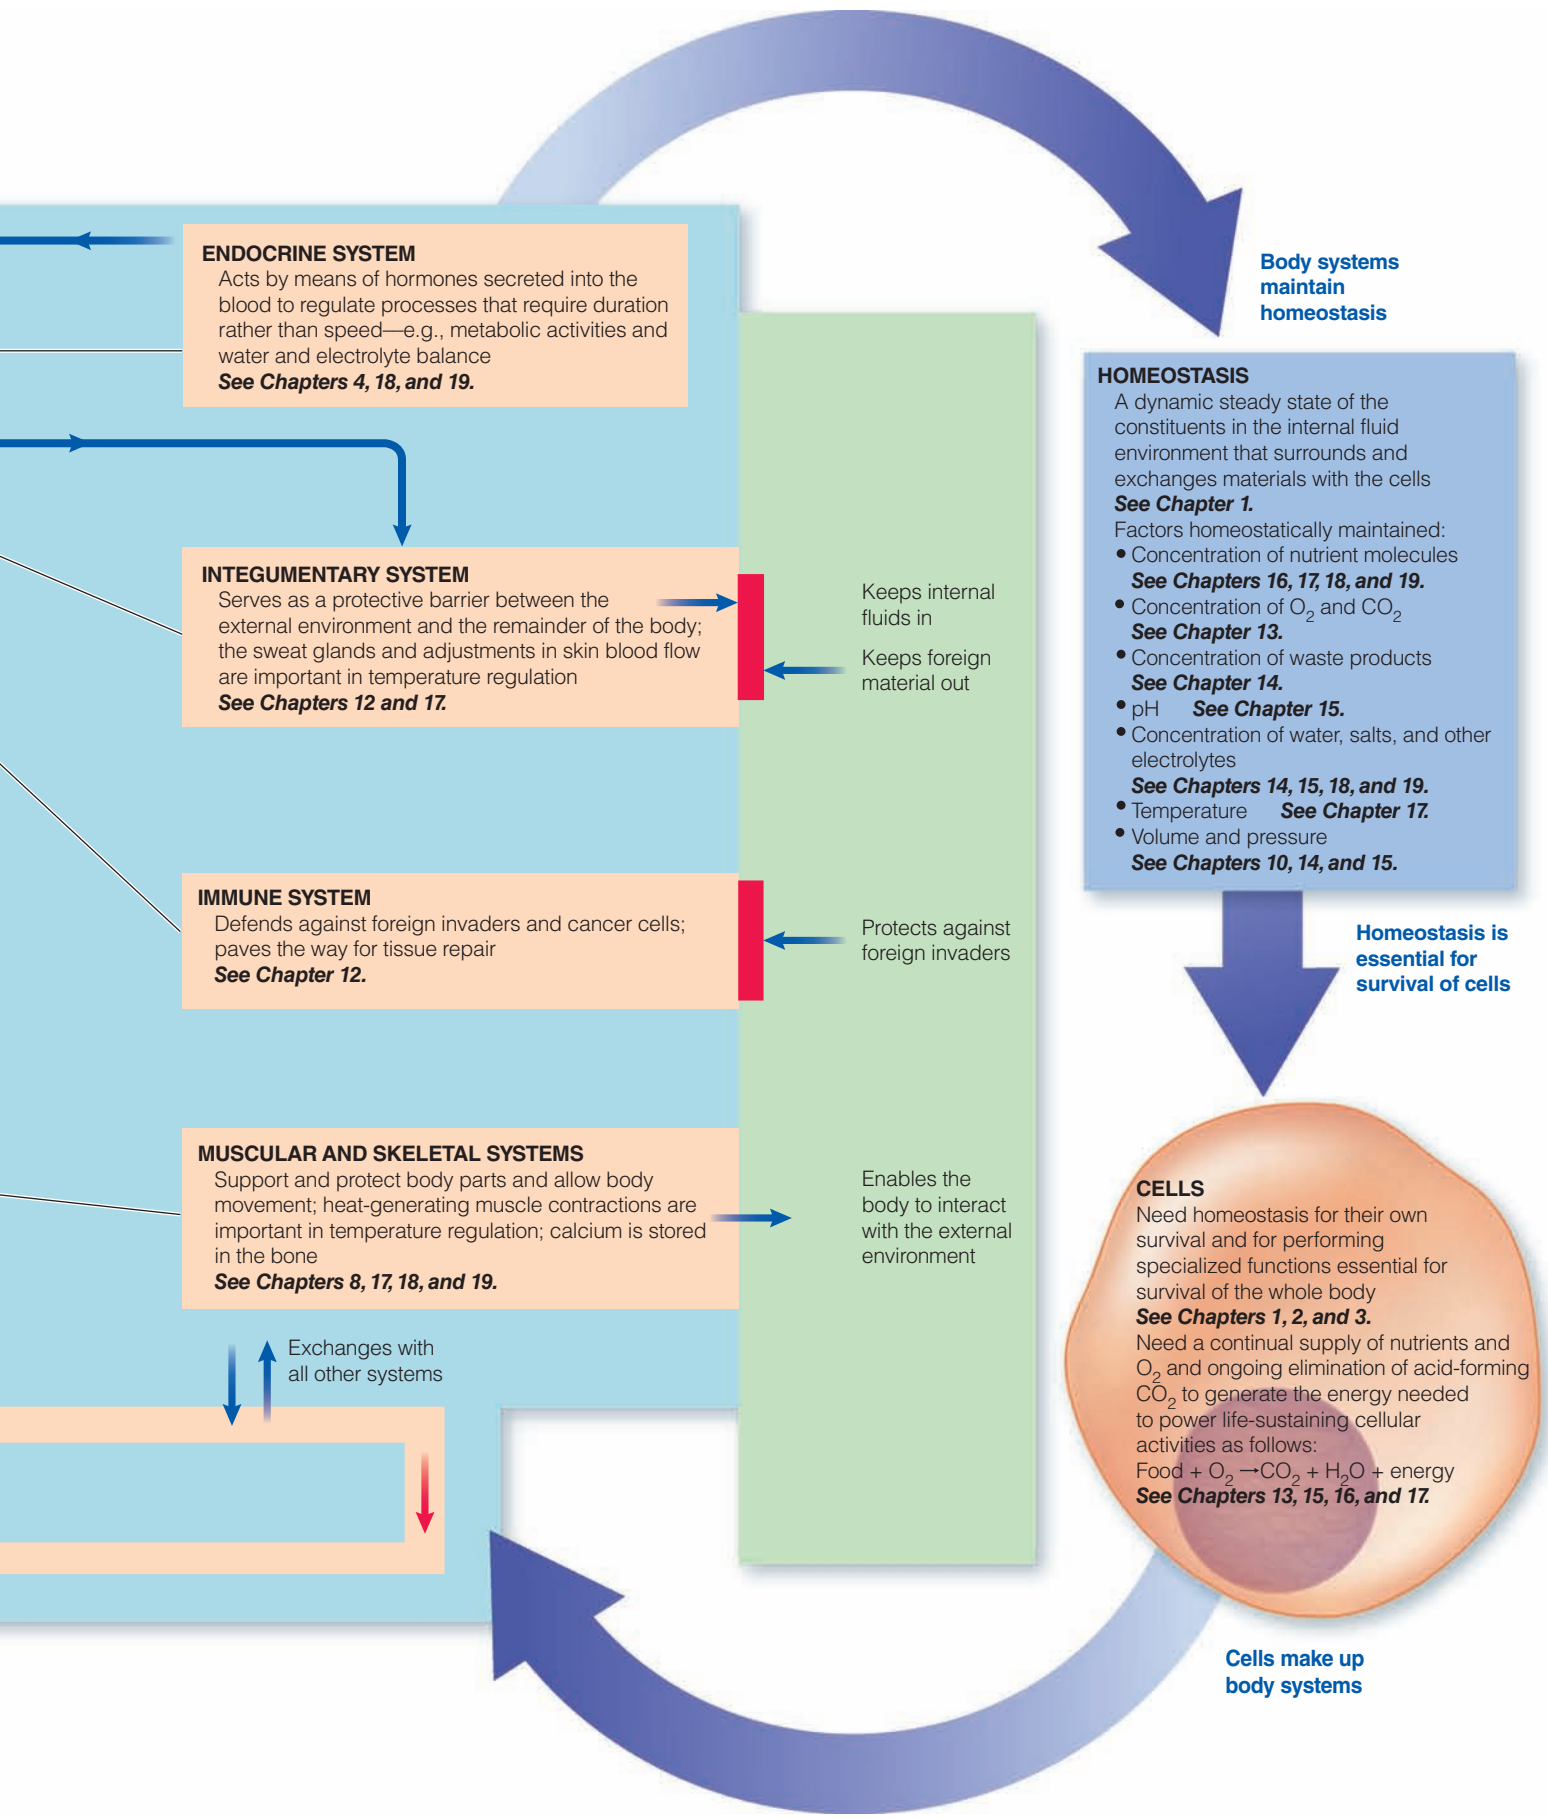
Lauralee Sherwood

HUMAN PHYSIOLOGY

From Cells to Systems

Ninth Edition


BODY SYSTEMS
Made up of cells organized according to specialization to maintain homeostasis
See Chapter 1.

NERVOUS SYSTEM
Acts through electrical signals to control rapid responses of the body; also responsible for higher functions—e.g., consciousness, memory, and creativity
See Chapters 4, 5, 6, and 7.

Information from the external environment relayed through the nervous system

Regulate

RESPIRATORY SYSTEM
Obtains O_2 from and eliminates CO_2 to the external environment; helps regulate pH by adjusting the rate of removal of acid-forming CO_2
See Chapters 13 and 15.

O_2
CO_2

URINARY SYSTEM
Is important in regulating the volume, electrolyte composition, and pH of the internal environment; removes wastes and excess water, salt, acid, and other electrolytes from the plasma and eliminates them in the urine
See Chapters 14 and 15.

Urine containing wastes and excess water and electrolytes

DIGESTIVE SYSTEM
Obtains nutrients, water, and electrolytes from the external environment and transfers them into the plasma; eliminates undigested food residues to the external environment
See Chapter 16.

Nutrients, water, and electrolytes

Feces containing undigested food residue

REPRODUCTIVE SYSTEM
Is not essential for homeostasis, but essential for perpetuation of the species
See Chapter 20.

Sperm leave male

Sperm enter female

Exchanges with all other systems

EXTERNAL ENVIRONMENT

CIRCULATORY SYSTEM
Transports nutrients, O_2, CO_2, wastes, electrolytes, and hormones throughout the body
See Chapters 9, 10, and 11.

This pictorial homeostatic model is developed in Chapter 1 to show you the relationship among cells, systems, and homeostasis (maintenance of relatively stable conditions in the internal fluid environment that surrounds the cells). The accompanying icon marks special sections at the beginning and end of each chapter that focus on how the topic of the chapter contributes to homeostasis. Together these features will give you a better perspective on homeostasis and the interdependency of body systems.

Body systems maintain homeostasis

ENDOCRINE SYSTEM
Acts by means of hormones secreted into the blood to regulate processes that require duration rather than speed—e.g., metabolic activities and water and electrolyte balance
See Chapters 4, 18, and 19.

