrial pressure of 5 mm Hg.

The sympathetic reflexes become maximally developed in about 30 seconds. Therefore, a person who has a sudden, moderate heart attack might experience nothing more than cardiac pain and a few seconds of fainting. Shortly thereafter, with the aid of the sympathetic reflex compensations, the cardiac output may return to a level adequate to sustain the person if he or she remains quiet, although the pain might persist.

CHRONIC STAGE OF FAILURE—FLUID RETENTION AND COMPENSATED CARDIAC OUTPUT

After the first few minutes of an acute heart attack, a prolonged semichronic state begins, characterized mainly by two events: (1) retention of fluid by the kidneys; and (2) varying degrees of recovery of the heart over a period of weeks to months, as illustrated by the light green curve in **Figure 22-1**. This topic was also discussed in **Chapter 21**.

Renal Retention of Fluid and Increase in Blood Volume Occur for Hours to Days

A low cardiac output has a profound effect on renal function, sometimes causing anuria when the cardiac output falls to 50% to 60% of normal. In general, the urine output remains below normal as long as the cardiac output and arterial pressure remain significantly less than normal; urine output usually does not return all the way to normal after an acute heart attack until the cardiac output and arterial pressure rise almost to normal levels.

Moderate Fluid Retention in Cardiac Failure Can Be Beneficial. Many cardiologists have considered fluid retention always to have a detrimental effect in cardiac failure. However, a moderate increase in body fluid and blood volume is an important factor in helping to compensate for the diminished pumping ability of the heart by increasing the venous return. The increased blood volume increases venous return in two ways. First, it increases the mean systemic filling pressure, which *increases the pressure gradient for causing venous flow of blood toward the heart*. Second, it distends the veins, which *reduces the venous resistance* and allows even more ease of flow of blood to the heart.

If the heart is not damaged too much, this increased venous return can almost fully compensate for the heart's diminished pumping ability—enough so that even when the heart's pumping ability is reduced to as low as 40% to 50% of normal, the increased venous return can often cause nearly normal cardiac output as long as the person remains in a quiet resting state.

When the heart's pumping capability is reduced further, blood flow to the kidneys finally becomes too low for the kidneys to excrete enough salt and water to equal salt and water intake. Therefore, fluid retention begins and continues indefinitely unless major therapeutic procedures are used to prevent this outcome. Furthermore, because the heart is already pumping at its maximum capacity, *this excess fluid no longer has a beneficial effect on the circulation*. Instead, the fluid retention increases the workload on the already damaged heart, and severe edema develops throughout the body, which can be very detrimental and can lead to death.

Detrimental Effects of Excess Fluid Retention in Severe Cardiac Failure. In contrast to the beneficial effects of moderate fluid retention in cardiac failure, in severe cardiac failure, extreme excesses of fluid can have serious physiologic consequences. These include the following: (1) increasing the workload on the damaged heart; (2) overstretching of the heart, which further weakens the heart; (3) filtration of fluid into the lungs, causing pulmonary edema and consequent deoxygenation of the blood; and (4) development of extensive edema in most parts of the body. These detrimental effects of excessive fluid are discussed in later sections of this chapter.

Recovery of the Heart After Myocardial Infarction

After a heart becomes suddenly damaged as a result of myocardial infarction, the natural reparative processes of the body begin to help restore normal cardiac function. For example, a new collateral blood supply begins to penetrate the peripheral portions of the infarcted area of the heart, often causing some of the heart muscle in the fringe areas to become functional again. Also, the undamaged portion of the heart musculature hypertrophies, offsetting some of the cardiac damage.

The degree of recovery, which depends on the type and severity of cardiac damage, varies from no recovery to almost complete recovery. After an acute myocardial infarction, the heart ordinarily recovers rapidly during the first few days and weeks and achieves most of its final state of recovery within 5 to 7 weeks, although mild degrees of additional recovery can continue for months.

Cardiac Output Curve After Partial Recovery. Figure 22-1 shows function of the partially recovered heart a week or so after an acute myocardial infarction. By this time, considerable fluid has been retained in the body, and the tendency for venous return has increased markedly as well; therefore, the right atrial pressure has risen even more. As a result, the state of the circulation is now changed from point C to point D, which shows a normal cardiac output of 5 L/min but right atrial pressure increased to 6 mm Hg.

Because the cardiac output has returned to normal, renal output of fluid also returns to normal, and no further fluid retention occurs, except that *the retention of fluid that has already occurred continues to maintain moderate excesses of fluid*. Therefore, except for the high right atrial pressure represented by point D in this figure, the person now has essentially normal cardiovascular dynamics *as long as he or she remains at rest*.

If the heart recovers to a significant extent, and if adequate fluid volume has been retained, the cardiac output increases toward normal and sympathetic stimulation gradually abates toward normal. As the heart recovers, the fast pulse rate, cold skin, and pallor resulting from sympathetic stimulation in the acute stage of cardiac failure gradually disappear.

SUMMARY OF CHANGES AFTER ACUTE CARDIAC FAILURE—COMPENSATED HEART FAILURE

To summarize the events discussed in the past few sections describing the dynamics of circulatory changes after an acute, moderate heart attack, we can divide the stages into the following: (1) the instantaneous effect of the cardiac damage; (2) compensation by the sympathetic nervous system, which occurs mainly within the first 30 to 60 seconds; and (3) chronic compensations resulting from partial heart recovery and renal retention of fluid. All these changes are shown graphically by the black line in Figure 22-1. The progression of this line shows the normal state of the circulation (point A), the state a few seconds after the heart attack but before sympathetic reflexes have occurred (point B), the rise in cardiac output toward normal caused by sympathetic stimulation (point C), and final return of the cardiac output to almost normal after several days to several weeks of partial cardiac recovery and fluid retention (point D). This final state is called *compensated heart failure*.

Figure 22-2 Greatly depressed cardiac output that indicates decompensated heart disease. Progressive fluid retention raises the right atrial pressure over a period of days, and the cardiac output progresses from point A to point F until death occurs.

Compensated Heart Failure. Note especially in Figure 22-1 that the maximum pumping ability of the partly recovered heart, as depicted by the plateau level of the light green curve, is still depressed to less than half-normal. This demonstrates that an increase in right atrial pressure can maintain the cardiac output at a normal level, despite continued weakness of the heart. Thus, many people, especially older adults, have normal resting cardiac outputs but mildly to moderately elevated right atrial pressures because of various degrees of compensated heart failure. They may not know that they have cardiac damage because the damage often has occurred a little at a time, and the compensation has occurred concurrently with the progressive stages of damage.

When a person is in a state of compensated heart failure, any attempt to perform heavy exercise usually causes immediate return of the symptoms of acute heart failure because the heart is not able to increase its pumping capacity to the levels required for the exercise. Therefore, it is said that the *cardiac reserve* is reduced in compensated heart failure. This concept of cardiac reserve is discussed later in the chapter.

DYNAMICS OF SEVERE CARDIAC FAILURE—DECOMPENSATED HEART FAILURE

If the heart becomes severely damaged, no amount of compensation by sympathetic nervous reflexes or fluid retention can make the excessively weakened heart pump a normal cardiac output. As a consequence, the cardiac output cannot rise high enough to make the kidneys excrete normal quantities of fluid. Therefore, fluid continues to be retained, the person develops more and more edema, and this state of events eventually leads to death. This condition is called *decompensated heart failure*. Thus, a major cause of decompensated heart failure is failure of the heart to pump sufficient blood to make the kidneys excrete the necessary amounts of fluid every day.

Graphic Analysis of Decompensated Heart Failure. Figure 22-2 shows greatly depressed cardiac output at

different times (points A to F) after the heart has become severely weakened. Point A on this curve represents the approximate state of the circulation before any compensation has occurred, and point B represents the state a few minutes later, after sympathetic stimulation has compensated as much as it can but before fluid retention has begun. At this time, the cardiac output has risen to 4 L/min and the right atrial pressure has risen to 5 mm Hg. The person appears to be in reasonably good condition, but this state will not remain stable because the cardiac output has not risen high enough to cause adequate kidney excretion of fluid; therefore, fluid retention continues and can eventually be the cause of death. These events can be explained quantitatively in the following way.

Note the straight line in **Figure 22-2**, at a cardiac output level of 5 L/min. This level is approximately the critical cardiac output level that is required in the average adult person to make the kidneys reestablish normal fluid balance—that is, for the output of salt and water to be as high as the intake of these substances. At cardiac outputs below this level, the fluid-retaining mechanisms discussed in the earlier section remain in play, and the body fluid volume increases progressively. Because of this progressive increase in fluid volume, the mean systemic filling pressure of the circulation continues to rise, which forces progressively increasing quantities of blood from the person's peripheral veins into the right atrium, thus increasing the right atrial pressure. After 1 day or so, the state of the circulation changes in **Figure 22-2** from point B to point C, with the right atrial pressure rising to 7 mm Hg and the cardiac output rising to 4.2 L/min. Note again that the cardiac output is still not high enough to cause normal renal output of fluid; therefore, fluid continues to be retained. After another day or so, the right atrial pressure rises to 9 mm Hg, and the circulatory state becomes that depicted by point D. Still, the cardiac output is not enough to establish normal fluid balance.

After another few days of fluid retention, the right atrial pressure has risen further but, by now, cardiac function is beginning to decline toward a lower level. This decline is caused by overstretch of the heart, edema of the heart muscle, and other factors that diminish the heart's pumping performance. It is now clear that further retention of fluid will be more detrimental than beneficial to the circulation. Yet, the cardiac output still is not high enough to bring about normal renal function, so fluid retention not only continues but accelerates because of the falling cardiac output (and the falling arterial pressure that also occurs). Consequently, within a few days, the state of the circulation has reached point F on the curve, with the cardiac output now less than 2.5 L/min and the right atrial pressure 16 mm Hg. This state has approached or reached incompatibility with life, and the patient will die unless this chain of events can be reversed. This state of heart failure in which the failure continues to worsen is called *decompensated heart failure*.

Thus, one can see from this analysis that failure of the cardiac output (and arterial pressure) to rise to the critical level required for normal renal function results in the following: (1) progressive retention of more and more fluid; (2) progressive elevation of the mean systemic filling pressure; and (3) progressive elevation of the right atrial pressure until, finally, the heart is so overstretched or so edematous that it cannot pump even moderate quantities of blood and, therefore, fails completely. Clinically, one detects this serious condition of decompensation principally by the progressing edema, especially edema of the lungs, which leads to bubbling *rales* (a crackling sound) in the lungs and to *dyspnea* (air hunger). Lack of appropriate therapy at this stage rapidly leads to death.

Treatment of Decompensation. The decompensation process can often be stopped by the following: (1) *strengthening the heart* in any one of several ways, especially by *administering a cardiotonic drug*, such as *digitalis*, so that the heart becomes strong enough to pump adequate quantities of blood required to make the kidneys function normally again; or (2) *administering diuretic drugs to increase kidney excretion* while at the same time reducing water and salt intake, which results in a balance between fluid intake and output, despite low cardiac output.

Both methods stop the decompensation process by reestablishing normal fluid balance so that at least as much fluid leaves the body as enters it.

Mechanism of Action of Cardiotonic Drugs. Cardiotonic drugs, such as digitalis, when administered to a person with a healthy heart, have little effect on increasing the contractile strength of the cardiac muscle. However, when administered to someone with a chronically failing heart, the same drugs can sometimes increase the strength of the failing myocardium by as much as 50% to 100%. Therefore, they are one of the mainstays of therapy in persons with chronic heart failure.

Digitalis and other cardiotonic glycosides are believed to strengthen heart contractions by increasing the quantity of calcium ions in muscle fibers. This effect is likely due to inhibition of sodium-potassium adenosine triphosphatase in cardiac cell membranes. Inhibition of the sodium-potassium pump increases the intracellular sodium concentration and slows the sodium-calcium exchange pump, which extrudes calcium from the cell in exchange for sodium. Because the sodium-calcium exchange pump relies on a high sodium gradient across the cell membrane, accumulation of sodium inside the cell reduces its activity.

In the failing heart muscle, the sarcoplasmic reticulum fails to accumulate normal quantities of calcium and, therefore, cannot release enough calcium ions into the free fluid compartment of the muscle fibers to cause full contraction of the muscle. The effect of digitalis to depress the sodium-calcium exchange pump and raise calcium

ion concentration in cardiac muscle provides the extra calcium needed to increase the muscle contractile force. Therefore, it is usually beneficial to depress the calcium pumping mechanism by a moderate amount using digitalis, allowing the muscle fiber intracellular calcium level to rise slightly.

UNILATERAL LEFT HEART FAILURE

Thus far we have considered failure of the heart as a whole. Yet, in a large number of patients, especially those with early acute heart failure, left-sided failure predominates over right-sided failure and, in rare cases, the right side fails without significant failure of the left side.

When the left side of the heart fails without concomitant failure of the right side, blood continues to be pumped into the lungs with usual right heart vigor, whereas it is not pumped adequately out of the lungs by the left heart into the systemic circulation. As a result, the *mean pulmonary filling pressure* rises because of the shift of large volumes of blood from the systemic circulation into the pulmonary circulation.

As the volume of blood in the lungs increases, the pulmonary capillary pressure increases and, if this pressure rises above a value approximately equal to the colloid osmotic pressure of the plasma—about 28 mm Hg—fluid begins to filter out of the capillaries into the lung interstitial spaces and alveoli, resulting in pulmonary edema.

Thus, the most important problems of left heart failure include *pulmonary vascular congestion* and *pulmonary edema*. In severe, acute, left heart failure, pulmonary edema occasionally occurs so rapidly that it can cause death by suffocation in 20 to 30 minutes, discussed later in this chapter.

LOW-OUTPUT CARDIAC FAILURE—CARDIOGENIC SHOCK

In many cases after acute heart attacks, and often after prolonged periods of slow progressive cardiac deterioration, the heart becomes incapable of pumping even the minimal amount of blood flow required to keep the body alive. Consequently, the body tissues begin to suffer and even to deteriorate, often leading to death within a few hours to a few days. The picture, then, is one of circulatory shock, as explained in [Chapter 24](#). Even the cardiovascular system suffers from lack of nutrition and deteriorates, along with the remainder of the body, thus hastening death. This circulatory shock syndrome caused by inadequate cardiac pumping is called *cardiogenic shock* or simply *cardiac shock*. Once cardiogenic shock develops, the survival rate is often less than 30%, even with appropriate medical care.

Vicious Cycle of Cardiac Deterioration in Cardiogenic Shock. The discussion of circulatory shock in [Chapter 24](#) emphasizes the tendency for the heart to become progres-

sively more damaged when its coronary blood supply is reduced during the course of the shock. That is, the low arterial pressure that occurs during shock reduces the coronary blood supply even more. This reduction further weakens the heart, which makes the arterial pressure fall further, which makes the shock progressively worse; the process eventually becomes a vicious cycle of cardiac deterioration. In cardiogenic shock caused by myocardial infarction, this problem is greatly compounded by already existing coronary vessel blockage. For example, in a healthy heart, the arterial pressure usually must be reduced below about 45 mm Hg before cardiac deterioration sets in. However, in a heart that already has a blocked major coronary vessel, deterioration begins when the coronary arterial pressure falls below 80 to 90 mm Hg. In other words, even a small decrease in arterial pressure can now set off a vicious cycle of cardiac deterioration. For this reason, in treating myocardial infarction, it is extremely important to prevent even short periods of hypotension.

Physiology of Cardiogenic Shock Treatment. Often, a patient dies of cardiogenic shock before the various compensatory processes can return the cardiac output (and arterial pressure) to a life-sustaining level. Therefore, treatment of this condition is one of the most important challenges in the management of acute heart attacks.

Digitalis is often administered immediately to strengthen the heart if the ventricular muscle shows signs of deterioration. Also, infusion of whole blood, plasma, or a blood pressure-raising drug is used to sustain the arterial pressure. If the arterial pressure can be elevated to a high enough level, the coronary blood flow often will increase enough to prevent the vicious cycle of deterioration. This process allows enough time for appropriate compensatory mechanisms in the circulatory system to correct the shock.

Some success has also been achieved in saving the lives of patients in cardiogenic shock by using one of the following procedures: (1) surgically removing the clot in the coronary artery, often in combination with a coronary bypass graft; or (2) catheterizing the blocked coronary artery and infusing *streptokinase* or *tissue-type plasminogen activator* enzymes that causes dissolution of the clot. The results are occasionally astounding when one of these procedures is instituted within the first hour of cardiogenic shock but are of little, if any, benefit after 3 hours.

EDEMA IN PATIENTS WITH CARDIAC FAILURE

Acute Cardiac Failure Does Not Cause Immediate Peripheral Edema. Acute *left* heart failure can cause rapid congestion of the lungs, with the development of *pulmonary edema* and even death within minutes to hours. However, left or right heart failure is slow to cause *peripheral edema*. This situation can best be explained by referring to [Figure 22-3](#). When a previously healthy

Figure 22-3 Progressive changes in mean aortic pressure, peripheral tissue capillary pressure, and right atrial pressure as the cardiac output falls from normal to zero.

heart acutely fails as a pump, the aortic pressure falls, and the right atrial pressure rises. As the cardiac output approaches zero, these two pressures approach each other at an equilibrium value of about 13 mm Hg. Capillary pressure also falls from its normal value of 17 mm Hg to the new equilibrium pressure of 13 mm Hg. Thus, *severe acute cardiac failure often causes a fall rather than a rise in peripheral capillary pressure*. Therefore, animal experiments, as well as experience in humans, have shown that acute cardiac failure almost never causes immediate development of peripheral edema.

LONG-TERM FLUID RETENTION BY THE KIDNEYS CAUSES PERIPHERAL EDEMA IN PERSISTING HEART FAILURE

After the first day or so of overall heart failure or right ventricular heart failure, peripheral edema begins to occur, principally *because of fluid retention by the kidneys*. The retention of fluid increases the mean systemic filling pressure, resulting in an increased tendency for blood to return to the heart. This further elevates the right atrial pressure and returns the arterial pressure back toward normal. Therefore, *the capillary pressure now also rises markedly*, thus causing loss of fluid into the tissues and the development of severe edema.

Reduced renal output of urine during cardiac failure has several known causes.

1. **Decreased glomerular filtration rate.** A decrease in cardiac output has a tendency to reduce the glomerular pressure in the kidneys because of the following: (a) *reduced arterial pressure*; and (b) *intense sympathetic constriction of the afferent arterioles of the kidney*. As a consequence, except in the mildest degrees of heart failure, the glomerular filtration rate is reduced. It is clear from the discussion of kidney function in Chapters 27 through 30 that *a decrease in glomerular filtration often markedly decreases*
2. **Activation of renin-angiotensin system and increased reabsorption of water and salt by renal tubules.** The reduced blood flow to the kidneys causes a marked increase in *renin secretion* by the kidneys, which in turn increases the *formation of angiotensin II*, as described in [Chapter 19](#). Angiotensin II, in turn, has a direct effect on the arterioles of the kidneys to decrease blood flow through the kidneys further, which reduces the pressure in the peritubular capillaries surrounding the renal tubules, promoting greatly increased reabsorption of water and salt from the tubules. Angiotensin II also acts directly on the renal tubular epithelial cells to stimulate reabsorption of salt and water. Therefore, loss of water and salt into the urine decreases greatly, and large quantities of salt and water accumulate in the blood and interstitial fluids throughout the body.
3. **Increased aldosterone secretion.** In the chronic stage of heart failure, large quantities of aldosterone are secreted by the adrenal cortex. This secretion results mainly from the effect of angiotensin II to stimulate aldosterone secretion by the adrenal cortex. However, some of the increase in aldosterone secretion often results from increased plasma potassium concentration. Excess potassium is one of the most powerful stimuli known for aldosterone secretion, and the potassium concentration rises in response to reduced renal function in those with cardiac failure. The elevated aldosterone level further increases reabsorption of sodium from the renal tubules, which in turn leads to a secondary increase in water reabsorption, as discussed in [Chapter 28](#).
4. **Increased antidiuretic hormone secretion.** In advanced heart failure, increased secretion of *antidiuretic hormone* (ADH) may contribute to excessive water reabsorption by the renal tubules. As discussed in Chapters 28 and 29, ADH is secreted by the hypothalamic–posterior pituitary gland system in response to increased extracellular fluid osmolarity, as well as nonosmotic stimuli from low-pressure (e.g., left atrial) and high-pressure (e.g., carotid sinus) baroreceptors. In severe heart failure, the nonosmotic effects of reductions in cardiac output and arterial pressure may predominate to stimulate secretion of ADH, which in turn causes excess water retention and *hyponatremia* (low plasma sodium concentration). Inappropriately high levels of ADH and hyponatremia are predictors for worsening outcomes in patients with heart failure.
5. **Activation of sympathetic nervous system.** As discussed previously, heart failure causes marked activation of the sympathetic nervous system, which in turn has several effects that lead to salt

and water retention by the kidneys: (a) constriction of renal afferent arterioles, which reduces the glomerular filtration rate; (b) stimulation of renal tubular reabsorption of salt and water by activation of alpha-adrenergic receptors on tubular epithelial cells; (c) stimulation of renin release and angiotensin II formation, which increases renal tubular reabsorption; and (d) stimulation of ADH release from the posterior pituitary, which then increases water reabsorption by the renal tubules. These effects of sympathetic stimulation are discussed in Chapters 27 and 28.

Role of Natriuretic Peptides in Delaying Onset of Cardiac Decompensation. *Natriuretic peptides* are hormones released by the heart when it becomes stretched. Atrial natriuretic peptide (ANP) is released by the atrial walls, and brain natriuretic peptide (BNP) is released by the ventricular walls. Because heart failure almost always increases the atrial and ventricular pressures that stretch the walls of these chambers, circulating levels of ANP and BNP in the blood may increase severalfold in severe heart failure. These natriuretic peptides, in turn, have a direct effect on the kidneys to increase their excretion of salt and water greatly. Therefore, the natriuretic peptides play a natural role to help prevent extreme congestive symptoms during cardiac failure. Because the half-life of BNP is significantly longer than that of ANP and can be easily measured in the bloodstream, it is often used to diagnose heart failure or to monitor volume status in patients with established heart failure. The renal effects of ANP are discussed in Chapters 28 and 30.

Acute Pulmonary Edema in Late-Stage Heart Failure—Another Lethal Vicious Cycle

A frequent cause of death is *acute pulmonary edema* in patients who have already had heart failure for a long time. When acute pulmonary edema occurs in a person without new cardiac damage, it usually is set off by some temporary overload of the heart, such as that which might result from a bout of heavy exercise, an emotional experience, or even a severe cold. The acute pulmonary edema is believed to result from the following vicious cycle:

1. A temporarily increased load on the already weak left ventricle initiates the vicious cycle. Because of limited pumping capacity of the left heart, blood begins to dam up in the lungs.
2. The increased blood in the lungs elevates the pulmonary capillary pressure, and a small amount of fluid begins to transude into the lung tissues and alveoli.
3. The increased fluid in the lungs diminishes the degree of oxygenation of the blood.
4. The decreased oxygen in the blood further weakens the heart and also causes peripheral vasodilation.
5. The peripheral vasodilation further increases venous return of blood from the peripheral circulation.
6. The increased venous return further increases damming of the blood in the lungs, leading to, for example, still more transudation of fluid, more arterial oxygen desaturation, and more venous return. Thus, a vicious cycle has been established.

Once this vicious cycle has proceeded beyond a certain critical point, it will continue until the patient dies, unless successful therapeutic measures are initiated within minutes. The types of measures that can reverse the process and save the patient's life include the following:

1. Putting tourniquets on both arms and legs to sequester much of the blood in the veins and, therefore, decrease the workload on the left side of the heart
2. Administering a rapidly acting diuretic, such as furosemide, to cause rapid loss of fluid from the body
3. Giving the patient pure oxygen to breathe to reverse the blood oxygen desaturation, heart deterioration, and peripheral vasodilation
4. Administering a rapidly acting cardiotoxic drug, such as digitalis, to strengthen the heart

This vicious cycle of acute pulmonary edema can proceed so rapidly that death can occur in 20 to 60 minutes. Therefore, any procedure that is to be successful must be instituted immediately.

CARDIAC RESERVE

The maximum percentage that the cardiac output can increase above normal is called the *cardiac reserve*. Thus, in the healthy young adult, the cardiac reserve is 300% to 400%. In athletically trained persons, it is 500% to 600% or more. However, in persons with severe heart failure, there is no cardiac reserve. As an example of normal reserve, the cardiac output of a healthy young adult during vigorous exercise can rise to about five times normal, which is an increase above normal of 400%—that is, a *cardiac reserve of 400%*.

Any factor that prevents the heart from pumping blood satisfactorily will decrease the cardiac reserve. A decrease in cardiac reserve can result from disorders such as ischemic heart disease, primary myocardial disease, vitamin deficiency that affects cardiac muscle, physical damage to the myocardium, valvular heart disease, and other factors, some of which are shown in [Figure 22-4](#).

Diagnosis of Low Cardiac Reserve—Exercise Test. As long as persons with low cardiac reserve remain in a state of rest, they usually will not experience major symptoms of heart disease. However, a diagnosis of low cardiac reserve usually can be made by requiring the person to exercise on a treadmill or by walking up and

Figure 22-4 Cardiac reserve in different conditions, showing less than zero reserve for two of the conditions.

down steps, either of which requires greatly increased cardiac output. The increased load on the heart rapidly uses up the small amount of reserve that is available, and the cardiac output soon fails to rise high enough to sustain the body's new level of activity. The acute effects are as follows:

1. Immediate and sometimes extreme shortness of breath (*dyspnea*) resulting from failure of the heart to pump sufficient blood to the tissues, thereby causing tissue ischemia and creating a sensation of air hunger
2. Extreme muscle fatigue resulting from muscle ischemia, thus limiting the person's ability to continue with the exercise
3. Excessive increase in heart rate because the nervous reflexes to the heart overreact in an attempt to overcome the inadequate cardiac output

Exercise tests are part of the armamentarium of the cardiologist. These tests take the place of cardiac output measurements that cannot easily be made in most clinical settings.

QUANTITATIVE GRAPHIC ANALYSIS OF CARDIAC FAILURE

Although it is possible to understand most general principles of cardiac failure using mainly qualitative logic, as we have done thus far in this chapter, one can grasp the importance of the different factors in cardiac failure in greater depth by using more quantitative approaches. One such approach is the graphic method for analysis of cardiac output regulation introduced in Chapter 20. In the rest of this chapter, we will use this graphic technique to analyze several aspects of cardiac failure.

Graphic Analysis of Acute Heart Failure and Chronic Compensation

Figure 22-5 shows *cardiac output* and *venous return curves* for different states of the heart and peripheral circulation. The two curves passing through point A are (1) the *normal cardiac output curve* and (2) the *normal venous return curve*. As indicated in Chapter 20, there is only one point on each of these two curves at which the circulatory system can operate—point A, where the two

Figure 22-5 Progressive changes in cardiac output, venous return, and right atrial pressure during different stages of cardiac failure.

curves cross. Therefore, the normal state of the circulation is a cardiac output and venous return of 5 L/min and a right atrial pressure of 0 mm Hg.

Acute Heart Attack Reduces Cardiac Output Curve.

During the first few seconds after a moderately severe heart attack, the cardiac output curve falls to the *lowermost blue curve*. During these few seconds, the venous return curve still has not changed because the peripheral circulatory system is still operating normally. Therefore, the new state of the circulation is depicted by point B, where the new cardiac output curve crosses the normal venous return curve. Thus, the right atrial pressure rises immediately to 4 mm Hg, whereas the cardiac output falls to 2 L/min.

Sympathetic Reflexes Raise Cardiac Output and Venous Return Curves.

Within the next 30 seconds, the sympathetic reflexes are activated. They raise the cardiac output and venous return curves (*brown dashed curves*). Sympathetic stimulation can increase the plateau level of the cardiac output curve by as much as 30% to 100%. It can also increase the mean systemic filling pressure (depicted by the point where the venous return curve crosses the zero venous return axis) by several millimeters of mercury—in this figure, from a normal value of 7 mm Hg up to 10 mm Hg. This increase in mean systemic filling pressure shifts the entire venous return curve to the right and upward. The new cardiac output and venous return curves now equilibrate at point C—that is, at a right atrial pressure of +5 mm Hg and a cardiac output of 4 L/min.

Compensation During the Next Few Days Further Increases Cardiac Output and Venous Return Curves.

During the ensuing week, the cardiac output and venous return curves rise further (*green dashed curves*) because of the following: (1) some recovery of the heart; and (2) renal retention of salt and water, which raises the mean systemic filling pressure still further—this time up to +12 mm Hg. The two new curves now equilibrate at point D. Thus, the cardiac output has now returned to normal. The right atrial pressure, however, has risen still further, to +6 mm Hg. Because the cardiac output is now normal, renal output is also normal, so a new state of equilibrated fluid balance has been achieved. The circulatory system will continue to function

Figure 22-6 Graphic analysis of decompensated heart disease showing progressive shift of the venous return curve to the right and increasing right atrial pressure as a result of continued fluid retention.

at point D and remain stable, with a normal cardiac output and an elevated right atrial pressure, until some additional extrinsic factor changes the cardiac output curve or venous return curve.

Using this technique for analysis, one can especially see the importance of moderate fluid retention and how it eventually leads to a new stable state of the circulation in mild to moderate heart failure. The interrelationship between mean systemic filling pressure and cardiac pumping at various degrees of heart failure can also be seen.

Note that the events described in [Figure 22-5](#) are the same as those presented in [Figure 22-1](#), although in a more quantitative manner.

Graphic Analysis of Decompensated Cardiac Failure

The black cardiac output curve in [Figure 22-6](#) is the same as the curve shown in [Figure 22-2](#)—a greatly depressed curve that has already reached a degree of recovery as much as this heart can achieve. In this figure, we have added venous return curves that occur during successive days after the acute fall of the cardiac output curve to this low level. At point A, the curve at time zero equates with the normal venous return curve to give a cardiac output of about 3 L/min. However, stimulation of the sympathetic nervous system, caused by this low cardiac output, increases the mean systemic filling pressure within 30 seconds from 7 to 10.5 mm Hg. This effect shifts the venous return curve upward and to the right to produce the curve labeled “autonomic compensation.” Thus, the new venous return curve equates with the cardiac output curve at point B. The cardiac output has been improved to a level of 4 L/min but at the expense of an additional rise in right atrial pressure to 5 mm Hg.

The cardiac output of 4 L/min is still too low for the kidneys to function normally. Therefore, fluid continues to be retained and the mean systemic filling pressure rises from 10.5 to almost 13 mm Hg. Now the venous return curve is labeled “2nd day” and equilibrates with the cardiac output

Figure 22-7 Treatment of decompensated heart disease showing the effect of digitalis in elevating the cardiac output curve, with this in turn causing increased urine output, progressive shift of the venous return curve to the left, and decreased right atrial pressure.

curve at point C. The cardiac output rises to 4.2 L/min, and the right atrial pressure rises to 7 mm Hg.

During the succeeding days, the cardiac output never rises high enough to re-establish normal renal function. Fluid continues to be retained, the mean systemic filling pressure continues to rise, the venous return curve continues to shift to the right, and the equilibrium point between the venous return curve and cardiac output curve also shifts progressively to point D, point E, and finally point F. The equilibration process is now on the downslope of the cardiac output curve, and thus further fluid retention causes even more severe cardiac edema and a detrimental effect on cardiac output. The condition accelerates downhill until death occurs.

Thus, *decompensation* results from the fact that the cardiac output curve never rises to the critical level of 5 L/min needed to re-establish the normal renal excretion of fluid required to result in a balance between fluid input and output.

Treatment of Decompensated Heart Disease With Digitalis. Assume that the stage of decompensation has already reached point E in [Figure 22-6](#), and then proceed to the same point E in [Figure 22-7](#). At this time, digitalis is given to strengthen the heart. This intervention raises the cardiac output curve to the level shown in [Figure 22-7](#), but there is no immediate change in the venous return curve. Therefore, the new cardiac output curve equates with the venous return curve at point G. The cardiac output is now 5.7 L/min, a value higher than the critical level of 5 liters required to make the kidneys excrete normal amounts of urine. The increased cardiac output, along with the well-known diuretic effect of digitalis, permits the kidneys to eliminate some of the excess fluid.

The progressive loss of fluid over a period of several days reduces mean systemic filling pressure down to 11.5 mm Hg, and the new venous return curve becomes the curve labeled “Several days later.” This curve equates with the cardiac output curve of the digitalized heart at point H, at an output of 5 L/min and a right atrial pressure of 4.6 mm Hg. This cardiac output is precisely that required for normal fluid balance. Therefore, no additional fluid will be lost, and none will be gained.

Consequently, the circulatory system has now stabilized or, in other words, the decompensation of the heart failure has been compensated. To state this another way, the final steady-state condition of the circulation is defined by the crossing point of three curves—the cardiac output curve, venous return curve, and the critical level for normal fluid balance. The compensatory mechanisms automatically stabilize the circulation when all three curves cross at the same point.

HEART FAILURE WITH DIASTOLIC DYSFUNCTION AND NORMAL EJECTION FRACTION

Our discussion thus far has focused mainly on cardiac failure due to decreased contractility of the myocardium following a myocardial infarction or impaired coronary blood flow. However, as discussed earlier in the chapter, heart failure can occur from any condition that decreases the heart's ability to pump enough blood to meet the body's needs. Heart failure associated with impaired cardiac contractility is often referred to as *systolic heart failure* or *heart failure with reduced ejection fraction* (HFrEF). As discussed in [Chapter 9](#), the ejection fraction (EF), often assessed by echocardiography, is the fraction of the end-diastolic volume of the left ventricle that is ejected with each contraction. An EF of 0.6 means that 60% of the end-diastolic volume ventricle is pumped with each heartbeat. Normal values for EF are considered to be from 50% to 70%. When the heart muscle is weakened, as a result of a myocardial infarction or impaired coronary blood flow, the EF is usually reduced, with values below 40% considered to be indicative of HFrEF.

Heart failure can also be associated with normal EF if the heart muscle becomes thickened and stiff (*concentric hypertrophy*), so that filling of the ventricles is impaired, and the ventricles hold a smaller than usual volume of blood. Under these conditions, the total amount of blood pumped by the heart may not be enough to meet the body's needs, even though it is pumping with a normal or even increased EF. This condition is often referred to as *heart failure with preserved ejection fraction* (HFpEF).

During the last 30 to 40 years, a growing proportion of heart failure patients have presented with HFpEF. Currently, over 50% of patients with heart failure patients have a normal EF. HFpEF occurs more commonly in women and older adults and especially in those who have obesity, diabetes mellitus, and hypertension, a constellation of disorders often called the *cardiometabolic syndrome*. In these individuals, diastolic dysfunction is characterized by impairment in the rate of ventricular filling, slowed relaxation of cardiomyocytes, increased thickness of the ventricular wall, proliferation of extracellular matrix, and fibrosis, which contribute to a stiffer left ventricle.

Although clinicians often classify patients into the categories of HFpEF or HFrEF using the EF threshold of 50%, most patients with advanced heart failure exhibit

Figure 22-8 Graphic analysis of two types of conditions that can cause high-output cardiac failure—arteriovenous (AV) fistula and beriberi heart disease.

abnormalities of ventricular filling as well as impaired contractility and impaired systolic function. Most of the neurohumoral changes in heart failure that have been discussed, including activation of the sympathetic and renin-angiotensin system, as well as excessive fluid retention by the kidneys, occur regardless of whether there is normal or reduced EF. Heart failure is a heterogeneous syndrome, rather than a specific disease, and occurs whenever the heart is unable to pump enough blood to meet the needs of the body.

Thus, measurements of EF, although useful, do not always provide an accurate assessment of cardiac function. A small thick heart with impaired diastolic filling may be unable to pump the appropriate stroke volume and cardiac output to meet the body's needs but could have a normal or elevated EF. This example illustrates the limitations of left ventricular EF as a marker of left ventricular function and as a means of categorizing patients with heart failure of different causes.

HIGH-OUTPUT CARDIAC FAILURE

[Figure 22-8](#) provides an analysis of two types of high-output cardiac failure. One is caused by an *arteriovenous fistula* that overloads the heart because of excessive venous return, even though the pumping capability of the heart is not depressed. The other type is caused by *beriberi*, in which the venous return is greatly increased because of diminished systemic vascular resistance but, at the same time, the pumping capability of the heart is depressed.

Arteriovenous Fistula Increases Venous Return.

The normal black curves of [Figure 22-8](#) depict the normal cardiac output and normal venous return curves. These curves equate with each other at point A, which depicts a normal cardiac output of 5 L/min and a normal right atrial pressure of 0 mm Hg.

Now let us assume that the systemic vascular resistance (the *total peripheral vascular resistance*) becomes greatly decreased because of the opening of a large arteriovenous

fistula (a direct opening between a large artery and large vein). The venous return curve rotates upward to produce the curve labeled “AV fistula.” This venous return curve equates with the normal cardiac output curve at point B, with a cardiac output of 12.5 L/min and a right atrial pressure of 3 mm Hg. Thus, the cardiac output has become greatly elevated, the right atrial pressure is slightly elevated, and there are mild signs of peripheral congestion. If the person attempts to exercise, he or she will have little cardiac reserve because the heart is already at near-maximum capacity to pump the extra blood through the arteriovenous fistula. This condition resembles a failure condition and is called *high-output failure*, but in reality the heart is overloaded by excess venous return.

Beriberi Weakens the Heart, Causes Fluid Retention by the Kidneys, and Increases Venous Return. **Figure 22-8** shows the approximate changes in the cardiac output and venous return curves caused by *beriberi*. The decreased level of the cardiac output curve is caused by weakening of the heart because of the avitaminosis (mainly lack of thiamine) that causes the beriberi syndrome. The weakening of the heart has decreased the blood flow to the kidneys. Therefore, the kidneys have retained a large amount of fluid, which in turn has increased the mean systemic filling pressure (represented by the point where the venous return curve now intersects the zero cardiac output level) from the normal value of 7 mm Hg up to 11 mm Hg. This has shifted the venous return curve to the right. Finally, the venous return curve has rotated upward from the normal curve because the avitaminosis has dilated the peripheral blood vessels, as explained in **Chapter 17**.

The two blue curves (cardiac output curve and venous return curve) intersect with each other at point C, which describes the circulatory condition in beriberi, with a right atrial pressure in this case of 9 mm Hg and a cardiac output about 65% above normal. This high cardiac output occurs despite the weak heart, as demonstrated by the depressed plateau level of the cardiac output curve.

Heart Valves and Heart Sounds; Valvular and Congenital Heart Defects

Function of the heart valves was discussed in [Chapter 9](#), where we pointed out that *closing* of the valves causes audible sounds. Ordinarily, no audible sounds occur when the valves open. In this chapter, we first discuss the factors that cause the sounds in the heart under normal and abnormal conditions. Then we discuss the overall circulatory changes that occur when valvular or congenital heart defects are present.

HEART SOUNDS

NORMAL HEART SOUNDS

When listening to a normal heart with a stethoscope, one hears a sound usually described as “lub, dub, lub, dub.” The “lub” is associated with closure of the atrioventricular (A-V) valves at the beginning of systole, and the “dub” is associated with closure of the semilunar (aortic and pulmonary) valves at the end of systole. The “lub” sound is called the *first heart sound*, and the “dub” is called the *second heart sound*, because the normal pumping cycle of the heart is considered to start when the A-V valves close at the onset of ventricular systole ([Audio 23-1](#)).

The First Heart Sound Is Associated With Closure of A-V. The main cause of the first heart sound is *vibration of the taut valves immediately after closure*, along with *vibration of the adjacent walls of the heart and major vessels around the heart*. That is, in generating the first heart sound, contraction of the ventricles first causes sudden backflow of blood against the A-V valves (tricuspid and mitral valves), causing them to close and bulge toward the atria until the chordae tendineae abruptly stop the back bulging. The elastic tautness of the chordae tendineae and valves then causes the back-surgling blood to bounce forward again into each respective ventricle. This mechanism causes the blood and the ventricular walls, as well as the taut valves, to vibrate and causes vibrating turbulence in the blood. The vibrations travel through the adjacent tissues to the chest wall, where they can be heard as sound by using the stethoscope.

The Second Heart Sound Is Associated With Closure of the Aortic and Pulmonary Valves. The second heart sound results from sudden closure of the semilunar valves (aortic and pulmonary valves) at the end of systole. When the semilunar valves close, they bulge backward toward the ventricles, and their elastic stretch recoils the blood back into the arteries, which causes a short period of reverberation of blood back and forth between the walls of the arteries and the semilunar valves, as well as between these valves and the ventricular walls. The vibrations occurring in the arterial walls are then transmitted mainly along the arteries. When the vibrations of the vessels or ventricles come into contact with a sounding board, such as the chest wall, they create sound that can be heard using a stethoscope.

Duration and Pitch of First and Second Heart Sounds.

The duration of each of the heart sounds is slightly more than 0.10 second, with the first sound about 0.14 second and the second about 0.11 second. The reason for the shorter second sound is that the semilunar valves are tauter than the A-V valves, so they vibrate for a shorter time than do the A-V valves.

The audible range of frequency (pitch) in the first and second heart sounds, as shown in [Figure 23-1](#), begins at the lowest frequency the ear can detect, about 40 cycles/sec, and goes up above 500 cycles/sec. When a special electronic apparatus is used to record these sounds, a larger proportion of the recorded sound is at frequencies and sound levels below the audible range, going down to 3 to 4 cycles/sec and peaking at about 20 cycles/sec, as illustrated by the lower shaded area in [Figure 23-1](#). For this reason, major portions of the heart sounds can be recorded electronically by phonocardiography, even though they cannot be heard with a stethoscope.

The second heart sound normally has a higher frequency than the first heart sound for two reasons: (1) the tautness of the semilunar valves in comparison with the much less taut A-V valves; and (2) the greater elastic coefficient of the taut arterial walls, which provides the principal vibrating chambers for the second sound, in comparison with the much looser, less elastic ventricular

Figure 23-1 Amplitude of different frequency vibrations in the heart sounds and heart murmurs in relationship to the threshold of audibility, showing that the range of sounds that can be heard is between 40 and 520 cycles/sec. (Modified from Butterworth JS, Chassin JL, McGrath JJ: *Cardiac Auscultation*, 2nd ed. New York: Grune & Stratton, 1960.)

chambers, which provides the vibrating system for the first heart sound. The clinician uses these differences to distinguish special characteristics of the two respective sounds.

The Third Heart Sound Occurs at the Beginning of the Middle Third of Diastole. Occasionally, a weak, rumbling third heart sound is heard at the beginning of the *middle third of diastole*. A logical but unproved explanation of this sound is oscillation of blood back and forth between the walls of the ventricles initiated by inrushing blood from the atria. This is analogous to running water from a faucet into a paper sack, with the inrushing water reverberating back and forth between the walls of the sack to cause vibrations in its walls. The reason the third heart sound does not occur until the middle third of diastole is believed to be that in the early part of diastole, the ventricles are not filled sufficiently to create even the small amount of elastic tension necessary for reverberation. The frequency of this sound is usually so low that the ear cannot hear it, yet it can often be recorded in the phonocardiogram. The third heart sound may be normally present in children, adolescents, and young adults but generally indicates systolic heart failure in older adults.

Atrial Contraction—Fourth Heart Sound. An atrial heart sound can sometimes be recorded in the phonocardiogram, but it can almost never be heard with a stethoscope because of its weakness and very low frequency—usually 20 cycles/sec or less. This sound occurs when the atria contract, and presumably, it is caused by the inrush of blood into the ventricles, which initiates vibrations similar to those of the third heart sound. A fourth heart sound is common in persons who derive benefit from atrial contraction for ventricular filling as a result of decreased ventricular wall compliance and increased resistance to ventricular filling. For example, a fourth heart sound is often heard in older patients with left ventricular hypertrophy.

Figure 23-2 Chest areas from which sounds from each valve are heard best.

Chest Surface Areas for Auscultation of Normal Heart Sounds. Listening to the sounds of the body, usually with the aid of a stethoscope, is called *auscultation*. **Figure 23-2** shows the areas of the chest wall from which the different heart valvular sounds can best be distinguished. Although the sounds from all the valves can be heard from all these areas, the cardiologist distinguishes the sounds from the different valves by a process of elimination. That is, he or she moves the stethoscope from one area to another, noting the loudness of the sounds in different areas and gradually picking out the sound components from each valve.

The areas for listening to the different heart sounds are not directly over the valves themselves. The aortic area is upward along the aorta because of sound transmission up the aorta, and the pulmonic area is upward along the pulmonary artery. The tricuspid area is over the right ventricle, and the mitral area is over the apex of the left ventricle, which is the portion of the heart nearest the surface of the chest; the heart is rotated so that the remainder of the left ventricle lies more posteriorly.

Phonocardiogram. If a microphone specially designed to detect low-frequency sound is placed on the chest, the heart sounds can be amplified and recorded by a high-speed recording apparatus. The recording is called a *phonocardiogram*, and the heart sounds appear as waves, as shown schematically in **Figure 23-3**. Recording A is an example of normal heart sounds, showing the vibrations of the first, second, and third heart sounds and even the very weak atrial sound. Note specifically that the third and atrial heart sounds are each a very low rumble. The third heart sound can be recorded in only one-third to one-half of people, and the atrial heart sound can be recorded in perhaps one-fourth of people.

Figure 23-3 A—F, Phonocardiograms from normal and abnormal hearts.

VALVULAR LESIONS

Rheumatic Valvular Lesions

Rheumatic fever is an autoimmune disease in which the heart valves are likely to be damaged or destroyed. The disease is usually initiated by a streptococcal toxin.

The sequence of events almost always begins with a preliminary streptococcal infection caused specifically by group A hemolytic streptococci. These bacteria initially cause a sore throat, scarlet fever, or middle ear infection. However, the streptococci also release several different proteins against which the person's reticuloendothelial system produces *antibodies*. The antibodies react not only with the streptococcal protein but also with other protein tissues of the body, often causing severe immunologic damage. These reactions continue to take place as long as the antibodies persist in the blood—1 year or more.

Rheumatic fever particularly causes damage in certain susceptible areas, such as the heart valves. The degree of heart valve damage is directly correlated with the concentration and persistence of the antibodies. The principles of immunity that relate to this type of reaction are discussed in [Chapter 35](#), and it is noted in [Chapter 32](#) that acute glomerular nephritis of the kidneys has a similar immunologic basis.

In persons with rheumatic fever, large hemorrhagic, fibrinous, bulbous lesions grow along the inflamed edges of the heart valves. Because the mitral valve undergoes more trauma during valvular action than any of the other valves, it is the one most often seriously damaged, and the aortic valve is the second most frequently damaged. The right heart valves—that is, the tricuspid and pulmonary valves—are usually affected much less severely, probably because the low-pressure stresses that act on these valves are slight compared with the high-pressure stresses that act on the left heart valves.

The lesions of acute rheumatic fever frequently occur on adjacent valve leaflets simultaneously, so the edges of the leaflets become stuck together. Then, weeks, months, or years later, the lesions become scar tissue, permanently fusing portions of adjacent valve leaflets. Also, the free edges of the leaflets, which are normally filmy and free-flapping, often become solid scarred masses.

A valve in which the leaflets adhere to one another so extensively that blood cannot flow through it normally is said to be *stenosed*. Conversely, when the valve edges are so destroyed by scar tissue that they cannot close as the ventricles contract, *regurgitation* (backflow) of blood occurs when the valve should be closed. Stenosis usually does not occur without the coexistence of at least some degree of regurgitation, and vice versa.

Aging and Aortic Valve Stenosis

With aging, the aortic valve often thickens, becomes calcified and stiffer, and may partially obstruct outflow from the left ventricle. With increased life expectancy and aging of the population, *aortic valve stenosis* has become the most common heart valve disease.

Stenosis of a previously normal aortic valve, often called *senile calcific aortic valve stenosis*, is characterized by valve calcium deposition and ossification, which lead to narrowing of the aortic valve orifice. As a compensatory response to the increased workload imposed on the heart by the stenotic aortic valve, the left ventricle undergoes *concentric hypertrophy*. This type of hypertrophy is associated with increased left ventricular wall thickness, which permits the heart to pump with greater vigor against the partially obstructed outflow. An increasing pressure gradient then develops across the calcified valve, reaching 75 to 100 mm Hg in severe cases of aortic valve stenosis.

The hypertrophied left ventricle also becomes more fibrotic and tends to be ischemic because of impaired microcirculatory perfusion, although some patients may also have atherosclerosis of the coronary arteries. The ejection fraction may be normal, and the patient may be able to maintain adequate cardiac output under resting conditions, but with even moderate exercise, symptoms of heart failure may appear. As the stenosis progressively worsens, there are reductions in systolic heart function and inability of the left ventricle to develop enough pressure to pump effectively against the load imposed by the partially obstructed aortic valve. Consequently, symptoms of congestive heart failure appear, with reductions in stroke volume and cardiac output.

Calcific aortic valve stenosis usually does not become severe enough to draw clinical attention until after age 70. Important symptoms of aortic valve stenosis are exertion-related angina, reduced exercise tolerance, and congestive heart failure. Shortness of breath (*dyspnea*) is due to increased left ventricular filling pressure or inability to increase cardiac output adequately with exercise. Early recognition and management of aortic stenosis are

important because untreated symptomatic aortic valve stenosis is progressive and will ultimately be fatal.

The development of transcatheter aortic valve replacement technologies has provided new therapeutic opportunities, especially for older patients, in whom traditional surgical procedures cannot be performed or are associated with high risk.

Heart Murmurs Caused by Valvular Lesions

As shown by the phonocardiograms in **Figure 23-3**, many abnormal heart sounds, known as *heart murmurs*, occur when abnormalities of the valves are present, as discussed here.

Systolic Murmur of Aortic Stenosis. In persons with aortic stenosis, blood is ejected from the left ventricle through only a small fibrous opening of the aortic valve. Because of the resistance to ejection, the blood pressure in the left ventricle sometimes rises as high as 300 mm Hg; the pressure in the aorta is still normal. Thus, a nozzle effect is created *during systole*, with blood jetting at tremendous velocity through the small opening of the valve. This phenomenon causes *severe turbulence* of the blood in the root of the aorta. The turbulent blood impinging against the aortic walls causes intense vibration, and a loud murmur occurs during systole (see recording B, **Figure 23-3**; **Audio 23-2**) and is transmitted throughout the superior thoracic aorta and even into the large arteries of the neck. This sound is harsh, and in persons with severe stenosis it may be so loud that it can be heard several feet away from the patient. Also, the sound vibrations can often be felt with the hand on the upper chest and lower neck, a phenomenon known as a *thrill*.

Diastolic Murmur of Aortic Regurgitation. In aortic regurgitation, no abnormal sound is heard during systole, but *during diastole*, blood flows backward from the high-pressure aorta into the left ventricle, causing a “blowing” murmur of relatively high pitch, with a swishing quality heard maximally over the left ventricle (see recording D, **Figure 23-3**; **Audio 23-3**). This murmur results from the *turbulence* of blood jetting backward into the blood already in the low-pressure diastolic left ventricle.

Systolic Murmur of Mitral Regurgitation. In persons with mitral regurgitation, blood flows backward through the mitral valve into the left atrium *during systole*. This backward flow also causes a high-frequency blowing, swishing sound (see recording C, **Figure 23-3**; **Audio 23-4**) similar to that of aortic regurgitation but occurring during systole rather than diastole. It is transmitted most strongly into the left atrium. However, the left atrium is so deep within the chest that it is difficult to hear this sound directly over the atrium. As a result, the sound of mitral regurgitation is transmitted to the chest wall mainly through the left ventricle to the apex of the heart.

Diastolic Murmur of Mitral Stenosis. In persons with mitral stenosis, blood passes with difficulty through the stenosed mitral valve from the left atrium into the left ventricle, and because the pressure in the left atrium seldom rises above 30 mm Hg, a large pressure differential forcing blood from the left atrium into the left ventricle does not develop. Consequently, the abnormal sounds heard in mitral stenosis (see recording E, **Figure 23-3**; **Audio 23-5**) are usually weak and of very low frequency, so most of the sound spectrum is below the low-frequency end of human hearing.

During the early part of diastole, a left ventricle with a stenotic mitral valve has so little blood in it, and its walls are so flabby, that blood does not reverberate back and forth between the walls of the ventricle. For this reason, even in persons with severe mitral stenosis, no murmur may be heard during the first third of diastole. Then, after partial filling, the ventricle has stretched enough for blood to reverberate, and a low rumbling murmur begins.

Phonocardiograms of Valvular Murmurs. Phonocardiograms B, C, D, and E of **Figure 23-3** show, respectively, idealized records obtained from patients with aortic stenosis, mitral regurgitation, aortic regurgitation, and mitral stenosis. It is obvious from these phonocardiograms that the aortic stenotic lesion causes the loudest murmur, and the mitral stenotic lesion causes the weakest murmur. The phonocardiograms show how the intensity of the murmurs varies during different portions of systole and diastole, and the relative timing of each murmur is also evident. Note especially that the murmurs of aortic stenosis and mitral regurgitation occur only during systole, whereas the murmurs of aortic regurgitation and mitral stenosis occur only during diastole.

ABNORMAL CIRCULATORY DYNAMICS IN VALVULAR HEART DISEASE

CIRCULATORY DYNAMICS IN AORTIC STENOSIS AND AORTIC REGURGITATION

In *aortic stenosis*, the contracting left ventricle fails to empty adequately, whereas in *aortic regurgitation*, blood flows backward into the ventricle from the aorta after the ventricle has just pumped the blood into the aorta. Therefore, in both cases, the *net stroke volume output* of the heart is reduced.

Several important compensations take place that can ameliorate the severity of the circulatory defects. Some of these compensations are described in the following sections.

Hypertrophy of Left Ventricle. In both aortic stenosis and aortic regurgitation, the left ventricular musculature hypertrophies because of the increased ventricular workload. In *regurgitation*, the left ventricular chamber also enlarges to hold all the regurgitant blood from the aorta. This type of hypertrophy, with enlargement of the

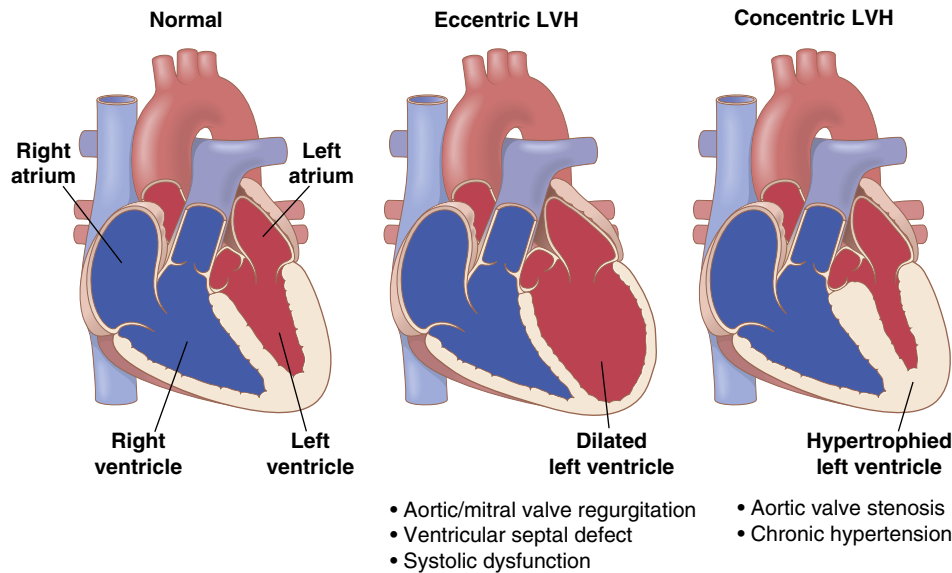

Figure 23-4 Comparison of the left ventricle in a normal heart, a heart with *eccentric* left ventricular hypertrophy (LVH), and a heart with *concentric* LVH. Left ventricular mass increases in eccentric and concentric LVH but there is an increase in left ventricular cavity size in eccentric LVH, whereas wall thickness increases in concentric LVH.

ventricular chamber, is often referred to as *eccentric hypertrophy* (Figure 23-4). Sometimes, the left ventricular muscle mass increases fourfold to fivefold, creating a tremendously large left side of the heart.

When the aortic valve is seriously *stenosed*, the hypertrophied muscle may allow the left ventricle to develop as much as 400 mm Hg of intraventricular pressure at systolic peak. This type of *concentric* hypertrophy is associated with thickened ventricular walls and a smaller ventricular chamber (see Figure 23-4) and also occurs in other circumstances where afterload of the heart is increased, such as in chronic hypertension.

In persons with severe aortic regurgitation, sometimes the enlarged left ventricle can pump a stroke volume output as great as 250 milliliters, although as much as 75% of this blood returns to the ventricle during diastole, and only 25% flows through the aorta to the body.

Increase in Blood Volume. Another effect that helps compensate for the diminished net pumping by the left ventricle is increased blood volume. This increased volume results from the following: (1) an initial slight decrease in arterial pressure; (2) nervous reflexes and hormonal changes induced by the decrease in pressure. These mechanisms together diminish renal output of urine, causing blood volume to increase and the mean arterial pressure to return to normal. Also, red blood cell mass eventually increases because of a slight degree of tissue hypoxia.

The increase in blood volume tends to increase venous return to the heart, which, in turn, causes the left ventricle to pump with the extra power required to overcome the abnormal pumping dynamics.

Aortic Valvular Lesions May Be Associated With Inadequate Coronary Blood Flow. When a person has stenosis of the aortic valve, the ventricular muscle must develop a high tension to create the high intraventricular pressure needed to force blood through the stenosed valve. This

action increases the workload and oxygen consumption of the ventricle, necessitating increased coronary blood flow to deliver this oxygen. The high wall tension of the ventricle, however, causes marked decreases in coronary flow during systole, particularly in the subendocardial vessels. Intraventricular diastolic pressure is also increased when there is aortic valve stenosis, and this increased pressure may cause compression of the inner layers of the heart muscle and reduced coronary blood flow. Thus, severe aortic valve stenosis often causes ischemia of the heart muscle.

With aortic regurgitation, the intraventricular diastolic pressure also increases, compressing the inner layer of the heart muscle and decreasing coronary blood flow. Aortic diastolic pressure decreases during aortic regurgitation, which can also decrease coronary blood flow and cause ischemia of the heart muscle.

Eventual Failure of Left Ventricle and Development of Pulmonary Edema. In the early stages of aortic stenosis or aortic regurgitation, the intrinsic ability of the left ventricle to adapt to increasing loads prevents significant abnormalities in circulatory function in the person during rest, other than the increased work output required of the left ventricle. Therefore, considerable degrees of aortic stenosis or aortic regurgitation often occur before the person knows that he or she has serious heart disease (e.g., a resting left ventricular systolic pressure as high as 200 mm Hg in persons with aortic stenosis or a left ventricular stroke volume output as high as twice normal in persons with aortic regurgitation).

Beyond a critical stage in these aortic valve lesions, the left ventricle finally cannot keep up with the work demand. As a consequence, the left ventricle dilates and cardiac output begins to fall; blood simultaneously dams up in the left atrium and in the lungs behind the failing left ventricle. The left atrial pressure rises progressively, and at mean left atrial pressures above 25 to 40 mm Hg, serious edema appears in the lungs, as discussed in detail in Chapter 39.

DYNAMICS OF MITRAL STENOSIS AND MITRAL REGURGITATION

In persons with mitral stenosis, blood flow from the left atrium into the left ventricle is impeded and, in persons with mitral regurgitation, much of the blood that has flowed into the left ventricle during diastole leaks back into the left atrium during systole rather than being pumped into the aorta. Therefore, either of these conditions reduces net movement of blood from the left atrium into the left ventricle.

Pulmonary Edema in Mitral Valvular Disease. The buildup of blood in the left atrium causes a progressive increase in left atrial pressure, eventually resulting in the development of serious pulmonary edema. Ordinarily, lethal edema does not occur until the mean left atrial pressure rises above 25 mm Hg, and sometimes as high as 40 mm Hg, because the lung lymphatic vessels enlarge many times and can carry fluid rapidly away from the lung tissues.

Enlarged Left Atrium and Atrial Fibrillation. The high left atrial pressure in mitral valvular disease also causes progressive enlargement of the left atrium, which increases the distance that the cardiac electrical excitatory impulse must travel in the atrial wall. This pathway may eventually become so long that it predisposes to the development of excitatory signal *circus movements*, as discussed in [Chapter 13](#). Therefore, in late stages of mitral valvular disease, especially in mitral stenosis, atrial fibrillation often occurs. This development further reduces the pumping effectiveness of the heart and causes further cardiac debility.

Compensation in Early Mitral Valvular Disease. As also occurs in aortic valvular disease and in many types of congenital heart disease, the blood volume increases in mitral valvular disease principally because of diminished excretion of water and salt by the kidneys. This increased blood volume increases venous return to the heart, thereby helping overcome the effect of the cardiac debility. Therefore, after compensation, cardiac output may fall only minimally until the late stages of mitral valvular disease, even though the left atrial pressure is rising.

As the left atrial pressure rises, blood begins to dam up in the lungs, eventually all the way back to the pulmonary artery. In addition, incipient edema of the lungs causes pulmonary arteriolar constriction. These two effects together increase systolic pulmonary arterial pressure and also right ventricular pressure, sometimes to as high as 60 mm Hg, which is more than double normal. This increased pressure, in turn, causes hypertrophy of the right side of the heart, which partially compensates for its increased workload.

CIRCULATORY DYNAMICS DURING EXERCISE IN PATIENTS WITH VALVULAR LESIONS

During exercise, increased blood flow is required to provide additional oxygen and nutrients to the exercising muscles and remove waste products of increased metabolism. Consequently, increased quantities of venous blood are returned to the heart from the peripheral circulation. Therefore, all the dynamic abnormalities that occur in the different types of valvular heart disease become exacerbated. Even in persons with mild valvular heart disease, in which the symptoms may be unrecognizable at rest, severe symptoms often develop during heavy exercise. For example, in patients with aortic valvular lesions, exercise can cause acute left ventricular failure followed by *acute pulmonary edema*. Also, in patients with mitral disease, exercise can cause so much damming of blood in the lungs that serious or even lethal pulmonary edema may ensue in as little as 10 minutes.

Even in mild to moderate cases of valvular disease, the patient's *cardiac reserve* diminishes in proportion to the severity of the valvular dysfunction. That is, the cardiac output does not increase as much as it should during exercise. Therefore, the muscles of the body fatigue rapidly because of too little increase in muscle blood flow.

ABNORMAL CIRCULATORY DYNAMICS IN CONGENITAL HEART DEFECTS

Occasionally, the heart or its associated blood vessels are malformed during fetal life; the defect is called a *congenital anomaly*. There are three major types of congenital anomalies of the heart and its associated vessels: (1) *stenosis* of the channel of blood flow at some point in the heart or in a closely allied major blood vessel; (2) an anomaly that allows blood to flow backward from the left side of the heart or aorta to the right side of the heart or pulmonary artery, thus failing to flow through the systemic circulation, called a *left-to-right shunt*; and (3) an anomaly that allows blood to flow directly from the right side of the heart into the left side of the heart, thus failing to flow through the lungs, called a *right-to-left shunt*.

The effects of the different stenotic lesions are easily understood. For instance, *congenital aortic valve stenosis* results in the same dynamic effects as aortic valve stenosis caused by other valvular lesions, namely, cardiac hypertrophy, heart muscle ischemia, reduced cardiac output, and a tendency to develop serious pulmonary edema.

Another type of congenital stenosis is *coarctation of the aorta*, often occurring above the level of the diaphragm. This stenosis causes the arterial pressure in the upper part of the body (above the level of the coarctation) to be much greater than the pressure in the lower body because of the great resistance to blood flow through the coarctation to the lower body; part of the blood must go around the coarctation through small collateral arteries, as discussed in [Chapter 19](#).

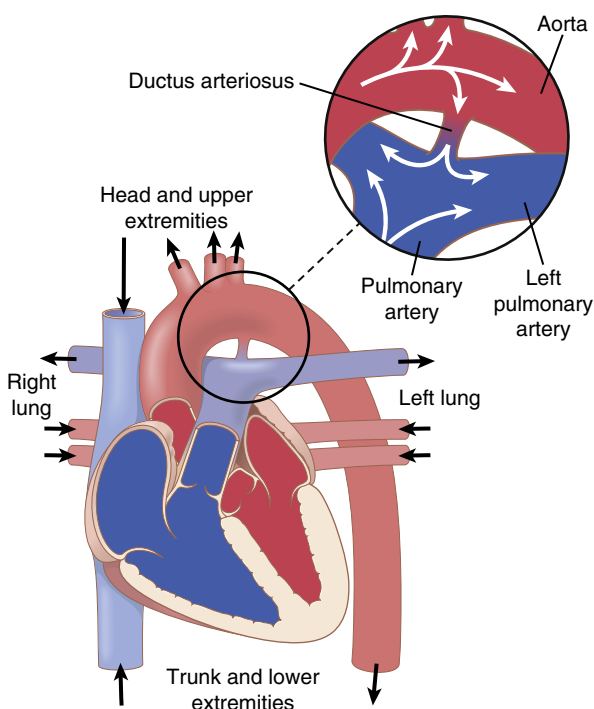

Figure 23-5 Patent ductus arteriosus, showing by the *blue color* that venous blood changes into oxygenated blood at different points in the circulation. *Inset*, Backflow of blood from the aorta into the pulmonary artery and then through the lungs for a second time.

PATENT DUCTUS ARTERIOSUS—A LEFT-TO-RIGHT SHUNT

During fetal life, the lungs are collapsed, and the elastic compression of the lungs that keeps the alveoli collapsed keeps most of the lung blood vessels collapsed as well. Therefore, resistance to blood flow through the lungs is so great that the pulmonary arterial pressure is high in the fetus. Also, because of low resistance to blood flow from the aorta through the large vessels of the placenta, the pressure in the aorta of the fetus is lower than normal—in fact, lower than in the pulmonary artery. This phenomenon causes almost all the pulmonary arterial blood to flow through a special artery present in the fetus that connects the pulmonary artery with the aorta (**Figure 23-5**), the *ductus arteriosus*, thus bypassing the lungs. This mechanism allows immediate recirculation of the blood through the systemic arteries of the fetus without the blood going through the lungs. This lack of blood flow through the lungs is not detrimental to the fetus because the blood is oxygenated by the placenta.

Closure of Ductus Arteriosus After Birth. As soon as a baby is born and begins to breathe, the lungs inflate. Not only do the alveoli fill with air, but also the resistance to blood flow through the pulmonary vascular tree decreases tremendously, allowing the pulmonary arterial pressure to fall. Simultaneously, the aortic pressure rises because of sudden cessation of blood flow from the aorta through the placenta. Thus, the pressure in the pulmonary artery falls, while that in the aorta rises. As a result, forward blood flow

through the ductus arteriosus ceases suddenly at birth and, in fact, blood begins to flow backward through the ductus, from the aorta into the pulmonary artery. This new state of backward blood flow causes the ductus arteriosus to become occluded within a few hours to a few days in most babies, so blood flow through the ductus does not persist. The ductus is believed to close because the oxygen concentration of the aortic blood now flowing through it is about twice as high as that of the blood flowing from the pulmonary artery into the ductus during fetal life. The oxygen presumably constricts the muscle in the ductus wall. This phenomenon is discussed further in Chapter 84.

Unfortunately, in about 1 of every 5500 babies, the ductus does not close, causing the condition known as *patent ductus arteriosus*, which is shown in **Figure 23-5**.

Dynamics of the Circulation With a Persistent Patent Ductus

During the early months of an infant's life, a patent ductus usually does not cause severely abnormal function. However, as the child grows older, the differential between the high pressure in the aorta and the lower pressure in the pulmonary artery progressively increases, with a corresponding increase in the backward flow of blood from the aorta into the pulmonary artery. Also, the high aortic blood pressure usually causes the diameter of the partially open ductus to increase with time, making the condition even worse.

Recirculation Through the Lungs. In an older child with a patent ductus, one-half to two-thirds of the aortic blood flows backward through the ductus into the pulmonary artery, then through the lungs, and finally back into the left ventricle and aorta, passing through the lungs and left side of the heart two or more times for every one time that it passes through the systemic circulation. People with this condition *do not show cyanosis until later in life, when the heart fails or the lungs become congested*. Indeed, early in life, the arterial blood is often better oxygenated than normal because of the extra times that it passes through the lungs.

Diminished Cardiac and Respiratory Reserve. The major effects of patent ductus arteriosus on the patient are decreased cardiac and respiratory reserve. The left ventricle is pumping about two or more times the normal cardiac output, and the maximum that it can pump after hypertrophy of the heart has occurred is about four to seven times normal. Therefore, during exercise, the net blood flow through the remainder of the body can never increase to the levels required for strenuous activity. With even moderately strenuous exercise, the person is likely to become weak and may even faint from momentary heart failure.

The high pressures in the pulmonary vessels caused by excess flow through the lungs may also lead to pulmonary congestion and pulmonary edema. As a result of the excessive load on the heart, and especially because the

pulmonary congestion becomes progressively more severe with age, most patients with uncorrected patent ductus die from heart disease between the ages of 20 and 40 years.

Heart Sounds: Machinery Murmur

In a newborn infant with patent ductus arteriosus, occasionally no abnormal heart sounds are heard because the quantity of reverse blood flow through the ductus may be insufficient to cause a heart murmur. However, as the baby grows older, to 1 to 3 years of age, a harsh blowing murmur begins to be heard in the pulmonary artery area of the chest, as shown in recording F, [Figure 23-3](#). This sound is much more intense during systole when the aortic pressure is high and much less intense during diastole when the aortic pressure falls low, so that the murmur waxes and wanes with each beat of the heart, creating the so-called *machinery murmur*.

Surgical Treatment

Surgical treatment of patent ductus arteriosus (PDA) is simple; one need only ligate the patent ductus or divide it and then close the two ends. This procedure was one of the first successful heart surgeries ever performed. Catheter-based devices often are used to close PDAs in infants or children who are large enough to have the procedure. A small metal coil or other occlusion device is passed up through the catheter and placed in the PDA to block blood flow through the vessel.

TETRALOGY OF FALLOT—A RIGHT-TO-LEFT SHUNT

Tetralogy of Fallot is shown in [Figure 23-6](#); it is the most common cause of *blue baby*. Most of the blood bypasses the lungs, so the aortic blood is mainly unoxygenated venous blood. In this condition, four abnormalities of the heart occur simultaneously:

1. The aorta originates from the right ventricle rather than the left, or it overrides a hole in the septum, as shown in [Figure 23-6](#), receiving blood from both ventricles.
2. Because the pulmonary artery is stenosed, much lower than normal amounts of blood pass from the right ventricle into the lungs; instead, most of the blood passes directly into the aorta, thus bypassing the lungs.
3. Blood from the left ventricle flows through a ventricular septal hole into the right ventricle and then into the aorta or directly into the aorta that overrides this hole.
4. Because the right side of the heart must pump large quantities of blood against the high pressure in the aorta, its musculature is highly developed, causing an enlarged right ventricle.

Abnormal Circulatory Dynamics. It is readily apparent that the major physiological difficulty caused by tetralogy

Figure 23-6 Tetralogy of Fallot, showing by the *blue color* that most of the venous blood is shunted from the right ventricle into the aorta without passing through the lungs.

of Fallot is the shunting of blood past the lungs without its becoming oxygenated. As much as 75% of the venous blood returning to the heart passes directly from the right ventricle into the aorta without becoming oxygenated. This can lead to *cyanosis* (blue coloration) of the baby's skin. Other signs include high right ventricular pressures, right ventricular enlargement, and a left-to-right shunt through the interventricular septum, which can be visualized by echocardiography.

Surgical Treatment. Tetralogy of Fallot can often be treated successfully with surgery. The usual procedure is to open the pulmonary stenosis, close the septal defect, and reconstruct the flow pathway into the aorta. When surgery is successful, the average life expectancy increases from only 3 to 4 years to 50 or more years.

CAUSES OF CONGENITAL ANOMALIES

Congenital heart disease is not uncommon, occurring in about 8 of every 1000 live births. One of the most common causes of congenital heart defects is a viral infection in the mother during the first trimester of pregnancy when the fetal heart is being formed. Defects are particularly prone to develop when the expectant mother contracts German measles (rubella) during the first trimester of pregnancy. Taking certain medications, such as angiotensin-converting enzyme (ACE) inhibitors and acne medications (e.g., isotretinoin), and alcohol or drug abuse during pregnancy also increases the risk for heart defects in the developing fetus.

Some congenital defects of the heart are hereditary because the same defect has been known to occur in

identical twins, as well as in succeeding generations. Children of patients surgically treated for congenital heart disease have about a 10 times greater chance of having congenital heart disease than other children. Congenital defects of the heart are also frequently associated with other congenital defects of the baby's body.

USE OF EXTRACORPOREAL CIRCULATION DURING CARDIAC SURGERY

It is almost impossible to repair intracardiac defects surgically while the heart is still pumping. Therefore, many types of artificial *heart-lung machines* have been developed to take the place of the heart and lungs during the course of an operation. Such a system is called *extracorporeal circulation*. The system consists principally of a pump and an oxygenating device. Almost any type of pump that does not cause hemolysis of the blood seems to be suitable.

Methods used for oxygenating blood include the following: (1) bubbling oxygen through the blood and removing the bubbles from the blood before passing it back into the patient; (2) dripping the blood downward over the surfaces of plastic sheets in the presence of oxygen; (3) passing the blood over surfaces of rotating discs; and (4) passing the blood between thin membranes or through thin tubes that are permeable to oxygen and carbon dioxide.

HYPERTROPHY OF THE HEART IN VALVULAR AND CONGENITAL HEART DISEASE

Hypertrophy of cardiac muscle is one of the most important mechanisms whereby the heart adapts to increased workloads whether these loads are caused by increased pressure against which the heart muscle must contract or by increased cardiac output that must be pumped. One can calculate approximately how much hypertrophy will occur in each chamber of the heart by multiplying the ventricular output by the pressure against which the ventricle must work, with an emphasis on pressure. Thus, hypertrophy occurs in most types of valvular and congenital disease, sometimes causing the heart to weigh as much as 800 grams instead of the normal 300 grams.

Detrimental Effects of Late Stages of Cardiac Hypertrophy. Although the most common cause of cardiac hypertrophy is hypertension, almost all forms of cardiac diseases, including valvular and congenital disease, can stimulate enlargement of the heart.

So-called *physiological cardiac hypertrophy* is generally considered to be a compensatory response of the heart to increased workload and is usually beneficial for maintaining cardiac output in the presence of abnormalities that impair the heart's effectiveness as a pump. However, extreme degrees of hypertrophy can lead to heart failure. One reason

for this is that the coronary vasculature typically does not increase to the same extent as the mass of cardiac muscle increases. The second reason is that fibrosis often develops in the muscle, especially in the subendocardial muscle where the coronary blood flow is poor, with fibrous tissue replacing degenerating muscle fibers. Because of the disproportionate increase in muscle mass relative to coronary blood flow, relative ischemia may develop as the cardiac muscle hypertrophies, and coronary blood flow insufficiency may ensue. Anginal pain is therefore a frequent accompaniment of cardiac hypertrophy associated with valvular and congenital heart disease. Enlargement of the heart is also associated with a greater risk for developing arrhythmias, which in turn can lead to further impairment of cardiac function and sudden death because of fibrillation.

Circulatory Shock and Its Treatment

Circulatory shock means generalized inadequate blood flow through the body to the extent that the body tissues are damaged, especially because too little oxygen and other nutrients are delivered to the tissue cells. Even the cardiovascular system itself—the heart musculature, walls of the blood vessels, vasomotor system, and other circulatory parts—begins to deteriorate, so the shock, once begun, is prone to become progressively worse.

PHYSIOLOGICAL CAUSES OF SHOCK

CIRCULATORY SHOCK CAUSED BY DECREASED CARDIAC OUTPUT

Shock usually results from inadequate cardiac output. Therefore, any condition that reduces the cardiac output far below normal may lead to circulatory shock. Two types of factors can severely reduce cardiac output:

1. *Cardiac abnormalities that decrease the ability of the heart to pump blood.* These abnormalities include in particular myocardial infarction but also toxic states of the heart, severe heart valve dysfunction, heart arrhythmias, and other conditions. The circulatory shock that results from diminished cardiac pumping ability is called *cardiogenic shock*. This condition is discussed in [Chapter 22](#), where it is noted that as many as 70% of people who experience cardiogenic shock do not survive.
2. *Factors that decrease venous return* also decrease cardiac output because the heart cannot pump blood that does not flow into it. The most common cause of decreased venous return is *diminished blood volume*, but venous return can also be reduced as a result of *decreased vascular tone*, especially of the venous blood reservoirs, or *obstruction to blood flow* at some point in the circulation, especially in the venous return pathway to the heart.

CIRCULATORY SHOCK WITHOUT DIMINISHED CARDIAC OUTPUT

Occasionally, cardiac output is normal or even more than normal, yet the person is in a state of circulatory shock.

This situation can result from the following: (1) *excessive metabolic rate, so even a normal cardiac output is inadequate*; or (2) *abnormal tissue perfusion patterns, so most of the cardiac output is passing through blood vessels besides those that supply the local tissues with nutrition.*

The specific causes of shock are discussed later in this chapter. For the present, it is important to note that all of them lead to *inadequate delivery of nutrients to critical tissues and critical organs, as well as inadequate removal of cellular waste products from the tissues.*

WHAT HAPPENS TO THE ARTERIAL PRESSURE IN CIRCULATORY SHOCK?

In the minds of many physicians, the arterial pressure level is the principal measure of adequacy of circulatory function. However, the arterial pressure can often be seriously misleading. At times, a person may be in severe shock and still have an almost normal arterial pressure because of powerful nervous reflexes that keep the pressure from falling. At other times, the arterial pressure can fall to half of normal, but the person still has normal tissue perfusion and is not in shock.

In most types of shock, especially shock caused by severe blood loss, the arterial blood pressure decreases at the same time the cardiac output decreases, although usually not as much.

TISSUE DETERIORATION IS THE END RESULT OF CIRCULATORY SHOCK

Once circulatory shock reaches a critical state of severity, regardless of its initiating cause, *the shock itself leads to more shock*. That is, the inadequate blood flow causes the body tissues to begin deteriorating, including the heart and circulatory system. This deterioration causes even greater decreases in cardiac output, and a vicious cycle ensues, with progressively increasing circulatory shock, less adequate tissue perfusion, and more shock until death occurs. It is with this late stage of circulatory shock that we are especially concerned because appropriate physiological treatment can often reverse the rapid slide to death.

STAGES OF SHOCK

Because the characteristics of circulatory shock change with different degrees of severity, shock is often divided into the following three major stages:

1. A *nonprogressive stage* (sometimes called the *compensated stage*), in which the normal circulatory compensatory mechanisms eventually cause full recovery without help from outside therapy.
2. A *progressive stage*, in which, without therapy, the shock becomes steadily worse until death occurs.
3. An *irreversible stage*, in which the shock has progressed to such an extent that all forms of known therapy are inadequate to save the person's life even though, for the moment, the person is still alive.

We will now discuss the stages of circulatory shock caused by decreased blood volume, which illustrate the basic principles. Then we will consider special characteristics of shock initiated by other causes.

SHOCK CAUSED BY HYPOVOLEMIA—HEMORRHAGIC SHOCK

Hypovolemia means diminished blood volume. Hemorrhage is the most common cause of hypovolemic shock. Hemorrhage *decreases the filling pressure of the circulation* and, as a consequence, decreases venous return. As a result, the cardiac output falls below normal, and shock may ensue.

Relationship of Bleeding Volume to Cardiac Output and Arterial Pressure

Figure 24-1 shows the approximate effects on cardiac output and arterial pressure of removing blood from the circulatory system over a period of about 30 minutes. About 10% of the total blood volume can be removed with almost no effect on arterial pressure or cardiac output, but greater blood loss usually diminishes the cardiac output first and later the arterial pressure, both of which

Figure 24-1 Effect of hemorrhage on cardiac output and arterial pressure.

fall to zero when about 40% to 45% of the total blood volume has been removed.

Sympathetic Reflex Compensations in Shock—Their Special Value to Maintain Arterial Pressure. The decrease in arterial pressure after hemorrhage, as well as decreases in pressures in the pulmonary arteries and veins in the thorax, cause powerful sympathetic reflexes (initiated mainly by the arterial baroreceptors and other vascular stretch receptors, as explained in [Chapter 18](#)). These reflexes stimulate the sympathetic vasoconstrictor system in most tissues of the body, resulting in three important effects:

1. The arterioles constrict in most parts of the systemic circulation, thereby increasing the total peripheral resistance.
2. The veins and venous reservoirs constrict, thereby helping maintain adequate venous return, despite diminished blood volume.
3. Heart activity increases markedly, sometimes increasing the heart rate from the normal value of 72 beats/min to as high as 160 to 180 beats/min.

In the absence of the sympathetic reflexes, only 15% to 20% of the blood volume can be removed over a period of 30 minutes before a person dies; in contrast, a person can sustain a 30% to 40% loss of blood volume when the reflexes are intact. Therefore, these reflexes extend the amount of blood loss that can occur without causing death to about twice that which is possible in their absence.

Greater Effect of Sympathetic Nervous Reflexes in Maintaining Arterial Pressure Than in Maintaining Cardiac Output. Referring again to [Figure 24-1](#), note that the arterial pressure is maintained at or near normal levels in the hemorrhaging person longer than is the cardiac output. The reason for this difference is that the sympathetic reflexes are geared more for maintaining arterial pressure than for maintaining cardiac output. They increase the arterial pressure mainly by increasing the total peripheral resistance, which has no beneficial effect on cardiac output. However, the *sympathetic constriction of the veins is important to keep venous return and cardiac output from falling too much*, in addition to their role in maintaining arterial pressure.

Especially interesting is the second plateau occurring at about 50 mm Hg in the arterial pressure curve of [Figure 24-1](#). This second plateau results from activation of the central nervous system ischemic response, which causes extreme stimulation of the sympathetic nervous system when the brain begins to experience lack of oxygen or excess buildup of carbon dioxide, as discussed in [Chapter 18](#). This effect of the central nervous system ischemic response can be called the “last-ditch stand” of the sympathetic reflexes in their attempt to keep the arterial pressure from falling too low.

Protection of Coronary and Cerebral Blood Flow by the Reflexes. A special value of the maintenance of normal arterial pressure, even in the presence of decreasing cardiac output, is protection of blood flow through the coronary and cerebral circulations. The sympathetic stimulation does not cause significant constriction of the cerebral or cardiac vessels. In addition, in both vascular beds, local blood flow autoregulation is excellent, which prevents moderate decreases in arterial pressure from significantly decreasing their blood flows. Therefore, blood flow through the heart and brain is maintained essentially at normal levels as long as the mean arterial pressure does not fall below about 70 mm Hg, despite the fact that blood flow in some other areas of the body might be decreased to as little as one-third to one-quarter normal by this time because of vasoconstriction.

PROGRESSIVE AND NONPROGRESSIVE HEMORRHAGIC SHOCK

Figure 24-2 shows an experiment that demonstrates the effects of different degrees of sudden acute hemorrhage on the subsequent course of arterial pressure. The animals in this experiment were anesthetized and bled rapidly until their arterial pressures fell to different levels. The animals whose pressures fell immediately to no lower than 45 mm Hg (groups I, II, and III) all eventually recovered; the recovery occurred rapidly if the pressure fell only slightly (group I) but occurred slowly if it fell almost to the 45-mm Hg level (group III). When the arterial pressure fell below 45 mm Hg (groups IV, V, and VI), all the animals died, although many of them hovered between life and death for hours before the circulatory system deteriorated to the stage of death.

This experiment demonstrates that the circulatory system can recover as long as the degree of hemorrhage is no greater than a certain critical amount. Crossing this critical threshold by even a few milliliters of blood loss makes the eventual difference between life and death. Thus, hemorrhage beyond a certain critical level causes shock to become *progressive*. That is, *the shock itself causes still*

more shock, and the condition becomes a vicious cycle that eventually leads to deterioration of the circulation and to death.

Nonprogressive Shock—Compensated Shock

If shock is not severe enough to cause its own progression, the person eventually recovers. Therefore, shock of this lesser degree is called *nonprogressive shock* or *compensated shock*, meaning that the sympathetic reflexes and other factors compensate enough to prevent further deterioration of the circulation.

The factors that cause a person to recover from moderate degrees of shock are the negative feedback control mechanisms of the circulation that attempt to return cardiac output and arterial pressure back to normal levels. They include the following:

1. *Baroreceptor reflexes*, which elicit powerful sympathetic stimulation of the circulation
2. *Central nervous system ischemic response*, which elicits even more powerful sympathetic stimulation throughout the body but is not activated significantly until the arterial pressure falls below 50 mm Hg
3. *Reverse stress-relaxation of the circulatory system*, which causes the blood vessels to contract around the diminished blood volume so that the blood volume that is available more adequately fills the circulation
4. *Increased secretion of renin by the kidneys and formation of angiotensin II*, which constricts the peripheral arterioles and also causes decreased output of water and salt by the kidneys, both of which help prevent progression of shock
5. *Increased secretion by the posterior pituitary gland of vasopressin (antidiuretic hormone)*, which constricts the peripheral arterioles and veins and greatly increases water retention by the kidneys
6. *Increased secretion by the adrenal medullae of epinephrine and norepinephrine*, which constricts the peripheral arterioles and veins and increases the heart rate
7. *Compensatory mechanisms that return the blood volume back toward normal*, including absorption of large quantities of fluid from the intestinal tract, absorption of fluid into the blood capillaries from the interstitial spaces of the body, conservation of water and salt by the kidneys, and increased thirst and increased appetite for salt, which make the person drink water and eat salty foods if they are able to do so

The sympathetic reflexes and increased secretion of catecholamines by the adrenal medullae provide rapid help toward bringing about recovery because they become maximally activated within 30 seconds to a few minutes after hemorrhage.

Figure 24-2 Time course of arterial pressure in dogs after different degrees of acute hemorrhage. Each curve represents average results from six dogs (curves I–VI).

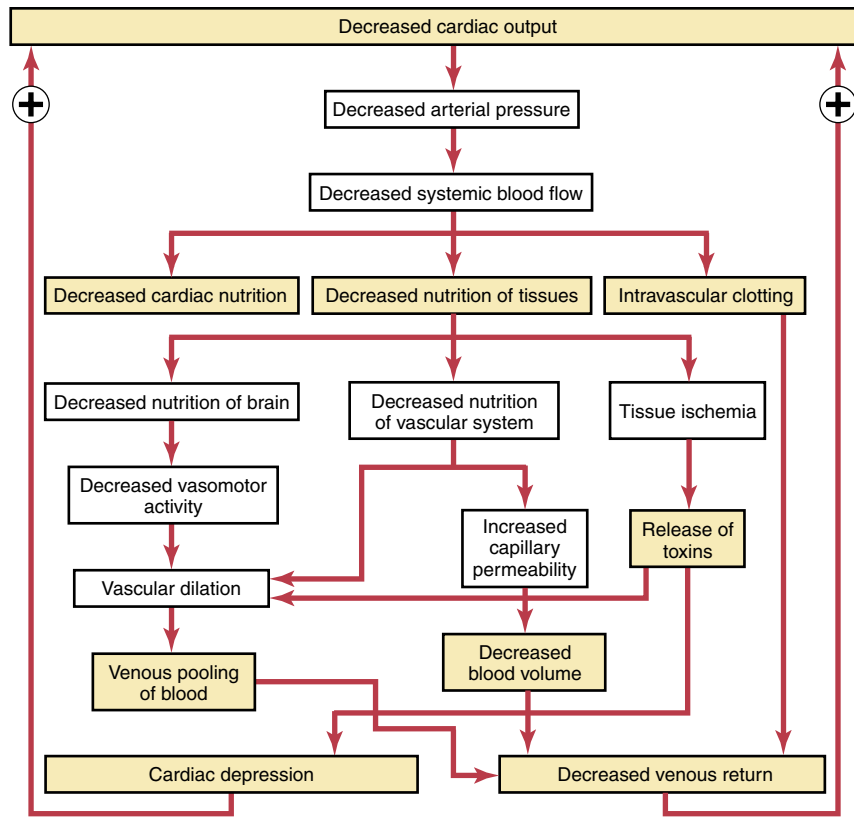

Figure 24-3 Different types of positive feedback that can lead to the progression of shock.

The angiotensin and vasopressin mechanisms, as well as the reverse stress-relaxation that causes contraction of the blood vessels and venous reservoirs, all require 10 to 60 minutes to respond completely, but they aid greatly in increasing the arterial pressure or increasing the circulatory filling pressure, thereby increasing the return of blood to the heart.

Finally, readjustment of blood volume by absorption of fluid from the interstitial spaces and intestinal tract, as well as oral ingestion and absorption of additional quantities of water and salt, may require from 1 to 48 hours, but recovery eventually takes place, provided the shock does not become severe enough to enter the progressive stage.

Progressive Shock—Caused by Vicious Cycle of Cardiovascular Deterioration

Figure 24-3 shows some of the positive feedbacks that further depress cardiac output in shock, thus causing the shock to become progressive. Some of the more important feedbacks are described in the following sections.

Cardiac Depression. When the arterial pressure falls low enough, *coronary blood flow decreases below that required for adequate nutrition of the myocardium*, weakening the heart muscle and decreasing the cardiac output more. Thus, a positive feedback cycle has developed, whereby the shock becomes more and more severe.

Figure 24-4 shows cardiac output curves extrapolated to the human heart from studies in experimental

Figure 24-4 Cardiac output curves of the heart at different times after hemorrhagic shock begins. (These curves have been extrapolated to the human heart from data obtained in dog experiments by Dr. J.W. Crowell.)

animals, demonstrating progressive deterioration of the heart at different times after the onset of shock. An anesthetized animal was bled until the arterial pressure fell to 30 mm Hg, and the pressure was held at this level by further bleeding or retransfusion of blood, as required. Note from the second curve in the figure that there was little deterioration of the heart during the first 2 hours, but by 4 hours, the heart had deteriorated about 40%. Then, rapidly, during the last hour of the experiment (after 4 hours of low coronary blood pressure), the heart deteriorated completely.

Thus, one of the important features of progressive shock, whether it is hemorrhagic in origin or has another cause, is eventual progressive deterioration of the heart. In the early stages of shock, this deterioration plays very little role in the condition of the person, partly because deterioration of the heart is not severe during the first hour or so of shock, but mainly because the heart has reserve capability that normally allows it to pump 300% to 400% more blood than is required by the body for adequate tissue nutrition. In the latest stages of shock, however, deterioration of the heart is probably the most important factor in the final lethal progression of the shock.

Vasomotor Failure. In the early stages of shock, various circulatory reflexes cause intense activity of the sympathetic nervous system. This activity helps delay depression of cardiac output and especially helps prevent decreased arterial pressure. However, there comes a point when diminished blood flow to the brain's vasomotor center depresses the center so much that it, too, becomes progressively less active and, finally, totally inactive. For example, during the first 4 to 8 minutes, *complete circulatory arrest to the brain* causes the most intense of all sympathetic discharges, but by the end of 10 to 15 minutes, the vasomotor center becomes so depressed that no further evidence of sympathetic discharge can be demonstrated. Fortunately, the vasomotor center usually does not fail in the early stages of shock if the arterial pressure remains above 30 mm Hg.

Blockage of Very Small Vessels by Sludged Blood. In time, blockage occurs in many of the very small blood vessels in the circulatory system, and this blockage also causes the shock to progress. The initiating cause of this blockage is sluggish blood flow in the microvessels. Because tissue metabolism continues despite the low flow, large amounts of acid, both carbonic acid and lactic acid, continue to empty into the local blood vessels and greatly increase the local acidity of the blood. This acidic effect, plus other deterioration products from the ischemic tissues, causes local blood agglutination, resulting in minute blood clots and leading to very small plugs in the small vessels. Even if the vessels do not become plugged, an increased tendency for the blood cells to stick to one another makes it more difficult for blood to flow through the microvasculature, giving rise to the term *sludged blood*.

Increased Capillary Permeability. After many hours of capillary hypoxia and lack of other nutrients, the permeability of the capillaries gradually increases, and large quantities of fluid begin to transude into the tissues. This phenomenon decreases the blood volume even more, with a resultant further decrease in cardiac output, making the shock still more severe. Capillary hypoxia does not cause increased capillary permeability until the late stages of prolonged shock.

Release of Toxins by Ischemic Tissue. Shock has been suggested to cause tissues to release toxic substances, such as histamine, serotonin, and tissue enzymes, that cause further deterioration of the circulatory system. Experimental studies have proved the significance of at least one toxin, *endotoxin*, in some types of shock.

Cardiac Depression Caused by Endotoxin. *Endotoxin* is released from the bodies of dead gram-negative bacteria in the intestines. Diminished blood flow to the intestines often causes enhanced formation and absorption of this toxic substance. The circulating toxin then causes increased cellular metabolism, despite inadequate nutrition of the cells, which has a specific effect on the heart muscle, causing *cardiac depression*. Endotoxin can play a major role in some types of shock, especially septic shock, discussed later in this chapter.

Generalized Cellular Deterioration. As shock becomes severe, many signs of generalized cellular deterioration occur throughout the body. One organ especially affected is the *liver*, as illustrated in [Figure 24-5](#). The liver is especially affected mainly because of the lack of enough nutrients to support the normally high rate of metabolism in liver cells, but also partly because of the exposure of the liver cells to any vascular toxin or other abnormal metabolic factor occurring in shock.

Among the damaging cellular effects that are known to occur in most body tissues are the following:

1. Active transport of sodium and potassium through the cell membrane is greatly diminished. As a result, sodium and chloride accumulate in the cells, and potassium is lost from the cells. In addition, the cells begin to swell.

Figure 24-5 Necrosis of the central portion of a liver lobule during severe circulatory shock. (Courtesy Dr. J.W. Crowell.)

- Mitochondrial activity in the liver cells, as well as in many other tissues of the body, becomes severely depressed.
- Lysosomes in the cells in widespread tissue areas begin to break open, with intracellular release of *hydrolases*, which cause further intracellular deterioration.
- Cellular metabolism of nutrients, such as glucose, eventually becomes greatly depressed in the last stages of shock. The actions of some hormones are depressed as well, including almost 100% depression of the actions of insulin.

All these effects contribute to further deterioration of many organs of the body, including especially the following: (1) the *liver*, with depression of its many metabolic and detoxification functions; (2) the *lungs*, with eventual development of pulmonary edema and poor ability to oxygenate the blood; and (3) the *heart*, thereby further depressing its contractility.

Patchy Areas of Tissue Necrosis Caused by Patchy Blood Flows in Different Organs. Not all cells of the body are equally damaged by shock because some tissues have better blood supplies than others. For example, the cells adjacent to the arterial ends of capillaries receive better nutrition than cells adjacent to the venous ends of the same capillaries. Therefore, more nutritive deficiency occurs around the venous ends of capillaries than elsewhere. **Figure 24-5** shows necrosis in the center of a liver lobule, the portion of the lobule that is the last to be exposed to the blood as it passes through the liver sinusoids.

Similar punctate lesions occur in heart muscle, although here a definite repetitive pattern, such as occurs in the liver, cannot be demonstrated. Nevertheless, the cardiac lesions play an important role in leading to the final irreversible stage of shock. Deteriorative lesions also occur in the kidneys, especially in the epithelium of the kidney tubules, leading to kidney failure and occasionally uremic death several days later. Deterioration of the lungs also often leads to respiratory distress and death several days later, called the *shock lung syndrome*.

Acidosis in Shock. Metabolic derangements that occur in shocked tissue can lead to acidosis throughout the body. This results from poor delivery of oxygen to the tissues, which greatly diminishes oxidative metabolism of the foodstuffs. When this occurs, the cells obtain most of their energy by the anaerobic process of glycolysis, which leads to *excess lactic acid* in the blood. In addition, poor blood flow through tissues prevents normal removal of carbon dioxide. The carbon dioxide reacts locally in the cells with water to form high concentrations of intracellular carbonic acid, which, in turn, reacts with various tissue chemicals to form additional intracellular acidic substances. Thus, another deteriorative effect of shock is generalized and local tissue acidosis, leading to further progression of the shock.

Positive Feedback Deterioration of Tissues in Shock and Vicious Cycle of Progressive Shock. All the factors just discussed that can lead to further progression of shock are types of *positive feedback*—that is, each increase in the degree of shock causes a further increase in the shock. However, positive feedback does not necessarily lead to a vicious cycle. Development of a vicious cycle depends on the intensity of the positive feedback. In mild degrees of shock, the negative feedback mechanisms of the circulation, including sympathetic reflexes, reverse stress-relaxation mechanism of the blood reservoirs, and absorption of fluid into the blood from the interstitial spaces, can easily overcome the positive feedback influences and, therefore, cause recovery. In severe shock, however, the deteriorative feedback mechanisms become more and more powerful, leading to such rapid deterioration of the circulation that all the normal negative feedback systems of circulatory control acting together cannot return the cardiac output to normal.

Considering once again the principles of positive feedback and vicious cycles discussed in **Chapter 1**, one can readily understand why there is a critical cardiac output level above which a person in shock recovers and below which a person enters a vicious cycle of circulatory deterioration that proceeds until death.

IRREVERSIBLE SHOCK

After shock has progressed to a certain stage, transfusion or any other type of therapy becomes incapable of saving the person's life. The person is then said to be in the *irreversible stage of shock*. Ironically, even in this irreversible stage, therapy can, on rare occasions, return the arterial pressure and even the cardiac output to normal or near normal for short periods, but the circulatory system nevertheless continues to deteriorate, and death ensues in another few minutes to few hours.

Figure 24-6 shows that transfusion during the irreversible stage can sometimes cause cardiac output (as well as the arterial pressure) to return to nearly normal. However, the cardiac output soon begins to fall again, and subsequent transfusions have less and less effect. By this time, multiple deteriorative changes have occurred in the heart

Figure 24-6 Failure of transfusion to prevent death in irreversible shock.

muscle cells that may not necessarily affect the heart's *immediate* ability to pump blood but, over a long period, depress heart pumping enough to cause death. Beyond a certain point, so much tissue damage has occurred, so many destructive enzymes have been released into the body fluids, so much acidosis has developed, and so many other destructive factors are now in progress that even a normal cardiac output for a few minutes cannot reverse the continuing deterioration. Therefore, in severe shock, a stage is eventually reached at which the person will die, even though vigorous therapy might still return the cardiac output to normal for short periods.

Depletion of Cellular High-Energy Phosphate Reserves in Irreversible Shock. The high-energy phosphate reserves in the tissues of the body, especially in the liver and heart, are greatly diminished in severe shock. Essentially all the *creatine phosphate* has been degraded, and almost all the *adenosine triphosphate* has downgraded to *adenosine diphosphate*, *adenosine monophosphate* and, eventually, *adenosine*. Much of this adenosine then diffuses out of the cells into the circulating blood and is converted into uric acid, a substance that cannot re-enter the cells to reconstitute the adenosine phosphate system. New adenosine can be synthesized at a rate of only about 2% of the normal cellular amount an hour, meaning that once the high-energy phosphate stores of the cells are depleted, they are difficult to replenish.

Thus, one of the most devastating end results in shock, and the one that is perhaps most significant for development of the final state of irreversibility, is cellular depletion of these high-energy compounds.

HYPOVOLEMIC SHOCK CAUSED BY PLASMA LOSS

Loss of plasma from the circulatory system, even without loss of red blood cells, can sometimes be severe enough to reduce the total blood volume markedly, causing typical hypovolemic shock similar in almost all details to that caused by hemorrhage. Severe plasma loss occurs in the following conditions:

1. *Intestinal obstruction* may cause severely reduced plasma volume. Distention of the intestine in intestinal obstruction partly blocks venous blood flow in the intestinal walls, which increases intestinal capillary pressure, causing fluid to leak from the capillaries into the intestinal walls and intestinal lumen. Because the lost fluid has high protein content, the result is reduced total blood plasma protein, as well as reduced plasma volume.
2. *Severe burns or other denuding conditions of the skin* cause loss of plasma through the denuded skin areas so that the plasma volume becomes markedly reduced.

The hypovolemic shock that results from plasma loss has almost the same characteristics as the shock caused

by hemorrhage, except for one additional complicating factor: the blood viscosity increases greatly as a result of increased red blood cell concentration in the remaining blood, and this increase in viscosity exacerbates the sluggishness of blood flow.

Loss of fluid from all fluid compartments of the body is called *dehydration*; this condition can also reduce the blood volume and cause hypovolemic shock similar to that resulting from hemorrhage. Some of the causes of this type of shock are the following: (1) excessive sweating; (2) fluid loss in severe diarrhea or vomiting; (3) excess loss of fluid by the kidneys; (4) inadequate intake of fluid and electrolytes; or (5) destruction of the adrenal cortices, with loss of aldosterone secretion and consequent failure of the kidneys to reabsorb sodium, chloride, and water, which occurs in the absence of the adrenocortical hormone aldosterone.

HYPOVOLEMIC SHOCK CAUSED BY TRAUMA

One of the most common causes of circulatory shock is trauma to the body. Often, the shock results simply from hemorrhage caused by the trauma, but it can also occur even without hemorrhage because extensive contusion of the body can damage the capillaries sufficiently to allow excessive loss of plasma into the tissues. This phenomenon results in greatly reduced plasma volume, with resultant hypovolemic shock.

Various attempts have been made to implicate toxic factors released by the traumatized tissues as one of the causes of shock after trauma. However, cross-transfusion experiments with normal animals have failed to show significant toxic elements. Traumatic shock, therefore, seems to result mainly from hypovolemia, although there might also be a moderate degree of concomitant neurogenic shock caused by loss of vasomotor tone, as discussed next.

NEUROGENIC SHOCK—INCREASED VASCULAR CAPACITY

Shock occasionally occurs without any loss of blood volume. Instead, the *vascular capacity* increases so much that even the normal amount of blood is incapable of filling the circulatory system adequately. One of the major causes of this condition is *sudden loss of vasomotor tone* throughout the body, resulting especially in massive dilation of the veins. The resulting condition is known as *neurogenic shock*.

The role of vascular capacity in helping regulate circulatory function was discussed in [Chapter 15](#), where it was noted that an increase in vascular capacity or a decrease in blood volume *reduces the mean systemic filling pressure*, which reduces venous return to the heart. Diminished venous return caused by vascular dilation is called *venous pooling* of blood.

Causes of Neurogenic Shock. Some neurogenic factors that can cause loss of vasomotor tone include the following:

1. *Deep general anesthesia* often depresses the vasomotor center enough to cause vasomotor paralysis, with resulting neurogenic shock.
2. *Spinal anesthesia*, especially when this extends all the way up the spinal cord, blocks the sympathetic nervous outflow from the nervous system and can be a potent cause of neurogenic shock.
3. *Brain damage* is often a cause of vasomotor paralysis. Many patients who have had a brain concussion or contusion of the basal regions of the brain experience profound neurogenic shock. Also, even though brain ischemia for a few minutes almost always causes extreme vasomotor stimulation and increased blood pressure, prolonged ischemia (lasting >5–10 minutes) can cause the opposite effect—total inactivation of the vasomotor neurons in the brain stem, with a consequent decrease in arterial pressure and development of severe neurogenic shock.

ANAPHYLACTIC SHOCK AND HISTAMINE SHOCK

Anaphylaxis is an allergic condition in which cardiac output and arterial pressure often decrease drastically. This condition is discussed in [Chapter 35](#). It results primarily from an antigen-antibody reaction that rapidly occurs after an antigen to which the person is sensitive enters the circulation. One of the principal effects is to cause the *basophils* in the blood and *mast* cells in the pericapillary tissues to release *histamine* or a *histamine-like substance*. The histamine causes the following: (1) an increase in vascular capacity because of venous dilation, thus causing a marked decrease in venous return; (2) dilation of the arterioles, resulting in greatly reduced arterial pressure; and (3) greatly increased capillary permeability, with rapid loss of fluid and protein into the tissue spaces. The net effect is a great reduction in venous return and, sometimes, such serious shock that the person may die within minutes.

Intravenous injection of large amounts of histamine causes histamine shock, which has characteristics almost identical to those of anaphylactic shock.

SEPTIC SHOCK

Septic shock refers to a bacterial infection widely disseminated to many areas of the body, with the infection being carried through the blood from one tissue to another and causing extensive damage. There are many varieties of septic shock because of the many types of bacterial infections that can cause it, and because infection in different parts of the body produces different effects. Most cases of septic shock, however, are caused by Gram-positive bacteria, followed by endotoxin-producing Gram-negative bacteria.

Septic shock is extremely important to the clinician because, other than cardiogenic shock, septic shock is currently the most frequent cause of shock-related death in the hospital.

Some of the typical causes of septic shock include the following:

1. Peritonitis caused by spread of infection from the uterus and fallopian tubes, sometimes resulting from an instrumental abortion performed under unsterile conditions
2. Peritonitis resulting from rupture of the gastrointestinal system, sometimes caused by intestinal disease or by wounds
3. Generalized bodily infection resulting from spread of a skin infection such as streptococcal or staphylococcal infection
4. Generalized gangrenous infection resulting specifically from gas gangrene bacilli, spreading first through peripheral tissues and finally via the blood to the internal organs, especially the liver
5. Infection spreading into the blood from the kidney or urinary tract, often caused by colon bacilli.

Special Features of Septic Shock. Because of the multiple types of septic shock, it is difficult to categorize this condition. The following features are often observed:

1. High fever
2. Often marked vasodilation throughout the body, especially in the infected tissues
3. High cardiac output in perhaps half of patients, caused by arteriolar dilation in the infected tissues and by high metabolic rate and vasodilation elsewhere in the body, resulting from bacterial toxin stimulation of cellular metabolism and from a high body temperature
4. Sludging of the blood, caused by red cell agglutination in response to degenerating tissues
5. Development of micro-blood clots in widespread areas of the body, a condition called *disseminated intravascular coagulation*; also, this causes the blood clotting factors to be used up, so hemorrhaging occurs in many tissues, especially in the gut wall of the intestinal tract

In early stages of septic shock, the patient usually does not have signs of circulatory collapse but only signs of the bacterial infection. As the infection becomes more severe, the circulatory system usually becomes involved because of direct extension of the infection or secondarily as a result of toxins from the bacteria, with resultant loss of plasma into the infected tissues through deteriorating blood capillary walls. There finally comes a point at which deterioration of the circulation becomes progressive in the same way that progression occurs in all other types of shock. The end stages of septic shock are not greatly different from the end stages of hemorrhagic shock, even though the initiating factors are markedly different in the two conditions.

PHYSIOLOGY OF TREATMENT IN SHOCK

REPLACEMENT THERAPY

Blood and Plasma Transfusion. If a person is in shock caused by hemorrhage, the best possible therapy is usually transfusion of whole blood. If the shock is caused by plasma loss, the best therapy is administration of plasma. When dehydration is the cause, administration of an appropriate electrolyte solution can correct the shock.

Whole blood is not always available, such as under battlefield conditions. Plasma can usually substitute adequately for whole blood because it increases the blood volume and restores normal hemodynamics. Plasma cannot restore a normal hematocrit, but the body can usually stand a decrease in hematocrit to about half of normal before serious consequences result if cardiac output is adequate. Therefore, in emergency conditions, it is reasonable to use plasma in place of whole blood for treatment of hemorrhagic or most other types of hypovolemic shock.

Sometimes, plasma is unavailable. In these cases, various *plasma substitutes* have been developed that perform almost exactly the same hemodynamic functions as plasma. One of these substitutes is dextran solution.

Dextran Solution as a Plasma Substitute. The principal requirement of a truly effective plasma substitute is that it remain in the circulatory system—that is, it does not filter through the capillary pores into the tissue spaces. In addition, the solution must be nontoxic and must contain appropriate electrolytes to prevent derangement of the body's extracellular fluid electrolytes on administration.

To remain in the circulation, the plasma substitute must contain some substance that has a large enough molecular size to exert colloid osmotic pressure. One substance developed for this purpose is *dextran*, a large polysaccharide polymer of glucose. Dextrans of appropriate molecular size do not pass through the capillary pores and, therefore, can replace plasma proteins as colloid osmotic agents.

Few toxic reactions have been observed when using purified dextran to provide colloid osmotic pressure; therefore, solutions containing this substance have been used as a substitute for plasma in fluid replacement therapy.

TREATMENT OF NEUROGENIC AND ANAPHYLACTIC SHOCK WITH SYMPATHOMIMETIC DRUGS

A *sympathomimetic drug* is a drug that mimics sympathetic stimulation. These drugs include *norepinephrine*, *epinephrine*, and a large number of long-acting drugs that have the same basic effects as epinephrine and norepinephrine.

In two types of shock, sympathomimetic drugs have proven to be especially beneficial. The first of these is *neurogenic shock*, in which the sympathetic nervous system is severely depressed. Administering a sympathomimetic

drug takes the place of the diminished sympathetic actions and can often restore full circulatory function.

The second type of shock in which sympathomimetic drugs are valuable is *anaphylactic shock*, in which excess histamine plays a prominent role. The sympathomimetic drugs have a vasoconstrictor effect that opposes the vasodilating effect of histamine. Therefore, epinephrine, norepinephrine, or other sympathomimetic drugs are often lifesaving.

Sympathomimetic drugs have not proved to be very valuable in hemorrhagic shock. The reason is that in this type of shock, the sympathetic nervous system is almost always maximally activated by the circulatory reflexes; so much norepinephrine and epinephrine are already circulating in the blood that sympathomimetic drugs have essentially no additional beneficial effect.

OTHER THERAPY

Treatment by the Head-Down Position. When the pressure falls too low in most types of shock, especially in hemorrhagic and neurogenic shock, placing the patient with the head at least 12 inches lower than the feet helps in promoting venous return, thereby also increasing cardiac output. This head-down position is the first essential step in the treatment of many types of shock.

Oxygen Therapy. Because a major deleterious effect of most types of shock is too little delivery of oxygen to the tissues, giving the patient oxygen to breathe can be of benefit in some cases. However, this intervention frequently is far less beneficial than one might expect because the problem in most types of shock is not inadequate oxygenation of the blood by the lungs but inadequate transport of the blood after it is oxygenated.

Treatment With Glucocorticoids. Glucocorticoids—adrenal cortex hormones that control glucose metabolism—are frequently given to patients in severe shock for several reasons: (1) experiments have shown empirically that glucocorticoids frequently increase the strength of the heart in the late stages of shock; (2) glucocorticoids stabilize lysosomes in tissue cells and thereby prevent the release of lysosomal enzymes into the cytoplasm of the cells, thus preventing deterioration from this source; and (3) glucocorticoids might aid in the metabolism of glucose by the severely damaged cells.

CIRCULATORY ARREST

A condition closely allied to circulatory shock is circulatory arrest, in which all blood flow stops. This condition can occur, for example, as a result of *cardiac arrest* or *ventricular fibrillation*.

Ventricular fibrillation can usually be stopped by strong electroshock of the heart, the basic principles of which are described in [Chapter 13](#).

In the case of complete cardiac arrest, a normal cardiac rhythm can sometimes be restored by immediately applying cardiopulmonary resuscitation procedures while at the same time supplying the patient's lungs with adequate quantities of ventilatory oxygen.

Effect of Circulatory Arrest on the Brain

A special challenge in circulatory arrest is to prevent detrimental effects of the arrest on the brain. In general, more than 5 to 8 minutes of total circulatory arrest can cause at least some degree of permanent brain damage in more than half of patients. Circulatory arrest for as long as 10 to 15 minutes almost always permanently destroys significant amounts of mental capacity.

For many years, it was thought that this detrimental effect on the brain was caused by the acute cerebral hypoxia that occurs during circulatory arrest. However, experiments have shown that if blood clots are prevented from occurring in the blood vessels of the brain, this will also prevent much of the early deterioration of the brain during circulatory arrest. For example, in animal experiments, all the blood was removed from the animal's blood vessels at the beginning of circulatory arrest and then replaced at the end of circulatory arrest so that no intravascular blood clotting could occur. In this experiment, the brain was usually able to withstand up to 30 minutes of circulatory arrest without permanent brain damage. Also, administration of heparin or streptokinase (to prevent blood coagulation) before cardiac arrest was shown to increase the survivability of the brain up to two to four times longer than usual.

Regulation of Body Fluid Compartments: Extracellular and Intracellular Fluids; Edema

The maintenance of a relatively constant volume and stable composition of the body fluids is essential for homeostasis. Some of the most common and important problems in clinical medicine arise because of abnormalities in the control systems that maintain this relative constancy of the body fluids. In this chapter and in the following chapters on the kidneys, we discuss overall regulation of body fluid volume, constituents of the extracellular fluid, acid–base balance, and control of fluid exchange between extracellular and intracellular compartments.

FLUID INTAKE AND OUTPUT ARE BALANCED DURING STEADY-STATE CONDITIONS

The relative constancy of the body fluids is remarkable, because there is continuous exchange of fluid and solutes with the external environment, as well as within the different body compartments. For example, fluid added to the body is highly variable and must be carefully matched by an equal output of water from the body to prevent body fluid volumes from increasing or decreasing.

DAILY INTAKE OF WATER

Water is added to the body by two major sources: (1) it is ingested in the form of liquids or water in food, which together normally add about 2100 ml/day to the body fluids; and (2) it is synthesized in the body by oxidation of carbohydrates, adding about 200 ml/day. These mechanisms provide a total water intake of about 2300 ml/day ([Table 25-1](#)). However, intake of water is highly variable among different people and even within the same person on different days, depending on climate, habits, and level of physical activity.

DAILY LOSS OF BODY WATER

Insensible Water Loss. Some water losses cannot be precisely regulated. For example, humans experience continuous water loss by evaporation from the respiratory tract and diffusion through the skin, which together account for about 700 ml/day of water loss under normal conditions. This loss is termed *insensible water loss* because we

are not consciously aware of it, even though it occurs continually in all living people.

Insensible water loss through the skin occurs independently of sweating and is present even in people who are born without sweat glands; the average water loss by diffusion through the skin is about 300 to 400 ml/day. This loss is minimized by the cholesterol-filled, cornified layer of the skin, which provides a barrier against excessive loss by diffusion. When the cornified layer becomes denuded, as occurs with extensive burns, the rate of evaporation can increase as much as 10-fold, to 3 to 5 L/day. For this reason, persons with burns must be given large amounts of fluid, usually intravenously, to balance fluid loss.

Insensible water loss through the respiratory tract normally averages about 300 to 400 ml/day. As air enters the respiratory tract, it becomes saturated with moisture to a vapor pressure of about 47 mm Hg before it is expelled. Because the vapor pressure of the inspired air is usually less than 47 mm Hg, water is continuously lost through the lungs with respiration. In cold weather, the atmospheric vapor pressure decreases to nearly 0, causing an even greater loss of water from the lungs as the temperature decreases. This process explains the dry feeling in the respiratory passages in cold weather.

Fluid Loss in Sweat. The amount of water lost by sweating is highly variable, depending on physical activity and environmental temperature. The volume of sweat normally is about 100 ml/day, but in very hot weather or during heavy exercise, fluid loss in sweat occasionally increases to 1 to 2 L/hour. This fluid loss would rapidly deplete the body fluids if intake were not also increased by activating the thirst mechanism, as discussed in [Chapter 29](#).

Water Loss in Feces. Only a small amount of water (100 ml/day) normally is lost in the feces. This loss can increase to several liters a day in people with severe diarrhea. Therefore, severe diarrhea can be life-threatening if not corrected within a few days.

Water Loss by the Kidneys. The remaining water loss from the body occurs in the urine excreted by the kidneys. Multiple mechanisms control the rate of urine excretion.

Table 25-1 Daily Intake and Output of Water (ml/day)

Intake or Output	Normal	Prolonged Heavy Exercise
Intake		
Fluids ingested	2100	?
From metabolism	200	200
Total intake	2300	?
Output		
Insensible: skin	350	350
Insensible: lungs	350	650
Sweat	100	5000
Feces	100	100
Urine	1400	500
Total output	2300	6600

The most important means whereby the body maintains balance between water intake and output, as well as a balance between intake and output of most electrolytes in the body, is by controlling the rate at which the kidneys excrete these substances. For example, urine volume can be as low as 0.5 L/day in a dehydrated person or as high as 20 L/day in a person who has been drinking tremendous amounts of water.

This variability of intake is also true for most of the electrolytes of the body, such as sodium, chloride, and potassium. In some people, sodium intake may be as low as 20 mEq/day, whereas in others, sodium intake may be as high as 300 to 500 mEq/day. The kidneys have the task of adjusting the excretion rate of water and electrolytes to match the intake of these substances precisely, as well as compensating for excessive losses of fluids and electrolytes that occur in certain disease states. In [Chapters 26 through 32](#), we discuss the mechanisms that allow the kidneys to perform these remarkable tasks.

BODY FLUID COMPARTMENTS

The total body fluid is distributed mainly between two compartments, the *extracellular fluid* and the *intracellular fluid* ([Figure 25-1](#)). The extracellular fluid is divided into the *interstitial fluid* and the blood *plasma*.

There is another small compartment of fluid that is referred to as *transcellular fluid*. This compartment includes fluid in the synovial, peritoneal, pericardial, and intraocular spaces, as well as the cerebrospinal fluid; it is usually considered to be a specialized type of extracellular fluid, although in some cases its composition may differ markedly from that of the plasma or interstitial fluid. All the transcellular fluids together constitute about 1 to 2 liters.

In a 70-kg adult man, the total body water is about 60% of the body weight, or about 42 liters. This percentage depends on age, sex, and degree of obesity. As a person grows older, the percentage of total body weight that is fluid gradually decreases. This decrease is due in part to

Figure 25-1. Summary of body fluid regulation, including the major body fluid compartments and the membranes that separate these compartments. The values shown are for an average 70-kg man.

the fact that aging is usually associated with an increased percentage of the body weight being fat, which decreases the percentage of water in the body.

Because women normally have a greater percentage of body fat compared with men, their total body water averages about 50% of the body weight. In premature and newborn babies, the total body water ranges from 70% to 75% of body weight. Therefore, when discussing average body fluid compartments, we should realize that variations exist, depending on age, sex, and percentage of body fat.

In many other countries, the average body weight (and fat mass) has increased rapidly during the past 30 years. The average body weight for adult men older than 20 years in the United States is estimated to be approximately 88.8 kg (~196 pounds), and for adult women it is 77.4 kg (~170 pounds). Therefore, data discussed for an average 70-kg man in this and other chapters would need to be adjusted accordingly when considering body fluid compartments in most people.

INTRACELLULAR FLUID COMPARTMENT

About 28 of the 42 liters of fluid in the body are inside the trillions of cells and is collectively called the *intracellular fluid*. Thus, the intracellular fluid constitutes about 40% of the total body weight in an “average” person.

The fluid of each cell contains its individual mixture of different constituents, but the concentrations of these substances are similar from one cell to another. In fact, the composition of cell fluids is remarkably similar, even in different animals, ranging from the most primitive

microorganisms to humans. For this reason, the intracellular fluid of all the different cells together is considered to be one large fluid compartment.

EXTRACELLULAR FLUID COMPARTMENT

All the fluids outside the cells are collectively called the *extracellular fluid*. Together these fluids account for about 20% of the body weight, or about 14 liters in a 70-kg man. The two largest compartments of the extracellular fluid are the *interstitial fluid*, which makes up more than three-fourths (11 liters) of the extracellular fluid, and the *plasma*, which makes up almost one-fourth of the extracellular fluid, or about 3 liters. The plasma is the noncellular part of the blood; it exchanges substances continuously with the interstitial fluid through the pores of the capillary membranes. These pores are highly permeable to almost all solutes in the extracellular fluid, except the proteins. Therefore, the extracellular fluids are constantly mixing, so the plasma and interstitial fluids have about the same composition, except for proteins, which have a higher concentration in the plasma.

BLOOD VOLUME

Blood contains extracellular fluid (the fluid in plasma) and intracellular fluid (the fluid in the red blood cells). However, blood is considered to be a separate fluid compartment because it is contained in a chamber of its own, the circulatory system. The blood volume is especially important in the control of cardiovascular dynamics.

The average blood volume of adults is about 7% of body weight, or about 5 liters. About 60% of the blood is plasma and 40% is red blood cells, but these percentages can vary considerably in different people, depending on sex, weight, and other factors.

Hematocrit (Packed Red Blood Cell Volume). The hematocrit is the fraction of the blood composed of red blood cells, as determined by centrifuging blood in a hematocrit tube until the cells become tightly packed in the bottom of the tube. Because the centrifuge does not completely pack the red blood cells together, about 3% to 4% of the plasma remains entrapped among the cells, and the true hematocrit is only about 96% of the measured hematocrit.

In men, the measured hematocrit is normally about 0.40, and in women, it is about 0.36. In persons with severe *anemia*, the hematocrit may fall as low as 0.10, a value that is barely sufficient to sustain life. Conversely, in persons with some conditions, excessive production of red blood cells occurs, resulting in *polycythemia*. In these persons, the hematocrit can rise to 0.65.

CONSTITUENTS OF EXTRACELLULAR AND INTRACELLULAR FLUIDS

Comparisons of the composition of the extracellular fluid, including the plasma and interstitial fluid, and the

Figure 25-2. Major cations and anions of the intracellular and extracellular fluids. The concentrations of Ca²⁺ and Mg²⁺ represent the sum of these two ions. The concentrations shown represent the total of free ions and complexed ions.

ionic composition is similar. The most important difference between these two compartments is the higher concentration of protein in the plasma; because the capillaries have a low permeability to the plasma proteins, only small amounts of proteins are leaked into the interstitial spaces in most tissues.

Because of the *Donnan effect*, the concentration of positively charged ions (cations) is slightly greater (~2%) in plasma than in interstitial fluid. Plasma proteins have a net negative charge and therefore tend to bind cations such as sodium and potassium ions, thus holding extra amounts of these cations in the plasma, along with the plasma proteins. Conversely, negatively charged ions (anions) tend to have a slightly higher concentration in interstitial fluid compared with plasma because the negative charges of the plasma proteins repel the negatively charged anions. For practical purposes, however, the concentrations of ions in interstitial fluid and plasma are considered to be about equal.

Referring again to **Figure 25-2**, one can see that the extracellular fluid, including the plasma and interstitial

Figure 25-4. Indicator-dilution method for measuring fluid volumes.

fluid, contains large amounts of sodium and chloride ions and reasonably large amounts of bicarbonate ions but only small quantities of potassium, calcium, magnesium, phosphate, and organic acid ions. The composition of extracellular fluid is carefully regulated by various mechanisms, but especially by the kidneys, as discussed later. This regulation allows the cells to remain continually bathed in a fluid that contains the proper concentration of electrolytes and nutrients for optimal cell function.

INTRACELLULAR FLUID CONSTITUENTS

The intracellular fluid is separated from the extracellular fluid by a cell membrane that is highly permeable to water but is not permeable to most electrolytes in the body. In contrast to the extracellular fluid, the intracellular fluid contains only small quantities of sodium and chloride ions and almost no calcium ions. Instead, it contains large amounts of potassium and phosphate ions plus moderate quantities of magnesium and sulfate ions, all of which have low concentrations in the extracellular fluid. Also, cells contain large amounts of protein—almost four times as much as in the plasma.

MEASUREMENT OF BODY FLUID COMPARTMENT VOLUMES—INDICATOR-DILUTION PRINCIPLE

The volume of a fluid compartment in the body can be measured by placing an indicator substance in the compartment, allowing it to disperse evenly throughout the compartment's fluid, and then analyzing the extent to which the substance becomes diluted. **Figure 25-4** shows this *indicator-dilution method* of measuring the volume of a fluid compartment. This method is based on the conservation of mass principle, which means that the total mass of a substance after dispersion in the fluid

compartment will be the same as the total mass injected into the compartment.

In the example shown in **Figure 25-4**, a small amount of dye or other substance contained in the syringe is injected into a chamber, and the substance is allowed to disperse throughout the chamber until it becomes mixed in equal concentrations in all areas. Then a sample of fluid containing the dispersed substance is removed, and the concentration is analyzed chemically, photoelectrically, or by other means. If none of the substance leaks out of the compartment, the total mass of substance in the compartment (Volume B \times Concentration B) will equal the total mass of the substance injected (Volume A \times Concentration A). By simple rearrangement of the equation, one can calculate the unknown volume of chamber B as follows:

$$\text{Volume B} = \frac{\text{Volume A} \times \text{Concentration A}}{\text{Concentration B}}$$

For this calculation, one needs to know the following: (1) the total amount of substance injected into the chamber (the numerator of the equation); and (2) the concentration of the fluid in the chamber after the substance has been dispersed (the denominator).

For example, if 1 milliliter of a solution containing 10 mg/ml of dye is dispersed into chamber B, and the final concentration in the chamber is 0.01 mg/ml of fluid, the unknown volume of the chamber can be calculated as follows:

$$\text{Volume B} = \frac{1 \text{ ml} \times 10 \text{ mg/ml}}{0.01 \text{ mg/ml}} = 1000 \text{ ml}$$

This method can be used to measure the volume of virtually any compartment in the body as long as the following occur: (1) the indicator disperses *evenly* throughout the compartment; (2) the indicator disperses *only* in the compartment that is being measured; and (3) the indicator is *not metabolized or excreted*. If the indicator is metabolized or excreted, correction must be made for loss of the indicator from the body. Several substances can be used to measure the volume of each of the different body fluids.

DETERMINATION OF VOLUMES OF SPECIFIC BODY FLUID COMPARTMENTS

Measurement of Total Body Water. Radioactive water (tritium, $^3\text{H}_2\text{O}$) or heavy water (deuterium, $^2\text{H}_2\text{O}$) can be used to measure total body water. These forms of water mix with the total body water within a few hours after being injected into the blood, and the dilution principle can be used to calculate total body water (**Table 25-3**). Another substance that has been used to measure total body water is *antipyrine*, which is very lipid-soluble, rapidly penetrates cell membranes, and distributes uniformly throughout the intracellular and extracellular compartments.

Table 25-3 Measurement of Body Fluid Volumes

Volume	Indicators
Total body water	$^3\text{H}_2\text{O}$, $^2\text{H}_2\text{O}$, antipyrine
Extracellular fluid	^{22}Na , ^{125}I -iothalamate, thiosulfate, inulin
Intracellular fluid	(Calculated as total body water—extracellular fluid volume)
Plasma volume	^{125}I -albumin, Evans blue dye (T-1824)
Blood volume	^{51}Cr -labeled red blood cells, or calculated as blood volume = plasma volume/(1 – hematocrit)
Interstitial fluid	Calculated as extracellular fluid volume – plasma volume

Measurement of Extracellular Fluid Volume. The volume of extracellular fluid can be estimated using any of several substances that disperse in the plasma and interstitial fluid but do not readily permeate the cell membrane. These include radioactive sodium, radioactive chloride, radioactive iothalamate, thiosulfate ion, and inulin. When any one of these substances is injected into the blood, it usually disperses almost completely throughout the extracellular fluid within 30 to 60 minutes. Some of these substances, however, such as radioactive sodium, may diffuse into the cells in small amounts. Therefore, one frequently speaks of the *sodium space* or *inulin space* instead of calling the measurement the true extracellular fluid volume.

Calculation of Intracellular Volume. The intracellular volume cannot be measured directly. However, it can be calculated as follows:

$$\begin{aligned} \text{Intracellular volume} \\ &= \text{Total body water} - \text{Extracellular volume} \end{aligned}$$

Measurement of Plasma Volume. Plasma volume can be measured using a substance that does not readily penetrate capillary membranes but remains in the vascular system after injection. One of the most commonly used substances for measuring plasma volume is serum albumin labeled with radioactive iodine (^{125}I -albumin) or with a dye that avidly binds to the plasma proteins, such as *Evans blue dye* (also called *T-1824*).

Calculation of Interstitial Fluid Volume. Interstitial fluid volume cannot be measured directly, but it can be calculated as follows:

$$\begin{aligned} \text{Interstitial fluid volume} \\ &= \text{Extracellular fluid volume} - \text{Plasma volume} \end{aligned}$$

Measurement of Blood Volume. If one measures the *hematocrit* (the fraction of the total blood volume composed of cells) and plasma volume using the methods described earlier, blood volume can also be calculated using the following equation:

$$\text{Total blood volume} = \frac{\text{Plasma volume}}{1 - \text{Hematocrit}}$$

For example, if the plasma volume is 3 liters and hematocrit is 0.40, the total blood volume would be calculated as follows:

$$\frac{3 \text{ liters}}{1 - 0.4} = 5 \text{ liters}$$

Another way to measure blood volume is to inject red blood cells that have been labeled with radioactive material into the circulation. After these mix in the circulation, the radioactivity of a mixed blood sample can be measured, and the total blood volume can be calculated using the indicator-dilution principle. One substance that can be used to label the red blood cells is radioactive chromium (^{51}Cr), which binds tightly with the red blood cells.

FLUID EXCHANGE AND OSMOTIC EQUILIBRIUM BETWEEN INTRACELLULAR AND EXTRACELLULAR FLUID

A frequent problem in treating seriously ill patients is maintaining adequate fluids in one or both of the intracellular and extracellular compartments. As discussed in [Chapter 16](#) and later in this chapter, the relative amounts of extracellular fluid distributed between the plasma and interstitial spaces are determined mainly by the balance of hydrostatic and colloid osmotic forces across the capillary membranes.

The distribution of fluid between intracellular and extracellular compartments, in contrast, is determined mainly by the osmotic effect of smaller solutes—especially sodium, chloride, and other electrolytes—acting across the cell membrane. The reason for this is that the cell membranes are highly permeable to water but relatively impermeable to even small ions such as sodium and chloride. Therefore, water moves across the cell membrane rapidly, and the intracellular fluid remains isotonic with the extracellular fluid.

In the next section, we discuss the interrelations between intracellular and extracellular fluid volumes and the osmotic factors that can cause shifts of fluid between these two compartments.

BASIC PRINCIPLES OF OSMOSIS AND OSMOTIC PRESSURE

The basic principles of osmosis and osmotic pressure were presented in [Chapter 4](#). Therefore, we review here only the most important aspects of these principles as they apply to volume regulation.

Because cell membranes are relatively impermeable to most solutes but are highly permeable to water (i.e., they are selectively permeable), whenever there is a higher concentration of solute on one side of the cell membrane, water diffuses across the membrane toward the region of higher solute concentration. Thus, if a solute such as sodium chloride is added to the extracellular fluid, water rapidly diffuses from the cells through the cell membranes

into the extracellular fluid until the water concentration on both sides of the membrane becomes equal. Conversely, if a solute such as sodium chloride is removed from the extracellular fluid, water diffuses from the extracellular fluid through the cell membranes and into the cells.

Osmolality and Osmolarity. The osmolal concentration of a solution is called *osmolality* when the concentration is expressed as *osmoles per kilogram of water*; it is called *osmolarity* when it is expressed as *osmoles per liter of solution*. In dilute solutions such as the body fluids, these two terms can be used almost synonymously because the differences are small. Most of the calculations used clinically and the calculations expressed in the next several chapters are based on osmolarities rather than osmolalities.

Calculation of the Osmolarity and Osmotic Pressure of a Solution. Using the van't Hoff law, one can calculate the potential osmotic pressure of a solution, assuming that the cell membrane is impermeable to the solute. For example, the osmotic pressure of a 0.9% sodium chloride solution is calculated as follows. A 0.9% solution means that there is 0.9 gram of sodium chloride per 100 milliliters of solution, or 9 g/L. Because the molecular weight of sodium chloride is 58.5 g/mol, the molarity of the solution is 9 g/L divided by 58.5 g/mol, or about 0.154 mol/L. Because each molecule of sodium chloride is equal to 2 osmoles, the osmolarity of the solution is 0.154×2 , or 0.308 Osm/L. Therefore, the osmolarity of this solution is 308 mOsm/L. The potential osmotic pressure of this solution would therefore be $308 \text{ mOsm/L} \times 19.3 \text{ mm Hg/mOsm/L}$, or 5944 mm Hg.

This calculation is an approximation, because sodium and chloride ions do not behave entirely independently in solution as a result of interionic attraction between them. One can correct for these deviations from the predictions of van't Hoff's law by using a correction factor called the *osmotic coefficient*. For sodium chloride, the osmotic coefficient is about 0.93. Therefore, the actual osmolarity of a 0.9% sodium chloride solution is 308×0.93 , or about 286 mOsm/L. For practical reasons, the osmotic coefficients of different solutes are sometimes neglected in determining the osmolarity and osmotic pressures of physiologic solutions.

Osmolarity of Body Fluids. Referring back to [Table 25-2](#), note the approximate osmolarity of the various osmotically active substances in plasma, interstitial fluid, and intracellular fluid. About 80% of the total osmolarity of the interstitial fluid and plasma is due to sodium and chloride ions, whereas for intracellular fluid, almost half the osmolarity is due to potassium ions, and the remainder is divided among many other intracellular substances.

As shown in [Table 25-2](#), the total osmolarity of each of the three compartments is about 300 mOsm/L, with the plasma being about 1 mOsm/L greater than that of the interstitial and intracellular fluids. The slight difference between plasma and interstitial fluid is caused by the osmotic effects of the plasma proteins, which maintain

about 20 mm Hg greater pressure in the capillaries than in the surrounding interstitial spaces, as discussed in Chapter 16.

Corrected Osmolar Activity of Body Fluids. At the bottom of Table 25-2 are shown *corrected osmolar activities* of plasma, interstitial fluid, and intracellular fluid. The reason for these corrections is that cations and anions exert interionic attraction, which can cause a slight decrease in the osmotic activity of the dissolved substances.

Osmotic Equilibrium Between Intracellular and Extracellular Fluids

High osmotic pressures can develop across the cell membrane with relatively small changes in the concentrations of solutes in the extracellular fluid. As discussed earlier, for each milliosmole concentration gradient of an *impermeant solute* (one that will not permeate the cell membrane), about 19.3 mm Hg of osmotic pressure is exerted across the cell membrane. If the cell membrane is exposed to pure water, and the osmolarity of intracellular fluid is 282 mOsm/L, the potential osmotic pressure that can develop across the cell membrane is more than 5400 mm Hg. This demonstrates the large force that can move water across the cell membrane when the intracellular and extracellular fluids are not in osmotic equilibrium. As a result of these forces, relatively small changes in the concentration of impermeant solutes in the extracellular fluid can cause large changes in cell volume.

Isotonic, Hypotonic, and Hypertonic Fluids. The effects of different concentrations of impermeant solutes in the extracellular fluid on cell volume are shown in Figure 25-5. If a cell is placed in a solution of impermeant solutes having an osmolarity of 282 mOsm/L, the cells will not

shrink or swell because the water concentration in the intracellular and extracellular fluids is equal, and the solutes cannot enter or leave the cell. Such a solution is said to be *isotonic* because it neither shrinks nor swells the cells. Examples of isotonic solutions include a 0.9% solution of sodium chloride or a 5% glucose solution. These solutions are important in clinical medicine because they can be infused into the blood without the danger of upsetting the osmotic equilibrium between the intracellular and extracellular fluids.

If a cell is placed into a *hypotonic* solution that has a lower concentration of impermeant solutes (<282 mOsm/L), water will diffuse into the cell, causing it to swell; water will continue to diffuse into the cell, diluting the intracellular fluid while also concentrating the extracellular fluid until both solutions have about the same osmolarity. Solutions of sodium chloride with a concentration of less than 0.9% are hypotonic and cause cells to swell.

If a cell is placed in a *hypertonic* solution having a higher concentration of impermeant solutes, water will flow out of the cell into the extracellular fluid, concentrating the intracellular fluid and diluting the extracellular fluid. In this case, the cell will shrink until the two concentrations become equal. Sodium chloride solutions of more than 0.9% are hypertonic.

Isosmotic, Hyperosmotic, and Hypo-Osmotic Fluids. The terms *isotonic*, *hypotonic*, and *hypertonic* refer to whether solutions will cause a change in cell volume. The tonicity of solutions depends on the concentration of impermeant solutes. Some solutes, however, can permeate the cell membrane. Solutions with an osmolarity the same as the cell are called *isosmotic*, regardless of whether the solute can penetrate the cell membrane.

The terms *hyperosmotic* and *hypo-osmotic* refer to solutions that have a higher or lower osmolarity, respectively, compared with the normal extracellular fluid, without regard for whether the solute permeates the cell membrane. Highly permeating substances, such as urea, can cause transient shifts in fluid volume between the intracellular and extracellular fluids but, given enough time, the concentrations of these substances eventually become equal in the two compartments and have little effect on intracellular volume under steady-state conditions.

Osmotic Equilibrium Between Intracellular and Extracellular Fluids Is Rapidly Attained. Transfer of fluid across the cell membrane occurs so rapidly that any differences in osmolarities between these two compartments are usually corrected within seconds or, at the most, minutes. This rapid movement of water across the cell membrane does not mean that complete equilibrium occurs between the intracellular and extracellular compartments throughout the whole body within the same short period. This is because fluid usually enters the body through the gut and must be transported by the blood to all tissues before complete osmotic equilibrium can occur.

Figure 25-5. Effects of isotonic (A), hypertonic (B), and hypotonic (C) solutions on cell volume.

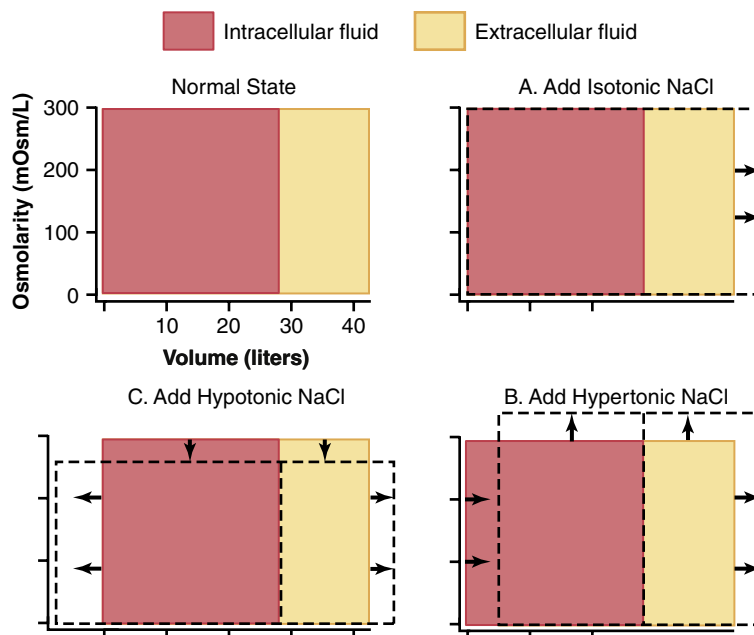

Figure 25-6. Effect of adding isotonic (A), hypertonic (B), and hypotonic solutions (A) to the extracellular fluid after osmotic equilibrium. The normal state is indicated by the *solid lines*, and the shifts from normal are shown by the *shaded areas*. The volumes of intracellular and extracellular fluid compartments are shown in the abscissa of each diagram, and the osmolarities of these compartments are shown on the ordinates.

It usually takes about 30 minutes to achieve osmotic equilibrium everywhere in the body after drinking water.

VOLUME AND OSMOLALITY OF EXTRACELLULAR AND INTRACELLULAR FLUIDS IN ABNORMAL STATES

Some of the different factors that can cause extracellular and intracellular volumes to change markedly are excess ingestion or renal retention of water, dehydration, intravenous infusion of different types of solutions, loss of large amounts of fluid from the gastrointestinal tract, and loss of abnormal amounts of fluid by sweating or through the kidneys.

The changes in intracellular and extracellular fluid volumes and the types of therapy that should be instituted can be calculated if the following basic principles are kept in mind:

1. *Water moves rapidly across cell membranes;* therefore, the osmolarities of intracellular and extracellular fluids remain almost exactly equal to each other, except for a few minutes after a change in one of the compartments.
2. *Cell membranes are almost completely impermeable to many solutes,* such as sodium and chloride; therefore, the number of osmoles in the extracellular or intracellular fluid generally remains relatively constant unless solutes are added to or lost from the extracellular compartment.

With these basic principles in mind, we can analyze the effects of different abnormal fluid conditions on extracellular and intracellular fluid volumes and osmolarities.

Effect of Adding Saline Solution to the Extracellular Fluid

If *isotonic* saline is added to the extracellular fluid compartment, the osmolarity of the extracellular fluid does not change. The main effect is an increase in extracellular fluid volume (Figure 25-6A). The sodium and chloride largely remain in the extracellular fluid because the cell membrane behaves as though it were virtually impermeable to the sodium chloride.

If a *hypertonic* solution is added to the extracellular fluid, the extracellular osmolarity increases and causes osmosis of water out of the cells and into the extracellular compartment (see Figure 25-6B). Again, almost all the added sodium chloride remains in the extracellular compartment, and fluid diffuses from the cells into the extracellular space to achieve osmotic equilibrium. The net effect is an increase in extracellular volume (greater than the volume of fluid added), a decrease in intracellular volume, and a rise in osmolarity in both compartments.

If a *hypotonic* solution is added to the extracellular fluid, the osmolarity of the extracellular fluid decreases, and some of the extracellular water diffuses into the cells until the intracellular and extracellular compartments have the same osmolarity (see Figure 25-6C). Both the intracellular and extracellular volumes are increased by the addition of hypotonic fluid, although the intracellular volume increases to a greater extent.

Calculation of Fluid Shifts and Osmolarities After Infusion of Hypertonic Saline Solution. We can calculate the sequential effects of infusing different solutions on extracellular and intracellular fluid volumes and osmolarities. For example, if 2 liters of a hypertonic 3.0%

sodium chloride solution were infused into the extracellular fluid compartment of a 70-kg patient whose initial plasma osmolarity is 280 mOsm/L, what would be the intracellular and extracellular fluid volumes and osmolarities after osmotic equilibrium?

The first step is to calculate the initial conditions, including the volume, concentration, and total milliosmoles in each compartment. Assuming that extracellular fluid volume is 20% of body weight, and intracellular fluid volume is 40% of body weight, the following volumes and concentrations can be calculated.

Step 1. Initial Conditions

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	14	280	3920
Intracellular fluid	28	280	7840
Total body fluid	42	280	11,760

Next, we calculate the total milliosmoles added to the extracellular fluid in 2 liters of 3.0% sodium chloride. A 3.0% solution means that there are 3.0 g/100 ml, or 30 grams of sodium chloride per liter. Because the molecular weight of sodium chloride is about 58.5 g/mol, this means that there is about 0.5128 mole of sodium chloride per liter of solution. For 2 liters of solution, this would be 1.0256 mole of sodium chloride. Because 1 mole of sodium chloride is equal to approximately 2 osmoles (sodium chloride has two osmotically active particles per mole), the net effect of adding 2 liters of this solution is to add 2051 milliosmoles of sodium chloride to the extracellular fluid.

In step 2, we calculate the instantaneous effect of adding 2051 milliosmoles of sodium chloride to the extracellular fluid along with 2 liters of volume. There would be no change in the *intracellular fluid* concentration or volume, and there would be no osmotic equilibrium. In the *extracellular fluid*, however, there would be an additional 2051 milliosmoles of total solute, yielding a total of 5971 milliosmoles. Because the extracellular compartment now has 16 liters of volume, the concentration can be calculated by dividing 5971 milliosmoles by 16 liters to yield a concentration of about 373 mOsm/L. Thus, the following values would occur instantly after adding the solution.

Step 2. Instantaneous Effect of Adding 2 Liters of 3.0% Sodium Chloride

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	16	373	5971
Intracellular fluid	28	280	7840
Total body fluid	44	No equilibrium	13,811

In the third step, we calculate the volumes and concentrations that would be found within a few minutes after

osmotic equilibrium develops. In this case, the concentrations in the intracellular and extracellular fluid compartments would be equal and can be calculated by dividing the total milliosmoles in the body, 13,811, by the total volume, which is now 44 liters. This calculation yields a concentration of 313.9 mOsm/L. Therefore, all the body fluid compartments will have this same concentration after osmotic equilibrium. Assuming that no solute or water has been lost from the body, and that there is no movement of sodium chloride into or out of the cells, we then calculate the volumes of the intracellular and extracellular compartments. The intracellular fluid volume is calculated by dividing the total milliosmoles in the intracellular fluid (7840) by the concentration (313.9 mOsm/L) to yield a volume of 24.98 liters. Extracellular fluid volume is calculated by dividing the total milliosmoles in extracellular fluid (5971) by the concentration (313.9 mOsm/L) to yield a volume of 19.02 liters. Again, these calculations are based on the assumption that the sodium chloride added to the extracellular fluid remains there and does not move into the cells.

Step 3. Effect of Adding 2 Liters of 3.0% Sodium Chloride After Osmotic Equilibrium

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	19.02	313.9	5971
Intracellular fluid	24.98	313.9	7840
Total body fluid	44.0	313.9	13,811

Thus, one can see from this example that adding 2 liters of a hypertonic sodium chloride solution causes more than a 5-liter increase in extracellular fluid volume while *decreasing* intracellular fluid volume by almost 3 liters.

This method of calculating changes in intracellular and extracellular fluid volumes and osmolarities can be applied to virtually any clinical problem of fluid volume regulation. The reader should be familiar with such calculations because an understanding of the mathematical aspects of osmotic equilibrium between intracellular and extracellular fluid compartments is essential for understanding almost all fluid abnormalities of the body and their treatment.

GLUCOSE AND OTHER SOLUTIONS ADMINISTERED FOR NUTRITIVE PURPOSES

Several types of solutions are administered intravenously to provide nutrition to people who cannot otherwise ingest adequate amounts of nutrition. Glucose solutions are widely used; amino acid and homogenized fat solutions are used to a lesser extent. When these solutions are administered, their concentrations of osmotically active substances are usually adjusted nearly to isotonicity, or

they are given slowly enough that they do not upset the osmotic equilibrium of the body fluids.

After the glucose or other nutrients are metabolized, an excess of water often remains, especially if additional fluid is ingested. Ordinarily, the kidneys excrete this fluid in the form of dilute urine. The net result, therefore, is the addition of only nutrients to the body.

A 5% glucose solution, which is nearly isosmotic, is often used to treat dehydration. Because the solution is isosmotic, it can be infused intravenously without causing red blood cell swelling, as would occur with an infusion of pure water. Glucose in the solution is rapidly transported into the cells and metabolized. Therefore, infusion of a 5% glucose solution reduces extracellular fluid osmolarity and therefore helps correct the increase in extracellular fluid osmolarity associated with dehydration.

CLINICAL ABNORMALITIES OF FLUID VOLUME REGULATION: HYPONATREMIA AND HYPERNATREMIA

A measurement that is readily available to the clinician for evaluating a patient's fluid status is the plasma sodium concentration. Plasma osmolarity is not routinely measured but, because sodium and its associated anions (mainly chloride) account for more than 90% of the solute in the extracellular fluid, plasma sodium concentration is a reasonable indicator of plasma osmolarity under many conditions. When plasma sodium concentration is reduced more than a few milliequivalents below normal (about 142 mEq/L), a person is said to have *hyponatremia*. When plasma sodium concentration is elevated above normal, a person is said to have *hypernatremia*.

Causes of Hyponatremia: Excess Water or Loss of Sodium

Decreased plasma sodium concentration can result from loss of sodium from the extracellular fluid or addition of excess water to the extracellular fluid (Table 25-4). A primary loss of sodium usually results in *hyponatremia and dehydration* and is associated with decreased extracellular

fluid volume. Conditions that can cause hyponatremia as a result of the loss of sodium include *diarrhea* and *vomiting*. *Overuse of diuretics* that inhibit the ability of the kidneys to conserve sodium and certain types of sodium-wasting kidney diseases can also cause modest degrees of hyponatremia. *Addison disease*, which results from decreased secretion of the hormone aldosterone, impairs the ability of the kidneys to reabsorb sodium and can cause a modest degree of hyponatremia.

Hyponatremia can also be associated with excess water retention, which dilutes the sodium in the extracellular fluid, a condition referred to as *hyponatremia-overhydration*. For example, *excessive secretion of antidiuretic hormone (ADH)*, which increases water reabsorption by the kidney tubules, can lead to hyponatremia and overhydration.

Hyponatremia Causes Cell Edema

Rapid changes in cell volume as a result of hyponatremia can have profound effects on tissue and organ function, especially the brain. A rapid reduction in plasma sodium concentration, for example, can cause brain cell edema and neurological symptoms, including headache, nausea, lethargy, and disorientation. If plasma sodium concentration rapidly falls below 115 to 120 mmol/L, brain swelling may lead to seizures, coma, permanent brain damage, and death. Because the skull is rigid, the brain cannot increase its volume by more than about 10% without it being forced down the neck (*herniation*), which can lead to permanent brain injury and death.

When hyponatremia evolves more slowly, over several days, the brain and other tissues respond by transporting sodium, chloride, potassium, and organic solutes, such as glutamate, from the cells into the extracellular compartment. This response attenuates osmotic flow of water into the cells and swelling of the tissues (Figure 25-7).

Transport of solutes from the cells during slowly developing hyponatremia, however, can make the brain vulnerable to injury if the hyponatremia is corrected too rapidly. When hypertonic solutions are added too rapidly to correct hyponatremia, this intervention can outpace the brain's ability to recapture the solutes lost from the

Table 25-4 Abnormalities of Body Fluid Volume Regulation: Hyponatremia and Hypernatremia

Abnormality	Cause	Plasma Na ⁺ Concentration	Extracellular Fluid Volume	Intracellular Fluid Volume
Hyponatremia—dehydration	Adrenal insufficiency; overuse of diuretics	↓	↓	↑
Hyponatremia—overhydration	Excess ADH (SIADH); bronchogenic tumors	↓	↑	↑
Hypernatremia—dehydration	Diabetes insipidus; excessive sweating	↑	↓	↓
Hypernatremia—overhydration	Cushing disease; primary aldosteronism	↑	↑	↓

ADH, Antidiuretic hormone; SIADH, syndrome of inappropriate ADH.

Figure 25-7. Brain cell volume regulation during hyponatremia. During acute hyponatremia, caused by loss of Na^+ or excess H_2O , there is diffusion of H_2O into the cells (1) and swelling of the brain tissue (indicated by the *dashed lines*). This process stimulates transport of Na^+ , K^+ , and organic solutes out of the cells (2), which then causes water diffusion out of the cells (3). With chronic hyponatremia, the brain swelling is attenuated by transport of solutes from the cells.

cells and may lead to osmotic injury of the neurons that is associated with *demyelination*, a loss of the myelin sheath from nerves. This osmosis-mediated demyelination of neurons can be avoided by limiting the correction of chronic hyponatremia to less than 10 to 12 mmol/L in 24 hours and to less than 18 mmol/L in 48 hours. This slow rate of correction permits the brain to recover the osmoles that were lost from the cells as a result of adaptation to chronic hyponatremia.

Hyponatremia is the most common electrolyte disorder encountered in clinical practice and may occur in up to 15% to 25% of hospitalized patients.

Causes of Hypernatremia: Water Loss or Excess Sodium

An increased plasma sodium concentration, which also causes increased osmolarity, can be due to loss of water from the extracellular fluid, which concentrates the sodium ions, or excess sodium in the extracellular fluid. Primary loss of water from the extracellular fluid results in *hypernatremia and dehydration*. This condition can occur from an inability to secrete ADH, which is needed for the kidneys to conserve water. As a result of lack of ADH, the kidneys excrete large amounts of dilute urine (a disorder referred to as *central diabetes insipidus*), causing dehydration and increased concentration of sodium chloride in the extracellular fluid. In certain types of renal diseases, the kidneys cannot respond to ADH, causing a type of *nephrogenic diabetes insipidus*. A more common cause of hypernatremia associated with decreased extracellular fluid volume is simple *dehydration* caused by water intake that is less than water loss, as can occur with sweating during prolonged heavy exercise.

Hypernatremia can also occur when excessive sodium chloride is added to the extracellular fluid. This often results in *hypernatremia-overhydration* because excess extracellular sodium chloride is also usually associated with at least some degree of water retention by the kidneys. For example, excessive secretion of the sodium-retaining hormone *aldosterone* can cause a mild degree of hypernatremia and overhydration. The reason that the hypernatremia is not more severe is that the sodium retention also stimulates secretion of ADH and causes the kidneys to reabsorb greater amounts of water.

Thus, in analyzing abnormalities of plasma sodium concentration and deciding on proper therapy, one should first determine whether the abnormality is caused by a primary loss or gain of sodium or a primary loss or gain of water.

Hypernatremia Causes Cell Shrinkage

Hypernatremia is much less common than hyponatremia and severe symptoms usually occur only with rapid and large increases in the plasma sodium concentration above 158 to 160 mmol/L. Hypernatremia usually promotes intense thirst and stimulates secretion of ADH, which both protect against a large increase in plasma and extracellular fluid sodium, as discussed in [Chapter 29](#). However, severe hypernatremia can occur in patients with hypothalamic lesions that impair their sense of thirst, in infants who may not have ready access to water, in older patients with altered mental status, or in persons with diabetes insipidus.

Correction of hypernatremia can be achieved by administering a hypo-osmotic sodium chloride or dextrose solution. However, it is prudent to correct the

hypernatremia slowly in patients who have had chronic increases in their plasma sodium concentration because hypernatremia also activates defense mechanisms that protect the cell from changes in volume. These defenses are the opposite of those that occur for hyponatremia and consist of mechanisms that increase the intracellular concentration of sodium and other solutes.

EDEMA: EXCESS FLUID IN THE TISSUES

Edema refers to the presence of excess fluid in the body tissues. In many cases, edema occurs mainly in the extracellular fluid compartment, but it can also involve intracellular fluid accumulation.

INTRACELLULAR EDEMA

Three conditions are especially prone to cause intracellular swelling: (1) hyponatremia, as discussed earlier; (2) depression of the metabolic systems of the tissues; and (3) lack of adequate nutrition to the cells. For example, when blood flow to a tissue is decreased, the delivery of oxygen and nutrients is reduced. If blood flow becomes too low to maintain normal tissue metabolism, the cell membrane ionic pumps become depressed, and sodium ions that normally leak into the interior of the cell can no longer be pumped out of the cells. The excess intracellular sodium ions then cause osmosis of water into the cells. Sometimes this process can increase intracellular volume of a tissue area—even of an entire ischemic leg, for example—to two to three times normal. When such an increase in intracellular volume occurs, it is usually a prelude to death of the tissue.

Intracellular edema can also occur in inflamed tissues. Inflammation usually increases cell membrane permeability, allowing sodium and other ions to diffuse into the interior of the cell, with subsequent osmosis of water into the cells.

EXTRACELLULAR EDEMA

Extracellular edema occurs when excess fluid accumulates in the extracellular spaces. There are two general causes of extracellular edema: (1) abnormal leakage of fluid from the plasma to the interstitial spaces across the capillaries; and (2) failure of the lymphatics to return fluid from the interstitium back into the blood, often called *lymphedema*. The most common clinical cause of interstitial fluid accumulation is excessive capillary fluid filtration.

Factors That Can Increase Capillary Filtration

To understand the causes of excessive capillary filtration, it is useful to review the determinants of capillary filtration discussed in Chapter 16. Mathematically, the capillary filtration rate can be expressed as follows:

$$\text{Filtration} = K_f \times (P_c - P_{if} - \pi_c + \pi_{if})$$

where K_f is the capillary filtration coefficient (the product of the permeability and surface area of the capillaries), P_c is the capillary hydrostatic pressure, P_{if} is the interstitial fluid hydrostatic pressure, π_c is the capillary plasma colloid osmotic pressure, and π_{if} is the interstitial fluid colloid osmotic pressure. From this equation, one can see that any one of the following changes can increase the capillary filtration rate:

- Increased capillary filtration coefficient
- Increased capillary hydrostatic pressure
- Decreased plasma colloid osmotic pressure

Lymphedema—Failure of Lymph Vessels to Return Fluid and Protein to the Blood

When lymphatic function is greatly impaired as a result of blockage or loss of the lymph vessels, edema can become especially severe because plasma proteins that leak into the interstitium cannot be removed in any other way. The rise in protein concentration raises the colloid osmotic pressure of interstitial fluid, which draws even more fluid out of the capillaries.

Blockage of lymph flow can be especially severe with infections of the lymph nodes, such as occurs with infection by *filarial nematodes* (*Wuchereria bancrofti*), which are microscopic threadlike worms. The adult worms live in the human lymph system and are spread from person to person by mosquitoes. People with filarial infections can have severe lymphedema and *elephantiasis* and men can have swelling of the scrotum, called *hydrocele*. Lymphatic filariasis affects more than 120 million people in 80 countries throughout the tropics and subtropics of Asia, Africa, the Western Pacific, and parts of the Caribbean and South America.

Lymphedema can also occur in persons who have certain types of cancer or after surgery in which lymph vessels are removed or obstructed. For example, large numbers of lymph vessels are removed during a radical mastectomy, impairing the removal of protein and fluid from the breast and arm areas and causing edema and swelling of the tissue spaces. A few lymph vessels eventually regrow after this type of surgery; thus, the interstitial edema is usually temporary.

Summary of Causes of Extracellular Edema

A large number of conditions can cause fluid accumulation in the interstitial spaces by abnormal leaking of fluid from the capillaries or by preventing the lymphatics from returning fluid from the interstitium back to the circulation. The following is a partial list of conditions that can cause extracellular edema by these two types of abnormalities:

- I. Increased capillary pressure
 - A. Excessive kidney retention of salt and water
 1. Acute or chronic kidney failure
 2. Mineralocorticoid excess

- B. High venous pressure and venous constriction
 - 1. Heart failure
 - 2. Venous obstruction
 - 3. Failure of venous pumps
 - a) Paralysis of muscles
 - b) Immobilization of parts of the body
 - c) Failure of venous valves
- C. Decreased arteriolar resistance
 - 1. Excessive body heat
 - 2. Insufficiency of sympathetic nervous system
 - 3. Vasodilator drugs
- II. Decreased plasma proteins
 - A. Loss of proteins in urine (nephrotic syndrome)
 - B. Loss of protein from denuded skin areas
 - 1. Burns
 - 2. Wounds
 - C. Failure to produce proteins
 - 1. Liver disease (e.g., cirrhosis)
 - 2. Serious protein or caloric malnutrition
- III. Increased capillary permeability
 - A. Immune reactions that cause release of histamine and other immune products
 - B. Toxins
 - C. Bacterial infections
 - D. Vitamin deficiency, especially vitamin C
 - E. Prolonged ischemia
 - F. Burns
- IV. Blockage of lymph return
 - A. Cancer
 - B. Infections (e.g., filarial nematodes)
 - C. Surgery
 - D. Congenital absence or abnormality of lymphatic vessels

Edema Caused by Heart Failure. One of the most serious and common causes of edema is heart failure, which was discussed in [Chapter 22](#). In heart failure, the heart fails to pump blood normally from the veins into the arteries, which raises venous and capillary pressures, causing increased capillary filtration. In addition, the arterial pressure tends to fall, causing decreased excretion of salt and water by the kidneys, which causes still more edema. Also, blood flow to the kidneys is reduced in persons with heart failure, and this reduced blood flow stimulates secretion of renin, causing increased formation of angiotensin II and aldosterone, which both cause additional salt and water retention by the kidneys. In advanced heart failure, increased secretion of ADH stimulates water reabsorption by the renal tubules, leading to hyponatremia as well as intracellular and extracellular edema. Thus, in persons with untreated heart failure, all these factors acting together can cause serious generalized edema.

In patients with left-sided heart failure but without significant failure of the right side of the heart, blood is pumped into the lungs normally by the right side of the heart but cannot escape easily from the pulmonary veins

to the left side of the heart because this part of the heart has been greatly weakened. Consequently, all the pulmonary vascular pressures, including pulmonary capillary pressure, rise far above normal, causing serious and life-threatening pulmonary edema. When untreated, fluid accumulation in the lungs can rapidly progress, causing death within a few hours.

Edema Caused by Decreased Kidney Excretion of Salt and Water. Most sodium chloride added to the blood remains in the extracellular compartment, and only a small amount enters the cells. Therefore, in kidney diseases that compromise urinary excretion of salt and water, large amounts of sodium chloride and water are added to the extracellular fluid. Most of this salt and water leaks from the blood into the interstitial spaces, but some remains in the blood. The main effects of this are as follows: (1) widespread increases in interstitial fluid volume (extracellular edema); and (2) hypertension because of the increase in blood volume, as explained in [Chapter 19](#). As an example, in children who have acute glomerulonephritis, in which the renal glomeruli are injured by inflammation and therefore fail to filter adequate amounts of fluid, serious extracellular fluid edema also develops; along with the edema, severe hypertension usually develops.

Edema Caused by Decreased Plasma Proteins. Failure to produce normal amounts of proteins or leakage of proteins from the plasma causes the plasma colloid osmotic pressure to fall. This leads to increased capillary filtration throughout the body and extracellular edema.

One of the most important causes of decreased plasma protein concentration is loss of proteins in the urine in certain kidney diseases, a condition referred to as *nephrotic syndrome*. Multiple types of renal diseases can damage the membranes of the renal glomeruli, causing the membranes to become leaky to the plasma proteins and often allowing large quantities of these proteins to pass into the urine. When this loss exceeds the ability of the body to synthesize proteins, a reduction in plasma protein concentration occurs. Serious generalized edema occurs when the plasma protein concentration falls below 2.5 g/100 ml.

Cirrhosis of the liver is another condition that reduces plasma protein concentration. Cirrhosis means the development of large amounts of fibrous tissue among the liver parenchymal cells. One result is failure of these cells to produce sufficient plasma proteins, leading to decreased plasma colloid osmotic pressure and the generalized edema that accompanies this condition.

Another way that cirrhosis causes edema is that the liver fibrosis sometimes compresses the abdominal portal venous drainage vessels as they pass through the liver before emptying back into the general circulation. Blockage of this portal venous outflow raises capillary hydrostatic pressure throughout the gastrointestinal area and further increases fluid filtration out of the plasma into

the intra-abdominal areas. When this occurs, the combined effects of decreased plasma protein concentration and high portal capillary pressures cause transudation of large amounts of fluid and protein into the abdominal cavity, a condition referred to as *ascites*.

SAFETY FACTORS THAT NORMALLY PREVENT EDEMA

Even though many disturbances can cause edema, the abnormality must usually be severe before serious edema develops. The reason the abnormality must be severe is that three major safety factors prevent excessive fluid accumulation in the interstitial spaces: (1) low compliance of the interstitium when interstitial fluid pressure is in the negative pressure range; (2) the ability of lymph flow to increase 10- to 50-fold; and (3) washdown of the interstitial fluid protein concentration, which reduces interstitial fluid colloid osmotic pressure as capillary filtration increases.

Safety Factor Caused by Low Compliance of the Interstitium in the Negative Pressure Range

In Chapter 16, we noted that interstitial fluid hydrostatic pressure in loose subcutaneous tissues of the body is slightly less than atmospheric pressure, averaging about -3 mm Hg. This slight suction in the tissues helps hold the tissues together. Figure 25-8 shows the approximate

Figure 25-8. Relationship between interstitial fluid hydrostatic pressure and interstitial fluid volumes, including total volume, free fluid volume, and gel fluid volume, for loose tissues such as skin. Note that significant amounts of free fluid occur only when the interstitial fluid pressure becomes positive. (Modified from Guyton AC, Granger HJ, Taylor AE: *Interstitial fluid pressure*. *Physiol Rev* 51:527, 1971.)

relationships between different levels of interstitial fluid pressure and interstitial fluid volume, as extrapolated to people from animal studies. Note in Figure 25-8 that as long as the interstitial fluid pressure is in the negative range, small changes in interstitial fluid volume are associated with relatively large changes in interstitial fluid hydrostatic pressure. Therefore, in the negative pressure range, the *compliance* of the tissues, defined as the change in volume per millimeter of Hg pressure change, is low.

How does the low compliance of the tissues in the negative pressure range act as a safety factor against edema? To answer this question, recall the determinants of capillary filtration discussed previously. When interstitial fluid hydrostatic pressure increases, this increased pressure tends to oppose further capillary filtration. Therefore, as long as the interstitial fluid hydrostatic pressure is in the negative pressure range, small increases in interstitial fluid volume cause relatively large increases in interstitial fluid hydrostatic pressure, opposing further filtration of fluid into the tissues.

Because the normal interstitial fluid hydrostatic pressure is -3 mm Hg, the interstitial fluid hydrostatic pressure must increase by about 3 mm Hg before large amounts of fluid will begin to accumulate in the tissues. Therefore, the safety factor against edema is a change of interstitial fluid pressure of about 3 mm Hg. In the positive tissue pressure range, this safety factor against edema is lost because of the large increase in compliance of the tissues.

Importance of Interstitial Gel in Preventing Fluid Accumulation in the Interstitium.

Note in Figure 25-8 that in normal tissues with negative interstitial fluid pressure, virtually all the fluid in the interstitium is in gel form. That is, the fluid is bound in a proteoglycan meshwork so that there are virtually no free fluid spaces larger than a few hundredths of a micrometer in diameter. The importance of the gel is that it prevents fluid from *flowing easily* through the tissues because of impediment from the brush pile of trillions of proteoglycan filaments. Also, when the interstitial fluid pressure falls to very negative values, the gel does not contract very much because the meshwork of proteoglycan filaments offers an elastic resistance to compression. In the negative fluid pressure range, the interstitial fluid volume does not change much, regardless of whether the degree of suction is only a few mm Hg negative pressure or 10 to 20 mm Hg negative pressure. In other words, the compliance of the tissues is very low in the negative pressure range.

By contrast, when interstitial fluid pressure rises to the positive pressure range, there is a tremendous accumulation of *free fluid* in the tissues. In this pressure range, the tissues are compliant, allowing large amounts of fluid to accumulate, with relatively small additional increases in interstitial fluid hydrostatic pressure. Most of the extra fluid that accumulates is free fluid because it pushes the brush pile of proteoglycan filaments apart. Therefore, the

fluid can flow freely through the tissue spaces because it is not in gel form. When this free flow of fluid occurs, the edema is said to be *pitting edema* because one can press the thumb against the tissue area and push the fluid out of the area. When the thumb is removed, a pit is left in the skin for a few seconds until the fluid flows back from the surrounding tissues. This type of edema is distinguished from *nonpitting edema*, which occurs when the tissue cells swell instead of the interstitium or when the fluid in the interstitium becomes clotted with fibrinogen so that it cannot move freely within the tissue spaces.

Importance of Proteoglycan Filaments as a Spacer for Cells and in Preventing Rapid Flow of Fluid in Tissues.

The proteoglycan filaments, along with much larger collagen fibrils in the interstitial spaces, act as a spacer between the cells. Nutrients and ions do not diffuse readily through cell membranes; therefore, without adequate spacing between the cells, these nutrients, electrolytes, and cell waste products cannot be rapidly exchanged between the blood capillaries and cells located at a distance from one another.

The proteoglycan filaments also prevent fluid from flowing too easily through the tissue spaces. If it were not for the proteoglycan filaments, the simple act of a person standing up would cause large amounts of interstitial fluid to flow from the upper body to the lower body. When too much fluid accumulates in the interstitium, as occurs in edema, this extra fluid creates large channels that allow the fluid to flow readily through the interstitium. Therefore, when severe edema occurs in the legs, the edema fluid often can be decreased by simply elevating the legs.

Even though fluid does not *flow* easily through the tissues in the presence of the compacted proteoglycan filaments, different substances within the fluid can *diffuse* through the tissues at least 95% as easily as they normally diffuse. Therefore, the usual diffusion of nutrients to the cells and the removal of waste products from the cells are not compromised by the proteoglycan filaments of the interstitium.

Increased Lymph Flow as a Safety Factor Against Edema

A major function of the lymphatic system is to return the fluid and proteins filtered from the capillaries into the interstitium to the circulation. Without this continuous return of the filtered proteins and fluid to the blood, the plasma volume would be rapidly depleted, and interstitial edema would occur.

The lymphatics act as a safety factor against edema because lymph flow can increase 10- to 50-fold when fluid begins to accumulate in the tissues. This increased lymph flow allows the lymphatics to carry away large amounts of fluid and proteins in response to increased capillary filtration, preventing the interstitial pressure from rising into the positive pressure range. The safety factor caused by increased lymph flow has been calculated to be about 7 mm Hg.

Washdown of Interstitial Fluid Protein as a Safety Factor Against Edema

As increased amounts of fluid are filtered into the interstitium, the interstitial fluid pressure increases, causing increased lymph flow. In most tissues, the protein concentration of the interstitium decreases as lymph flow is increased because larger amounts of protein are carried away than can be filtered out of the capillaries. The reason for this phenomenon is that the capillaries are relatively impermeable to proteins compared with the lymph vessels. Therefore, the proteins are washed out of the interstitial fluid as lymph flow increases.

Because the interstitial fluid colloid osmotic pressure caused by the proteins tends to draw fluid out of the capillaries, decreasing the interstitial fluid proteins lowers the net filtration force across the capillaries and tends to prevent further accumulation of fluid. The safety factor from this effect has been calculated to be about 7 mm Hg.

SUMMARY OF SAFETY FACTORS THAT PREVENT EDEMA

Putting together all the safety factors against edema, we find the following:

1. The safety factor caused by low tissue compliance in the negative pressure range is about 3 mm Hg.
2. The safety factor caused by increased lymph flow is about 7 mm Hg.
3. The safety factor caused by washdown of proteins from the interstitial spaces is about 7 mm Hg.

Therefore, the total safety factor against edema is about 17 mm Hg. This means that the capillary pressure in a peripheral tissue could theoretically rise by 17 mm Hg, or approximately double the normal value, before marked edema would occur.

FLUIDS IN POTENTIAL SPACES OF THE BODY

Some examples of potential spaces are the pleural, pericardial, peritoneal, and synovial cavities, including both the joint cavities and the bursae. Virtually all these potential spaces have surfaces that almost touch each other, with only a thin layer of fluid in between, and the surfaces slide over each other. To facilitate the sliding, a viscous proteinaceous fluid lubricates the surfaces.