INTEGUMENTARY SYSTEM
Serves as a protective barrier between the external environment and the remainder of the body; the sweat glands and adjustments in skin blood flow are important in temperature regulation
See Chapters 12 and 17.

Keeps internal fluids in

Keeps foreign material out

HOMEOSTASIS
A dynamic steady state of the constituents in the internal fluid environment that surrounds and exchanges materials with the cells
See Chapter 1.
Factors homeostatically maintained:
- Concentration of nutrient molecules
  See Chapters 16, 17, 18, and 19.
- Concentration of O_2 and CO_2
  See Chapter 13.
- Concentration of waste products
  See Chapter 14.
- pH   *See Chapter 15.*
- Concentration of water, salts, and other electrolytes
  See Chapters 14, 15, 18, and 19.
- Temperature   *See Chapter 17.*
- Volume and pressure
  See Chapters 10, 14, and 15.

IMMUNE SYSTEM
Defends against foreign invaders and cancer cells; paves the way for tissue repair
See Chapter 12.

Protects against foreign invaders

Homeostasis is essential for survival of cells

MUSCULAR AND SKELETAL SYSTEMS
Support and protect body parts and allow body movement; heat-generating muscle contractions are important in temperature regulation; calcium is stored in the bone
See Chapters 8, 17, 18, and 19.

Enables the body to interact with the external environment

Exchanges with all other systems

CELLS
Need homeostasis for their own survival and for performing specialized functions essential for survival of the whole body
See Chapters 1, 2, and 3.
Need a continual supply of nutrients and O_2 and ongoing elimination of acid-forming CO_2 to generate the energy needed to power life-sustaining cellular activities as follows:
Food + $O_2 \rightarrow CO_2 + H_2O$ + energy
See Chapters 13, 15, 16, and 17.

**Cells make up body systems**

MindTap™

Tap into **engagement**

MindTap empowers you to produce your best work—consistently.

MindTap is designed to help you master the material. Interactive videos, animations, and activities create a learning path designed by your instructor to guide you through the course and focus on what's important.

MindTap delivers real-world activities and assignments

that will help you in your academic life as well as your career.

APPENDIXES

Preface

Goals, Philosophy, and Theme

I am constantly awestruck at the miraculous intricacies and efficiency of body function. No machine can perform even a portion of natural body function as effectively. My goal in writing physiology textbooks is not only to help students learn about how the body works, but also to share my enthusiasm for the subject matter. Most of us, even infants, have a natural curiosity about how our bodies work. When babies first discover they can control their hands, they are fascinated and spend many hours manipulating them in front of their faces. By capitalizing on students' natural curiosity about themselves, I try to make physiology a subject they can enjoy learning.

Even the most tantalizing subject can be difficult to comprehend if not effectively presented, however. Therefore, this book has a logical, understandable format with an emphasis on how each concept is an integral part of the entire subject. Too often, students view the components of a physiology course as isolated entities; by understanding how each component depends on the others, a student can appreciate the integrated functioning of the human body. The text focuses on the mechanisms of body function from cells to systems and is organized around the central theme of *homeostasis*—how the body meets changing demands while maintaining the internal constancy necessary for all cells and organs to function. The text is written in simple, straightforward language, and every effort has been made to ensure smooth reading through good transitions, common-sense reasoning, and integration of ideas throughout.

This text is designed for undergraduate students preparing for health-related careers, but its approach and depth also are appropriate for other undergraduates. Because this book is intended as an introduction and, for most students, may be their only exposure to a formal physiology text, all aspects of physiology receive broad coverage, yet depth, where needed, is not sacrificed. The scope of this text has been limited by judicious selection of pertinent content that a student can reasonably be expected to assimilate in a one-semester physiology course. Materials were selected for inclusion on a "need to know" basis, so the book is not cluttered with unnecessary detail. Instead, content is restricted to relevant information needed to understand basic physiological concepts and to serve as a foundation for future careers in the health professions. Some controversial ideas and hypotheses are presented to illustrate that physiology is a dynamic, changing discipline.

To keep pace with today's rapid advances in the health sciences, students in the health professions must be able to draw on their conceptual understanding of physiology instead of merely recalling isolated facts that soon may be out of date. Therefore, this text is designed to promote understanding of the basic principles and concepts of physiology rather than memorization of details.

In consideration of the clinical orientation of most students, research methodologies and data are not emphasized, although the material is based on up-to-date evidence. New information based on recent discoveries has been included throughout. Students can be assured of the timeliness and accuracy of the material presented. To make room for new, applicable information, I have carefully trimmed content while clarifying, modifying, and simplifying as needed to make this edition fresh, reader-friendly, and current.

Because the function of an organ depends on the organ's construction, enough relevant anatomy is integrated within the text to make the inseparable relation between form and function meaningful.

Hallmark Features and Learning Aids

Implementing the homeostasis theme

Homeostasis is the first word in this text, in the caption for the chapter opener photo for Chapter 1, "Introduction to Physiology and Homeostasis," indicative of the importance placed on homeostasis (see p. 1).

Each chapter begins with **Homeostasis Highlights,** an opening feature that emphasizes the big picture of how the content to come plays a part in homeostasis and functionally fits in with the body as a whole. As an example, see *Homeostasis Highlights* for Chapter 8, "Muscle Physiology," p. 251.

At the close of each chapter, **Homeostasis: Chapter in Perspective** points out specific ways in which the topic covered in the chapter contributes to homeostasis, returning the reader to this central theme, no matter how far the content appears to be removed from playing a role in maintaining internal constancy, as exemplified by *Homeostasis: Chapter in Perspective* for Chapter 3, "The Plasma Membrane and Membrane Potential," p. 84.