Fluid Is Exchanged Between Capillaries and Potential Spaces.

The surface membrane of a potential space usually does not offer significant resistance to the passage of fluids, electrolytes, or even proteins, which all move back and forth between the space and interstitial fluid in the surrounding tissue with relative ease. Therefore, each potential space is in reality a large tissue space. Consequently, fluid in the capillaries adjacent to the potential space diffuses not only into the interstitial fluid but also into the potential space.

Lymphatic Vessels Drain Protein From the Potential Spaces. Proteins collect in the potential spaces because of leakage out of the capillaries, similar to the collection of protein in the interstitial spaces throughout the body. The protein must be removed through lymphatics or other channels and returned to the circulation. Each potential space is directly or indirectly connected with lymph vessels. In some cases, such as the pleural cavity and peritoneal cavity, large lymph vessels arise directly from the cavity itself.

Edema Fluid in the Potential Spaces Is Called Effusion.

When edema occurs in the subcutaneous tissues adjacent to the potential space, edema fluid usually collects in the potential space as well; this fluid is called *effusion*. Thus, lymph blockage or any of the multiple abnormalities that can cause excessive capillary filtration can cause effusion in the same way that interstitial edema is caused. The abdominal cavity is especially prone to collect effusion fluid, and in this case, the effusion is called *ascites*. In serious cases, 20 liters or more of ascitic fluid can accumulate.

The other potential spaces, such as the pleural cavity, pericardial cavity, and joint spaces, can become seriously swollen when generalized edema is present. Also, injury or local infection in any one of the cavities often blocks the lymph drainage, causing isolated swelling in the cavity.

The dynamics of fluid exchange in the pleural cavity are discussed in detail in [Chapter 39](#). These dynamics are mainly representative of all the other potential spaces as well. The normal fluid pressure in most or all of the potential spaces in the nonedematous state is *negative* in the same way that this pressure is negative (subatmospheric) in loose subcutaneous tissue. For example, the interstitial fluid hydrostatic pressure is normally about -7 to -8 mm Hg in the pleural cavity, -3 to -5 mm Hg in

the joint spaces, and -5 to -6 mm Hg in the pericardial cavity.

The Urinary System: Functional Anatomy and Urine Formation by the Kidneys

MULTIPLE FUNCTIONS OF THE KIDNEYS

Most people are familiar with one important function of the kidneys—to rid the body of waste materials that are ingested or produced by metabolism. A second function that is especially critical is to control the volume and electrolyte composition of the body fluids. For water and virtually all electrolytes in the body, the balance between intake (due to ingestion or metabolic production) and output (due to excretion or metabolic consumption) is maintained largely by the kidneys. This regulatory function of the kidneys maintains the stable internal environment necessary for the cells to perform their various activities.

The kidneys perform their most critical functions by filtering the plasma and removing substances from the filtrate at variable rates, depending on the needs of the body. Ultimately, the kidneys clear unwanted substances from the filtrate (and therefore from the blood) by excreting them in the urine while returning substances that are needed back to the blood.

Although this chapter and the next few chapters focus mainly on the control of renal excretion of water, electrolytes, and metabolic waste products, the kidneys serve many important homeostatic functions, including the following:

- Excretion of metabolic waste products and foreign chemicals
- Regulation of water and electrolyte balances
- Regulation of body fluid osmolality and electrolyte concentrations
- Regulation of arterial pressure
- Regulation of acid-base balance
- Regulation of erythrocyte production
- Secretion, metabolism, and excretion of hormones
- Gluconeogenesis

Excretion of Metabolic Waste Products, Foreign Chemicals, Drugs, and Hormone Metabolites. The kidneys are the primary means for eliminating most of the waste products of metabolism that are no longer needed by the body. These products include *urea* (from the metabolism of amino acids), *creatinine* (from muscle

creatinine), *uric acid* (from nucleic acids), *end products of hemoglobin breakdown* (e.g., bilirubin), and *metabolites of various hormones*. These waste products must be eliminated from the body as rapidly as they are produced. The kidneys also eliminate most toxins and other foreign substances that are produced by the body or ingested, such as pesticides, drugs, and food additives.

Regulation of Water and Electrolyte Balances. For maintenance of homeostasis, excretion of water and electrolytes must match intake precisely. If intake exceeds excretion, the amount of that substance in the body will increase. If intake is less than excretion, the amount of that substance in the body will decrease. Although temporary (or cyclic) imbalances of water and electrolytes may occur in various physiological and pathophysiological conditions associated with altered intake or renal excretion, the maintenance of life depends on restoration of water and electrolyte balance.

Intake of water and many electrolytes is usually governed by a person's eating and drinking habits, requiring the kidneys to adjust their excretion rates to match the intakes of various substances. **Figure 26-1** shows the response of the kidneys to a sudden 10-fold increase in sodium intake from a low level of 30 mEq/day to a high level of 300 mEq/day. Within 2 to 3 days after raising the sodium intake, renal excretion also increases to about 300 mEq/day so that the balance between intake and output is rapidly re-established. However, during the 2 to 3 days of renal adaptation to the high sodium intake, there is a modest accumulation of sodium that raises extracellular fluid volume slightly and triggers hormonal changes and other compensatory responses that signal the kidneys to increase their sodium excretion.

The capability of the kidneys to alter sodium excretion in response to changes in sodium intake is tremendous. Experimental studies have shown that in many people, sodium intake can be increased to 1500 mEq/day (more than 10 times normal) or decreased to 10 mEq/day (<0.1 of normal), with relatively small changes in extracellular fluid volume or plasma sodium concentration. This phenomenon is also true for water and for most

Figure 26-1. Effect of increasing sodium intake 10-fold (from 30 to 300 mEq/day) on urinary sodium excretion and extracellular fluid volume. The shaded areas represent the net sodium retention or net sodium loss, determined by the difference between sodium intake and sodium excretion.

other electrolytes, such as chloride, potassium, calcium, hydrogen, magnesium, and phosphate ions. In the next few chapters, we discuss the specific mechanisms that permit the kidneys to perform these amazing feats of homeostasis.

Regulation of Arterial Pressure. As discussed in Chapter 19, the kidneys play a dominant role in long-term regulation of arterial pressure by excreting variable amounts of sodium and water. The kidneys also contribute to short-term arterial pressure regulation by secreting hormones and vasoactive factors or substances (e.g., *renin*) that lead to the formation of vasoactive products (e.g., angiotensin II).

Regulation of Acid–Base Balance. The kidneys contribute to acid–base regulation, along with the lungs and body fluid buffers, by excreting acids and by regulating the body fluid buffer stores. The kidneys are the only means of eliminating certain types of acids from the body, such as sulfuric acid and phosphoric acid, which are generated by the metabolism of proteins.

Regulation of Erythrocyte Production. The kidneys secrete *erythropoietin*, which stimulates production of red blood cells by *hematopoietic stem cells* in the bone marrow, as discussed in Chapter 33. One important stimulus for erythropoietin secretion by the kidneys is *hypoxia*. The kidneys normally account for almost all the erythropoietin secreted into the circulation. In people with severe kidney disease or who have had their kidneys removed and have been placed on hemodialysis, severe anemia develops as a result of decreased erythropoietin production.

Regulation of 1,25-Dihydroxyvitamin D₃ Production.

The kidneys produce 1,25-dihydroxyvitamin D₃ (*calcitriol*), the active form of vitamin D, by hydroxylating this vitamin at the “number 1” position. Calcitriol is essential for normal calcium deposition in bone and calcium reabsorption by the gastrointestinal tract. As discussed in Chapter 80, calcitriol plays an important role in calcium and phosphate regulation.

Glucose Synthesis. The kidneys synthesize glucose from amino acids and other precursors during prolonged fasting, a process referred to as *gluconeogenesis*. The kidneys’ capacity to add glucose to the blood during prolonged periods of fasting rivals that of the liver.

With chronic kidney disease or acute failure of the kidneys, these homeostatic functions are disrupted, and severe abnormalities of body fluid volumes and composition rapidly occur. With complete renal failure, enough potassium, acids, fluid, and other substances accumulate in the body to cause death within a few days unless clinical interventions such as hemodialysis are initiated to restore, at least partially, the body fluid and electrolyte balances.

PHYSIOLOGIC ANATOMY OF THE KIDNEYS

GENERAL ORGANIZATION OF THE KIDNEYS AND URINARY TRACT

The two kidneys lie on the posterior wall of the abdomen, outside the peritoneal cavity (Figure 26-2). Each kidney of the adult human weighs about 150 grams and is about the size of a clenched fist. The medial side of each kidney contains an indented region called the *hilum* through which pass the renal artery and vein, lymphatics, nerve supply, and ureter, which carries the final urine from the kidney to the bladder, where it is stored until the bladder is emptied. The kidney is surrounded by a tough fibrous *capsule* that protects its delicate inner structures.

If the kidney is bisected from top to bottom, the two major regions that can be visualized are the outer *cortex* and the inner *medulla* regions. The medulla is divided into 8 to 10 cone-shaped masses of tissue called *renal pyramids*. The base of each pyramid originates at the border between the cortex and medulla and terminates in the *papilla*, which projects into the space of the *renal pelvis*, a funnel-shaped continuation of the upper end of the ureter. The outer border of the pelvis is divided into open-ended pouches called *major calyces* that extend downward and divide into *minor calyces*, which collect urine from the tubules of each papilla. The walls of the calyces, pelvis, and ureter contain contractile elements that propel the urine toward the *bladder*, where urine is stored until it is emptied by *micturition*, discussed later in this chapter.

Figure 26-2. General organization of the kidneys and the urinary system.

RENAL BLOOD SUPPLY

Blood flow to the two kidneys is normally about 22% of the cardiac output, or 1100 ml/min. The renal artery enters the kidney through the hilum and then branches progressively to form the *interlobar arteries*, *arcuate arteries*, *interlobular arteries* (also called *radial arteries*), and *afferent arterioles*, which lead to the *glomerular capillaries*, where large amounts of fluid and solutes (except the plasma proteins) are filtered to begin urine formation (Figure 26-3). The distal ends of the capillaries of each glomerulus coalesce to form the *efferent arteriole*, which leads to a second capillary network, the *peritubular capillaries*, that surrounds the renal tubules.

The renal circulation is unique in having two capillary beds, the glomerular and peritubular capillaries, which are arranged in series and are separated by the efferent arterioles. These arterioles help regulate the hydrostatic pressure in both sets of capillaries. High hydrostatic pressure in the glomerular capillaries (≈ 60 mm Hg) causes rapid fluid filtration, whereas a much lower hydrostatic pressure in the peritubular capillaries (≈ 13 mm Hg) permits rapid fluid reabsorption. By adjusting the resistance of the afferent and efferent arterioles, the kidneys can regulate the hydrostatic pressure in the glomerular and the peritubular capillaries, thereby changing the rate of glomerular filtration, tubular reabsorption, or both in response to the body's homeostatic demands.

The peritubular capillaries empty into the vessels of the venous system, which run parallel to the arteriolar vessels. The blood vessels of the venous system progressively form the *interlobular vein*, *arcuate vein*, *interlobar vein*, and *renal vein*, which leaves the kidney beside the renal artery and ureter.

THE NEPHRON IS THE FUNCTIONAL UNIT OF THE KIDNEY

Each human kidney contains about 800,000 to 1,000,000 *nephrons*, each of which is capable of forming urine.

The kidney cannot regenerate new nephrons. Therefore, with renal injury, disease, or normal aging, the number of nephrons gradually decreases. After age 40 years, the number of functioning nephrons usually decreases about 10% every 10 years; thus, at age 80 years, many people have 40% fewer functioning nephrons than they did at age 40 years. This loss is not life-threatening because adaptive changes in the remaining nephrons allow them to excrete the proper amounts of water, electrolytes, and waste products, as discussed in Chapter 32.

Each nephron contains (1) a tuft of glomerular capillaries called the *glomerulus*, through which large amounts of fluid are filtered from the blood, and (2) a long *tubule* in which the filtered fluid is converted into urine on its way to the pelvis of the kidney (see Figure 26-3).

The glomerulus contains a network of branching and anastomosing glomerular capillaries that, compared with other capillaries, have high hydrostatic pressure (≈ 60 mm Hg). The glomerular capillaries are covered by epithelial cells, and the total glomerulus is encased in *Bowman's capsule*.

Fluid filtered from the glomerular capillaries flows into Bowman's capsule and then into the *proximal tubule*, which lies in the cortex of the kidney (Figure 26-4). From the proximal tubule, fluid flows into the *loop of Henle*, which dips into the renal medulla. Each loop consists of a *descending* and an *ascending limb*. The walls of the descending limb and lower end of the ascending limb are very thin and therefore are called the *thin segment of the loop of Henle*. After the ascending limb of the loop returns partway back to the cortex, its wall becomes much thicker; this segment is referred to as the *thick segment of the ascending limb*.

At the end of the thick ascending limb is a short segment that has in its wall a plaque of specialized epithelial cells, known as the *macula densa*. As discussed later, the macula densa plays an important role

Figure 26-3. Section of the human kidney showing the major vessels that supply the blood flow to the kidney and a schematic of the microcirculation of each nephron.

in controlling nephron function. Beyond the macula densa, fluid enters the *distal tubule*, which, like the proximal tubule, lies in the renal cortex. The distal tubule is followed by the *connecting tubule* and *cortical collecting tubule*, which lead to the *cortical collecting duct*. The initial parts of 8 to 10 cortical collecting ducts join to form a single, larger collecting duct that runs downward into the medulla and becomes the *medullary collecting duct*. The collecting ducts merge to form progressively larger ducts that eventually empty into the renal pelvis through the tips of the *renal papillae*. In each kidney, there are about 250 of these very large collecting ducts, each of which collects urine from about 4000 nephrons.

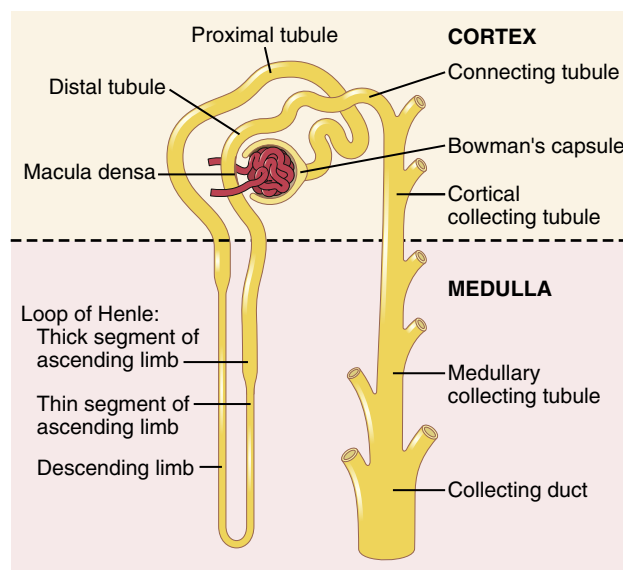

Figure 26-4. Basic tubular segments of the nephron. The relative lengths of the different tubular segments are not drawn to scale.

Regional Differences in Nephron Structure: Cortical and Juxtamedullary Nephrons. Although each nephron has all the components described earlier, there are some differences, depending on how deep the nephron lies within the kidney mass. The nephrons that have glomeruli located in the outer cortex are called *cortical nephrons*; they have short loops of Henle that penetrate only a short distance into the medulla (**Figure 26-5**).

About 20% to 30% of the nephrons have glomeruli that lie deep in the renal cortex near the medulla and are called *juxtamedullary nephrons*. These nephrons have long loops of Henle that dip deeply into the medulla, in some cases all the way to the tips of the renal papillae.

The vascular structures supplying the juxtamedullary nephrons also differ from those supplying the cortical nephrons. For the cortical nephrons, the entire tubular system is surrounded by an extensive network of peritubular capillaries. For the juxtamedullary nephrons, long efferent arterioles extend from the glomeruli down into the outer medulla and then divide into specialized peritubular capillaries called *vasa recta*, which extend downward into the medulla, lying side by side with the loops of Henle. Like the loops of Henle, the *vasa recta* return toward the cortex and empty into the cortical veins. This specialized network of capillaries in the medulla plays an essential role in the formation of a concentrated urine, discussed in **Chapter 29**.

MICTURITION

Micturition is the process whereby the urinary bladder empties when it becomes filled. This process involves two main steps. First, the bladder fills progressively until the tension in its walls rises above a threshold level. This tension elicits the second step, which is a nervous reflex called the *micturition reflex* that empties the bladder or,

Figure 26-5. Schematic of relationships between blood vessels and tubular structures and differences between cortical and juxtamedullary nephrons.

if this fails, at least causes a conscious desire to urinate. Although the micturition reflex is an autonomic spinal cord reflex, it can also be inhibited or facilitated by centers in the cerebral cortex or brain stem.

PHYSIOLOGIC ANATOMY OF THE BLADDER

The urinary bladder, shown in [Figure 26-6](#), is a smooth muscle chamber composed of two main parts: (1) the *body*, which is the major part of the bladder in which urine collects; and (2) the *neck*, which is a funnel-shaped extension of the body, passing inferiorly and anteriorly into the urogenital triangle and connecting with the urethra. The lower part of the bladder neck is also called the *posterior urethra* because of its relationship to the urethra.

The smooth muscle of the bladder is called the *detrusor muscle*. Its muscle fibers extend in all directions and, when contracted, can increase the pressure in the bladder to 40 to 60 mm Hg. Thus, *contraction of the detrusor muscle is a major step in emptying the bladder*. Smooth muscle cells of the detrusor muscle fuse with one another so that low-resistance electrical pathways exist from one muscle cell to the other. Therefore, an action potential can spread throughout the detrusor muscle, from one muscle cell to the next, to cause contraction of the entire bladder at once.

On the posterior wall of the bladder, lying immediately above the bladder neck, is a small triangular area called the *trigone*. At the lowermost apex of the trigone, the bladder neck opens into the *posterior urethra*, and the two ureters enter the bladder at the uppermost angles of the trigone. The trigone can be identified by the fact that its *mucosa*, the inner lining of the bladder, is smooth, in contrast to the remaining bladder mucosa, which is folded to form *rugae*.

Each ureter, as it enters the bladder, courses obliquely through the detrusor muscle and then passes another 1 to 2 centimeters beneath the bladder mucosa before emptying into the bladder.

The bladder neck (posterior urethra) is 2 to 3 centimeters long, and its wall is composed of detrusor muscle interlaced with a large amount of elastic tissue. The muscle in this area is called the *internal sphincter*. Its natural tone normally keeps the bladder neck and posterior urethra empty of urine and, therefore, prevents emptying of the bladder until the pressure in the main part of the bladder rises above a critical threshold.

Beyond the posterior urethra, the urethra passes through the *urogenital diaphragm*, which contains a layer of muscle called the *external sphincter* of the bladder. This muscle is a voluntary skeletal muscle, in contrast to the muscle of the bladder body and bladder neck, which is entirely smooth muscle. The external sphincter muscle is

Figure 26-6. Anatomy of the urinary bladder and urethra in males and females.

Figure 26-7. Innervation of the urinary bladder.

under voluntary control of the nervous system and can be used to consciously prevent urination, even when involuntary controls are attempting to empty the bladder.

Innervation of the Bladder. The principal nerve supply of the bladder is via the *pelvic nerves*, which connect with the spinal cord through the *sacral plexus*, mainly connecting with cord segments S2 and S3 (Figure 26-7). Coursing through the pelvic nerves are both *sensory nerve fibers* and *motor nerve fibers*. The sensory fibers detect the degree of stretch in the bladder wall. Stretch signals from the posterior urethra are especially strong and are mainly

responsible for initiating the reflexes that cause bladder emptying.

The motor nerves transmitted in the pelvic nerves are *parasympathetic fibers*. These fibers terminate on ganglion cells located in the wall of the bladder. Short postganglionic nerves then innervate the detrusor muscle.

In addition to the pelvic nerves, two other types of innervation are important in bladder function. Most important are the *skeletal motor fibers* transmitted through the *pudendal nerve* to the external bladder sphincter. These fibers are *somatic nerve fibers* that innervate and control the voluntary skeletal muscle of the

sphincter. Also, the bladder receives *sympathetic innervation* from the sympathetic chain through the *hypogastric nerves*, connecting mainly with the L2 segment of the spinal cord. These sympathetic fibers stimulate mainly the blood vessels and have little to do with bladder contraction. Some sensory nerve fibers also pass via the sympathetic nerves and may be important in the sensation of fullness and, in some cases, pain.

URINE TRANSPORT FROM THE KIDNEYS THROUGH THE URETERS AND INTO THE BLADDER

Urine that is expelled from the bladder has essentially the same composition as fluid flowing out of the collecting ducts. There are no significant changes in the composition of urine as it flows through the renal calyces and ureters to the bladder.

Urine flowing from the collecting ducts into the renal calyces stretches the calyces and increases their inherent *pacemaker activity*, which in turn initiates peristaltic contractions that spread to the renal pelvis and then downward along the length of the ureter, thereby forcing urine from the renal pelvis toward the bladder. In adults, the ureters are normally 25 to 35 centimeters (10–14 inches) long.

The walls of the ureters contain smooth muscle and are innervated by sympathetic and parasympathetic nerves, as well as by an intramural plexus of neurons and nerve fibers that extends along the entire length of the ureters. As with other visceral smooth muscle, *peristaltic contractions in the ureter are enhanced by parasympathetic stimulation and inhibited by sympathetic stimulation*.

The ureters enter the bladder through the *detrusor muscle* in the trigone region of the bladder, as shown in [Figure 26-6](#). Normally, the ureters course obliquely for several centimeters through the bladder wall. The normal tone of the detrusor muscle in the bladder wall tends to compress the ureter, thereby preventing backflow (reflux) of urine from the bladder when pressure builds up in the bladder during micturition or bladder compression. Each peristaltic wave along the ureter increases the pressure within the ureter so that the region passing through the bladder wall opens and allows urine to flow into the bladder.

In some people, the distance that the ureter courses through the bladder wall is less than normal, and thus contraction of the bladder during micturition does not always lead to complete occlusion of the ureter. As a result, some of the urine in the bladder is propelled backward into the ureter, a condition called *vesicoureteral reflux*. Such reflux can lead to enlargement of the ureters and, if severe, can increase the pressure in the renal calyces and structures of the renal medulla, causing damage to these regions.

Pain Sensation in the Ureters and the Ureterorenal Reflex. The ureters are extensively supplied with pain

Figure 26-8. A normal cystometrogram, showing also acute pressure waves (*dashed spikes*) caused by micturition reflexes.

nerve fibers. When a ureter becomes blocked (e.g., by a ureteral stone), intense reflex constriction occurs, which is associated with severe pain. Also, the pain impulses cause a sympathetic reflex back to the kidney to constrict the renal arterioles, thereby decreasing urine output from the kidney. This effect is called the *ureterorenal reflex* and is important for attenuating flow of fluid into the pelvis of a kidney with a blocked ureter.

Filling of the Bladder and Bladder Wall Tone—the Cystometrogram

[Figure 26-8](#) shows the approximate changes in intravesicular pressure as the bladder fills with urine. When there is no urine in the bladder, the intravesicular pressure is about 0, but by the time 30 to 50 milliliters of urine have collected, the pressure rises to 5 to 10 centimeters of water. Additional urine—200 to 300 milliliters—can collect with only a small additional rise in pressure; this constant level of pressure is caused by intrinsic tone of the bladder wall. Beyond 300 to 400 milliliters, collection of more urine in the bladder causes the pressure to rise rapidly.

Superimposed on the tonic pressure changes during filling of the bladder are periodic acute increases in pressure that last from a few seconds to more than 1 minute. The pressure peaks may rise only a few centimeters of water or may rise to more than 100 centimeters of water. These pressure peaks are called *micturition waves* in the cystometrogram and are caused by the micturition reflex.

MICTURITION REFLEX

Referring again to [Figure 26-8](#), one can see that as the bladder fills, many superimposed *micturition contractions* begin to appear, as shown by the dashed spikes. These are the result of a stretch reflex initiated by *sensory stretch receptors* in the bladder wall, especially by the receptors in the posterior urethra when this area begins to fill with

urine at the higher bladder pressures. Sensory signals from the bladder stretch receptors are conducted to the sacral segments of the cord through the *pelvic nerves* and then reflexively back again to the bladder through the *parasympathetic nerve fibers* by way of these same nerves.

When the bladder is only partially filled, these micturition contractions usually relax spontaneously after a fraction of a minute, the detrusor muscles stop contracting, and pressure falls back to the baseline. As the bladder continues to fill, the micturition reflexes become more frequent and cause greater contractions of the detrusor muscle.

Once a micturition reflex begins, it is self-regenerative. That is, initial contraction of the bladder activates the stretch receptors to cause a greater increase in sensory impulses from the bladder and posterior urethra, which causes a further increase in reflex contraction of the bladder; thus, the cycle is repeated again and again until the bladder has reached a strong degree of contraction. Then, after a few seconds to more than a minute, the self-regenerative reflex begins to fatigue, and the regenerative cycle of the micturition reflex ceases, permitting the bladder to relax.

Thus, the micturition reflex is a single complete cycle of the following: (1) progressive and rapid increase of pressure; (2) a period of sustained pressure; and (3) return of the pressure to the basal tone of the bladder. Once a micturition reflex has occurred but has not succeeded in emptying the bladder, the nervous elements of this reflex usually remain in an inhibited state for a few minutes to 1 hour or more before another micturition reflex occurs. As the bladder becomes filled more and more, micturition reflexes occur more and more often and powerfully.

Once the micturition reflex becomes powerful enough, it causes another reflex, which passes through the *pudendal nerves* to the *external sphincter* to inhibit it. If this inhibition is more potent in the brain than the voluntary constrictor signals to the external sphincter, urination will occur. If not, urination will not occur until the bladder fills still further, and the micturition reflex becomes more powerful.

Facilitation or Inhibition of Micturition by the Brain.

The micturition reflex is an autonomic spinal cord reflex, but it can be inhibited or facilitated by centers in the brain. These centers include the following: (1) strong *facilitative* and *inhibitory centers in the brain stem, located mainly in the pons*; and (2) several *centers located in the cerebral cortex* that are mainly inhibitory but can become excitatory.

The micturition reflex is the basic cause of micturition, but the higher centers normally exert final control of micturition, as follows:

1. The higher centers keep the micturition reflex partially inhibited, except when micturition is desired.
2. The higher centers can prevent micturition, even if the micturition reflex occurs, by tonic contraction

of the external bladder sphincter until a convenient time presents itself.

3. When it is time to urinate, the cortical centers can facilitate the sacral micturition centers to help initiate a micturition reflex and, at the same time, inhibit the external urinary sphincter so that urination can occur.

Voluntary urination is usually initiated in the following way. First, a person voluntarily contracts the abdominal muscles, which increases pressure in the bladder and allows extra urine to enter the bladder neck and posterior urethra under pressure, thus stretching their walls. This action stimulates the stretch receptors, which excites the micturition reflex and simultaneously inhibits the external urethral sphincter. Ordinarily, all the urine will be emptied, with rarely more than 5 to 10 milliliters left in the bladder.

Abnormalities of Micturition

Atonic Bladder and Incontinence Caused by Destruction of Sensory Nerve Fibers. Micturition reflex contraction cannot occur if the sensory nerve fibers from the bladder to the spinal cord are destroyed, thereby preventing transmission of stretch signals from the bladder. When this happens, a person loses bladder control, despite intact efferent fibers from the cord to the bladder and despite intact neurogenic connections within the brain. Instead of emptying periodically, the bladder fills to capacity and overflows a few drops at a time through the urethra. This occurrence is called *overflow incontinence*.

A common cause of atonic bladder is crush injury to the sacral region of the spinal cord. Certain diseases can also cause damage to the dorsal root nerve fibers that enter the spinal cord. For example, syphilis can cause constrictive fibrosis around the dorsal root nerve fibers, destroying them. This condition is called *tabes dorsalis*, and the resulting bladder condition is called *tabetic bladder*.

Automatic Bladder Caused by Spinal Cord Damage Above the Sacral Region. If the spinal cord is damaged above the sacral region but the sacral cord segments are still intact, typical micturition reflexes can still occur. However, they are no longer controlled by the brain. During the first few days to several weeks after the damage to the cord has occurred, the micturition reflexes are suppressed because of the state of spinal shock caused by the sudden loss of facilitative impulses from the brain stem and cerebrum. However, if the bladder is emptied periodically by catheterization to prevent bladder injury caused by overstretching of the bladder, the excitability of the micturition reflex gradually increases until typical micturition reflexes return; then, periodic (but unannounced) bladder emptying occurs.

Uninhibited Neurogenic Bladder Caused by Lack of Inhibitory Signals From the Brain. Another abnormality of micturition is the so-called *uninhibited neurogenic bladder*, which results in frequent and relatively uncontrolled micturition. This condition derives from partial damage in the spinal cord or the brain stem that interrupts most of the inhibitory signals. Therefore, facilitative impulses passing continually down the cord keep the sacral centers so excitable that even a small quantity of urine elicits an uncontrollable micturition reflex, thereby promoting frequent urination.

Excretion = Filtration – Reabsorption + Secretion

Figure 26-9. Basic kidney processes that determine the composition of the urine. The urinary excretion rate of a substance is equal to the rate at which the substance is filtered minus its reabsorption rate plus the rate at which it is secreted from the peritubular capillary blood into the tubules.

URINE FORMATION RESULTS FROM GLOMERULAR FILTRATION, TUBULAR REABSORPTION, AND TUBULAR SECRETION

The rates at which different substances are excreted in the urine represent the sum of three renal processes, shown in **Figure 26-9**: (1) glomerular filtration of substances in the blood; (2) reabsorption of substances from the renal tubules into the blood; and (3) secretion of substances from the blood into the renal tubules as follows:

Urinary excretion rate
 = Filtration rate – Reabsorption rate + Secretion rate

Urine formation begins when a large amount of fluid that is virtually free of protein is filtered from the glomerular capillaries into Bowman’s capsule. Most substances in the plasma, except for proteins, are freely filtered, so their concentration in the glomerular filtrate in Bowman’s capsule is almost the same as in the plasma. As filtered fluid leaves Bowman’s capsule and passes through the tubules, it is modified by reabsorption of water and specific solutes back into the blood or by secretion of other substances from the peritubular capillaries into the tubules.

Figure 26-10 shows the renal handling of four hypothetical substances. The substance shown in panel A is freely filtered by the glomerular capillaries but is neither reabsorbed nor secreted. Therefore, its excretion rate is

Figure 26-10. Renal handling of four hypothetical substances. **A,** The substance is freely filtered but not reabsorbed. **B,** The substance is freely filtered, but part of the filtered load is reabsorbed back in the blood. **C,** The substance is freely filtered but is not excreted in the urine because all the filtered substance is reabsorbed from the tubules back into the blood. **D,** The substance is freely filtered and is not reabsorbed but is secreted from the peritubular capillary blood into the renal tubules.

equal to the rate at which it was filtered. Certain waste products in the body, such as creatinine, are handled by the kidneys in this manner, allowing excretion of essentially all that is filtered.

In panel B, the substance is freely filtered but is also partly reabsorbed from the tubules back into the blood. Therefore, the rate of urinary excretion is less than the rate of filtration at the glomerular capillaries. In this case, the excretion rate is calculated as the filtration rate minus the reabsorption rate. This pattern is typical for many of the electrolytes of the body, such as sodium and chloride ions.

In panel C, the substance is freely filtered at the glomerular capillaries but is not excreted into the urine because all the filtered substance is reabsorbed from the tubules back into the blood. This pattern occurs for some of the nutritional substances in the blood, such as amino acids and glucose, allowing them to be conserved in the body fluids.

The substance in panel D is freely filtered at the glomerular capillaries and is not reabsorbed, but additional quantities of this substance are secreted from the peritubular

capillary blood into the renal tubules. This pattern often occurs for organic acids and bases, permitting them to be cleared from the blood rapidly and excreted in large amounts in the urine. The excretion rate in this case is calculated as filtration rate plus tubular secretion rate.

For each substance in the plasma, a particular combination of filtration, reabsorption, and secretion occurs. The rate at which the substance is excreted in the urine depends on the relative rates of these three basic renal processes.

FILTRATION, REABSORPTION, AND SECRETION OF DIFFERENT SUBSTANCES

In general, tubular reabsorption is quantitatively more important than tubular secretion in the formation of urine, but secretion plays an important role in determining the amounts of potassium and hydrogen ions and a few other substances that are excreted in the urine. Most substances that must be cleared from the blood, especially the end products of metabolism, such as urea, creatinine, uric acid, and urates, are poorly reabsorbed and are therefore excreted in large amounts in the urine. Certain foreign substances and drugs are also poorly reabsorbed but, in addition, are secreted from the blood into the tubules, so their excretion rates are high. Conversely, electrolytes, such as sodium ions, chloride ions, and bicarbonate ions, are highly reabsorbed, so only small amounts appear in the urine. Certain nutritional substances, such as amino acids and glucose, are completely reabsorbed from the tubules and do not appear in the urine, even though large amounts are filtered by the glomerular capillaries.

Each of the processes—glomerular filtration, tubular reabsorption, and tubular secretion—is regulated according to the needs of the body. For example, when there is excess sodium in the body, the rate at which sodium is filtered usually increases slightly, and a smaller fraction of

the filtered sodium is reabsorbed, causing increased urinary excretion of sodium.

For most substances, the rates of filtration and reabsorption are extremely large relative to the rates of excretion. Therefore, even slight changes of filtration or reabsorption can lead to relatively large changes in renal excretion. For example, an increase in the glomerular filtration rate (GFR) of only 10% (from 180 to 198 L/day) would raise the urine volume by 13-fold (from 1.5 to 19.5 L/day) if tubular reabsorption remained constant. In reality, changes in glomerular filtration and tubular reabsorption usually act in a coordinated manner to produce the necessary changes in renal excretion.

Why Are Large Amounts of Solutes Filtered and Then Reabsorbed by the Kidneys? One might question the wisdom of filtering such large amounts of water and solutes and then reabsorbing most of these substances. One advantage of a high GFR is that it allows the kidneys to remove waste products rapidly from the body that depend mainly on glomerular filtration for their excretion. Most waste products are poorly reabsorbed by the tubules and, therefore, depend on a high GFR for effective removal from the body.

A second advantage of a high GFR is that it allows all the body fluids to be filtered and processed by the kidneys many times each day. Because the entire plasma volume is only about 3 liters, whereas the GFR is about 180 L/day, the entire plasma can be filtered and processed about 60 times each day. This high GFR allows the kidneys to control the volume and composition of the body fluids precisely and rapidly.

Glomerular Filtration, Renal Blood Flow, and Their Control

GLOMERULAR FILTRATION—THE FIRST STEP IN URINE FORMATION

The first step in urine formation is filtration of large amounts of fluid through the glomerular capillaries into Bowman's capsule—almost 180 L/day. Most of this filtrate is reabsorbed, leaving only about 1 liter of fluid to be excreted each day, although the renal fluid excretion rate is highly variable, depending on fluid intake. The high rate of glomerular filtration depends on a high rate of kidney blood flow, as well as the special properties of the glomerular capillary membranes. In this chapter, we discuss the physical forces that determine the glomerular filtration rate (GFR), as well as the physiological mechanisms that regulate GFR and renal blood flow.

COMPOSITION OF THE GLOMERULAR FILTRATE

Like most capillaries, the glomerular capillaries are relatively impermeable to proteins, so the filtered fluid (called the *glomerular filtrate*) is essentially protein-free and devoid of cellular elements, including red blood cells. The concentrations of other constituents of the glomerular filtrate, including most salts and organic molecules, are similar to the concentrations in the plasma. Exceptions to this generalization include a few low-molecular-weight substances such as calcium and fatty acids that are not freely filtered because they are partially bound to the plasma proteins. For example, almost half of the plasma calcium and most of the plasma fatty acids are bound to proteins, and these bound portions are not filtered through the glomerular capillaries.

GLOMERULAR FILTRATION RATE IS ABOUT 20% OF RENAL PLASMA FLOW

Similar to other capillaries, the glomerular capillaries filter fluid at a rate that is determined by the following: (1) the balance of hydrostatic and colloid osmotic forces acting across the capillary membrane; and (2) the capillary filtration coefficient (K_f), the product of the permeability and filtering surface area of the capillaries. The glomerular capillaries have a much higher rate of filtration than most other capillaries because of a high glomerular hydrostatic pressure and a large K_f . In the average adult human, the

GFR is about 125 ml/min, or 180 L/day. The fraction of the renal plasma flow that is filtered (the filtration fraction) averages about 0.2, which means that about 20% of the plasma flowing through the kidney is filtered through the glomerular capillaries (Figure 27-1). The filtration fraction is calculated as follows:

$$\text{Filtration fraction} = \text{GFR}/\text{Renal plasma flow}$$

GLOMERULAR CAPILLARY MEMBRANE

The glomerular capillary membrane is similar to that of other capillaries, except that it has three (instead of the usual two) major layers: (1) the *endothelium* of the capillary; (2) a *basement membrane*; and (3) a layer of *epithelial cells (podocytes)* surrounding the outer surface of the capillary basement membrane (Figure 27-2). Together, these layers make up the filtration barrier, which, despite the three layers, filters several hundred times as much water and solutes as the usual capillary membrane. Even with this high rate of filtration, the glomerular capillary membrane normally filters only a small amount of plasma proteins.

The high filtration rate across the glomerular capillary membrane is due partly to its special characteristics. The capillary *endothelium* is perforated by thousands of small holes called *fenestrae*, similar to the fenestrated capillaries found in the liver, although smaller than the fenestrae of the liver. Although the fenestrations are relatively large, endothelial cell proteins are richly endowed with fixed negative charges that hinder the passage of plasma proteins.

Surrounding the endothelium is the *basement membrane*, which consists of a meshwork of collagen and proteoglycan fibrillae that have large spaces through which large amounts of water and small solutes can filter. The basement membrane greatly hinders filtration of plasma proteins, partly because of strong negative electrical charges associated with the proteoglycans.

The final part of the glomerular membrane is a layer of epithelial cells (podocytes) that line the outer surface of the glomerulus. These podocytes are not continuous but have long footlike processes (pedicels) that encircle the outer surface of the capillaries (see Figure 27-2). The foot

Figure 27-1. Average values for total renal plasma flow (RPF), glomerular filtration rate (GFR), tubular reabsorption (REAB), and urine flow rate. RPF is equal to renal blood flow \times (1 – hematocrit). Note that the GFR averages about 20% of the RPF, whereas urine flow rate is less than 1% of the GFR. Therefore, more than 99% of the fluid filtered is normally reabsorbed. The filtration fraction is GFR/RPF .

Figure 27-2. **A,** Basic ultrastructure of the glomerular capillaries. **B,** Cross section of the glomerular capillary membrane and its major components: capillary endothelium, basement membrane, and epithelium (podocytes).

Table 27-1 Filterability of Substances by Glomerular Capillaries Based on Molecular Weight

Substance	Molecular Weight	Filterability
Water	18	1.0
Sodium	23	1.0
Glucose	180	1.0
Inulin	5500	1.0
Myoglobin	17,000	0.75
Albumin	69,000	0.005

processes are separated by gaps called *slit pores* through which the glomerular filtrate moves. The epithelial cells, which also have negative charges, provide additional restriction to filtration of plasma proteins. Thus, all layers of the glomerular capillary wall provide a barrier to the filtration of plasma proteins but permit rapid filtration of water and most solutes in the plasma.

Filterability of Solutes Inversely Related to Their Size. The glomerular capillary membrane is thicker than most other capillaries, but it is also much more porous and therefore filters fluid at a high rate. Despite the high filtration rate, the glomerular filtration barrier is selective in determining which molecules will be filtered, based on their size and electrical charge.

Table 27-1 lists the effect of molecular size on filterability of different molecules. A filterability of 1.0 means that the substance is filtered as freely as water, whereas a filterability of 0.75 means that the substance is filtered only 75% as rapidly as water. Note that electrolytes such as sodium and small organic compounds such as glucose are freely filtered. As the molecular weight of the molecule approaches that of albumin, the filterability rapidly decreases, approaching zero.

Negatively Charged Large Molecules Are Filtered Less Easily Than Positively Charged Molecules of Equal Molecular Size. The molecular diameter of the plasma protein albumin is only about 6 nanometers, whereas the pores of the glomerular membrane are thought to be about 8 nanometers (80 angstroms [\AA]). Albumin is restricted from filtration, however, because of its negative charge and the electrostatic repulsion exerted by negative charges of the glomerular capillary wall proteoglycans.

Figure 27-3 shows how electrical charge affects the filtration of different molecular weight dextrans by the glomerulus. Dextrans are polysaccharides that can be manufactured as neutral molecules or with negative or positive charges. Note that for any given molecular radius, positively charged molecules are filtered much more readily than negatively charged molecules. Neutral dextrans are also filtered more readily than negatively charged dextrans of equal molecular weight. The

Figure 27-3. Effect of molecular radius and electrical charge of dextran on its filterability by the glomerular capillaries. A value of 1.0 indicates that the substance is filtered as freely as water, whereas a value of 0 indicates that it is not filtered. Dextran is polysaccharides that can be manufactured as neutral molecules or with negative or positive charges and with varying molecular weights.

reason for these differences in filterability is that the negative charges of the basement membrane and podocytes provide an important means for restricting large negatively charged molecules, including the plasma proteins.

Minimal-Change Nephropathy and Increased Glomerular Permeability to Plasma Proteins. In *minimal-change nephropathy*, the glomeruli become more permeable to plasma proteins, even though they may look normal when viewed with a standard light microscope. However, when viewed at high magnification with an electron microscope, the glomeruli usually display flattened podocytes with foot processes that may be detached from the glomerular basement membrane (*podocyte effacement*).

The causes of minimal change nephropathy are unclear but may be at least partly related to an immunological response and abnormal T-cell secretion of cytokines that injure the podocytes and increase their permeability to some of the lower molecular weight proteins, especially albumin. This increased permeability permits the proteins to be filtered by the glomerular capillaries and excreted in the urine, a condition known as *proteinuria* or *albuminuria*. Minimal change nephropathy is most common in young children but can also occur in adults, especially in those who have autoimmune disorders.

DETERMINANTS OF THE GLOMERULAR FILTRATION RATE

The GFR is determined by the following: (1) the sum of the hydrostatic and colloid osmotic forces across the glomerular membrane, which gives the *net filtration pressure*; and (2) the glomerular K_f . Expressed mathematically,

Net filtration pressure (10 mm Hg)	=	Glomerular hydrostatic pressure (60 mm Hg)	-	Bowman's capsule pressure (18 mm Hg)	-	Glomerular colloid osmotic pressure (32 mm Hg)
------------------------------------	---	--	---	--------------------------------------	---	--

Figure 27-4. Summary of forces causing filtration by the glomerular capillaries. The values shown are estimates for healthy humans.

the GFR equals the product of K_f and the net filtration pressure:

$$GFR = K_f \times \text{Net filtration pressure}$$

The net filtration pressure represents the sum of the hydrostatic and colloid osmotic forces that favor or oppose filtration across the glomerular capillaries (Figure 27-4). These forces include the following: (1) hydrostatic pressure inside the glomerular capillaries (glomerular hydrostatic pressure, P_G), which promotes filtration; (2) the hydrostatic pressure in Bowman's capsule (P_B) outside the capillaries, which opposes filtration; (3) the colloid osmotic pressure of the glomerular capillary plasma proteins (π_G), which opposes filtration; and (4) the colloid osmotic pressure of the proteins in Bowman's capsule (π_B), which promotes filtration. Under normal conditions, the concentration of protein in the glomerular filtrate is so low that the colloid osmotic pressure of the Bowman's capsule fluid is considered to be zero.

The GFR can therefore be expressed as follows:

$$GFR = K_f \times (P_G - P_B - \pi_G + \pi_B)$$

Although the normal values for the determinants of GFR have not been measured directly in humans, they have been estimated in animals such as dogs and rats. Based on the results in experimental animals, the approximate normal forces favoring and opposing glomerular filtration in humans are believed to be as follows (see Figure 27-4):

Forces Favoring Filtration (mm Hg)	
Glomerular hydrostatic pressure	60
Bowman's capsule colloid osmotic pressure	0
Forces Opposing Filtration (mm Hg)	
Bowman's capsule hydrostatic pressure	18
Glomerular capillary colloid osmotic pressure	32

Thus, the net filtration pressure = 60 - 18 - 32 = +10 mm Hg.

Some of these values can change markedly under different physiological conditions, whereas others are altered mainly in disease states, as discussed later.

INCREASED GLOMERULAR CAPILLARY FILTRATION COEFFICIENT INCREASES GLOMERULAR FILTRATE RATE

The K_f is a measure of the product of the hydraulic conductivity and surface area of the glomerular capillaries. The K_f cannot be measured directly, but can be estimated experimentally by dividing the GFR by the net filtration pressure:

$$K_f = \text{GFR} / \text{Net filtration pressure}$$

Because the total GFR for both kidneys is about 125 ml/min, and the net filtration pressure is 10 mm Hg, the normal K_f is calculated to be about 12.5 ml/min per mm Hg of filtration pressure. When K_f is expressed per 100 grams of kidney weight, it averages about 4.2 ml/min per mm Hg, a value about 400 times as high as the K_f of most other capillary systems of the body. The average K_f of many other tissues in the body is only about 0.01 ml/min per mm Hg/100 g. This high K_f for the glomerular capillaries contributes to their rapid rate of fluid filtration.

Although increased K_f raises the GFR and decreased K_f reduces the GFR, changes in K_f probably do not provide a primary mechanism for the normal daily regulation of GFR. Some diseases, however, lower K_f by reducing the number of functional glomerular capillaries (thereby reducing the surface area for filtration) or by increasing the thickness of the glomerular capillary membrane and reducing its hydraulic conductivity. For example, chronic uncontrolled hypertension may gradually reduce K_f by increasing the thickness of the glomerular capillary basement membrane and, eventually, by damaging the capillaries so severely that there is loss of capillary function.

INCREASED BOWMAN'S CAPSULE HYDROSTATIC PRESSURE DECREASES GLOMERULAR FILTRATION RATE

Direct measurements of hydrostatic pressure in Bowman's capsule and at different points in the proximal tubule in experimental animals using micropipettes have suggested that a reasonable estimate for Bowman's capsule pressure in humans is about 18 mm Hg under normal conditions. Increasing the hydrostatic pressure in Bowman's capsule reduces GFR, whereas decreasing this pressure raises GFR. However, changes in Bowman's capsule pressure normally do not serve as a primary means for regulating GFR.

In certain pathological states associated with obstruction of the urinary tract, Bowman's capsule pressure can increase markedly, causing serious reduction of GFR. For example, precipitation of calcium or of uric acid may lead

Figure 27-5. Increase in colloid osmotic pressure in plasma flowing through the glomerular capillary. Normally, about one-fifth of the fluid in the glomerular capillaries filters into Bowman's capsule, thereby concentrating the plasma proteins that are not filtered. Increases in the filtration fraction (glomerular filtration rate/renal plasma flow) increase the rate at which the plasma colloid osmotic pressure rises along the glomerular capillary; decreases in the filtration fraction have the opposite effect.

to formation of stones that lodge in the urinary tract, often in the ureter, thereby obstructing outflow of the urinary tract and raising Bowman's capsule pressure. This situation reduces GFR and eventually can cause *hydronephrosis* (distention and dilation of the renal pelvis and calyces) and can damage or even destroy the kidney unless the obstruction is relieved.

INCREASED GLOMERULAR CAPILLARY COLLOID OSMOTIC PRESSURE DECREASES GLOMERULAR FILTRATION RATE

As blood passes from the afferent arteriole through the glomerular capillaries to the efferent arterioles, the plasma protein concentration increases about 20% (Figure 27-5). The reason for this increase is that about one-fifth of the fluid in the capillaries filters into Bowman's capsule, thereby concentrating the glomerular plasma proteins that are not filtered. Assuming that the normal colloid osmotic pressure of plasma entering the glomerular capillaries is 28 mm Hg, this value usually rises to about 36 mm Hg by the time the blood reaches the efferent end of the capillaries. Therefore, the average colloid osmotic pressure of the glomerular capillary plasma proteins is midway between 28 and 36 mm Hg, or about 32 mm Hg.

Two factors that influence the glomerular capillary colloid osmotic pressure are the following: (1) the arterial plasma colloid osmotic pressure; and (2) the fraction of plasma filtered by the glomerular capillaries (filtration fraction). Increasing the arterial plasma colloid osmotic pressure raises the glomerular capillary colloid osmotic pressure, which in turn tends to decrease the GFR.

Increasing the filtration fraction also concentrates the plasma proteins and raises the glomerular colloid osmotic pressure (see Figure 27-5). Because the filtration fraction is defined as the GFR divided by the renal plasma flow, the filtration fraction can be increased by raising the GFR or

by reducing renal plasma flow. For example, a reduction in renal plasma flow with no initial change in GFR would tend to increase the filtration fraction, which would raise the glomerular capillary colloid osmotic pressure and tend to reduce the GFR. For this reason, changes in renal blood flow can influence GFR independently of changes in glomerular hydrostatic pressure.

With increasing renal blood flow, a lower fraction of the plasma is initially filtered out of the glomerular capillaries, causing a slower rise in the glomerular capillary colloid osmotic pressure and less inhibitory effect on the GFR. *Consequently, even with a constant glomerular hydrostatic pressure, a greater rate of blood flow into the glomerulus tends to increase the GFR and a lower rate of blood flow into the glomerulus tends to decrease the GFR.*

INCREASED GLOMERULAR CAPILLARY HYDROSTATIC PRESSURE INCREASES GLOMERULAR FILTRATION RATE

The glomerular capillary hydrostatic pressure has been estimated to be about 60 mm Hg under normal conditions. Changes in glomerular hydrostatic pressure serve as the primary means for physiological regulation of GFR. Increases in glomerular hydrostatic pressure raise the GFR, whereas decreases in glomerular hydrostatic pressure reduce the GFR.

Glomerular hydrostatic pressure is determined by three variables, each of which is under physiological control: (1) *arterial pressure*; (2) *afferent arteriolar resistance*; and (3) *efferent arteriolar resistance*.

Increased arterial pressure tends to raise glomerular hydrostatic pressure and, therefore, to increase the GFR. However, as discussed later, this effect is buffered by autoregulatory mechanisms that maintain a relatively constant glomerular pressure as arterial pressure fluctuates.

Increased resistance of afferent arterioles reduces glomerular hydrostatic pressure and decreases the GFR (Figure 27-6). Conversely, dilation of the afferent arterioles increases glomerular hydrostatic pressure and GFR.

Constriction of the efferent arterioles increases the resistance to outflow from the glomerular capillaries. This mechanism raises glomerular hydrostatic pressure and, as long as the increase in efferent resistance does not reduce renal blood flow too much, GFR increases slightly (see Figure 27-6). However, because efferent arteriolar constriction also reduces renal blood flow, filtration fraction and glomerular colloid osmotic pressure increase as efferent arteriolar resistance increases. Therefore, if constriction of efferent arterioles is severe (more than about a threefold increase in efferent arteriolar resistance), the rise in colloid osmotic pressure exceeds the increase in glomerular capillary hydrostatic pressure caused by efferent arteriolar constriction. When this situation occurs, the *net force* for filtration actually decreases, causing a reduction in GFR.

Figure 27-6. Effect of increases in afferent arteriolar resistance (R_A , top panel) or efferent arteriolar resistance (R_E , bottom panel) on renal blood flow, glomerular hydrostatic pressure (P_G), and glomerular filtration rate (GFR).

Figure 27-7. Effect of change in afferent arteriolar resistance or efferent arteriolar resistance on glomerular filtration rate and renal blood flow.

Thus, efferent arteriolar constriction has a biphasic effect on GFR (Figure 27-7). At moderate levels of constriction, there is a slight increase in GFR but, with severe constriction, there is a decrease in GFR. The primary cause of the eventual decrease in GFR is as follows. As efferent constriction becomes severe, and as plasma

Table 27-2 Factors That Can Decrease the Glomerular Filtration Rate

Physical Determinants ^a	Physiological or Pathophysiological Causes
$\downarrow K_f \rightarrow \downarrow \text{GFR}$	Renal disease, diabetes mellitus, hypertension, aging
$\uparrow P_B \rightarrow \downarrow \text{GFR}$	Urinary tract obstruction (e.g., kidney stones)
$\uparrow \pi_G \rightarrow \downarrow \text{GFR}$	\downarrow Renal blood flow, increased plasma proteins
$\downarrow P_G \rightarrow \downarrow \text{GFR}$ $\downarrow A_p \rightarrow \downarrow P_G$	\downarrow Arterial pressure (has only a small effect because of autoregulation)
$\downarrow R_E \rightarrow \downarrow P_G$	\downarrow Angiotensin II (drugs that block angiotensin II formation)
$\uparrow R_A \rightarrow \downarrow P_G$	\uparrow Sympathetic activity, vasoconstrictor hormones (e.g., norepinephrine, endothelin)

^aOpposite changes in the determinants usually increase the GFR. A_p , Systemic arterial pressure; GFR, glomerular filtration rate; K_f , glomerular filtration coefficient; P_B , Bowman's capsule hydrostatic pressure; π_G , glomerular capillary colloid osmotic pressure; P_G , glomerular capillary hydrostatic pressure; R_A , afferent arteriolar resistance; R_E , efferent arteriolar resistance.

protein concentration increases, there is a rapid nonlinear increase in colloid osmotic pressure caused by the Donnan effect; the higher the protein concentration, the more rapidly the colloid osmotic pressure rises because of the interaction of ions bound to the plasma proteins, which also exert an osmotic effect, as discussed in [Chapter 16](#).

To summarize, constriction of afferent arterioles reduces GFR. However, the effect of efferent arteriolar constriction depends on the severity of the constriction; modest efferent constriction raises GFR, but severe efferent constriction (more than a threefold increase in resistance) tends to reduce GFR.

Table 27-2 summarizes the factors that can decrease the GFR.

RENAL BLOOD FLOW

In a 70-kg man, the combined blood flow through both kidneys is about 1100 ml/min, or about 22% of the cardiac output. Considering that the two kidneys constitute only about 0.4% of the total body weight, one can readily see that they receive extremely high blood flow compared with other organs.

As with other tissues, blood flow supplies the kidneys with nutrients and removes waste products. However, the high blood flow to the kidneys greatly exceeds this need. The purpose of this additional flow is to supply enough plasma for the high rates of glomerular filtration that are necessary for precise regulation of body fluid volumes and solute concentrations. As might be expected, the mechanisms that regulate renal blood flow are closely linked to control of GFR and excretory functions of the kidneys.

Figure 27-8. Relationship between oxygen consumption and sodium reabsorption in dog kidneys. (From Kramer K, Deetjen P: [Relation of renal oxygen consumption to blood supply and glomerular filtration during variations of blood pressure.] *Pflugers Arch Physiol* 271:782, 1960.)

RENAL BLOOD FLOW AND OXYGEN CONSUMPTION

On a per gram-weight basis, the kidneys normally consume oxygen at twice the rate of the brain but have almost seven times the blood flow of the brain. Thus, the oxygen delivered to the kidneys far exceeds their metabolic needs, and the arterial-venous extraction of oxygen is relatively low compared with that of most other tissues.

A large fraction of the oxygen consumed by the kidneys is related to the high rate of active sodium reabsorption by the renal tubules. If renal blood flow and GFR are reduced, and less sodium is filtered, less sodium is reabsorbed and less oxygen is consumed. Therefore, renal oxygen consumption varies in proportion to renal tubular sodium reabsorption, which in turn is closely related to GFR and the rate of sodium filtered (**Figure 27-8**). If glomerular filtration ceases completely, renal sodium reabsorption also ceases and oxygen consumption decreases to about one-fourth normal. This residual oxygen consumption reflects the basic metabolic needs of the renal cells.

DETERMINANTS OF RENAL BLOOD FLOW

Renal blood flow (RBF) is determined by the pressure gradient across the renal vasculature (the difference between renal artery and renal vein hydrostatic pressures), divided by the total renal vascular resistance:

$$\text{RBF} = \frac{(\text{Renal artery pressure} - \text{Renal vein pressure})}{\text{Total renal vascular resistance}}$$

Renal artery pressure is about equal to systemic arterial pressure, and renal vein pressure averages about 3 to 4 mm Hg under most conditions. As in other vascular

Table 27-3 Approximate Pressures and Vascular Resistances in Circulation of a Normal Kidney

Vessel	Pressure in Vessel (mm Hg)		Percentage of Total Renal Vascular Resistance
	Beginning	End	
Renal artery	100	100	≈0
Interlobar, arcuate, and interlobular arteries	≈100	85	≈16
Afferent arteriole	85	60	≈26
Glomerular capillaries	60	59	≈1
Efferent arteriole	59	18	≈43
Peritubular capillaries	18	8	≈10
Interlobar, interlobular, and arcuate veins	8	4	≈4
Renal vein	4	≈4	≈0

beds, the total vascular resistance through the kidneys is determined by the sum of the resistances in the individual vasculature segments, including the arteries, arterioles, capillaries, and veins (Table 27-3).

Most of the renal vascular resistance resides in three major segments—interlobular arteries, afferent arterioles, and efferent arterioles. Resistance of these vessels is controlled by the sympathetic nervous system, various hormones, and local internal renal control mechanisms, as discussed later. An increase in the resistance of any of the vascular segments of the kidneys tends to reduce the renal blood flow, whereas a decrease in vascular resistance increases renal blood flow if renal artery and renal vein pressures remain constant.

Although changes in arterial pressure have some influence on renal blood flow, the kidneys have effective mechanisms for maintaining renal blood flow and GFR relatively constant over an arterial pressure range between 80 and 170 mm Hg, a process called *autoregulation*. This capacity for autoregulation occurs through mechanisms that are intrinsic to the kidneys, as discussed later in this chapter.

BLOOD FLOW IN VASA RECTA OF RENAL MEDULLA IS LOW COMPARED WITH RENAL CORTIX FLOW

The outer part of the kidney, the renal cortex, receives most of the kidney's blood flow. Blood flow in the renal medulla accounts for only 1% to 2% of the total renal blood flow. Flow to the renal medulla is supplied by a specialized portion of the peritubular capillary system called the *vasa recta*. These vessels descend into the medulla in parallel with the loops of Henle and then loop back along with the loops of Henle and return to the cortex before emptying into the venous system. As discussed in Chapter 29,

Table 27-4 Hormones and Autacoids That Influence the Glomerular Filtration Rate (GFR)

Hormone or Autacoid	Effect on GFR
Norepinephrine	↓
Epinephrine	↓
Endothelin	↓
Angiotensin II	↔ (prevents ↓)
Endothelial-derived nitric oxide	↑
Prostaglandins	↑

the vasa recta play an important role in allowing the kidneys to form concentrated urine.

PHYSIOLOGICAL CONTROL OF GLOMERULAR FILTRATION AND RENAL BLOOD FLOW

The determinant of GFR that is most variable and subject to physiological control is the glomerular hydrostatic pressure. This variable, in turn, is influenced by the sympathetic nervous system, hormones, autacoids (vasoactive substances that are released in the kidneys and act locally), and other feedback controls that are intrinsic to the kidneys.

STRONG SYMPATHETIC NERVOUS SYSTEM ACTIVATION DECREASES GLOMERULAR FILTRATION RATE

Essentially all the blood vessels of the kidneys, including the afferent and efferent arterioles, are richly innervated by sympathetic nerve fibers. Strong activation of the renal sympathetic nerves can constrict the renal arterioles and decrease renal blood flow and GFR. Moderate or mild sympathetic stimulation has little influence on renal blood flow and GFR. For example, reflex activation of the sympathetic nervous system resulting from moderate decreases in pressure at the carotid sinus baroreceptors or cardiopulmonary receptors has little influence on renal blood flow or GFR. However, as discussed in Chapter 28, even mild increases in renal sympathetic activity can stimulate renin release and increase renal tubular reabsorption, causing decreased sodium and water excretion.

The renal sympathetic nerves seem to be the most important in reducing GFR during severe acute disturbances lasting for a few minutes to a few hours, such as those elicited by the defense reaction, brain ischemia, or severe hemorrhage.

HORMONAL AND AUTACOID CONTROL OF RENAL CIRCULATION

Several hormones and autacoids can influence GFR and renal blood flow, as summarized in Table 27-4.

Norepinephrine, Epinephrine, and Endothelin Constrict Renal Blood Vessels and Decrease Glomerular Filtration Rate. Hormones that constrict afferent and efferent arterioles, causing reductions in GFR and renal blood flow, include *norepinephrine* and *epinephrine* released from the adrenal medulla. In general, blood levels of these hormones parallel the activity of the sympathetic nervous system; thus, norepinephrine and epinephrine have little influence on renal hemodynamics except under conditions associated with strong activation of the sympathetic nervous system, such as severe hemorrhage.

Another vasoconstrictor, *endothelin*, is a peptide that can be released by damaged vascular endothelial cells of the kidneys, as well as by other tissues. The physiological role of this autacoid is not completely understood. However, endothelin may contribute to hemostasis (minimizing blood loss) when a blood vessel is severed, which damages the endothelium and releases this powerful vasoconstrictor. Plasma endothelin levels are also increased in many disease states associated with vascular injury, such as toxemia of pregnancy, acute renal failure, and chronic uremia, and may contribute to renal vasoconstriction and decreased GFR in some of these pathophysiological conditions.

Angiotensin II Preferentially Constricts Efferent Arterioles in Most Physiological Conditions. A powerful renal vasoconstrictor, *angiotensin II*, can be considered to be a circulating hormone and a locally produced *autacoid* or *paracrine hormone* because it is formed in the kidneys and in the systemic circulation. Receptors for angiotensin II are present in virtually all blood vessels of the kidneys. However, the preglomerular blood vessels, especially the afferent arterioles, appear to be relatively protected from angiotensin II–mediated constriction in most physiological conditions associated with activation of the renin-angiotensin system, such as during a low-sodium diet or reduced renal perfusion pressure due to renal artery stenosis. This protection is due to release of vasodilators, especially *nitric oxide* and *prostaglandins*, which counteract the vasoconstrictor effects of angiotensin II in these blood vessels.

The efferent arterioles, however, are highly sensitive to angiotensin II. Because angiotensin II preferentially constricts efferent arterioles in most physiological conditions, increased angiotensin II levels raise glomerular hydrostatic pressure while reducing renal blood flow. It should be kept in mind that increased angiotensin II formation usually occurs in circumstances associated with decreased arterial pressure or volume depletion, which tend to decrease GFR. In these circumstances, the increased level of angiotensin II, by constricting efferent arterioles, helps *prevent* decreases in glomerular hydrostatic pressure and GFR. At the same time, though, the reduction in renal blood flow caused by efferent arteriolar constriction contributes to decreased flow through the peritubular capillaries, which in turn increases the

reabsorption of sodium and water, as discussed in [Chapter 28](#).

Thus, increased angiotensin II levels that occur with a low-sodium diet or volume depletion help maintain GFR and normal excretion of metabolic waste products, such as urea and creatinine, which depend on glomerular filtration for their excretion. At the same time, the angiotensin II–induced constriction of efferent arterioles increases tubular reabsorption of sodium and water, which helps restore blood volume and blood pressure. This effect of angiotensin II in helping autoregulate GFR is discussed in more detail later in this chapter.

Endothelial-Derived Nitric Oxide Decreases Renal Vascular Resistance and Increases Glomerular Filtration Rate. An autacoid that decreases renal vascular resistance and is released by the vascular endothelium throughout the body is *endothelial-derived nitric oxide*. A basal level of nitric oxide production appears to be important for maintaining vasodilation of the kidneys and normal excretion of sodium and water. Therefore, administration of drugs that inhibit formation of nitric oxide increases renal vascular resistance and decreases GFR and urinary sodium excretion, eventually causing high blood pressure. In some hypertensive patients or in patients with atherosclerosis, damage of the vascular endothelium and impaired nitric oxide production may contribute to increased renal vasoconstriction and elevated blood pressure.

Prostaglandins and Bradykinin Decrease Renal Vascular Resistance and Tend to Increase Glomerular Filtration Rate. Prostaglandins (PGE₂ and PGI₂) and bradykinin serve as hormones and autacoids that cause vasodilation, increased renal blood flow, and increased GFR. These substances are discussed in [Chapter 17](#). Although these vasodilators do not appear to be of major importance in regulating renal blood flow or the GFR in normal conditions, they may dampen the renal vasoconstrictor effects of the sympathetic nerves or angiotensin II, especially their effects to constrict the afferent arterioles.

By opposing vasoconstriction of afferent arterioles, the prostaglandins help prevent excessive reductions in GFR and renal blood flow. Under stressful conditions, such as volume depletion or after surgery, the administration of nonsteroidal antiinflammatory drugs (NSAIDs), such as aspirin, that inhibit prostaglandin synthesis may cause significant reductions in GFR.

AUTOREGULATION OF GLOMERULAR FILTRATION RATE AND RENAL BLOOD FLOW

Feedback mechanisms intrinsic to the kidneys normally keep renal blood flow and GFR relatively constant, despite marked changes in arterial blood pressure.

Figure 27-9. Autoregulation of renal blood flow and glomerular filtration rate but lack of autoregulation of urine flow during changes in renal arterial pressure.

These mechanisms still function in blood-perfused kidneys that have been removed from the body, independent of systemic influences. This relative constancy of GFR and renal blood flow is referred to as *autoregulation* (Figure 27-9).

The primary function of blood flow autoregulation in most tissues, other than the kidneys, is to maintain the delivery of oxygen and nutrients at a normal level and remove the waste products of metabolism, despite changes in the arterial pressure. In the kidneys, the normal blood flow is much higher than that required for these functions. The major function of autoregulation in the kidneys is to maintain a relatively constant the GFR and allow precise control of renal excretion of water and solutes.

The GFR normally remains relatively constant, despite considerable arterial pressure fluctuations that occur during a person's usual activities. For example, a decrease in arterial pressure to as low as 70 to 75 mm Hg or an increase to as high as 160 to 180 mm Hg usually changes the GFR less than 10%. In general, renal blood flow is autoregulated in parallel with GFR, but GFR is more efficiently autoregulated under certain conditions.

Importance of Glomerular Filtration Rate Autoregulation in Preventing Extreme Changes in Renal Excretion

Although the renal autoregulatory mechanisms are not perfect, they do prevent potentially large changes in GFR and renal excretion of water and solutes that would otherwise occur with changes in blood pressure. One can understand the quantitative importance of autoregulation by considering the relative magnitudes of glomerular filtration, tubular reabsorption, and renal excretion and

the changes in renal excretion that would occur without autoregulatory mechanisms.

Normally, GFR is about 180 L/day, and tubular reabsorption is 178.5 L/day, leaving 1.5 L/day of fluid to be excreted in the urine. In the absence of autoregulation, a relatively small increase in blood pressure (from 100 to 125 mm Hg) would cause a similar 25% increase in GFR (from about 180 to 225 L/day). If tubular reabsorption remained constant at 178.5 L/day, the urine flow would increase to 46.5 L/day (the difference between GFR and tubular reabsorption)—a total increase in urine of more than 30-fold. Because the total plasma volume is only about 3 liters, such a change would quickly deplete the blood volume.

In reality, changes in arterial pressure usually exert much less of an effect on urine volume for two reasons: (1) renal autoregulation prevents large changes in GFR that would otherwise occur; and (2) there are additional adaptive mechanisms in the renal tubules that cause them to increase their reabsorption rate when GFR rises, a phenomenon referred to as *glomerulotubular balance* (discussed in Chapter 28). Even with these special control mechanisms, changes in arterial pressure still have significant effects on renal excretion of water and sodium; this effect is referred to as *pressure diuresis* or *pressure natriuresis*, and it is crucial in the regulation of body fluid volumes and arterial pressure, as discussed in Chapters 19 and 30.

TUBULOGLOMERULAR FEEDBACK AND AUTOREGULATION OF GLOMERULAR FILTRATION RATE

The kidneys have a special feedback mechanism that links changes in the sodium chloride concentration at the macula densa with the control of renal arteriolar resistance and autoregulation of GFR. This feedback helps ensure a relatively constant delivery of sodium chloride to the distal tubule and helps prevent spurious fluctuations in renal excretion that would otherwise occur. In many circumstances, this feedback autoregulates renal blood flow and GFR in parallel. However, because this mechanism is specifically directed toward stabilizing sodium chloride delivery to the distal tubule, instances occur when GFR is autoregulated at the expense of changes in renal blood flow, as discussed later. In other cases, this mechanism may actually cause changes in GFR in response to primary changes in renal tubular sodium chloride reabsorption.

The tubuloglomerular feedback mechanism has two components that act together to control GFR: (1) an afferent arteriolar feedback mechanism; and (2) an efferent arteriolar feedback mechanism. These feedback mechanisms depend on special anatomical arrangements of the *juxtaglomerular complex* (Figure 27-10).

The juxtaglomerular complex consists of *macula densa cells* in the initial portion of the distal tubule and *juxtaglomerular cells* in the walls of the afferent and efferent arterioles. The macula densa is a specialized group

Figure 27-10. Structure of the juxtaglomerular apparatus, demonstrating its possible feedback role in the control of nephron function.

of epithelial cells in the distal tubules that comes in close contact with the afferent and efferent arterioles. The macula densa cells contain the Golgi apparatus, which consists of intracellular secretory organelles directed toward the arterioles, suggesting that these cells may be secreting a substance toward the arterioles.

Decreased Macula Densa Sodium Chloride Causes Dilation of Afferent Arterioles and Increased Renin Release. The macula densa cells sense changes in sodium chloride delivery to the distal tubule by way of signals that are not completely understood. Experimental studies have suggested that a decreased GFR slows the flow rate in the loop of Henle, causing increased reabsorption of the percentage of sodium and chloride ions delivered to the ascending loop of Henle and thereby reducing the concentration of sodium chloride at the macula densa cells. This decrease in sodium chloride concentration initiates a signal from the macula densa that has two effects (**Figure 27-11**): (1) it decreases resistance to blood flow in the afferent arterioles, which raises glomerular hydrostatic pressure and helps return GFR toward normal; and (2) it increases renin release from the juxtaglomerular cells of the afferent and efferent arterioles, which are the major storage sites for renin. Renin released from these cells then functions as an enzyme to increase the formation of angiotensin I, which is converted to angiotensin II. Finally, angiotensin II constricts the efferent arterioles, thereby increasing glomerular hydrostatic pressure and helping return GFR toward normal.

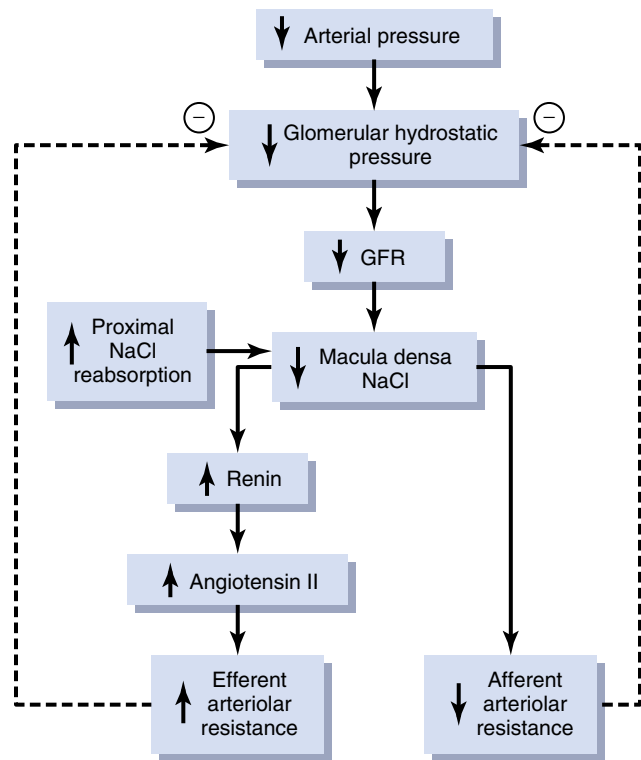

Figure 27-11. Macula densa feedback mechanism for autoregulation of glomerular hydrostatic pressure and glomerular filtration rate (GFR) during decreased renal arterial pressure.

These two components of the tubuloglomerular feedback mechanism, operating together by way of the special anatomical structure of the juxtaglomerular apparatus, provide feedback signals to the afferent and efferent arterioles for efficient autoregulation of GFR during changes in arterial pressure. When both of these mechanisms are functioning together, GFR changes by only a few percentage points, even with large fluctuations in arterial pressure between the limits of 75 and 160 mm Hg.

Blockade of Angiotensin II Formation Further Reduces Glomerular Filtration Rate During Renal Hypoperfusion.

As discussed earlier, a preferential constrictor action of angiotensin II on efferent arterioles helps prevent serious reductions in glomerular hydrostatic pressure and GFR when renal perfusion pressure falls below normal. The administration of drugs that block the formation of angiotensin II (angiotensin-converting enzyme inhibitors) or that block the action of angiotensin II (angiotensin II receptor antagonists) may cause greater reductions in GFR than usual when the renal arterial pressure falls below normal. Therefore, an important complication of using these drugs to treat patients who have hypertension because of renal artery stenosis (partial blockage of the renal artery) is a severe decrease in GFR that can, in some cases, cause acute renal failure. Nevertheless, angiotensin II–blocking drugs are important therapeutic agents in many patients with hypertension, congestive heart failure, and other conditions, as long as the patients are monitored to ensure that severe decreases in GFR do not occur.

MYOGENIC AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Another mechanism that contributes to the maintenance of a relatively constant renal blood flow and GFR is the ability of individual blood vessels to resist stretching during increased arterial pressure, referred to as the *myogenic mechanism*. Studies of individual blood vessels (especially small arterioles) throughout the body have shown that they respond to increased wall tension or wall stretch by contraction of the vascular smooth muscle. Stretch of the vascular wall allows increased movement of calcium ions from the extracellular fluid into the cells, causing them to contract through the mechanisms discussed in [Chapter 8](#). This contraction prevents excessive stretch of the vessel and, at the same time, by raising vascular resistance, helps prevent excessive increases in renal blood flow and the GFR when arterial pressure increases.

Although the myogenic mechanism probably operates in most arterioles throughout the body, its importance in renal blood flow and GFR autoregulation has been questioned by some physiologists because this pressure-sensitive mechanism has no means of directly detecting changes in renal blood flow or GFR per se. On the other hand, this mechanism may be more important in protecting the kidney from hypertension-induced injury. In response to sudden increases in blood pressure, the myogenic constrictor response in afferent arterioles occurs within seconds and therefore attenuates transmission of increased arterial pressure to the glomerular capillaries.

High Protein Intake and Hyperglycemia Increase Renal Blood Flow and Glomerular Filtration Rate. Although renal blood flow and GFR are relatively stable under most conditions, there are circumstances in which these variables change significantly. For example, *a high protein intake is known to increase renal blood flow and GFR*. With a long-term, high-protein diet, such as one that contains large amounts of meat, increases in GFR and renal blood flow are due partly to growth of the kidneys. However, the GFR and renal blood flow also increase 20% to 30% within 1 or 2 hours after a person eats a high-protein meal.

One likely explanation for the increased GFR is the following. A high-protein meal releases into the blood amino acids, which are reabsorbed in the proximal tubules. Because amino acids and sodium are reabsorbed together by cotransport in the proximal tubules, increased amino acid reabsorption also stimulates sodium reabsorption. This increased reabsorption of sodium decreases sodium delivery to the macula densa (see [Figure 27-12](#)), which elicits a tubuloglomerular feedback–mediated decrease in resistance of the afferent arterioles, as discussed earlier. The decreased afferent arteriolar resistance then raises renal blood flow and GFR, allowing sodium excretion to be maintained at a nearly normal level while increasing excretion of the waste products of protein metabolism, such as urea.

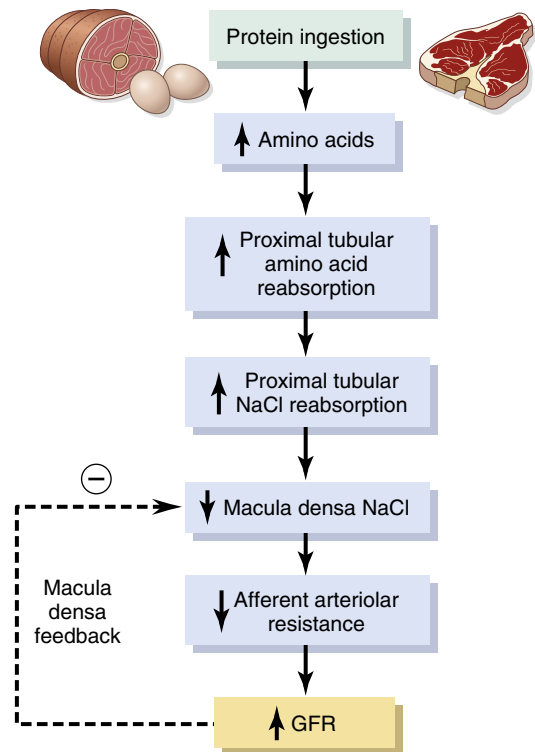

Figure 27-12. Possible role of macula densa feedback in mediating increased glomerular filtration rate (GFR) after a high-protein meal.

A similar mechanism may also explain the marked increases in renal blood flow and the GFR that occur with large increases in blood glucose levels in persons with uncontrolled diabetes mellitus. Because glucose, like some of the amino acids, is also reabsorbed along with sodium in the proximal tubule, increased glucose delivery to the tubules causes them to reabsorb excess sodium along with glucose. This increased reabsorption of sodium, in turn, decreases the sodium chloride concentration at the macula densa, activating a tubuloglomerular feedback–mediated dilation of the afferent arterioles and subsequent increases in renal blood flow and GFR.

These examples demonstrate that renal blood flow and GFR per se are not the primary variables controlled by the tubuloglomerular feedback mechanism. The main purpose of this feedback is to ensure a constant delivery of sodium chloride to the distal tubule, where final processing of the urine takes place. Thus, disturbances that tend to increase the reabsorption of sodium chloride at tubular sites before the macula densa tend to elicit increased renal blood flow and GFR, which helps return distal sodium chloride delivery toward normal so that normal rates of sodium and water excretion can be maintained (see [Figure 27-12](#)).

An opposite sequence of events occurs when proximal tubular reabsorption is reduced. For example, when the proximal tubules are damaged (which can occur as a result of poisoning by heavy metals, such as mercury, or large doses of drugs, such as tetracyclines), their ability to reabsorb sodium chloride is decreased. As a consequence, large amounts of sodium chloride are delivered to the distal tubule and, without appropriate compensation, would quickly cause excessive volume depletion. One of the important compensatory responses appears to be a

Table 27-5 Some Conditions That Influence Renal Blood Flow (RBF) and the Glomerular Filtration Rate (GFR)

Condition	RBF	GFR
Aging	↓	↓
High dietary protein	↑	↑
Hyperglycemia ^a	↑	↑
Obesity ^a	↑	↑
High NaCl intake ^a	↑	↑
Glucocorticoids	↑	↑
Fever, pyrogens	↑	↑

^aRefers to early effects, prior to development of glomerular injury that may occur with chronic hyperglycemia, obesity, and high salt intake.

tubuloglomerular feedback–mediated renal vasoconstriction that occurs in response to the increased sodium chloride delivery to the macula densa in these circumstances. These examples again demonstrate the importance of this feedback mechanism for ensuring that the distal tubules receive the proper rate of delivery of sodium chloride, other tubular fluid solutes, and tubular fluid volume so that appropriate amounts of these substances are excreted in the urine.

Other Factors That Influence Renal Blood Flow and Glomerular Filtration Rate. The GFR and renal blood flow are low at birth, approach normal adult levels after about 2 years of life, and in the absence of kidney disease, are maintained relatively constant until the fourth decade. Thereafter, GFR declines by about 5% to 10% per decade, although there is considerable variability among individuals. This decline in GFR coincides with nitric oxide deficiency, increased oxidative stress, and loss of functional nephrons, which may be related partly to increasing blood pressure, metabolic disorders, and other insults that cause cumulative glomerular injury with aging.

Men have higher renal blood flow and GFR than women, even when corrected for body mass. However, men also have a more rapid decline in GFR with aging than premenopausal women. Although the mechanisms responsible for these sex differences are not fully understood, beneficial effects of estrogens and damaging effects of androgens on the kidneys have been suggested as a partial explanation. **Table 27-5** summarizes some additional factors that influence renal blood flow and GFR regulation, and should be considered when assessing kidney function.

Renal Tubular Reabsorption and Secretion

As the glomerular filtrate enters the renal tubules, it flows sequentially through the successive parts of the tubule—the *proximal tubule*, *loop of Henle*, *distal tubule*, *collecting tubule*, and *collecting duct*—before it is excreted as urine. Along this course, some substances are selectively reabsorbed from the tubules back into the blood, whereas others are secreted from the blood into the tubular lumen. Eventually, the urine that is formed and all the substances in the urine represent the sum of three basic renal processes—glomerular filtration, tubular reabsorption, and tubular secretion:

$$\text{Urinary excretion} = \text{Glomerular filtration} - \text{Tubular reabsorption} + \text{Tubular secretion}$$

For many substances, tubular reabsorption plays a much more important role than secretion in determining the final urinary excretion rate. However, tubular secretion accounts for significant amounts of potassium ions, hydrogen ions, and a few other substances that appear in the urine.

TUBULAR REABSORPTION IS QUANTITATIVELY LARGE AND HIGHLY SELECTIVE

Table 28-1 shows the renal handling of several substances that are all freely filtered in the kidneys and reabsorbed at variable rates. The rate at which each of these substances is filtered is calculated as follows:

$$\text{Filtration} = \text{Glomerular filtration rate} \times \text{Plasma concentration}$$

This calculation assumes that the substance is freely filtered and not bound to plasma proteins. For example, if plasma glucose concentration is 1 g/L, the amount of glucose filtered each day is about 180 L/day \times 1 g/L, or 180 g/day. Because virtually none of the filtered glucose is normally excreted, the rate of glucose reabsorption is also 180 g/day.

From **Table 28-1**, two things are immediately apparent. First, the processes of glomerular filtration and tubular reabsorption are quantitatively large relative to urinary

excretion for many substances. Thus, a small change in glomerular filtration or tubular reabsorption can potentially cause a relatively large change in urinary excretion. For example, a 10% decrease in tubular reabsorption, from 178.5 to 160.7 L/day, would increase urine volume from 1.5 to 19.3 L/day (almost a 13-fold increase) if the glomerular filtration rate (GFR) remained constant. In reality, changes in tubular reabsorption and glomerular filtration are closely coordinated so that large fluctuations in urinary excretion are avoided.

Second, unlike glomerular filtration, which is relatively nonselective (essentially all solutes in the plasma are filtered except the plasma proteins or substances bound to them), *tubular reabsorption is highly selective*. Some substances, such as glucose and amino acids, are almost completely reabsorbed from the tubules, so the urinary excretion rate is essentially zero. Many ions in the plasma, such as sodium, chloride, and bicarbonate, are also highly reabsorbed, but their rates of reabsorption and urinary excretion are variable, depending on the needs of the body. Waste products, such as urea and creatinine, conversely, are poorly reabsorbed from the tubules and are excreted in relatively large amounts.

Therefore, by controlling their reabsorption of different substances, the kidneys regulate excretion of solutes independently of one another, a capability that is essential for precise control of the body fluid composition. In this chapter, we discuss the mechanisms that allow the kidneys to selectively reabsorb or secrete different substances at variable rates.

TUBULAR REABSORPTION INCLUDES PASSIVE AND ACTIVE MECHANISMS

For a substance to be reabsorbed, it must first be transported (1) across the tubular epithelial membranes into the renal interstitial fluid and then (2) through the peritubular capillary membrane back into the blood (**Figure 28-1**). Thus, reabsorption of water and solutes includes a series of transport steps. Reabsorption across the tubular epithelium into the interstitial fluid includes active or passive transport by the same basic mechanisms discussed

Table 28-1 Filtration, Reabsorption, and Excretion Rates of Different Substances by the Kidneys

Substance	Amount Filtered	Amount Reabsorbed	Amount Excreted	% of Filtered Load Reabsorbed
Glucose (g/day)	180	180	0	100
Bicarbonate (mEq/day)	4320	4318	2	>99.9
Sodium (mEq/day)	25,560	25,410	150	99.4
Chloride (mEq/day)	19,440	19,260	180	99.1
Potassium (mEq/day)	756	664	92	87.8
Urea (g/day)	46.8	23.4	23.4	50
Creatinine (g/day)	1.8	0	1.8	0

Figure 28-1 Reabsorption of filtered water and solutes from the tubular lumen across the tubular epithelial cells, through the renal interstitium, and back into the blood. Solute transport is through the cells (*transcellular path*) by passive diffusion or active transport, or between the cells (*paracellular path*) by diffusion. Water is transported through the cells and between the tubular cells by osmosis. Transport of water and solutes from the interstitial fluid into the peritubular capillaries occurs by ultrafiltration (*bulk flow*).

in Chapter 4 for transport across other cell membranes of the body. For example, water and solutes can be transported through the cell membranes (*transcellular route*) or through the spaces between the cell junctions (*paracellular route*). Then, after absorption across the tubular epithelial cells into the interstitial fluid, water and solutes are transported through the peritubular capillary walls into the blood by *ultrafiltration (bulk flow)* that is mediated by hydrostatic and colloid osmotic forces. The peritubular capillaries behave like the venous ends of most other capillaries because there is a net reabsorptive force that moves the fluid and solutes from the interstitium into the blood.

ACTIVE TRANSPORT

Active transport can move a solute against an electrochemical gradient; this requires energy derived from metabolism. Transport that is coupled directly to an energy source, such as the hydrolysis of adenosine

triphosphate (ATP), is termed *primary active transport*. An example of this mechanism is the sodium-potassium adenosine triphosphatase (ATPase) pump ($\text{Na}^+\text{-K}^+$ ATPase pump) that functions throughout most parts of the renal tubule. Transport that is coupled *indirectly* to an energy source, such as that due to an ion gradient, is referred to as *secondary active transport*. Reabsorption of glucose by the renal tubule is an example of secondary active transport. Although solutes can be reabsorbed by active and/or passive mechanisms by the tubule, water is always reabsorbed passively across the tubular epithelial membrane by the process of *osmosis*.

Solute Transport Through Epithelial Cells or Between Cells. Renal tubular cells, like other epithelial cells, are held together by *tight junctions*. Lateral intercellular spaces lie behind the tight junctions and separate the epithelial cells of the tubule. Solute transport can be reabsorbed or secreted across the cells through the *transcellular pathway* or between the cells by moving across the tight junctions and intercellular spaces via the *paracellular pathway*. Sodium is a substance that moves through both routes, although most of the sodium is transported through the transcellular pathway. In some nephron segments, especially the proximal tubule, water is also reabsorbed across the paracellular pathway, and substances dissolved in the water, especially potassium, magnesium, and chloride ions, are carried with the reabsorbed fluid between the cells.

Primary Active Transport Through the Tubular Membrane Linked to Hydrolysis of Adenosine Triphosphatase. The special importance of primary active transport is that it can move solutes against an electrochemical gradient. The energy for this active transport comes from the hydrolysis of ATP by way of membrane-bound ATPase, which is also a component of the carrier mechanism that binds and moves solutes across the cell membranes. The primary active transporters in the kidneys that are known include *$\text{Na}^+\text{-K}^+$ ATPase*, *hydrogen ATPase*, *hydrogen-potassium ATPase*, and *calcium ATPase*.

A good example of a primary active transport system is the reabsorption of sodium ions across the proximal tubular membrane, as shown in Figure 28-2. On the

Figure 28-2 Basic mechanism for active transport of sodium through the tubular epithelial cell. The sodium-potassium pump transports sodium from the interior of the cell across the basolateral membrane, creating a low intracellular sodium concentration and a negative intracellular electrical potential. The low intracellular sodium concentration and negative electrical potential cause sodium ions to diffuse from the tubular lumen into the cell through the brush border.

basolateral sides of the tubular epithelial cell, the cell membrane has an extensive $\text{Na}^+\text{-K}^+$ ATPase system that hydrolyzes ATP and uses the released energy to transport sodium ions out of the cell into the interstitium. At the same time, potassium is transported from the interstitium to the inside of the cell. The operation of this ion pump maintains low intracellular sodium and high intracellular potassium concentrations and creates a net negative charge of about -70 millivolts within the cell. This active pumping of sodium out of the cell across the *basolateral* membrane of the cell favors passive diffusion of sodium across the *luminal* membrane of the cell, from the tubular lumen into the cell, for two reasons: (1) there is a concentration gradient favoring sodium diffusion into the cell because the intracellular sodium concentration is low (12 mEq/L) and tubular fluid sodium concentration is high (140 mEq/L); and (2) the negative, -70 -millivolt, intracellular potential attracts the positive sodium ions from the tubular lumen into the cell.

Active reabsorption of sodium by $\text{Na}^+\text{-K}^+$ ATPase occurs in most parts of the tubule. In certain parts of the nephron, there are also additional provisions for moving large amounts of sodium into the cell. In the proximal tubule, there is an extensive brush border on the luminal side of the membrane (the side that faces the tubular lumen) that multiplies the surface area by about 20-fold. There are also carrier proteins that bind sodium ions on the luminal surface of the membrane and release them inside the cell, providing *facilitated diffusion* of sodium through the membrane into the cell. These sodium carrier proteins are also important for secondary active transport of other substances, such as glucose and amino acids, as discussed later.

Thus, the net reabsorption of sodium ions from the tubular lumen back into the blood involves at least three steps:

1. Sodium diffuses across the luminal membrane (also called the *apical membrane*) into the cell down an electrochemical gradient established by the $\text{Na}^+\text{-K}^+$ ATPase pump on the basolateral side of the membrane.
2. Sodium is transported across the basolateral membrane against an electrochemical gradient by the $\text{Na}^+\text{-K}^+$ ATPase pump.
3. Sodium, water, and other substances are reabsorbed from the interstitial fluid into the peritubular capillaries by ultrafiltration, a passive process driven by the hydrostatic and colloid osmotic pressure gradients.

Secondary Active Reabsorption Through the Tubular Membrane.

In secondary active transport, two or more substances interact with a specific membrane protein (a carrier molecule) and are transported together across the membrane. As one of the substances (e.g., sodium) diffuses down its electrochemical gradient, the energy released is used to drive another substance (e.g., glucose) against its electrochemical gradient. Thus, secondary active transport does not require energy directly from ATP or from other high-energy phosphate sources. Rather, the direct source of the energy is that liberated by the simultaneous facilitated diffusion of another transported substance down its own electrochemical gradient.

Figure 28-3 shows secondary active transport of glucose and amino acids in the proximal tubule. In both cases, specific carrier proteins in the brush border combine with a sodium ion and an amino acid or a glucose molecule at the same time. These transport mechanisms are so efficient that they remove virtually all the glucose and amino acids from the tubular lumen. After entry into the cell, glucose and amino acids exit across the basolateral membranes by diffusion, driven by the high glucose and amino acid concentrations in the cell facilitated by specific transport proteins.

Sodium glucose co-transporters (*SGLT2* and *SGLT1*) are located on the brush border of proximal tubular cells and carry glucose into the cell cytoplasm against a concentration gradient, as described previously. Approximately 90% of the filtered glucose is reabsorbed by *SGLT2* in the early part of the proximal tubule (S1 segment), and the residual 10% is transported by *SGLT1* in the latter segments of the proximal tubule. On the basolateral side of the membrane, glucose diffuses out of the cell into the interstitial spaces with the help of *glucose transporters*—*GLUT2* in the S1 segment and *GLUT1* in the latter part (S3 segment) of the proximal tubule.

Although transport of glucose against a chemical gradient does not directly use ATP, the reabsorption of glucose depends on energy expended by the primary active $\text{Na}^+\text{-K}^+$ ATPase pump in the basolateral membrane. Because of the activity of this pump, an electrochemical gradient for

Figure 28-3 Mechanisms of secondary active transport. The upper cell shows the *co-transport* of glucose and amino acids along with sodium ions through the apical side of the tubular epithelial cells, followed by facilitated diffusion through the basolateral membranes. The lower cell shows the *counter-transport* of hydrogen ions from the interior of the cell across the apical membrane and into the tubular lumen; movement of sodium ions into the cell, down an electrochemical gradient established by the sodium-potassium pump on the basolateral membrane, provides the energy for transport of the hydrogen ions from inside the cell into the tubular lumen. ATP, Adenosine triphosphate; GLUT, glucose transporter; NHE, sodium-hydrogen exchanger; SGLT, sodium-glucose co-transporter.

facilitated diffusion of sodium across the luminal membrane is maintained, and it is this downhill diffusion of sodium to the interior of the cell that provides the energy for the simultaneous uphill transport of glucose across the luminal membrane. Thus, this reabsorption of glucose is referred to as *secondary active transport* because glucose itself is reabsorbed uphill against a chemical gradient, but it is secondary to primary active transport of sodium.

Another important point is that a substance is said to undergo active transport when at least one of the steps in the reabsorption involves primary or secondary active transport, even though other steps in the reabsorption process may be passive. For glucose reabsorption, secondary active transport occurs at the luminal membrane, but passive facilitated diffusion occurs at the basolateral membrane, and passive uptake by bulk flow occurs at the peritubular capillaries.

Secondary Active Secretion Into the Tubules. Some substances are secreted into the tubules by secondary active transport, which often involves *counter-transport* of the substance with sodium ions. In counter-transport, the energy liberated from the downhill movement of one of the substances (e.g., sodium ions) enables the uphill movement of a second substance in the opposite direction.

One example of counter-transport, shown in **Figure 28-3**, is the active secretion of hydrogen ions coupled to sodium reabsorption in the luminal membrane of the proximal tubule. In this case, sodium entry into the cell is coupled with hydrogen extrusion from the cell by sodium-hydrogen counter-transport. This transport is mediated by a specific protein (*sodium-hydrogen exchanger*) in the brush border of the luminal membrane. As sodium is carried to the interior of the cell, hydrogen ions are forced outward in the opposite direction into the tubular lumen. The basic principles of primary and secondary active transport are discussed in **Chapter 4**.

Pinocytosis Is an Active Transport Mechanism for Reabsorption of Proteins. Some parts of the tubule, especially the proximal tubule, reabsorb large molecules such as proteins via *pinocytosis*, a type of *endocytosis*. In this process, the protein attaches to the brush border of the luminal membrane, and this portion of the membrane then invaginates to the interior of the cell until it is completely pinched off and a vesicle is formed containing the protein. Once inside the cell, the protein is digested into its constituent amino acids, which are reabsorbed through the basolateral membrane into the interstitial fluid. Because pinocytosis requires energy, it is considered a form of active transport.

Transport Maximum for Substances That Are Actively Reabsorbed. For most substances that are actively reabsorbed or secreted, there is a limit to the rate at which the solute can be transported, which is often referred to as the *transport maximum*. This limit is due to saturation of the specific transport systems involved when the amount of solute delivered to the tubule (referred to as the *tubular load*) exceeds the capacity of the carrier proteins and specific enzymes involved in the transport process.

The glucose transport system in the proximal tubule is a good example. Normally, measurable glucose does not appear in the urine because essentially all the filtered glucose is reabsorbed in the proximal tubule. However, when the filtered load exceeds the capability of the tubules to reabsorb glucose, urinary excretion of glucose does occur.

In the adult human, the transport maximum for glucose averages about 375 mg/min, whereas the filtered load of glucose is only about 125 mg/min ($\text{GFR} \times \text{plasma glucose} = 125 \text{ ml/min} \times 1 \text{ mg/ml}$). With large increases in GFR and/or plasma glucose concentration that increase the filtered load of glucose above 375 mg/min, the excess glucose filtered is not reabsorbed and passes into the urine.

Figure 28-4 shows the relationship between plasma concentration of glucose, filtered load of glucose, tubular transport maximum for glucose, and rate of glucose loss in the urine. Note that when the plasma glucose concentration is 100 mg/100 ml and the filtered load is at its normal level (125 mg/min), there is no loss of glucose in the urine. However, when the plasma concentration of glucose rises above about 200 mg/100 ml, increasing the filtered load to about 250 mg/min, a small amount of glucose begins to appear in the urine. This point is termed the *threshold* for

Figure 28-4 Relationships among the filtered load of glucose, rate of glucose reabsorption by the renal tubules, and rate of glucose excretion in the urine. The *transport maximum* is the maximum rate at which glucose can be reabsorbed from the tubules. The *threshold* for glucose refers to the filtered load of glucose at which glucose first begins to be excreted in the urine.

glucose. Note that this appearance of glucose in the urine (at the threshold) occurs before the transport maximum is reached. One reason for the difference between the threshold and transport maximum is that not all nephrons have the same transport maximum for glucose, and some of the nephrons therefore begin to excrete glucose before others have reached their transport maximum. The overall transport maximum for the kidneys, which is normally about 375 mg/min, is reached when all nephrons have reached their maximal capacity to reabsorb glucose.

The plasma glucose of a healthy person almost never becomes high enough to cause glucose excretion in the urine, even after eating a meal. However, in uncontrolled *diabetes mellitus*, plasma glucose concentration may rise to high levels, causing the filtered load of glucose to exceed the transport maximum and resulting in urinary glucose excretion. Some of the important transport maximums for substances actively reabsorbed by the tubules are as follows:

Substance	Transport Maximum
Glucose	375 mg/min
Phosphate	0.10 mmol/min
Sulfate	0.06 mmol/min
Amino acids	1.5 mmol/min
Urate	15 mg/min
Lactate	75 mg/min
Plasma protein	30 mg/min

Transport Maximums for Actively Secreted Substances. Substances that are actively secreted also exhibit transport maximums, as follows:

Substance	Transport Maximum
Creatinine	16 mg/min
Para-aminohippuric acid	80 mg/min

Substances That Are Actively Transported but Do Not Exhibit a Transport Maximum. The reason that actively transported solutes often exhibit a transport maximum is that the transport carrier system becomes saturated as the tubular load increases. Some substances that are actively reabsorbed do not demonstrate a transport maximum because their rate of transport is determined by other factors, such as the following: (1) the electrochemical gradient for diffusion of the substance across the membrane; (2) the permeability of the membrane for the substance; and (3) the time that the fluid containing the substance remains within the tubule. Transport of this type is referred to as *gradient-time transport* because the rate of transport depends on the electrochemical gradient and the time that the substance is in the tubule, which in turn depends on the tubular flow rate.

An example of gradient-time transport is sodium reabsorption in the proximal tubule, where the maximum transport capacity of the basolateral $\text{Na}^+\text{-K}^+$ ATPase pump is usually far greater than the actual rate of net sodium reabsorption because a significant amount of sodium transported out of the cell leaks back into the tubular lumen through junctions of the epithelial cells. The rate at which this backleak occurs depends on (1) the permeability of the tight junctions; and (2) the interstitial physical forces, which determine the rate of bulk flow reabsorption from the interstitial fluid into the peritubular capillaries. Therefore, sodium transport in the proximal tubules obeys mainly gradient-time transport principles rather than tubular maximum transport characteristics. This observation means that the higher the concentration of sodium in the proximal tubules, the higher is its reabsorption rate. Also, the slower the flow rate of tubular fluid, the greater the percentage of sodium that can be reabsorbed from the proximal tubules.

In the more distal parts of the nephron, the epithelial cells have much tighter junctions and transport much smaller amounts of sodium. In these segments, sodium reabsorption exhibits a transport maximum similar to that for other actively transported substances. Furthermore, this transport maximum can be increased by certain hormones, such as *aldosterone*.

PASSIVE WATER REABSORPTION BY OSMOSIS COUPLED MAINLY TO SODIUM REABSORPTION

When solutes are transported out of the tubule by primary or secondary active transport, their concentrations tend to decrease inside the tubule while increasing in the renal interstitium. This phenomenon creates a concentration difference that causes osmosis of water in the

same direction that the solutes are transported, from the tubular lumen to the renal interstitium. Some parts of the renal tubule, especially the proximal tubule, are highly permeable to water, and water reabsorption occurs so rapidly that there is only a small concentration gradient for solutes across the tubular membrane.

A large part of the osmotic flow of water in the proximal tubules occurs through water channels (*aquaporins*) in the cell membranes, as well as through the *tight junctions* between the epithelial cells. As noted previously, the junctions between the cells are not as tight as their name would imply and permit significant diffusion of water and small ions. This condition is especially true in the proximal tubules, which have a high permeability for water and a smaller but significant permeability to most ions, such as sodium, chloride, potassium, calcium, and magnesium.

Water moving across the tight junctions by osmosis also carries with it some of the solutes, a process referred to as *solvent drag*. In addition, because the reabsorption of water, organic solutes, and ions is coupled to sodium reabsorption, changes in sodium reabsorption significantly influence the reabsorption of water and many other solutes.

In the more distal parts of the nephron, beginning in the loop of Henle and extending through the collecting tubule, the tight junctions become far less permeable to water and solutes, and the epithelial cells also have a greatly decreased membrane surface area. Therefore, water cannot move easily across the tight junctions of the tubular membrane by osmosis. However, antidiuretic hormone (ADH) greatly increases the water permeability in the distal and collecting tubules.

Thus, water movement across the tubular epithelium can occur only if the membrane is permeable to water, no matter how large the osmotic gradient. In the proximal tubule and descending loop of Henle, water permeability is always high, and water is rapidly reabsorbed to reach osmotic equilibrium with the surrounding interstitial fluid. This high permeability is due to abundant expression of the water channel *aquaporin-1* (AQP-1) in the luminal and basolateral membranes. In the ascending loop of Henle, water permeability is always low, so almost no water is reabsorbed, despite a large osmotic gradient. Water permeability in the last parts of the tubules—the distal tubules, collecting tubules, and collecting ducts—occurs through aquaporins and can be high or low, depending on the presence or absence of ADH.

REABSORPTION OF CHLORIDE, UREA, AND OTHER SOLUTES BY PASSIVE DIFFUSION

When sodium is reabsorbed through the tubular epithelial cell, negative ions such as chloride are transported along with sodium because of electrical potentials. That is, transport of positively charged sodium ions out of the lumen leaves the inside of the lumen negatively charged, compared with the interstitial fluid causing chloride ions

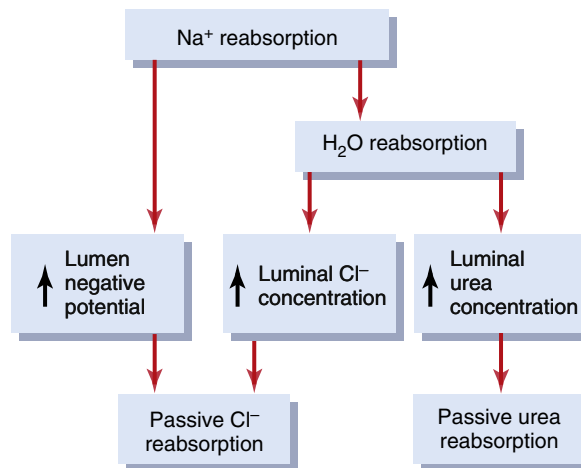

Figure 28-5 Mechanisms whereby water, chloride, and urea reabsorption are coupled with sodium reabsorption.

to diffuse *passively* through the *paracellular pathway*. Additional reabsorption of chloride ions occurs because of a chloride concentration gradient that develops when water is reabsorbed from the tubule by osmosis, thereby concentrating the chloride ions in the tubular lumen (**Figure 28-5**). Thus, active reabsorption of sodium is closely coupled to passive reabsorption of chloride by way of an electrical potential and a chloride concentration gradient.

Chloride ions can also be reabsorbed by secondary active transport. The most important of the secondary active transport processes for chloride reabsorption involves the co-transport of chloride with sodium across the luminal membrane.

Urea is also passively reabsorbed from the tubule, but to a much lesser extent than chloride ions. As water is reabsorbed from the tubules (by osmosis coupled to sodium reabsorption), urea concentration in the tubular lumen increases (see **Figure 28-5**). This increase creates a concentration gradient favoring reabsorption of urea. However, urea does not permeate the tubule as readily as water. In some parts of the nephron, especially the inner medullary collecting duct, passive urea reabsorption is facilitated by specific *urea transporters*. Yet, only about half of the urea that is filtered by the glomerular capillaries is reabsorbed from the tubules. The remaining urea passes into the urine, allowing the kidneys to excrete large amounts of this waste product of metabolism. In mammals, more than 90% of waste nitrogen, mainly generated in the liver as a product of protein metabolism, is normally excreted by the kidneys as urea.

Another waste product of metabolism, creatinine, is an even larger molecule than urea and is essentially impermeant to the tubular membrane. Therefore, almost none of the creatinine that is filtered is reabsorbed, so virtually all the creatinine filtered by the glomerulus is excreted in the urine.

Figure 28-6 Cellular ultrastructure and primary transport characteristics of the proximal tubule. The proximal tubules reabsorb about 65% of the filtered sodium, chloride, bicarbonate, and potassium and essentially all the filtered glucose and amino acids. The proximal tubules also secrete organic acids, bases, and hydrogen ions into the tubular lumen.

REABSORPTION AND SECRETION ALONG DIFFERENT PARTS OF THE NEPHRON

In the previous sections, we discussed the basic principles whereby water and solutes are transported across the tubular membrane. With these generalizations in mind, we can now discuss the different characteristics of the individual tubular segments that enable them to perform their specific functions. Only the tubular transport functions that are quantitatively most important will be discussed, especially as they relate to the reabsorption of sodium, chloride, and water. In subsequent chapters, we discuss the reabsorption and secretion of other substances in different parts of the tubular system.

PROXIMAL TUBULAR REABSORPTION

Normally, about 65% of the filtered load of sodium and water and a slightly lower percentage of filtered chloride are reabsorbed by the proximal tubule before the filtrate reaches the loops of Henle. These percentages can be increased or decreased in different physiological conditions, as discussed later.

Proximal Tubules Have High Capacity for Active and Passive Reabsorption. The high capacity of the proximal tubule for reabsorption results from its special cellular characteristics, as shown in [Figure 28-6](#). The proximal tubule epithelial cells are highly metabolic and have large numbers of mitochondria to support powerful active transport processes. In addition, the proximal tubular cells have an extensive brush border on the luminal (apical) side of the membrane, as well as an extensive labyrinth of intercellular and basal channels, all of which together provide an extensive membrane surface area on the luminal and basolateral sides of the epithelium for rapid transport of sodium ions and other substances.

The extensive membrane surface of the epithelial brush border is also loaded with protein carrier molecules that transport a large fraction of the sodium ions across the luminal membrane linked via the *co-transport* mechanism with multiple organic nutrients such as amino acids and glucose. Additional sodium is transported from the tubular lumen into the cell by *counter-transport* mechanisms that reabsorb sodium while secreting other substances into the tubular lumen, especially hydrogen ions. As discussed in [Chapter 31](#), secretion of hydrogen ions into the tubular lumen is an important step in the removal of bicarbonate ions from the tubule (by combining H^+ with the HCO_3^- to form H_2CO_3 , which then dissociates into H_2O and CO_2).

Although the Na^+K^+ ATPase pump provides the major force for the reabsorption of sodium, chloride, and water throughout proximal tubule, there are some differences in the mechanisms whereby sodium and chloride are transported through the luminal side of the early and late portions of the proximal tubular membrane.

In the first half of the proximal tubule, sodium is reabsorbed by co-transport along with glucose, amino acids, and other solutes. However, in the second half of the proximal tubule, little glucose and few amino acids remain to be reabsorbed. Instead, sodium is now reabsorbed, mainly with chloride ions. The second half of the proximal tubule has a relatively high concentration of chloride (≈ 140 mEq/L) compared with the early proximal tubule (≈ 105 mEq/L) because when sodium is reabsorbed, it preferentially carries with it glucose, bicarbonate, and organic ions in the early proximal tubule, leaving behind a solution that has a higher concentration of chloride. In the second half of the proximal tubule, the higher chloride concentration favors diffusion of this ion from the tubule lumen through the intercellular junctions into the renal interstitial fluid. Smaller amounts of chloride may also be reabsorbed through specific chloride channels in the proximal tubular cell membrane.

Concentrations of Solutes Along Proximal Tubules.

[Figure 28-7](#) summarizes the changes in concentration of various solutes along the proximal tubule. Although the *amount* of sodium in the tubular fluid decreases markedly along the proximal tubule, sodium *concentration* (and total osmolarity) remains relatively constant because water permeability of the proximal tubules is so great that water reabsorption keeps pace with sodium reabsorption. Certain organic solutes, such as glucose, amino acids, and bicarbonate, are much more avidly reabsorbed than water, and their concentrations decrease markedly along the length of the proximal tubule. Other organic solutes that are less permeant and not actively reabsorbed, such as creatinine, increase their concentration along the proximal tubule. The total solute concentration, as reflected by osmolarity, remains essentially the same all along the proximal tubule because of the extremely high permeability of this part of the nephron to water.

Figure 28-7 Changes in concentrations of different substances in tubular fluid along the proximal convoluted tubule relative to the concentrations of these substances in the plasma and glomerular filtrate. A value of 1.0 indicates that the concentration of the substance in the tubular fluid is the same as the concentration in the plasma. Values below 1.0 indicate that the substance is reabsorbed more avidly than water, whereas values above 1.0 indicate that the substance is reabsorbed to a lesser extent than water or is secreted into the tubules.

Secretion of Organic Acids and Bases by Proximal Tubules. The proximal tubule is also an important site for secretion of organic acids and bases such as *bile salts*, *oxalate*, *urate*, and *catecholamines*. Many of these substances are the end products of metabolism and must be rapidly removed from the body. The *secretion* of these substances into the proximal tubule plus *filtration* into the proximal tubule by the glomerular capillaries and almost total lack of reabsorption by the tubules, all combined, contribute to rapid excretion in the urine.

In addition to the waste products of metabolism, the kidneys secrete many potentially harmful drugs or toxins into the tubules and rapidly clear these substances from the blood. In the case of certain drugs, such as penicillin and salicylates, the rapid clearance by the kidneys creates a challenge in maintaining a therapeutically effective drug concentration.

Another compound that is rapidly secreted by the proximal tubule is para-aminohippuric acid (PAH). PAH is secreted so rapidly that the average person can clear about 90% of the PAH from the plasma flowing through the kidneys and excrete it in the urine. For this reason, the rate of PAH clearance can be used to estimate the renal plasma flow (RPF), as discussed later.

SOLUTE AND WATER TRANSPORT IN LOOPS OF HENLE

The loop of Henle consists of three functionally distinct segments—the *thin descending segment*, *thin ascending segment*, and *thick ascending segment*. The thin

Figure 28-8 Cellular ultrastructure and transport characteristics of the thin descending loop of Henle (*top*) and thick ascending segment of the loop of Henle (*bottom*). The descending part of the thin segment of the loop of Henle is highly permeable to water and moderately permeable to most solutes but has few mitochondria and little or no active reabsorption. The thick ascending limb of the loop of Henle reabsorbs about 25% of the filtered loads of sodium, chloride, and potassium, as well as large amounts of calcium, bicarbonate, and magnesium. This segment also secretes hydrogen ions into the tubular lumen.

descending and thin ascending segments, as their names imply, have thin epithelial membranes with no brush borders, few mitochondria, and minimal levels of metabolic activity (**Figure 28-8**).

The descending part of the thin segment is highly permeable to water and moderately permeable to most solutes, including urea and sodium. The function of this nephron segment is mainly to allow simple diffusion of substances through its walls. About 20% of the filtered water is reabsorbed in the loop of Henle, and almost all of this occurs in the thin descending limb. The ascending limb, including both the thin and thick portions, is virtually impermeable to water, a characteristic that is important for concentrating the urine.

The thick segment of the loop of Henle, which begins about halfway up the ascending limb, has thick epithelial cells that have high metabolic activity and are capable of active reabsorption of sodium, chloride, and potassium (see **Figure 28-8**). About 25% of the filtered loads of sodium, chloride, and potassium are reabsorbed in the loop of Henle, mostly in the thick ascending limb. Considerable amounts of other ions, such as calcium, bicarbonate, and magnesium, are also reabsorbed in the thick

Figure 28-9 Mechanisms of sodium, chloride, and potassium transport in the thick ascending loop of Henle. The $\text{Na}^+\text{-K}^+$ ATPase pump in the basolateral cell membrane maintains a low intracellular sodium concentration and a negative electrical potential in the cell. The 1-sodium, 2-chloride, 1-potassium co-transporter in the luminal membrane transports these three ions from the tubular lumen into the cells, using the potential energy released by the diffusion of sodium down an electrochemical gradient into the cells. Sodium is also transported into the tubular cell by sodium-hydrogen counter-transport. The positive charge (+8 mV) of the tubular lumen relative to the interstitial fluid forces cations such as Mg^{2+} and Ca^{2+} to diffuse from the lumen to the interstitial fluid via the paracellular pathway.

ascending loop of Henle. The thin segment of the ascending limb has a much lower reabsorptive capacity than the thick segment, and the thin descending limb does not reabsorb significant amounts of any of these solutes.

An important component of solute reabsorption in the thick ascending limb is the $\text{Na}^+\text{-K}^+$ ATPase pump in the epithelial cell basolateral membranes. As in the proximal tubule, the reabsorption of other solutes in the thick segment of the ascending loop of Henle is closely linked to the reabsorptive capability of the $\text{Na}^+\text{-K}^+$ ATPase pump, which maintains a low intracellular sodium concentration. The low intracellular sodium concentration in turn provides a favorable gradient for movement of sodium from the tubular fluid into the cell. *In the thick ascending loop, movement of sodium across the luminal membrane is mediated primarily by a 1-sodium, 2-chloride, 1-potassium cotransporter (NKCC2) (Figure 28-9).* This co-transport protein in the luminal membrane uses the potential energy released by downhill diffusion of sodium into the cell to drive the reabsorption of potassium into the cell against a concentration gradient.

The thick ascending limb of the loop of Henle is the site of action of the powerful *loop diuretics furosemide, ethacrynic acid, and bumetanide*, all of which inhibit the action of the NKCC2 co-transporter. These diuretics are

discussed in Chapter 32. The thick ascending limb also has a sodium-hydrogen counter-transport mechanism in its luminal cell membrane that mediates sodium reabsorption and hydrogen secretion (see Figure 28-9).

There is also significant paracellular reabsorption of cations, such as Mg^{2+} , Ca^{2+} , Na^+ , and K^+ , in the thick ascending limb as a result of the slight positive charge of the tubular lumen relative to the interstitial fluid. Although the NKCC2 co-transporter moves equal amounts of cations and anions into the cell, there is a slight backleak of potassium ions into the lumen, creating a positive charge of about +8 millivolts in the tubular lumen. This positive charge forces cations such as Mg^{2+} and Ca^{2+} to diffuse from the tubular lumen through the paracellular space and into the interstitial fluid.

The thick segment of the ascending loop of Henle is virtually impermeable to water. Therefore, most of the water delivered to this segment remains in the tubule, despite reabsorption of large amounts of solute. The tubular fluid in the ascending limb becomes very dilute as it flows toward the distal tubule, a feature that is important in allowing the kidneys to dilute or concentrate the urine under different conditions, as discussed in more detail in Chapter 29.

DISTAL TUBULES

The thick segment of the ascending limb of the loop of Henle empties into the *distal tubule*. The first portion of the distal tubule forms the *macula densa*, a group of closely packed epithelial cells that is part of the *juxtaglomerular complex* and provides feedback control of the GFR and blood flow in this same nephron.

The next part of the distal tubule is highly convoluted and has many of the same reabsorptive characteristics of the thick segment of the ascending limb of the loop of Henle. That is, it avidly reabsorbs most of the ions, including sodium, potassium, and chloride, but is virtually impermeable to water and urea. For this reason, it is referred to as the *diluting segment* because it also dilutes the tubular fluid.

Approximately 5% of the filtered load of sodium chloride is reabsorbed in the early distal tubule. The *sodium-chloride co-transporter* moves sodium chloride from the tubular lumen into the cell, and the $\text{Na}^+\text{-K}^+$ ATPase pump transports sodium out of the cell across the basolateral membrane (Figure 28-10). Chloride diffuses out of cell into the renal interstitial fluid through chloride channels in the basolateral membrane.

The thiazide diuretics, which are widely used to treat disorders such as hypertension and heart failure, inhibit the sodium-chloride co-transporter.

LATE DISTAL TUBULES AND CORTICAL COLLECTING TUBULES

The second half of the distal tubule and subsequent cortical collecting tubule have similar functional characteristics. Anatomically, they are composed of two distinct cell types, the *principal cells* and *intercalated cells*

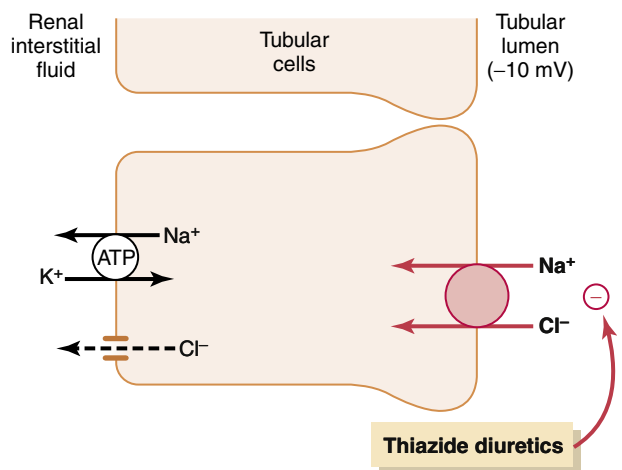

Figure 28-10 Mechanism of sodium chloride transport in the early distal tubule. Sodium and chloride are transported from the tubular lumen into the cell by a co-transporter that is inhibited by thiazide diuretics. Sodium is pumped out of the cell by $\text{Na}^+\text{-K}^+$ ATPase adenosine triphosphatase, and chloride diffuses into the interstitial fluid via chloride channels.

(**Figure 28-11**). The principal cells reabsorb sodium and water from the lumen and secrete potassium ions into the lumen. The type A intercalated cells reabsorb potassium ions and secrete hydrogen ions into the tubular lumen.

Principal Cells Reabsorb Sodium and Secrete Potassium.

Sodium *reabsorption* and potassium *secretion* by the principal cells depend on the activity of a $\text{Na}^+\text{-K}^+$ ATPase pump in each cell's basolateral membrane (**Figure 28-12**). This pump maintains a low sodium concentration inside the cell and, therefore, favors sodium diffusion into the cell through special channels. Secretion of potassium by these cells from the blood into the tubular lumen involves two steps: (1) potassium enters the cell because of the $\text{Na}^+\text{-K}^+$ ATPase pump, which maintains a high intracellular potassium concentration; and (2) once in the cell, potassium diffuses down its concentration gradient across the luminal membrane into the tubular fluid.

The principal cells are the primary sites of action of the *potassium-sparing diuretics*, including spironolactone, eplerenone, amiloride, and triamterene. *Spironolactone* and *eplerenone* are *mineralocorticoid receptor antagonists* that compete with aldosterone for receptor sites in the principal cells and therefore inhibit the stimulatory effects of aldosterone on sodium reabsorption and potassium secretion. *Amiloride* and *triamterene* are *sodium channel blockers* that directly inhibit the entry of sodium into the sodium channels of the luminal membranes and therefore reduce the amount of sodium that can be transported across the basolateral membranes by the $\text{Na}^+\text{-K}^+$ ATPase pump. This, in turn, decreases transport of potassium into the cells and ultimately reduces potassium secretion into the tubular fluid. For this reason, sodium channel blockers, as well as aldosterone antagonists, decrease urinary excretion of potassium and act as *potassium-sparing diuretics*.

Figure 28-11 Cellular ultrastructure and transport characteristics of the early distal tubule and late distal tubule and collecting tubule. The early distal tubule has many of the same characteristics as the thick ascending loop of Henle and reabsorbs sodium, chloride, calcium, and magnesium but is virtually impermeable to water and urea. The late distal tubules and cortical collecting tubules are composed of two distinct cell types, the *principal cells* and *intercalated cells*. The principal cells reabsorb sodium from the lumen and secrete potassium ions into the lumen. Type A intercalated cells reabsorb potassium and bicarbonate ions from the lumen and secrete hydrogen ions into the lumen. The reabsorption of water from this tubular segment is controlled by the concentration of *antidiuretic hormone*.

Intercalated Cells Can Secrete or Reabsorb Hydrogen, Bicarbonate, and Potassium Ions.

Intercalated cells play a major role in acid–base regulation and constitute 30% to 40% of the cells in the collecting tubules and collecting ducts. There are two types of intercalated cells, type A and type B (**Figure 28-13**). Type A intercalated cells secrete hydrogen ions by a hydrogen-ATPase transporter and by a hydrogen-potassium-ATPase transporter. Hydrogen is generated in this cell by the action of carbonic anhydrase on water and carbon dioxide to form carbonic acid, which then dissociates into hydrogen ions and bicarbonate ions. The hydrogen ions are then secreted into the tubular lumen and, for each hydrogen ion secreted, a bicarbonate ion becomes available for reabsorption across the basolateral membrane. Type A intercalated cells are especially important in eliminating hydrogen ions while reabsorbing bicarbonate in acidosis.

Type B intercalated cells have functions opposite to those of type A cells and secrete bicarbonate into the tubular lumen while reabsorbing hydrogen ions in alkalosis. Type B intercalated cells have hydrogen and bicarbonate

Figure 28-12 Mechanism of sodium-chloride reabsorption and potassium secretion in the principal cells of the late distal tubules and cortical collecting tubules. Sodium enters the cell through special channels and is transported out of the cell by the Na⁺-K⁺ ATPase pump. Aldosterone antagonists compete with aldosterone for binding sites in the cell and therefore inhibit the effects of aldosterone to stimulate sodium reabsorption and potassium secretion. Sodium channel blockers directly inhibit the entry of sodium into the sodium channels.

transporters on opposite sides of the cell membrane compared with type A cells. The chloride-bicarbonate counter-transporter on the apical membrane of type B cells is called *pendrin* and is different than the chloride-bicarbonate transporter of type A cells. Hydrogen ions are actively transported out of the type B intercalated cell on the basolateral side of the cell membrane by hydrogen-ATPase, and bicarbonate is secreted into the lumen, thus eliminating excess plasma bicarbonate in alkalosis. Induction of chronic metabolic alkalosis increases the number of type B intercalated cells, which contribute to increased excretion of bicarbonate, whereas acidosis increases the number of type A cells.

A more detailed discussion of this mechanism is presented in [Chapter 31](#). The intercalated cells can also reabsorb or secrete potassium ions, as shown in [Figure 28-13](#).

The functional characteristics of the *late distal tubule* and *cortical collecting tubule* can be summarized as follows:

1. The tubular membranes of both segments are almost completely impermeable to urea, similar to the diluting segment of the early distal tubule. Thus, almost all the urea that enters these segments passes on through and into the collecting duct to be excreted in the urine, although some reabsorption of urea occurs in the medullary collecting ducts.
2. Both the late distal tubule and cortical collecting tubule segments reabsorb sodium ions, and the rate of reabsorption is controlled by hormones, especially aldosterone. At the same time, these segments secrete potassium ions from the peritubular capillary blood

Figure 28-13 Type A and type B intercalated cells of the collecting tubule. Type A cells contain hydrogen-ATPase and hydrogen-potassium-ATPase in the luminal membrane and secrete hydrogen ions while reabsorbing bicarbonate and potassium ions in acidosis. In type B cells, the hydrogen-ATPase and hydrogen-potassium-ATPase transporters are located in the basolateral membrane and reabsorb hydrogen ions while secreting bicarbonate and potassium ions in alkalosis. The chloride-bicarbonate counter-transporter on the apical membrane of type B cells is called *pendrin* and is different than the chloride-bicarbonate transporter of type A intercalated cells.

into the tubular lumen, a process that is also controlled by aldosterone and other factors, such as the concentration of potassium ions in the body fluids.

3. The type A intercalated cells of these nephron segments can avidly secrete hydrogen ions by an active hydrogen-ATPase mechanism in acidosis. This process is different from the secondary active secretion of hydrogen ions by the proximal tubule because it is capable of secreting hydrogen ions against a large concentration gradient, as much as 1000 to 1. This is in contrast to the relatively small gradient (4- to 10-fold) for hydrogen ions that can be achieved by secondary active secretion in the proximal tubule.

Figure 28-14 Cellular ultrastructure and transport characteristics of the medullary collecting duct. The medullary collecting ducts actively reabsorb sodium and secrete hydrogen ions and are permeable to urea, which is reabsorbed in these tubular segments. The reabsorption of water in medullary collecting ducts is controlled by the concentration of antidiuretic hormone.

In alkalosis, the type B intercalated cells secrete bicarbonate and actively reabsorb hydrogen ions. Thus, the intercalated cells play a key role in acid–base regulation of the body fluids.

- The permeability of the late distal tubule and cortical collecting duct to water is controlled by the concentration of ADH, which is also called *vasopressin*. With high levels of ADH, these tubular segments are permeable to water but, in the absence of ADH, they are virtually impermeable to water. This special characteristic provides an important mechanism for controlling the degree of dilution or concentration of the urine.

MEDULLARY COLLECTING DUCTS

Although the medullary collecting ducts usually reabsorb less than 5% of the filtered water and sodium, they are the final site for processing the urine and, therefore, play a critical role in determining the final urine output of water and solutes.

The epithelial cells of the collecting ducts are nearly cuboidal in shape, with smooth surfaces and relatively few mitochondria (**Figure 28-14**). Special characteristics of this tubular segment are as follows:

- The permeability of the medullary collecting duct to water is controlled by the level of ADH. With high levels of ADH, water is avidly reabsorbed into the medullary interstitium, thereby reducing the urine volume and concentrating most of the solutes in the urine.
- Unlike the cortical collecting tubule, the medullary collecting duct is permeable to urea, and there are special *urea transporters* that facilitate urea diffusion across the luminal and basolateral membranes. Therefore, some of the tubular urea is reabsorbed into the medullary interstitium, helping raise the osmolality in this region of the kidneys and contributing to the kidneys' overall ability to form concentrated urine. This topic is discussed in **Chapter 29**.
- The medullary collecting duct is capable of secreting hydrogen ions against a large concentration

Figure 28-15 Changes in average concentrations of different substances at different points in the tubular system relative to the concentration of that substance in the plasma and glomerular filtrate. A value of 1.0 indicates that the concentration of the substance in the tubular fluid is the same as the concentration of that substance in the plasma. Values below 1.0 indicate that the substance is reabsorbed more avidly than water, whereas values above 1.0 indicate that the substance is reabsorbed to a lesser extent than water or is secreted into the tubules. PAH, Para-aminohippuric acid.

gradient, as also occurs in the cortical collecting tubule. Thus, the medullary collecting duct also plays a key role in regulating acid–base balance.

SUMMARY OF CONCENTRATIONS OF DIFFERENT SOLUTES IN DIFFERENT TUBULAR SEGMENTS

Whether a solute will become concentrated in the tubular fluid is determined by the relative degree of reabsorption of that solute versus the reabsorption of water. If a greater percentage of water is reabsorbed, the substance becomes more concentrated. If a greater percentage of the solute is reabsorbed, the substance becomes more diluted.

Figure 28-15 shows the degree of concentration of several substances in different tubular segments. All the values in this figure represent the tubular fluid concentration divided by the plasma concentration of a substance. If plasma concentration of the substance is assumed to be constant, any change in the tubular fluid/plasma concentration ratio reflects changes in tubular fluid concentration.

As the filtrate moves along the tubular system, the concentration rises progressively to higher than 1.0 if more water is reabsorbed than solute, or if there has been a net secretion of the solute into the tubular fluid. If the concentration ratio becomes progressively less than 1.0, this

means that relatively more solute has been reabsorbed than water.

The substances represented at the top of **Figure 28-15**, such as creatinine, become highly concentrated in the urine. In general, these substances are not needed by the body, and the kidneys have become adapted to reabsorb them only slightly or not at all or even to secrete them into the tubules, thereby excreting large quantities into the urine. Conversely, the substances represented at the bottom of the figure, such as glucose and amino acids, are all strongly reabsorbed. These are all substances that the body needs to conserve, and almost none of them are lost in the urine.

Tubular Fluid/Plasma Inulin Concentration Ratio Can Be Used to Assess Water Reabsorption by Renal Tubules. Inulin, a polysaccharide used to measure the GFR, is not reabsorbed or secreted by the renal tubules. Changes in inulin concentration at different points along the renal tubule, therefore, reflect changes in the amount of water present in the tubular fluid.

For example, the tubular fluid/plasma concentration ratio for inulin rises to about 3.0 at the end of the proximal tubules, indicating that inulin concentration in the tubular fluid is three times greater than in the plasma and glomerular filtrate. Because inulin is not secreted or reabsorbed from the tubules, a tubular fluid/plasma concentration ratio of 3.0 means that only one-third of the water that was filtered remains in the renal tubule and that two-thirds of the filtered water has been reabsorbed as the fluid passes through the proximal tubule. At the end of the collecting ducts, the tubular fluid/plasma inulin concentration ratio rises to about 125 (see **Figure 28-15**), indicating that only 1/125 of the filtered water remains in the tubule and that more than 99% has been reabsorbed.

REGULATION OF TUBULAR REABSORPTION

Because it is essential to maintain a precise balance between tubular reabsorption and glomerular filtration, there are multiple nervous, hormonal, and local control mechanisms that regulate tubular reabsorption, just as there are for control of glomerular filtration. An important feature of tubular reabsorption is that reabsorption of some solutes can be regulated independently of others, especially through hormonal control mechanisms.

GLOMERULOTUBULAR BALANCE—REABSORPTION RATE INCREASES IN RESPONSE TO INCREASED TUBULAR LOAD

One of the most basic mechanisms for controlling tubular reabsorption is the intrinsic ability of the tubules to increase their reabsorption rate in response to increased tubular load (increased tubular inflow). This phenomenon is referred to as *glomerulotubular balance*. For example, if the GFR increases from 125 to 150 ml/min, the absolute

rate of proximal tubular reabsorption also increases from about 81 ml/min (65% of GFR) to about 97.5 ml/min (65% of GFR). Thus, glomerulotubular balance refers to the fact that the total rate of reabsorption increases as the filtered load increases, even though the percentage of GFR reabsorbed in the proximal tubule remains relatively constant, at about 65%.

Some degree of glomerulotubular balance also occurs in other tubular segments, especially the loop of Henle. The precise mechanisms responsible for this are not fully understood but may be due partly to changes in physical forces in the tubule and surrounding renal interstitium, as discussed later. It is clear that the mechanisms for glomerulotubular balance can occur independently of hormones and can be demonstrated in completely isolated kidneys or even in completely isolated proximal tubular segments.

Glomerulotubular balance helps prevent overloading of the distal tubular segments when GFR increases. Glomerulotubular balance acts as another line of defense to buffer the effects of spontaneous changes in the GFR on urine output. (The other line of defense, discussed earlier, includes the renal autoregulatory mechanisms, especially tubuloglomerular feedback, which help prevent large changes in GFR.) Working together, the autoregulatory and glomerulotubular balance mechanisms prevent large changes in fluid flow in the distal tubules when the arterial pressure changes or when there are other disturbances that would otherwise upset sodium and volume homeostasis.

PERITUBULAR CAPILLARY AND RENAL INTERSTITIAL FLUID PHYSICAL FORCES

Hydrostatic and colloid osmotic forces govern the rate of reabsorption across the peritubular capillaries, just as they control filtration in the glomerular capillaries. Changes in peritubular capillary reabsorption can in turn influence the hydrostatic and colloid osmotic pressures of the renal interstitium and, ultimately, reabsorption of water and solutes from the renal tubules.

Normal Values for Physical Forces and Reabsorption Rate. As the glomerular filtrate passes through the renal tubules, more than 99% of the water and most of the solutes are normally reabsorbed. Fluid and electrolytes are reabsorbed from the tubules into the renal interstitium and from there into the peritubular capillaries. The normal rate of peritubular capillary reabsorption is about 124 ml/min.

Reabsorption across the peritubular capillaries can be calculated as follows:

$$\text{Reabsorption} = K_f \times \text{Net reabsorptive force}$$

The net reabsorptive force represents the sum of the hydrostatic and colloid osmotic forces that favor or oppose reabsorption across the peritubular capillaries. These forces include the following: (1) hydrostatic pressure inside the peritubular capillaries (peritubular hydrostatic pressure [P_{cl}]), which opposes reabsorption;

Figure 28-16 Summary of the hydrostatic and colloid osmotic forces that determine fluid reabsorption by the peritubular capillaries. The numerical values shown are estimates of the normal values for humans. The net reabsorptive pressure is normally about 10 mm Hg, causing fluid and solutes to be reabsorbed into the peritubular capillaries as they are transported across the renal tubular cells. ATP, Adenosine triphosphate; P_c , peritubular capillary hydrostatic pressure; P_{if} , interstitial fluid hydrostatic pressure; π_c , peritubular capillary colloid osmotic pressure; π_{if} , interstitial fluid colloid osmotic pressure.

(2) hydrostatic pressure in the renal interstitium (P_{if}) outside the capillaries, which favors reabsorption; (3) colloid osmotic pressure of the peritubular capillary plasma proteins (π_c), which favors reabsorption; and (4) colloid osmotic pressure of the proteins in the renal interstitium (π_{if}), which opposes reabsorption.

Figure 28-16 shows the approximate normal forces that favor and oppose peritubular reabsorption. Because the normal peritubular capillary pressure averages about 13 mm Hg and the renal interstitial fluid hydrostatic pressure averages 6 mm Hg, there is a positive hydrostatic pressure gradient from the peritubular capillary to the interstitial fluid of about 7 mm Hg, which opposes fluid reabsorption. This opposition to fluid reabsorption is more than counterbalanced by the colloid osmotic pressures that favor reabsorption. The plasma colloid osmotic pressure, which favors reabsorption, is about 32 mm Hg, and the colloid osmotic pressure of the interstitium, which opposes reabsorption, is 15 mm Hg, causing a net colloid osmotic force of about 17 mm Hg, favoring reabsorption. Therefore, subtracting the net hydrostatic forces that oppose reabsorption (7 mm Hg) from the net colloid osmotic forces that favor reabsorption (17 mm Hg) gives a net reabsorptive force of about 10 mm Hg. This value is high, similar to that found in the glomerular capillaries, but in the opposite direction.

The other factor that contributes to the high rate of fluid reabsorption in the peritubular capillaries is a large filtration coefficient (K_f) because of the high hydraulic conductivity and large surface area of the capillaries. Because the reabsorption rate is normally about 124 ml/min and net reabsorption pressure is 10 mm Hg, K_f normally is about 12.4 ml/min per mm Hg.

Regulation of Peritubular Capillary Physical Forces.

The two determinants of peritubular capillary reabsorption

that are directly influenced by renal hemodynamic changes are the hydrostatic and colloid osmotic pressures of the peritubular capillaries. The *peritubular capillary hydrostatic pressure* is influenced by the arterial pressure and resistances of the afferent and efferent arterioles as follows:

1. Increases in arterial pressure tend to raise peritubular capillary hydrostatic pressure and decrease the reabsorption rate. This effect is buffered to some extent by autoregulatory mechanisms that maintain relatively constant renal blood flow, as well as relatively constant hydrostatic pressures in the renal blood vessels.
2. An increase in resistance of the afferent or efferent arterioles reduces peritubular capillary hydrostatic pressure and tends to increase reabsorption rate. Although constriction of the efferent arterioles increases glomerular capillary hydrostatic pressure, it lowers peritubular capillary hydrostatic pressure.

The second major determinant of peritubular capillary reabsorption is the *colloid osmotic pressure* of the plasma in these capillaries; raising the colloid osmotic pressure increases peritubular capillary reabsorption. *The colloid osmotic pressure of peritubular capillaries is determined by the following:* (1) the *systemic plasma colloid osmotic pressure* (increasing the plasma protein concentration of systemic blood tends to raise peritubular capillary colloid osmotic pressure, thereby increasing reabsorption); and (2) the *filtration fraction*—the higher the filtration fraction, the greater the fraction of plasma filtered through the glomerulus and, consequently, the more concentrated the protein becomes in the plasma that remains behind. Thus, increasing the filtration fraction also tends to increase the peritubular capillary reabsorption rate. Because filtration fraction is defined as the ratio of GFR/RPF, an increased filtration fraction can occur as a result of increased GFR or decreased RPF. Some renal vasoconstrictors, such as angiotensin II, increase peritubular capillary reabsorption by decreasing RPF and increasing filtration fraction, as discussed later.

Changes in the peritubular capillary K_f can also influence the reabsorption rate because K_f is a measure of the permeability and surface area of the capillaries. Increases in K_f raise reabsorption, whereas decreases in K_f lower peritubular capillary reabsorption. K_f remains relatively constant in most physiological conditions. **Table 28-2** summarizes the factors that can influence the peritubular capillary reabsorption rate.

Renal Interstitial Hydrostatic and Colloid Osmotic Pressures.

Ultimately, changes in peritubular capillary physical forces influence tubular reabsorption by changing the physical forces in the renal interstitium surrounding the tubules. For example, a decrease in the reabsorptive force across the peritubular capillary membranes, caused by increased peritubular capillary hydrostatic pressure or decreased peritubular capillary colloid osmotic pressure, reduces the uptake of fluid and solutes from the

Table 28-2 Factors That Can Influence Peritubular Capillary Reabsorption

interstitium into the peritubular capillaries. This action in turn raises renal interstitial fluid hydrostatic pressure and decreases interstitial fluid colloid osmotic pressure because of dilution of the proteins in the renal interstitium. These changes then decrease the net reabsorption of fluid from the renal tubules into the interstitium, especially in the proximal tubules.

The mechanisms whereby changes in interstitial fluid hydrostatic and colloid osmotic pressures influence tubular reabsorption can be understood by examining the pathways through which solute and water are reabsorbed (Figure 28-17). Once the solutes enter the intercellular channels or renal interstitium by active transport or passive diffusion, water is drawn from the tubular lumen into the interstitium by osmosis. Furthermore, once the water and solutes are in the interstitial spaces, they can be swept up into the peritubular capillaries or diffuse back through the epithelial junctions into the tubular lumen. The so-called tight junctions between the epithelial cells of the proximal tubule are actually leaky, so considerable amounts of sodium can diffuse in both directions through these junctions. With the normal high rate of peritubular capillary reabsorption, the net movement of water and solutes is into the peritubular capillaries, with little backleak into the lumen of the tubule. However, when peritubular capillary reabsorption is reduced, there is increased interstitial fluid hydrostatic pressure and a tendency for greater amounts of solute and water to leak back into the tubular lumen, thereby reducing the rate of net reabsorption (see Figure 28-17).

The opposite is true when peritubular capillary reabsorption increases above the normal level. An initial increase in reabsorption by the peritubular capillaries tends to reduce interstitial fluid hydrostatic pressure and raise interstitial fluid colloid osmotic pressure. Both these forces favor movement of fluid and solutes out of the tubular lumen and into the interstitium; therefore, backleak of water and solutes into the tubular lumen is reduced, and net tubular reabsorption is increased.

Thus, through changes in the hydrostatic and colloid osmotic pressures of the renal interstitium, the uptake of water and solutes by the peritubular capillaries is closely

Figure 28-17 Proximal tubular and peritubular capillary reabsorption under normal conditions (top) and during decreased peritubular capillary reabsorption (bottom) caused by increasing peritubular capillary hydrostatic pressure (P_c) or decreasing peritubular capillary colloid osmotic pressure (π_c). Reduced peritubular capillary reabsorption, in turn, decreases the net reabsorption of solutes and water by increasing the amounts of solutes and water that leak back into the tubular lumen through the tight junctions of the tubular epithelial cells, especially in the proximal tubule.

matched to the net reabsorption of water and solutes from the tubular lumen into the interstitium. In general, forces that increase peritubular capillary reabsorption also increase reabsorption from the renal tubules. Conversely, hemodynamic changes that inhibit peritubular capillary reabsorption also inhibit tubular reabsorption of water and solutes.

EFFECT OF ARTERIAL PRESSURE ON URINE OUTPUT—PRESSURE NATRIURESIS AND PRESSURE DIURESIS

Even small increases in arterial pressure can cause marked increases in urinary excretion of sodium and water, phenomena referred to as *pressure natriuresis* and *pressure diuresis*. Because of the autoregulatory mechanisms described in Chapter 27, increasing the arterial pressure between the limits of 75 and 160 mm Hg usually has only a small effect on renal blood flow and GFR. The slight increase in GFR that does occur contributes in part to

the effect of increased arterial pressure on urine output. When GFR autoregulation is impaired, as often occurs in kidney disease, increases in arterial pressure can cause much larger increases in the GFR.

A second effect of increased renal arterial pressure that raises urine output is that it decreases the percentages of the filtered loads of sodium and water that are reabsorbed by the tubules. Although the mechanisms responsible for this effect are not fully understood, they include a cascade of physical factors, as well as paracrine and hormonal effects. Increased arterial pressure causes a slight increase in peritubular capillary hydrostatic pressure, especially in the vasa recta of the renal medulla, and a subsequent *increase in the renal interstitial fluid hydrostatic pressure*. As discussed earlier, an increase in the renal interstitial fluid hydrostatic pressure enhances backleak of sodium into the tubular lumen, thereby reducing the net reabsorption of sodium and water and further increasing the rate of urine output when renal arterial pressure rises.

A third factor that contributes to pressure natriuresis and pressure diuresis is *reduced angiotensin II formation*. Angiotensin II itself increases sodium reabsorption by the tubules and stimulates aldosterone secretion, which further increases sodium reabsorption. Therefore, decreased angiotensin II formation contributes to the decreased tubular sodium reabsorption that occurs when arterial pressure is increased.

A fourth factor that may contribute to pressure natriuresis is *internalization of sodium transporter proteins* from the apical membranes to the cytoplasm of the renal tubules, thereby reducing the amount of sodium that can be transported across the cell membranes. This effect of increased arterial pressure may be mediated, in part, by decreased angiotensin II formation and other autacoid or paracrine signals.

HORMONAL CONTROL OF TUBULAR REABSORPTION

Precise regulation of body fluid volumes and solute concentrations requires the kidneys to excrete different solutes and water at variable rates, sometimes independently of one another. For example, when potassium intake is increased, the kidneys must excrete more potassium while maintaining normal excretion of sodium and other

electrolytes. Likewise, when sodium intake is changed, the kidneys must adjust urinary sodium excretion appropriately without major changes in excretion of other electrolytes. Several hormones in the body provide this specificity of tubular reabsorption for different electrolytes and water. **Table 28-3** summarizes some of the most important hormones for regulating tubular reabsorption, their principal sites of action on the renal tubule, and their effects on solute and water excretion. Some of these hormones are discussed in more detail in **Chapters 29** and **30**, but here we briefly review their renal tubular actions.

Aldosterone Stimulates Renal Sodium Reabsorption and Potassium Secretion. Aldosterone, secreted by the zona glomerulosa cells of the adrenal cortex, is an important regulator of sodium reabsorption and secretion of potassium and hydrogen ions by the renal tubules. *A major renal tubular site of aldosterone action is on the principal cells of the cortical collecting tubule.* The mechanism whereby aldosterone increases sodium reabsorption and potassium secretion is by stimulating the Na⁺-K⁺ ATPase pump on the basolateral side of the cortical collecting tubule membrane. Aldosterone also increases the sodium permeability of the luminal side of the membrane by the insertion of epithelial sodium channels. The cellular mechanisms of aldosterone action are discussed in **Chapter 78**.

The most important stimuli for aldosterone are the following: (1) increased extracellular potassium concentration; and (2) increased angiotensin II levels, which typically occur in conditions associated with sodium and volume depletion or low blood pressure. Increased secretion of aldosterone associated with these conditions causes renal sodium and water retention, helping restore extracellular fluid volume and blood pressure toward normal.

When there is a deficit of aldosterone, as occurs with adrenal destruction or malfunction (*Addison disease*), there is marked sodium loss from the body and accumulation of potassium. Conversely, excess aldosterone secretion, as occurs in patients with adrenal tumors (*Conn syndrome*), is associated with sodium retention and decreased plasma potassium concentration due, in part, to excessive potassium secretion by the kidneys. Although daily regulation of sodium balance can be maintained as long as minimal levels of aldosterone are present, the

Table 28-3 Hormones That Regulate Tubular Reabsorption

Hormone	Site of Action	Effects
Aldosterone	Collecting tubule and duct	↑NaCl, H ₂ O reabsorption; ↑K ⁺ secretion; ↑H ⁺ secretion
Angiotensin II	Proximal tubule, thick ascending loop of Henle, distal tubule, collecting tubule	↑NaCl, H ₂ O reabsorption; ↑H ⁺ secretion
Antidiuretic hormone	Distal tubule/collecting tubule and duct	↑H ₂ O reabsorption
Atrial natriuretic peptide	Distal tubule/collecting tubule and duct	↓NaCl reabsorption
Parathyroid hormone	Proximal tubule, thick ascending loop of Henle, distal tubule	↓PO ₄ ⁻ reabsorption; ↑Ca ²⁺ reabsorption

inability to adjust aldosterone secretion appropriately greatly impairs the regulation of renal potassium excretion and potassium concentration of the body fluids. Thus, aldosterone is even more important as a regulator of potassium concentration than for sodium concentration, as discussed in [Chapter 30](#).

Angiotensin II Increases Sodium and Water Reabsorption. Angiotensin II is perhaps the body's most powerful sodium-retaining hormone. As discussed in [Chapter 19](#), angiotensin II formation increases in circumstances associated with low blood pressure and/or low extracellular fluid volume, such as during hemorrhage or loss of salt and water from the body fluids by excessive sweating or severe diarrhea. Increased formation of angiotensin II helps return blood pressure and extracellular volume toward normal by increasing sodium and water reabsorption from the renal tubules through three main effects:

1. *Angiotensin II stimulates aldosterone secretion*, which in turn increases sodium reabsorption.
2. *Angiotensin II constricts the efferent arterioles*, which has two effects on peritubular capillary dynamics that increase sodium and water reabsorption. First, efferent arteriolar constriction reduces peritubular capillary hydrostatic pressure, which increases net tubular reabsorption, especially from the proximal tubules. Second, efferent arteriolar constriction, by reducing renal blood flow, raises filtration fraction in the glomerulus and increases the concentration of proteins and colloid osmotic pressure in the peritubular capillaries. This mechanism also increases the reabsorptive force at the peritubular capillaries and raises tubular reabsorption of sodium and water.
3. *Angiotensin II directly stimulates sodium reabsorption in the proximal tubules, the loops of Henle, the distal tubules, and the collecting tubules.* One of the direct effects of angiotensin II is to stimulate the $\text{Na}^+\text{-K}^+$ ATPase pump on the tubular epithelial cell basolateral membrane. A second effect is to stimulate sodium-hydrogen exchange in the luminal membrane, especially in the proximal tubule. A third effect of angiotensin II is to stimulate sodium-bicarbonate co-transport in the basolateral membrane ([Figure 28-18](#)).

Thus, angiotensin II stimulates sodium transport across both the luminal and basolateral surfaces of the epithelial cell membrane in most renal tubular segments. These multiple actions of angiotensin II cause marked sodium and water retention by the kidneys when angiotensin II levels are increased and play a critical role in permitting the body to adapt to wide variations in sodium intake without large changes in extracellular fluid volume and blood pressure, as discussed in [Chapter 30](#).

At the same time that angiotensin II increases renal tubular sodium reabsorption, its vasoconstrictor effect on efferent arterioles also aids in the maintenance of normal excretion of metabolic waste products such as urea and

creatinine that depend mainly on an adequate GFR for their excretion. Thus, increased formation of angiotensin II permits the kidneys to retain sodium and water without causing retention of metabolic waste products.

Antidiuretic Hormone Increases Water Reabsorption.

The most important renal action of ADH is to increase the water permeability of the distal tubule, collecting tubule, and collecting duct epithelia. This effect helps the body conserve water in circumstances such as dehydration. In the absence of ADH, the permeability of the distal tubules and collecting ducts to water is low, causing the kidneys to excrete large amounts of dilute urine, a condition called *diabetes insipidus*. Thus, the actions of ADH play a key role in controlling the degree of dilution or concentration of the urine, as discussed further in [Chapters 29](#) and [76](#).

ADH binds to specific V_2 receptors in the late distal tubules, collecting tubules, and collecting ducts, increasing the formation of cyclic adenosine monophosphate and activating protein kinases ([Figure 28-19](#)). This action, in turn, stimulates movement of an intracellular protein, called *aquaporin-2* (AQP-2), to the luminal side of the cell membranes. The molecules of AQP-2 cluster together and fuse with the cell membrane by exocytosis to form *water channels* that permit rapid diffusion of water through the cells. There are other aquaporins, AQP-3 and AQP-4, in the basolateral side of the cell membrane that provide a path for water to exit the cells rapidly, although these aquaporins are not regulated by ADH. Chronic increases in ADH levels also increase the formation of AQP-2 protein in the renal tubular cells by stimulating AQP-2 gene transcription. When the concentration of ADH decreases, the molecules of AQP-2 are shuttled back to the cell cytoplasm, thereby removing the water channels from the luminal membrane and reducing water permeability. These actions of ADH are discussed further in [Chapters 29](#) and [76](#).

Figure 28-18 Direct effects of angiotensin II (*Ang II*) to increase proximal tubular sodium reabsorption. *Ang II* stimulates sodium-hydrogen exchange (*NHE*) on the luminal membrane and $\text{Na}^+\text{-K}^+$ ATPase transporter as well as sodium-bicarbonate co-transport on the basolateral membrane. These same effects of *Ang II* likely occur in several other parts of the renal tubule, including the loop of Henle, distal tubule, and collecting tubule. *AT₁*, Angiotensin II type I receptor.

Figure 28-19 Mechanism of action of arginine vasopressin (AVP) on the epithelial cells of the late distal tubules, collecting tubules, and collecting ducts. AVP binds to its V_2 receptors, which are coupled with stimulatory G proteins (G_s) that activate adenylate cyclase (AC) and stimulate formation of cyclic adenosine monophosphate (cAMP). This, in turn, activates protein kinase A and phosphorylation of intracellular proteins, causing movement of aquaporin-2 (AQP-2) to the luminal side of the cell membrane. The molecules of AQP-2 fuse together to form water channels. On the basolateral side of the cell membrane are other aquaporins, AQP-3 and AQP-4, that permit water to flow out of the cell, although these aquaporins do not appear to be regulated by AVP.

Atrial Natriuretic Peptide Decreases Sodium and Water Reabsorption. When specific cells of the cardiac atria are stretched because of plasma volume expansion and increased atrial blood pressure, they secrete a peptide called *atrial natriuretic peptide* (ANP). Increased levels of this peptide in turn directly inhibit reabsorption of sodium and water by the renal tubules, especially in the collecting ducts. ANP also inhibits renin secretion and therefore angiotensin II formation, which in turn reduces renal tubular reabsorption. This decreased sodium and water reabsorption increases urinary excretion, which helps return the blood volume back toward normal.

ANP levels are greatly elevated in congestive heart failure when the cardiac atria are stretched because of impaired pumping of the ventricles. The increased ANP level helps attenuate sodium and water retention in heart failure.

Parathyroid Hormone Increases Calcium Reabsorption. Parathyroid hormone is one of the most important calcium-regulating hormones in the body. Its principal action in the kidneys is to increase tubular reabsorption of calcium, especially in the *distal tubules* and *connecting tubules*, a tubular segment that connects the distal tubules with the cortical collecting duct. Parathyroid hormone also has other actions, including inhibition of phosphate reabsorption by the proximal tubule and stimulation of magnesium reabsorption by the loop of Henle, as discussed in [Chapter 30](#).

SYMPATHETIC NERVOUS SYSTEM ACTIVATION INCREASES SODIUM REABSORPTION

Activation of the sympathetic nervous system, if severe, can decrease sodium and water excretion by constricting the renal arterioles, thereby reducing the GFR. Even low levels of sympathetic activation, however, decrease sodium and water excretion by increasing sodium reabsorption in the proximal tubule, the thick ascending limb of the loop of Henle, and perhaps in more distal parts of the renal tubule. This occurs by activation of α -adrenergic receptors on the renal tubular epithelial cells.

Sympathetic nervous system stimulation also increases renin release and angiotensin II formation, which adds to the overall effect to increase tubular reabsorption and decrease renal excretion of sodium.

USE OF CLEARANCE METHODS TO QUANTIFY KIDNEY FUNCTION

The rates at which different substances are cleared from the plasma provide a useful way of quantitating the effectiveness with which the kidneys excrete various substances ([Table 28-4](#)). By definition, the renal clearance of a substance is the volume of plasma that is completely cleared of *the substance by the kidneys per unit of time*.

Although there is no single volume of plasma that is *completely* cleared of a substance, renal clearance provides a useful way of quantifying excretory function of the kidneys. We can use renal clearance to quantify renal blood flow, GFR, tubular reabsorption, and tubular secretion.

To illustrate the clearance principle, consider the following example. If the plasma passing through the kidneys contains 1 milligram of a substance in each milliliter, and if 1 milligram of this substance is also excreted into the urine each minute, then 1 ml/min of the plasma is cleared of the substance. Clearance refers to the volume of plasma that would be necessary to supply the amount of substance excreted in the urine per unit of time. Stated mathematically:

$$C_s \times P_s = U_s \times V$$

where C_s is the clearance rate of a substance s , P_s is the plasma concentration of the substance, U_s is the urine concentration of that substance, and V is the urine flow rate. Rearranging this equation, clearance can be expressed as:

$$C_s = \frac{U_s \times V}{P_s}$$

Thus, renal clearance of a substance is calculated from the urinary excretion rate ($U_s \times V$) of that substance divided by its plasma concentration.

INULIN CLEARANCE CAN BE USED TO ESTIMATE GLOMERULAR FILTRATION RATE

If a substance is freely filtered (filtered as freely as water) and is not reabsorbed or secreted by the renal tubules, then the rate at which that substance is excreted in the

Table 28-4 Use of Clearance to Quantify Kidney Function

Term	Equation	Units
Clearance rate	$C_s = \frac{U_s \times \dot{V}}{P_s}$	ml/min
Glomerular filtration rate	$GFR = \frac{U_{\text{inulin}} \times \dot{V}}{P_{\text{inulin}}}$	
Clearance ratio	Clearance ratio = $\frac{C_s}{C_{\text{inulin}}}$	None
Effective renal plasma flow	$ERPF = C_{\text{PAH}} = \frac{U_{\text{PAH}} \times \dot{V}}{P_{\text{PAH}}}$	ml/min
Renal plasma flow	$RPF = \frac{C_{\text{PAH}}}{E_{\text{PAH}}} = \frac{(U_{\text{PAH}} \times \dot{V} / P_{\text{PAH}})}{(P_{\text{PAH}} - V_{\text{PAH}}) / P_{\text{PAH}}}$ $= \frac{U_{\text{PAH}} \times \dot{V}}{P_{\text{PAH}} - V_{\text{PAH}}}$	ml/min
Renal blood flow	$RBF = \frac{RPF}{1 - \text{Hematocrit}}$	ml/min
Excretion rate	Excretion rate = $U_s \times \dot{V}$	mg/min, mmol/min, or mEq/min
Reabsorption rate	Reabsorption rate = Filtered load – Excretion rate $= (GFR \times P_s) - (\dot{U} \times V)$	mg/min, mmol/min, or mEq/min
Secretion rate	Secretion rate = Excretion rate – Filtered load	mg/min, mmol/min, or mEq/min

C_s , Clearance rate of substance s ; E_{PAH} , PAH extraction ratio; ERPF, effective renal plasma flow; GFR, glomerular filtration rate; P , plasma concentration; PAH, para-aminohippuric acid; P_{PAH} , renal arterial PAH concentration; RBF, renal blood flow; RPF, renal plasma flow; S , a substance; U , urine concentration; \dot{V} , urine flow rate; V_{PAH} , renal venous PAH concentration.

urine ($U_s \times V$) is equal to the filtration rate of the substance by the kidneys ($GFR \times P_s$). Thus:

$$GFR \times P_s = U_s \times V$$

The GFR, therefore, can be calculated as the clearance of the substance as follows:

$$GFR = \frac{U_s \times V}{P_s} = C_s$$

A substance that fits these criteria is *inulin*, a polysaccharide molecule with a molecular weight of about 5200. Inulin, which is not produced in the body, is found in the roots of certain plants and must be administered intravenously to a patient to measure GFR.

Figure 28-20 shows the renal handling of inulin. In this example, the plasma concentration is 1 mg/ml, urine concentration is 125 mg/ml, and urine flow rate is 1 ml/min. Therefore, 125 mg/min of inulin passes into the urine. Then, inulin clearance is calculated as the urine excretion rate of inulin divided by the plasma concentration, which yields a value of 125 ml/min. Thus, 125 milliliters of plasma flowing through the kidneys must be filtered to deliver the inulin that appears in the urine.

Inulin is not the only substance that can be used for determining the GFR. Other substances that have been used clinically to estimate the GFR include *iothalamate*, *chromium ethylenediaminetetraacetic acid* (EDTA), *cystatin C*, and *creatinine*.

CREATININE CLEARANCE AND PLASMA CREATININE CONCENTRATION CAN BE USED TO ESTIMATE GLOMERULAR FILTRATION RATE

Creatinine is a by-product of muscle metabolism and is cleared from the body fluids almost entirely by glomerular filtration. Therefore, creatinine clearance can also be used to assess GFR. Because measurement of creatinine clearance does not require intravenous infusion into the patient, this method is much more widely used than inulin clearance for estimating GFR clinically. However, creatinine clearance is not a perfect marker of GFR because a small amount of it is secreted by the tubules, so the amount of creatinine excreted slightly exceeds the amount filtered. There is normally a slight error in measuring plasma creatinine that leads to an overestimation of the plasma creatinine concentration; fortuitously, these two errors tend to cancel each other. Therefore, creatinine clearance provides a reasonable estimate of GFR.

In some cases, it may not be practical to collect urine in a patient for measuring creatinine clearance (C_{Cr}). An approximation of *changes* in GFR, however, can be obtained by simply measuring the plasma creatinine concentration (P_{Cr}), which is inversely proportional to the GFR:

$$GFR \approx C_{\text{Cr}} = \frac{U_{\text{Cr}} \times \dot{V}}{P_{\text{Cr}}}$$

Figure 28-20 Measurement of glomerular filtration rate (GFR) from the renal clearance of inulin. Inulin is freely filtered by the glomerular capillaries but is not reabsorbed by the renal tubules. P_{inulin} , Plasma inulin concentration; U_{inulin} , urine inulin concentration; \dot{V} , urine flow rate.

If GFR suddenly decreases by 50%, the kidneys will transiently filter and excrete only half as much creatinine, causing the accumulation of creatinine in the body fluids and raising plasma concentration. The plasma concentration of creatinine will continue to rise until the filtered load of creatinine ($P_{\text{Cr}} \times \text{GFR}$) and creatinine excretion ($U_{\text{Cr}} \times \dot{V}$) return to normal, and a balance between creatinine production and creatinine excretion is re-established. This response will occur when the plasma creatinine level increases to approximately twice normal, as shown in **Figure 28-21**.

If GFR falls to one-fourth normal, plasma creatinine level would increase to about four times normal, and a decrease of GFR to one-eighth normal would raise plasma creatinine level to eight times normal. Thus, under steady-state conditions, creatinine excretion rate equals the rate of creatinine production, despite reductions in GFR. However, this normal rate of creatinine excretion occurs at the expense of an elevated plasma creatinine concentration, as shown in **Figure 28-22**.

PARA-AMINOHIPPURIC ACID CLEARANCE CAN BE USED TO ESTIMATE RENAL PLASMA FLOW

Theoretically, if a substance is *completely* cleared from the plasma, the clearance rate of that substance is equal to the total RPF. In other words, the amount of the substance delivered to the kidneys in the blood ($\text{RPF} \times P_s$) would be equal to the amount excreted in the urine ($U_s \times \dot{V}$). Thus, RPF could be calculated as follows:

$$\text{RPF} = \frac{U_s \times \dot{V}}{P_s} = C_s$$

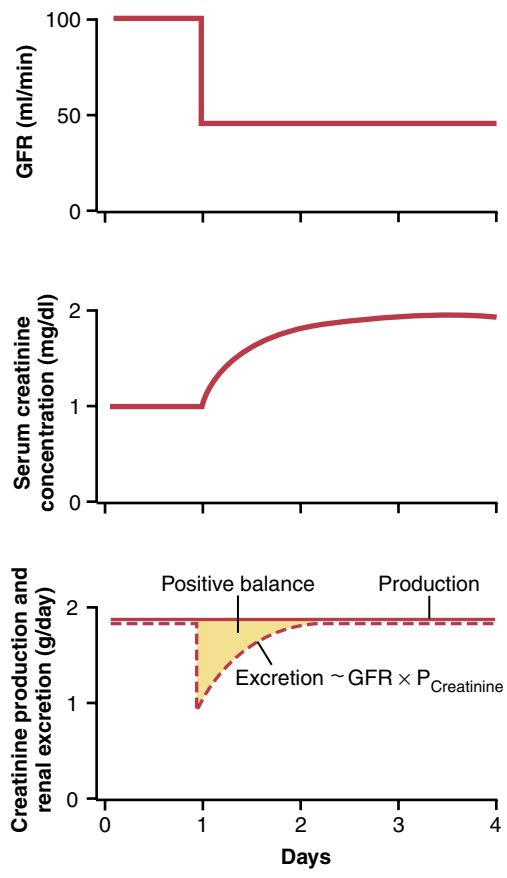

Figure 28-21 Effect of reducing glomerular filtration rate (GFR) by 50% on the serum creatinine concentration and on creatinine excretion rate when the production rate of creatinine remains constant. $P_{\text{Creatinine}}$, Plasma creatinine concentration.

Figure 28-22 Approximate relationship between glomerular filtration rate (GFR) and plasma creatinine concentration under steady-state conditions. Decreasing GFR by 50% will increase plasma creatinine level to twice normal if creatinine production by the body remains constant.

Figure 28-23 Measurement of renal plasma flow from the renal clearance of para-aminohippuric acid (PAH). PAH is freely filtered by the glomerular capillaries and is also secreted from the peritubular capillary blood into the tubular lumen. The amount of PAH in the plasma of the renal artery is about equal to the amount of PAH excreted in the urine. Therefore, the renal plasma flow can be calculated from the clearance of PAH. To be more accurate, one can correct for the percentage of PAH that is still in the blood when it leaves the kidneys. P_{PAH} , Arterial plasma PAH concentration; U_{PAH} , urine PAH concentration; \dot{V} , urine flow rate.

Because the GFR is only about 20% of the total plasma flow, a substance that is completely cleared from the plasma must be excreted by tubular secretion, as well as by glomerular filtration (Figure 28-23). There is no known substance that is *completely* cleared by the kidneys. One substance, PAH, is about 90% cleared from the plasma. Therefore, clearance of PAH can be used to approximate RPF. To be more accurate, one can correct for the percentage of PAH that is still in the blood when it leaves the kidneys. The percentage of PAH removed from the blood is known as the *extraction ratio of PAH* and averages about 90% in normal kidneys. In diseased kidneys, this extraction ratio may be reduced because of the inability of damaged tubules to secrete PAH into the tubular fluid.

The calculation of RPF can be demonstrated by the following example. Assume that the plasma concentration of PAH is 0.01 mg/ml, urine concentration is 5.85 mg/ml, and urine flow rate is 1 ml/min. PAH clearance can be calculated from the rate of urinary PAH excretion ($5.85 \text{ [mg/ml]} \times 1 \text{ [ml/min]}$) divided by the plasma PAH concentration (0.01 mg/ml). Thus, the clearance of PAH is calculated to be 585 ml/min.

If the extraction ratio for PAH is 90%, the actual RPF can be calculated by dividing 585 ml/min by 0.9, yielding a value of 650 ml/min. Thus, total RPF can be calculated as follows:

$$\text{Total renal plasma flow} = \frac{\text{PAH clearance}}{\text{PAH extraction ratio}}$$

The extraction ratio (E_{PAH}) is calculated as the difference between the renal arterial PAH (P_{PAH}) and renal venous PAH (V_{PAH}) concentrations, divided by the renal arterial PAH concentration:

$$E_{PAH} = \frac{P_{PAH} - V_{PAH}}{P_{PAH}}$$

One can calculate the total blood flow through the kidneys from the total RPF and hematocrit (the percentage of red blood cells in the blood). If the hematocrit is 0.45 and the total RPF is 650 ml/min, the total blood flow through both kidneys is $650/(1 - 0.45)$, or 1182 ml/min.

FILTRATION FRACTION IS CALCULATED FROM GFR DIVIDED BY RPF

To calculate the filtration fraction, which is the fraction of plasma that filters through the glomerular membrane, one must first know the RPF (PAH clearance) and the GFR (inulin clearance). If the RPF is 650 ml/min and the GFR is 125 ml/min, the filtration fraction (FF) is calculated as follows:

$$FF = GFR/RPF = 125/650 = 0.19$$

CALCULATION OF TUBULAR REABSORPTION OR SECRETION FROM RENAL CLEARANCES

If the rates of glomerular filtration and renal excretion of a substance are known, one can calculate whether there is a net reabsorption or net secretion of that substance by the renal tubules. For example, if the rate of excretion of the substance ($U_s \times \dot{V}$) is less than the filtered load of the substance ($GFR \times P_s$), then some of the substance must have been reabsorbed from the renal tubules. Conversely, if the excretion rate of the substance is greater than its filtered load, then the rate at which it appears in the urine represents the sum of the rate of glomerular filtration plus tubular secretion.

The following example demonstrates the calculation of tubular reabsorption. Assume the following laboratory values for a patient were obtained:

- Urine flow rate = 1 ml/min
- Urine concentration of sodium (U_{Na}) = 70 mEq/L = 70 μ Eq/ml
- Plasma sodium concentration = 140 mEq/L = 140 μ Eq/ml
- GFR (inulin clearance) = 100 ml/min

In this example, the filtered sodium load is $GFR \times P_{Na}$, or $100 \text{ ml/min} \times 140 \text{ } \mu\text{Eq/ml} = 14,000 \text{ } \mu\text{Eq/min}$. Urinary sodium excretion ($U_{Na} \times \text{urine flow rate}$) is 70 μ Eq/min. Therefore, tubular reabsorption of sodium is the difference between the filtered load and urinary excretion, or $14,000 \text{ } \mu\text{Eq/min} - 70 \text{ } \mu\text{Eq/min} = 13,930 \text{ } \mu\text{Eq/min}$.

Comparisons of Inulin Clearance with Clearances of Different Solutes. The following generalizations can be made by comparing the clearance of a substance with the clearance of inulin, the gold standard for measuring GFR: (1) if the clearance rate of the substance equals that of inulin, the substance is only filtered and not reabsorbed or secreted; (2) if the clearance rate of a substance is less than inulin clearance, the substance must have been reabsorbed by the nephron tubules; and (3) if the clearance rate of a substance is greater than that of inulin, the substance must be secreted by the nephron tubules. Listed below are the approximate clearance rates for some of the substances normally handled by the kidneys:

Substance	Clearance Rate (ml/min)
Glucose	0
Sodium	0.9
Chloride	1.3
Potassium	12.0
Phosphate	25.0
Inulin	125.0
Creatinine	140.0

Urine Concentration and Dilution; Regulation of Extracellular Fluid Osmolarity and Sodium Concentration

For the cells of the body to function properly, they must be bathed in extracellular fluid with a relatively constant concentration of electrolytes. The *total concentration* of solutes in the extracellular fluid—and therefore the osmolarity—must also be precisely regulated to prevent the cells from shrinking or swelling. The osmolarity is determined by the amount of solute (mainly sodium chloride) divided by the volume of the extracellular fluid. Thus, to a large extent, extracellular fluid osmolarity and sodium chloride concentration are regulated by the amount of extracellular water. The total body water is controlled by (1) fluid intake, which is regulated by factors that determine thirst; and (2) renal water excretion, which is controlled by multiple factors that influence glomerular filtration and tubular reabsorption.

In this chapter, we discuss the following: (1) mechanisms that cause the kidneys to eliminate excess water by excreting a dilute urine; (2) mechanisms that cause the kidneys to conserve water by excreting a concentrated urine; (3) renal feedback mechanisms that control the extracellular fluid sodium concentration and osmolarity; and (4) thirst and salt appetite mechanisms that determine the intakes of water and salt, which also help control extracellular fluid volume, osmolarity, and sodium concentration.

KIDNEYS EXCRETE EXCESS WATER BY FORMING DILUTE URINE

Normal kidneys have a tremendous capability to vary the relative proportions of solutes and water in the urine in response to various challenges. When there is excess water in the body, and body fluid osmolarity is reduced, the kidneys can excrete urine with an osmolarity as low as 50 mOsm/L, a concentration that is only about one-sixth the osmolarity of normal extracellular fluid. Conversely, when there is a deficit of water in the body, and extracellular fluid osmolarity is high, the kidneys can excrete highly concentrated urine with an osmolarity of 1200 to 1400 mOsm/L. Equally important, the kidneys can excrete a large volume of dilute urine or a small volume

of concentrated urine without major changes in rates of excretion of solutes such as sodium and potassium. This ability to regulate water excretion independently of solute excretion is necessary for survival, especially when fluid intake is limited.

ANTIDIURETIC HORMONE CONTROLS URINE CONCENTRATION

The body has a powerful feedback system for regulating plasma osmolarity and sodium concentration that operates by altering renal excretion of water independently of solute excretion rate. A primary effector of this feedback is *antidiuretic hormone* (ADH), also called *vasopressin*.

When osmolarity of the body fluids increases above normal (i.e., the solutes in the body fluids become too concentrated), the posterior pituitary gland secretes more ADH, which increases the permeability of the distal tubules and collecting ducts to water, as discussed in [Chapter 28](#). This mechanism increases water reabsorption and decreases urine volume but does not markedly alter the rate of renal excretion of the solutes.

When there is excess water in the body, and extracellular fluid osmolarity is reduced, secretion of ADH by the posterior pituitary decreases, thereby reducing the permeability of the distal tubule and collecting ducts to water, which causes increased amounts of more dilute urine to be excreted. Thus, the rate of ADH secretion determines, to a large extent, whether the kidney excretes dilute or concentrated urine.