A unique, easy-to-follow, pictorial homeostatic model showing the relationship among cells, systems, and homeostasis is developed in the introductory chapter (see pp. 14–15) and presented on the inside front cover as a quick reference.

These opening and closing features and the homeostatic model work together to facilitate students' comprehension of the interactions and interdependency of body systems, even though each system is discussed separately.

Chapter openers

The chapter openers consist of three key components: an eye-catching, informative photo relevant to the chapter; *Chapter at a Glance,* a concise list of contents; and the brief *Homeostasis Highlights* narrative that orients the readers to the homeostatic aspects of the material that follows. Check out the chapter opener for Chapter 13, "The Respiratory System," on p. 445 as an example.

Pedagogical illustrations

Anatomic illustrations, schematic representations, step-by-step descriptions within process-oriented figures, photographs, tables, and graphs complement and reinforce the written material.

Widespread use of integrated descriptions within figures, including numerous **process-oriented figures with incorporated step-by-step descriptions**, allows visually oriented students to review processes through figures. Check out Figure 5-17, p. 161; Figure 8-11, p. 260; and Figure 11-11, p. 396, for examples.

Flow diagrams are used extensively to help students integrate the written information. In the flow diagrams, lighter and darker shades of the same color denote a decrease or increase in a controlled variable, such as blood pressure or the concentration of blood glucose. Physical entities, such as body structures and chemicals, are distinguished visually from actions. Icons of physical entities are incorporated into the flow diagrams. See Figure 15-4, p. 545; Figure 16-12, p. 592; and Figure 20-9, p. 729, for examples.

Most chapters feature one or more **showcase figures**, which are art-enhanced, visually appealing, broad-based foundation figures that draw students' attention to key structural and functional components relevant to the chapter. Examples include the following:

■ Figure 2-1, A diagram of cell structures visible under an electron microscope, p. 23

■ Figure 14-1, The urinary system, p. 493

■ Figure 19-7, Anatomy of and hormonal secretion by the adrenal glands, p. 672

Also, integrated **color-coded figure/table combinations** help students better visualize what part of the body is responsible for what activities. For example, anatomic depiction of the brain is integrated with a table of the functions of the major brain components, with each component shown in the same color in the figure and the table (see Table 5-1, pp. 144–145).

A unique feature of this book is that people depicted in the various illustrations are realistic representatives of a cross-section of humanity. Sensitivity to various races, sexes, and ages should enable all students to identify with the material being presented.

Analogies

Many analogies and frequent references to everyday experiences are included to help students relate to the physiology

concepts presented. These useful tools have been drawn in large part from my more than four decades of teaching experience. Knowing which areas are likely to give students the most difficulty, I have tried to develop links that help them relate the new material to something with which they are already familiar. As examples, the lymphatic system as an accessory drainage route for interstitial fluid is compared to a storm sewer that picks up and carries away excess rainwater so that it does not accumulate and flood an area (p. 358); and the effect of sildenafil (Viagra) is likened to pushing a pedal on a piano not causing a note to be played but prolonging a played note (p. 734).

Pathophysiology and clinical coverage

Clinical Note Another effective way to keep students' interest is to help them realize they are learning worthwhile and applicable material. Because many students using this text will have health-related careers, frequent references to pathophysiology and clinical physiology demonstrate the content's relevance to their professional goals. Clinical Note icons flag clinically relevant material, which is integrated throughout the text.

Boxed features

Two types of boxed features are incorporated within the chapters. ▮Concepts, Challenges, and Controversies boxes expose students to high-interest information on such diverse topics as new technologies involving "seeing" with the tongue or the ear (see p. 210); historical highlights, for example, development of vaccinations (see p. 422); body responses to different environments such as those encountered in mountain climbing and deep-sea diving (see pp. 480–481); and in-depth discussions regarding common diseases such as Alzheimer's disease (see pp. 164–165).

▮A Closer Look at Exercise Physiology boxes are included for three reasons: increasing national awareness of the importance of physical fitness, increasing recognition of the value of prescribed therapeutic exercise programs for a variety of conditions, and growing career opportunities related to fitness and exercise. As an example, see the exercise physiology box on p. 542 regarding the importance of acclimatization to exercising in the heat.

Major section heads and feedforward statements as subsection titles

Major section heads and subsections logically break up large concepts into smaller, manageable chunks. Instead of traditional short topic titles for each subsection (for example, "Glial cells"), feedforward statements alert students to the main point of the subsection to come (for example, "Glial cells support the interneurons physically, metabolically, and functionally"). As an added bonus, the listing of these headings in the **Contents** at the beginning of the book serves as a set of objectives for each chapter.

Key terms and word derivations

Key terms are defined as they appear in the text. Because physiology is laden with new vocabulary words, many of which are rather intimidating at first glance, word derivations are provided to enhance understanding of new words.

Review and self-evaluation tools in the text

Students are provided opportunities to review and are encouraged to assess their comprehension in a variety of ways.

Check Your Understanding Questions Questions at the end of each major section serve as study breaks for students to test their knowledge before starting the next section. These questions are different than the questions that cover the same content at the end of the chapter. Many of these section questions involve doing something other than copying an answer from a text description, such as drawing and labeling, preparing a chart, predicting based on information provided, and so on. In response to positive feedback regarding the usefulness of this pedagogical tool, which was introduced in the last edition, I have added nearly 100 new Check Your Understanding questions to this edition, bringing them to a total of about 350.

NEW! Figure Focus Questions Designed to check and promote student comprehension, focus questions have been added to specific figures throughout the text. To answer these critical thinking questions correctly, the reader must analyze, interpret, infer, and apply the content of 120 key figures. Check out examples of these new questions in Figures 13-20 and 13-21, p. 467; Figure 14-27, p. 525; and Figure 19-2, p. 667.