RENAL MECHANISMS FOR EXCRETING DILUTE URINE

When there is a large excess of water in the body, the kidney can excrete as much as 20 L/day of dilute urine, with a concentration as low as 50 mOsm/L. The kidney performs this impressive feat by continuing to reabsorb solutes without reabsorbing large amounts of water in the distal parts of the nephron, including the late distal tubule and collecting ducts.

Figure 29-1. Water diuresis in a person after ingestion of 1 liter of water. Note that after water ingestion, urine volume increases and urine osmolarity decreases, causing excretion of a large volume of dilute urine; however, the total amount of solute excreted by the kidneys remains relatively constant. These responses of the kidneys prevent plasma osmolarity from decreasing markedly during excess water ingestion.

Figure 29-1 shows the approximate renal responses in a human after ingestion of 1 liter of water. Note that urine volume increased to about six times normal within 45 minutes after the water had been ingested. However, the total amount of solute excreted remained relatively constant because the urine formed became dilute, and urine osmolarity decreased from 600 to about 100 mOsm/L. Thus, after ingestion of excess water, the kidney rids the body of the excess water but does not excrete excess amounts of solutes.

When the glomerular filtrate is initially formed, its osmolarity is about the same as that of plasma (300 mOsm/L). To excrete excess water, the filtrate is diluted as it passes along the tubule by reabsorbing solutes to a greater extent than water, as shown in **Figure 29-2**. This dilution, however, occurs only in certain segments of the tubular system, as described in the following sections.

Tubular Fluid Remains Isosmotic in Proximal Tubules. As fluid flows through the proximal tubule, solutes and water are reabsorbed in equal proportions, so little change in osmolarity occurs. Thus, the proximal tubule fluid remains isosmotic to the plasma, with an osmolarity of about 300 mOsm/L. As fluid passes down the descending loop of Henle, water is reabsorbed by osmosis, and the tubular fluid reaches equilibrium with the surrounding interstitial fluid of the renal medulla, which is very hypertonic—about two to four times the osmolarity of the original glomerular filtrate. Therefore, the tubular fluid becomes more concentrated as it flows into the inner medulla.

Figure 29-2. Formation of dilute urine when antidiuretic hormone (ADH) levels are very low. Note that in the ascending loop of Henle, the tubular fluid becomes very dilute. In the distal tubules and collecting tubules, the tubular fluid is further diluted by the reabsorption of sodium chloride and the failure to reabsorb water when ADH levels are very low. The failure to reabsorb water and continued reabsorption of solutes lead to a large volume of dilute urine. (Numerical values are in milliosmoles per liter.)

Tubular Fluid Is Diluted in the Ascending Loop of Henle.

In the ascending limb of the loop of Henle, especially in the thick segment, sodium, potassium, and chloride are avidly reabsorbed. However, this portion of the tubular segment is impermeable to water, even in the presence of large amounts of ADH. Therefore, the tubular fluid becomes more dilute as it flows up the ascending loop of Henle into the early distal tubule, with the osmolarity decreasing progressively to about 100 mOsm/L by the time the fluid enters the early distal tubular segment. Thus, regardless of whether ADH is present or absent, fluid leaving the early distal tubular segment is hypo-osmotic, with an osmolarity of only about one-third the osmolarity of plasma.

Tubular Fluid in Distal and Collecting Tubules Is Further Diluted in Absence of ADH.

As the dilute fluid in the early distal tubule passes into the late distal convoluted tubule, cortical collecting duct, and medullary collecting duct, there is additional reabsorption of sodium chloride. In the absence of ADH, this portion of the tubule is also impermeable to water, and the additional reabsorption of solutes causes the tubular fluid to become even more dilute, decreasing its osmolarity to as low as 50 mOsm/L. The failure to reabsorb water and continued reabsorption of solutes lead to a large volume of dilute urine.

To summarize, the mechanism for forming dilute urine is to continue reabsorbing solutes from the distal segments of the tubular system while reducing water reabsorption. In healthy kidneys, fluid leaving the ascending loop of Henle and early distal tubule is always dilute, regardless of the level of ADH. In the absence of ADH, the urine is further diluted in the late distal tubule and collecting ducts, and a large volume of dilute urine is excreted.

KIDNEYS CONSERVE WATER BY EXCRETING CONCENTRATED URINE

The ability of the kidney to form concentrated urine is essential for survival of mammals that live on land, including humans. Water is continuously lost from the body through various routes, including the lungs by evaporation into the expired air, the gastrointestinal tract by way of the feces, the skin through evaporation and perspiration, and the kidneys through excretion of urine. Fluid intake is required to match this loss, but the ability of the kidneys to form a small volume of concentrated urine minimizes the fluid intake required to maintain homeostasis, a function that is especially important when water is in short supply.

When there is a water deficit in the body, the kidneys form concentrated urine by continuing to excrete solutes while increasing water reabsorption and decreasing the urine volume. The human kidney can produce a maximal urine concentration of 1200 to 1400 mOsm/L, four to five times the osmolarity of plasma.

Some desert animals, such as the Australian hopping mouse, can concentrate urine to as high as 10,000 mOsm/L. This ability allows the mouse to survive in the desert without drinking water; sufficient water can be obtained through the ingested food and water produced in the body by metabolism of the food. Animals adapted to freshwater environments usually have minimal urine-concentrating ability. Beavers, for example, can concentrate the urine only to about 500 mOsm/L.

Obligatory Urine Volume

The maximal concentrating ability of the kidney dictates how much urine volume must be excreted each day to rid the body of metabolic waste products and electrolytes that are ingested. A normal 70-kg person must excrete about 600 milliosmoles of solute each day. If the maximal urine concentrating ability is 1200 mOsm/L, the *minimal* volume of urine that must be excreted, called the *obligatory urine volume*, can be calculated as follows:

$$\frac{600 \text{ mOsm/day}}{1200 \text{ mOsm/L}} = 0.5 \text{ L/day}$$

This minimal loss of volume in the urine contributes to dehydration, along with water loss from the skin, respiratory tract, and gastrointestinal tract, when water is not available to drink.

The limited ability of the human kidney to concentrate the urine to only about 1200 mOsm/L explains why severe dehydration occurs if one attempts to drink seawater. Sodium chloride concentration in the ocean averages about 3.0% to 3.5%, with an osmolarity between about 1000 and 1200 mOsm/L. Drinking 1 liter of seawater with a concentration of 1200 mOsm/L would provide a total sodium chloride intake of 1200 milliosmoles. If the maximal urine concentrating ability is 1200 mOsm/L, the amount of urine volume needed to excrete 1200 milliosmoles would be 1.0 liter. Why then does drinking seawater cause dehydration? The answer is that the kidney must also excrete other solutes, especially urea, which contribute about 600 mOsm/L when the urine is maximally concentrated. Therefore, the

maximum concentration of sodium chloride that can be excreted by the kidneys is about 600 mOsm/L. Thus, for every liter of seawater ingested, 1.5 liters of urine volume would be required to rid the body of 1200 milliosmoles of sodium chloride ingested in addition to 600 milliosmoles of other solutes, such as urea. This would result in a net fluid loss of 0.5 liter for every liter of seawater, explaining the rapid dehydration that occurs in shipwreck victims who drink seawater. However, a shipwreck victim's pet Australian hopping mouse could drink seawater with impunity.

Urine Specific Gravity

Urine *specific gravity* is often used in clinical settings to provide a rapid estimate of urine solute concentration. The more concentrated the urine, the higher the urine specific gravity. In most cases, urine specific gravity increases linearly with increasing urine osmolarity (Figure 29-3). Urine specific gravity, however, is a measure of the weight of solutes in a given volume of urine and is therefore determined by the number and size of the solute molecules. In contrast, osmolarity is determined only by the number of solute molecules in a given volume.

Urine specific gravity is generally expressed in grams per milliliter (g/ml) and, in humans, normally ranges from 1.002 to 1.028 g/ml, rising by 0.001 for every 35- to 40-mOsm/L increase in urine osmolarity. This relationship between specific gravity and osmolarity is altered when there are significant amounts of large molecules in the urine, such as glucose, radiocontrast media used for diagnostic purposes, or some antibiotics. In these cases, urine specific gravity measurements may falsely suggest a highly concentrated urine, despite a normal urine osmolarity.

Dipsticks are available that measure approximate urine specific gravity, but most laboratories measure specific gravity with a *refractometer*.

Figure 29-3. Relationship between specific gravity and osmolarity of the urine.

EXCRETING CONCENTRATED URINE REQUIRES HIGH ADH LEVELS AND HYPEROSMOTIC RENAL MEDULLA

The basic requirements for forming a concentrated urine are (1) a *high level of ADH*, which increases the permeability of the distal tubules and collecting ducts to water, thereby allowing these tubular segments to avidly reabsorb water; and (2) a *high osmolarity of the renal medullary interstitial fluid*, which provides the osmotic gradient necessary for water reabsorption to occur in the presence of high levels of ADH.

The renal medullary interstitium surrounding the collecting ducts is normally hyperosmotic, so when ADH levels are high, water moves through the tubular membrane by osmosis into the renal interstitium; from there it is carried away by the vasa recta back into the blood. Thus, the urine-concentrating ability is limited by the level of ADH and by the degree of hyperosmolarity of the renal medulla. We discuss the factors that control ADH secretion later, but for now, what is the process whereby renal medullary interstitial fluid becomes hyperosmotic? This process involves the operation of the *countercurrent multiplier mechanism*.

The *countercurrent multiplier mechanism depends on the special anatomical arrangement of the loops of Henle and vasa recta, the specialized peritubular capillaries of the renal medulla*. In humans, about 25% of the nephrons are *juxtamedullary nephrons*, with loops of Henle and vasa recta that go deeply into the medulla before returning to the cortex. Some of the loops of Henle dip all the way to the tips of the renal papillae that project from the medulla into the renal pelvis. Paralleling the long loops of Henle are the vasa recta, which also loop down into the medulla before returning to the renal cortex. And finally, the collecting ducts, which carry urine through the hyperosmotic renal medulla before it is excreted, also play a critical role in the countercurrent mechanism.

COUNTERCURRENT MULTIPLIER MECHANISM PRODUCES HYPEROSMOTIC RENAL MEDULLARY INTERSTITIUM

The osmolarity of interstitial fluid in almost all parts of the body is about 300 mOsm/L, which is similar to the plasma osmolarity. (As discussed in [Chapter 25](#), the *corrected osmolar activity*, which accounts for intermolecular attraction, is about 282 mOsm/L.) The osmolarity of the interstitial fluid in the medulla of the kidney is much higher and may increase progressively to about 1200 to 1400 mOsm/L in the pelvic tip of the medulla. This means that the renal medullary interstitium has accumulated solutes in great excess of water. Once the high solute concentration in the medulla is achieved, it is maintained by a balanced inflow and outflow of solutes and water in the medulla.

The major factors that contribute to the buildup of solute concentration into the renal medulla are as follows:

1. Active transport of sodium ions and co-transport of potassium, chloride, and other ions out of the thick portion of the ascending limb of the loop of Henle into the medullary interstitium
2. Active transport of ions from the collecting ducts into the medullary interstitium
3. Facilitated diffusion of urea from the inner medullary collecting ducts into the medullary interstitium
4. Diffusion of only small amounts of water from the medullary tubules into the medullary interstitium—far less than the reabsorption of solutes into the medullary interstitium

LOOP OF HENLE CHARACTERISTICS THAT CAUSE SOLUTES TO BE TRAPPED IN THE RENAL MEDULLA

The transport characteristics of the loops of Henle are summarized in [Table 29-1](#), along with the properties of the proximal tubules, distal tubules, cortical collecting tubules, and inner medullary collecting ducts.

A major reason for the high medullary osmolarity is active transport of sodium and co-transport of potassium, chloride, and other ions from the thick ascending loop of Henle into the interstitium. This pump is capable of establishing about a 200-mOsm/L concentration gradient between the tubular lumen and interstitial fluid. Because the thick ascending limb is virtually impermeable to water, the solutes pumped out are not followed by osmotic flow of water into the interstitium. Thus, the active transport of sodium and other ions out of the thick ascending loop adds solutes in excess of water to the renal

Table 29-1 Summary of Tubule Characteristics—Urine Concentration

Structure	Active NaCl Transport	Permeability		
		H ₂ O	NaCl	Urea
Proximal tubule	++	++	+	+
Thin descending limb	0	++	+	+
Thin ascending limb	0	0	+	+
Thick ascending limb	++	0	0	0
Distal tubule	+	+ADH	0	0
Cortical collecting tubule	+	+ADH	0	0
Inner medullary collecting duct	+	+ADH	0	+ADH

ADH, Antidiuretic hormone; NaCl, sodium chloride; 0, minimal level of active transport or permeability; +, moderate level of active transport or permeability; ++, high level of active transport or permeability; +ADH, permeability to water or urea is increased by ADH.

medullary interstitium. There is some passive reabsorption of sodium chloride from the thin ascending limb of Henle's loop, which is also essentially impermeable to water, adding further to the high solute concentration of the renal medullary interstitium.

The descending limb of Henle's loop, in contrast to the ascending limb, is very permeable to water, and the tubular fluid osmolarity quickly becomes equal to the renal medullary osmolarity. Therefore, water diffuses out of the descending limb of Henle's loop into the interstitium, and the tubular fluid osmolarity gradually rises as it flows toward the tip of the loop of Henle.

Steps Involved in Causing Hyperosmotic Renal Medullary Interstitium. Keeping in mind these characteristics of the loop of Henle, let us now discuss how the renal medulla becomes hyperosmotic (Video 29-1). First, assume that the loop of Henle is filled with fluid having a concentration of 300 mOsm/L, the same as that leaving the proximal tubule (Figure 29-4, step 1). Next, the active ion pump of the *thick ascending limb* on the loop of Henle reduces the concentration inside the tubule and raises the interstitial concentration; this pump establishes a 200-mOsm/L concentration gradient between the tubular fluid and interstitial fluid (Figure 29-4, step 2). The limit to the gradient is about 200 mOsm/L because paracellular diffusion of ions back into the tubule eventually counterbalances the transport of ions out of the lumen when the 200-mOsm/L concentration gradient is achieved.

Step 3 is that the tubular fluid in the *descending limb* of the loop of Henle and interstitial fluid quickly reaches osmotic equilibrium due to osmosis of water out of the descending limb. The interstitial osmolarity is maintained at 400 mOsm/L because of continued transport of ions out of the thick ascending loop of Henle. Thus, by itself, active transport of sodium chloride out of the thick ascending limb is capable of establishing only a 200-mOsm/L concentration gradient, which is much less than that achieved by the countercurrent multiplier system.

Step 4 is the additional flow of fluid into the loop of Henle from the proximal tubule, which causes the hyperosmotic fluid previously formed in the descending limb to flow into the ascending limb. Once this fluid is in the ascending limb, additional ions are pumped into the interstitium and water remains in the tubular fluid until a 200-mOsm/L osmotic gradient is established, and the interstitial fluid osmolarity rises to 500 mOsm/L (step 5). Then, once again, fluid in the descending limb reaches equilibrium with the hyperosmotic medullary interstitial fluid (step 6) and, as the hyperosmotic tubular fluid from the descending limb of the loop of Henle flows into the ascending limb, still more solute is continuously pumped out of the tubules and deposited into the medullary interstitium.

These steps are repeated over and over, with the net effect of adding more and more solute to the medulla in excess of water. With sufficient time, *this process gradually traps solutes in the medulla and multiplies the concentration gradient established by the active pumping of ions out of the thick ascending loop of Henle, eventually raising the interstitial fluid osmolarity to 1200 to 1400 mOsm/L, as shown in step 7.*

Thus, the repetitive reabsorption of sodium chloride by the thick ascending loop of Henle and continued inflow of new sodium chloride from the proximal tubule into the loop of Henle is called the *countercurrent multiplier*. The sodium chloride reabsorbed from the ascending loop of Henle keeps adding to the newly arrived sodium chloride, thus "multiplying" its concentration in the medullary interstitium.

ROLE OF DISTAL TUBULE AND COLLECTING DUCTS IN EXCRETING CONCENTRATED URINE

When the tubular fluid leaves the loop of Henle and flows into the distal convoluted tubule in the renal cortex, the fluid is dilute, with an osmolarity of only about 100 to

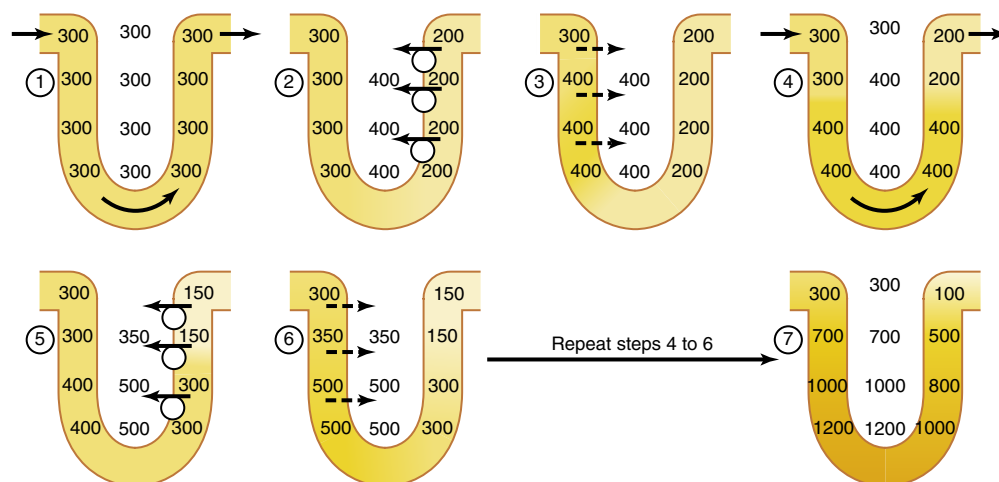

Figure 29-4. Countercurrent multiplier system in the loop of Henle for producing a hyperosmotic renal medulla. (Numerical values are in milliosmoles per liter.)

Figure 29-5. Formation of a concentrated urine when antidiuretic hormone (ADH) levels are high. Note that the fluid leaving the loop of Henle is dilute but becomes concentrated as water is absorbed from the distal tubules and collecting tubules. With high ADH levels, the osmolarity of the urine is about the same as the osmolarity of the renal medullary interstitial fluid in the papilla, which is about 1200 mOsm/L. (Numerical values are in milliosmoles per liter.)

140 mOsm/L (Figure 29-5). The early distal tubule further dilutes the tubular fluid because this segment, like the ascending loop of Henle, actively transports sodium chloride out of the tubule but is relatively impermeable to water.

As fluid flows into the cortical collecting tubule, the amount of water reabsorbed is critically dependent on the plasma concentration of ADH. In the absence of ADH, this segment is almost impermeable to water and fails to reabsorb water but continues to reabsorb solutes and further dilutes the urine. When there is a high concentration of ADH, the cortical collecting tubule becomes highly permeable to water, so large amounts of water are now reabsorbed from the tubule into the cortex interstitium, where it is swept away by the rapidly flowing peritubular capillaries. *Because large amounts of water are reabsorbed into the cortex, rather than into the renal medulla, this helps preserve the high medullary interstitial fluid osmolarity.*

As the tubular fluid flows along the medullary collecting ducts, there is further water reabsorption from the tubular fluid into the interstitium, but the total amount of water is relatively small compared with that added to the cortex interstitium. The reabsorbed water is carried away by the vasa recta into the venous blood. When high levels of ADH are present, the collecting ducts become permeable to water, so the fluid at the end of the collecting ducts has essentially the same osmolarity as the interstitial fluid of the renal medulla—about 1200 mOsm/L (see Figure 29-4). Thus, by reabsorbing as much water as possible, the kidneys form highly concentrated urine, excreting normal amounts of solutes in the urine while adding water back to the extracellular fluid and compensating for deficits of body water.

UREA CONTRIBUTES TO HYPEROSMOTIC RENAL MEDULLARY INTERSTITIUM AND FORMATION OF CONCENTRATED URINE

Urea contributes about 40% to 50% of the osmolarity (500–600 mOsm/L) of the renal medullary interstitium when the kidney is forming a maximally concentrated urine. Unlike sodium chloride, urea is passively reabsorbed from the tubule. When there is a water deficit and blood concentration of ADH is high, large amounts of urea are passively reabsorbed from the inner medullary collecting ducts into the interstitium.

The mechanism for reabsorption of urea into the renal medulla is as follows. As water flows up the ascending loop of Henle and into the distal and cortical collecting tubules, little urea is reabsorbed because these segments are impermeable to urea (see Table 29-1). In the presence of high concentrations of ADH, water is reabsorbed rapidly from the cortical collecting tubule, and the urea concentration increases rapidly because urea is not very permeant in this part of the tubule.

As the tubular fluid flows into the inner medullary collecting ducts, still more water reabsorption takes place, resulting in an even higher concentration of urea in the fluid. This high concentration of urea in the tubular fluid of the inner medullary collecting duct causes urea to diffuse out of the tubule into the renal interstitial fluid. This diffusion is greatly facilitated by specific *urea transporters*, *UT-A1* and *UT-A3*. These urea transporters are activated by ADH, increasing transport of urea out of the inner medullary collecting duct even more when ADH levels are elevated. The simultaneous movement of water and urea out of the inner medullary collecting ducts maintains a high concentration of urea in the tubular fluid and, eventually, in the urine, even though urea is being reabsorbed.

The fundamental role of urea in contributing to urine-concentrating ability is evidenced by the fact that people who ingest a high-protein diet, yielding large amounts of urea as a nitrogenous waste product, can concentrate their urine much better than people whose protein intake and urea production are low. Malnutrition is associated with a low urea concentration in the medullary interstitium and considerable impairment of urine-concentrating ability.

Recirculation of Urea from Collecting Duct to Loop of Henle Contributes to Hyperosmotic Renal Medulla.

A healthy person usually excretes about 20% to 60% of the filtered load of urea, depending on urine flow rate and state of hydration. In general, the rate of urea excretion is determined mainly by the following: (1) concentration of urea in the plasma; (2) glomerular filtration rate (GFR); and (3) renal tubular urea reabsorption. In patients with renal disease who have large reductions in GFR, the plasma urea concentration increases markedly, returning the filtered urea load and urea excretion rate to the normal level (equal to the rate of urea production), despite the reduced GFR.

Figure 29-6. Recirculation of urea absorbed from the medullary collecting duct into the interstitial fluid. This urea diffuses into the thin loop of Henle, then passes through the distal tubules, and finally passes back into the collecting duct. The recirculation of urea helps trap urea in the renal medulla and contributes to the hyperosmolarity of the renal medulla. The *heavy lines*, from the thick ascending loop of Henle to the medullary collecting ducts, indicate that these segments are not very permeable to urea. The urea transporters UT-A1 and UT-A3 facilitate diffusion of urea out of the medullary collecting ducts while UT-A2 facilitates urea diffusion into the thin descending loop of Henle. (Numerical values are in milliosmoles per liter of urea during antidiuresis, when large amounts of antidiuretic hormone are present. Percentages of the filtered load of urea that remain in the tubules are indicated in the boxes.)

In the proximal tubule, 40% to 50% of the filtered urea is reabsorbed but, even so, the tubular fluid urea concentration increases because urea is not nearly as permeant as water. The concentration of urea continues to rise as the tubular fluid flows into the thin segments of the loop of Henle, partly because of water reabsorption out of the descending loop of Henle but also because of some *secretion* of urea into the thin loop of Henle from the medullary interstitium (**Figure 29-6**). The passive secretion of urea into the thin loops of Henle is facilitated by the *urea transporter UT-A2*.

The thick limb of the loop of Henle, distal tubule, and cortical collecting tubule are all less permeable to urea, and only small amounts of urea reabsorption normally occur in these tubular segments. When the kidney is forming concentrated urine, and high levels of ADH are present, reabsorption of water from the distal tubule and cortical collecting tubule further raises the tubular fluid concentration of urea. As this urea flows into the inner medullary collecting duct, the high tubular fluid concentration of urea and urea transporters UT-A1 and UT-A3 cause urea to diffuse into the medullary interstitium. A moderate share of the urea that moves into the medullary interstitium eventually diffuses into the thin loop of Henle and then passes upward through the ascending loop of

Henle, distal tubule, and cortical collecting tubule and back down into the medullary collecting duct again. In this way, urea can recirculate through these terminal parts of the tubular system several times before it is excreted. Each time around the circuit contributes to a higher concentration of urea.

This urea recirculation provides an additional mechanism for forming a hyperosmotic renal medulla. Because urea is one of the most abundant waste products that must be excreted by the kidneys, this mechanism for concentrating urea before it is excreted is essential to the economy of the body fluid when water is in short supply.

When there is excess water in the body, urine flow rate increases, and therefore the concentration of urea in the inner medullary collecting ducts decreases, causing less diffusion of urea into the renal medullary interstitium. ADH levels are also reduced when there is excess body water, and this reduction, in turn, decreases the permeability of the inner medullary collecting ducts to both water and urea, and more urea is excreted in the urine.

COUNTERCURRENT EXCHANGE IN VASA RECTA PRESERVES HYPEROSMOLARITY OF RENAL MEDULLA

Blood flow must be provided to the renal medulla to supply the metabolic needs of the cells in this part of the kidney. Without a special medullary blood flow system, the solutes pumped into the renal medulla by the countercurrent multiplier system would be rapidly dissipated.

Two special features of the renal medullary blood flow contribute to the preservation of the high solute concentrations:

1. The medullary blood flow is low, accounting for less than 5% of the total renal blood flow. This sluggish blood flow is sufficient to supply the metabolic needs of the tissues but helps minimize solute loss from the medullary interstitium.
2. The vasa recta serve as *countercurrent exchangers*, minimizing the washout of solutes from the medullary interstitium.

The countercurrent exchange mechanism operates as follows (**Figure 29-7**). Blood enters and leaves the medulla via the vasa recta at the boundary of the cortex and renal medulla. The vasa recta, like other capillaries, are highly permeable to solutes in the blood, except for the plasma proteins. As blood descends into the medulla toward the papillae, it becomes progressively more concentrated, partly by solute entry from the interstitium and partly by loss of water into the interstitium. By the time the blood reaches the tips of the vasa recta, it has a concentration of about 1200 mOsm/L, the same as that of the medullary interstitium. As blood ascends back toward the cortex, it becomes progressively less concentrated as solutes diffuse back out into the medullary interstitium and as water moves into the vasa recta.

Although large amounts of fluid and solute are exchanged across the vasa recta, there is little net dilution of the concentration of the interstitial fluid at each level of the renal medulla because of the U shape of the vasa recta capillaries, which act as countercurrent exchangers. Thus, the vasa recta do not create the medullary hyperosmolarity, but they do prevent it from being dissipated.

The U-shaped structure of the vessels minimizes loss of solute from the interstitium but does not prevent bulk flow of fluid and solutes into the blood through the usual colloid osmotic and hydrostatic pressures that favor reabsorption in these capillaries. Under steady-state conditions, the vasa recta carry away only as much solute and water as is absorbed from the medullary tubules, and the

high concentration of solutes established by the counter-current mechanism is preserved.

Increased Medullary Blood Flow Reduces Urine-Concentrating Ability. Certain vasodilators can markedly increase renal medullary blood flow, thereby washing out some of the solutes from the renal medulla and reducing the maximum urine-concentrating ability. Large increases in arterial pressure may also increase the blood flow of the renal medulla to a greater extent than in other regions of the kidney and tend to wash out the hyperosmotic interstitium, thereby reducing urine-concentrating ability. As discussed earlier, maximum concentrating ability of the kidney is determined not only by the level of ADH but also by the osmolarity of the renal medulla interstitial fluid. Even with maximal ADH levels, the urine-concentrating ability will be reduced if medullary blood flow increases enough to reduce the hyperosmolarity in the renal medulla.

Figure 29-7. Countercurrent exchange in the vasa recta. Plasma flowing down the descending limb of the vasa recta becomes more hyperosmotic because of diffusion of water out of the blood and diffusion of solutes from the renal interstitial fluid into the blood. In the ascending limb of the vasa recta, solutes diffuse back into the interstitial fluid, and water diffuses back into the vasa recta. Large amounts of solutes would be lost from the renal medulla without the U shape of the vasa recta capillaries. (Numerical values are in milliosmoles per liter.)

SUMMARY OF URINE-CONCENTRATING MECHANISM AND CHANGES IN OSMOLARITY IN DIFFERENT TUBULAR SEGMENTS

The changes in osmolarity and volume of the tubular fluid as it passes through the different parts of the nephron are shown in **Figure 29-8**.

Proximal Tubule. About 65% of most filtered electrolytes is reabsorbed in the proximal tubule. However, the proximal tubular membranes are highly permeable to water so, whenever solutes are reabsorbed, water also diffuses through the tubular membrane by osmosis. Water diffusion across the proximal tubular epithelium is aided by the water channel *aquaporin 1* (AQP-1). Therefore, the osmolarity of the fluid remains about the same as the glomerular filtrate—300 mOsm/L.

Figure 29-8. Changes in osmolarity of the tubular fluid as it passes through the different tubular segments in the presence of high levels of antidiuretic hormone (ADH) and absence of ADH. (Numerical values indicate the approximate volumes in milliliters per minute or in osmolarities in milliosmoles per liter of fluid flowing along the different tubular segments.)

Descending Loop of Henle. As fluid flows down the descending loop of Henle, water is absorbed into the medulla. The descending limb also contains AQP-1 and is highly permeable to water but much less permeable to sodium chloride and urea. Therefore, the osmolarity of the fluid flowing through the descending loop gradually increases until it is nearly equal to that of the surrounding interstitial fluid, which is about 1200 mOsm/L when the blood concentration of ADH is high.

When dilute urine is being formed, as a result of low ADH concentrations, the medullary interstitial osmolarity is less than 1200 mOsm/L; consequently, the descending loop tubular fluid osmolarity also becomes less concentrated. This decrease in concentration is due partly to the fact that less urea is absorbed into the medullary interstitium from the collecting ducts when ADH levels are low, and the kidney is forming a large volume of dilute urine.

Thin Ascending Loop of Henle. The thin ascending limb is essentially impermeable to water but reabsorbs some sodium chloride. Because of the high concentration of sodium chloride in the tubular fluid as a result of water removal from the descending loop of Henle, there is some passive diffusion of sodium chloride from the thin ascending limb into the medullary interstitium. Thus, the tubular fluid becomes more dilute as the sodium chloride diffuses out of the tubule and water remains in the tubule.

Some of the urea absorbed into the medullary interstitium from the collecting ducts also diffuses into the ascending limb, thereby returning the urea to the tubular system and helping prevent its washout from the renal medulla. This *urea recycling* is an additional mechanism that contributes to the hyperosmotic renal medulla.

Thick Ascending Loop of Henle. The thick part of the ascending loop of Henle is also virtually impermeable to water, but large amounts of sodium, chloride, potassium, and other ions are actively transported from the tubule into the medullary interstitium. Therefore, fluid in the thick ascending limb of the loop of Henle becomes very dilute, falling to a concentration of about 140 mOsm/L.

Early Distal Tubule. The early distal tubule has properties similar to those of the thick ascending loop of Henle, so further dilution of the tubular fluid to about 100 mOsm/L occurs as solutes are reabsorbed while water remains in the tubule.

Late Distal Tubule and Cortical Collecting Tubules. In the late distal tubule and cortical collecting tubules, the osmolarity of the fluid depends on the level of ADH. With high ADH levels, these tubules are highly permeable to water, and significant amounts of water are reabsorbed. Urea, however, is not very permeant in this part of the nephron, resulting in increased urea concentration as water is reabsorbed. This process allows most of the urea delivered to the distal tubule and collecting

tubule to pass into the inner medullary collecting ducts, from which it is eventually reabsorbed or excreted in the urine. In the absence of ADH, little water is reabsorbed in the late distal tubule and cortical collecting tubule; therefore, osmolarity decreases even further because of continued active reabsorption of ions from these segments.

Inner Medullary Collecting Ducts. The concentration of fluid in the inner medullary collecting ducts also depends on the following: (1) ADH; and (2) the surrounding medullary interstitium osmolarity established by the counter-current mechanism. In the presence of large amounts of ADH, these ducts are highly permeable to water, and water diffuses from the tubule into the interstitial fluid until osmotic equilibrium is reached, with the tubular fluid having about the same concentration as the renal medullary interstitium (1200–1400 mOsm/L). Thus, a small volume of concentrated urine is produced when ADH levels are high. Because water reabsorption increases urea concentration in the tubular fluid, and because the inner medullary collecting ducts have specific urea transporters that greatly facilitate diffusion, much of the highly concentrated urea in the ducts diffuses out of the tubular lumen into the medullary interstitium. This absorption of the urea into the renal medulla contributes to the high osmolarity of the medullary interstitium and high concentrating ability of the kidney.

Several important points to consider may not be obvious from this discussion. First, although sodium chloride is one of the principal solutes that contribute to the hyperosmolarity of the medullary interstitium, *the kidney can, when needed, excrete a highly concentrated urine that contains little sodium chloride.* The hyperosmolarity of the urine in these circumstances is due to high concentrations of other solutes, especially of waste products such as urea. One condition in which this occurs is dehydration accompanied by low sodium intake. As discussed in [Chapter 30](#), a low sodium intake stimulates formation of the hormones angiotensin II and aldosterone, which together cause avid sodium reabsorption from the tubules while leaving the urea and other solutes to maintain the highly concentrated urine.

Second, *large quantities of dilute urine can be excreted without increasing sodium excretion.* This feat is accomplished by decreasing ADH secretion, which reduces water reabsorption in the more distal tubular segments without significantly altering sodium reabsorption.

Finally, there is an *obligatory urine volume* dictated by the maximum concentrating ability of the kidney and amount of solute that must be excreted. Therefore, if large amounts of solute must be excreted, they must be accompanied by the minimal amount of water necessary to excrete them. For example, if 600 milliosmoles of solute must be excreted each day, this requires *at least* 0.5 liter of urine if the maximal urine concentrating ability is 1200 mOsm/L.

Quantifying Renal Urine Concentration and Dilution: Free Water and Osmolar Clearances

The process of concentrating or diluting the urine requires the kidneys to excrete water and solutes somewhat independently. When the urine is dilute, water is excreted in excess of solutes. Conversely, when the urine is concentrated, solutes are excreted in excess of water.

The total clearance of solutes from the blood can be expressed as the *osmolar clearance* (C_{osm}). This is the volume of plasma cleared of solutes each minute, in the same way that clearance of a single substance is calculated:

$$C_{\text{osm}} = \frac{U_{\text{osm}} \times \dot{V}}{P_{\text{osm}}}$$

where U_{osm} is the urine osmolarity, \dot{V} is the urine flow rate, and P_{osm} is plasma osmolarity. For example, if the plasma osmolarity is 300 mOsm/L, urine osmolarity is 600 mOsm/L, and urine flow rate is 1 ml/min (0.001 L/min), the rate of osmolar excretion is 0.6 mOsm/min (600 mOsm/L \times 0.001 L/min), and osmolar clearance is 0.6 mOsm/min divided by 300 mOsm/L, or 0.002 L/min (2.0 ml/min). This means that 2 milliliters of plasma are being cleared of solute each minute.

Free Water Clearance—Relative Rates at Which Solutes and Water Are Excreted

Free water clearance ($C_{\text{H}_2\text{O}}$) is calculated as the difference between water excretion (urine flow rate) and osmolar clearance:

$$C_{\text{H}_2\text{O}} = \dot{V} - C_{\text{osm}} = \dot{V} - \frac{(U_{\text{osm}} \times \dot{V})}{P_{\text{osm}}}$$

Thus, the rate of free water clearance represents the rate at which solute-free water is excreted by the kidneys. When free water clearance is positive, excess water is being excreted by the kidneys; when free water clearance is negative, excess solutes are being removed from the blood by the kidneys, and water is being conserved.

Using the example discussed earlier, if urine flow rate is 1 ml/min and osmolar clearance is 2 ml/min, free water clearance would be -1 ml/min. This means that instead of water being cleared from the kidneys in excess of solutes, the kidneys are actually returning water to the systemic circulation, as occurs during water deficits. *Thus, whenever urine osmolarity is greater than plasma osmolarity, free water clearance is negative, indicating water conservation.*

When the kidneys are forming a dilute urine (i.e., urine osmolarity $<$ plasma osmolarity), free water clearance will be a positive value, denoting that water is being removed from the plasma by the kidneys in excess of solutes. Thus, water free of solutes, called *free water*, is being lost from the body, and the plasma is being concentrated when free water clearance is positive.

Disorders of Urinary Concentrating Ability

Impairment in the ability of the kidneys to concentrate or dilute the urine appropriately can occur with one or more of the following abnormalities:

1. *Inappropriate secretion of ADH.* Either too much or too little ADH secretion results in abnormal water excretion by the kidneys.
2. *Impairment of the countercurrent mechanism.* A hyperosmotic medullary interstitium is required for maximal

urine-concentrating ability. No matter how much ADH is present, maximal urine concentration is limited by the degree of hyperosmolarity of the medullary interstitium.

3. *Inability of the distal tubules, collecting tubules, and collecting ducts to respond to ADH.*

Failure to Produce ADH: Central Diabetes Insipidus.

An inability to produce or release ADH from the posterior pituitary can be caused by head injuries or infections, or it can be congenital. Because the distal tubular segments cannot reabsorb water in the absence of ADH, this condition, called *central diabetes insipidus*, results in the formation of a large volume of dilute urine, with urine volumes that can exceed 15 L/day. The thirst mechanisms, discussed later in this chapter, are activated when excessive water is lost from the body; therefore, as long as the person drinks enough water, large decreases in body fluid water do not occur. The primary abnormality observed clinically in people with this condition is the large volume of dilute urine. However, if water intake is restricted, as can occur in a hospital setting when fluid intake is restricted or the patient is unconscious (e.g., because of a head injury), severe dehydration can rapidly occur.

The treatment for central diabetes insipidus is administration of a synthetic analogue of ADH, *desmopressin*, which acts selectively on V_2 receptors to increase water permeability in the late distal and collecting tubules. Desmopressin can be given by injection, as a nasal spray, or orally, and it rapidly restores urine output toward normal.

Inability of Kidneys to Respond to ADH: Nephrogenic Diabetes Insipidus. In some circumstances, normal or elevated levels of ADH are present but the renal tubular segments cannot respond appropriately. This condition is referred to as *nephrogenic diabetes insipidus* because the abnormality resides in the kidneys. This abnormality can be due to failure of the countercurrent mechanism to form a hyperosmotic renal medullary interstitium or failure of the distal and collecting tubules and collecting ducts to respond to ADH. In either case, large volumes of dilute urine are formed, which causes dehydration unless fluid intake is increased by the same amount as urine volume is increased.

Many types of renal diseases can impair the concentrating mechanism, especially those that damage the renal medulla (see [Chapter 32](#) for further discussion). Also, impairment of the function of the loop of Henle, as occurs with diuretics that inhibit electrolyte reabsorption by this segment, such as furosemide, can compromise urine-concentrating ability. Furthermore, certain drugs such as lithium (used to treat manic-depressive disorders) and tetracyclines (used as antibiotics) can impair the ability of the distal nephron segments to respond to ADH.

Nephrogenic diabetes insipidus can be distinguished from central diabetes insipidus by administration of desmopressin, the synthetic analogue of ADH. Lack of a prompt decrease in urine volume and an increase in urine osmolarity within 2 hours after injection of desmopressin is strongly suggestive of nephrogenic diabetes insipidus. The appropriate treatment for nephrogenic diabetes insipidus is to correct, if possible, the underlying renal disorder. The hypernatremia can also be attenuated by a low-sodium diet and administration of a diuretic that enhances renal sodium excretion, such as a thiazide diuretic.

CONTROL OF EXTRACELLULAR FLUID OSMOLARITY AND SODIUM CONCENTRATION

Regulation of extracellular fluid osmolarity and sodium concentration are closely linked because sodium is the most abundant ion in the extracellular compartment. Plasma sodium concentration is normally regulated within close limits of 140 to 145 mEq/L, with an average concentration of about 142 mEq/L. Osmolarity averages about 300 mOsm/L (≈ 282 mOsm/L when corrected for interionic attraction) and seldom changes more than $\pm 2\%$ to 3%. As discussed in Chapter 25, these variables must be precisely controlled because they determine the distribution of fluid between the intracellular and extracellular compartments.

Estimating Plasma Osmolarity From Plasma Sodium Concentration

In most clinical laboratories, plasma osmolarity is not routinely measured. However, because sodium and its associated anions account for about 94% of the solute in the extracellular compartment, plasma osmolarity (P_{osm}) can be roughly estimated from the plasma sodium concentration (P_{Na^+}) as follows:

$$P_{\text{osm}} = 2.1 \times P_{\text{Na}^+} \text{ (mmol/L)}$$

For example, with a plasma sodium concentration of 142 mEq/L, the plasma osmolarity would be estimated from this formula to be about 298 mOsm/L. To be more exact, especially in conditions associated with renal disease, the contribution of the plasma concentrations (in units of mmol/L) of two other solutes, glucose and urea, are usually included:

$$P_{\text{osm}} = 2 \times [P_{\text{Na}^+}, \text{mmol/L}] + [P_{\text{glucose}}, \text{mmol/L}] + [P_{\text{urea}}, \text{mmol/L}]$$

Such estimates of plasma osmolarity are usually accurate within a few percentage points of those measured directly.

Normally, sodium ions and associated anions (primarily bicarbonate and chloride) represent about 94% of the extracellular osmoles, with glucose and urea contributing about 3% to 5% of the total osmoles. However, because urea easily permeates most cell membranes, it exerts little *effective* osmotic pressure under steady-state conditions. Therefore, the sodium ions in the extracellular fluid and associated anions are the principal determinants of fluid movement across the cell membrane. Consequently, we can discuss the control of osmolarity and control of sodium ion concentration at the same time.

Although multiple mechanisms control the *amount* of sodium and water excretion by the kidneys, two primary systems are especially involved in regulating the *concentration* of sodium and osmolarity of extracellular fluid: (1) the osmoreceptor-ADH system; and (2) the thirst mechanism.

Figure 29-9. Osmoreceptor-antidiuretic hormone (ADH) feedback mechanism for regulating extracellular fluid osmolarity in response to a water deficit.

OSMORECEPTOR-ADH FEEDBACK SYSTEM

Figure 29-9 shows the basic components of the osmoreceptor-ADH feedback system for control of extracellular fluid sodium concentration and osmolarity. When osmolarity increases above normal because of water deficit, for example, this feedback system operates as follows:

1. An increase in extracellular fluid osmolarity (which in practical terms means an increase in plasma sodium concentration) causes the special nerve cells called *osmoreceptor cells*, located in the *anterior hypothalamus* near the supraoptic nuclei, to shrink.
2. Shrinkage of the osmoreceptor cells causes them to fire, sending nerve signals to additional nerve cells in the supraoptic nuclei, which then relay these signals down the stalk of the pituitary gland to the posterior pituitary.
3. These action potentials conducted to the posterior pituitary stimulate release of ADH, which is stored in secretory granules (or vesicles) in the nerve endings.
4. ADH enters the blood stream and is transported to the kidneys, where it increases the water permeability of the late distal tubules, cortical collecting tubules, and medullary collecting ducts.

- The increased water permeability in the distal nephron segments causes increased water reabsorption and excretion of a small volume of concentrated urine.

Thus, water is conserved while sodium and other solutes continue to be excreted in the urine. This causes dilution of the solutes in the extracellular fluid, thereby correcting the initial excessively concentrated extracellular fluid.

The opposite sequence of events occurs when the extracellular fluid becomes too dilute (hypo-osmotic). For example, with excess water ingestion and a decrease in extracellular fluid osmolarity, less ADH is formed, the renal tubules decrease their permeability for water, less water is reabsorbed, and a large volume of dilute urine is formed. This in turn concentrates the body fluids and returns plasma osmolarity toward normal.

ADH SYNTHESIS IN SUPRAOPTIC AND PARAVENTRICULAR NUCLEI OF HYPOTHALAMUS AND ADH RELEASE FROM POSTERIOR PITUITARY

Figure 29-10 shows the neuroanatomy of the hypothalamus and the pituitary gland, where ADH is synthesized and released. The hypothalamus contains two types of *magnocellular* (large) neurons that synthesize ADH in the *supraoptic* and *paraventricular* nuclei of the hypothalamus, about five-sixths in the supraoptic nuclei and about one-sixth in the paraventricular nuclei. Both of these nuclei have axonal extensions to the posterior pituitary. Once ADH is synthesized, it is transported down the axons of the neurons to their tips, terminating in the posterior pituitary gland. When the supraoptic and paraventricular nuclei are stimulated by increased osmolarity or other factors, nerve impulses pass down these nerve endings, changing their membrane permeability and increasing calcium entry. ADH stored in the secretory granules (also called *vesicles*) of the nerve endings is released in response to increased calcium entry. The released ADH is then carried away in the capillary blood of the posterior pituitary into the systemic circulation. The secretion of ADH in response to an osmotic stimulus is rapid, so plasma ADH levels can increase several-fold within minutes, thereby providing a rapid means for altering renal excretion of water.

A second neuronal area important in controlling osmolarity and ADH secretion is located along the *anteroventral region of the third ventricle*, called the *AV3V region*. At the upper part of this region is a structure called the *subfornical organ* and, at the inferior part, is another structure called the *organum vasculosum of the lamina terminalis*. Between these two organs is the *median preoptic nucleus*, which has multiple nerve connections with the two organs, as well as with the supraoptic nuclei and blood pressure control centers in the medulla of the brain. Lesions of the AV3V

Figure 29-10. Neuroanatomy of the hypothalamus, where antidiuretic hormone (ADH) is synthesized, and the posterior pituitary gland, where ADH is released.

region cause multiple deficits in the control of ADH secretion, thirst, sodium appetite, and blood pressure. Electrical stimulation of this region or stimulation by angiotensin II can increase ADH secretion, thirst, and sodium appetite.

In the vicinity of the AV3V region and supraoptic nuclei are neuronal cells that are excited by small increases in extracellular fluid osmolarity—hence, the term *osmoreceptors* has been used to describe these neurons. These cells send nerve signals to the supraoptic nuclei to control their firing and secretion of ADH. It is also likely that they induce thirst in response to increased extracellular fluid osmolarity.

Both the subfornical organ and organum vasculosum of the lamina terminalis have vascular supplies that lack the typical blood–brain barrier that impedes the diffusion of most ions from the blood into brain tissue. This characteristic makes it possible for ions and other solutes to cross between the blood and local interstitial fluid in this region. As a result, the osmoreceptors rapidly respond to changes in osmolarity of the extracellular fluid, exerting powerful control over the secretion of ADH and over thirst, as discussed later.

Figure 29-11. Effect of increased plasma osmolarity or decreased blood volume on the level of plasma (P) antidiuretic hormone (ADH), also called *arginine vasopressin* (AVP). (Modified from Dunn FL, Brennan TJ, Nelson AE, et al: *The role of blood osmolality and volume in regulating vasopressin secretion in the rat.* *J Clin Invest* 52[12]:3212, 1973.)

STIMULATION OF ADH RELEASE BY DECREASED ARTERIAL PRESSURE AND/OR DECREASED BLOOD VOLUME

ADH release is also controlled by cardiovascular reflexes that respond to decreases in blood pressure and/or blood volume, including the following: (1) the *arterial baroreceptor reflexes*; and (2) the *cardiopulmonary reflexes*, both of which are discussed in [Chapter 18](#). These reflex pathways originate in high-pressure regions of the circulation, such as the aortic arch and carotid sinus, and in low-pressure regions, especially in the cardiac atria. Afferent stimuli are carried by the vagus and glossopharyngeal nerves, with synapses in the nuclei of the tractus solitarius. Projections from these nuclei relay signals to the hypothalamic nuclei that control ADH synthesis and secretion.

Thus, in addition to increased osmolarity, two other stimuli increase ADH secretion: (1) decreased arterial pressure; and (2) decreased blood volume. Whenever blood pressure and blood volume are reduced, such as during hemorrhage, increased ADH secretion causes increased fluid reabsorption by the kidneys, helping restore blood pressure and blood volume toward normal.

Quantitative Importance of Osmolarity and Cardiovascular Reflexes in Stimulating ADH Secretion

As shown in [Figure 29-11](#), a decrease in effective blood volume or an increase in extracellular fluid osmolarity stimulates ADH secretion. However, ADH is considerably

Table 29-2 Control of Antidiuretic Hormone Secretion

Increase ADH	Decrease ADH
↑ Plasma osmolarity	↓ Plasma osmolarity
↓ Blood volume	↑ Blood volume
↓ Blood pressure	↑ Blood pressure
Nausea	
Hypoxia	
Drugs	Drugs
Morphine	Alcohol
Nicotine	Clonidine (antihypertensive)
Cyclophosphamide	Haloperidol (dopamine blocker)

more sensitive to small changes in osmolarity than to similar percentage changes in blood volume. For example, a change in plasma osmolarity of only 1% is sufficient to increase ADH levels. By contrast, after blood loss, plasma ADH levels do not change appreciably until blood volume is reduced by about 10%. With further decreases in blood volume, ADH levels rapidly increase. Thus, with severe decreases in blood volume, the cardiovascular reflexes play a major role in stimulating ADH secretion. The usual daily regulation of ADH secretion during simple dehydration is effected mainly by changes in plasma osmolarity. Decreases in blood volume and blood pressure, however, greatly enhance the ADH response to increased osmolarity.

OTHER STIMULI FOR ADH SECRETION

ADH secretion can also be increased or decreased by other stimuli to the central nervous system, as well as by various drugs and hormones, as shown in [Table 29-2](#). For example, *nausea* is a potent stimulus for ADH release, which may increase to as much as 100 times normal after vomiting. Also, drugs such as *nicotine* and *morphine* stimulate ADH release, whereas some drugs, such as *alcohol*, inhibit ADH release. The marked diuresis that occurs after ingestion of alcohol is due in part to the inhibition of ADH release.

IMPORTANCE OF THIRST IN CONTROLLING EXTRACELLULAR FLUID OSMOLARITY AND SODIUM CONCENTRATION

The kidneys minimize fluid loss during water deficits through the osmoreceptor-ADH feedback system. Adequate fluid intake, however, is necessary to counterbalance whatever fluid loss does occur through sweating and breathing and through the gastrointestinal tract. Fluid intake is regulated by the thirst mechanism, which, together with the osmoreceptor-ADH mechanism, maintains precise control of extracellular fluid osmolarity and sodium concentration.

Table 29-3 Control of Thirst

Increase Thirst	Decrease Thirst
↑ Plasma osmolarity	↓ Plasma osmolarity
↓ Blood volume	↑ Blood volume
↓ Blood pressure	↑ Blood pressure
↑ Angiotensin II	↓ Angiotensin II
Dry mouth	Gastric distention

Many of the same factors that stimulate ADH secretion also increase thirst, which is defined as the conscious desire for water.

CENTRAL NERVOUS SYSTEM CENTERS FOR THIRST

Referring again to **Figure 29-10**, the same area along the anteroventral wall of the third ventricle that promotes ADH release also stimulates thirst. Located anterolaterally in the preoptic nucleus is another small area that when stimulated electrically, causes immediate drinking that continues as long as the stimulation lasts. All these areas together are called the *thirst center*.

The neurons of the thirst center respond to injections of hypertonic salt solutions by stimulating drinking behavior. These cells almost certainly function as osmoreceptors to activate the thirst mechanism in the same way that the osmoreceptors stimulate ADH release.

Increased osmolarity of the cerebrospinal fluid in the third ventricle has essentially the same effect to promote drinking. It is likely that the *organum vasculosum of the lamina terminalis*, which lies immediately beneath the ventricular surface at the inferior end of the AV3V region, is intimately involved in mediating this response.

STIMULI FOR THIRST

Table 29-3 summarizes some of the known stimuli for thirst.

1. *One of the most important is increased extracellular fluid osmolarity, which causes intracellular dehydration in the thirst centers, thereby stimulating the sensation of thirst.*

The value of this response is obvious: it helps dilute extracellular fluids and returns osmolarity toward normal.

2. *Decreases in extracellular fluid volume and arterial pressure also stimulate thirst by a pathway that is independent of the one stimulated by increased plasma osmolarity.*

Thus, blood volume loss by hemorrhage stimulates thirst, even though there might be no change in plasma osmolarity. This stimulation probably occurs because of neural input from cardiopulmonary and systemic arterial baroreceptors in the circulation.

3. *A third important stimulus for thirst is angiotensin II.*

Studies in animals have shown that angiotensin II acts on the subfornical organ and on the organum vasculosum of the lamina terminalis. These regions are outside the blood–brain barrier, and peptides such as angiotensin II diffuse into the tissues. Because angiotensin II is also stimulated by factors associated with hypovolemia and low blood pressure, its effect on thirst helps restore blood volume and blood pressure toward normal along with the other actions of angiotensin II on the kidneys to decrease fluid excretion.

4. *Dryness of the mouth and mucous membranes of the esophagus can elicit the sensation of thirst.*

As a result, a thirsty person may receive relief from thirst almost immediately after drinking water, even though the water has not been absorbed from the gastrointestinal tract and has not yet had an effect on extracellular fluid osmolarity.

5. *Gastrointestinal and pharyngeal stimuli influence thirst.*

In animals that have an esophageal opening to the exterior so that water is never absorbed into the blood, partial relief of thirst occurs after drinking, although the relief is only temporary. Also, gastrointestinal distention may partially alleviate thirst; For example, simple inflation of a balloon in the stomach can relieve thirst. However, relief of thirst sensations through gastrointestinal or pharyngeal mechanisms is short-lived; the desire to drink is completely satisfied only when plasma osmolarity and/or blood volume returns to normal.

The ability of animals and humans to “meter” fluid intake is important because it prevents overhydration. After a person drinks water, 30 to 60 minutes may be required for the water to be reabsorbed and distributed throughout the body. If the thirst sensation were not temporarily relieved after drinking water, the person would continue to drink more and more, eventually leading to overhydration and excess dilution of the body fluids. Experimental studies have repeatedly shown that animals drink almost exactly the amount necessary to return plasma osmolarity and volume to normal.

THRESHOLD FOR OSMOLAR STIMULUS OF DRINKING

The kidneys must continually excrete an obligatory amount of water, even in a dehydrated person, to rid the body of excess solutes that are ingested or produced by metabolism. Water is also lost by evaporation from the lungs and the gastrointestinal tract and by evaporation and sweating from the skin. Therefore, there is always a tendency for dehydration, with resultant increased extracellular fluid sodium concentration and osmolarity.

When the sodium concentration increases only about 2 mEq/L above normal, the thirst mechanism is activated, causing a desire to drink water. This is called the *threshold for drinking*. Thus, even small increases in plasma osmolarity are normally followed by water intake, which restores extracellular fluid osmolarity and volume toward

normal. In this way, the extracellular fluid osmolarity and sodium concentration are precisely controlled.

Disorders of Thirst and Water Intake. As discussed previously, increased thirst occurs in various medical disorders associated with increased urine volume and reductions in extracellular fluid volume, such as poorly controlled diabetes mellitus or diabetes insipidus. In these cases, increased water intake serves as a compensatory response for increased plasma osmolarity and/or extracellular fluid volume depletion. *Polydipsia*, or excessive thirst, occasionally occurs in the absence of known physiological stimuli for thirst. *Psychogenic polydipsia*, for example, may be caused by mental illnesses such as schizophrenia or obsessive-compulsive disorders and can lead to significant *hyponatremia*. In contrast, *adipsia*, the absence of thirst even in the presence of hypernatremia or volume depletion, is rare but usually results from lesions to the hypothalamic thirst centers caused by trauma, infection, or surgery. Partial deficiency of the thirst mechanism, causing inadequate water intake (*hypodipsia*), or an inability to access fluid may occur in patients who have suffered stroke, in older patients with dementia, or in critically ill patients. In the absence of adequate water intake, dehydration and hypernatremia occur, despite large increases in ADH levels.

INTEGRATED RESPONSES OF OSMORECEPTOR-ADH AND THIRST MECHANISMS

In a healthy person, the osmoreceptor-ADH and thirst mechanisms work in parallel to regulate extracellular fluid osmolarity and sodium concentration precisely, despite the constant challenges of dehydration. Even with additional challenges, such as high salt intake, these feedback systems are usually able to keep plasma osmolarity reasonably constant. **Figure 29-12** shows that an increase in sodium intake to as high as six times normal has only a small effect on plasma sodium concentration as long as the ADH and thirst mechanisms are both functioning normally.

When the ADH or thirst mechanism fails, ordinarily the other can still control extracellular osmolarity and sodium concentration with reasonable effectiveness as long as there is enough fluid intake to balance the daily obligatory urine volume and water losses caused by respiration, sweating, or gastrointestinal losses. However, if both the ADH and thirst mechanisms fail simultaneously, plasma sodium concentration and osmolarity are poorly controlled. Thus, when sodium intake is increased after blocking the total ADH-thirst system, relatively large changes in plasma sodium concentration occur. In the absence of the ADH-thirst mechanisms, no other feedback mechanism is capable of adequately regulating plasma sodium concentration and osmolarity.

Role of Angiotensin II and Aldosterone in Controlling Extracellular Fluid Osmolarity and Sodium Concentration

As discussed in **Chapter 28**, both angiotensin II and aldosterone play an important role in regulating sodium reab-

Figure 29-12. Effect of large changes in sodium intake on extracellular fluid sodium concentration in dogs under normal conditions (*red line*) and after the antidiuretic hormone (ADH) and thirst feedback systems were blocked (*blue line*). Note that control of extracellular fluid sodium concentration was poor in the absence of these feedback systems. (Courtesy Dr. David B. Young.)

sorption by the renal tubules. When sodium intake is low, increased levels of these hormones stimulate sodium reabsorption by the kidneys and prevent large sodium losses, even though sodium intake may be reduced to as low as 10% of normal. Conversely, with high sodium intake, decreased formation of these hormones permits the kidneys to excrete large amounts of sodium.

Because of the importance of angiotensin II and aldosterone in regulating sodium excretion by the kidneys, one might mistakenly infer that they also play a major role in regulating extracellular fluid sodium concentration. Although these hormones increase the *amount* of sodium in the extracellular fluid, they also increase the extracellular fluid volume by increasing reabsorption of water along with the sodium. Therefore, *angiotensin II and aldosterone have little effect on sodium concentration, except under extreme conditions.*

This relative unimportance of aldosterone in regulating extracellular fluid sodium concentration is shown by the experiment depicted in **Figure 29-13**. This figure shows the effect on plasma sodium concentration of changing sodium intake more than sixfold under two conditions: (1) under normal conditions; and (2) after the aldosterone feedback system was blocked by removing the adrenal glands and infusing the animals with aldosterone at a constant rate so that plasma levels could not increase or decrease. Note that when sodium intake was increased sixfold, plasma concentration changed only about 1% to 2% in either case. This finding indicates that even without a functional aldosterone feedback system, plasma sodium concentration can be well regulated. The same type of experiment has been conducted after blocking angiotensin II formation, with the same result.

Figure 29-13. Effect of large changes in sodium intake on extracellular fluid sodium concentration in dogs under normal conditions (red line) and after the aldosterone feedback system was blocked (blue line). Note that the sodium concentration was maintained relatively constant over this wide range of sodium intakes, with or without aldosterone feedback control. (Courtesy Dr. David B. Young.)

There are two primary reasons why changes in angiotensin II and aldosterone do not have a major effect on plasma sodium concentration. First, as discussed earlier, angiotensin II and aldosterone increase both sodium and water reabsorption by the renal tubules, leading to increases in extracellular fluid volume and sodium *quantity* but little change in sodium *concentration*. Second, as long as the ADH-thirst mechanism is functional, any tendency toward increased plasma sodium concentration is compensated for by increased water intake or increased plasma ADH secretion, which tends to dilute the extracellular fluid back toward normal. The ADH-thirst system far overshadows the angiotensin II and aldosterone systems for regulating sodium concentration under normal conditions. Even in patients with *primary aldosteronism*, who have extremely high levels of aldosterone, the plasma sodium concentration usually increases only about 3 to 5 mEq/L above normal.

Under extreme conditions caused by complete loss of aldosterone secretion as a result of adrenalectomy or in patients with Addison disease (severely impaired secretion or total lack of aldosterone), there is tremendous loss of sodium by the kidneys, which can lead to a marked reduction in plasma sodium concentration. One reason for this is that large losses of sodium eventually cause severe volume depletion and decreased blood pressure, which can activate the thirst mechanism through the cardiovascular reflexes. This activation leads to a further dilution of the plasma sodium concentration, even though the increased water intake helps minimize the decrease in body fluid volumes under these conditions.

Thus, there are extreme situations in which the plasma sodium concentration may change significantly, even with a functional ADH-thirst mechanism. Even so, the ADH-thirst mechanism is the most powerful feedback system in the body for controlling extracellular fluid osmolarity and sodium concentration.

Salt-Appetite Mechanism for Controlling Extracellular Fluid Sodium Concentration and Volume

The maintenance of a normal extracellular fluid volume and sodium concentration requires a balance between sodium excretion and sodium intake. Currently, sodium intake is almost always greater than necessary for homeostasis. In fact, the average sodium intake for persons in industrialized cultures who eat processed foods usually ranges between 100 and 200 mEq/day, even though humans can survive and function normally while ingesting only 10 to 20 mEq/day. Thus, most people eat far more sodium than is necessary for homeostasis, and evidence indicates that our usual high sodium intake may contribute to cardiovascular disorders such as hypertension.

Salt appetite is due in part to the fact that animals and humans like salt and eat it, regardless of whether they are salt-deficient. Salt appetite also has a regulatory component in which there is a behavioral drive to obtain salt when a sodium deficiency exists in the body. This behavioral drive is particularly important in herbivores, which naturally eat a low-sodium diet, but salt craving may also be important in humans, especially in those who have an extreme deficiency of sodium, such as occurs in Addison disease. In this case, there is a deficiency of aldosterone secretion, which causes excessive loss of sodium in the urine and leads to decreased extracellular fluid volume and decreased sodium concentration; both of these changes elicit the desire for salt.

In general, the primary stimuli that increase salt appetite are those associated with sodium deficits and decreased blood volume or decreased blood pressure associated with circulatory insufficiency.

The neuronal mechanism for salt appetite is analogous to that of the thirst mechanism. Some of the same neuronal centers in the AV3V region of the brain seem to be involved because lesions in this region frequently affect both thirst and salt appetite simultaneously in animals. Also, circulatory reflexes elicited by low blood pressure or decreased blood volume affect both thirst and salt appetite at the same time.

Renal Regulation of Potassium, Calcium, Phosphate, and Magnesium; Integration of Renal Mechanisms for Control of Blood Volume and Extracellular Fluid Volume

REGULATION OF EXTRACELLULAR FLUID POTASSIUM CONCENTRATION AND POTASSIUM EXCRETION

The extracellular fluid potassium concentration normally is regulated at about 4.2 mEq/L, seldom rising or falling more than ± 0.3 mEq/L. This precise control is necessary because many cell functions are sensitive to changes in extracellular fluid potassium concentration. For example, an increase in plasma potassium concentration of only 3 to 4 mEq/L can cause cardiac arrhythmias, and higher concentrations can lead to cardiac arrest or fibrillation.

A special difficulty in regulating extracellular potassium concentration is the fact that more than 98% of the total body potassium is contained in the cells, and only 2% is contained in the extracellular fluid (Figure 30-1). For a 70-kg adult, who has about 28 liters of intracellular fluid (40% of body weight) and 14 liters of extracellular fluid (20% of body weight), about 3920 mEq of potassium are inside the cells, and only about 59 mEq are in the extracellular fluid. Also, the potassium contained in a single meal may be as high as 50 mEq, and the daily intake usually ranges between 50 and 200 mEq/day; therefore, failure to rapidly rid the extracellular fluid of the ingested potassium could cause life-threatening *hyperkalemia* (increased plasma potassium concentration). Likewise, a small loss of potassium from the extracellular fluid could cause severe *hypokalemia* (low plasma potassium concentration) in the absence of rapid and appropriate compensatory responses.

Maintenance of a balance between intake and output of potassium depends primarily on excretion by the kidneys because the amount excreted in the feces is only about 5% to 10% of the potassium intake. Thus, the maintenance of a normal potassium balance requires the kidneys to adjust their potassium excretion rapidly and precisely in response to wide variations in intake, as is also true for most other electrolytes.

Control of potassium distribution between the extracellular and intracellular compartments also plays an important role in potassium homeostasis. Because more

than 98% of the total body potassium is contained in the cells, they can serve as an overflow site for excess extracellular fluid potassium during hyperkalemia or as a source of potassium during hypokalemia. Thus, redistribution of potassium between the intracellular and extracellular fluid compartments provides a first line of defense against changes in extracellular fluid potassium concentration.

REGULATION OF INTERNAL POTASSIUM DISTRIBUTION

After ingestion of a potassium-rich meal, extracellular fluid potassium concentration would rise to a dangerous level if the ingested potassium did not move into the cells rapidly. For example, absorption of 40 mEq of potassium (the amount contained in a meal rich in vegetables and fruit) into an extracellular fluid volume of 14 liters would raise plasma potassium concentration by about 2.9 mEq/L if all the potassium remained in the extracellular compartment. Fortunately, most of the ingested potassium rapidly moves into the cells until the kidneys can eliminate the excess. Between meals, plasma potassium concentration also remains nearly constant as potassium

Figure 30-1. Normal potassium intake, distribution of potassium in the body fluids, and potassium output from the body.

Table 30-1 Factors That Can Alter Potassium Distribution Between Intracellular and Extracellular Fluids

Factors That Shift K ⁺ Into Cells (Decrease Extracellular [K ⁺])	Factors That Shift K ⁺ Out of Cells (Increase Extracellular [K ⁺])
Insulin	Insulin deficiency (diabetes mellitus)
Aldosterone	Aldosterone deficiency (Addison disease)
β-Adrenergic stimulation	β-Adrenergic blockade
Alkalosis	Acidosis Cell lysis Strenuous exercise Increased extracellular fluid osmolarity

is released by the cells to balance the extracellular fluid potassium excreted by the kidneys. **Table 30-1** summarizes some of the factors that can influence the distribution of potassium between the intracellular and extracellular compartments.

Insulin Stimulates Potassium Uptake Into Cells.

Insulin stimulates sodium-potassium adenosine triphosphatase (ATPase) activity in many tissues, including skeletal muscle, which in turn transports potassium into the cells. Insulin is important for increasing cell potassium uptake after a meal. In people who have insulin-deficient diabetes mellitus, the rise in plasma potassium concentration after eating a meal is much greater than normal. Injections of insulin, however, can help correct the hyperkalemia.

Aldosterone Increases Potassium Uptake Into Cells.

Increased potassium intake also stimulates secretion of aldosterone, which increases cell potassium uptake. Excess aldosterone secretion (*Conn syndrome*) is almost invariably associated with hypokalemia, due in part to movement of extracellular potassium into the cells. Conversely, patients with deficient aldosterone production (*Addison disease*) often have clinically significant hyperkalemia due to accumulation of potassium in the extracellular space, as well as renal retention of potassium.

β-Adrenergic Stimulation Increases Cellular Uptake of Potassium. Increased secretion of catecholamines, especially epinephrine, can cause movement of potassium from the extracellular to the intracellular fluid, mainly by activation of β₂-adrenergic receptors. Conversely, treatment of hypertension with β-adrenergic receptor blockers, such as propranolol, causes potassium to move out of the cells and creates a tendency toward hyperkalemia.

Acid-Base Abnormalities Can Cause Changes in Potassium Distribution. Metabolic acidosis increases extracellular potassium concentration, in part by causing loss of potassium from the cells, whereas metabolic alkalosis decreases extracellular fluid potassium concentration. Although the mechanisms responsible for the effect of hydrogen ion concentration on internal distribution of potassium are not completely understood, one effect of increased hydrogen ion concentration is to reduce activity of the Na⁺-K⁺ ATPase pump. This reduction, in turn, decreases cellular uptake of potassium and raises extracellular potassium concentration. Alkalosis has the opposite effect, shifting potassium from the extracellular fluid into the cells and tending to cause hypokalemia.

Cell Lysis Causes Increased Extracellular Potassium Concentration.

As cells are destroyed, the large amounts of potassium contained in the cells are released into the extracellular fluid. This release of potassium can cause significant hyperkalemia if large amounts of tissue are destroyed, as occurs with severe muscle injury or with red blood cell lysis.

Strenuous Exercise Can Cause Hyperkalemia by Releasing Potassium From Skeletal Muscle.

During prolonged exercise, potassium is released from skeletal muscle into the extracellular fluid. Usually the hyperkalemia is mild, but it may be clinically significant after heavy exercise, especially in patients treated with β-adrenergic blockers or in individuals with insulin deficiency. In rare cases, hyperkalemia after exercise may be severe enough to cause cardiac toxicity.

Increased Extracellular Fluid Osmolarity Causes Redistribution of Potassium From Cells to Extracellular Fluid.

Increased extracellular fluid osmolarity causes osmotic flow of water out of the cells. The cellular dehydration increases intracellular potassium concentration, thereby promoting diffusion of potassium out of the cells and increasing extracellular fluid potassium concentration. Decreased extracellular fluid osmolarity has the opposite effect.

OVERVIEW OF RENAL POTASSIUM EXCRETION

Renal potassium excretion is determined by the sum of three processes: (1) the rate of potassium filtration (glomerular filtration rate [GFR] multiplied by the plasma potassium concentration); (2) the rate of potassium reabsorption by the tubules; and (3) the rate of potassium secretion by the tubules. The normal rate of potassium filtration by the glomerular capillaries is about 756 mEq/day (GFR, 180 L/day, multiplied by plasma potassium concentration, 4.2 mEq/L). This rate of filtration is relatively

Figure 30-2. Renal tubular sites of potassium reabsorption and secretion. Potassium is reabsorbed in the proximal tubule and ascending loop of Henle, so only about 8% of the filtered load is delivered to the distal tubule. Secretion of potassium by the principal cells of the late distal tubules and collecting ducts adds to the amount delivered, but there is some additional reabsorption by the intercalated cells; therefore, the daily excretion is about 12% of the potassium filtered at the glomerular capillaries. The percentages indicate how much of the filtered load is reabsorbed or secreted into the different tubular segments.

constant in healthy persons because of the autoregulatory mechanisms for GFR discussed previously and the precision with which plasma potassium concentration is regulated. Severe decreases in GFR in certain renal diseases, however, can cause serious potassium accumulation and hyperkalemia.

Figure 30-2 summarizes the tubular handling of potassium under normal conditions. About 65% of the filtered potassium is reabsorbed in the proximal tubule. Another 25% to 30% of the filtered potassium is reabsorbed in the loop of Henle, especially in the thick ascending part, where potassium is actively co-transported along with sodium and chloride. In the proximal tubule and loop of Henle, a relatively constant fraction of the filtered potassium load is reabsorbed. Changes in potassium reabsorption in these segments can influence potassium excretion, but most of the daily variation of potassium excretion is not due to changes in reabsorption in the proximal tubule or loop of Henle. The collecting tubules and collecting ducts reabsorb potassium at variable rates, depending on the potassium intake.

Variable Potassium Secretion in Distal and Collecting Tubules Mediates Most Daily Changes in Potassium Excretion. The most important sites for regulating potassium excretion are the principal cells of the late distal tubules and cortical collecting tubules. In these tubular segments, potassium can at times be reabsorbed or at

Figure 30-3. Mechanisms of potassium secretion and sodium reabsorption by the principal cells of the late distal and collecting tubules. BK, “big” potassium channel; ENaC, epithelial sodium channel; ROMK, renal outer medullary potassium channel.

other times can be secreted, depending on the needs of the body. With a normal potassium intake of 100 mEq/day, the kidneys must excrete about 92 mEq/day (the remaining 8 mEq are lost in the feces). About 60 mEq/day of potassium are secreted into the distal and collecting tubules, accounting for most of the excreted potassium.

With a high potassium intake, the required extra excretion of potassium is achieved almost entirely by increasing the secretion of potassium into the distal and collecting tubules. In fact, in those who consume extremely high-potassium diets, the rate of potassium excretion can exceed the amount of potassium in the glomerular filtrate, indicating a powerful mechanism for secreting potassium.

When potassium intake is low, secretion of potassium in the distal and collecting tubules decreases, causing a reduction in urinary potassium excretion. There is also increased reabsorption of potassium by the intercalated cells in the distal segments of the nephron, and potassium excretion can fall to less than 1% of the potassium in the glomerular filtrate (to <10 mEq/day). With potassium intakes below this level, severe hypokalemia can develop.

Thus, most of the daily regulation of potassium excretion occurs in the late distal and cortical collecting tubules, where potassium can be reabsorbed or secreted, depending on the needs of the body. In the next section, we consider the basic mechanisms of potassium secretion and the factors that regulate this process.

PRINCIPAL CELLS OF LATE DISTAL AND CORTICAL COLLECTING TUBULES SECRETE POTASSIUM

The cells in the late distal and cortical collecting tubules that secrete potassium are called *principal cells* and make up most of the epithelial cells in these regions. **Figure 30-3** shows the basic cellular mechanisms of potassium secretion by the principal cells.

Secretion of potassium from the blood into the tubular lumen is a two-step process, beginning with uptake from the interstitium into the cell by the $\text{Na}^+\text{-K}^+$ ATPase pump in the basolateral cell membrane. This pump moves sodium out of the cell into the interstitium and, at the same time, moves potassium to the interior of the cell.

The second step of the process is passive diffusion of potassium from the interior of the cell into the tubular fluid. The $\text{Na}^+\text{-K}^+$ ATPase pump creates a high intracellular potassium concentration, which provides the driving force for passive diffusion of potassium from the cell into the tubular lumen. The luminal membrane of the principal cells is highly permeable to potassium because there are two types of special channels that allow potassium ions to diffuse across the membrane rapidly: (1) the *renal outer medullary potassium (ROMK) channels*, and (2) high-conductance, “big” potassium (BK) channels. Both types of potassium channels are required for efficient renal potassium excretion, and their abundance in the luminal membrane is increased during high potassium intake.

Control of Potassium Secretion by Principal Cells.

The primary factors that control potassium secretion by the principal cells of the late distal and cortical collecting tubules are the following: (1) the activity of the $\text{Na}^+\text{-K}^+$ ATPase pump; (2) the electrochemical gradient for potassium secretion from the blood to the tubular lumen; and (3) the permeability of the luminal membrane for potassium. These three determinants of potassium secretion are, in turn, regulated by several factors, discussed later.

Intercalated Cells Can Reabsorb or Secrete Potassium.

In circumstances associated with severe potassium depletion, there is a cessation of potassium secretion and a net reabsorption of potassium in the late distal and collecting tubules. This reabsorption occurs through the *type A intercalated cells*. Although this reabsorptive process is not completely understood, one mechanism believed to contribute is a *hydrogen-potassium ATPase* transport mechanism located in the luminal membrane (see [Chapter 28, Figure 28-13](#)). This transporter reabsorbs potassium in exchange for hydrogen ions secreted into the tubular lumen, and the potassium then diffuses through basolateral membrane potassium channels into the interstitial fluid. This abundance of intercalated cell hydrogen-potassium ATPase transporters is enhanced with potassium depletion and hypokalemia, causing increased hydrogen ion secretion and alkalosis. Under normal conditions, however, potassium reabsorption by intercalated cells plays only a small role in controlling potassium excretion.

When there is excess potassium in the body fluids, *type B intercalated cells* in the late distal tubules and collecting tubules actively secrete potassium into the tubular lumen and have functions that are opposite to those of type A cells (see [Chapter 28, Figure 28-13](#)). Potassium is

Figure 30-4. Effect of plasma aldosterone concentration (red line) and extracellular potassium ion concentration (black line) on the rate of urinary potassium excretion. These factors stimulate potassium secretion by the principal cells of the cortical collecting tubules. (Data from Young DB, Paulsen AW: *Interrelated effects of aldosterone and plasma potassium on potassium excretion*. *Am J Physiol* 244:F28, 1983.)

pumped into the type B intercalated cell by a hydrogen-potassium ATPase transporter on the basolateral membrane, and it then diffuses into the tubular lumen through potassium channels.

SUMMARY OF MAJOR FACTORS THAT REGULATE POTASSIUM SECRETION

Because the normal regulation of potassium excretion occurs mainly as a result of changes in potassium secretion by the principal cells of the late distal and collecting tubules, in this chapter we discuss the primary factors that influence secretion by these cells. The most important factors that *stimulate* potassium secretion by the principal cells include the following: (1) increased extracellular fluid potassium concentration; (2) increased aldosterone; and (3) increased tubular flow rate.

One factor that *decreases* potassium secretion is an increased hydrogen ion concentration (acidosis).

Increased Extracellular Fluid Potassium Concentration Stimulates Potassium Secretion. The rate of potassium secretion in the late distal and cortical collecting tubules is directly stimulated by increased extracellular fluid potassium concentration, leading to increases in potassium excretion, as shown in [Figure 30-4](#). This effect is especially pronounced when extracellular fluid potassium concentration rises above about 4.1 mEq/L, slightly less than the normal concentration. Increased plasma potassium concentration, therefore, serves as one of the most important mechanisms for increasing potassium secretion and regulating extracellular fluid potassium ion concentration.

Increased dietary potassium intake and increased extracellular fluid potassium concentration stimulate potassium secretion by at least four mechanisms:

1. Increased extracellular fluid potassium concentration stimulates the $\text{Na}^+\text{-K}^+$ ATPase pump, thereby increasing potassium uptake across the basolateral membrane. This increased potassium uptake in turn increases intracellular potassium ion concentration, causing potassium to diffuse across the luminal membrane into the tubule.
2. Increased extracellular potassium concentration increases the potassium gradient from the renal interstitial fluid to the interior of the epithelial cell, which reduces backleakage of potassium ions from inside the cells through the basolateral membrane.
3. Increased potassium intake stimulates synthesis of potassium channels and their translocation from the cytosol to the luminal membrane, which, in turn, increases the ease of potassium diffusion through the membrane.
4. Increased potassium concentration stimulates aldosterone secretion by the adrenal cortex, which further stimulates potassium secretion, as discussed next.

Aldosterone Stimulates Potassium Secretion. Aldosterone stimulates active reabsorption of sodium ions by the principal cells of the late distal tubules and collecting ducts (see Chapter 28). This effect is mediated through a $\text{Na}^+\text{-K}^+$ ATPase pump that transports sodium outward through the basolateral membrane of the cell and into the renal interstitial fluid at the same time that it pumps potassium into the cell. Thus, aldosterone also has a powerful effect on controlling the rate at which the principal cells secrete potassium and reabsorb sodium.

A second effect of aldosterone is to increase the number of potassium channels in the luminal membrane and therefore its permeability for potassium, further adding to the effectiveness of aldosterone in stimulating potassium secretion. Therefore, aldosterone has a powerful effect to increase potassium excretion, as shown in Figure 30-4.

Increased Extracellular Potassium Ion Concentration Stimulates Aldosterone Secretion. In negative feedback control systems, the factor that is controlled usually has a feedback effect on the controller. In the case of the aldosterone-potassium control system, the rate of aldosterone secretion by the adrenal gland is controlled strongly by extracellular fluid potassium ion concentration. Figure 30-5 shows that an increase in plasma potassium concentration of about 3 mEq/L can increase the plasma aldosterone concentration from nearly 0 to as high as 60 ng/100 ml, a concentration almost 10 times normal.

The effect of potassium ion concentration to stimulate aldosterone secretion is part of a powerful feedback system for regulating potassium excretion, as shown

Figure 30-5. Effect of extracellular fluid potassium ion concentration on plasma aldosterone concentration. Note that small changes in potassium concentration cause large changes in aldosterone concentration.

Figure 30-6. Basic feedback mechanism for control of extracellular fluid potassium concentration by aldosterone (Ald).

in Figure 30-6. In this feedback system, an increase in plasma potassium concentration stimulates aldosterone secretion and, therefore, increases plasma aldosterone concentration (block 1). The increase in plasma aldosterone then causes a marked increase in potassium excretion by the kidneys (block 2). The increased potassium excretion then reduces the extracellular fluid potassium concentration back toward normal (circle 3 and block 4). Thus, this feedback mechanism acts synergistically, with the direct effect of increased extracellular potassium concentration to elevate potassium excretion when potassium intake is raised (Figure 30-7).

Blockade of Aldosterone Feedback System Greatly Impairs Potassium Regulation. In the absence of aldosterone secretion, as occurs in patients with Addison disease, renal secretion of potassium is impaired, thus causing the extracellular fluid potassium concentration to rise to dangerously high levels. Conversely, with excess aldosterone secretion (primary aldosteronism), potassium secretion becomes greatly increased, causing potassium loss by the kidneys, thus leading to hypokalemia.

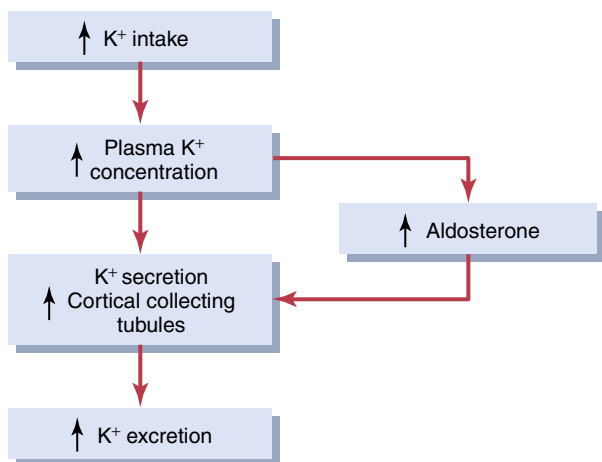

Figure 30-7. Primary mechanisms whereby high potassium intake raises potassium excretion. Note that increased plasma potassium concentration directly raises potassium secretion by the cortical collecting tubules and indirectly increases potassium secretion by raising plasma aldosterone concentration.

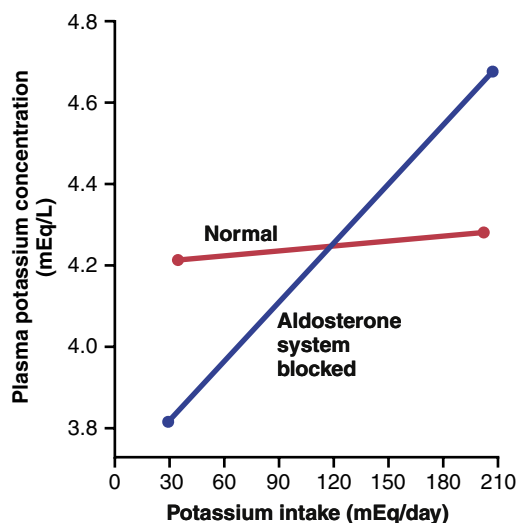

Figure 30-8. Effect of large changes in potassium intake on plasma potassium concentration under normal conditions (red line) and after the aldosterone feedback was blocked (blue line). Note that after blockade of the aldosterone system, regulation of potassium concentration was greatly impaired. (Courtesy Dr. David B. Young.)

In addition to its stimulatory effect on renal secretion of potassium, aldosterone also increases cellular uptake of potassium. This contributes to the powerful aldosterone-potassium feedback system, as discussed previously.

The special quantitative importance of the aldosterone feedback system in controlling potassium concentration is shown in **Figure 30-8**. In this experiment, potassium intake was increased almost sevenfold in dogs under two conditions: (1) under normal conditions; and (2) after the aldosterone feedback system had been blocked by removing the adrenal glands and placing the animals on a fixed rate of aldosterone infusion, so that plasma aldosterone concentration was maintained at a normal level but could neither increase nor decrease as potassium intake was altered.

Figure 30-9. Relationship between flow rate in the cortical collecting tubules and potassium secretion and the effect of changes in potassium intake. Note that a high dietary potassium intake greatly enhances the effect of increased tubular flow rate to increase potassium secretion. The shaded bar shows the approximate normal tubular flow rate under most physiological conditions. (Data from Malnic G, Berliner RW, Giebisch G: Flow dependence of K^+ secretion in cortical distal tubes of the rat. *Am J Physiol* 256:F932, 1989.)

Note that in the normal animals, a sevenfold increase in potassium intake caused only a slight increase in plasma potassium concentration, from 4.2 to 4.3 mEq/L. Thus, when the aldosterone feedback system is functioning normally, potassium concentration is precisely controlled, despite large changes in potassium intake.

When the aldosterone feedback system was blocked, the same increases in potassium intake caused a much larger increase in plasma potassium concentration, from 3.8 to almost 4.7 mEq/L. Thus, control of potassium concentration is greatly impaired when the aldosterone feedback system is blocked. A similar impairment of potassium regulation is observed in people with poorly functioning aldosterone feedback systems, such as occurs in patients with primary aldosteronism (too much aldosterone) or Addison disease (too little aldosterone).

Increased Distal Tubular Flow Rate Stimulates Potassium Secretion. A rise in distal tubular flow rate, as occurs with volume expansion, high sodium intake, or treatment with some diuretics, stimulates potassium secretion (**Figure 30-9**). Conversely, a decrease in distal tubular flow rate, as caused by sodium depletion, reduces potassium secretion.

The effect of the tubular flow rate on potassium secretion in the distal and collecting tubules is strongly influenced by potassium intake. When potassium intake is high, increased tubular flow rate has a much greater effect to stimulate potassium secretion than when potassium intake is low (see **Figure 30-9**).

There are two main effects of a high-volume flow rate that increase potassium secretion:

1. When potassium is secreted into the tubular fluid, the luminal concentration of potassium increases,

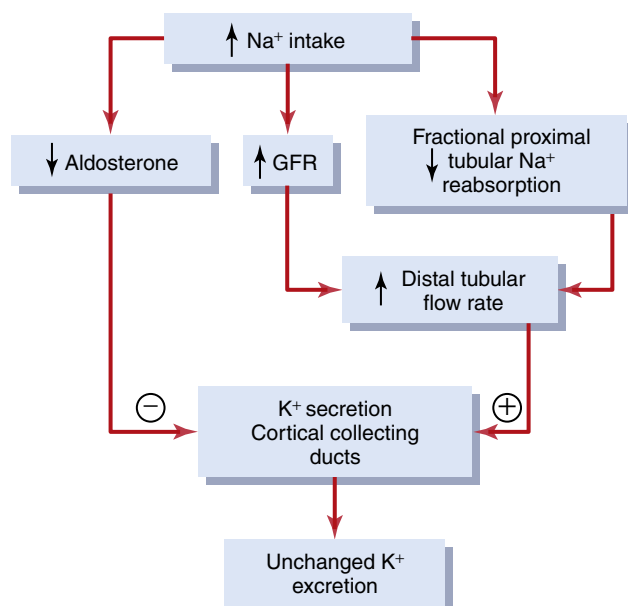

Figure 30-10. Effect of high sodium intake on renal excretion of potassium. Note that a high-sodium diet decreases plasma aldosterone, which tends to decrease potassium secretion by the cortical collecting tubules. However, the high-sodium diet simultaneously increases fluid delivery to the cortical collecting duct, which tends to increase potassium secretion. The opposing effects of a high-sodium diet counterbalance each other, so there is little change in potassium excretion. GFR, Glomerular filtration rate.

thereby reducing the driving force for potassium diffusion across the luminal membrane. With increased tubular flow rate, the secreted potassium is continuously flushed down the tubule, minimizing the rise in tubular potassium concentration and increasing net potassium secretion.

2. A high tubular flow rate also increases the number of high-conductance BK channels in the luminal membrane. Although the BK channels are normally quiescent, they become active in response to increases in flow rate, thereby greatly increasing potassium conductance across the luminal membrane.

The effect of increased tubular flow rate is especially important in helping preserve normal potassium excretion during changes in sodium intake. For example, with a high sodium intake, there is decreased aldosterone secretion, which by itself would tend to decrease the rate of potassium secretion and, therefore, reduce urinary excretion of potassium. However, the high distal tubular flow rate that occurs with a high sodium intake tends to increase potassium secretion (Figure 30-10). Therefore, the two effects of a high sodium intake—decreased aldosterone secretion and high tubular flow rate—counterbalance each other, so there is little change in potassium excretion. Likewise, with a low sodium intake, there is little change in potassium excretion because of the counterbalancing effects of increased aldosterone secretion and decreased tubular flow rate on potassium secretion.

Acute Acidosis Decreases Potassium Secretion. Acute increases in extracellular fluid hydrogen ion concentration (acidosis) reduce potassium secretion, whereas decreased hydrogen ion concentration (alkalosis) increases potassium secretion. The primary mechanism whereby increased hydrogen ion concentration inhibits potassium secretion is by reducing activity of the $\text{Na}^+\text{-K}^+$ ATPase pump. This reduction in turn decreases intracellular potassium concentration and subsequent passive diffusion of potassium across the luminal membrane into the tubule. Acidosis may also reduce the number of potassium channels in the luminal membrane.

With more prolonged acidosis, lasting over a period of several days, there is an increase in urinary potassium excretion. The mechanism for this effect is due in part to an effect of chronic acidosis to inhibit proximal tubular sodium chloride and water reabsorption, which increases distal volume delivery, thereby stimulating potassium secretion. This effect overrides the inhibitory effect of hydrogen ions on the $\text{Na}^+\text{-K}^+$ ATPase pump. Thus, chronic acidosis leads to a loss of potassium, whereas acute acidosis leads to decreased potassium excretion.

Beneficial Effects of Diet High in Potassium and Low in Sodium Content

For most of human history, the typical diet has been one that is low in sodium and high in potassium content, compared with the typical modern diet. In isolated populations that have not experienced industrialization, such as the Yanomamo tribe living in the Amazon region of Northern Brazil, sodium intake may be as low as 10 to 20 mmol/day, and potassium intake may be as high as 200 mmol/day. This intake is due to their consumption of a diet containing large amounts of fruits and vegetables and no processed foods. Populations consuming this type of diet typically do not experience age-related increases in blood pressure and cardiovascular diseases.

With industrialization and increased consumption of processed foods, which often have high sodium and low potassium content, there have been dramatic increases in sodium intake and decreases in potassium intake. In most industrialized countries, potassium consumption averages only 30 to 70 mmol/day, and sodium intake averages 140 to 180 mmol/day.

Experimental and clinical studies have shown that the combination of a high-sodium and low-potassium diet increases the risk for hypertension and associated cardiovascular and kidney diseases. A diet rich in potassium, however, seems to protect against the adverse effects of a high-sodium diet, reducing blood pressure and the risk for stroke, coronary artery disease, and kidney disease. The beneficial effects of increasing potassium intake are especially apparent when combined with a low-sodium diet.

Dietary guidelines published by various organizations have recommended reducing the dietary intake of sodium chloride to about 65 to 100 mmol/day (corresponding to 1.5–2.3 g/day of sodium or 3.8–5.8 g/day sodium chloride) while increasing potassium intake to 120 mmol/day (4.7 g/day) for healthy adults.

REGULATION OF RENAL CALCIUM EXCRETION AND EXTRACELLULAR CALCIUM ION CONCENTRATION

The mechanisms for regulating calcium ion concentration are discussed in detail in [Chapter 80](#), along with the endocrinology of the calcium-regulating hormones, parathyroid hormone (PTH), and calcitonin. Therefore, calcium ion regulation is discussed only briefly in this chapter.

The extracellular fluid calcium ion concentration normally remains tightly controlled within a few percentage points of its normal level, 2.4 mEq/L. When the calcium ion concentration falls to low levels (*hypocalcemia*), the excitability of nerve and muscle cells increases markedly and can, in extreme cases, result in *hypocalcemic tetany*. This condition is characterized by spastic skeletal muscle contractions. *Hypercalcemia* (increased calcium concentration) depresses neuromuscular excitability and can lead to cardiac arrhythmias.

About 50% of the *total* calcium in the plasma (5 mEq/L) exists in the ionized form, which is the form that has biological activity at cell membranes. The remainder is bound to plasma proteins ($\approx 40\%$) or complexed in the nonionized form with anions such as phosphate and citrate ($\approx 10\%$).

Changes in plasma hydrogen ion concentration influence calcium binding to plasma proteins. With acidosis, less calcium is bound to the plasma proteins. Conversely, with alkalosis, a greater amount of calcium is bound to the plasma proteins. Therefore, *patients with alkalosis are more susceptible to hypocalcemic tetany*.

As with other substances in the body, calcium intake must be balanced with the net loss of calcium over the long term. Unlike ions such as sodium and chloride, however, much of the calcium excretion occurs in the feces. The usual rate of dietary calcium intake is about 1000 mg/day, with about 900 mg/day of calcium excreted in the feces. Under certain conditions, fecal calcium excretion can exceed calcium ingestion because calcium can also be secreted into the intestinal lumen. Therefore, the gastrointestinal tract and regulatory mechanisms that influence intestinal calcium absorption and secretion play a major role in calcium homeostasis, as discussed in [Chapter 80](#).

Almost all the calcium in the body (99%) is stored in the bone, with only about 0.1% in the extracellular fluid and 1.0% in the intracellular fluid and cell organelles. The bone, therefore, acts as a large reservoir for calcium and as a source of calcium when extracellular fluid calcium concentration tends to decrease.

One of the most important regulators of bone uptake and release of calcium is PTH. When extracellular fluid calcium concentration falls below normal, activity of *calcium-sensing receptors* (CSRs) on the cell membrane of the parathyroid glands is reduced, promoting increased secretion of PTH. This hormone then acts directly on the bones to increase resorption of bone salts (release of salts from the bones) and release large amounts of calcium into the extracellular fluid, thereby returning calcium

Figure 30-11. Compensatory responses to decreased plasma ionized calcium concentration mediated by parathyroid hormone (PTH) and vitamin D.

levels back toward normal. When the calcium ion concentration is elevated, CSR activity of the parathyroid cells is stimulated, causing a reduction in PTH secretion, so almost no bone resorption occurs; instead, excess calcium is deposited in the bones. Thus, the daily regulation of calcium ion concentration is mediated in large part by the effects of PTH on bone resorption.

The bones, however, do not have an inexhaustible supply of calcium. Therefore, over the long term, intake of calcium must be balanced with calcium excretion by the gastrointestinal tract and kidneys. The most important regulator of calcium reabsorption at both these sites is PTH, which regulates the plasma calcium concentration through three main effects: (1) by stimulating bone resorption; (2) by stimulating activation of vitamin D, which then increases intestinal reabsorption of calcium; and (3) by increasing renal tubular calcium reabsorption ([Figure 30-11](#)). The control of gastrointestinal calcium reabsorption and calcium exchange in the bones is discussed elsewhere; the remainder of this section focuses on the mechanisms that control renal calcium excretion.

CONTROL OF CALCIUM EXCRETION BY THE KIDNEYS

Calcium is filtered and reabsorbed in the kidneys but is not secreted. Therefore, the rate of renal calcium excretion is calculated as follows:

$$\text{Renal calcium excretion} = \text{Calcium filtered} - \text{Calcium reabsorbed}$$

Only about 60% of the plasma calcium is ionized, with 40% being bound to the plasma proteins and 10% complexed with anions such as phosphate. Therefore, only about 60% of the plasma calcium is filtered at the glomerulus. Normally, about 99% of the filtered calcium is reabsorbed by the tubules, with only about 1% of the filtered calcium being excreted. About 65% of the filtered calcium is reabsorbed in the proximal tubule, 25% to 30% is reabsorbed in the loop of Henle, and 4% to 9% is reabsorbed in the distal and collecting tubules. This pattern of reabsorption is similar to that for sodium.

Figure 30-12. Mechanisms of calcium reabsorption by paracellular and transcellular pathways in the proximal tubular cells.

As is true with the other ions, calcium excretion is adjusted to meet the body's needs. With an increase in calcium intake, there is also increased renal calcium excretion, although much of the increase of calcium intake is eliminated in the feces. With calcium depletion, calcium excretion by the kidneys decreases as a result of enhanced tubular reabsorption.

Proximal Tubular Calcium Reabsorption. Most of the calcium reabsorption in the proximal tubule occurs through the paracellular pathway; it is dissolved in water and carried with the reabsorbed fluid as it flows between the cells. Only about 20% of proximal tubular calcium reabsorption occurs through the transcellular pathway in two steps;

1. Calcium diffuses from the tubular lumen into the cell down an electrochemical gradient due to the much higher concentration of calcium in the tubular lumen, compared with the epithelial cell cytoplasm, and because the cell interior has a negative charge relative to the tubular lumen.
2. Calcium exits the cell across the basolateral membrane by a calcium-ATPase pump and by the sodium-calcium counter-transporter (**Figure 30-12**).

Loop of Henle and Distal Tubule Calcium Reabsorption. In the loop of Henle, calcium reabsorption is restricted to the thick ascending limb. Approximately 50% of calcium reabsorption in the thick ascending limb occurs through the paracellular route by passive diffusion due to the slight positive charge of the tubular lumen relative to the interstitial fluid. The remaining 50% of calcium reabsorption in the thick ascending limb occurs through the transcellular pathway, a process that is stimulated by PTH.

In the distal tubule, calcium reabsorption occurs almost entirely by active transport through the cell

membrane. The mechanism for this active transport is similar to that in the proximal tubule and thick ascending limb. It involves diffusion across the luminal membrane through calcium channels and exit across the basolateral membrane by a calcium-ATPase pump, as well as a sodium-calcium counter-transport mechanism. In this segment, as well as in the loops of Henle, PTH stimulates calcium reabsorption. Vitamin D (calcitriol) and calcitonin also stimulate calcium reabsorption in the thick ascending limb of Henle's loop and in the distal tubule, although these hormones are not as important quantitatively as PTH in reducing renal calcium excretion.

Regulation of Tubular Calcium Reabsorption. One of the primary controllers of renal tubular calcium reabsorption is PTH. Increased levels of PTH stimulate calcium reabsorption in the thick ascending loops of Henle and distal tubules, which reduces urinary excretion of calcium. Conversely, reduction of PTH promotes calcium excretion by decreasing reabsorption in the loops of Henle and distal tubules.

Increased extracellular fluid calcium ion concentration also directly stimulates CSRs, which inhibit calcium reabsorption in the thick ascending loops of Henle. Conversely, reductions in calcium concentration decrease CSR activity and increase calcium reabsorption in the thick ascending loop of Henle.

In the proximal tubule, calcium reabsorption usually parallels sodium and water reabsorption and is independent of PTH. Therefore, in cases of extracellular volume expansion or increased arterial pressure—both of which decrease proximal sodium and water reabsorption—there is also reduction in calcium reabsorption and, consequently, increased urinary calcium excretion. Conversely, with reduced extracellular volume or decreased blood pressure, calcium excretion decreases primarily because of increased proximal tubular reabsorption.

Another factor that influences calcium reabsorption is the plasma concentration of phosphate. Increased plasma phosphate stimulates PTH, which increases calcium reabsorption by the renal tubules, thereby reducing calcium excretion. The opposite occurs with a reduction in plasma phosphate concentration.

Calcium reabsorption is also stimulated by metabolic alkalosis and inhibited by metabolic acidosis. Thus, acidosis tends to increase calcium excretion, whereas alkalosis tends to reduce calcium excretion. Most of the effect of hydrogen ion concentration on calcium excretion results from changes in calcium reabsorption in the distal tubule.

A summary of the factors known to influence calcium excretion is shown in **Table 30-2**.

REGULATION OF RENAL PHOSPHATE EXCRETION

Phosphate excretion by the kidneys is controlled primarily by an overflow mechanism that can be explained as follows. The

Table 30-2 Factors That Alter Renal Calcium Excretion

renal tubules have a normal transport maximum for reabsorbing phosphate of about 0.1 mmol/min. When less than this amount of phosphate is present in the glomerular filtrate, essentially *all* the filtered phosphate is reabsorbed. When more than this amount is present, the *excess* is excreted. Therefore, phosphate normally begins to spill into the urine when its concentration in the extracellular fluid rises above a threshold of about 0.8 mM/L, which gives a tubular load of phosphate of about 0.1 mmol/min, assuming a GFR of 125 ml/min. Because most people ingest large quantities of phosphate in milk products and meat, the concentration of phosphate is usually maintained above 1 mM/L; at this level, there is continual excretion of phosphate into the urine.

The proximal tubule normally reabsorbs 75% to 80% of the filtered phosphate. The distal tubule reabsorbs about 10% of the filtered load, and only small amounts are reabsorbed in the loop of Henle, collecting tubules, and collecting ducts. Approximately 10% of the filtered phosphate is excreted in the urine.

In the proximal tubule, phosphate reabsorption occurs mainly through the transcellular pathway. Phosphate enters the cell from the lumen by a sodium-phosphate co-transporter and exits the cell across the basolateral membrane by a process that is not well understood but may involve a counter-transport mechanism in which phosphate is exchanged for an anion.

Changes in tubular phosphate reabsorptive capability can also occur in different conditions and influence phosphate excretion. For example, a diet low in phosphate can, over time, increase the reabsorptive transport maximum for phosphate, thereby reducing the tendency for phosphate to spill over into the urine.

PTH can play a significant role in regulating phosphate concentration through two effects: (1) PTH promotes bone resorption, thereby releasing large amounts of phosphate into the extracellular fluid from the bone salts; and (2) PTH decreases the abundance of sodium-phosphate co-transporters in the apical membrane, which in turn reduces phosphate reabsorption by the renal tubules. *Thus, whenever plasma PTH is increased, tubular phosphate reabsorption is decreased, and more phosphate is excreted.* These interrelationships among phosphate, PTH, and calcium are discussed in more detail in [Chapter 80](#).

REGULATION OF RENAL MAGNESIUM EXCRETION AND EXTRACELLULAR MAGNESIUM ION CONCENTRATION

More than half of the body's magnesium is stored in the bones. Most of the rest is within the cells, with less than 1% located in the extracellular fluid. Although the total plasma magnesium concentration is about 1.8 mEq/L, more than half of this is bound to plasma proteins. Therefore, the free ionized concentration of magnesium is only about 0.8 mEq/L.

The normal daily intake of magnesium is about 250 to 300 mg/day, but only about half of this intake is absorbed by the gastrointestinal tract. To maintain magnesium balance, the kidneys must excrete this absorbed magnesium, about half the daily intake of magnesium, or 125 to 150 mg/day. The kidneys normally excrete about 10% to 15% of the magnesium in the glomerular filtrate.

Renal excretion of magnesium can increase markedly during magnesium excess or decrease to almost zero during magnesium depletion. Because magnesium is involved in many biochemical processes in the body, including activation of many enzymes, its concentration must be closely regulated.

Regulation of magnesium excretion is achieved mainly by changing tubular reabsorption. The proximal tubule usually reabsorbs only about 25% of the filtered magnesium. The primary site of reabsorption is the loop of Henle, where about 65% of the filtered load of magnesium is reabsorbed. Only a small amount (usually <5%) of filtered magnesium is reabsorbed in the distal and collecting tubules.

The mechanisms that regulate magnesium reabsorption are not well understood, but **Table 30-4** summarizes some of the factors that influence renal magnesium excretion. Note that several factors that alter renal calcium excretion have similar effects on magnesium excretion.

INTEGRATION OF RENAL MECHANISMS FOR CONTROL OF EXTRACELLULAR FLUID

Extracellular fluid volume is determined mainly by the balance between intake and output of water and salt. In

Table 30-4 Factors That Alter Renal Magnesium Excretion

many cases, salt and fluid intakes are dictated by a person's habits rather than by physiological control mechanisms. Therefore, the burden of extracellular volume regulation is often placed on the kidneys, which must adapt their excretion of salt and water to match intake under steady-state conditions.

In discussing the regulation of extracellular fluid volume, we consider the factors that control the amount of sodium chloride in the extracellular fluid because changes in extracellular fluid sodium chloride content usually cause parallel changes in extracellular fluid volume, provided the antidiuretic hormone (ADH)–thirst mechanisms are operative. When the ADH–thirst mechanisms are functioning normally, a change in extracellular fluid sodium chloride content is usually matched by a similar change in the amount of extracellular water, and thus maintenance of osmolality and sodium concentration is relatively constant.

SODIUM INTAKE AND EXCRETION ARE BALANCED UNDER STEADY-STATE CONDITIONS

An important consideration in overall control of sodium excretion—or excretion of most electrolytes, for that matter—is that under steady-state conditions, excretion by the kidneys is determined by intake. To maintain life, a person must, over the long term, excrete almost precisely the amount of sodium ingested. Therefore, even with disturbances that cause major changes in kidney function, balance between intake and output of sodium usually is restored within a few days.

If disturbances of kidney function are not too severe, sodium balance may be achieved mainly by intrarenal adjustments, with minimal changes in the extracellular fluid volume or other systemic adjustments. However, when perturbations to the kidneys are severe, and intrarenal compensations are exhausted, systemic adjustments are often invoked, such as changes in blood pressure, circulating hormones, and sympathetic nervous system activity.

These adjustments can be costly in terms of overall homeostasis because they cause other changes throughout the body that may, in the long run, be damaging. For example, impaired kidney function may lead to increased

blood pressure that, in turn, helps maintain normal sodium excretion. Over the long term, the high blood pressure may injure the blood vessels, heart, and other organs. These compensations, however, are necessary because a sustained imbalance between fluid and electrolyte intake and excretion would quickly lead to accumulation or loss of electrolytes and fluid, causing severe cardiovascular consequences within a few days. Thus, one can view the systemic adjustments that occur in response to abnormalities of kidney function as a necessary trade-off that brings electrolyte and fluid excretion back into balance with intake.

SODIUM EXCRETION IS CONTROLLED BY ALTERING GLOMERULAR FILTRATION OR TUBULAR SODIUM REABSORPTION RATES

The two variables that influence sodium and water excretion are the rates of glomerular filtration and tubular reabsorption:

$$\text{Excretion} = \text{Glomerular filtration} - \text{Tubular reabsorption}$$

The GFR normally is about 180 L/day, tubular reabsorption is 178.5 L/day, and urine excretion is 1.5 L/day. Thus, small changes in GFR or tubular reabsorption potentially can cause large changes in renal excretion. For example, a 5% increase in GFR (to 189 L/day) would cause a 9-L/day increase in urine volume if tubular compensations did not occur; this increase would quickly cause catastrophic changes in body fluid volumes. Similarly, small changes in tubular reabsorption, in the absence of compensatory adjustments of GFR, would also lead to dramatic changes in urine volume and sodium excretion. Tubular reabsorption and the GFR usually are regulated precisely in parallel, so that excretion by the kidneys can be exactly matched to the intake of water and electrolytes.

Even with disturbances that alter GFR or tubular reabsorption, changes in urinary excretion are minimized by various buffering mechanisms. For example, if the kidneys become greatly vasodilated, and GFR increases (as can occur with certain drugs or high fever), this condition raises sodium chloride delivery to the tubules, which in turn leads to at least two intrarenal compensations: (1) increased tubular reabsorption of much of the extra sodium chloride filtered, called *glomerulotubular balance*; and (2) *macula densa feedback*, in which increased sodium chloride delivery to the distal tubule causes afferent arteriolar constriction and return of GFR toward normal. Likewise, abnormalities of tubular reabsorption in the proximal tubule or loop of Henle are partially compensated for by these same intrarenal feedbacks, as discussed in [Chapter 27](#).

Because neither of these two mechanisms operates perfectly to restore distal sodium chloride delivery all the way back to normal, changes in GFR or tubular reabsorption can lead to significant changes in urine sodium and

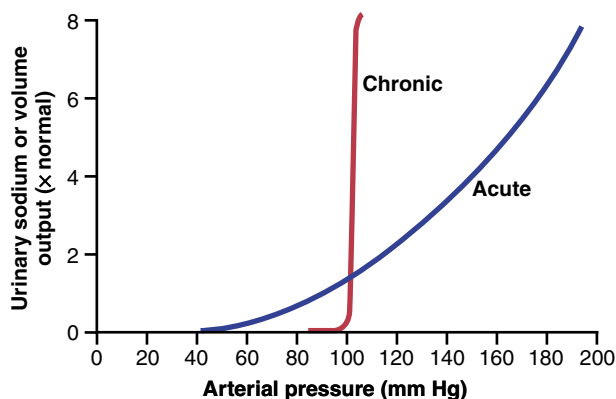

Figure 30-13. Acute and chronic effects of arterial pressure on sodium output by the kidneys (pressure natriuresis). Note that chronic increases in arterial pressure cause much greater increases in sodium output than those measured during acute increases in arterial pressure.

water excretion. When this occurs, other feedback mechanisms may come into play, such as changes in blood pressure and various hormones; these mechanisms eventually return sodium excretion to equal sodium intake. In the next few sections, we review how these mechanisms operate together to control sodium and water balance and, in so doing, also act to control extracellular fluid volume. All these feedback mechanisms control renal excretion of sodium and water by altering GFR or tubular reabsorption.

IMPORTANCE OF PRESSURE NATRIURESIS AND PRESSURE DIURESIS IN MAINTAINING BODY SODIUM AND FLUID BALANCE

One of the most basic and powerful mechanisms for maintaining sodium and fluid balance, as well as for controlling blood volume and extracellular fluid volume, is the effect of blood pressure on sodium and water excretion—the *pressure natriuresis* and *pressure diuresis* mechanisms, respectively. As discussed in [Chapter 19](#), this feedback also plays a dominant role in long-term blood pressure regulation.

Figure 30-13 shows the effect of arterial pressure on urinary sodium output. Note that acute increases in blood pressure of 30 to 50 mm Hg cause a twofold to threefold increase in urinary sodium output. This effect is independent of changes in activity of the sympathetic nervous system or of various hormones, such as angiotensin II (Ang II), ADH, or aldosterone, because pressure natriuresis can be demonstrated in an isolated kidney that has been removed from the influence of these factors. With chronic increases in blood pressure, the effectiveness of pressure natriuresis is greatly enhanced because the increased blood pressure also, after a short time delay, suppresses renin release and, therefore, decreases the formation of Ang II and aldosterone. As discussed previously, decreased levels of Ang II and aldosterone inhibit

renal tubular reabsorption of sodium, thereby amplifying the direct effects of increased blood pressure to increase sodium and water excretion.

PRESSURE NATRIURESIS AND DIURESIS: KEY COMPONENTS OF A RENAL–BODY FLUID FEEDBACK FOR REGULATING BODY FLUID VOLUMES AND ARTERIAL PRESSURE

The effect of increased blood pressure to raise urine output is part of a powerful feedback system that operates to maintain balance between fluid intake and output, as shown in [Figure 30-14](#). This mechanism is the same mechanism discussed in [Chapter 19](#) for arterial pressure control. The extracellular fluid volume, blood volume, cardiac output, arterial pressure, and urine output are all controlled at the same time as separate parts of this basic feedback mechanism.

During changes in sodium and fluid intake, this feedback mechanism helps maintain fluid balance and minimizes changes in blood volume, extracellular fluid volume, and arterial pressure as follows:

1. An increase in fluid intake (assuming that sodium accompanies the fluid intake) above the level of urine output causes a temporary accumulation of fluid in the body.
2. As long as fluid intake exceeds urine output, fluid accumulates in the blood and interstitial spaces, causing parallel increases in blood volume and extracellular fluid volume. As discussed later, the actual increases in these variables are usually small because of the effectiveness of this feedback.
3. An increase in blood volume raises mean circulatory filling pressure.
4. An increase in mean circulatory filling pressure raises the pressure gradient for venous return.
5. An increased pressure gradient for venous return elevates cardiac output.
6. An increased cardiac output raises arterial pressure.
7. An increased arterial pressure increases urine output by way of pressure diuresis. The steepness of the normal pressure natriuresis relationship indicates that only a slight increase in blood pressure is required to raise urinary excretion severalfold.
8. The increased fluid excretion balances the increased intake, and further accumulation of fluid is prevented.

Thus, the renal–body fluid feedback mechanism operates to prevent continuous accumulation of salt and water in the body during increased salt and water intake. As long as the kidneys and various nervous and hormonal mechanisms are operating effectively, large changes in salt and water intake can be accommodated with minimal changes in blood volume, extracellular fluid volume, cardiac output, and arterial pressure.

Figure 30-14. The basic renal-body fluid feedback mechanism for control of blood volume, extracellular fluid volume, and arterial pressure. *Solid lines indicate positive effects; dashed lines indicate negative effects.*

Figure 30-15. Approximate effect of changes in daily fluid intake on blood volume. Note that blood volume remains relatively constant in the normal range of daily fluid intakes.

The opposite sequence of events occurs when fluid intake falls below normal. In this case, there is a tendency toward decreased blood volume and extracellular fluid volume, as well as reduced arterial pressure. Even a small decrease in blood pressure causes a large decrease in urine output, thereby allowing fluid balance to be maintained, with minimal changes in blood pressure, blood volume, or extracellular fluid volume. The effectiveness of this mechanism in preventing large changes in blood volume is demonstrated in **Figure 30-15**, which shows that changes in blood volume are almost imperceptible, despite large variations in daily intake of water and electrolytes, except when intake becomes so low that it is not sufficient to make up for fluid losses caused by evaporation or other inescapable losses.

As discussed later, there are nervous and hormonal systems, in addition to intrarenal mechanisms, that can

raise sodium excretion to match increased sodium intake, even without measurable increases in cardiac output or arterial pressure in many persons. Other individuals who are more “salt-sensitive” have significant increases in arterial pressure with even moderate increases in sodium intake. With prolonged high-sodium intake, lasting over several years, high blood pressure may occur, even in persons who are not initially salt-sensitive. When blood pressure does rise, pressure natriuresis provides a critical means of maintaining balance between sodium intake and urinary sodium excretion.

EFFECTIVENESS OF BLOOD VOLUME AND EXTRACELLULAR FLUID VOLUME REGULATION

By studying **Figure 30-14**, one can see the main reasons that blood volume remains almost exactly constant, despite extreme changes in daily fluid intake: (1) a slight change in blood volume causes a marked change in cardiac output; (2) a slight change in cardiac output causes a large change in blood pressure; and (3) a slight change in blood pressure causes a large change in urine output. These factors work together to provide effective feedback control of blood volume.

The same control mechanisms operate whenever there is blood loss because of hemorrhage. In this case, a fall in blood pressure along with nervous and hormonal factors (discussed later) cause fluid retention by the kidneys. Other parallel processes occur to reconstitute the red blood cells and plasma proteins in the blood. If abnormalities of red blood cell volume remain, such as when there is deficiency of erythropoietin or other factors needed to stimulate red blood cell production, the plasma volume

Figure 30-16. Approximate relationship between extracellular fluid volume and blood volume, showing a nearly linear relationship in the normal range but also showing the failure of blood volume to continue to increase when the extracellular fluid volume becomes excessive. When this condition occurs, the additional extracellular fluid volume resides in the interstitial spaces, and edema results.

will usually make up the difference, and the overall blood volume will return essentially to normal, despite the low red blood cell mass.

DISTRIBUTION OF EXTRACELLULAR FLUID BETWEEN INTERSTITIAL SPACES AND VASCULAR SYSTEM

From [Figure 30-14](#) it is apparent that blood volume and extracellular fluid volume are usually controlled in parallel with each other. Ingested fluid initially goes into the blood, but it rapidly becomes distributed between the interstitial spaces and the plasma. Therefore, blood volume and extracellular fluid volume usually are controlled simultaneously.

There are circumstances, however, in which the distribution of extracellular fluid between the interstitial spaces and blood can vary greatly. As discussed in [Chapter 25](#), the principal factors that can cause accumulation of fluid in the interstitial spaces include the following: (1) increased capillary hydrostatic pressure; (2) decreased plasma colloid osmotic pressure; (3) increased permeability of the capillaries; and (4) obstruction of lymphatic vessels. In all these conditions, an unusually high proportion of the extracellular fluid becomes distributed to the interstitial spaces.

[Figure 30-16](#) shows the normal distribution of fluid between the interstitial spaces and vascular system and the distribution that occurs in edema states. When small amounts of fluid accumulate in the blood as a result of too much fluid intake or a decrease in renal output of fluid, about 20% to 30% of it stays in the blood and increases the blood volume. The remainder is distributed to the interstitial spaces. When the extracellular fluid volume rises more than 30% to 50% above normal, almost all the additional fluid goes into the interstitial spaces, and little remains in the blood. Once the interstitial fluid pressure rises from its normally negative value to become positive,

the tissue interstitial spaces become compliant, and large amounts of fluid then pour into the tissues without the interstitial fluid pressure rising much more. In other words, the safety factor against edema, owing to a rising interstitial fluid pressure that counteracts fluid accumulation in the tissues, is lost once the tissues become highly compliant.

Thus, under normal conditions, the interstitial spaces act as an overflow reservoir for excess fluid, sometimes increasing in volume 10 to 30 liters. This situation causes edema, as explained in [Chapter 25](#), but it also acts as an important overflow release valve for the circulation, protecting the cardiovascular system against a dangerous overload that could lead to pulmonary edema and cardiac failure.

To summarize, extracellular fluid volume and blood volume are often controlled simultaneously, but the quantitative amounts of fluid distribution between the interstitium and the blood depend on the physical properties of the circulation and the interstitial spaces, as well as on the dynamics of fluid exchange through the capillary membranes.

NERVOUS AND HORMONAL FACTORS INCREASE EFFECTIVENESS OF RENAL-BODY FLUID FEEDBACK CONTROL

In [Chapters 27 and 28](#), we discuss the nervous and hormonal factors that influence GFR and tubular reabsorption and, therefore, renal excretion of salt and water. These nervous and hormonal mechanisms usually act together with the pressure natriuresis and pressure diuresis mechanisms, making them more effective in minimizing the changes in blood volume, extracellular fluid volume, and arterial pressure that occur in response to daily challenges. In many cases, nervous and hormonal mechanisms can regulate renal sodium and water excretion and maintain balance between intake and output without significant changes in blood pressure. However, abnormalities of kidney function or of the various nervous and hormonal factors that influence the kidneys can lead to serious changes in blood pressure and body fluid volumes, as discussed later.

SYMPATHETIC NERVOUS SYSTEM CONTROL OF RENAL EXCRETION: ARTERIAL BARORECEPTOR AND LOW-PRESSURE STRETCH RECEPTOR REFLEXES

Because the kidneys receive extensive sympathetic innervation, changes in sympathetic activity can alter renal sodium and water excretion, as well as regulation of extracellular fluid volume under some conditions. For example, when blood volume is reduced by hemorrhage, pressures in the pulmonary blood vessels and other low-pressure regions of the thorax decrease, causing reflex activation of the sympathetic nervous system. This, in turn, increases

renal sympathetic nerve activity, which has several effects to decrease sodium and water excretion: (1) constriction of the renal arterioles, which decreases GFR if the sympathetic activation is severe; (2) increased tubular reabsorption of salt and water; and (3) stimulation of renin release and increased Ang II and aldosterone formation, both of which further increase tubular reabsorption. If the reduction in blood volume is great enough to lower systemic arterial pressure, further activation of the sympathetic nervous system occurs because of decreased stretch of the arterial baroreceptors located in the carotid sinus and aortic arch. All these reflexes together play an important role in the rapid restitution of blood volume that occurs in acute conditions such as hemorrhage. Also, reflex inhibition of renal sympathetic activity may contribute to the rapid elimination of excess fluid in the circulation that occurs after eating a meal that contains large amounts of salt and water.

Excessive and inappropriate activation of the sympathetic nervous system, however, can lead to a cascade of effects, including increases in renin secretion, Ang II formation, and renal sodium reabsorption that elevate blood pressure. In fact, ablation of the renal sympathetic nerves often lowers arterial pressure in hypertension, especially when associated with obesity.

ROLE OF ANGIOTENSIN II IN CONTROLLING RENAL EXCRETION

One of the body's most powerful controllers of sodium excretion is Ang II. Changes in sodium intake are associated with reciprocal changes in Ang II formation, and this in turn contributes greatly to the maintenance of body sodium balances. When sodium intake is elevated above normal, renin secretion and Ang II formation decrease. Because Ang II has several important effects to increase tubular reabsorption of sodium, as explained in [Chapter 28](#), a reduced level of Ang II decreases tubular reabsorption of sodium and water, thus increasing renal excretion of sodium and water. The net result is to minimize the rise in extracellular fluid volume and arterial pressure that would otherwise occur when sodium intake increases.

Conversely, when sodium intake decreases below normal, increased levels of Ang II cause sodium and water retention and oppose reductions in arterial blood pressure that would otherwise occur. Thus, changes in activity of the renin-angiotensin system act as a powerful regulator of sodium excretion and as an amplifier of the pressure natriuresis mechanism for maintaining stable blood pressures and body fluid volumes.

Importance of Changes in Angiotensin II in Regulating Sodium Balance and Altering Pressure Natriuresis. The importance of Ang II in regulating sodium balance and making the pressure natriuresis mechanism more effective is shown in [Figure 19-13](#)

Figure 30-17. Effects of excessive angiotensin II (Ang II) formation or blocking Ang II formation on the renal-pressure natriuresis curve. Note that high levels of Ang II formation decrease the slope of pressure natriuresis, making blood pressure very sensitive to changes in sodium intake. Blockade of Ang II formation shifts pressure natriuresis to lower blood pressures.

and [Figure 30-17](#). Note that when the angiotensin control of natriuresis is fully functional, the pressure natriuresis curve is steep (normal curve), indicating that increases in sodium excretion can be achieved when the sodium intake is raised with minimal changes in arterial pressure.

In contrast, when Ang II levels cannot be suppressed in response to increased sodium intake (high angiotensin II curve), as occurs in some hypertensive patients who have an impaired ability to decrease renin secretion and Ang II formation, the pressure natriuresis curve is not nearly as steep. Therefore, when sodium intake is raised, much greater increases in arterial pressure are necessary to increase sodium excretion and maintain sodium balance. For example, in most people, a 10-fold increase in sodium intake causes an increase of only a few mm of Hg in arterial pressure, whereas in subjects who cannot suppress Ang II formation appropriately in response to excess sodium, the same rise in sodium intake causes blood pressure to rise by as much as 50 mm Hg. Thus, the inability to suppress Ang II formation when there is excess sodium reduces the slope of pressure natriuresis and makes arterial pressure very salt-sensitive, as discussed in [Chapter 19](#).

The use of drugs to block the effects of Ang II has proved to be important clinically for improving the kidneys' ability to excrete salt and water. When Ang II formation is blocked with an angiotensin-converting enzyme (ACE) inhibitor (see [Figures 19-13](#) and [30-17](#)) or an Ang II receptor antagonist, the renal-pressure natriuresis curve is shifted to lower pressures, which indicates an enhanced ability of the kidneys to excrete sodium because normal levels of sodium excretion can now be maintained at reduced arterial pressures. This shift of pressure natriuresis provides the basis for the chronic blood pressure-lowering effects of the ACE inhibitors and Ang II receptor antagonists in hypertensive patients.

Excessive Angiotensin II Does Not Usually Cause Large Increases in Extracellular Fluid Volume Because Increased Arterial Pressure Counterbalances Angiotensin II–Mediated Sodium Retention. Although Ang II is one of the most powerful sodium- and water-retaining hormones in the body, neither a decrease nor increase in circulating Ang II has a large effect on extracellular fluid volume or blood volume as long as heart failure or kidney failure does not occur. The reason for this phenomenon is that with large increases in Ang II levels, as occurs with a renin-secreting tumor of the kidney, the high Ang II levels initially cause sodium and water retention by the kidneys and a small increase in extracellular fluid volume. This also initiates a rise in arterial pressure that quickly increases kidney output of sodium and water, thereby overcoming the sodium- and water-retaining effects of the Ang II and re-establishing a balance between the intake and output of sodium at a higher blood pressure. Conversely, after blockade of Ang II formation with an ACE inhibitor or an Ang II receptor antagonist, there is initial loss of sodium and water, but the fall in blood pressure rapidly offsets this effect, and sodium excretion is once again restored to normal.

If the heart is weakened, or there is underlying heart disease, cardiac pumping ability may not be great enough to raise arterial pressure enough to overcome the sodium-retaining effects of high levels of Ang II; in these cases, Ang II may cause large amounts of sodium and water retention that may progress to *congestive heart failure*. Blockade of Ang II formation may, in these cases, relieve some of the sodium and water retention and attenuate the large expansion of extracellular fluid volume associated with heart failure.

ROLE OF ALDOSTERONE IN CONTROLLING RENAL EXCRETION

Aldosterone increases sodium reabsorption, especially in the collecting tubules and collecting ducts. The increased sodium reabsorption is also associated with increased water reabsorption and potassium secretion. Therefore, the net effect of aldosterone is to make the kidneys retain sodium and water and increase potassium excretion in the urine.

The function of aldosterone in regulating sodium balance is closely related to that described for Ang II. That is, with a reduction in sodium intake, increased Ang II levels stimulate secretion of aldosterone, which in turn contributes to the reduction in urinary sodium excretion and, therefore, to maintenance of sodium balance. Conversely, with high sodium intake, suppression of aldosterone formation decreases tubular reabsorption, allowing the kidneys to excrete larger amounts of sodium. Thus, changes in aldosterone formation also aid the pressure natriuresis mechanism in maintaining sodium balance during variations in salt intake.

During Chronic Oversecretion of Aldosterone, the Kidneys Escape From Sodium Retention as Arterial Pressure Rises. Although aldosterone has powerful effects on sodium reabsorption, when there is excessive formation of aldosterone, as occurs in patients with tumors of the adrenal gland (Conn syndrome), the increased sodium reabsorption and decreased sodium excretion by the kidneys are transient. After 1 to 3 days of sodium and water retention, the extracellular fluid volume rises by about 10% to 15%, and there is a simultaneous increase in arterial blood pressure. When the arterial pressure rises sufficiently, the kidneys “escape” from the sodium and water retention and thereafter excrete amounts of sodium equal to the daily intake, despite the continued presence of high levels of aldosterone. The primary reason for this escape is the pressure natriuresis and diuresis that occur when the arterial pressure rises (see [Chapter 78, Figure 78-3](#)).

In patients with adrenal insufficiency who do not secrete enough aldosterone (Addison disease), there is increased excretion of sodium and water, reduction in extracellular fluid volume, and a tendency toward low blood pressure. In the complete absence of aldosterone, the volume depletion may be severe unless the person is allowed to eat large amounts of salt and drink large amounts of water to balance the increased urine output of salt and water.

ROLE OF ANTIDIURETIC HORMONE IN CONTROLLING RENAL WATER EXCRETION

As discussed in [Chapter 29](#), ADH plays an important role in allowing the kidneys to form a small volume of concentrated urine while excreting normal amounts of salt. This effect is especially important during water deprivation, which strongly elevates plasma levels of ADH that, in turn, increase water reabsorption by the kidneys and help minimize the decreases in extracellular fluid volume and arterial pressure that would otherwise occur. Water deprivation for 24 to 48 hours normally causes only a small decrease in extracellular fluid volume and arterial pressure. However, if the effects of ADH are blocked with a drug that antagonizes the action of ADH to promote water reabsorption in the distal and collecting tubules, the same period of water deprivation causes a substantial fall in extracellular fluid volume and arterial pressure. Conversely, when there is excess extracellular volume, *decreased* ADH levels reduce the reabsorption of water by the kidneys, thus helping rid the body of the excess volume.

Excess Antidiuretic Hormone Secretion Usually Causes Only Small Increases in Extracellular Fluid Volume but Large Decreases in Sodium Concentration. Although ADH is important in regulating extracellular fluid volume, excessive levels of ADH seldom cause large increases in arterial pressure or extracellular fluid volume. Infusion of large amounts of ADH into animals initially causes renal

retention of water and a 10% to 15% increase in extracellular fluid volume. As the arterial pressure rises in response to this increased volume, much of the excess volume is excreted because of the pressure diuresis mechanism. Also, the rise in blood pressure causes pressure natriuresis and loss of sodium from the extracellular fluid. After several days of ADH infusion, the blood volume and extracellular fluid volume are elevated by no more than 5% to 10%, and the arterial pressure is also elevated by less than 10 mm Hg. The same is true for patients with *inappropriate ADH syndrome*, in which ADH levels may be elevated several-fold.

Thus, high levels of ADH do not cause major increases of body fluid volume or arterial pressure, although *high ADH levels can cause severe reductions in extracellular sodium ion concentration*. The reason for this is that increased water reabsorption by the kidneys dilutes the extracellular sodium and, at the same time, the small increase in blood pressure that does occur causes loss of sodium from the extracellular fluid in the urine through pressure natriuresis.

In patients who have lost their ability to secrete ADH because of destruction of the supraoptic nuclei, the urine volume may become 5 to 10 times normal. This increase in volume is almost always compensated for by ingestion of enough water to maintain fluid balance. If free access to water is prevented, the inability to secrete ADH may lead to marked reductions in blood volume and arterial pressure.

ROLE OF ATRIAL NATRIURETIC PEPTIDE IN CONTROLLING RENAL EXCRETION

Thus far, we have discussed mainly the role of sodium- and water-retaining hormones in controlling extracellular fluid volume. However, several different natriuretic hormones may also contribute to volume regulation. One of the most important of these is a peptide referred to as *atrial natriuretic peptide* (ANP), released by the cardiac atrial muscle fibers. A major stimulus for release of this peptide is increased stretch of the atria, which can result from excess blood volume. Once released by the cardiac atria, ANP enters the circulation and acts on the kidneys to cause small increases in GFR, decreases in renin secretion and Ang II formation, and reductions in sodium reabsorption by the collecting ducts. These combined actions of ANP lead to increased excretion of salt and water, which helps compensate for the excess blood volume.

Changes in ANP levels help minimize changes in blood volume during various disturbances, such as increased salt and water intake. However, excessive production of ANP or even complete lack of ANP does not cause major changes in blood volume because these effects can be overcome by small changes in blood pressure, acting through pressure natriuresis. For example, infusions of large amounts of ANP initially raise urine output of salt and water and cause slight decreases in blood volume. In less than 24 hours, this effect is overcome by a slight decrease in blood pressure that returns urine output toward normal, despite continued excess of ANP.

INTEGRATED RESPONSES TO CHANGES IN SODIUM INTAKE

The integration of different control systems that regulate sodium and fluid excretion under normal conditions can be summarized by examining the homeostatic responses to progressive increases in dietary sodium intake. As noted previously, the kidneys have an amazing capability to match their excretion of salt and water to intakes, which can range from as low as one tenth of normal to as high as 10 times normal.

High Sodium Intake Suppresses Antinatriuretic Systems and Activates Natriuretic Systems. As sodium intake is increased, sodium output initially lags slightly behind intake. The time delay results in a small increase in the cumulative sodium balance, which causes a slight increase in extracellular fluid volume. It is mainly this small increase in extracellular fluid volume that triggers various mechanisms in the body to increase sodium excretion. These mechanisms include the following:

1. *Activation of low-pressure receptor reflexes* that originate from the stretch receptors of the right atrium and the pulmonary blood vessels. Signals from the stretch receptors go to the brain stem and there inhibit sympathetic nerve activity to the kidneys to decrease tubular sodium reabsorption. This mechanism is most important in the first few hours—or perhaps the first day—after a large increase in salt and water intake.
2. *Suppression of Ang II and aldosterone formation*, caused by increased arterial pressure and extracellular fluid volume expansion, decreases tubular sodium reabsorption by eliminating the normal effect of Ang II and aldosterone to increase sodium reabsorption.
3. *Stimulation of natriuretic systems*, especially ANP, contributes further to increased sodium excretion. Thus, the combined activation of natriuretic systems and suppression of sodium- and water-retaining systems leads to an increase in sodium excretion when sodium intake is increased. The opposite changes take place when sodium intake is reduced below normal levels.
4. *Small increases in arterial pressure*, caused by volume expansion, may occur with large increases in sodium intake, especially in salt-sensitive individuals; this mechanism raises sodium excretion through pressure natriuresis. As discussed previously, if the nervous, hormonal, and intrarenal mechanisms are operating effectively, measurable increases in blood pressure may not occur, even with large increases in sodium intake over several days. However, when high sodium intake is sustained for months or years, the kidneys may become damaged and less effective in excreting sodium, necessitating increased blood pressure to maintain sodium balance through the pressure natriuresis mechanism.

CONDITIONS THAT CAUSE LARGE INCREASES IN BLOOD VOLUME AND EXTRACELLULAR FLUID VOLUME

Despite the powerful regulatory mechanisms that maintain blood volume and extracellular fluid volume reasonably constant, there are abnormal conditions that can cause large increases in both these variables. Almost all these conditions result from circulatory abnormalities.

INCREASED BLOOD VOLUME AND EXTRACELLULAR FLUID VOLUME CAUSED BY HEART DISEASES

In persons with congestive heart failure, blood volume may increase by 15% to 20%, and the extracellular fluid volume sometimes increases by 200% or more. The reason for these increases can be understood by re-examination of [Figure 30-14](#). Initially, heart failure reduces cardiac output and, consequently, decreases arterial pressure. This effect in turn activates multiple sodium-retaining systems, especially the renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous systems. In addition, the low blood pressure itself causes the kidneys to retain salt and water. Therefore, the kidneys retain volume in an attempt to return the arterial pressure and cardiac output toward normal.

If the heart failure is not too severe, the rise in blood volume can often return cardiac output and arterial pressure virtually all the way to normal, and sodium excretion will eventually increase back to normal, although increased extracellular fluid volume and blood volume will remain to keep the weakened heart pumping adequately. However, if the heart is greatly weakened, arterial pressure may not be able to increase enough to restore urine output to normal. When this situation occurs, the kidneys continue to retain volume until severe circulatory congestion develops, and the person may eventually die of pulmonary edema unless corrective measures are taken.

In myocardial failure, heart valvular disease, and congenital abnormalities of the heart, increased blood volume serves as an important circulatory compensation that helps return cardiac output and blood pressure toward normal. This compensation allows even the weakened heart to maintain a life-sustaining level of cardiac output.

INCREASED BLOOD VOLUME CAUSED BY INCREASED VASCULAR CAPACITY

Any condition that increases vascular capacity will also cause the blood volume to increase to fill this extra capacity. An increase in vascular capacity initially reduces mean circulatory filling pressure (see [Figure 30-14](#)), which leads to decreased cardiac output and decreased arterial pressure. The fall in pressure causes salt and water retention by the kidneys until blood volume increases sufficiently to fill the extra capacity.

During pregnancy, increased vascular capacity of the uterus, placenta, and other enlarged organs of the woman's body generally increases blood volume by 15% to 25%. Similarly, in patients who have large varicose veins of the legs, which in rare cases may hold up to an extra liter of blood, the blood volume increases to fill the extra vascular capacity. In these cases, salt and water are retained by the kidneys until the total vascular bed is filled enough to raise blood pressure to the level required to balance renal output of fluid with daily intake of fluid.

CONDITIONS THAT CAUSE LARGE INCREASES IN EXTRACELLULAR FLUID VOLUME WITH NORMAL OR REDUCED BLOOD VOLUME

In several conditions, extracellular fluid volume becomes markedly increased, but blood volume remains normal or even slightly reduced. These conditions are usually initiated by leakage of fluid and protein into the interstitium, which tends to decrease the blood volume. The kidneys' response to these conditions is similar to the response after hemorrhage—that is, the kidneys retain salt and water in an attempt to restore blood volume toward normal. Much of the extra fluid, however, leaks into the interstitium, causing further edema.

NEPHROTIC SYNDROME—LOSS OF PLASMA PROTEINS IN URINE AND SODIUM RETENTION BY THE KIDNEYS

The general mechanisms that lead to extracellular edema are reviewed in [Chapter 25](#). An important clinical cause of edema is *nephrotic syndrome*. In nephrotic syndrome, the glomerular capillaries leak large amounts of protein into the filtrate and urine because of increased glomerular capillary permeability. Thirty to 50 grams of plasma protein may be lost in the urine each day, sometimes causing the plasma protein concentration to fall to less than one-third normal and reducing plasma colloid osmotic pressure to low levels. This effect causes the capillaries all over the body to filter large amounts of fluid into the various tissues, which in turn causes edema and decreases the plasma volume.

Renal sodium retention in nephrotic syndrome occurs through multiple mechanisms activated by leakage of protein and fluid from the plasma into the interstitial fluid, including stimulation of various sodium-retaining systems, such as the RAAS and sympathetic nervous system. The kidneys continue to retain sodium and water until plasma volume is restored nearly to normal. However, because of the large amount of sodium and water retention, the plasma protein concentration becomes further diluted, causing still more fluid to leak into the tissues of the body. The net result is massive fluid retention by the kidneys until tremendous extracellular edema occurs, unless treatment is instituted to restore the plasma proteins.

LIVER CIRRHOSIS—DECREASED SYNTHESIS OF PLASMA PROTEINS BY THE LIVER AND SODIUM RETENTION BY THE KIDNEYS

In liver cirrhosis, a reduction in plasma protein concentration results from destruction of liver cells, thus reducing the ability of the liver to synthesize enough plasma proteins. Cirrhosis is also associated with large amounts of fibrous tissue in the liver structure, which greatly impedes the flow of portal blood through the liver. This impedance in turn raises capillary pressure throughout the portal vascular bed, which also contributes to the leakage of fluid and proteins into the peritoneal cavity, a condition called *ascites*.

Once fluid and protein are lost from the circulation, the renal responses are similar to those observed in other conditions associated with decreased plasma volume. That is, the kidneys continue to retain salt and water until plasma volume and arterial pressure are restored to normal. In some cases, plasma volume may actually increase above normal because of increased vascular capacity in cirrhosis; the high pressures in the portal circulation can greatly distend veins and therefore increase vascular capacity.

Acid–Base Regulation

The regulation of hydrogen ion (H^+) balance is similar in some ways to the regulation of other ions in the body. For example, there must be a balance between the intake or production of H^+ and the net removal of H^+ from the body to achieve homeostasis. And, as is true for other ions, the kidneys play a key role in regulating H^+ removal from the body. However, precise control of extracellular fluid H^+ concentration involves much more than the simple elimination of H^+ by the kidneys. Multiple acid–base buffering mechanisms involving the blood, cells, and lungs also are essential in maintaining normal H^+ concentrations in extracellular and intracellular fluids.

In this chapter, we consider the mechanisms that regulate H^+ concentration, with special emphasis on renal H^+ secretion and renal reabsorption, production, and excretion of bicarbonate ions (HCO_3^-), one of the key components of acid–base control systems in the body fluids.

HYDROGEN ION CONCENTRATION IS PRECISELY REGULATED

Precise H^+ regulation is essential because the activities of almost all enzyme systems in the body are influenced by H^+ concentration. Therefore, changes in H^+ concentration alter virtually all cell and body functions.

Compared with other ions, the H^+ concentration of the body fluids normally is kept at a low level. For example, the concentration of sodium in extracellular fluid (142 mEq/L) is about 3.5 million times as great as the normal concentration of H^+ , which averages only 0.00004 mEq/L. Equally important, the normal variation in H^+ concentration in extracellular fluid is only about one millionth as great as the normal variation in sodium ion (Na^+) concentration. Thus, the precision with which H^+ is regulated emphasizes its importance to the various cell functions.

ACIDS AND BASES—DEFINITIONS AND MEANINGS

A hydrogen ion is a single free proton released from a hydrogen atom. Molecules containing hydrogen atoms that can release hydrogen ions in a solution are referred

to as *acids*. An example is hydrochloric acid (HCl), which ionizes in water to form hydrogen ions (H^+) and chloride ions (Cl^-). Likewise, carbonic acid (H_2CO_3) ionizes in water to form H^+ and bicarbonate ions (HCO_3^-).

A *base* is an ion or a molecule that can accept an H^+ . For example, HCO_3^- is a base because it can combine with H^+ to form H_2CO_3 . Likewise, HPO_4^{2-} is a base because it can accept an H^+ to form H_2PO_4^- . The proteins in the body also function as bases because some of the amino acids that make up proteins have net negative charges that readily accept H^+ . The protein *hemoglobin* in the red blood cells and proteins in the other cells of the body are among the most important of the body's bases.

The terms *base* and *alkali* are often used synonymously. An *alkali* is a molecule formed by the combination of one or more of the alkaline metals—such as sodium, potassium, and lithium—with a highly basic ion such as a hydroxyl ion (OH^-). The base portion of these molecules reacts quickly with H^+ to remove it from solution and are, therefore, typical bases. For similar reasons, the term *alkalosis* refers to the excess removal of H^+ from the body fluids, in contrast to the excess addition of H^+ , which is referred to as *acidosis*.

Strong and Weak Acids and Bases. A strong acid, such as HCl , rapidly dissociates and releases especially large amounts of H^+ in solution. Weak acids such as H_2CO_3 are less likely to dissociate their ions and, therefore, release H^+ with less vigor. A strong base is one that reacts rapidly and strongly with H^+ and, therefore, quickly removes H^+ from a solution. A typical example is OH^- , which reacts with H^+ to form water (H_2O). A typical weak base is HCO_3^- because it binds with H^+ much more weakly than OH^- . Most acids and bases in the extracellular fluid that are involved in normal acid–base regulation are weak acids and bases. The most important ones that we discuss are carbonic acid (H_2CO_3) and HCO_3^- base.

Normal H^+ Concentration and pH of Body Fluids and Changes That Occur in Acidosis and Alkalosis. The blood H^+ concentration is normally maintained within tight limits around a normal value of about 0.00004

mEq/L (40 nEq/L). Normal variations are only about 3 to 5 nEq/L but, under extreme conditions, the H^+ concentration can vary from as low as 10 nEq/L to as high as 160 nEq/L without resulting in death.

Because H^+ concentration normally is low, and because these small numbers are cumbersome, it is customary to express H^+ concentration on a logarithm scale using pH units. pH is related to the actual H^+ concentration by the following formula (H^+ concentration $[H^+]$ is expressed in *equivalents per liter*):

$$pH = \log \frac{1}{[H^+]} = -\log [H^+]$$

For example, normal $[H^+]$ is 40 nEq/L (0.00000004 Eq/L). Therefore, the normal pH is as follows:

$$pH = -\log[0.00000004]$$

$$pH = 7.4$$

From this formula, one can see that pH is inversely related to the H^+ concentration; therefore, a low pH corresponds to a high H^+ concentration, and a high pH corresponds to a low H^+ concentration.

The normal pH of arterial blood is 7.4, whereas the pH of venous blood and interstitial fluids is about 7.35 because of the extra amounts of carbon dioxide (CO_2) released from the tissues to form H_2CO_3 in these fluids (Table 31-1). Because the normal pH of arterial blood is 7.4, a person is considered to have *acidemia* when the pH falls significantly below this value and *alkalemia* when the pH rises above 7.4. The lower limit of pH at which a person can live more than a few hours is about 6.8, and the upper limit is about 8.0.

Intracellular pH usually is slightly lower than plasma pH because cell metabolism produces acid, especially H_2CO_3 . Depending on the type of cells, the pH of intracellular fluid has been estimated to range between 6.0 and 7.4. Hypoxia of the tissues and poor blood flow to the tissues can cause acid accumulation and decreased intracellular pH. The terms *acidosis* and *alkalosis* describe the processes that lead to acidemia and alkalemia, respectively.

The pH of urine can range from 4.5 to 8.0, depending on the acid–base status of the extracellular fluid. As discussed later, the kidneys play a major role in correcting abnormalities of extracellular fluid H^+ concentration by excreting acids or bases at variable rates.

Table 31-1 pH and H^+ Concentration of Body Fluids

	H^+ Concentration (mEq/L)	pH
Extracellular Fluid		
• Arterial blood	• 4.0×10^{-5}	• 7.40
• Venous blood	• 4.5×10^{-5}	• 7.35
• Interstitial fluid	• 4.5×10^{-5}	• 7.35
Intracellular fluid	1×10^{-3} to 4×10^{-5}	6.0–7.4
Urine	3×10^{-2} to 1×10^{-5}	4.5–8.0
Gastric HCl	160	0.8

An extreme example of an acidic body fluid is the HCl secreted into the stomach by the *oxyntic (parietal)* cells of the stomach mucosa, as discussed in Chapter 65. The H^+ concentration in these cells is about 4 million times greater than the hydrogen concentration in blood, with a pH of 0.8. In the remainder of this chapter, we discuss the regulation of extracellular fluid H^+ concentration.

DEFENDING AGAINST CHANGES IN H^+ CONCENTRATION: BUFFERS, LUNGS, AND KIDNEYS

Three primary systems regulate the H^+ concentration in the body fluids: (1) the *chemical acid–base buffer systems of the body fluids*, which immediately combine with an acid or a base to prevent excessive changes in H^+ concentration; (2) the *respiratory center*, which regulates the removal of CO_2 (and, therefore, H_2CO_3) from the extracellular fluid; and (3) the *kidneys*, which can excrete acidic or alkaline urine, thereby readjusting the extracellular fluid H^+ concentration toward normal during acidosis or alkalosis.

When there is a change in H^+ concentration, the *buffer systems* of the body fluids react within seconds to minimize these changes. Buffer systems do not eliminate H^+ from or add H^+ to the body but only keep them tied up until balance can be re-established.

The second line of defense, the *respiratory system*, acts within a few minutes to eliminate CO_2 and, therefore, H_2CO_3 from the body.

These first two lines of defense keep the H^+ concentration from changing too much until the more slowly responding third line of defense, the *kidneys*, can eliminate the excess acid or base from the body. Although the kidneys are relatively slow to respond compared with the other defenses, over a period of hours to several days, they are by far the most powerful of the acid–base regulatory systems.

BUFFERING OF H^+ IN THE BODY FLUIDS

A buffer is any substance that can reversibly bind H^+ . The general form of the buffering reaction is as follows:

In this example, a free H^+ combines with the buffer to form a weak acid (H buffer) that can either remain as an unassociated molecule or dissociate back to the buffer and H^+ . When the H^+ concentration increases, the reaction is forced to the right, and more H^+ binds to the buffer, as long as buffer is available. Conversely, when the H^+ concentration decreases, the reaction shifts toward the left, and H^+ is released from the buffer. In this way, changes in H^+ concentration are minimized.

The importance of the body fluid buffers can be quickly realized if one considers the low concentration of H^+ in the body fluids and the relatively large amounts

of acids produced by the body each day. About 80 milliequivalents of H^+ is ingested or produced each day by metabolism, whereas the H^+ concentration of the body fluids normally is only about 0.00004 mEq/L. Without buffering, the daily production and ingestion of acids would cause lethal changes in the body fluid H^+ concentration.

The action of acid–base buffers can perhaps best be explained by considering the buffer system that is quantitatively the most important in the extracellular fluid—the bicarbonate buffer system.

BICARBONATE BUFFER SYSTEM

The bicarbonate buffer system consists of a water solution that contains two ingredients: (1) a weak acid, H_2CO_3 ; and (2) a bicarbonate salt, such as sodium bicarbonate ($NaHCO_3$).

H_2CO_3 is formed in the body by the reaction of CO_2 with H_2O :

This reaction is slow, and exceedingly small amounts of H_2CO_3 are formed unless the enzyme *carbonic anhydrase* is present. This enzyme is especially abundant in the walls of the lung alveoli, where CO_2 is released; carbonic anhydrase is also present in the epithelial cells of the renal tubules, where CO_2 reacts with H_2O to form H_2CO_3 .

H_2CO_3 ionizes weakly to form small amounts of H^+ and HCO_3^- :

The second component of the system, bicarbonate salt, occurs predominantly as $NaHCO_3$ in the extracellular fluid. $NaHCO_3$ ionizes almost completely to form HCO_3^- and Na^+ , as follows:

Now, putting the entire system together, we have the following:

Because of the weak dissociation of H_2CO_3 , the H^+ concentration is extremely low.

When a strong acid such as HCl is added to the bicarbonate buffer solution, the increased H^+ released from the acid ($HCl \rightarrow H^+ + Cl^-$) is buffered by HCO_3^- :

As a result, more H_2CO_3 is formed, causing increased CO_2 and H_2O production. From these reactions, one can see that H^+ from the strong acid HCl reacts with

HCO_3^- to form the very weak acid H_2CO_3 , which in turn forms CO_2 and H_2O . The excess CO_2 greatly stimulates respiration, which eliminates the CO_2 from the extracellular fluid.

The opposite reactions take place when a strong base, such as sodium hydroxide ($NaOH$), is added to the bicarbonate buffer solution.

In this case, the OH^- from the $NaOH$ combines with H_2CO_3 to form additional HCO_3^- . Thus, the weak base $NaHCO_3$ replaces the strong base $NaOH$. At the same time, the concentration of H_2CO_3 decreases (because it reacts with $NaOH$), causing more CO_2 to combine with H_2O to replace the H_2CO_3 :

The net result, therefore, is a tendency for the CO_2 levels in the blood to decrease, but the decreased CO_2 in the blood inhibits respiration and decreases the rate of CO_2 expiration. The rise in blood HCO_3^- concentration that occurs is compensated for by increased renal excretion of HCO_3^- .

Quantitative Dynamics of the Bicarbonate Buffer System

All acids, including H_2CO_3 , are ionized to some extent. From mass balance considerations, the concentrations of H^+ and HCO_3^- are proportional to the concentration of H_2CO_3 :

For any acid, the concentration of the acid relative to its dissociated ions is defined by the *dissociation constant*, K' :

$$K' = \frac{H^+ \times HCO_3^-}{H_2CO_3} \quad (1)$$

This equation indicates that in an H_2CO_3 solution, the amount of free H^+ is equal to

$$H^+ = K' \times \frac{H_2CO_3}{HCO_3^-} \quad (2)$$

The concentration of undissociated H_2CO_3 cannot be measured in solution because it rapidly dissociates into CO_2 and H_2O or into H^+ and HCO_3^- . However, the CO_2 dissolved in the blood is directly proportional to the amount of undissociated H_2CO_3 . Therefore, Equation 2 can be rewritten as follows:

$$H^+ = K \times \frac{CO_2}{HCO_3^-} \quad (3)$$

The dissociation constant (K) for Equation 3 is only about 1/400 of the dissociation constant (K') of Equation 2 because the proportionality ratio between H_2CO_3 and CO_2 is 1:400.

Equation 3 is written in terms of the total amount of CO_2 dissolved in solution. However, most clinical laboratories measure the blood CO_2 tension (PCO_2) rather than the actual amount of CO_2 . Fortunately, the amount of CO_2 in the blood is a linear function of PCO_2 multiplied by the solubility coefficient for CO_2 ; under physiological conditions, the solubility coefficient for CO_2 is 0.03 mmol/mm Hg at body temperature. This means that 0.03 millimole of H_2CO_3 is present in the blood for each mm Hg PCO_2 measured. Therefore, Equation 3 can be rewritten as

$$\text{H}^+ = K \times \frac{(0.03 \times \text{PCO}_2)}{\text{HCO}_3^-} \quad (4)$$

Henderson-Hasselbalch Equation. As discussed earlier, it is customary to express the H^+ concentration in pH units rather than in actual concentrations. Recall that $\text{pH} = -\log \text{H}^+$.

The dissociation constant (pK) can be expressed in a similar manner.

$$\text{pK} = -\log K$$

Therefore, we can express the H^+ concentration in Equation 4 in pH units by taking the negative logarithm of that equation, which yields the following:

$$-\log \text{H}^+ = -\log \text{pK} - \log \frac{(0.03 \times \text{PCO}_2)}{\text{HCO}_3^-} \quad (5)$$

Therefore,

$$\text{pH} = \text{pK} - \log \frac{(0.03 \times \text{PCO}_2)}{\text{HCO}_3^-} \quad (6)$$

Rather than work with a negative logarithm, we can change the sign of the logarithm and invert the numerator and denominator in the last term, using the law of logarithms, to yield the following:

$$\text{pH} = \text{pK} + \log \frac{\text{HCO}_3^-}{(0.03 \times \text{PCO}_2)} \quad (7)$$

For the bicarbonate buffer system, the pK is 6.1, and Equation 7 can be written as follows:

$$\text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{0.03 \times \text{PCO}_2} \quad (8)$$

Equation 8 is the Henderson-Hasselbalch equation and, with it, one can calculate the pH of a solution if the molar concentration of HCO_3^- and the PCO_2 are known.

From the Henderson-Hasselbalch equation, it is apparent that an increase in HCO_3^- concentration causes the pH to rise, shifting the acid–base balance toward alkalosis. An increase in PCO_2 causes the pH to decrease, shifting the acid–base balance toward acidosis.

The Henderson-Hasselbalch equation, in addition to defining the determinants of normal pH regulation and acid–base balance in the extracellular fluid, provides insight into the physiological control of the acid and base composition of the extracellular fluid. As discussed later, the HCO_3^- concentration is regulated mainly by the

kidneys, whereas the PCO_2 in extracellular fluid is controlled by the rate of respiration. By increasing the rate of respiration, the lungs remove CO_2 from the plasma and, by decreasing respiration, the lungs elevate PCO_2 . Normal physiological acid–base homeostasis results from the coordinated efforts of both the lungs and kidneys, and acid–base disorders occur when one or both of these control mechanisms are impaired, thus altering either the HCO_3^- concentration or PCO_2 of extracellular fluid.

When disturbances of acid–base balance result from a primary change in extracellular fluid HCO_3^- concentration, they are referred to as *metabolic* acid–base disorders. Therefore, acidosis caused by a primary decrease in HCO_3^- concentration is termed *metabolic acidosis*, whereas alkalosis caused by a primary increase in HCO_3^- concentration is called *metabolic alkalosis*. Acidosis caused by an increase in PCO_2 is called *respiratory acidosis*, whereas alkalosis caused by a decrease in PCO_2 is termed *respiratory alkalosis*.

Bicarbonate Buffer System Titration Curve. Figure 31-1 shows the changes in pH of the extracellular fluid when the ratio of HCO_3^- to CO_2 in extracellular fluid is altered. When the concentrations of these two components are equal, the right-hand portion of Equation 8 becomes the log of 1, which is equal to 0. Therefore, when the two components of the buffer system are equal, the pH of the solution is the same as the pK (6.1) of the bicarbonate buffer system. When base is added to the system, part of the dissolved CO_2 is converted into HCO_3^- , causing an increase in the ratio of HCO_3^- to CO_2 and increasing the pH, as is evident from the Henderson-Hasselbalch equation. When acid is added, it is buffered by HCO_3^- , which is then converted into dissolved CO_2 , decreasing the ratio of HCO_3^- to CO_2 and decreasing the pH of the extracellular fluid.

Buffer Power Determined by Amount and Relative Concentrations of Buffer Components. From the titration curve in Figure 31-1, several points are apparent. First, the pH of the system is the same as the pK when each of the components (HCO_3^- and CO_2) constitutes 50% of the total concentration of the buffer system. Second, the buffer system is most effective in the central part of

Figure 31-1. Titration curve for bicarbonate buffer system showing the pH of extracellular fluid when the percentages of buffer in the form of HCO_3^- and CO_2 (or H_2CO_3) are altered.

the curve, where the pH is near the pK of the system. This phenomenon means that the change in pH for any given amount of acid or base added to the system is least when the pH is near the pK of the system. The buffer system is still reasonably effective for 1.0 pH unit on either side of the pK, which, for the bicarbonate buffer system, extends from a pH of about 5.1 to 7.1 units. Beyond these limits, the buffering power rapidly diminishes. And, when all the CO_2 has been converted into HCO_3^- , or when all the HCO_3^- has been converted into CO_2 , the system has no more buffering power.

The absolute concentration of the buffers is also an important factor in determining the buffer power of a system. With low concentrations of the buffers, only a small amount of acid or base added to the solution changes the pH considerably.

Bicarbonate Buffer System Is the Most Important Extracellular Buffer. From the titration curve shown in **Figure 31-1**, one would not expect the bicarbonate buffer system to be powerful, for two reasons. First, the pH of the extracellular fluid is about 7.4, whereas the pK of the bicarbonate buffer system is 6.1, which means that there is about 20 times as much of the bicarbonate buffer system in the form of HCO_3^- as in the form of dissolved CO_2 . For this reason, this system operates on the portion of the buffering curve where the slope is low, and the buffering power is poor. Second, the concentrations of the two elements of the bicarbonate system, CO_2 and HCO_3^- , are not high.

Despite these characteristics, the bicarbonate buffer system is the most powerful extracellular buffer in the body. This apparent paradox is due mainly to the fact that the two elements of the buffer system, HCO_3^- and CO_2 , are regulated, respectively, by the kidneys and lungs, as discussed later. As a result of this regulation, the pH of the extracellular fluid can be precisely controlled by the relative rate of removal and addition of HCO_3^- by the kidneys and rate of removal of CO_2 by the lungs.

PHOSPHATE BUFFER SYSTEM

Although the phosphate buffer system is not a major extracellular fluid buffer, it plays an important role in buffering renal tubular fluid and intracellular fluids.

The main elements of the phosphate buffer system are H_2PO_4^- and HPO_4^{2-} . When a strong acid such as HCl is added to a mixture of these two substances, the hydrogen is accepted by the base HPO_4^{2-} and converted to H_2PO_4^- :

The result of this reaction is that the strong acid, HCl, is replaced by an additional amount of a weak acid, NaH_2PO_4 , and the decrease in pH is minimized.

When a strong base, such as NaOH, is added to the buffer system, the OH^- is buffered by the H_2PO_4^- to form additional amounts of $\text{HPO}_4^{2-} + \text{H}_2\text{O}$:

In this case, a strong base, NaOH, is traded for a weak base, Na_2HPO_4 , causing only a slight increase in pH.

The phosphate buffer system has a pK of 6.8, which is not far from the normal pH of 7.4 in the body fluids, allows the system to operate near its maximum buffering power. However, its concentration in the extracellular fluid is low, at only about 8% of the concentration of the bicarbonate buffer. Therefore, the total buffering power of the phosphate system in the extracellular fluid is much less than that of the bicarbonate buffering system.

In contrast to its minor role as an extracellular buffer, *the phosphate buffer is especially important in the tubular fluids of the kidneys* for two reasons: (1) phosphate usually becomes greatly concentrated in the tubules, thereby increasing the buffering power of the phosphate system; and (2) the tubular fluid usually has a considerably lower pH than the extracellular fluid, bringing the operating range of the buffer closer to the pK (6.8) of the system.

The phosphate buffer system is also important in buffering intracellular fluid because the concentration of phosphate in this fluid is many times higher than in the extracellular fluid. Also, the pH of intracellular fluid is lower than that of extracellular fluid and, therefore, is usually closer to the pK of the phosphate buffer system compared with the extracellular fluid.

PROTEINS ARE IMPORTANT INTRACELLULAR BUFFERS

Proteins are among the most plentiful buffers in the body because of their high concentrations, especially in the cells. The pH of the cells, although slightly lower than in the extracellular fluid, nevertheless changes approximately in proportion to extracellular fluid pH changes. There is a slight diffusion of H^+ and HCO_3^- through the cell membrane, although these ions require several hours to reach equilibrium with the extracellular fluid, except for the rapid equilibrium that occurs in the red blood cells. CO_2 , however, can rapidly diffuse through all the cell membranes. *This diffusion of the elements of the bicarbonate buffer system causes the pH in intracellular fluid to change when there are changes in extracellular pH.* For this reason, the buffer systems in the cells help prevent changes in the pH of the extracellular fluid but may take several hours to become maximally effective.

In the red blood cell, hemoglobin (Hb) is an important buffer, as follows:

Approximately 60% to 70% of the total chemical buffering of the body fluids is inside the cells, and most of this buffering results from the intracellular proteins. However, except for the red blood cells, the slow rate at which H^+ and HCO_3^- move through the cell membranes often delays the maximum ability of the intracellular proteins to buffer extracellular acid–base abnormalities for several hours.

In addition to the high concentration of proteins in the cells, another factor that contributes to their buffering power is the fact that the pKs of many of these protein systems are fairly close to intracellular pH.

Isohydric Principle: All Buffers in a Common Solution Are in Equilibrium With the Same H⁺ Concentration

We have been discussing buffer systems as though they operate individually in the body fluids. However, they all work together because H⁺ is common to the reactions of all these systems. Therefore, whenever there is a change in H⁺ concentration in the extracellular fluid, the balance of all the buffer systems changes at the same time. This phenomenon is called the *isohydric principle* and is illustrated by the following formula:

$$H^+ = K_1 \times \frac{HA_1}{A_1} = K_2 \times \frac{HA_2}{A_2} = K_3 \times \frac{HA_3}{A_3}$$

K₁, K₂, and K₃ are the dissociation constants of three respective acids—HA₁, HA₂, HA₃—and A₁, A₂, A₃ are the concentrations of the free negative ions that constitute the bases of the three buffer systems.

The implication of this principle is that any condition that changes the balance of one of the buffer systems also changes the balance of all the others because the buffer systems actually buffer one another by shifting H⁺ back and forth between them.

RESPIRATORY REGULATION OF ACID-BASE BALANCE

The second line of defense against acid–base disturbances is control of extracellular fluid CO₂ concentration by the lungs. An increase in ventilation eliminates CO₂ from extracellular fluid, which, by mass action, reduces the H⁺ concentration. Conversely, decreased ventilation increases CO₂ and H⁺ concentrations in the extracellular fluid.

PULMONARY EXPIRATION OF CO₂ BALANCES METABOLIC FORMATION OF CO₂

CO₂ is formed continually in the body by intracellular metabolic processes. After it is formed, it diffuses from the cells into the interstitial fluids and blood, and the flowing blood transports it to the lungs, where it diffuses into the alveoli and then is transferred to the atmosphere by pulmonary ventilation. About 1.2 mol/L of dissolved CO₂ is normally in the extracellular fluid, corresponding to a P_{CO₂} of 40 mm Hg.

If the rate of metabolic formation of CO₂ increases, the P_{CO₂} of the extracellular fluid is likewise increased. Conversely, a decreased metabolic rate lowers the P_{CO₂}. If the rate of pulmonary ventilation is increased, CO₂ is blown off from the lungs, and the P_{CO₂} in the extracellular fluid decreases. Therefore, changes in pulmonary ventilation or the rate of CO₂ formation by the tissues can change the extracellular fluid P_{CO₂}.

Figure 31-2. Change in extracellular fluid pH caused by an increased or decreased rate of alveolar ventilation, expressed as times normal.

INCREASING ALVEOLAR VENTILATION DECREASES EXTRACELLULAR FLUID H⁺ CONCENTRATION AND RAISES PH

If the metabolic formation of CO₂ remains constant, the only other factor that affects P_{CO₂} in extracellular fluid is the rate of alveolar ventilation. The higher the alveolar ventilation, the lower the P_{CO₂}. As discussed previously, when CO₂ concentration increases, the H₂CO₃ concentration and H⁺ concentration also increase, thereby lowering extracellular fluid pH.

Figure 31-2 shows the approximate changes in blood pH that are caused by increasing or decreasing the alveolar ventilation rate. Note that increasing alveolar ventilation to about twice normal raises extracellular fluid pH by about 0.23. If the pH of the body fluids is 7.40 with normal alveolar ventilation, doubling the ventilation rate raises the pH to about 7.63. Conversely, a decrease in alveolar ventilation to one-fourth normal reduces the pH by 0.45. That is, if the pH is 7.4 at a normal alveolar ventilation, reducing the ventilation to one-fourth normal reduces the pH to 6.95. Because the alveolar ventilation rate can change markedly, from as low as 0 to as high as 15 times normal, one can easily understand how much the pH of the body fluids can be changed by the respiratory system.

INCREASED H⁺ CONCENTRATION STIMULATES ALVEOLAR VENTILATION

Not only does the alveolar ventilation rate influence H⁺ concentration by changing P_{CO₂} of the body fluids, but the H⁺ concentration affects the rate of alveolar ventilation. Thus, **Figure 31-3** shows that alveolar ventilation rate increases four to five times normal as pH decreases from the normal value of 7.4 to the strongly acidic value of 7.0. Conversely, a rise in plasma pH above 7.4 causes a decrease in the ventilation rate. The change in ventilation rate per unit pH change is much greater at reduced levels of pH (corresponding to elevated H⁺ concentration) compared with increased levels of pH. The reason for this is that as the

Figure 31-3. Effect of blood pH on the alveolar ventilation rate.

alveolar ventilation rate decreases, as a result of an increase in pH (decreased H^+ concentration), the amount of oxygen added to the blood decreases, and the partial pressure of oxygen (PO_2) in the blood also decreases, which stimulates the ventilation rate. Therefore, the respiratory compensation for an increase in pH is not nearly as effective as the response to a marked reduction in pH.

Feedback Control of H^+ Concentration by the Respiratory System. Because increased H^+ concentration stimulates respiration and because increased alveolar ventilation decreases H^+ concentration, the respiratory system acts as a typical negative feedback controller of H^+ concentration:

That is, whenever H^+ concentration increases above normal, the respiratory system is stimulated, and alveolar ventilation increases. This mechanism decreases the PCO_2 in extracellular fluid and reduces H^+ concentration back toward normal. Conversely, if H^+ concentration falls below normal, the respiratory center becomes depressed, alveolar ventilation decreases, and H^+ concentration increases back toward normal. Although alkalosis tends to depress the respiratory centers, the response is generally less robust and less predictable than the response to metabolic acidosis; the hypoxemia associated with reduced alveolar ventilation eventually activates oxygen-sensitive chemoreceptors that tend to stimulate ventilation and limit the respiratory compensation for metabolic alkalosis.

Efficiency of Respiratory Control of H^+ Concentration. Respiratory control cannot return the H^+ concentration all the way back to normal when a disturbance outside the respiratory system has altered the pH. Ordinarily, the respiratory mechanism for controlling H^+ concentration is approximately 50% to 75% effective, corresponding to a *feedback gain* of 1 to 3 for metabolic acidosis. That is, if the pH is suddenly decreased by adding acid to the ex-

tracellular fluid, and the pH falls from 7.4 to 7.0, the respiratory system can return the pH to a value of about 7.2 to 7.3. This response occurs within 3 to 12 minutes. As discussed previously, the respiratory responses to metabolic alkalosis are limited by hypoxemia associated with reduced alveolar ventilation.

Buffering Power of the Respiratory System. *Respiratory regulation of acid–base balance is a physiological type of buffer system* because it acts rapidly and keeps the H^+ concentration from changing too much until the slowly responding kidneys can eliminate the imbalance. In general, the overall buffering power of the respiratory system is one to two times as great as the buffering power of all other chemical buffers in the extracellular fluid combined. That is, one to two times as much acid or base can normally be buffered by this mechanism as by the chemical buffers.

Impairment of Lung Function Can Cause Respiratory Acidosis. We have discussed thus far the role of the *normal* respiratory mechanism as a means of buffering changes in H^+ concentration. However, *abnormalities of respiration* can also cause changes in H^+ concentration. For example, an impairment of lung function, such as severe emphysema, decreases the ability of the lungs to eliminate CO_2 , which causes a buildup of CO_2 in the extracellular fluid and a tendency toward *respiratory acidosis*. Also, the ability to respond to metabolic acidosis is impaired because the compensatory reductions in PCO_2 that would normally occur by means of increased ventilation are blunted. In these circumstances, the kidneys represent the sole remaining physiological mechanism for returning pH toward normal after the initial chemical buffering in the extracellular fluid has occurred.

RENAL CONTROL OF ACID–BASE BALANCE

The kidneys control acid–base balance by excreting acidic or basic urine. Excreting acidic urine reduces the amount of acid in extracellular fluid, whereas excreting basic urine removes base from the extracellular fluid.

The overall mechanism whereby the kidneys excrete acidic or basic urine is as follows. Large amounts of HCO_3^- are filtered continuously into the tubules and, if excreted into the urine, remove base from the blood. Large numbers of H^+ are also secreted into the tubular lumen by the tubular epithelial cells, thus removing acid from the blood. If more H^+ is secreted than HCO_3^- is filtered, there will be a net loss of acid from the extracellular fluid. Conversely, if more HCO_3^- is filtered than H^+ is secreted, there will be a net loss of base.

Each day, the body produces about 80 mEq of nonvolatile acids, mainly from metabolism of proteins. These acids are called *nonvolatile* because they are not H_2CO_3 and,

therefore, cannot be excreted by the lungs. The primary mechanism for removal of these acids from the body is renal excretion. The kidneys must also prevent the loss of bicarbonate in the urine, a task that is quantitatively more important than the excretion of nonvolatile acids. Each day, the kidneys filter about 4320 mEq of HCO_3^- ($180 \text{ L/day} \times 24 \text{ mEq/L}$); under normal conditions, almost all of this is reabsorbed from the tubules, thereby conserving the primary buffer system of the extracellular fluid.

As discussed later, both the reabsorption of HCO_3^- and excretion of H^+ are accomplished through the process of H^+ secretion by the tubules. Because HCO_3^- must react with a secreted H^+ to form H_2CO_3 before it can be reabsorbed, 4320 mEq of H^+ must be secreted each day just to reabsorb the filtered HCO_3^- . Then, an additional 80 mEq of H^+ must be secreted to rid the body of the nonvolatile acids produced each day for a total of 4400 mEq of H^+ secreted into the tubular fluid each day.

When there is a reduction in the extracellular fluid H^+ concentration (alkalosis), the kidneys usually secrete less H^+ and fail to reabsorb all the filtered HCO_3^- , thereby increasing the excretion of HCO_3^- . Because HCO_3^- normally buffers H^+ in the extracellular fluid, this loss of HCO_3^- is the same as adding an H^+ to the extracellular fluid. Therefore, in alkalosis, the removal of HCO_3^- raises the extracellular fluid H^+ concentration back toward normal.

In acidosis, the kidneys secrete additional H^+ and do not excrete HCO_3^- into the urine but reabsorb all the filtered HCO_3^- and produce new HCO_3^- , which is added back to the extracellular fluid. This action reduces the extracellular fluid H^+ concentration back toward normal.

Thus, the kidneys regulate extracellular fluid H^+ concentration through three fundamental mechanisms: (1) secretion of H^+ ; (2) reabsorption of filtered HCO_3^- ; and (3) production of new HCO_3^- . All these processes are accomplished through the same basic mechanisms, as discussed in the next few sections.

SECRETION OF H^+ AND REABSORPTION OF HCO_3^- BY THE RENAL TUBULES

Hydrogen ion secretion and HCO_3^- reabsorption occur in virtually all parts of the tubules except the descending and ascending thin limbs of the loop of Henle. **Figure 31-4** summarizes HCO_3^- reabsorption along the tubule. Keep in mind that for *each HCO_3^- reabsorbed, an H^+ must be secreted*.