NEW! Blooms-Based Organization of Review Exercises The Review Exercises at the end of each chapter are now organized into categories using the educational tool *Bloom's Taxonomy of Learning Domains* as a guide. Questions are grouped in a hierarchy from lower- to higher-order levels as follows:

■ **Reviewing Terms and Facts:** The objective-type questions in this exercise are intended for students to self-test their basic knowledge of the chapter by recalling terms and facts.

■ **Understanding Concepts:** With this level, students demonstrate their understanding of the concepts presented by describing, explaining, comparing, stating main ideas, and so on in their own words.

■ **Solving Quantitative Exercises:** These problem-solving exercises provide students with an opportunity to practice calculations that enhance their understanding of complex relationships.

■ **Applying Clinical Reasoning:** This mini case history challenges students to apply acquired knowledge to a patient's specific symptoms, a situation relevant to the health-profession career goals of most students using this textbook.

■ **Thinking at a Higher Level:** This section features thought-provoking problems that encourage students to analyze, synthesize, reorganize, or apply in a different way what they have learned in the chapter.

Answers and explanations for these exercises are available in an appendix and online as described in the next section.

Study Cards A tear-out study card is available for each chapter. Each study card presents the major points of the chapter in concise, section-by-section bulleted lists, including cross-references for page numbers, figures, and tables. Students can carry these handy chapter summaries instead of the book to conveniently review key concepts for exams. The tear-out design lets students more efficiently review material even with the book in hand because they can see the written summary and visual information side-by-side without having to flip pages back and forth. This feature enables students to easily review main concepts before moving on.

Appendixes and glossary

Most undergraduate physiology texts have a chapter on chemistry, yet physiology instructors rarely teach basic chemistry concepts. Knowledge of chemistry beyond that introduced in secondary schools is not required for understanding this text. Therefore, I provide instead *Appendix A,* **A Review of Chemical Principles,** as a handy reference for students who need a brief review of basic chemistry concepts that apply to physiology. The following additional review materials are available online at **www.cengagebrain.com** *Storage, Replication, and Expression of Genetic Information* and *Principles of Quantitative Reasoning.*

Appendix B, **Text References to Exercise Physiology,** provides an index of all relevant content on this topic.

Appendix C, **Answers,** provides answers to all objective learning activities, including in-chapter *Check Your Understanding* questions and *Figure Focus* questions and end-of-chapter *Reviewing Terms and Facts,* solutions to the *Solving Quantitative Exercises,* and explanations for *Applying Clinical Reasoning* and *Thinking at a Higher Level* exercises. Answers to *Understanding Concepts* questions can be found at **www. cengagebrain.com.**

The **Glossary,** which offers a way to review the meaning of key terminology, includes phonetic pronunciations of the entries.

Organization

There is no ideal organization of physiologic processes into a logical sequence. In the sequence I chose, most chapters build on material presented in immediately preceding chapters, yet each chapter is designed to stand on its own, allowing the instructor flexibility in curriculum design. This flexibility is facilitated by cross-references to related material in other chapters. The cross-references let students quickly refresh their memory of material already learned or proceed, if desired, to a more in-depth coverage of a particular topic.

The general flow is from introductory background information to cells to excitable tissue (nerve and muscle) to organ systems, with logical transitions from one chapter to the next. For example, Chapter 8, "Muscle Physiology," ends with a discussion of cardiac (heart) muscle, which is carried forward in Chapter 9, "Cardiac Physiology." Even topics that seem unrelated in sequence, such as Chapter 12, "Body Defenses," and Chapter 13, "The Respiratory System," are linked together, in this case by ending Chapter 12 with a discussion of respiratory defense mechanisms.

Several organizational features warrant specific mention. The most difficult decision in organizing this text was placement of the endocrine material. There is merit in placing the chapters on the nervous and the endocrine (hormone-secreting) systems in close proximity because they are the body's two major regulatory systems. However, discussing details of the endocrine system immediately after the nervous system would disrupt the logical flow of material related to excitable tissue. In addition, the endocrine system cannot be covered in the depth its importance warrants if it is discussed before students have the background to understand this system's roles in maintaining homeostasis.

My solution to this dilemma is Chapter 4, "Principles of Neural and Hormonal Communication." This chapter introduces the underlying mechanisms of neural and hormonal action before the nervous system and specific hormones are mentioned in later chapters. It contrasts how nerve cells and endocrine cells communicate with other cells in carrying out their regulatory actions. Building on the different modes of action of nerve and endocrine cells, the last section of this chapter compares, in a general way, how the nervous and endocrine systems differ as regulatory systems. Chapter 5 then begins with the nervous system, providing a good link between Chapters 4 and 5. Chapters 5, 6, and 7 are devoted to the nervous system. Specific hormones are introduced in appropriate chapters, such as hormonal control of the heart and blood vessels in maintaining blood pressure in Chapters 9 and 10 and hormonal control of the kidneys in maintaining fluid balance in Chapters 14 and 15. The body's processing of absorbed energy-rich nutrient molecules is largely under endocrine control, providing a link from digestion (Chapter 16) and energy balance (Chapter 17) to the endocrine system (Chapters 18 and 19). These endocrine chapters pull together the source, functions, and control of specific endocrine secretions and serve as a summarizing and unifying capstone for homeostatic body function. Finally, building on the hormones that control the gonads (testes and ovaries) introduced in the endocrine chapters, the last chapter, Chapter 20, diverges from the theme of homeostasis to focus on reproductive physiology.

Besides the novel handling of hormones and the endocrine system, other organizational features are unique to this book. For example, unlike other physiology texts, the skin is covered in the chapter on defense mechanisms of the body (Chapter 12), in consideration of the skin's recently recognized immune functions. Bone is also covered more extensively in the endocrine chapter than in most undergraduate physiology texts, especially with regard to hormonal control of bone growth and bone's dynamic role in calcium metabolism.