About 80% to 90% of the HCO_3^- reabsorption (and H^+ secretion) occurs in the proximal tubule, so only a small amount of HCO_3^- flows into the distal tubules and collecting ducts. In the thick ascending loop of Henle, another 10% of the filtered HCO_3^- is reabsorbed, and the remainder of the reabsorption takes place in the distal tubules and collecting ducts. As discussed previously, the mechanism whereby HCO_3^- is reabsorbed also involves tubular secretion of H^+ , but different tubular segments accomplish this task differently.

Figure 31-4. Reabsorption of HCO_3^- in different segments of the renal tubule. The percentages of the filtered load of HCO_3^- absorbed by the various tubular segments are shown, as well as the number of milliequivalents reabsorbed per day under normal conditions.

H^+ SECRETED BY SECONDARY ACTIVE TRANSPORT IN EARLY TUBULAR SEGMENTS

The epithelial cells of the proximal tubule, the thick segment of the ascending loop of Henle, and the early distal tubule all secrete H^+ into the tubular fluid by sodium-hydrogen counter-transport, as shown in **Figure 31-5**. This secondary active secretion of H^+ is coupled with the transport of Na^+ into the cell at the luminal membrane by the *sodium-hydrogen exchanger protein*, and the energy for H^+ secretion against a concentration gradient is derived from the sodium gradient favoring Na^+ movement into the cell. This gradient is established by the sodium-potassium adenosine triphosphatase (Na^+/K^+ ATPase) pump in the basolateral membrane. About 95% of the bicarbonate is reabsorbed in this manner, requiring about 4000 mEq of H^+ to be secreted each day by the tubules. This mechanism, however, can establish a minimum pH of only about 6.7; the tubular fluid becomes very acidic only in the collecting tubules and collecting ducts, which can establish a urine pH as low as about 4.5.

Figure 31-5 shows how the process of H^+ secretion achieves HCO_3^- reabsorption. The secretory process begins when CO_2 either diffuses into the tubular cells or is formed by metabolism in the tubular epithelial cells. Under the influence of the enzyme *carbonic anhydrase*, CO_2 combines with H_2O to form H_2CO_3 , which dissociates into HCO_3^- and H^+ . The H^+ is secreted from the cell into the tubular lumen by sodium-hydrogen counter-transport. That is, when Na^+ moves from the lumen of the tubule to the interior of the cell, it first combines with a

Figure 31-5. Shown are the cellular mechanisms for the following: (1) active secretion of H⁺ into the renal tubule; (2) tubular reabsorption of HCO₃⁻ by combination with H⁺ to form H₂CO₃, which dissociates to form CO₂ and H₂O; and (3) Na⁺ reabsorption in exchange for H⁺ secreted. This pattern of H⁺ secretion occurs in the proximal tubule, thick ascending segment of the loop of Henle, and early distal tubule.

carrier protein in the luminal border of the cell membrane; at the same time, a H⁺ in the interior of the cells combines with the carrier protein. The Na⁺ moves into the cell down a concentration gradient that has been established by the Na⁺-K⁺ ATPase pump in the basolateral membrane. The gradient for Na⁺ movement into the cell then provides the energy for moving H⁺ in the opposite direction from the interior of the cell to the tubular lumen.

The HCO₃⁻ generated in the cell (when H⁺ dissociates from H₂CO₃) then moves downhill across the basolateral membrane, into the renal interstitial fluid and peritubular capillary blood. The net result is that for every H⁺ secreted into the tubular lumen, an HCO₃⁻ enters the blood.

FILTERED HCO₃⁻ IS REABSORBED BY INTERACTION WITH H⁺ IN THE TUBULES

Bicarbonate ions do not readily permeate the luminal membranes of the renal tubular cells; therefore, HCO₃⁻ that is filtered by the glomerulus cannot be directly reabsorbed. Instead, HCO₃⁻ is reabsorbed by a special process in which it first combines with H⁺ to form H₂CO₃, which eventually becomes CO₂ and H₂O, as shown in [Figure 31-5](#).

This reabsorption of HCO₃⁻ is initiated by a reaction in the tubules between HCO₃⁻ filtered at the glomerulus and H⁺ secreted by the tubular cells. The H₂CO₃ formed then dissociates into CO₂ and H₂O. The CO₂ can move easily across the tubular membrane; therefore, it instantly diffuses into the tubular cell, where it recombines with H₂O, under the influence of carbonic anhydrase, to generate a new H₂CO₃ molecule. This H₂CO₃ dissociates to form HCO₃⁻ and H⁺; the HCO₃⁻ then diffuses through the basolateral membrane into the interstitial fluid and is taken up into the peritubular capillary blood. The transport of HCO₃⁻ across the basolateral membrane is facilitated by two mechanisms: (1) Na⁺-HCO₃⁻ co-transport in the proximal tubules; and (2) Cl⁻-HCO₃⁻ exchange in

the late segments of the proximal tubule, thick ascending loop of Henle, and collecting tubules and ducts.

Thus, each time a H⁺ is formed in the tubular epithelial cells, an HCO₃⁻ is also formed and released back into the blood. The net effect of these reactions is “reabsorption” of HCO₃⁻ from the tubules, although the HCO₃⁻ that actually enters the extracellular fluid is not the same as that filtered into the tubules. The reabsorption of filtered HCO₃⁻ does not result in net secretion of H⁺ because the secreted H⁺ combines with the filtered HCO₃⁻ and is therefore not excreted.

HCO₃⁻ Is Titrated Against H⁺ in the Tubules. Under normal conditions, the rate of tubular H⁺ secretion is about 4400 mEq/day, and the rate of filtration by HCO₃⁻ is about 4320 mEq/day. Thus, the quantities of these two ions entering the tubules are almost equal, and they combine with each other to form CO₂ and H₂O. Therefore, it is said that HCO₃⁻ and H⁺ normally “titrate” each other in the tubules.

The titration process is not quite exact because there is usually a slight excess of H⁺ in the tubules to be excreted in the urine. This excess H⁺ (≈80 mEq/day) rids the body of nonvolatile acids produced by metabolism. As discussed later, most of this H⁺ is not excreted as free H⁺ but is in combination with other urinary buffers, especially phosphate and ammonia.

When there is an excess of HCO₃⁻ over H⁺ in the urine, as occurs in metabolic alkalosis, the excess HCO₃⁻ cannot be reabsorbed. Therefore, the excess HCO₃⁻ is left in the tubules and eventually excreted into the urine, which helps correct the metabolic alkalosis.

In acidosis, there is excess H⁺ relative to HCO₃⁻, causing complete reabsorption of the HCO₃⁻; the excess H⁺ passes into the urine in combination with urinary buffers, especially phosphate and ammonia, and eventually is excreted as salts. Thus, the basic mechanism whereby the kidneys correct acidosis or alkalosis is incomplete titration of H⁺ against HCO₃⁻, leaving one or the other to pass into the urine and be removed from the extracellular fluid.

PRIMARY ACTIVE SECRETION OF H⁺ IN THE INTERCALATED CELLS OF LATE DISTAL AND COLLECTING TUBULES

Beginning in the late distal tubules and continuing through the remainder of the tubular system, the tubular epithelium secretes H⁺ by *primary active transport*. The characteristics of this transport are different from those discussed for the proximal tubule, loop of Henle, and early distal tubule.

The mechanism for primary active H⁺ secretion was discussed in [Chapter 28](#) and is shown in [Figure 31-6](#). It occurs at the luminal membrane of the tubular cell, where H⁺ is transported directly by specific proteins, a *hydrogen-transporting ATPase* and a *hydrogen-potassium-ATPase transporter*. The energy required for pumping the H⁺ is derived from the breakdown of ATP to adenosine diphosphate.

Figure 31-6. Active secretion of H^+ through the luminal membrane of the type A intercalated epithelial cells of the late distal and collecting tubules. Type A cells contain hydrogen-adenosine triphosphatase (ATPase) and hydrogen-potassium-ATPase in the luminal membrane and secrete H^+ while reabsorbing HCO_3^- and K^+ in acidosis. Note that one HCO_3^- is reabsorbed for each H^+ secreted, and one Cl^- is passively secreted along with H^+ .

Primary active secretion of H^+ occurs in special types of cells called the *type A intercalated cells* of the late distal tubule and in the collecting tubules. Hydrogen ion secretion in these cells is accomplished in two steps: (1) the dissolved CO_2 in this cell combines with H_2O to form H_2CO_3 ; and (2) the H_2CO_3 then dissociates into HCO_3^- , which is reabsorbed into the blood, plus H^+ , which is secreted into the tubule by means of the hydrogen-ATPase and the hydrogen-potassium-ATPase transporters. For each H^+ secreted, a HCO_3^- is reabsorbed, similar to the process in the proximal tubules. The main difference is that H^+ moves across the luminal membrane by an active H^+ pump instead of by counter-transport, as occurs in the early parts of the nephron.

Although secretion of H^+ in the late distal tubule and collecting tubules accounts for only about 5% of the total H^+ secreted, this mechanism is important in forming maximally acidic urine. In the proximal tubules, H^+ concentration can be increased only about threefold to fourfold and the tubular fluid pH can be reduced to only about 6.7, although large *amounts* of H^+ are secreted by this nephron segment. However, H^+ concentration can be increased as much as 900-fold in the collecting tubules. This mechanism decreases the pH of the tubular fluid to about 4.5, which is the lower limit of pH that can be achieved in normal kidneys.

COMBINATION OF EXCESS H^+ WITH PHOSPHATE AND AMMONIA BUFFERS IN THE TUBULE GENERATES "NEW" HCO_3^-

When H^+ is secreted in excess of the HCO_3^- filtered into the tubular fluid, only a small part of the excess H^+ can be excreted in the ionic form (H^+) in the urine.

This is because the minimal urine pH is about 4.5, corresponding to an H^+ concentration of $10^{-4.5}$ mEq/L, or 0.03 mEq/L. Thus, for each liter of urine formed, a maximum of only about 0.03 mEq of free H^+ can be excreted. To excrete the 80 mEq of nonvolatile acid formed by metabolism each day, about 2667 liters of urine would have to be excreted if the H^+ remained free in solution.

The excretion of large amounts of H^+ (on occasion as much as 500 mEq/day) in the urine is accomplished primarily by combining the H^+ with buffers in the tubular fluid. The most important buffers are phosphate buffer and ammonia buffer. Other weak buffer systems, such as urate and citrate, are much less important.

When H^+ is titrated in the tubular fluid with HCO_3^- , this leads to reabsorption of one HCO_3^- for each H^+ secreted, as discussed earlier. However, when there is excess H^+ in the tubular fluid, it combines with buffers other than HCO_3^- , and this leads to generation of new HCO_3^- that can also enter the blood. Thus, when there is excess H^+ in the extracellular fluid, the kidneys not only reabsorb all the filtered HCO_3^- but also generate new HCO_3^- , thereby helping replenish the HCO_3^- lost from the extracellular fluid in acidosis. In the next two sections, we discuss the mechanisms whereby phosphate and ammonia buffers contribute to generation of new HCO_3^- .

PHOSPHATE BUFFER SYSTEM CARRIES EXCESS H^+ INTO THE URINE AND GENERATES NEW HCO_3^-

The phosphate buffer system is composed of HPO_4^{2-} . Both become concentrated in the tubular fluid because water is normally reabsorbed to a greater extent than phosphate by the renal tubules. Therefore, although phosphate is not an important extracellular fluid buffer, it is much more effective as a buffer in the tubular fluid.

Another factor that makes phosphate important as a tubular buffer is the fact that the pK of this system is about 6.8. Under normal conditions, the urine is slightly acidic, and the urine pH is near the pK of the phosphate buffer system. Therefore, in the tubules, the phosphate buffer system normally functions near its most effective pH range.

Figure 31-7 shows the sequence of events whereby H^+ is excreted in combination with phosphate buffer and the mechanism whereby new HCO_3^- is added to the blood. The process of H^+ secretion into the tubules is the same as described earlier. As long as there is excess HCO_3^- in the tubular fluid, most of the secreted H^+ combines with HCO_3^- . However, once all the HCO_3^- has been reabsorbed and is no longer available to combine with H^+ , any excess H^+ can combine with HPO_4^{2-} and other tubular buffers. After the H^+ combines with HPO_4^{2-} to form $H_2PO_4^-$, it can be excreted as a sodium salt (NaH_2PO_4), carrying with it the excess H^+ .

Figure 31-7. Buffering of secreted H^+ by filtered phosphate (NaH_2PO_4). Note that a new HCO_3^- is returned to the blood for each NaH_2PO_4 that reacts with a secreted H^+ .

There is one important difference in this sequence of H^+ excretion from that discussed previously. In this case, the HCO_3^- that is generated in the tubular cell and enters the peritubular blood represents a net gain of HCO_3^- by the blood, rather than merely a replacement of filtered HCO_3^- . Therefore, whenever an H^+ secreted into the tubular lumen combines with a buffer other than HCO_3^- , the net effect is the addition of a new HCO_3^- to the blood. This process demonstrates one of the mechanisms whereby the kidneys can replenish the extracellular fluid stores of HCO_3^- .

Under normal conditions, much of the filtered phosphate is reabsorbed, and only 30 to 40 mEq/day are available for buffering H^+ . Therefore, much of the buffering of excess H^+ in the tubular fluid in acidosis occurs through the ammonia buffer system.

EXCRETION OF EXCESS H^+ AND GENERATION OF NEW HCO_3^- BY AMMONIA BUFFER SYSTEM

A second buffer system in the tubular fluid that is even more important quantitatively than the phosphate buffer system is composed of ammonia (NH_3) and the ammonium ion (NH_4^+). Ammonium ion is synthesized from glutamine, which comes mainly from metabolism of amino acids in the liver. The glutamine delivered to the kidneys is transported into epithelial cells of the proximal tubules, thick ascending limb of the loop of Henle, and distal tubules (Figure 31-8). Once inside the cell, each molecule of glutamine is metabolized in a series of reactions to ultimately form two NH_4^+ and two HCO_3^- . The NH_4^+ is secreted into the tubular lumen by a counter-transport mechanism in exchange for sodium, which is reabsorbed. The HCO_3^- is transported across the basolateral membrane, along with the reabsorbed Na^+ , into the interstitial fluid and is taken up by the peritubular capillaries. Thus, for each molecule of glutamine metabolized in the proximal tubules, two NH_4^+ are secreted into the

Figure 31-8. Production and secretion of ammonium ion (NH_4^+) by proximal tubular cells. Glutamine is metabolized in the cell, yielding NH_4^+ and HCO_3^- . The NH_4^+ is secreted into the lumen by a Na^+ - NH_4^+ exchanger. For each glutamine molecule metabolized, two NH_4^+ are produced and secreted, and two HCO_3^- are returned to the blood.

Figure 31-9. Buffering of H^+ secretion by ammonia (NH_3) in the collecting tubules. NH_3 diffuses into the tubular lumen, where it reacts with secreted H^+ to form NH_4^+ , which is then excreted. For each NH_4^+ excreted, a new HCO_3^- is formed in the tubular cells and returned to the blood.

urine and two HCO_3^- are reabsorbed into the blood. The HCO_3^- generated by this process constitutes new HCO_3^- .

In the collecting tubules, the addition of NH_4^+ to the tubular fluids occurs through a different mechanism (Figure 31-9). Here, H^+ is actively secreted by the tubular membrane into the lumen, where it combines with NH_3 to form NH_4^+ , which is then excreted. The collecting ducts are permeable to NH_3 , which can easily diffuse into the tubular lumen. However, the luminal membrane of this part of the tubules is much less permeable to NH_4^+ ; therefore, once the H^+ has reacted with NH_3 to form NH_4^+ , the NH_4^+ is trapped in the tubular lumen and eliminated in the urine. For each NH_4^+ excreted, a new HCO_3^- is generated and added to the blood.

Chronic Acidosis Increases NH_4^+ Excretion. One of the most important features of the renal ammonium-ammonia buffer system is that it is subject to physiological

control. An increase in extracellular fluid H^+ concentration stimulates renal glutamine metabolism and, therefore, increases formation of NH_4^+ and new HCO_3^- to be used in H^+ buffering; a decrease in H^+ concentration has the opposite effect.

Under *normal conditions*, the amount of H^+ eliminated by the ammonia buffer system accounts for about 50% of the acid excreted and 50% of the new HCO_3^- generated by the kidneys. However, with *chronic acidosis*, the rate of NH_4^+ excretion can increase to as much as 500 mEq/day. *Therefore, with chronic acidosis, the dominant mechanism for acid elimination is excretion of NH_4^+ .* This process also provides the most important mechanism for generating new bicarbonate during chronic acidosis.

QUANTIFYING RENAL ACID-BASE EXCRETION

Based on the principles discussed earlier, we can quantify the kidneys' net excretion of acid or net addition or elimination of HCO_3^- from the blood as follows.

Bicarbonate excretion is calculated as urine flow rate multiplied by the urinary HCO_3^- concentration and indicates how rapidly the kidneys are removing HCO_3^- from the blood, which is the same as adding an H^+ to the blood. In alkalosis, the loss of HCO_3^- helps return the plasma pH toward normal.

The amount of new HCO_3^- contributed to the blood at any given time is equal to the amount of H^+ secreted that ends up in the tubular lumen with non-bicarbonate urinary buffers. As discussed previously, the primary sources of nonbicarbonate urinary buffers are NH_4^+ and phosphate. Therefore, part of the HCO_3^- added to the blood (and H^+ excreted by NH_4^+) is calculated by measuring NH_4^+ excretion (urine flow rate multiplied by urinary NH_4^+ concentration).

The rest of the non-bicarbonate, non- NH_4^+ buffer excreted in the urine is measured by determining a value known as *titratable acid*. The amount of titratable acid in the urine is measured by titrating the urine with a strong base, such as NaOH, to a pH of 7.4, the pH of normal plasma and the pH of the glomerular filtrate. This titration reverses the events that occurred in the tubular lumen when the tubular fluid was titrated by secreted H^+ . Therefore, the number of milliequivalents of NaOH required to return the urinary pH to 7.4 equals the number of milliequivalents of H^+ added to the tubular fluid that combined with phosphate and other organic buffers. The titratable acid measurement does not include H^+ in association with NH_4^+ because the pK of the ammonia-ammonium reaction is 9.2, and titration with NaOH to a pH of 7.4 does not remove the H^+ from NH_4^+ .

Thus, the *net acid excretion* by the kidneys can be assessed as follows:

$$\text{Net acid excretion} = \text{NH}_4^+ \text{ excretion} + \text{Urinary titratable acid} - \text{HCO}_3^- \text{ excretion}$$

The reason we subtract HCO_3^- excretion is that the loss of HCO_3^- is the same as the addition of H^+ to the blood. To maintain acid-base balance, the net acid excretion must equal the nonvolatile acid production in the body.

In acidosis, the net acid excretion increases markedly, especially because of increased NH_4^+ excretion, thereby removing acid from the blood. The net acid excretion also equals the rate of net HCO_3^- addition to the blood. *Therefore, in acidosis, there is a net addition of HCO_3^- back to the blood as more NH_4^+ and urinary titratable acid are excreted.*

In alkalosis, titratable acid and NH_4^+ excretion drop to 0, whereas HCO_3^- excretion increases. *Therefore, in alkalosis, there is a negative net acid secretion*, which means that there is a net loss of HCO_3^- from the blood, which is the same as adding H^+ to the blood, and that no new HCO_3^- is generated by the kidneys.

REGULATION OF RENAL TUBULAR H^+ SECRETION

As discussed earlier, H^+ secretion by the tubular epithelium is necessary for HCO_3^- reabsorption and generation of new HCO_3^- associated with titratable acid formation. Therefore, the rate of H^+ secretion must be carefully regulated if the kidneys are to perform their functions in acid-base homeostasis effectively. Under normal conditions, the kidney tubules must secrete at least enough H^+ to reabsorb almost all the HCO_3^- that is filtered, and there must be enough H^+ left over to be excreted as titratable acid or NH_4^+ to rid the body of the nonvolatile acids produced each day from metabolism.

In alkalosis, the tubular secretion of H^+ is reduced to a level that is too low to achieve complete HCO_3^- reabsorption, enabling the kidneys to increase HCO_3^- excretion. Titratable acid and ammonia are not excreted in alkalosis because there is no excess H^+ available to combine with nonbicarbonate buffers; therefore, no new HCO_3^- is added to the blood in alkalosis.

During acidosis, the tubular H^+ secretion is increased sufficiently to reabsorb all the filtered HCO_3^- , with enough H^+ left over to excrete large amounts of NH_4^+ and titratable acid, thereby contributing large amounts of new HCO_3^- to the total body extracellular fluid. *The most important stimuli for increasing H^+ secretion by the tubules in acidosis are as follows: (1) an increase in PCO_2 of the extracellular fluid in respiratory acidosis; and (2) an increase in H^+ concentration of the extracellular fluid (decreased pH) in respiratory or metabolic acidosis.*

The tubular cells respond directly to an increase in PCO_2 of the blood, as in respiratory acidosis, with an increase in the rate of H^+ secretion, as follows. The increased PCO_2 raises the PCO_2 of the tubular cells, causing increased formation of H^+ in the tubular cells, which in turn stimulates secretion of H^+ . The second factor that stimulates H^+ secretion is an increase in extracellular fluid H^+ concentration (decreased pH).

Table 31-2 Plasma or Extracellular Fluid Factors That Increase or Decrease H⁺ Secretion and HCO₃⁻ Reabsorption by the Renal Tubules

Increase H ⁺ Secretion and HCO ₃ ⁻ Reabsorption	Decrease H ⁺ Secretion and HCO ₃ ⁻ Reabsorption
↑P _{CO₂}	↓P _{CO₂}
↑H ⁺ , ↓HCO ₃ ⁻	↓H ⁺ , ↑HCO ₃ ⁻
↓Extracellular fluid volume	↑Extracellular fluid volume
↑Angiotensin II	↓Angiotensin II
↑Aldosterone	↓Aldosterone
Hypokalemia	Hyperkalemia

A special factor that can increase H⁺ secretion under some pathophysiological conditions is excessive aldosterone secretion. Aldosterone stimulates secretion of H⁺ by type A intercalated cells of the collecting tubules and ducts. Therefore, excessive secretion of aldosterone, as in persons with Conn syndrome, increases secretion of H⁺ into the tubular fluid and, consequently, increases the amount of HCO₃⁻ added back to the blood. This action usually causes alkalosis in patients with excessive aldosterone secretion.

The tubular cells usually respond to a decrease in H⁺ concentration (alkalosis) by reducing H⁺ secretion. The decreased H⁺ secretion results from decreased extracellular P_{CO₂}, as in respiratory alkalosis, or from a decrease in H⁺ concentration, as in both respiratory and metabolic alkalosis.

Table 31-2 summarizes the major factors that influence H⁺ secretion and HCO₃⁻ reabsorption. Some of these factors are not directly related to the regulation of acid–base balance. For example, H⁺ secretion is coupled to Na⁺ reabsorption by the Na⁺-H⁺ exchanger in the proximal tubule and the thick ascending loop of Henle. Therefore, factors that stimulate Na⁺ reabsorption, such as decreased extracellular fluid volume and increased angiotensin II (Ang II), may also secondarily increase H⁺ secretion and HCO₃⁻ reabsorption.

Extracellular fluid volume depletion stimulates sodium reabsorption by the renal tubules and increases H⁺ secretion and HCO₃⁻ reabsorption through multiple mechanisms, including the following: (1) increased Ang II levels, which directly stimulate activity of the Na⁺-H⁺ exchanger in the renal tubules; and (2) increased aldosterone levels, which stimulate H⁺ secretion by the intercalated cells of the cortical collecting tubules. Therefore, extracellular fluid volume depletion tends to cause alkalosis due to excess H⁺ secretion and HCO₃⁻ reabsorption.

Changes in plasma potassium concentration can also influence H⁺ secretion, with hypokalemia stimulating and hyperkalemia inhibiting H⁺ secretion in the proximal tubule. Decreased plasma potassium concentration tends to increase H⁺ concentration in the renal tubular cells. This, in turn, stimulates H⁺ secretion and

HCO₃⁻ reabsorption and leads to alkalosis. Hyperkalemia decreases H⁺ secretion and HCO₃⁻ reabsorption and tends to cause acidosis.

RENAL CORRECTION OF ACIDOSIS— INCREASED EXCRETION OF H⁺ AND ADDITION OF HCO₃⁻ TO THE EXTRACELLULAR FLUID

Now that we have described the mechanisms whereby the kidneys secrete H⁺ and reabsorb HCO₃⁻, we can explain how the kidneys readjust the pH of the extracellular fluid when it becomes abnormal.

Referring to [Equation 8](#), the Henderson-Hasselbalch equation, we can see that acidosis occurs when the ratio of HCO₃⁻ to CO₂ in the extracellular fluid decreases, thereby decreasing the pH. If this ratio decreases because of a fall in HCO₃⁻, the acidosis is referred to as *metabolic acidosis*. If the pH falls because of an increase in P_{CO₂}, the acidosis is referred to as *respiratory acidosis*.

ACIDOSIS DECREASES HCO₃⁻/H⁺ RATIO IN RENAL TUBULAR FLUID

Respiratory and metabolic acidosis both cause a decrease in the ratio of HCO₃⁻/H⁺ in the renal tubular fluid. As a result, there is excess H⁺ in the renal tubules, causing complete reabsorption of HCO₃⁻ and still leaving additional H⁺ available to combine with the urinary buffers NH₄⁺ and HPO₄⁼. Thus, in acidosis, the kidneys reabsorb all the filtered HCO₃⁻ and contribute new HCO₃⁻ through formation of NH₄⁺ and titratable acid.

In metabolic acidosis, an excess of H⁺ over HCO₃⁻ occurs in the tubular fluid, primarily because of decreased extracellular fluid concentration of HCO₃⁻ and therefore decreased glomerular filtration of HCO₃⁻.

In respiratory acidosis, the excess H⁺ in the tubular fluid is due mainly to the rise in extracellular fluid P_{CO₂}, which stimulates H⁺ secretion.

As discussed previously, with chronic acidosis, regardless of whether it is respiratory or metabolic, there is increased production of NH₄⁺, which further contributes to excretion of H⁺ and addition of new HCO₃⁻ to the extracellular fluid. With severe chronic acidosis, as much as 500 mEq/day of H⁺ can be excreted in the urine, mainly in the form of NH₄⁺; this excretion, in turn, contributes up to 500 mEq/day of new HCO₃⁻ that is added to the blood.

Thus, with chronic acidosis, increased secretion of H⁺ by the tubules helps eliminate excess H⁺ from the body and increases the quantity of HCO₃⁻ in the extracellular fluid. This process increases the HCO₃⁻ part of the bicarbonate buffer system, which, in accordance with the Henderson-Hasselbalch equation, helps raise the extracellular pH and corrects the acidosis. If the acidosis is metabolically mediated, additional compensation by the lungs causes a reduction in P_{CO₂}, also helping correct the acidosis.

Table 31-3 Extracellular Fluid Characteristics of Primary Acid–Base Disturbances^a

	pH	H ⁺	Pco ₂	HCO ₃ ⁻
Normal	7.4	40 mEq/L	40 mm Hg	24 mEq/L
Respiratory acidosis	↓	↑	↑↑	↑
Respiratory alkalosis	↑	↓	↓↓	↓
Metabolic acidosis	↓	↑	↓	↓↓
Metabolic alkalosis	↑	↓	↑	↑↑

^aThe primary event is indicated by the double arrows (↑↑ or ↓↓). Note that respiratory acid–base disorders are initiated by an increase or decrease in Pco₂, whereas metabolic disorders are initiated by an increase or decrease in HCO₃⁻.

Table 31-3 summarizes the extracellular fluid characteristics associated with respiratory and metabolic acidosis, as well as respiratory and metabolic alkalosis, discussed in the next section. Note that in *respiratory acidosis*, there is a reduction in pH, an increase in extracellular fluid H⁺ concentration, and an increase in Pco₂, which is the initial cause of the acidosis. *The compensatory response is increase in plasma HCO₃⁻, caused by the addition of new HCO₃⁻ to the extracellular fluid by the kidneys.* The rise in HCO₃⁻ helps offset the increase in Pco₂, thereby returning the plasma pH toward normal.

In *metabolic acidosis*, there is also a decrease in pH and a rise in the extracellular fluid H⁺ concentration. However, in this case, the primary abnormality is a decrease in plasma HCO₃⁻. *The primary compensations include increased ventilation rate, which reduces Pco₂, and renal compensation, which, by adding new HCO₃⁻ to the extracellular fluid, helps minimize the initial fall in extracellular HCO₃⁻ concentration.*

RENAL CORRECTION OF ALKALOSIS—DECREASED TUBULAR SECRETION OF H⁺ AND INCREASED EXCRETION OF HCO₃⁻

The compensatory responses to alkalosis are basically opposite to those that occur in acidosis. In alkalosis, the ratio of HCO₃⁻ to CO₂ in the extracellular fluid increases, causing a rise in pH (a decrease in H⁺ concentration), as evident from the Henderson-Hasselbalch equation.

ALKALOSIS INCREASES HCO₃⁻/H⁺ RATIO IN RENAL TUBULAR FLUID

Regardless of whether alkalosis is caused by metabolic or respiratory abnormalities, there is still an increase in the ratio of HCO₃⁻/H⁺ in the renal tubular fluid. The net effect of this is an excess of HCO₃⁻ that cannot be reabsorbed from the tubules and is, therefore, excreted

in the urine. Thus, in alkalosis, HCO₃⁻ is removed from the extracellular fluid by renal excretion, which has the same effect as adding an H⁺ to the extracellular fluid. This process helps return the H⁺ concentration and pH toward normal.

Table 31-3 shows the overall extracellular fluid characteristics of respiratory and metabolic alkalosis. In *respiratory alkalosis*, there is an increase in extracellular fluid pH and a decrease in H⁺ concentration. *The cause of the alkalosis is decreased plasma Pco₂, caused by hyperventilation.* Reduction in Pco₂ then leads to decreased renal tubular H⁺ secretion. Consequently, there is not enough H⁺ in the renal tubular fluid to react with all the HCO₃⁻ that is filtered. Therefore, the HCO₃⁻ that cannot react with H⁺ is not reabsorbed and is excreted in the urine. This results in a decreased plasma HCO₃⁻ concentration and correction of the alkalosis. *Therefore, the compensatory response to a primary reduction in Pco₂ in respiratory alkalosis is a reduction in plasma HCO₃⁻ concentration, caused by increased renal excretion of HCO₃⁻.*

In *metabolic alkalosis*, there is also decreased plasma H⁺ concentration and increased pH. *The cause of metabolic alkalosis, however, is a rise in the extracellular fluid HCO₃⁻ concentration.* This rise is partly compensated for by a reduction in the respiration rate, which increases Pco₂ and helps return the extracellular fluid pH toward normal. In addition, increased HCO₃⁻ concentration in the extracellular fluid increases the filtered load of HCO₃⁻, which, in turn, causes excess HCO₃⁻ over H⁺ secreted in the renal tubular fluid. The excess HCO₃⁻ in the tubular fluid fails to be reabsorbed because there is no H⁺ with which it can react, and it is excreted in the urine. *In metabolic alkalosis, the primary compensations are decreased ventilation, which raises Pco₂, and increases renal HCO₃⁻ excretion, which helps compensate for the initial rise in extracellular fluid HCO₃⁻ concentration.*

Clinical Causes of Acid–Base Disorders

Respiratory Acidosis Results From Decreased Ventilation and Increased Pco₂

From the previous discussion, it is obvious that any factor that decreases the rate of pulmonary ventilation also increases the Pco₂ of extracellular fluid. This causes an increase in H₂CO₃ and H⁺ concentrations, thus resulting in acidosis. Because the acidosis is caused by an abnormality in respiration, it is called *respiratory acidosis*.

Respiratory acidosis can occur from pathological conditions that damage the respiratory centers or that decrease the ability of the lungs to eliminate CO₂. For example, damage to the respiratory center in the medulla oblongata can lead to respiratory acidosis. Also, obstruction of the passageways of the respiratory tract, pneumonia, emphysema, or decreased pulmonary membrane surface area, as well as any factor that interferes with exchange of gases between the blood and alveolar air, can cause respiratory acidosis.

In respiratory acidosis, the compensatory responses available are as follows: (1) the buffers of the body fluids; and (2) the kidneys, which require several days to compensate for the disorder.

Respiratory Alkalosis Results From Increased Ventilation and Decreased P_{CO_2}

Respiratory alkalosis is caused by excessive ventilation by the lungs. Rarely does this occur because of physical pathological conditions. However, a psychoneurosis can occasionally increase breathing to the extent that a person becomes alkalotic.

A physiological type of respiratory alkalosis occurs when a person ascends to a high altitude. The low oxygen content of the air stimulates respiration, which causes loss of CO_2 and development of mild respiratory alkalosis. Again, the major means for compensation are the chemical buffers of the body fluids and ability of the kidneys to increase HCO_3^- excretion.

Metabolic Acidosis Results From Decreased Extracellular Fluid HCO_3^- Concentration

The term *metabolic acidosis* refers to all other types of acidosis besides those caused by excess CO_2 in the body fluids. Metabolic acidosis can result from several general causes: (1) failure of the kidneys to excrete metabolic acids normally formed in the body; (2) formation of excess quantities of metabolic acids in the body; (3) addition of metabolic acids to the body by ingestion or infusion of acids; and (4) loss of base from the body fluids, which has the same effect as adding an acid to the body fluids. Some specific conditions that cause metabolic acidosis are described in the following sections.

Renal Tubular Acidosis. Renal tubular acidosis results from a defect in renal secretion of H^+ , reabsorption of HCO_3^- , or both. These disorders are generally of two types: (1) impairment of renal tubular HCO_3^- reabsorption, causing loss of HCO_3^- in the urine; or (2) inability of the renal tubular H^+ secretory mechanism to establish normal acidic urine, causing the excretion of alkaline urine. In these cases, inadequate amounts of titratable acid and NH_4^+ are excreted, so there is net accumulation of acid in the body fluids. Some causes of renal tubular acidosis include *chronic renal failure*, *insufficient aldosterone secretion* (Addison disease), and several hereditary and acquired disorders that impair tubular function, such as *Fanconi syndrome* (see Chapter 32).

Diarrhea. Severe diarrhea is probably the most frequent cause of metabolic acidosis. *The cause of this acidosis is the loss of large amounts of sodium bicarbonate into the feces.* The gastrointestinal secretions normally contain large amounts of bicarbonate, and diarrhea results in the loss of HCO_3^- from the body, which has the same effect as losing large amounts of bicarbonate in the urine. This form of metabolic acidosis can be serious and can cause death, especially in young children.

Vomiting of Intestinal Contents. Vomiting of gastric contents alone would cause a loss of acid and a tendency toward alkalosis because the stomach secretions are highly acidic. However, vomiting large amounts from deeper in the gastrointestinal tract causes loss of bicarbonate and results in metabolic acidosis in the same way that diarrhea causes acidosis.

Diabetes Mellitus. Diabetes mellitus is caused by lack of insulin secretion by the pancreas (type 1 diabetes) or by insufficient insulin secretion to compensate for decreased sensitivity to the effects of insulin (type 2 diabetes). In the absence of sufficient insulin, the normal metabolism of glucose is prevented. Instead, some of the fats are split into acetoacetic acid, and this acid is metabolized by the tissues for energy in place of glucose. With severe diabetes mellitus, blood acetoacetic acid levels can rise very high, causing severe metabolic acidosis. In an attempt to compensate for this acidosis, large amounts of acid are excreted in the urine—sometimes as much as 500 mmol/day.

Ingestion of Acids. Rarely are large amounts of acids ingested in normal foods. However, severe metabolic acidosis occasionally results from the ingestion of certain acidic poisons. Some of these substances include some acetylsalicylic compounds (e.g., aspirin) and methyl alcohol, which forms formic acid when it is metabolized.

Chronic Renal Failure. When kidney function declines markedly, there is a buildup in the body fluids of the anions of weak acids that are not being excreted by the kidneys. In addition, the decreased glomerular filtration rate reduces excretion of phosphates and NH_4^+ , which reduces the amount of HCO_3^- added back to the body fluids. Thus, chronic renal failure can be associated with severe metabolic acidosis.

Metabolic Alkalosis Results From Increased Extracellular Fluid HCO_3^- Concentration

Excess retention of HCO_3^- or loss of H^+ from the body causes metabolic alkalosis. Metabolic alkalosis is not nearly as common as metabolic acidosis, but some of the causes of metabolic alkalosis are described in the following sections.

Administration of Diuretics (Except Carbonic Anhydrase Inhibitors). All diuretics cause increased flow of fluid along the tubules, usually increasing flow in the distal and collecting tubules. This effect leads to increased reabsorption of Na^+ from these parts of the nephrons. Because the sodium reabsorption here is coupled with H^+ secretion, the enhanced sodium reabsorption also leads to an increase in H^+ secretion and increase in bicarbonate reabsorption. Reductions in extracellular fluid volume associated with the use of diuretics is also generally associated with increased formation of Ang II and aldosterone, which both stimulate H^+ secretion and HCO_3^- reabsorption. These changes lead to the development of alkalosis, characterized by increased extracellular fluid bicarbonate concentration.

Excess Aldosterone. When large amounts of aldosterone are secreted by the adrenal glands, a mild metabolic alkalosis develops. As discussed previously, aldosterone promotes extensive reabsorption of Na^+ from the distal and collecting tubules and, at the same time, stimulates secretion of H^+ and HCO_3^- reabsorption by the intercalated cells of the collecting tubules. This increased secretion of H^+ and HCO_3^- reabsorption leads to metabolic alkalosis.

Vomiting of Gastric Contents. Vomiting of the gastric contents alone, without vomiting of the lower gastrointestinal contents, causes loss of the HCl secreted by the stomach mucosa. The net result is loss of acid from the extracellular fluid and development of metabolic alkalosis. This type of alkalosis occurs especially in neonates who have pyloric stenosis caused by hypertrophied pyloric sphincter muscles.

Ingestion of Alkaline Drugs. A common cause of metabolic alkalosis is ingestion of alkaline drugs, such as sodium bicarbonate, for the treatment of gastritis or peptic ulcer.

Treatment of Acidosis or Alkalosis

The best treatment for acidosis or alkalosis is to correct the condition that caused the abnormality. This is often difficult, especially in chronic diseases that cause impaired lung function or kidney failure. In these circumstances, various agents can be used to neutralize the excess acid or base in the extracellular fluid.

To neutralize excess acid, large amounts of *sodium bicarbonate* can be ingested by mouth. The sodium bicarbonate is absorbed from the gastrointestinal tract into the blood and increases the HCO_3^- portion of the bicarbonate buffer system, thereby increasing pH toward normal. Sodium bicarbonate can also be infused intravenously but, because of the potentially dangerous physiological effects of such treatment, other substances are often used instead, such as *sodium lactate* and *sodium gluconate*. The lactate and gluconate portions of the molecules are metabolized in the body, leaving the sodium in the extracellular fluid in the form of sodium bicarbonate and thereby increasing the pH of the fluid toward normal.

For the treatment of alkalosis, *ammonium chloride* can be administered by mouth. When ammonium chloride is absorbed into the blood, the ammonia portion is converted by the liver into urea. This reaction liberates HCl, which immediately reacts with the buffers of the body fluids to shift the H^+ concentration in the acidic direction. Ammonium chloride occasionally is infused intravenously, but NH_4^+ is highly toxic, and this procedure can be dangerous. The most appropriate treatment is to reverse the underlying cause of the alkalosis. For example, if metabolic alkalosis is associated with extracellular fluid volume depletion, but not heart failure, appropriate repletion of volume by infusion of isotonic saline solution is often beneficial in correcting the alkalosis.

Clinical Measurements and Analysis of Acid–Base Disorders

The appropriate therapy of acid–base disorders requires proper diagnosis. The simple acid–base disorders described previously can be diagnosed by analyzing three measurements from an arterial blood sample: pH, plasma HCO_3^- concentration, and PCO_2 .

The diagnosis of simple acid–base disorders involves several steps, as shown in **Figure 31-10**. By examining the pH, one can determine whether the disorder is acidosis or alkalosis. A pH less than 7.4 indicates acidosis, whereas a pH greater than 7.4 indicates alkalosis.

The second step is to examine the plasma PCO_2 and HCO_3^- concentrations. The normal value for PCO_2 is about 40 mm Hg, and for HCO_3^- it is 24 mEq/L. If the disorder has been characterized as acidosis and the plasma PCO_2 is increased, there must be a respiratory component to the acidosis. After renal compensation, the plasma HCO_3^- concentration in respiratory acidosis would tend to increase above normal. *Therefore, the expected values for a simple respiratory acidosis would be reduced plasma pH, increased PCO_2 , and increased plasma HCO_3^- concentration after partial renal compensation.*

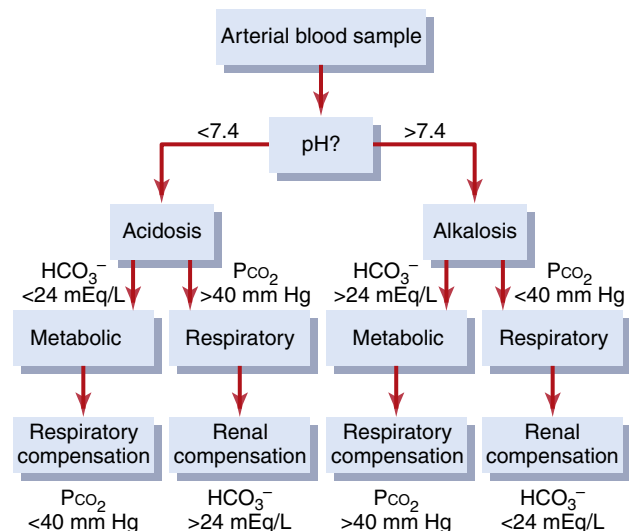

Figure 31-10. Analysis of simple acid–base disorders. If the compensatory responses are markedly different from those shown at the bottom of the figure, one should suspect a mixed acid–base disorder.

For metabolic acidosis, there would also be a decrease in plasma pH. However, with metabolic acidosis, the primary abnormality is a decrease in plasma HCO_3^- concentration. Therefore, if a low pH is associated with a low HCO_3^- concentration, there must be a metabolic component to the acidosis. In simple metabolic acidosis, the PCO_2 is reduced because of partial respiratory compensation, in contrast to respiratory acidosis, in which PCO_2 is increased. *Therefore, in simple metabolic acidosis, one would expect to find a low pH, a low plasma HCO_3^- concentration, and a reduction in PCO_2 after partial respiratory compensation.*

The procedures for categorizing the types of alkalosis involve the same basic steps. First, alkalosis implies that there is an increase in plasma pH. If the increase in pH is associated with decreased PCO_2 , there must be a respiratory component to the alkalosis. If the rise in pH is associated with increased HCO_3^- , there must be a metabolic component to the alkalosis. *Therefore, in simple respiratory alkalosis, one would expect to find increased pH, decreased PCO_2 , and decreased HCO_3^- concentration in the plasma. In simple metabolic alkalosis, one would expect to find increased pH, increased plasma HCO_3^- , and increased PCO_2 .*

Complex Acid–Base Disorders and Use of Acid–Base Nomogram for Diagnosis

In some cases, acid–base disorders are not accompanied by appropriate compensatory responses. When this situation occurs, the abnormality is referred to as a *mixed acid–base disorder*, which means that there are two or more underlying causes for the acid–base disturbance. For example, a patient with a low pH would be categorized as acidotic. If the disorder was metabolically mediated, this would also be accompanied by a low plasma HCO_3^- concentration and, after appropriate respiratory compensation, a low PCO_2 . However, if the low plasma pH and low HCO_3^- concentration are associated with an elevated PCO_2 , one would suspect a respiratory component to the acidosis, as well as a metabolic component. Therefore, this disorder would be categorized as a mixed acidosis. This disorder could occur, for example, in a patient with acute

Figure 31-11. Acid–base nomogram showing arterial blood pH, arterial plasma HCO_3^- , and PCO_2 values. The central open circle shows the approximate limits for acid–base status in normal people. The shaded areas in the nomogram show the approximate limits for the normal compensations caused by simple metabolic and respiratory disorders. For values lying outside the shaded areas, one should suspect a mixed acid–base disorder. (Modified from Cogan MG, Rector FC Jr: *Acid-Base Disorders in the Kidney*, 3rd ed. Philadelphia: WB Saunders, 1986.)

HCO_3^- loss from the gastrointestinal tract because of diarrhea (metabolic acidosis) and emphysema (respiratory acidosis).

A convenient way to diagnose acid–base disorders is to use an acid–base nomogram, as shown in **Figure 31-11**. This diagram can be used to determine the type of acidosis or alkalosis, as well as its severity. In this acid–base diagram, pH, HCO_3^- concentration, and PCO_2 values intersect according to the Henderson-Hasselbalch equation. The central open circle shows normal values and the deviations that can still be considered within the normal range. The shaded areas of the diagram show the 95% confidence limits for the normal compensations to simple metabolic and respiratory disorders.

When using this diagram, one must assume that sufficient time has elapsed for a full compensatory response, which is 6 to 12 hours for the ventilatory compensations in primary metabolic disorders and 3 to 5 days for the metabolic compensations in primary respiratory disorders. If a value is within the shaded area, this suggests that there is a simple acid–base disturbance. Conversely, if the values for pH, bicarbonate, or PCO_2 lie outside the shaded area, this suggests that the patient may have a mixed acid–base disorder.

It is important to recognize that an acid–base value within the shaded area does not *always* mean that a simple acid–base disorder is present. With this reservation in mind, the acid–base diagrams can be used as a quick means of determining the specific type and severity of an acid–base disorder.

For example, assume that the arterial plasma from a patient yields the following values: pH, 7.30; plasma HCO_3^- concentration, 12.0 mEq/L; and plasma PCO_2 , 25 mm Hg. With these values, one can look at the diagram and find that this represents a simple metabolic acidosis, with appropriate respiratory compensation that reduces the PCO_2 from its normal value of 40 mm Hg to 25 mm Hg.

A second example would be a patient with the following values: pH, 7.15; plasma HCO_3^- concentration, 17 mEq/L; and plasma PCO_2 , 50 mm Hg. In this example, the patient is acidotic, and there appears to be a metabolic component because the plasma HCO_3^- concentration is lower than the normal value of 24 mEq/L. However, the respiratory compensation that would normally reduce PCO_2 is absent and PCO_2 is slightly increased above the normal value of 40 mm Hg. This finding is consistent with a mixed acid–base disturbance consisting of metabolic acidosis, as well as a respiratory component.

The acid–base nomogram serves as a quick way to assess the type and severity of disorders that may be contributing to abnormal pH, PCO_2 , and plasma bicarbonate concentrations. In a clinical setting, the patient's history and other physical findings also provide important clues concerning the causes and treatment of the acid–base disorders.

Use of Anion Gap to Diagnose Acid–Base Disorders

The concentrations of anions and cations in plasma must be equal to maintain electrical neutrality. Therefore, there is no real anion gap in the plasma. However, only certain cations and anions are routinely measured in the clinical laboratory. The cation normally measured is Na^+ , and the anions are usually Cl^- and HCO_3^- . The anion gap—which is only a diagnostic concept—is the difference between unmeasured anions and unmeasured cations and is estimated as follows:

$$\begin{aligned} \text{Plasma anion gap} &= [\text{Na}^+] - [\text{HCO}_3^-] - [\text{Cl}^-] \\ &= 144 - 24 - 108 = 12 \text{ mEq/L} \end{aligned}$$

The anion gap will increase if unmeasured anions rise or if unmeasured cations fall. The most important unmeasured cations include calcium, magnesium, and potassium, and the major unmeasured anions are albumin, phosphate, sulfate, and other organic anions. Usually, the unmeasured anions exceed the unmeasured cations, and the anion gap ranges between 8 and 16 mEq/L.

Table 31-4 Metabolic Acidosis Associated With Normal or Increased Plasma Anion Gap

Increased Anion Gap (Normochloremia)	Normal Anion Gap (Hyperchloremia)
Diabetes mellitus (ketoacidosis)	Diarrhea
Lactic acidosis	Renal tubular acidosis
Chronic renal failure	Carbonic anhydrase inhibitors
Aspirin (acetylsalicylic acid) poisoning	Addison disease
Methanol poisoning	
Ethylene glycol poisoning	
Starvation	

The plasma anion gap is used mainly in diagnosing different causes of metabolic acidosis. In metabolic acidosis, plasma HCO_3^- concentration is reduced. If plasma sodium concentration is unchanged, the concentration of anions (Cl^- or an unmeasured anion) increases to maintain electro-neutrality. If plasma Cl^- increases in proportion to the fall in plasma HCO_3^- , the anion gap will remain normal. This is often referred to as *hyperchloremic metabolic acidosis*.

If the decrease in plasma HCO_3^- is not accompanied by increased Cl^- , there must be increased levels of unmeasured anions and therefore an increase in the calculated anion gap. Metabolic acidosis caused by excess nonvolatile acids (besides HCl), such as lactic acid or ketoacids, is associated with an increased plasma anion gap because the fall in HCO_3^- is not matched by an equal increase in Cl^- . Some examples of metabolic acidosis associated with a normal or increased anion gap are shown in [Table 31-4](#). By calculating the anion gap, one can narrow some of the potential causes of metabolic acidosis.

Diuretics and Kidney Diseases

DIURETICS AND THEIR MECHANISMS OF ACTION

Diuretics increase the rate of urine volume output, as the name implies. Most diuretics also increase the urinary excretion of solutes, especially sodium and chloride. In fact, most diuretics that are used clinically act by decreasing renal tubular sodium reabsorption, which causes natriuresis (increased sodium output), in turn causing diuresis (increased water output). That is, in most cases, increased water excretion occurs secondary to inhibition of tubular sodium reabsorption because sodium remaining in the tubules acts osmotically to decrease water reabsorption. Because renal tubular reabsorption of many solutes, such as potassium, chloride, magnesium, and calcium, is also influenced secondarily by sodium reabsorption, many diuretics raise the renal excretion of these solutes as well.

The most common clinical use of diuretics is to reduce extracellular fluid volume, especially in diseases associated with edema and in hypertension. As discussed in [Chapter 25](#), loss of sodium from the body mainly decreases extracellular fluid volume; therefore, diuretics are usually administered in clinical conditions in which extracellular fluid volume is expanded.

Some diuretics can increase urine output more than 20-fold within a few minutes after they are administered. However, the effect of most diuretics on renal output of salt and water subsides within a few days due to activation of compensatory mechanisms initiated by decreased extracellular fluid volume ([Figure 32-1](#)). For example, a decrease in extracellular fluid volume may reduce arterial pressure and glomerular filtration rate (GFR) and increase renin secretion and angiotensin II (Ang II) formation; all these responses together eventually override the chronic effects of the diuretic on urine output. Thus, in the steady state, urine output becomes equal to intake, but only after reductions in arterial pressure and extracellular fluid volume have occurred, relieving the hypertension or edema that prompted the use of diuretics in the first place.

The many diuretics available for clinical use have different mechanisms of action and, therefore, inhibit tubular reabsorption at different sites along the renal nephron.

The general classes of diuretics, their mechanisms of action, and their tubular sites of action are shown in [Table 32-1](#).

Osmotic Diuretics Decrease Water Reabsorption by Increasing Osmotic Pressure of Tubular Fluid

Injection of substances into the blood stream that are filtered by the glomerular capillaries but are not easily reabsorbed by the renal tubules, such as urea, mannitol, and sucrose, causes a marked increase in the concentration of osmotically active molecules in the tubules. The osmotic pressure of these solutes then reduces water reabsorption, flushing large amounts of tubular fluid into the urine.

Large volumes of urine are also formed in certain diseases associated with excess solutes that fail to be reabsorbed from the tubular fluid. For example, when blood glucose concentration rises to high levels in diabetes mellitus, the increased filtered load of glucose into the tubules exceeds their capacity to reabsorb glucose (i.e., exceeds their *transport maximum* for glucose). Above a plasma glucose concentration of about 250 mg/dl, little of the extra glucose is reabsorbed by the tubules; instead, the excess glucose remains in the tubules, acts as an osmotic diuretic, and increases urine flow rate. Therefore, one of the hallmarks of uncontrolled diabetes mellitus is *polyuria* (frequent urination), which is balanced by a high level of fluid intake (*polydipsia*) secondary to dehydration, increased extracellular fluid osmolarity, and activation of the thirst mechanism.

Loop Diuretics Decrease Sodium-Chloride-Potassium Reabsorption in the Thick Ascending Loop of Henle

Furosemide, *ethacrynic acid*, and *bumetanide* are powerful diuretics that decrease reabsorption in the thick ascending limb of the loop of Henle by blocking the 1-sodium, 2-chloride, 1-potassium co-transporter located in the luminal membrane of the epithelial cells (see [Figure 28-9](#)). These loop diuretics are among the most powerful of the clinically used diuretics.

By blocking sodium-chloride-potassium co-transport in the luminal membrane of the loop of Henle, the loop diuretics increase urine output of sodium, chloride, potassium, and other electrolytes, as well as water, for two reasons: (1) they greatly increase the quantities of solutes delivered to the distal parts of the nephrons, and these solutes act as osmotic agents to prevent water reabsorption; and (2) they disrupt the countercurrent multiplier system by decreasing absorption of ions from the loop of Henle into the medullary interstitium, thereby decreasing the osmolarity of the medullary interstitial fluid. Therefore, loop diuretics impair the ability of

Figure 32-1. Sodium excretion and extracellular fluid volume during diuretic administration. The immediate increase in sodium excretion is accompanied by a decrease in extracellular fluid volume. If sodium intake is held constant, compensatory mechanisms will eventually return sodium excretion to equal sodium intake, thus re-establishing sodium balance.

the kidneys to concentrate or dilute the urine. Urinary dilution is impaired because the inhibition of sodium and chloride reabsorption in the loop of Henle causes more of these ions to be excreted, along with increased water excretion. Urine concentrating ability is impaired because the renal medullary interstitial fluid concentration of these ions, and therefore renal medullary osmolarity, is reduced. Consequently, reabsorption of fluid from the collecting ducts is decreased, so the maximal concentrating ability of the kidneys is also greatly reduced. In addition, decreased renal medullary interstitial fluid osmolarity reduces reabsorption of water from the descending loop of Henle. Because of these multiple effects, 20% to 30% of the glomerular filtrate may be delivered into the urine, causing urine output, under acute conditions, to be as great as 25 times normal for at least a few minutes.

Thiazide Diuretics Inhibit Sodium-Chloride Reabsorption in the Early Distal Tubule

The thiazide derivatives, such as chlorothiazide, act mainly on the early distal tubules to block the sodium-chloride co-transporter in the luminal membrane of the tubular cells (see **Figure 28-10**). Under favorable conditions, these agents may cause a maximum of 5% to 10% of the glomerular filtrate to pass into the urine, which is about the same amount of sodium normally reabsorbed by the distal tubules.

Carbonic Anhydrase Inhibitors Block Sodium Bicarbonate Reabsorption

Acetazolamide inhibits the enzyme *carbonic anhydrase*, which is critical for reabsorption of bicarbonate (HCO_3^-) in the renal tubules, as discussed in **Chapter 31**. Carbonic anhydrase is especially abundant in the proximal tubule, the primary site of action of carbonic anhydrase inhibitors. Some carbonic anhydrase is also present in other tubular cells, such as in the intercalated cells of the collecting tubule.

Table 32-1 Classes of Diuretics, Their Mechanisms of Action, and Tubular Sites of Action

Class of Diuretic (examples)	Mechanism of Action	Tubular Site of Action
Osmotic diuretics (mannitol)	Inhibit water and solute reabsorption by increasing osmolarity of tubular fluid	Mainly proximal tubules
Loop diuretics (furosemide, bumetanide)	Inhibit $\text{Na}^+\text{-K}^+\text{-Cl}^-$ co-transport in luminal membrane	Thick ascending loop of Henle
Thiazide diuretics (hydrochlorothiazide, chlorthalidone)	Inhibit $\text{Na}^+\text{-Cl}^-$ co-transport in luminal membrane	Early distal tubules
Carbonic anhydrase inhibitors (acetazolamide)	Inhibit H^+ secretion and HCO_3^- reabsorption, which reduces Na^+ reabsorption	Mainly proximal tubules
Aldosterone antagonists (spironolactone, eplerenone)	Inhibit action of aldosterone on tubular receptor, decrease Na^+ reabsorption, decrease K^+ secretion	Collecting tubules
Sodium channel blockers (triamterene, amiloride)	Block entry of Na^+ into Na^+ channels of luminal membrane, decrease Na^+ reabsorption, decrease K^+ secretion	Collecting tubules

Because hydrogen ion (H^+) secretion and HCO_3^- reabsorption in the proximal tubules are coupled to sodium reabsorption through the sodium-hydrogen ion counter-transport mechanism in the luminal membrane, decreasing HCO_3^- reabsorption also reduces sodium reabsorption. The blockage of sodium and HCO_3^- reabsorption from the tubular fluid causes these ions to remain in the tubules and act as an osmotic diuretic. Predictably, a disadvantage of the carbonic anhydrase inhibitors is that they cause some degree of acidosis because of the excessive loss of HCO_3^- in the urine.

Mineralocorticoid Receptor Antagonists Decrease Sodium Reabsorption From and Potassium Secretion Into the Collecting Tubules

Spironolactone and *eplerenone* are mineralocorticoid receptor antagonists that compete with aldosterone for receptor-binding sites in the collecting tubule and collecting duct epithelial cells and, therefore, can decrease the reabsorption of sodium and secretion of potassium in these tubular segments (see **Figure 28-12**). As a consequence, sodium remains in the tubules and acts as an osmotic diuretic, causing increased excretion of water, as well as sodium. Because these drugs also block the effect of aldosterone to promote potassium secretion in the tubules, they decrease the excretion of potassium.

Mineralocorticoid receptor antagonists also cause movement of potassium from the cells to the extracellular fluid. In some cases, this movement causes extracellular fluid potassium concentration to increase excessively. For this reason, spironolactone and other mineralocorticoid receptor antagonists are referred to as *potassium-sparing diuretics*. Many of the other diuretics cause loss of potassium in the urine, in contrast to the mineralocorticoid receptor antagonists, which spare the loss of potassium.

Sodium Channel Blockers Decrease Sodium Reabsorption in the Collecting Tubules

Amiloride and *triamterene* also inhibit sodium reabsorption and potassium secretion in the collecting tubules, similar to the effects of spironolactone. However, at the cellular level, these drugs act directly to block the entry of sodium into the sodium channels of the luminal membrane of the collecting tubule epithelial cells (see **Figure 28-12**). Because of this decreased sodium entry into the epithelial cells, there is also decreased sodium transport across the cells' basolateral membranes and, therefore, decreased activity of the sodium-potassium-adenosine triphosphatase pump (Na^+-K^+ ATPase pump). This decreased activity reduces the transport of potassium into the cells and ultimately decreases the secretion of potassium into the tubular fluid. For this reason, the sodium channel blockers are also potassium-sparing diuretics and decrease the urinary excretion rate of potassium.

KIDNEY DISEASES

Diseases of the kidneys are among the most important causes of death and disability in many countries throughout the world. For example, in 2018, more than 14% of adults in the United States, or more than 30 million people, were estimated to have chronic kidney disease, and many more millions have acute renal injury or less severe forms of kidney dysfunction.

Severe kidney diseases can be divided into two main categories:

1. *Acute kidney injury* (AKI), in which there is an abrupt loss of kidney function within a few days. The term *acute renal failure* is usually reserved for severe acute kidney injury, in which the kidneys may abruptly stop working entirely or almost entirely, necessitating renal replacement therapy such as dialysis, as discussed later in this chapter. In some cases, patients with AKI may eventually recover nearly normal kidney function.
2. *Chronic kidney disease* (CKD), in which there is progressive loss of function of more and more nephrons that gradually decreases overall kidney function.

Within these two general categories, there are many specific kidney diseases that can affect the kidney blood vessels, glomeruli, tubules, renal interstitium, and parts of the urinary tract outside the kidney, including the ureters and bladder. In this chapter, we discuss specific physiologic abnormalities that occur in a few of the more important types of kidney diseases.

ACUTE KIDNEY INJURY

The causes of AKI are often divided into three main categories:

1. AKI resulting from decreased blood supply to the kidneys. This condition is often referred to as *prerenal AKI* to reflect an abnormality originating outside the kidneys. For example, prerenal AKI can be a consequence of heart failure with reduced cardiac output and low blood pressure or conditions associated with diminished blood volume and low blood pressure, such as severe hemorrhage.
2. *Intrarenal AKI* resulting from abnormalities within the kidney itself, including those that affect the blood vessels, glomeruli, or tubules.
3. *Postrenal AKI*, resulting from obstruction of the urinary collecting system anywhere from the calyces to the outflow from the bladder. The most common causes of obstruction of the urinary tract outside the kidney are kidney stones, caused by precipitation of calcium, urate, or cystine.

In some important causes of AKI, such as sepsis, prerenal (e.g., reduced blood pressure) and intrarenal (endothelial and tubular injury) abnormalities may occur simultaneously.

PRERENAL ACUTE KIDNEY INJURY CAUSED BY DECREASED BLOOD FLOW TO THE KIDNEY

The kidneys normally receive an abundant blood supply of about 1100 ml/min, or about 20% to 25% of the cardiac output. The main purpose of this high blood flow to the kidneys is to provide enough plasma for the high rates of glomerular filtration needed for effective regulation of body fluid volumes and solute concentrations. Therefore, decreased renal blood flow is usually accompanied by decreased GFR and decreased urine output of water and solutes. Consequently, conditions that acutely diminish blood flow to the kidneys usually cause *oliguria*, which refers to diminished urine output below the level of intake of water and solutes. This condition causes accumulation of water and solutes in the body fluids. If renal blood flow is markedly reduced, total cessation of urine output can occur, a condition referred to as *anuria*.

As long as renal blood flow does not fall below about 20% to 25% of normal, AKI can usually be reversed if the cause of the ischemia is corrected before damage to the renal cells has occurred. Unlike some tissues, the kidney can endure a relatively large reduction in blood flow before there is major damage to the renal cells. The reason for this phenomenon is that as renal blood flow is reduced, the GFR and amount of sodium chloride filtered by the glomeruli (as well as the filtration rate of water and other electrolytes) are reduced. This decreases the amount of sodium chloride that must be reabsorbed by the tubules, which use most of the energy and oxygen consumed by the normal kidney. Therefore, as renal blood flow and GFR fall, renal oxygen consumption is also reduced. As the GFR approaches zero, oxygen consumption of the kidney approaches the rate that is required to keep the renal tubular cells alive when they are not reabsorbing sodium. When blood flow is reduced below this basal requirement, which is usually less than 20% to 25% of the normal renal blood flow, the renal cells become hypoxic, and further decreases in renal blood flow, if prolonged, will cause damage or even death of the renal cells, especially the tubular epithelial cells.

If the cause of prerenal AKI is not corrected, and ischemia of the kidney persists longer than a few hours, this type of renal failure can evolve into intrarenal AKI, as discussed later. Acute reduction of renal blood flow is a common cause of AKI in hospitalized patients, especially those who have sustained severe injuries. [Table 32-2](#) shows some of the common causes of decreased renal blood flow and prerenal AKI.

INTRARENAL ACUTE KIDNEY INJURY CAUSED BY ABNORMALITIES IN THE KIDNEY

Abnormalities that originate in the kidney and that abruptly diminish urine output fall into the general category of *intrarenal AKI*. This category of AKI can be

Table 32-2 Some Causes of Prerenal Acute Kidney Injury

Intravascular Volume Depletion
Hemorrhage (e.g., trauma, surgery, postpartum, gastrointestinal)
Diarrhea or vomiting
Burns
Cardiac Failure
Myocardial infarction
Valvular damage
Peripheral vasodilation and resultant hypotension
Anaphylactic shock
Anesthesia
Sepsis, severe infections
Primary renal hemodynamic abnormalities
Renal artery stenosis, embolism, or thrombosis of renal artery or vein

Table 32-3 Some Causes of Intrarenal Acute Kidney Injury

Small vessel and/or glomerular injury
Vasculitis (polyarteritis nodosa)

Malignant hypertension
Acute glomerulonephritis
Tubular epithelial injury (tubular necrosis)
Acute tubular necrosis due to ischemia
Acute tubular necrosis due to toxins (e.g., heavy metals, ethylene glycol, insecticides, poison mushrooms, carbon tetrachloride)
Renal interstitial injury
Acute pyelonephritis
Acute allergic interstitial nephritis

further divided into the following: (1) conditions that injure the glomerular capillaries or other small renal vessels; (2) conditions that damage the renal tubular epithelium; and (3) conditions that cause damage to the renal interstitium. This type of classification refers to the primary site of injury, but because the renal vasculature and tubular system are functionally interdependent, damage to the renal blood vessels can lead to tubular damage, and primary tubular damage can lead to damage of the renal blood vessels. Some causes of intrarenal acute kidney injury are listed in [Table 32-3](#).

Acute Kidney Injury Caused by Glomerulonephritis

Acute glomerulonephritis is a type of *intrarenal AKI* usually caused by an abnormal immune reaction that damages the glomeruli. In about 95% of patients with this disease, damage to the glomeruli occurs 1 to 3 weeks after an infection elsewhere in the body, often caused by

certain types of group A beta streptococci. The infection may have been a streptococcal sore throat, streptococcal tonsillitis, or even streptococcal infection of the skin. It is not the infection itself that damages the kidneys. Instead, over a few weeks, as antibodies develop against the streptococcal antigen, the antibodies and antigen react with each other to form an insoluble immune complex that becomes entrapped in the glomeruli, especially in the basement membrane portion of the glomeruli.

Once the immune complex has been deposited in the glomeruli, many of the glomerular cells begin to proliferate, but mainly the mesangial cells that lie between the endothelium and epithelium. In addition, large numbers of white blood cells become entrapped in the glomeruli. Many of the glomeruli become blocked by this inflammatory reaction, and those that are not blocked usually become excessively permeable, allowing protein and red blood cells to leak from the blood of the glomerular capillaries into the glomerular filtrate. In severe cases, total or almost complete renal shutdown occurs.

The acute inflammation of the glomeruli usually subsides in about 2 weeks and, in most patients, the kidneys return to almost normal function within the next few weeks to few months. Sometimes, however, many of the glomeruli are destroyed beyond repair and, in a small percentage of patients, progressive renal deterioration continues indefinitely, leading to CKD, as described in a subsequent section of this chapter.

Tubular Necrosis as a Cause of Acute Kidney Injury

Another cause of intrarenal acute renal failure is *tubular necrosis*, which means destruction of epithelial cells in the tubules. Some common causes of tubular necrosis are as follows: (1) severe ischemia and inadequate supply of oxygen and nutrients to the tubular epithelial cells; and (2) poisons, toxins, or medications that destroy the tubular epithelial cells.

Acute Tubular Necrosis Caused by Severe Renal Ischemia. Severe ischemia of the kidney can result from circulatory shock or other disturbances that severely impair the blood supply to the kidneys. If the ischemia is severe enough to seriously impair the delivery of nutrients and oxygen to the renal tubular epithelial cells, and if the insult is prolonged, damage or eventual destruction of the epithelial cells can occur. When this damage occurs, tubular cells slough off and plug many of the nephrons so that there is no urine output from the blocked nephrons; the affected nephrons often fail to excrete urine, even when renal blood flow is restored to normal, as long as the tubules remain plugged. The most common causes of ischemic damage to the tubular epithelium are the pre-renal causes of AKI associated with circulatory shock, as discussed earlier in this chapter.

Acute Tubular Necrosis Caused by Toxins or Medications. There is a long list of renal poisons and medications that can damage the tubular epithelium and cause AKI.

Some of these substances are *carbon tetrachloride*, *heavy metals* (e.g., mercury and lead), *ethylene glycol* (which is a major component in antifreeze), various *insecticides*, some *medications* (e.g., tetracyclines) used as antibiotics, and *cis-platinum*, used in treating certain cancers. Each of these substances has a specific toxic action on the renal tubular epithelial cells, causing death of many of them. As a result, the epithelial cells slough away from the basement membrane and plug the tubules. In some cases, the basement membrane also is destroyed. If the basement membrane remains intact, new tubular epithelial cells can grow along the surface of the membrane, so the tubule may repair itself within 10 to 20 days.

POSTRENAL ACUTE KIDNEY INJURY CAUSED BY ABNORMALITIES OF THE LOWER URINARY TRACT

Multiple abnormalities in the lower urinary tract can block or partially block urine flow and therefore lead to AKI, even when the kidneys' blood supply and other functions are initially normal. If the urine output of only one kidney is diminished, no major change in body fluid composition will occur because the contralateral kidney can increase its urine output sufficiently to maintain relatively normal levels of extracellular electrolytes and solutes, as well as normal extracellular fluid volume. With this type of renal injury, normal kidney function can be restored if the basic cause of the problem is corrected within a few hours. However, chronic obstruction of the urinary tract that lasts for several days or weeks can lead to irreversible kidney damage. Some of the causes of postrenal AKI include the following: (1) bilateral obstruction of the ureters or renal pelvises caused by large stones or blood clots; (2) bladder obstruction; and (3) obstruction of the urethra.

PHYSIOLOGICAL EFFECTS OF ACUTE KIDNEY INJURY

A major physiological effect of AKI is the retention of water, waste products of metabolism, and electrolytes in the blood and extracellular fluid. This can lead to water and salt overload, which, in turn, can lead to edema and hypertension. Excessive retention of potassium, however, is often a more serious threat to patients with AKI because increases in the plasma potassium concentration (hyperkalemia) above 8 mEq/L (only twice normal) can be fatal. Because the kidneys are also unable to excrete sufficient hydrogen ions, patients with AKI may experience metabolic acidosis, which in itself can be lethal or can aggravate the hyperkalemia.

In the most severe cases of AKI, complete anuria occurs. The patient will die in 8 to 14 days unless kidney function is restored or unless an artificial kidney is used to rid the body of the excessive retained water, electrolytes, and waste products of metabolism. Other effects of diminished urine output, as well as treatment with an artificial kidney, are discussed in the next section in relation to CKD.

Table 32-4 Some Causes of Chronic Kidney Disease

Hypertrophy of prostate
Urethral constriction
Congenital Disorders
Polycystic disease
Congenital absence of kidney tissue (renal hypoplasia)

CHRONIC KIDNEY DISEASE IS OFTEN ASSOCIATED WITH IRREVERSIBLE LOSS OF FUNCTIONAL NEPHRONS

CKD is usually defined as the presence of kidney damage or decreased kidney function that persists for at least 3 months. CKD is often associated with progressive and irreversible loss of large numbers of functioning nephrons. Serious clinical symptoms usually do not occur until the number of functional nephrons falls to at least 70% to 75% below normal. In fact, relatively normal blood concentrations of most electrolytes and normal body fluid volumes can still be maintained until the number of functioning nephrons decreases below 20% to 25% of normal.

Table 32-4 lists some of the most important causes of CKD. In general, CKD, like AKI, can occur because of disorders of the blood vessels, glomeruli, tubules, renal interstitium, and lower urinary tract. Despite the wide variety of diseases that can lead to CKD, the end result is essentially the same—a decrease in the number of functional nephrons.

VICIOUS CYCLE OF CHRONIC KIDNEY DISEASE LEADING TO END-STAGE RENAL DISEASE

In some cases, an initial insult to the kidney leads to progressive deterioration of kidney function and further loss of nephrons to the point where the person must

Figure 32-2. Shown is the vicious cycle that can occur with primary kidney disease. Loss of nephrons because of disease may increase pressure and flow in the surviving glomerular capillaries, which in turn may eventually injure these normal capillaries as well, thus causing progressive sclerosis and eventual loss of these glomeruli.

undergo dialysis treatment or transplantation with a functional kidney to survive. This condition is referred to as *end-stage renal disease (ESRD)*.

Experimental studies have shown that surgical removal of large portions of the kidney initially causes adaptive changes in the remaining nephrons, which lead to increased blood flow, increased GFR, and increased urine output in the surviving nephrons. The exact mechanisms responsible for these changes are not well understood but involve hypertrophy (growth of the various structures of the surviving nephrons), as well as functional changes that decrease vascular resistance and tubular reabsorption in the surviving nephrons. These adaptive changes permit a person to excrete normal amounts of water and solutes, even when kidney mass is reduced to 20% to 25% of normal. Over a period of several years, however, these renal adaptive changes may lead to further injury of the remaining nephrons, particularly to the glomeruli of these nephrons.

This progressive injury may be related in part to increased pressure or stretch of the remaining glomeruli, which occurs as a result of functional vasodilation of afferent arterioles or increased blood pressure. The chronic increase in pressure and stretch of the small arterioles and glomeruli are believed to cause injury and sclerosis of these vessels (replacement of normal tissue with connective tissue). These sclerotic lesions can eventually obliterate the glomerulus, leading to further reduction in kidney function, further adaptive changes in the remaining nephrons, and a slowly progressing vicious cycle that eventually terminates in ESRD (Figure 32-2). The most effective method of slowing down this progressive loss of kidney function is to lower arterial pressure and glomerular

Table 32-5 Most Common Causes of End-Stage Renal Disease (ESRD)

Other, unknown	18

hydrostatic pressure, especially by using drugs such as angiotensin-converting enzyme (ACE) inhibitors or Ang II receptor antagonists.

Table 32-5 lists the most common causes of ESRD. In the early 1980s, *glomerulonephritis* in all its various forms was believed to be the most common initiating cause of ESRD. More recently, *diabetes mellitus* and *hypertension* have become recognized as the leading causes of ESRD, together accounting for more than 70% of all ESRD.

Excessive weight gain (obesity) appears to be the most important risk factor for the two main causes of ESRD—diabetes and hypertension. As discussed in **Chapter 79**, type 2 diabetes, which is closely linked to obesity, accounts for more than 90% of all cases of diabetes mellitus. Excess weight gain is also a major cause of essential hypertension, accounting for 65% to 75% of the risk for developing hypertension in adults. In addition to causing renal injury through diabetes and hypertension, obesity may have additive or synergistic effects to worsen renal function in patients with pre-existing kidney disease.

INJURY TO RENAL BLOOD VESSELS AS A CAUSE OF CHRONIC KIDNEY DISEASE

Many types of vascular lesions can lead to renal ischemia and death of kidney tissue. The most common of these lesions are the following: (1) *atherosclerosis* of the larger renal arteries, with progressive sclerotic constriction of the vessels; (2) *fibromuscular hyperplasia* of one or more of the large arteries, which also causes occlusion of the vessels; and (3) *nephrosclerosis*, caused by sclerotic lesions of the smaller arteries, arterioles, and glomeruli.

Atherosclerotic or hyperplastic lesions of the large arteries frequently affect one kidney more than the other and, therefore, cause unilaterally diminished kidney function. As discussed in **Chapter 19**, hypertension often occurs when the artery of one kidney is constricted while the artery of the other kidney is still normal, a condition analogous to so-called two-kidney Goldblatt hypertension.

Benign nephrosclerosis, the most common form of kidney disease, is seen to at least some extent in about 70% of postmortem examinations in people who die after the age of 60 years. This type of vascular lesion occurs in the smaller interlobular arteries and in the afferent arterioles of the kidney. It is believed to begin with leakage of plasma

**Figure 32-3.** Effect of aging on the number of functional glomeruli.

through the intimal membrane of these vessels. This leakage causes fibrinoid deposits to develop in the medial layers of these vessels, followed by progressive thickening of the vessel wall that eventually constricts the vessels and, in some cases, occludes them. Because there is essentially no collateral circulation among the smaller renal arteries, occlusion of one or more of them causes destruction of a comparable number of nephrons. Therefore, much of the kidney tissue becomes replaced by small amounts of fibrous tissue. When sclerosis occurs in the glomeruli, the injury is referred to as *glomerulosclerosis*.

Nephrosclerosis and glomerulosclerosis occur to some extent in most people after the fourth decade of life, causing about a 10% decrease in the number of functional nephrons for every 10 years after the age of 40 years (**Figure 32-3**). This loss of glomeruli and overall nephron function is reflected by a progressive decrease in renal blood flow and GFR. Even in healthy people without underlying hypertension or diabetes, renal plasma flow and GFR may decrease by 40% to 50% by the age of 80 years.

The frequency and severity of nephrosclerosis and glomerulosclerosis are greatly increased by concurrent *hypertension* or *diabetes mellitus*. Thus, benign nephrosclerosis in association with severe hypertension can lead to a rapidly progressing *malignant nephrosclerosis*. The characteristic histological features of malignant nephrosclerosis include large amounts of fibrinoid deposits in the arterioles and progressive thickening of the vessels, with severe ischemia occurring in the affected nephrons. For unknown reasons, the incidence of malignant nephrosclerosis and severe glomerulosclerosis is significantly higher in blacks than in whites of similar ages who have similar degrees of severity of hypertension or diabetes.

INJURY TO THE GLOMERULI AS A CAUSE OF CHRONIC KIDNEY DISEASE—GLOMERULONEPHRITIS

Chronic glomerulonephritis can be caused by several diseases that cause inflammation and damage to the glomerular capillary loops of the kidneys. In contrast to the acute form of this disease, chronic glomerulonephritis is a

slowly progressive disease that often leads to irreversible renal failure. It may be a primary kidney disease, following acute glomerulonephritis, or it may be secondary to a systemic disease, such as *systemic lupus erythematosus*.

In most cases, chronic glomerulonephritis begins with accumulation of precipitated antigen-antibody complexes in the glomerular membrane. In contrast to acute glomerulonephritis, streptococcal infections account for only a small percentage of patients with the chronic form of glomerulonephritis. Accumulation of antigen-antibody complex in the glomerular membranes causes inflammation, progressive thickening of the membranes, and eventual invasion of the glomeruli by fibrous tissue. In later stages of the disease, the glomerular capillary filtration coefficient becomes greatly reduced because of decreased numbers of filtering capillaries in the glomerular tufts and because of thickened glomerular membranes. In the final stages of the disease, many glomeruli are replaced by fibrous tissue and are unable to filter fluid.

INJURY TO THE RENAL INTERSTITIUM AS A CAUSE OF CHRONIC KIDNEY DISEASE—INTERSTITIAL NEPHRITIS

Primary or secondary disease of the renal interstitium is referred to as *interstitial nephritis*. In general, this condition can result from vascular, glomerular, or tubular damage that destroys individual nephrons, or it can involve primary damage to the renal interstitium by poisons, drugs, and bacterial infections.

Renal interstitial injury caused by bacterial infection is called *pyelonephritis*. The infection can result from different types of bacteria but especially from *Escherichia coli*, which originate from fecal contamination of the urinary tract. These bacteria reach the kidneys either by way of the blood stream or, more commonly, by ascension from the lower urinary tract via the ureters to the kidneys.

Although the normal bladder is able to clear bacteria readily, there are two general clinical conditions that may interfere with the normal flushing of bacteria from the bladder: (1) the inability of the bladder to empty completely, leaving residual urine in the bladder; and (2) obstruction of urine outflow. With impaired ability to flush bacteria from the bladder, the bacteria multiply, and the bladder becomes inflamed, a condition termed *cystitis*. Once cystitis occurs, it may remain localized without ascending to the kidney or, in some people, bacteria may reach the renal pelvis because of a pathological condition in which urine is propelled up one or both of the ureters during micturition. This condition is called *vesicoureteral reflux* and is due to failure of the bladder wall to occlude the ureter during micturition; as a result, some of the urine is propelled upward toward the kidney, carrying with it bacteria that can reach the renal pelvis and renal medulla, where they can initiate infection and inflammation associated with pyelonephritis.

Pyelonephritis begins in the renal medulla and therefore usually affects the function of the medulla more than it affects the cortex, at least in the initial stages. Because

one of the primary functions of the medulla is to provide the countercurrent mechanism for concentrating urine, patients with pyelonephritis frequently have markedly impaired ability to concentrate the urine.

With long-standing pyelonephritis, invasion of the kidneys by bacteria not only causes damage to the renal medulla interstitium but also progressive damage of renal tubules, glomeruli, and other structures throughout the kidney. Consequently, large parts of functional renal tissue are lost, and CKD can develop.

NEPHROTIC SYNDROME—EXCRETION OF PROTEIN IN THE URINE

Nephrotic syndrome, characterized by the loss of large quantities of plasma proteins into the urine, develops in many patients with kidney disease. In some cases, this syndrome occurs without evidence of other major abnormalities of kidney function, but it is usually associated with some degree of CKD.

The cause of the protein loss in the urine is usually increased permeability of the glomerular membrane. Therefore, any disease that increases the permeability of this membrane can cause the nephrotic syndrome. Such diseases include the following: (1) *chronic glomerulonephritis*, which affects primarily the glomeruli and often causes greatly increased permeability of the glomerular membrane; (2) *amyloidosis*, which results from deposition of an abnormal proteinoid substance in the walls of the blood vessels and seriously damages the basement membrane of the glomeruli; and (3) *minimal-change nephrotic syndrome*, which is associated with no major abnormality in the glomerular capillary membrane that can be detected with light microscopy. As discussed in [Chapter 27](#), minimal-change nephropathy has been associated with an abnormal immune response and increased T-cell secretion of cytokines that cause podocyte injury and increased permeability to lower molecular weight proteins, such as albumin.

Minimal-change nephropathy can occur in adults, but more frequently it occurs in children between the ages of 2 and 6 years. Increased permeability of the glomerular capillary membrane occasionally allows as much as 40 grams of plasma protein loss into the urine each day, which is an extreme amount for a young child. Therefore, the child's plasma protein concentration often falls below 2 g/dl, and the colloid osmotic pressure falls from a normal value of 28 mm Hg to less than 10 mm Hg. As a consequence of this low colloid osmotic pressure in the plasma, large amounts of fluid leak from the capillaries all over the body into most of the tissues, causing severe edema, as discussed in [Chapter 25](#).

NEPHRON FUNCTION IN CHRONIC KIDNEY DISEASE

Loss of Functional Nephrons Requires Surviving Nephrons to Excrete More Water and Solutes. It would be reasonable to suspect that decreasing the number of

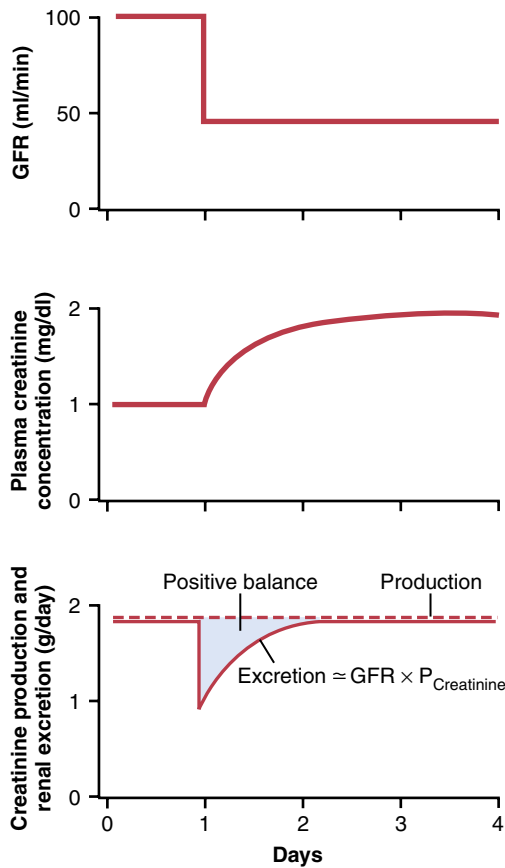

Figure 32-4. Effect of reducing the glomerular filtration rate (GFR) by 50% on the serum creatinine concentration and creatinine excretion rate when the production rate of creatinine remains constant.

functional nephrons, which reduces the GFR, would also cause major decreases in renal excretion of water and solutes. Yet, patients who have lost up to 75% to 80% of their nephrons are able to excrete normal amounts of water and electrolytes without serious accumulation of fluid or most electrolytes in the body fluids. Further reduction in the number of nephrons, however, leads to electrolyte and fluid retention, and death usually ensues when the number of nephrons falls below 5% to 10% of normal.

In contrast to the electrolytes, many of the waste products of metabolism, such as urea and creatinine, accumulate almost in proportion to the number of nephrons that have been destroyed. The reason for this is that substances such as creatinine and urea depend largely on glomerular filtration for their excretion, and they are not reabsorbed as avidly as the electrolytes. Creatinine, for example, is not reabsorbed at all, and the excretion rate is approximately equal to the rate at which it is filtered (neglecting the small amount that is secreted):

$$\begin{aligned} \text{Creatinine filtration rate} \\ &= \text{GFR} \times \text{Plasma creatinine concentration} \\ &= \text{Creatinine excretion rate} \end{aligned}$$

Therefore, if GFR decreases, creatinine excretion rate also transiently decreases, causing accumulation of creatinine in the body fluids and raising plasma concentration

Figure 32-5. Representative patterns of adaptation for different types of solutes in chronic renal failure. Curve A shows the approximate changes in the plasma concentrations of solutes such as creatinine and urea that are filtered and poorly reabsorbed. Curve B shows the approximate concentrations for solutes such as phosphate, urate, and hydrogen ion. Curve C shows the approximate concentrations for solutes such as sodium and chloride.

until excretion rate of creatinine returns to normal—the same rate at which creatinine is produced in the body (Figure 32-4). Thus, under steady-state conditions, creatinine excretion rate equals the rate of creatinine production, despite reductions in GFR; however, this normal rate of creatinine excretion occurs at the expense of an elevated plasma creatinine concentration, as shown in curve A of Figure 32-4.

Some solutes, such as phosphate, urate, and hydrogen ions, are often maintained near the normal range until GFR falls below 20% to 30% of normal. Thereafter, the plasma concentrations of these substances rise, but not in proportion to the fall in GFR, as shown in curve B of Figure 32-5. Maintenance of relatively constant plasma concentrations of these solutes as GFR declines is accomplished by excreting progressively larger fractions of the amounts of these solutes that are filtered at the glomerular capillaries; this occurs by decreasing the rate of tubular reabsorption or, in some cases, by increasing tubular secretion rates.

In the case of sodium and chloride ions, their plasma concentrations are maintained virtually constant, even with severe decreases in GFR (see curve C of Figure 32-5). This maintenance is accomplished by greatly decreasing tubular reabsorption of these electrolytes.

For example, with a 75% loss of functional nephrons, each surviving nephron must excrete four times as much sodium and four times as much volume as under normal conditions (Table 32-6). Part of this adaptation occurs because of increased blood flow and increased GFR in each of the surviving nephrons due to hypertrophy of the

Table 32-6 Total Kidney Excretion and Excretion per Nephron in Kidney Disease

	Normal	75% Loss of Nephrons
Number of nephrons	2,000,000	500,000
Total glomerular filtration rate (GFR; ml/min)	125	40
Single-nephron GFR (nl/min)	62.5	80
Volume excreted for all nephrons (ml/min)	1.5	1.5
Volume excreted per nephron (nl/min)	0.75	3.0

Figure 32-6. Development of isosthenuria in a patient with decreased numbers of functional nephrons.

blood vessels and glomeruli, as well as functional changes that cause the blood vessels to dilate. Even with large decreases in the total GFR, normal rates of renal excretion can still be maintained by decreasing the rate at which the tubules reabsorb water and solutes.

Isosthenuria—Inability of the Kidney to Concentrate or Dilute the Urine. One important effect of the rapid rate of tubular flow that occurs in the remaining nephrons of diseased kidneys is that the renal tubules lose their ability to concentrate or dilute the urine fully. The concentrating ability of the kidney is impaired mainly because of the following: (1) the rapid flow of tubular fluid through the collecting ducts prevents adequate water reabsorption; and (2) the rapid flow through both the loop of Henle and collecting ducts prevents the countercurrent mechanism from operating effectively to concentrate the medullary interstitial fluid solutes. Therefore, as progressively more nephrons are destroyed, the maximum concentrating ability of the kidney declines, and urine osmolarity and specific gravity approach the osmolarity and specific gravity of the glomerular filtrate, as shown in [Figure 32-6](#).

The diluting mechanism in the kidney is also impaired when the number of nephrons decreases markedly because the rapid flushing of fluid through the loops of Henle and high load of solutes such as urea cause a relatively high solute concentration in the tubular fluid of this part of the nephron. As a consequence, the diluting capacity of the

Figure 32-7. Effect of kidney failure on extracellular fluid constituents. NPN, Nonprotein nitrogens.

kidney is impaired, and the minimal urine osmolality and specific gravity approach those of the glomerular filtrate. Because the concentrating mechanism becomes impaired to a greater extent than the diluting mechanism in CKD, an important clinical test of renal function is to determine how well the kidneys can concentrate urine when a person's water intake is restricted for 12 or more hours.

Effects of Renal Failure on the Body Fluids—Uremia

The effect of CKD on the body fluids depends on the following: (1) water and food intake; and (2) the degree of impairment of renal function. Assuming that a person with complete renal failure continues to ingest the same amounts of water and food, the concentrations of different substances in the extracellular fluid would change, as shown in [Figure 32-7](#). Important effects include: (1) *generalized edema* resulting from water and salt retention; (2) *acidosis* resulting from failure of the kidneys to rid the body of normal acidic products; (3) *high concentration of the nonprotein nitrogens*—especially urea, creatinine, and uric acid—resulting from failure of the body to excrete the metabolic end products of proteins; and (4) *high concentrations of other substances* excreted by the kidney, including *phenols, sulfates, phosphates, potassium, and guanidine bases*. This total condition is called *uremia* because of the high concentration of urea in the body fluids.

Water Retention and Development of Edema in Chronic Kidney Disease. If water intake is restricted immediately after acute kidney injury begins, the total body fluid content may become only slightly increased. If fluid intake is not limited, and the patient drinks in response to the normal thirst mechanisms, the body fluids begin to increase rapidly.

As long as salt and fluid intake are not excessive, accumulation of fluid in CKD may not be severe until kidney function falls to 25% of normal or lower. The reason for this, as discussed previously, is that the surviving nephrons excrete larger amounts of salt and water. Even the small fluid retention that does occur, along with increased secretion of renin and Ang II formation that usually occurs in ischemic kidney disease, often causes severe hypertension. When kidney function is so reduced that dialysis is required to preserve life, hypertension almost invariably develops.

In many of these patients, severe reduction of salt intake or removal of extracellular fluid by dialysis can control the hypertension. Some patients continue to have hypertension, even after excess sodium has been removed by dialysis. In this group, removal of the ischemic kidneys usually corrects the hypertension (as long as fluid retention is prevented by dialysis) because it removes the source of excessive renin secretion and subsequent increased Ang II formation.

Increase in Urea and Other Nonprotein Nitrogens (Azotemia). The nonprotein nitrogens include urea, uric acid, creatinine, and a few less important compounds. These nonprotein nitrogens, in general, are the end products of protein metabolism and must be removed from the body to ensure continued normal protein metabolism in the cells. The concentrations of these nonprotein nitrogens, particularly of urea, can rise to as high as 10 times normal during 1 to 2 weeks of total renal failure. With CKD, the concentrations rise approximately in proportion to the degree of reduction of GFR. For this reason, measuring the concentrations of these substances, especially of urea and creatinine, provides an important means for assessing the severity of CKD.

Acidosis in CKD. Each day, the body normally produces about 50 to 80 millimoles more metabolic acid than metabolic alkali. Therefore, when the kidneys fail to function, acid accumulates in the body fluids. The buffers of the body fluids normally can buffer 500 to 1000 millimoles of acid without lethal increases in extracellular fluid H^+ concentration, and the phosphate compounds in the bones can buffer an additional few thousand millimoles of H^+ . However, when this buffering power is exhausted, the blood pH falls drastically, and the patient will become comatose and die if the pH falls below about 6.8.

Anemia in Chronic Kidney Disease Caused by Decreased Erythropoietin Secretion. Anemia almost always develops in patients with severe CKD. The most important cause of this anemia is decreased renal secretion of *erythropoietin*, which stimulates the bone marrow to produce red blood cells. If the kidneys are seriously damaged, they are unable to form adequate quantities of erythropoietin, which leads to diminished red blood cell production and consequent anemia.

The availability since 1989 of recombinant erythropoietin, however, has provided a means of treating anemia in patients with chronic renal failure.

Osteomalacia in Chronic Kidney Disease Caused by Decreased Production of Active Vitamin D and by Phosphate Retention by the Kidneys. Prolonged CKD also causes *osteomalacia*, a condition in which the bones are partially absorbed and, therefore, become greatly weakened. An important cause of osteomalacia is that vitamin D must be converted by a two-stage process, first in the liver and then in the kidneys, into 1,25-dihydroxycholecalciferol before it is able to promote calcium absorption from the intestine. Therefore, serious damage to the kidney greatly reduces the blood concentration of *active* vitamin D, which in turn decreases intestinal absorption of calcium and availability of calcium to the bones.

Another important cause of demineralization of the skeleton in CKD is the rise in serum phosphate concentration that occurs as a result of decreased GFR. This rise in serum phosphate level increases binding of phosphate with calcium in the plasma, thus decreasing plasma serum

ionized calcium concentration, which, in turn, stimulates *parathyroid hormone* secretion. This secondary hyperparathyroidism then stimulates the release of calcium from bones, causing further bone demineralization.

Hypertension and Kidney Disease

As discussed earlier in this chapter, hypertension can exacerbate injury to the glomeruli and blood vessels of the kidneys and is a major cause of ESRD. Abnormalities of kidney function can also cause hypertension, as discussed in [Chapter 19](#). Thus, the relationship between hypertension and kidney disease can, in some cases, propagate a vicious cycle—primary kidney damage leads to increased blood pressure, which causes further damage to the kidneys and further increases in blood pressure, until ESRD develops.

Not all types of kidney disease cause hypertension because damage to certain portions of the kidney causes uremia without hypertension. Nevertheless, some types of renal damage are particularly prone to cause hypertension. A classification of kidney disease relative to hypertensive or nonhypertensive effects is provided in the following sections.

Renal Lesions That Reduce the Ability of the Kidneys to Excrete Sodium and Water Promote Hypertension. Renal lesions that decrease the ability of the kidneys to excrete sodium and water almost invariably cause hypertension. Therefore, lesions that *decrease GFR* or *increase tubular reabsorption* usually lead to hypertension of varying degrees. Some specific types of renal abnormalities that can cause hypertension are as follows:

1. *Increased renal vascular resistance*, which reduces renal blood flow and GFR. An example is hypertension caused by renal artery stenosis.
2. *Decreased glomerular capillary filtration coefficient, which reduces GFR*. An example is chronic glomerulonephritis, which causes inflammation and thickening of the glomerular capillary membranes, thereby reducing the glomerular capillary filtration coefficient.
3. *Excessive tubular sodium reabsorption*. An example is hypertension caused by excessive aldosterone secretion, which increases sodium reabsorption mainly in the cortical collecting tubules.

Once hypertension has developed, renal excretion of sodium and water returns to normal because the high arterial pressure causes pressure natriuresis and pressure diuresis, so intake and output of sodium and water become balanced once again. Even when there are large increases in renal vascular resistance or decreases in the glomerular capillary coefficient, GFR may still return to nearly normal levels after the arterial blood pressure rises. Likewise, when tubular reabsorption is increased, as occurs with excessive aldosterone secretion, the urinary excretion rate is initially reduced but then returns to normal as arterial pressure rises. Thus, after hypertension develops, there may be no obvious sign of impaired excretion of sodium and water other than the hypertension. As explained in [Chapter 19](#), normal excretion of sodium and water at an elevated arterial pressure means that pressure natriuresis and pressure diuresis have been reset to a higher arterial pressure.

Hypertension Caused by Patchy Renal Damage and Increased Renal Secretion of Renin. If one part of the kidney is ischemic, and the remainder is not ischemic, such as when one renal artery is severely constricted, the ischemic

renal tissue secretes large quantities of renin. This secretion leads to increased formation of Ang II, which can cause hypertension. The most likely sequence of events in causing this hypertension, as discussed in [Chapter 19](#), is as follows: (1) the ischemic kidney tissue excretes less than normal amounts of water and salt; (2) the renin secreted by the ischemic kidney, as well as the subsequent increased Ang II formation, affects the nonischemic kidney tissue, causing it also to retain salt and water; and (3) excess salt and water cause hypertension in the usual manner.

A similar type of hypertension can result when patchy areas of one or both kidneys become ischemic as a result of arteriosclerosis or vascular injury in specific portions of the kidneys. When this occurs, the ischemic nephrons excrete less salt and water but secrete greater amounts of renin, which causes increased Ang II formation. The high levels of Ang II then impair the ability of the surrounding, otherwise normal nephrons to excrete sodium and water. As a result, hypertension develops, which restores the overall excretion of sodium and water by the kidney, so balance between intake and output of salt and water is maintained, but at the expense of high blood pressure.

Kidney Diseases That Cause Loss of Entire Nephrons Lead to Chronic Kidney Disease but May Not Cause Hypertension

Loss of large numbers of whole nephrons, such as occurs with the loss of one kidney and part of another kidney, almost always leads to CKD if the loss of kidney tissue is great enough. If the remaining nephrons are normal, and salt intake is not excessive, this condition might not cause clinically significant hypertension. This is because even a slight rise in blood pressure will raise GFR and decrease tubular sodium reabsorption in the surviving nephrons sufficiently to promote enough water and salt excretion in the urine, even with the few nephrons that remain intact. However, a patient with this type of abnormality may become severely hypertensive if additional stresses are imposed, such as eating a large amount of salt. In this case, the kidneys simply cannot clear adequate quantities of salt at a normal blood pressure with the small number of functioning nephrons that remain. Increased blood pressure restores excretion of salt and water to match intake of salt and water under steady-state conditions.

Effective treatment of hypertension requires enhancing the kidneys' capability to excrete salt and water by increasing GFR or by decreasing tubular reabsorption, so that balance between intake and renal excretion of salt and water excretion can be maintained at a lower blood pressure. This effect can be achieved by drugs that block the effects of nervous and hormonal signals that cause the kidneys to retain salt and water (e.g., with β -adrenergic blockers, Ang II receptor antagonists, or ACE inhibitors), with drugs that vasodilate the kidneys and increase GFR (e.g., calcium channel blockers), or with diuretic drugs that directly inhibit renal tubular reabsorption of salt and water.

Specific Tubular Disorders

In [Chapter 28](#), we discussed several mechanisms responsible for transporting different individual substances across the tubular epithelial membranes. In [Chapter 3](#), we also pointed out that each cellular enzyme and each carrier

protein is formed in response to a respective gene in the nucleus. If any required gene happens to be absent or abnormal, the tubules may be deficient in one of the appropriate carrier proteins or one of the enzymes needed for solute transport by the renal tubular epithelial cells. In other cases, too much of the enzyme or carrier protein is produced. Thus, many hereditary tubular disorders occur because of abnormal transport of individual substances or groups of substances through the tubular membrane. In addition, damage to the tubular epithelial membrane by toxins or ischemia can cause important renal tubular disorders.

Renal Glycosuria—Failure of the Kidneys to Reabsorb Glucose. In renal glycosuria, the blood glucose concentration may be normal, but the transport mechanism for tubular reabsorption of glucose is greatly limited or absent. Consequently, despite a normal blood glucose level, large amounts of glucose pass into the urine each day. Because diabetes mellitus is also associated with the presence of glucose in the urine, renal glycosuria, which is a relatively benign condition, must be ruled out before making the diagnosis of diabetes mellitus.

Aminoaciduria—Failure of the Kidneys to Reabsorb Amino Acids. Some amino acids share mutual transport systems for reabsorption, whereas other amino acids have their own distinct transport systems. Rarely, a condition called *generalized aminoaciduria* results from deficient reabsorption of all amino acids. More frequently, deficiencies of specific carrier systems may result in the following: (1) *essential cystinuria*, in which large amounts of cystine fail to be reabsorbed and often crystallize in the urine to form renal stones; (2) *simple glycinuria*, in which glycine fails to be reabsorbed; or (3) *beta-aminoisobutyricaciduria*, which occurs in about 5% of the population but apparently has no major clinical significance.

Renal Hypophosphatemia—Failure of the Kidneys to Reabsorb Phosphate. In renal hypophosphatemia, the renal tubules fail to reabsorb large enough phosphate ions when the phosphate concentration of the body fluids falls very low. This condition usually does not cause serious immediate abnormalities because the phosphate concentration of the extracellular fluid can vary widely without causing major cellular dysfunction. Over a long period, however, a low phosphate level causes diminished calcification of the bones, causing *rickets* to develop. This type of rickets is refractory to vitamin D therapy, in contrast to the rapid response of the usual type of rickets, as discussed in [Chapter 80](#).

Renal Tubular Acidosis—Reduced Tubular Secretion of Hydrogen Ions. In renal tubular acidosis, the renal tubules are unable to secrete adequate amounts of hydrogen ions. As a result, large amounts of sodium bicarbonate are continually lost in the urine. This loss causes a continued state of metabolic acidosis, as discussed in [Chapter 31](#). This type of renal abnormality can be caused by hereditary disorders or can occur as a result of widespread injury to the renal tubules.

Nephrogenic Diabetes Insipidus—Failure of the Kidneys to Respond to Antidiuretic Hormone. Occasionally, the renal tubules do not respond to antidiuretic hormone, causing large quantities of dilute urine to be excreted. As long as the person is supplied with plenty of water, this condition seldom causes severe difficulty. However, when adequate quantities of water are not available, the person rapidly becomes dehydrated.

Fanconi Syndrome—Generalized Reabsorptive Defect of the Renal Tubules. Fanconi syndrome is usually associated with increased urinary excretion of virtually all amino acids, glucose, and phosphate. In severe cases, other manifestations are also observed, such as (1) failure to reabsorb sodium bicarbonate, which results in metabolic acidosis; (2) increased excretion of potassium and sometimes calcium; and (3) nephrogenic diabetes insipidus.

There are multiple causes of Fanconi syndrome, which results from a generalized inability of the renal tubular cells to transport various substances. Some of these include the following: (1) hereditary defects in cell transport mechanisms; (2) toxins or drugs that injure the renal tubular epithelial cells; and (3) injury to the renal tubular cells as a result of ischemia. The proximal tubular cells are especially affected in Fanconi syndrome caused by tubular injury because these cells reabsorb and secrete many of the drugs and toxins that can cause damage.

Bartter Syndrome—Decreased Sodium, Chloride, and Potassium Reabsorption in the Loops of Henle. *Bartter syndrome* is a rare group of kidney disorders caused by mutations that impair function of the 1-sodium, 2-chloride, 1-potassium co-transporter or by defects in potassium channels in the luminal membrane or chloride channels in the basolateral membrane of the thick ascending loop of Henle. At least five mutations, usually inherited in an autosomal recessive manner, have been found to cause Bartter syndrome. These disorders result in increased excretion of water, sodium, chloride, potassium, and calcium by the kidneys. The salt and water loss leads to mild volume depletion, resulting in activation of the renin-angiotensin-aldosterone system (RAAS). The increased aldosterone and high distal tubular flow, due to impaired loop of Henle reabsorption, stimulate potassium and hydrogen secretion in the collecting tubules, leading to hypokalemia and metabolic alkalosis.

Gitelman Syndrome—Decreased Sodium Chloride Reabsorption in the Distal Tubules. *Gitelman syndrome* is an autosomal-recessive disorder of the thiazide-sensitive sodium-chloride co-transporter in the distal tubules. Patients with Gitelman syndrome have some of the same characteristics as patients with Bartter syndrome—salt and water loss, mild water volume depletion, and activation of the renin-angiotensin-aldosterone system—although these abnormalities are usually less severe in persons with Gitelman syndrome.

Because the tubular defects in Bartter or Gitelman syndrome cannot currently be corrected, treatment is usually focused on replacing the losses of sodium chloride and potassium. Some studies have suggested that blockade of prostaglandin synthesis with nonsteroidal antiinflammatory drugs (NSAIDs) and administration of aldosterone antagonists, such as spironolactone, may be useful in correcting the hypokalemia.

Liddle Syndrome—Increased Sodium Reabsorption. *Liddle syndrome* is a rare autosomal-dominant disorder resulting from various mutations in the amiloride-sensitive epithelial sodium channel (ENaC) in the distal and collecting tubules. These mutations cause excessive activity of ENaC, resulting in increased reabsorption of sodium and water, hypertension, and metabolic alkalosis similar to the changes that occur with oversecretion of aldosterone (primary aldosteronism).

Patients with Liddle syndrome, however, have sodium retention and decreased renin secretion and Ang II levels,

which, in turn, decrease adrenal secretion of aldosterone. Fortunately, Liddle syndrome can be treated with the diuretic amiloride, which blocks the excessive ENaC activity.

Treatment of Renal Failure by Transplantation or Dialysis With an Artificial Kidney

Severe loss of kidney function, acutely or chronically, is life-threatening and requires removal of toxic waste products and restoration of body fluid volume and composition toward normal. This can be accomplished by kidney transplantation or by dialysis with an artificial kidney. Over 700,000 patients in the United States are currently receiving some form of ESRD therapy.

Successful transplantation of a single donor kidney to a patient with ESRD can restore kidney function to a level sufficient to maintain essentially normal homeostasis of body fluids and electrolytes. Approximately 19,000 kidney transplantations are performed each year in the United States, but over 100,000 patients await kidney transplantation. Patients who receive kidney transplants typically live longer and have fewer health problems than those who are maintained with dialysis. Maintenance of immunosuppressive therapy is required for almost all patients to help prevent acute rejection and loss of the transplanted kidney. The side effects of drugs that suppress the immune system include increased risk for infections and some cancers, although the amount of immunosuppressive therapy can usually be reduced over time to reduce these risks greatly.

Over 475,000 people in the United States who have irreversible renal failure or total kidney removal are being maintained chronically by dialysis with artificial kidneys. Dialysis is also used in certain types of AKI to tide the patient over until the kidneys resume their function. If the loss of kidney function is irreversible, it is necessary to perform dialysis chronically to maintain life. Because dialysis cannot maintain completely normal body fluid composition and cannot replace all the multiple functions performed by the kidneys, the health of patients maintained with the use of artificial kidneys usually remains significantly impaired.

Basic Principles of Dialysis

The basic principle of the artificial kidney is to pass blood through minute blood channels bounded by a thin membrane. On the other side of the membrane is a *dialyzing fluid* into which unwanted substances in the blood pass by diffusion.

Figure 32-8 shows the components of one type of artificial kidney in which blood flows continually between two thin membranes of cellophane; outside the membrane is a dialyzing fluid. The cellophane is porous enough to allow the constituents of the plasma, except the plasma proteins, to diffuse in both directions—from plasma into the dialyzing fluid or from the dialyzing fluid back into the plasma. If the concentration of a substance is higher in the plasma than in the dialyzing fluid, there will be a *net* transfer of the substance from the plasma into the dialyzing fluid.

The rate of movement of solute across the dialyzing membrane depends on the following: (1) the concentration gradient of the solute between the two solutions; (2) the permeability of the membrane to the solute; (3) the surface area of the membrane; and (4) the length of time that the blood and fluid remain in contact with the membrane.

Table 32-7 Comparison of Dialyzing Fluid With Normal and Uremic Plasma

Constituent	Normal Plasma	Dialyzing Fluid	Uremic Plasma
Electrolytes (mEq/L)			
Na ⁺	142	133	142
K ⁺	5	1.0	7
Ca ²⁺	3	3.0	2
Mg ²⁺	1.5	1.5	1.5
Cl ⁻	107	105	107
HCO ₃ ⁻	24	35.7	14
Lactate ⁻	1.2	1.2	1.2
HPO ₄ ²⁻	3	0	9
Urate ⁻	0.3	0	2
Sulfate ⁼	0.5	0	3
Nonelectrolytes			
Glucose	100	125	100
Urea	26	0	200
Creatinine	1	0	6

Thus, the maximum rate of solute transfer occurs initially when the concentration gradient is greatest (when dialysis is begun) and slows down as the concentration gradient is dissipated. In a flowing system, as is the case with hemodialysis, in which blood and dialysate fluid flow through the artificial kidney, the dissipation of the concentration gradient can be reduced, and diffusion of solute across the membrane can be optimized, by increasing the flow rate of the blood, dialyzing fluid, or both.

In normal operation of the artificial kidney, blood flows continually or intermittently back into the vein. The total amount of blood in the artificial kidney at any one time is usually less than 500 milliliters, the rate of flow may be several hundred milliliters per minute, and the total diffusion surface area is between 0.6 and 2.5 m². To prevent coagulation of the blood in the artificial kidney, a small amount of heparin is infused into the blood as it enters the artificial kidney. In addition to the diffusion of solutes, mass transfer of solutes and water can be produced by applying a hydrostatic pressure to force the fluid and solutes across the membranes of the dialyzer; this type of filtration is called *bulk flow* or *hemofiltration*.

Dialyzing Fluid

Table 32-7 compares the constituents in a typical dialyzing fluid with those in normal plasma and uremic plasma. Note that the concentrations of ions and other substances in dialyzing fluid are not the same as the concentrations in normal plasma or in uremic plasma. Instead, they are adjusted to levels needed to cause the appropriate movement of water and solutes through the membrane during dialysis.

Note that there is no phosphate, urea, urate, sulfate, or creatinine in the dialyzing fluid; however, these substances are present in high concentrations in the uremic blood. Therefore, when a uremic patient undergoes dialysis, these substances are lost in large quantities into the dialyzing fluid.

Figure 32-8. Principles of dialysis with an artificial kidney.

The effectiveness of the artificial kidney can be expressed in terms of the amount of plasma that is cleared of different substances each minute, which, as discussed in [Chapter 28](#), is the primary means for expressing the functional effectiveness of the kidneys themselves to rid the body of unwanted substances. Most artificial kidneys can clear urea from the plasma at a rate of 100 to 225 ml/min, which shows that at least for the excretion of urea, the artificial kidney can function about twice as rapidly as two normal kidneys together, whose urea clearance is only 70 ml/min. Yet, the artificial kidney is used only for 4 to 6 hours/day, three times a week. Therefore, the overall plasma clearance is still considerably limited when the artificial kidney replaces the normal kidneys. Also, it is important to keep in mind that the artificial kidney cannot replace some of the other functions of the kidneys, such as secretion of erythropoietin, which is necessary for red blood cell production.

Red Blood Cells, Anemia, and Polycythemia

In this chapter, we begin discussing the *blood cells* and cells of the *macrophage system* and *lymphatic system*. We first present the functions of red blood cells (RBCs), which are the most abundant cells of the blood and are necessary for the delivery of oxygen to the tissues.

RED BLOOD CELLS (ERYTHROCYTES)

A major function of RBCs, also known as *erythrocytes*, is to transport *hemoglobin*, which, in turn, carries oxygen from the lungs to the tissues. In some animals, including many invertebrates, hemoglobin circulates as free protein in the circulatory fluids and is not enclosed in RBCs. When it is free in human plasma, about 3% of it leaks through the capillary membrane into the tissue spaces or through the glomerular membrane of the kidney into the glomerular filtrate each time the blood passes through the capillaries. Therefore, hemoglobin must remain inside RBCs to perform its functions in humans effectively.

The RBCs have other functions besides transport of hemoglobin. For example, they contain a large quantity of *carbonic anhydrase*, an enzyme that catalyzes the reversible reaction between carbon dioxide (CO_2) and water to form carbonic acid (H_2CO_3), increasing the rate of this reaction several thousandfold. The rapidity of this reaction makes it possible for the water of the blood to transport enormous quantities of CO_2 in the form of bicarbonate ion (HCO_3^-) from the tissues to the lungs, where it is reconverted to CO_2 and expelled into the atmosphere as a body waste product. The hemoglobin in the cells is an excellent *acid-base buffer* (as is true of most proteins), so the RBCs are responsible for most of the acid-base buffering power of whole blood.

Shape and Size of Red Blood Cells. Normal RBCs, shown in [Figure 33-3](#), are biconcave discs having a mean diameter of about 7.8 micrometers and a thickness of 2.5 micrometers at the thickest point and 1 micrometer or less in the center. The average volume of the RBC is 90 to 95 cubic micrometers.

The shapes of RBCs can change remarkably as the cells squeeze through capillaries. Actually, the RBC resembles a bag that can be deformed into almost any shape.

Furthermore, because the normal cell has a great excess of cell membrane for the quantity of material inside, deformation does not stretch the membrane greatly and, consequently, does not rupture the cell, as would be the case with many other cells.

Concentration of Red Blood Cells in the Blood. In healthy men, the average number of RBCs per cubic millimeter is 5,200,000 ($\pm 300,000$); in healthy women, it is 4,700,000 ($\pm 300,000$). Persons living at high altitudes have greater numbers of RBCs, as discussed later.

Quantity of Hemoglobin in the Cells. RBCs can concentrate hemoglobin in the cell fluid up to about 34 g/100 ml of cells. The concentration does not rise above this value because this is the metabolic limit of the cell's hemoglobin-forming mechanism. Furthermore, in normal people, the percentage of hemoglobin is almost always near the maximum in each cell. However, when hemoglobin formation is deficient, the percentage of hemoglobin in the cells may fall considerably below this value, and the volume of the RBC may also decrease because of diminished hemoglobin to fill the cell.

When the hematocrit (the percentage of blood that is comprised of cells—normally, 40% to 45%) and the quantity of hemoglobin in each respective cell are normal, the whole blood of men contains an average of 15 g hemoglobin/100 ml; for women, it contains an average of 14 g hemoglobin/100 ml.

As discussed in connection with blood transport of oxygen in [Chapter 41](#), each gram of hemoglobin can combine with 1.34 ml of oxygen if the hemoglobin is 100% saturated. Therefore, in the average man, a maximum of about 20 milliliters of oxygen can be carried in combination with hemoglobin in each 100 milliliters of blood, and in woman 19 milliliters of oxygen can be carried.

PRODUCTION OF RED BLOOD CELLS

Areas of the Body That Produce Red Blood Cells. In the early weeks of embryonic life, primitive nucleated RBCs are produced in the *yolk sac*. During the middle trimester of gestation, the *liver* is the main organ for RBC production but reasonable numbers are also produced in

the *spleen* and *lymph nodes*. Then, during the last month or so of gestation and after birth, RBCs are produced exclusively in the *bone marrow*.

As illustrated in **Figure 33-1**, the marrow of essentially all bones produces RBCs until a person is about 5 years old. The marrow of the long bones, except for the proximal portions of the humeri and tibiae, becomes fatty and produces no more RBCs after about the age of 20 years. Beyond this age, most RBCs continue to be produced in the marrow of the membranous bones, such as the vertebrae, sternum, ribs, and ilia. Even in these bones, the marrow becomes less productive as age increases.

Figure 33-1. Relative rates of red blood cell production in the bone marrow of different bones at different ages.

Genesis of Blood Cells

Multipotential Hematopoietic Stem Cells, Growth Inducers, and Differentiation Inducers. The blood cells begin their lives in the bone marrow from a single type of cell called the *multipotential hematopoietic stem cell*, from which all the cells of the circulating blood are eventually derived. **Figure 33-2** shows the successive divisions of the multipotential cells to form the different circulating blood cells. As these cells reproduce, a small portion of them remains exactly like the original multipotential cells and is retained in the bone marrow to maintain their supply, although their numbers diminish with age. Most of the reproduced cells, however, differentiate to form the other cell types, shown at the right in **Figure 33-2**. The intermediate-stage cells are very much like the multipotential stem cells, even though they have already become committed to a particular line of cells; these are called *committed stem cells*.

The different committed stem cells, when grown in culture, will produce colonies of specific types of blood cells. A committed stem cell that produces erythrocytes is called a *colony-forming unit–erythrocyte*, and the abbreviation CFU-E is used to designate this type of stem cell. Likewise, colony-forming units that form granulocytes and monocytes have the designation CFU-GM, and so forth.

Growth and reproduction of the different stem cells are controlled by multiple proteins called *growth inducers*.

Figure 33-2. Formation of the multiple different blood cells from the original multipotent hematopoietic stem cell in the bone marrow.

Figure 33-3. Genesis of normal red blood cells (RBCs) and characteristics of RBCs in different types of anemias.

At least four major growth inducers have been described, each having different characteristics. One of these, *interleukin-3*, promotes growth and reproduction of virtually all the different types of committed stem cells, whereas the others induce growth of only specific types of cells.

The growth inducers promote growth but not differentiation of the cells, which is the function of another set of proteins called *differentiation inducers*. Each of these differentiation inducers causes one type of committed stem cell to differentiate one or more steps toward a final adult blood cell.

Formation of the growth inducers and differentiation inducers is controlled by factors outside the bone marrow. For example, in the case of RBCs, exposure of the blood to a low oxygen level for a long time causes growth induction, differentiation, and production of greatly increased numbers of RBCs, as discussed later in this chapter. In the case of some of the white blood cells, infectious diseases cause growth, differentiation, and eventual formation of specific types of white blood cells that are needed to combat each infection.

Stages of Differentiation of Red Blood Cells

The first cell that can be identified as belonging to the RBC series is the *proerythroblast*, shown at the starting point in [Figure 33-3](#). Under appropriate stimulation, large numbers of these cells are formed from the CFU-E stem cells.

Once the proerythroblast has been formed, it divides multiple times, eventually forming many mature RBCs.

The first-generation cells are called *basophil erythroblasts* because they stain with basic dyes. Hemoglobin first appears in *polychromatophil erythroblasts*. In the succeeding generations, as shown in [Figure 33-3](#), the cells become filled with hemoglobin to a concentration of about 34%, the nucleus condenses to a small size, and its final remnant is absorbed or extruded from the cell. At the same time, the endoplasmic reticulum is also reabsorbed. The cell at this stage is called a *reticulocyte* because it still contains a small amount of basophilic material, consisting of remnants of the Golgi apparatus, mitochondria, and a few other cytoplasmic organelles. During this reticulocyte stage, the cells pass from the bone marrow into the blood capillaries by *diapedesis* (squeezing through the pores of the capillary membrane).

The remaining basophilic material in the reticulocyte normally disappears within 1 to 2 days, and the cell is then a *mature erythrocyte*. Because of the short life of the reticulocytes, their concentration among all the RBCs is normally slightly less than 1%.

Erythropoietin Regulates Red Blood Cell Production

The total mass of RBCs in the circulatory system is regulated within narrow limits, and thus (1) an adequate number of RBCs are always available to provide sufficient transport of oxygen from the lungs to the tissues, yet (2) the cells do not become so numerous that they impede blood flow. This control mechanism is diagrammed in [Figure 33-4](#) and is described in the following sections.

Figure 33-4. Function of the erythropoietin mechanism to increase production of red blood cells when tissue oxygenation decreases.

Tissue Oxygenation—Essential Regulator of Red Blood Cell Production. Conditions that decrease the quantity of oxygen transported to the tissues ordinarily increase the rate of RBC production. Thus, when a person becomes extremely *anemic* as a result of hemorrhage or any other condition, the bone marrow begins to produce large quantities of RBCs. Also, destruction of major portions of the bone marrow, especially by x-ray therapy, causes hyperplasia of the remaining bone marrow in an attempt to supply the body's need for RBCs.

At very *high altitudes*, where the quantity of oxygen in the air is greatly decreased, insufficient oxygen is transported to the tissues, and RBC production is greatly increased. In this case, it is not the concentration of RBCs in the blood that controls RBC production but the amount of oxygen transported to the tissues in relation to tissue demand for oxygen.

Various diseases of the circulation that decrease tissue blood flow, particularly those that cause failure of oxygen absorption by the blood as it passes through the lungs, can also increase the rate of RBC production. This result is especially apparent in prolonged *cardiac failure* and in many *lung diseases* because the tissue hypoxia resulting from these conditions increases RBC production, with a resultant increase in hematocrit and, usually, total blood volume.

Hypoxia Increases Formation of Erythropoietin Which Stimulates Red Blood Cell Production. The principal stimulus for RBC production in a low oxygen state is a circulating hormone called *erythropoietin*, a glycoprotein with a molecular weight of about 34,000. In the absence of erythropoietin, hypoxia has little or no effect to stimulate RBC production. However, when the erythropoietin system is functional, hypoxia causes a marked increase

in erythropoietin production and the erythropoietin, in turn, enhances RBC production until the hypoxia is relieved.

Erythropoietin Is Formed Mainly in the Kidneys. Normally, about 90% of all erythropoietin is formed in the kidneys, and the remainder is formed mainly in the liver. It is not known exactly where in the kidneys the erythropoietin is formed. Some studies have suggested that erythropoietin is secreted mainly by fibroblast-like interstitial cells surrounding the tubules in the cortex and outer medulla, where much of the kidney's oxygen consumption occurs. It is likely that other cells, including the renal epithelial cells, also secrete erythropoietin in response to hypoxia.

Renal tissue hypoxia leads to increased tissue levels of *hypoxia-inducible factor-1* (HIF-1), which serves as a transcription factor for a large number of hypoxia-inducible genes, including the erythropoietin gene. HIF-1 binds to a *hypoxia response element* in the erythropoietin gene, inducing transcription of messenger RNA and, ultimately, increased erythropoietin synthesis.

At times, hypoxia in other parts of the body, but not in the kidneys, stimulates kidney erythropoietin secretion, which suggests that there might be some nonrenal sensor that sends an additional signal to the kidneys to produce this hormone. In particular, norepinephrine and epinephrine and several of the prostaglandins stimulate erythropoietin production.

When both kidneys are removed from a person, or when the kidneys are destroyed by renal disease, the person invariably becomes very anemic. This is because the 10% of the normal erythropoietin formed in other tissues (mainly in the liver) is sufficient to cause only one third to half the RBC formation needed by the body.

Erythropoietin Stimulates Production of Proerythroblasts From Hematopoietic Stem Cells. When an animal or person is placed in an atmosphere of low oxygen, erythropoietin begins to be formed within minutes to hours, and it reaches maximum production within 24 hours. Yet, almost no new RBCs appear in the circulating blood until about 5 days later. From this, as well as from other studies, it has been determined that the important effect of erythropoietin is to stimulate production of proerythroblasts from hematopoietic stem cells in the bone marrow. In addition, once the proerythroblasts are formed, the erythropoietin causes these cells to pass more rapidly through the different erythroblastic stages than they normally do, further speeding up the production of new RBCs. The rapid production of cells continues as long as the person remains in a low oxygen state or until enough RBCs have been produced to carry adequate amounts of oxygen to the tissues despite the low level of oxygen; at this time, the rate of erythropoietin production decreases to a level that will maintain the required number of RBCs but not an excess.

In the absence of erythropoietin, few RBCs are formed by the bone marrow. At the other extreme, when large quantities of erythropoietin are formed, and if plenty of iron and other required nutrients are available, the rate of RBC production can rise to perhaps 10 or more times normal. Therefore, the erythropoietin mechanism for controlling RBC production is a powerful one.

Maturation of Red Blood Cells Requires Vitamin B₁₂ (Cyanocobalamin) and Folic Acid

Because of the continuing need to replenish RBCs, the erythropoietic cells of the bone marrow are among the most rapidly growing and reproducing cells in the entire body. Therefore, as would be expected, their maturation and rate of production are affected greatly by a person's nutritional status.

Especially important for final maturation of the RBCs are two vitamins, *vitamin B₁₂* and *folic acid*. Both these vitamins are essential for synthesis of DNA because each, in a different way, is required for formation of thymidine triphosphate, one of the essential building blocks of DNA. Therefore, lack of vitamin B₁₂ or folic acid causes abnormal and diminished DNA and, consequently, failure of nuclear maturation and cell division. Furthermore, the erythroblastic cells of the bone marrow, in addition to failing to proliferate rapidly, produce mainly larger than normal RBCs called *macrocytes*, which have a flimsy membrane and are often irregular, large, and oval instead of the usual biconcave disc. These poorly formed cells, after entering the circulating blood, are capable of carrying oxygen normally, but their fragility causes them to have a short life, half to one-third normal. Therefore, deficiency of vitamin B₁₂ or folic acid causes *maturation failure* in the process of erythropoiesis.

Maturation Failure Anemia Caused by Poor Absorption of Vitamin B₁₂ From the Gastrointestinal Tract—Pernicious Anemia. A common cause of RBC maturation failure is failure to absorb vitamin B₁₂ from the gastrointestinal tract. This situation often occurs in the disease *pernicious anemia*, in which the basic abnormality is an *atrophic gastric mucosa* that fails to produce normal gastric secretions. The parietal cells of the gastric glands secrete a glycoprotein called *intrinsic factor*, which combines with vitamin B₁₂ in food and makes the B₁₂ available for absorption by the gut in the following way:

1. Intrinsic factor binds tightly with the vitamin B₁₂. In this bound state, vitamin B₁₂ is protected from digestion by the gastrointestinal secretions.
2. Still in the bound state, intrinsic factor binds to specific receptor sites on the brush border membranes of the mucosal cells in the ileum.
3. Vitamin B₁₂ is then transported into the blood during the next few hours by the process of pinocytosis, carrying intrinsic factor and the vitamin together through the membrane.

Lack of intrinsic factor, therefore, decreases availability of vitamin B₁₂ because of faulty absorption of the vitamin.

Once vitamin B₁₂ has been absorbed from the gastrointestinal tract, it is first stored in large quantities in the liver and then released slowly as needed by the bone marrow. The minimum amount of vitamin B₁₂ required each day to maintain normal RBC maturation is only 1 to 3 micrograms, and the normal storage in the liver and other body tissues is about 1000 times this amount. Therefore, 3 to 4 years of defective vitamin B₁₂ absorption are usually required to cause maturation failure anemia.

Maturation Failure Anemia Caused by Folic Acid (Pteroylglutamic Acid) Deficiency. Folic acid is a normal constituent of green vegetables, some fruits, and meats (especially liver). However, it is easily destroyed during cooking. Also, people with gastrointestinal absorption abnormalities, such as the frequently occurring small intestinal disease called *sprue*, often have serious difficulty absorbing both folic acid and vitamin B₁₂. Therefore, in many cases of maturation failure, the cause is deficiency of intestinal absorption of folic acid and vitamin B₁₂.

HEMOGLOBIN FORMATION

The synthesis of hemoglobin begins in polychromatophil erythroblasts and continues even into the reticulocyte stage of the RBCs. Therefore, when reticulocytes leave the bone marrow and pass into the blood stream, they continue to form minute quantities of hemoglobin for another day or so until they become mature erythrocytes.

Figure 33-5 shows the basic chemical steps in the formation of hemoglobin. First, succinyl-CoA, which is formed in the Krebs metabolic cycle (as explained in **Chapter 68**), binds with glycine to form a pyrrole molecule. In turn, four pyrroles combine to form protoporphyrin IX, which then combines with iron to form the *heme* molecule. Finally, each heme molecule combines with a long polypeptide chain, a *globin* synthesized by ribosomes, forming a subunit of hemoglobin called a *hemoglobin chain* (**Figure 33-6**). Each chain has a molecular weight of about 16,000; four of these chains, in turn, bind together loosely to form the whole hemoglobin molecule.

There are several slight variations in the different subunit hemoglobin chains, depending on the amino acid

Figure 33-5. Formation of hemoglobin.

Figure 33-6. Basic structure of the heme moiety, showing one of the four heme chains that along with globin polypeptide, bind together to form the hemoglobin molecule.

composition of the polypeptide portion. The different types of chains are designated as *alpha* (α) chains, *beta* (β) chains, (γ) *gamma* chains, and (δ) *delta* chains. The most common form of hemoglobin in adults, *hemoglobin A*, is a combination of *two alpha chains* and *two beta chains*. Hemoglobin A has a molecular weight of 64,458.

Because each hemoglobin chain has a heme prosthetic group containing an atom of iron, and because there are four hemoglobin chains in each hemoglobin molecule, one finds four iron atoms in each hemoglobin molecule. Each of these can bind loosely with one molecule of oxygen, making a total of four molecules of oxygen (or eight oxygen atoms) that can be transported by each hemoglobin molecule.

The types of hemoglobin chains in the hemoglobin molecule determine the binding affinity of the hemoglobin for oxygen. Abnormalities of the chains can alter the physical characteristics of the hemoglobin molecule as well. For example, in *sickle cell anemia*, the amino acid *valine* is substituted for *glutamic acid* at one point in each of the two beta chains. When this type of hemoglobin is exposed to low oxygen, it forms elongated crystals inside the RBCs that are sometimes 15 micrometers in length. These crystals make it almost impossible for the cells to pass through many small capillaries, and the spiked ends of the crystals are likely to rupture the cell membranes, leading to sickle cell anemia.

Hemoglobin Combines Reversibly With Oxygen. The most important feature of the hemoglobin molecule is its ability to combine loosely and reversibly with oxygen. This ability is discussed in detail in [Chapter 41](#) in relation to respiration because the primary function of hemoglobin in the body is to combine with oxygen in the lungs

and then to release this oxygen readily in the peripheral tissue capillaries, where the gaseous tension of oxygen is much lower than in the lungs.

Oxygen *does not* combine with the two positive bonds of the iron in the hemoglobin molecule. Instead, it binds loosely with one of the so-called coordination bonds of the iron atom. This bond is extremely loose, so the combination is easily reversible. Furthermore, the oxygen does not become ionic oxygen but is carried as molecular oxygen (composed of two oxygen atoms) to the tissues, where, because of the loose, readily reversible combination, it is released into the tissue fluids still in the form of molecular oxygen rather than ionic oxygen.

IRON METABOLISM

Because iron is important for the formation not only of hemoglobin but also of other essential elements in the body (e.g., *myoglobin*, *cytochromes*, *cytochrome oxidase*, *peroxidase*, and *catalase*), it is important to understand the means whereby iron is used in the body. The total quantity of iron in the body averages 4 to 5 grams, about 65% of which is in the form of hemoglobin. About 4% is in the form of myoglobin, 1% is in the form of the various heme compounds that promote intracellular oxidation, 0.1% is combined with the protein transferrin in the blood plasma, and 15% to 30% is stored for later use, mainly in the reticuloendothelial system and liver parenchymal cells, principally in the form of ferritin.

Transport and Storage of Iron. Transport, storage, and metabolism of iron in the body are diagrammed in [Figure 33-7](#) and can be explained as follows. When iron is absorbed from the small intestine, it immediately combines in the blood plasma with a beta globulin, *apotransferrin*, to form *transferrin*, which is then transported in the plasma. The iron is loosely bound in the transferrin and, consequently, can be released to any tissue cell at any point in the body. Excess iron in the blood is deposited *especially* in the liver hepatocytes and less in the reticuloendothelial cells of the bone marrow.

In the cell cytoplasm, iron combines mainly with a protein, *apoferritin*, to form *ferritin*. Apoferritin has a molecular weight of about 460,000, and varying quantities of iron can combine in clusters of iron radicals with this large molecule; therefore, ferritin may contain only a small or a large amount of iron. This iron stored as ferritin is called *storage iron*.

Smaller quantities of the iron in the storage pool are in an extremely insoluble form called *hemosiderin*. This is especially true when the total quantity of iron in the body is more than the apoferritin storage pool can accommodate. Hemosiderin collects in cells in the form of large clusters that can be observed microscopically as large particles. In contrast, ferritin particles are so small and dispersed that they usually can be seen in the cell cytoplasm only with an electron microscope.

When the quantity of iron in the plasma falls low, some of the iron in the ferritin storage pool is removed easily and transported in the form of transferrin in the plasma to the areas of the body where it is needed. A unique characteristic of the transferrin molecule is that it binds strongly with receptors in the cell membranes of erythroblasts in the bone marrow. Then, along with its bound iron, it is ingested into the erythroblasts by endocytosis. There the transferrin delivers the iron directly to the mitochondria, where heme is synthesized. In people who do not have adequate quantities of transferrin in their blood, failure to transport iron to the erythroblasts in this manner can cause severe *hypochromic anemia* (i.e., RBCs that contain much less hemoglobin than normal).

When RBCs have lived their life span of about 120 days and are destroyed, the hemoglobin released from the cells is ingested by monocyte-macrophage cells. There, iron is liberated and is stored mainly in the ferritin pool to be used as needed for the formation of new hemoglobin.

Daily Loss of Iron. An average man excretes about 0.6 mg of iron each day, mainly into the feces. Additional quantities of iron are lost when bleeding occurs. For a woman, additional menstrual loss of blood brings long-term iron loss to an average of about 1.3 mg/day.

Absorption of Iron From the Intestinal Tract

Iron is absorbed from all parts of the small intestine, mostly by the following mechanism. The liver secretes moderate amounts of *apotransferrin* into the bile, which flows through the bile duct into the duodenum. Here, the apotransferrin binds with free iron and also with certain iron compounds, such as hemoglobin and myoglobin from meat, two of the most important sources of iron in the diet. This combination is called *transferrin*. In turn, it is attracted to and binds with receptors in the membranes of intestinal epithelial cells. Then, by pinocytosis, the transferrin molecule, carrying its iron store, is absorbed into the epithelial cells and later released into the blood capillaries beneath these cells in the form of *plasma transferrin*.

Iron absorption from the intestines is extremely slow, at a maximum rate of only a few milligrams per day. This slow rate of absorption means that even when tremendous quantities of iron are present in the food, only small proportions can be absorbed.

Regulation of Total Body Iron by Controlling Absorption Rate. When the body becomes saturated with iron so that essentially all apoferritin in the iron storage areas is already combined with iron, the rate of additional iron absorption from the intestinal tract markedly decreases. Conversely, when the iron stores become depleted, the rate of absorption can probably accelerate five or more times normal. Thus, total body iron is regulated mainly by altering the rate of absorption.

LIFE SPAN OF RED BLOOD CELLS IS ABOUT 120 DAYS

When RBCs are delivered from the bone marrow into the circulatory system, they normally circulate an average of 120 days before being destroyed. Even though mature RBCs do not have a nucleus, mitochondria, or endoplasmic reticulum, they do have cytoplasmic enzymes that are capable of metabolizing glucose and forming small amounts of adenosine triphosphate. These enzymes also do the following: (1) maintain pliability of the cell membrane; (2) maintain membrane transport of ions; (3) keep the iron of the cells' hemoglobin in the ferrous form rather than the ferric form; and (4) prevent oxidation of the proteins in the RBCs. Even so, the metabolic systems of old RBCs become progressively less active, and the cells become more and more fragile, presumably because their life processes wear out.

Once the RBC membrane becomes fragile, the cell ruptures during passage through some tight spot of the circulation. Many of the RBCs self-destruct in the spleen, where they squeeze through the red pulp of the spleen. There, the spaces between the structural trabeculae of the red pulp, through which most of the cells must pass, are only 3 micrometers wide, in comparison with the 8-micrometer diameter of the RBC. When the spleen is removed, the number of old abnormal RBCs circulating in the blood increases considerably.

Destruction of Hemoglobin by Macrophages. When RBCs burst and release their hemoglobin, the hemoglobin is phagocytized almost immediately by macrophages in many parts of the body, but especially by the Kupffer cells of the liver and macrophages of the spleen and bone marrow. During the next few hours to days, the macrophages release iron from the hemoglobin and pass it back into the blood to be carried by transferrin either to the bone marrow for production of new RBCs or to the liver and other tissues for storage in the form of ferritin. The porphyrin portion of the hemoglobin molecule is converted by the macrophages, through a series of stages, into the bile pigment *bilirubin*, which is released into the blood and later removed from the body by secretion through the liver into the bile. This process is discussed in relation to liver function in [Chapter 71](#).

ANEMIAS

Anemia means deficiency of hemoglobin in the blood, which can be caused by too few RBCs or too little hemoglobin in the cells. Some types of anemia and their physiological causes are described in the following sections.

Blood Loss Anemia. After rapid hemorrhage, the body replaces the fluid portion of the plasma in 1 to 3 days, but this response results in a low concentration of RBCs. If a second hemorrhage does not occur, the RBC concentration usually returns to normal within 3 to 6 weeks.

When chronic blood loss occurs, a person frequently cannot absorb enough iron from the intestines to form hemoglobin as rapidly as it is lost. RBCs that are much smaller than normal and have too little hemoglobin inside them are then produced, giving rise to *microcytic hypochromic anemia*, which is shown in [Figure 33-3](#).

Aplastic Anemia Due to Bone Marrow Dysfunction. Bone marrow aplasia means lack of functioning bone marrow. For example, exposure to high-dose radiation or chemotherapy for cancer treatment can damage stem cells of the bone marrow, followed in a few weeks by anemia. Likewise, high doses of certain toxic chemicals, such as insecticides or benzene in gasoline, may cause the same effect. In autoimmune disorders, such as lupus erythematosus, the immune system begins attacking healthy cells such as bone marrow stem cells, which may lead to aplastic anemia. In about half of aplastic anemia cases the cause is unknown, a condition called *idiopathic aplastic anemia*.

People with severe aplastic anemia usually die unless they are treated with blood transfusions—which can temporarily increase the numbers of RBCs—or by bone marrow transplantation.

Megaloblastic Anemia. Based on the earlier discussions of vitamin B₁₂, folic acid, and intrinsic factor from the stomach mucosa, one can readily understand that loss of any one of these can lead to slow reproduction of erythroblasts in the bone marrow. As a result, the RBCs grow too large, with odd shapes, and are called *megaloblasts*. Thus, atrophy of the stomach mucosa, as occurs in *pernicious anemia*, or loss of the entire stomach after surgical total *gastrectomy* can lead to megaloblastic anemia. Also, megaloblastic anemia often develops in patients who have *intestinal sprue*, in which folic acid, vitamin B₁₂, and other vitamin B compounds are poorly absorbed. Because the erythroblasts in these states cannot proliferate rapidly enough to form normal numbers of RBCs, the RBCs that are formed are mostly oversized, have bizarre shapes, and have fragile membranes. These cells rupture easily, leaving the person in dire need of an adequate number of RBCs.

Hemolytic Anemia. Different abnormalities of the RBCs, many of which are acquired through hereditary, make the cells fragile, so they rupture easily as they go through the capillaries, especially through the spleen. Even though

the number of RBCs formed may be normal, or even much greater than normal in some hemolytic diseases, the life span of the fragile RBC is so short that the cells are destroyed faster than they can be formed, and serious anemia results.

In *hereditary spherocytosis*, the RBCs are very small and *spherical* rather than being biconcave discs. These cells cannot withstand compression forces because they do not have the normal loose, baglike cell membrane structure of the biconcave discs. On passing through the splenic pulp and some other tight vascular beds, they are easily ruptured by even slight compression.

In *sickle cell anemia*, which is present in 0.3% to 1.0% of West African and American blacks, the cells have an abnormal type of hemoglobin called *hemoglobin S*, containing faulty beta chains in the hemoglobin molecule, as explained earlier in this chapter. When this hemoglobin is exposed to low concentrations of oxygen, it precipitates into long crystals inside the RBC. These crystals elongate the cell and give it the appearance of a sickle rather than a biconcave disc. The precipitated hemoglobin also damages the cell membrane, so the cells become highly fragile, leading to serious anemia. Such patients frequently experience a vicious circle of events called a *sickle cell disease crisis*, in which low oxygen tension in the tissues causes sickling, which leads to ruptured RBCs, which causes a further decrease in oxygen tension and still more sickling and RBC destruction. Once the process starts, it progresses rapidly, eventuating in a serious decrease in RBCs within a few hours and, in some cases, death.

In *erythroblastosis fetalis*, Rh-positive RBCs in the fetus are attacked by antibodies from an Rh-negative mother. These antibodies make the Rh-positive cells fragile, leading to rapid rupture and causing the child to be born with a serious case of anemia. This condition is discussed in [Chapter 36](#) in relation to the Rh factor of blood. The extremely rapid formation of new RBCs to make up for the destroyed cells in erythroblastosis fetalis causes a large number of early *blast* forms of RBCs to be released from the bone marrow into the blood.

EFFECTS OF ANEMIA ON CIRCULATORY SYSTEM FUNCTION

The viscosity of the blood, which was discussed in [Chapter 14](#), depends largely on the blood concentration of RBCs. In persons with severe anemia, the blood viscosity may fall to as low as 1.5 times that of water rather than the normal value of about 3. This change decreases the resistance to blood flow in the peripheral blood vessels, so far greater than normal quantities of blood flow through the tissues and return to the heart, thereby greatly increasing cardiac output. Moreover, hypoxia resulting from diminished transport of oxygen by the blood causes the peripheral tissue blood vessels to dilate, allowing a further increase in the return of blood to the heart and increasing the cardiac output to a still higher level—sometimes three to four times normal. Thus, one of the major effects of anemia is greatly *increased cardiac output*, as well as *increased pumping workload on the heart*.

The increased cardiac output in persons with anemia partially offsets the reduced oxygen-carrying effect of the anemia because, even though each unit quantity of blood carries only small quantities of oxygen, the rate of blood flow may be increased enough that almost normal quantities of oxygen are actually delivered to the tissues. However, when a person with anemia begins to exercise, the heart is not capable of pumping much greater quantities of blood than it is already pumping. Consequently, during exercise, which greatly increases tissue demand for oxygen, extreme tissue hypoxia results and *acute cardiac failure* may ensue.

POLYCYTHEMIA

Secondary Polycythemia. Whenever the tissues become hypoxic because of too little oxygen in the breathed air, such as at high altitudes, or because of failure of oxygen delivery to the tissues, such as in cardiac failure, the blood-forming organs automatically produce large quantities of extra RBCs. This condition is called *secondary polycythemia*, and the RBC count commonly rises to 6 to 7 million/mm³, about 30% above normal.

A common type of secondary polycythemia, called *physiological polycythemia*, occurs in those who live at altitudes of 14,000 to 17,000 feet, where the atmospheric oxygen is very low. The blood count is generally 6 to 7 million/mm³, which allows these people to perform reasonably high levels of continuous work, even in a rarefied atmosphere.

Polycythemia Vera (Erythremia). In addition to physiological polycythemia, a pathological condition known as *polycythemia vera* exists, in which the RBC count may be 7 to 8 million/mm³ and the hematocrit may be 60% to 70% instead of the normal 40% to 45%. Polycythemia vera is caused by a genetic aberration in the hemocytoblastic cells that produce the blood cells. The blast cells no longer stop producing RBCs when too many cells are already present. This causes excess production of RBCs in the same manner that a breast tumor causes excess production of a specific type of breast cell. It usually causes excess production of white blood cells and platelets as well.

In polycythemia vera, not only does the hematocrit increase, but the total blood volume also increases, sometimes to almost twice normal. As a result, the entire vascular system becomes intensely engorged. Also, many blood capillaries become plugged by the viscous blood; the viscosity of the blood in polycythemia vera sometimes increases from the normal of 3 times the viscosity of water to 10 times that of water.

EFFECT OF POLYCYTHEMIA ON FUNCTION OF THE CIRCULATORY SYSTEM

Because of the greatly increased viscosity of blood in polycythemia, blood flow through the peripheral blood vessels is often very sluggish. In accordance with the factors

that regulate return of blood to the heart, as discussed in [Chapter 20](#), increasing blood viscosity *decreases* the rate of venous return to the heart. Conversely, the blood volume is greatly increased in polycythemia, which tends to *increase* venous return. Actually, the cardiac output in polycythemia is not far from normal because these two factors more or less neutralize each other.

The arterial pressure is also normal in most people with polycythemia, although in about one-third of them, the arterial pressure is elevated. This means that the blood pressure–regulating mechanisms can usually offset the tendency for increased blood viscosity to increase peripheral resistance and, thereby, increase arterial pressure. Beyond certain limits, however, these regulations fail, and hypertension develops.

The color of the skin depends to a great extent on the quantity of blood in the skin subpapillary venous plexus. In polycythemia vera, the quantity of blood in this plexus is greatly increased. Furthermore, because blood passes sluggishly through the skin capillaries before entering the venous plexus, a larger than normal quantity of hemoglobin is deoxygenated. The blue color of all this deoxygenated hemoglobin masks the red color of the oxygenated hemoglobin. Therefore, a person with polycythemia vera ordinarily has a ruddy complexion, with a bluish (cyanotic) tint to the skin.

Resistance of the Body to Infection: I. Leukocytes, Granulocytes, the Monocyte-Macrophage System, and Inflammation

Our bodies are exposed continually to bacteria, viruses, fungi, and parasites, all of which occur normally and to varying degrees in the skin, mouth, respiratory passageways, intestinal tract, lining membranes of the eyes, and even the urinary tract. Many of these infectious agents are capable of causing serious abnormal physiological function or even death if they invade deeper tissues. We are also exposed intermittently to other highly infectious bacteria and viruses besides those that are normally present, and these agents can cause acute lethal diseases such as pneumonia, streptococcal infection, and typhoid fever.

Our bodies have a special system for combating the different infectious and toxic agents. This system is composed of blood leukocytes (white blood cells [WBCs]) and tissue cells derived from leukocytes. These cells work together in two ways to prevent disease: (1) by actually destroying invading bacteria or viruses by *phagocytosis*; and (2) by forming *antibodies* and *sensitized lymphocytes* that may destroy or inactivate the invader. This chapter discusses the first of these methods, and [Chapter 35](#) discusses the second.

LEUKOCYTES (WHITE BLOOD CELLS)

The leukocytes, also called *white blood cells*, are the *mobile units* of the body's protective system. They are formed partially in the bone marrow (*granulocytes* and *monocytes* and a few *lymphocytes*) and partially in the lymph tissue (*lymphocytes* and *plasma cells*). After formation, they are transported in the blood to different parts of the body where they are needed.

The real value of WBCs is that most of them are specifically transported to areas of serious infection and inflammation, thereby providing a rapid and potent defense against infectious agents. As we see later, the granulocytes and monocytes have a special ability to “seek out and destroy” a foreign invader.

GENERAL CHARACTERISTICS OF LEUKOCYTES

Types of White Blood Cells. Six types of WBCs are normally present in the blood: *neutrophils* (*polymorphonuclear*),

eosinophils (*polymorphonuclear*), *basophils* (*polymorphonuclear*), *monocytes*, *lymphocytes* and, occasionally, *plasma cells*. In addition, there are large numbers of *platelets*, which are fragments of another type of cell similar to the WBCs found in the bone marrow, the *megakaryocyte*. The first three types of cells, the polymorphonuclear cells, all have a granular appearance, as shown in cell numbers 7, 10, and 12 in [Figure 34-1](#), and for this reason they are called *granulocytes*.

The granulocytes and monocytes protect the body against invading organisms by ingesting them (by *phagocytosis*) or by releasing antimicrobial or inflammatory substances that have multiple effects that aid in destroying the offending organism. The lymphocytes and plasma cells function mainly in connection with the immune system, as discussed in [Chapter 35](#). Finally, the function of platelets is specifically to activate the blood-clotting mechanism, discussed in [Chapter 37](#).

Concentrations of Different White Blood Cells in Blood. An adult human has about 7000 WBCs per *microliter* of blood (in comparison with 5 million red blood cells [RBCs] per microliter). Of the total WBCs, the normal percentages of the different types are approximately the following:

- Neutrophils: 62.0%
- Eosinophils: 2.3%
- Basophils: 0.4%
- Monocytes: 5.3%
- Lymphocytes: 30.0%

The number of platelets, which are only cell fragments, in each microliter of blood is normally between 150,000 and 450,000, averaging about 300,000.

GENESIS OF WHITE BLOOD CELLS

Early differentiation of the multipotential hematopoietic stem cell into the different types of committed stem cells was shown in [Figure 33-2](#) in the previous chapter. Aside from the cells committed to form RBCs, two major lineages of WBCs are formed, the myelocytic and lymphocytic lineages. The left side of [Figure 34-1](#) shows the

Figure 34-1. Genesis of white blood cells. The different cells of the myelocyte series are shown: 1, myeloblast; 2, promyelocyte; 3, megakaryocyte; 4, neutrophil myelocyte; 5, young neutrophil metamyelocyte; 6, band neutrophil metamyelocyte; 7, neutrophil; 8, eosinophil myelocyte; 9, eosinophil metamyelocyte; 10, eosinophil; 11, basophil myelocyte; 12, basophil; 13–16, stages of monocyte formation.

myelocytic lineage, beginning with the *myeloblast*; the right side shows the *lymphocytic lineage*, beginning with the *lymphoblast*.

The granulocytes and monocytes are formed only in the bone marrow. Lymphocytes and plasma cells are produced mainly in the various lymphogenous tissues—especially the lymph glands, spleen, thymus, tonsils, and various pockets of lymphoid tissue elsewhere in the body, such as in the bone marrow and in *Peyer's patches* underneath the epithelium in the gut wall.

The WBCs formed in the bone marrow are stored in the marrow until they are needed in the circulatory system. Then, when the need arises, various factors cause them to be released (these factors are discussed later). Normally, about three times as many WBCs are stored in the marrow as circulate in the entire blood. This quantity represents about a 6-day supply of these cells.

The lymphocytes are mostly stored in the various lymphoid tissues, except for a small number that are temporarily being transported in the blood.

As shown in **Figure 34-1**, megakaryocytes (cell 3) are also formed in the bone marrow. These megakaryocytes fragment in the bone marrow and the small fragments, known as *platelets* (or *thrombocytes*), then pass into the blood. They are very important in the initiation of blood clotting.

LIFE SPAN OF WHITE BLOOD CELLS

The life of the granulocytes after being released from the bone marrow is normally 4 to 8 hours circulating in the blood and another 4 to 5 days in tissues where they are

needed. In times of serious tissue infection, this total life span is often shortened to only a few hours because the granulocytes proceed even more rapidly to the infected area, perform their functions, and in the process, are themselves destroyed.

The monocytes also have a short transit time, 10 to 20 hours in the blood, before wandering through the capillary membranes into the tissues. Once in the tissues, they swell to much larger sizes to become *tissue macrophages* and, in this form, they can live for months unless destroyed while performing phagocytic functions. These tissue macrophages are the basis of the *tissue macrophage system* (discussed in greater detail later), which provides continuing defense against infection.

Lymphocytes enter the circulatory system continually, along with drainage of lymph from the lymph nodes and other lymphoid tissue. After a few hours, they pass out of the blood back into the tissues by *diapedesis/extravasation*. Then, they re-enter the lymph and return to the blood again and again; thus, there is continual circulation of lymphocytes through the body. Lymphocytes have life spans of weeks or months, depending on the body's need for these cells.

The platelets in the blood are replaced about once every 10 days. In other words, about 30,000 platelets are formed each day for each microliter of blood.

NEUTROPHILS AND MACROPHAGES DEFEND AGAINST INFECTIONS

It is mainly the neutrophils and tissue macrophages that attack and destroy invading bacteria, viruses, and other

Figure 34-2. Movement of neutrophils by *diapedesis* or *extravasation* through capillary pores and by *chemotaxis* toward an area of tissue damage.

harmful agents. The neutrophils are mature cells that can attack and destroy bacteria, even in the circulating blood. Conversely, the tissue macrophages begin life as blood monocytes, which are immature cells while still in the blood and have little ability to fight infectious agents at that time. However, once they enter the tissues, they begin to swell—sometimes increasing their diameters as much as fivefold—to as great as 60 to 80 micrometers, a size that can barely be seen with the naked eye. These cells are now called *macrophages*, and they are extremely capable of combating disease agents in the tissues.

White Blood Cells Enter the Tissue Spaces by Diapedesis. Neutrophils and monocytes can squeeze through gaps between endothelial cells of the blood capillaries and postcapillary venules by *diapedesis*. Although the intercellular gaps are much smaller than a cell, a small portion of the cell slides through the gap at a time; the portion sliding through is momentarily constricted to the size of the gap, as shown in [Figure 34-2](#) (also see [Figure 34-6](#)).

White Blood Cells Move Through Tissue Spaces by Ameboid Motion. Both neutrophils and macrophages can move through the tissues by ameboid motion, described in [Chapter 2](#). Some cells move at velocities as great as 40 $\mu\text{m}/\text{min}$, a distance as great as their own length each minute.

White Blood Cells Are Attracted to Inflamed Tissue Areas by Chemotaxis. Many different chemical substances in the tissues cause both neutrophils and macrophages to move toward the source of the chemical. This phenomenon, shown in [Figure 34-2](#), is known as *chemotaxis*. When a tissue becomes inflamed, at least a dozen different products that can cause chemotaxis toward the

inflamed area are formed ([Video 34-1](#)). They include the following: (1) some of the bacterial or viral toxins; (2) degenerative products of the inflamed tissues; (3) several reaction products of the complement complex (discussed in [Chapter 35](#)) activated in inflamed tissues; and (4) several reaction products caused by plasma clotting in the inflamed area, as well as other substances.

As shown in [Figure 34-2](#), chemotaxis depends on the concentration gradient of the chemotactic substance. The concentration is greatest near the source, which directs the unidirectional movement of the WBCs. Chemotaxis is effective up to 100 micrometers away from an inflamed tissue. Therefore, because almost no tissue area is more than 50 micrometers away from a capillary, the chemotactic signal can easily move hordes of WBCs from the capillaries into the inflamed area.

PHAGOCYTOSIS

A major function of the neutrophils and macrophages is *phagocytosis*, which means cellular ingestion of the offending agent. Phagocytes must be selective of the material that is phagocytized; otherwise, normal cells and structures of the body might be ingested. Whether phagocytosis will occur especially depends on three selective procedures ([Figure 34-3](#)).

First, most natural structures in the tissues have smooth surfaces, which resist phagocytosis. However, if the surface is rough, the likelihood of phagocytosis is increased.

Second, most natural substances of the body have protective protein coats that repel the phagocytes. Conversely, most dead tissues and foreign particles have no protective coats, which makes them subject to phagocytosis.

Third, the immune system of the body (described in [Chapter 35](#)) develops *antibodies* against infectious agents such as bacteria. The antibodies then adhere to the bacterial membranes and thereby make the bacteria especially susceptible to phagocytosis. To do this, the antibody molecule also combines with the C3 product of the *complement cascade*, which is an additional part of the immune system discussed in the [next chapter](#). The C3 molecules, in turn, attach to receptors on the phagocyte membrane, thus initiating phagocytosis. This process whereby a pathogen is selected for phagocytosis and destruction is called *opsonization*.

Phagocytosis by Neutrophils. The neutrophils entering the tissues are already mature cells that can immediately begin phagocytosis. On approaching a particle to be phagocytized, the neutrophil first attaches itself to the particle and then projects *pseudopodia* in all directions around the particle. The pseudopodia meet one another on the opposite side and fuse. This action creates an enclosed chamber that contains the phagocytized particle. Then, the chamber invaginates to the inside of the cytoplasmic cavity and breaks away from the outer cell membrane to form a free-floating *phagocytic vesicle* (also called

Figure 34-3. Phagocytosis of pathogens, such as bacteria, by a phagocytic cell, such as a macrophage. Antibodies coat the bacteria, making them more susceptible to phagocytosis by the macrophage that engulfs the bacterium, bringing it into the cell and forming a *phagosome*. Lysosomes then attach to the phagosome to form a *phagolysosome*, which digests the invading pathogen. The phagocytic cell then releases the digested products by *exocytosis*.

a *phagosome*) inside the cytoplasm. A single neutrophil can usually phagocytize 3 to 20 bacteria before the neutrophil becomes inactivated and dies.

Phagocytosis by Macrophages. Macrophages are the end-stage product of monocytes that enter the tissues from the blood. When activated by the immune system, as described in [Chapter 35](#), they are much more powerful phagocytes than neutrophils, often capable of phagocytizing as many as 100 bacteria. They also have the ability to engulf much larger particles, even whole RBCs or, occasionally, malarial parasites, whereas neutrophils are not capable of phagocytizing particles much larger than bacteria. Also, after digesting particles, macrophages can extrude the residual products and often survive and function for many more months.

Once Phagocytized, Most Particles Are Digested by Intracellular Enzymes. Once a foreign particle has been phagocytized, lysosomes and other cytoplasmic granules in the neutrophil or macrophage immediately come into contact with the phagocytic vesicle, and their membranes fuse, thereby dumping many digestive enzymes and bactericidal agents into the vesicle. Thus, the phagocytic vesicle now becomes a *digestive vesicle*, and digestion of the phagocytized particle begins immediately.

Both neutrophils and macrophages contain an abundance of lysosomes filled with *proteolytic enzymes* especially geared for digesting bacteria and other foreign protein matter. The lysosomes of macrophages (but not of neutrophils) also contain large amounts of *lipases*, which digest the thick lipid membranes possessed by some bacteria, such as the tuberculosis bacillus.

Neutrophils and Macrophages Can Kill Bacteria.

In addition to the digestion of ingested bacteria in phagosomes, neutrophils and macrophages contain *bactericidal agents* that kill most bacteria, even when the lysosomal enzymes fail to digest them. This characteristic is especially important because some bacteria have protective coats or other factors that prevent their destruction by digestive enzymes. Much of the killing effect results from several powerful *oxidizing agents* formed by enzymes in the membrane of the phagosome or by a special organelle called the *peroxisome*. These oxidizing agents include large quantities of *superoxide* (O_2^-), *hydrogen peroxide* (H_2O_2), and *hydroxyl ions* (OH^-), which are lethal to most bacteria, even in small quantities. Also, one of the lysosomal enzymes, myeloperoxidase, catalyzes the reaction between H_2O_2 and chloride ions to form hypochlorite, which is exceedingly bactericidal.

Some bacteria, notably the tuberculosis bacillus, have coats that are resistant to lysosomal digestion and also secrete substances that partially resist the killing effects of the neutrophils and macrophages. These bacteria are responsible for many chronic diseases, such as tuberculosis.

MONOCYTE-MACROPHAGE CELL SYSTEM (RETICULOENDOTHELIAL SYSTEM)

In the preceding paragraphs, we described the macrophages mainly as mobile cells capable of wandering through the tissues. However, after entering the tissues and becoming macrophages, another large portion of monocytes becomes attached to the tissues and remains attached for months or even years until they are called on to perform specific local protective functions. They have the same capabilities as the mobile macrophages to phagocytize large quantities of bacteria, viruses, necrotic tissue, or other foreign particles in the tissue. In addition, when appropriately stimulated, they can break away from their attachments and, once again, become mobile macrophages that respond to chemotaxis and all the other stimuli related to the inflammatory process. Thus, the body has a widespread monocyte-macrophage system in virtually all tissue areas.

The total combination of monocytes, mobile macrophages, fixed tissue macrophages, and a few specialized endothelial cells in the bone marrow, spleen, and lymph nodes is called the *reticuloendothelial system*. However, all or almost all these cells originate from monocytic stem

Figure 34-4. Functional diagram of a lymph node.

cells; therefore, the reticuloendothelial system is almost synonymous with the monocyte-macrophage system. Because the term *reticuloendothelial system* is much better known in medical literature than the term *monocyte-macrophage system*, it should be remembered as a generalized phagocytic system located in all tissues, especially in the tissue areas where large quantities of particles, toxins, and other unwanted substances must be destroyed.

Tissue Macrophages in Skin and Subcutaneous Tissues (Histiocytes). The skin is mainly impregnable to infectious agents, except when it is broken. When infection begins in a subcutaneous tissue and local inflammation ensues, local tissue macrophages can divide in situ and form still more macrophages. Then, they perform the usual functions of attacking and destroying the infectious agents, as described earlier.

Macrophages in Lymph Nodes. Essentially no particulate matter that enters the tissues, such as bacteria, can be absorbed directly through the capillary membranes into the blood. Instead, if the particles are not destroyed locally in the tissues, they enter the lymph and flow to the lymph nodes located intermittently along the course of the lymph flow. The foreign particles are then trapped in these nodes in a meshwork of sinuses lined by *tissue macrophages*.

Figure 34-4 illustrates the general organization of the lymph node, showing lymph entering through the lymph node capsule via *afferent lymphatics*, then flowing through the *nodal medullary sinuses*, and finally passing out the *hilus* into *efferent lymphatics* that eventually empty into the venous blood.

Large numbers of macrophages line the lymph sinuses and if any particles enter the sinuses by way of the lymph the macrophages phagocytize them and prevent general dissemination throughout the body.

Alveolar Macrophages in Lungs. Another route whereby invading organisms frequently enter the body is through

Figure 34-5. Kupffer cells lining the liver sinusoids, showing phagocytosis of India ink particles into the cytoplasm of the Kupffer cells.

the lungs. Large numbers of tissue macrophages are present as integral components of the alveolar walls. They can phagocytize particles that become entrapped in the alveoli. If the particles are digestible, the macrophages can also digest them and release the digestive products into the lymph. If the particle is not digestible, the macrophages often form a giant cell capsule around the particle until such time—if ever—that it can be slowly dissolved. Such capsules are frequently formed around tuberculosis bacilli, silica dust particles, and even carbon particles.

Macrophages (Kupffer Cells) in Liver Sinusoids. Another route whereby bacteria invade the body is through the gastrointestinal tract. Large numbers of bacteria from ingested food constantly pass through the gastrointestinal mucosa into the portal blood. Before this blood enters the general circulation, it passes through the liver sinusoids, which are lined with tissue macrophages called *Kupffer cells*, shown in **Figure 34-5**. These cells form such an effective particulate filtration system that almost none of the bacteria from the gastrointestinal tract pass from the portal blood into the general systemic circulation. Indeed, videos of phagocytosis by Kupffer cells have demonstrated phagocytosis of a single bacterium in less than 0.01 second.

Macrophages of Spleen and Bone Marrow. If an invading organism succeeds in entering the general circulation, there are other lines of defense by the tissue macrophage system, especially by macrophages of the spleen and bone marrow. In both these tissues, macrophages become entrapped by the reticular meshwork of the two organs, and when foreign particles come into contact with these macrophages, they are phagocytized.

Figure 34-6. Functional structures of the spleen.

The spleen is similar to the lymph nodes, except that blood, instead of lymph, flows through the tissue spaces of the spleen. **Figure 34-6** shows a small peripheral segment of spleen tissue. Note that a small artery penetrates from the splenic capsule into the *splenic pulp* and terminates in small capillaries. The capillaries are highly porous, allowing whole blood to pass out of the capillaries into *cords of red pulp*. The blood then gradually *squeezes* through the trabecular meshwork of these cords and eventually returns to the circulation through the endothelial walls of the *venous sinuses*. The trabeculae of the red pulp and venous sinuses are lined with vast numbers of macrophages. This peculiar passage of blood through the cords of the red pulp provides an exceptional means of phagocytizing unwanted debris in the blood, including especially old and abnormal RBCs.

INFLAMMATION: ROLE OF NEUTROPHILS AND MACROPHAGES

INFLAMMATION

When tissue injury occurs, whether caused by bacteria, trauma, chemicals, heat, or any other phenomenon, multiple substances are released by the injured tissues and cause dramatic secondary changes in the surrounding uninjured tissues. This entire complex of tissue changes is called *inflammation*.

Inflammation is characterized by the following: (1) vasodilation of the local blood vessels, with consequent increased local blood flow; (2) increased permeability of the capillaries, allowing leakage of large quantities of fluid into the interstitial spaces; (3) often, clotting of the fluid in the interstitial spaces because of increased amounts of fibrinogen and other proteins leaking from the capillaries; (4) migration of large numbers of granulocytes and monocytes into the tissue; and (5) swelling of the tissue cells. Some of the many tissue products that cause these reactions are *histamine*, *bradykinin*, *serotonin*, *prostaglandins*, several different *reaction products of the complement*

system (described in [Chapter 35](#)), *reaction products of the blood clotting system*, and multiple substances called *lymphokines* that are released by sensitized T cells (part of the immune system; also discussed in [Chapter 35](#)). Several of these substances strongly activate the macrophage system, and within a few hours, the macrophages begin to devour the destroyed tissues. At times, however, the macrophages may also further injure the still-living tissue cells.

Walling-Off Effect of Inflammation. One of the first results of inflammation is to wall off the area of injury from the remaining tissues. The tissue spaces and the lymphatics in the inflamed area are blocked by fibrinogen clots so that after a while, fluid barely flows through the spaces. This walling-off process delays the spread of bacteria or toxic products.

The intensity of the inflammatory process is usually proportional to the degree of tissue injury. For example, when *staphylococci* invade tissues, they release extremely lethal cellular toxins. As a result, inflammation develops rapidly—indeed, much more rapidly than the staphylococci can multiply and spread. Therefore, local staphylococcal infection is characteristically walled off rapidly and prevented from spreading through the body. Streptococci, in contrast, do not cause such intense local tissue destruction. Therefore, the walling-off process develops slowly over many hours, while many streptococci reproduce and migrate. As a result, streptococci often have a far greater tendency to spread through the body and cause death than staphylococci, even though staphylococci are far more destructive to the tissues.

MACROPHAGE AND NEUTROPHIL RESPONSES DURING INFLAMMATION

Tissue Macrophages Provide First Line of Defense Against Infection. Within minutes after inflammation begins, the macrophages already present in the tissues, whether histiocytes in the subcutaneous tissues, alveolar macrophages in the lungs, microglia in the brain, or others, immediately begin their phagocytic actions. When activated by the products of infection and inflammation, the first effect is rapid enlargement of each of these cells. Next, many of the previously sessile macrophages break loose from their attachments and become mobile, forming the first line of defense against infection during the first hour or so. The numbers of these early mobilized macrophages often are not great, but they are lifesaving.

Neutrophil Invasion of the Inflamed Area Is a Second Line of Defense. Within the first hour or so after inflammation begins, large numbers of neutrophils begin to invade the inflamed area from the blood. This invasion is caused by inflammatory cytokines (e.g., tumor necrosis factor and interleukin-1) and other biochemical products produced by the inflamed tissues that initiate the following reactions:

Figure 34-7. Migration of neutrophils from the blood into inflamed tissue. Cytokines and other biochemical products of the inflamed tissue cause increased expression of selectins and intercellular adhesion molecule-1 (ICAM-1) on the surface of endothelial cells. These adhesion molecules bind to complementary molecules or receptors on the neutrophil, causing it to adhere to the wall of the capillary or venule. The neutrophil then migrates through the vessel wall by diapedesis or extravasation toward the site of tissue injury.

1. They cause increased expression of *adhesion molecules*, such as *selectins* and *intercellular adhesion molecule-1* (ICAM-1) on the surface of endothelial cells in the capillaries and venules. These adhesion molecules, reacting with complementary *integrin* molecules on the neutrophils, cause the neutrophils to stick to the capillary and venule walls in the inflamed area. This effect is called *marginination* and is shown in [Figure 34-2](#) and in more detail in [Figure 34-7](#).
2. They also cause the intercellular attachments between the endothelial cells of the capillaries and small venules to loosen, allowing openings large enough for neutrophils to crawl through the capillaries by diapedesis into the tissue spaces.
3. They then cause *chemotaxis* of the neutrophils toward the injured tissues, as explained earlier. The entire process of neutrophil (or other substances and cells such as monocytes) translocation through the capillaries into the tissues surrounding them is called *extravasation*; the specific passage of blood cells through the intact walls of the capillaries is called *diapedesis*, although this term is often used interchangeably with extravasation when discussing blood cell movement through the capillaries into tissues.

Thus, within several hours after tissue damage begins, the area becomes well supplied with neutrophils. Because the blood neutrophils are already mature cells, they are ready to begin their scavenger functions of killing bacteria and removing foreign matter immediately.

Acute Increase in the Number of Neutrophils in Blood—Neutrophilia. Also, within a few hours after the onset of acute severe inflammation, the number of

neutrophils in the blood sometimes increases fourfold to fivefold—from a normal of 4,000 to 5,000 to 15,000 to 25,000 neutrophils/ μl . This is called *neutrophilia*, which means an increase in the number of neutrophils in the blood. Neutrophilia is caused by products of inflammation that enter the blood stream, are transported to the bone marrow, and act there on the stored neutrophils of the marrow to mobilize these into the circulating blood. This makes even more neutrophils available to the inflamed tissue area.

Second Macrophage Invasion Into the Inflamed Tissue Is a Third Line of Defense. Along with the invasion of neutrophils, monocytes from the blood enter the inflamed tissue and enlarge to become macrophages. However, the number of monocytes in the circulating blood is low. Also, the storage pool of monocytes in the bone marrow is much less than that of neutrophils. Therefore, the buildup of macrophages in the inflamed tissue area is much slower than that of neutrophils, requiring several days to become effective. Furthermore, even after invading the inflamed tissue, monocytes are still immature cells, requiring 8 hours or more to swell to much larger sizes and develop tremendous quantities of lysosomes. Only then do they acquire the full capacity of *tissue macrophages* for phagocytosis. After several days to several weeks, the macrophages finally come to dominate the phagocytic cells of the inflamed area because of greatly increased bone marrow production of new monocytes, as explained later.

As already noted, macrophages can phagocytize far more bacteria (about five times as many) and far larger particles, including even neutrophils and large quantities of necrotic tissue, than can neutrophils. Also, the macrophages play an important role in initiating development of antibodies, as discussed in [Chapter 35](#).

Figure 34-8. Control of bone marrow production of granulocytes and monocyte-macrophages in response to multiple growth factors released from activated macrophages in an inflamed tissue. G-CSF, Granulocyte colony-stimulating factor; GM-CSF, granulocyte-monocyte colony-stimulating factor; IL-1, interleukin-1; M-CSF, monocyte colony-stimulating factor; TNF, tumor necrosis factor.

Increased Production of Granulocytes and Monocytes by Bone Marrow Is a Fourth Line of Defense.

The fourth line of defense is greatly increased production of granulocytes and monocytes by the bone marrow. This action results from stimulation of the granulocytic and monocytic progenitor cells of the marrow. However, it takes 3 to 4 days before newly formed granulocytes and monocytes reach the stage of leaving the bone marrow. If the stimulus from the inflamed tissue continues, the bone marrow can continue to produce these cells in large quantities for months and even years, sometimes at a rate 20 to 50 times normal.

Feedback Control of Macrophage and Neutrophil Responses

Although more than two dozen factors have been implicated in control of the macrophage response to inflammation, five of these are believed to play dominant roles. They are shown in **Figure 34-8** and consist of the following: (1) *tumor necrosis factor* (TNF); (2) *interleukin-1* (IL-1), (3) *granulocyte-monocyte colony-stimulating factor* (GM-CSF); (4) *granulocyte colony-stimulating factor* (G-CSF); and (5) *monocyte colony-stimulating factor* (M-CSF). These factors are formed by activated macrophage cells in the inflamed tissues and in smaller quantities by other inflamed tissue cells.

The cause of increased production of granulocytes and monocytes by the bone marrow is mainly the three