Although there is a rationale for covering the various aspects of physiology in the order given here, it is by no means the only logical way of presenting the topics. Because each chapter is able to stand on its own, especially with the cross-references provided, instructors can vary the sequence of presentation at their discretion. Some chapters may even be omitted, depending on the students' needs and interests and the time constraints of the course. For example, a cursory explanation of the defense role of the leukocytes appears in Chapter 11 on blood, so an instructor can choose to omit the more detailed explanations of immune defense in Chapter 12.

New to the Ninth Edition

This edition has a new look, new pedagogical features, updates, and numerous revisions to make the book as current, relevant, and accessible to students as possible. Every aspect of the text has been upgraded as the following examples illustrate. For a detailed list of all changes, contact your Cengage Learning sales representative.

New look

Not only does this edition have fresh colors but the pages are more visually interesting because of creative wrapping of some of the written material around the art for a contemporary look instead of just being wrapped with a traditional, single 90-degree corner. See pp. 111, 245, and 413 for examples.

New self-check pedagogical tools

Already mentioned, new to this edition are several new or revised self-check features, including the new *Figure Focus* questions, more *Check Your Understanding* questions, and new organization of the end-of-chapter *Review Exercises* into hierarchical learning levels.

New and revised figures

New Art The following exemplify first-time illustrations added in this edition:

- Figure 5-9, Layers of the cerebral cortex, p. 147
- Figure 10-11, Major local chemical and physical means of controlling arteriolar caliber, p. 347
- Figure 16-11, Mechanism of $NaHCO_3$ secretion, p. 591

Revised Art Examples of extensively revised, newly conceptualized, or reorganized figures include the following:

- Figure 8-1, Characteristics of three types of muscle, p. 252
- Figure 10-26, Skeletal muscle pump enhancing venous return and countering effect of gravity on venous pressure, p. 363
- Figure 16-5, Oropharyngeal and esophageal stages of swallowing, p. 577

New Photos More than 50 new photos and replacement photos are incorporated throughout the text, including replacing 45% of the chapter opener photos. For instance, see Chapter 5 opener, a diffusion resonance image (dMRI) scan of the white matter pathways of the brain, p. 133. The following are other examples of content not shown in photos in previous editions:

- Figure 4-7, A micrograph of dendritic spines incorporated into Anatomy of the most common type of neuron, p. 95
- Figure 6-37, A scanning electron micrograph of the tip links between adjacent stereocilia, incorporated into The role of stereocilia in sound transduction, p. 218
- Table 16-3, A scanning electron micrograph of stomach lining showing gastric pits, incorporated into an integrated figure/table featuring The stomach mucosa and the gastric glands, p. 583

New tables

More new tables that group and consolidate information for easier learning have been added to this edition than ever before, as the following samples demonstrate:

- Table 4-2, Major Neurotransmitters, p. 107
- Table 8-3, Motor Control by CNS, p. 280
- Table 20-4, Stages of Follicular Development, p. 743

New boxed features

Several old boxes have been retired and two new boxes regarding timely, relevant content have been added: (1) *The Ups (Causes) and Downs (Treatments) of Hypertension*, in consideration of the fact that one third of all adults in the United States have hypertension (see pp. 372–373); and (2) *Still a Big Question: Why Do We Age?*, which focuses on the current theories of aging, in view of the increased graying of America as baby boomers are reaching old age (see pp. 678–679).

New, updated content

Recent discoveries and hot topics have been incorporated throughout as the following examples illustrate:

- In Chapter 2, inserted a discussion and figure of proteasomes breaking down ubiquinated proteins into recyclable building blocks (p. 27)
- Among the numerous new topics in Chapter 5 is the glymphatic system, a recently identified glia substitute for the lymphatic system in the brain (p. 137)
- Added a comparison of the trichromatic theory and the opponent-process theory of color vision in Chapter 6 (p. 205)
- In Chapter 9, expanded presentation of cardiac autorhythmicity to include both the membrane clock mechanism and the Ca^{2+} mechanism (together, the coupled-clock system) responsible for the pacemaker potential (p. 304)
- Introduced in Chapter 12 newly identified immune cells (innate lymphoid cells [ILCs] and innate response activator [IRA] B cells) that straddle the innate and adaptive immune systems (p. 415)
- Significantly expanded coverage of the microbiota and microbiome in Chapter 16 in light of a torrent of new findings in this hot area of science (pp. 613–614)
- In Chapter 17, updated discussion of brown fat in view of recent studies suggesting that irisin, a newly discovered chemical mediator released from exercising muscles, may promote "browning" of white adipose tissue by stimulating synthesis of uncoupling proteins in mitochondria of white fat cells (p. 632)
- Augmented coverage of the underlying molecular mechanism responsible for the suprachiasmatic nucleus's circadian oscillations in Chapter 18 by adding the interactions of PER and CRY with CLOCK and BMAL-1 (see p. 660)
- Updated discussion of islets of Langerhans in Chapter 19 to include secretion of amylin in addition to insulin by the beta cells and secretion of ghrelin by newly found epsilon cells (pp. 692 and 689)

- Expanded coverage of clinically related issues, such as adding a new discussion of concussions and chronic traumatic encephalopathy (p. 172)

Reorganization

Although the focus of each chapter remains the same as previous editions, I moved some content between and within chapters for better grouping of material, as follows:

- Moved the discussion of eicosanoids from Chapter 20 (in association with male accessory sex gland secretions) to Chapter 4, the chapter devoted primarily to neural and hormonal communication and signal transduction. Eicosanoids and cytokines are now more appropriately grouped together and presented in a new section entitled *Introduction to Paracrine Communication* (pp. 118–120)
- Transferred introduction of the JAK/STAT pathway from Chapter 18, where it was treated more as an aside in the discussion of signal transduction by growth hormone and prolactin, to Chapter 4, where the topic more logically fits in with coverage of other means of signal transduction (pp. 116–117)
- Rearranged and grouped together the material within Chapter 5 related to brain waves and the electroencephalogram for better flow and improved clarity (pp. 168–169)
- Based on reviewer input, relocated presentation of specific somatic reflexes, namely the stretch reflex, withdrawal reflex, and crossed extensor reflex, from Chapter 5, Central Nervous System, where these reflexes were covered in conjunction with the spinal cord, to Chapter 8, Muscle Physiology, where they are now included in the section on Control of Motor Movement (pp. 282, 284–286)

Clearer, more concise coverage

I look at every edition for opportunities to make the writing as clear, concise, well-organized, and relevant for readers as possible. By careful tightening, I was able to shave 22 pages from the text while retaining all essential content and adding more beneficial learning tools and updated content, a win-win for readers.

New and Enhanced Technology for Instructors and Students

NEW! MindTap for Human Physiology

MindTap is a personalized, fully digital learning platform of authoritative content, assignments, and services that engages students with interactivity while also offering instructors their choice in the configuration of coursework and enhancement of the curriculum via Web-based applications known as MindApps. MindApps range from ReadSpeaker (which reads the text out loud to students) to Kaltura (allowing you to insert inline video and audio into your curriculum). MindTap is well

beyond an eBook, a homework solution, a digital supplement, a resource center Web site, a course delivery platform, or a Learning Management System. It is the first in a new category—the Personal Learning Experience. MindTap for *Human Physiology* includes an integrated study guide, homework, and clinical case studies, among other valuable learning tools.

NEW! Aplia for Human Physiology

Aplia for *Human Physiology* helps students learn and understand key concepts via focused assignments and active learning opportunities that include randomized, automatically graded questions, exceptional text interaction, and detailed explanations. With Aplia, students move away from just memorizing facts toward a more conceptual understanding of the course materials, In addition, Aplia has a full course management system that can be used independently or in conjunction with other course management systems such as MindTap, D2L, or Blackboard.

NEW! Virtual Physiology Labs 2.0

Virtual Physiology Labs enable students to conduct experiments online without expensive equipment. By acquiring data, performing experiments, and using that data to explain physiology concepts, students become involved in the scientific process—they don't just watch or read about it.

Resources for Instructors

Instructor Companion Site

Everything you need for your course in one place! This collection of book-specific lecture and class tools is available online via www.cengage.com/login. Access and download PowerPoint™ presentations, images, the instructor's manual, videos, and more.

Cognero for Human Physiology, Ninth Edition

Cengage Learning Testing Powered by Cognero is a flexible, online system that allows you to:

- Author, edit, and manage test bank content from multiple Cengage Learning solutions
- Create multiple test versions in an instant
- Deliver tests from your Learning Management System, your classroom, or wherever you want.

Resources for Students

Coloring book for Human Physiology, Ninth Edition

This helpful study tool contains key pieces of art from the book and provides opportunities for students to interact with the material and explain the processes associated with the figures in their own words.

Photo Atlas for Anatomy and Physiology

This full-color atlas (with more than 600 photographs) depicts structures in the same colors as they would appear in real life or in a slide. Labels and color differentiations within each structure are used to facilitate identification of the structure's various components. The atlas includes photographs of tissue and organ slides, the human skeleton, commonly used models, cat dissections, cadavers, some fetal pig dissections, and some physiology materials.

Fundamentals of Physiology Laboratory Manual

This manual, which may be required by the instructor in courses that have a laboratory component, contains a variety of exercises that reinforce concepts covered in *Human Physiology: From Cells to Systems*, Ninth Edition. These laboratory experiences increase students' understanding of the subject matter in a straightforward manner, with thorough directions to guide them through the process and relevant questions for reviewing, explaining, and applying results.

Acknowledgments

I gratefully acknowledge the many people who helped with the first eight editions or this edition of the textbook. Also, I remain indebted to four people who contributed substantially to the original content of the book: Rachel Yeater (West Virginia University), who contributed the original material for the exercise physiology boxes; Spencer Seager (Weber State University), who prepared Appendix A, "A Review of Chemical Principles"; and Kim Cooper (Midwestern University) and John Nagy (Scottsdale Community College), who provided the Solving Quantitative Exercises at the ends of chapters.

In addition to the 184 reviewers who carefully evaluated the forerunner books for accuracy, clarity, and relevance, I express sincere appreciation to the following individuals who served as reviewers for this edition:

Ahmed Al-Assal, West Coast University
Amy Banes-Berceli, Oakland University
Patricia Clark, Indiana University-Purdue University
Elizabeth Co, Boston University
Steve Henderson, Chico State University
James Herman, Texas A&M University
Qingsheng Li, University of Nebraska-Lincoln
Douglas McHugh, Quinnipiac University
Linda Ogren, University of California, Santa Cruz
Roy Silcox, Brigham Young University

Also, I am grateful to the users of the textbook who have taken time to send helpful comments.

I have been fortunate to work with a highly competent, dedicated team from Cengage Learning, along with other capable external suppliers selected by the publishing company. I would like

to acknowledge all of their contributions, which collectively made this book possible. It has been a source of comfort and inspiration to know that so many people have been working diligently in so many ways to bring this book to fruition.

From Cengage Learning, Yolanda Cossio, Senior Product Team Manager, deserves warm thanks for her vision, creative ideas, leadership, and ongoing helpfulness. Yolanda's decisions were guided by what is best for the instructors and students who will use the textbook and its learning resources. Thanks also to Product Assistant Victor Luu, who coordinated many tasks for Yolanda during the development process. I appreciate the efforts of Content Developer Alexis Glubka for helping us launch this project and for Managing Developer Trudy Brown for taking over and not missing a beat when Alexis moved to another position. Trudy facilitated most of the development process, which proceeded efficiently and on schedule. Having served as a Production Editor in the past, Trudy was especially helpful in paving the way for a smooth transition from development to production. I am grateful for the biweekly conference calls with Yolanda and Trudy. Their input, expertise, and support were invaluable as collectively we made decisions to make this the best edition yet.

I appreciate the creative insight of Cengage Learning Senior Art Director John Walker, who oversaw the overall artistic design of the text and found the dynamic cover image that displays simultaneous power, agility, and grace in a "body in motion," the theme of our covers. The upward and "over-the-hump" movement of the high jumper symbolizes that this book will move the readers upward and over the hump in their understanding of physiology. I thank John for his patience and perseverance as we sifted through and rejected many photos until we found just what we were looking for.

The technology-enhanced learning tools in the media package were updated under the guidance of Media Developer Lauren Oliveira. These include the online interactive tutorials, media exercises, and other e-Physiology learning opportunities at the CengageBrain Web site. Associate Content Developers Casey Lozier and Kellie Petruzzelli oversaw development of the multiple hard-copy components of the ancillary package, making sure it was a cohesive whole. A hearty note of gratitude is extended to all of them for the high-quality multimedia package that accompanies this edition.

On the production side, I would like to thank Senior Content Project Manager Tanya Nigh, who closely monitored every step of the production process while simultaneously overseeing the complex production process of multiple books. I felt confident knowing that she was making sure that everything was going according to plan. I also thank Photo Researcher Priya Subbrayal and Text Researcher Kavitha Balasundaram for tracking down photos and permissions for the art and other copyrighted materials incorporated in the text. With everything finally coming together, Manufacturing Planner Karen Hunt oversaw the manufacturing process, coordinating the actual printing of the book.

No matter how well a book is conceived, produced, and printed, it would not reach its full potential as an educational tool without being efficiently and effectively marketed. Market Development Manager Julie Schuster played the lead role in marketing this text, for which I am most appreciative.

Cengage Learning also did an outstanding job in selecting highly skilled vendors to carry out particular production tasks. First and foremost, it has been my personal and professional pleasure to work with Cassie Carey, Production Editor at Graphic World, who coordinated the day-to-day management of production. In her competent hands lay the responsibility of seeing that all copyediting, art, typesetting, page layout, and other related details got done right and in a timely fashion. Thanks to her, the production process went smoothly, the best ever. I also want to extend a hearty note of gratitude to compositor Graphic World for their accurate typesetting; execution of the art revisions; and attractive, logical layout. Lisa Buckley deserves thanks for the fresh and attractive, yet space-conscious, appearance of the book's interior and for envisioning the book's visually appealing exterior.

Finally, my love and gratitude go to my family for the sacrifices in family life as this ninth edition was being developed and produced. My husband, Peter Marshall, deserves special appreciation and recognition for assuming extra responsibilities while I was working on the book. I could not have done this, or any of the preceding books, without his help, support, and encouragement.

Thanks to all!

Lauralee Sherwood

Introduction to Physiology and Homeostasis

Oliver Eltinger/Agefotostock

Homeostasis (maintaining internal consistency) in action. Body temperature is maintained as evaporation of sweat cools the body to counterbalance heat gained through exertion on a hot day, and fluid balance is maintained as thirst encourages fluid intake to offset fluid lost in sweat.

Homeostasis Highlights

Physiology focuses on body functions. This book explores how the various components of the human body function to maintain **homeostasis**, the relatively stable conditions inside the body needed for survival. Each chapter begins with *Homeostasis Highlights* to give you a heads up on how the body part under discussion fits in with the big picture of homeostasis. Each chapter concludes with *Homeostasis: Chapter in Perspective,* which points out specific ways in which the topic covered in the chapter contributes to homeostasis.

1.1 Introduction to Physiology

Look at Figure 1-1. The activities described are a sampling of the body processes that occur all the time just to keep us alive. We usually take these life-sustaining activities for granted and do not really think about "what makes us tick," but that's what physiology is about. **Physiology** is the study of the functions of living things. Specifically, we will focus on how the human body works.

Physiology focuses on mechanisms of action.

Two approaches are used to explain events that occur in the body; one emphasizes the *purpose* of a body process and the other emphasizes the underlying *mechanism* by which this process occurs. In response to the question "Why do I shiver when I am cold?" one answer would be "to help my body warm up, because shivering generates heat." This approach, which explains body functions in terms of meeting a bodily need, emphasizes *why* body processes occur. Physiologists, however, explain *how* processes occur in the body. They view the body as a machine whose mechanisms of action can be explained in terms of cause-and-effect sequences of physical and chemical processes—the same types of processes that occur throughout the universe. A physiologist's explanation of shivering is that when temperature-sensitive nerve cells detect a fall in body temperature, they signal the area in the brain responsible for temperature regulation. In response, this brain area activates nerve pathways that ultimately bring about involuntary, oscillating muscle contractions (that is, shivering).

Structure and function are inseparable.

Physiology is closely related to **anatomy**, the study of the structure of the body. Physiological mechanisms are made possible by the structural design and relationships of the various body parts that carry out each of these functions. Just as the functioning of an automobile depends on the shapes, organization, and interactions of its various parts, the structure and function of the human body are inseparable. Therefore, as we tell the story of how the body works, we provide sufficient anatomic background for you to understand the function of the body part being discussed.

Some structure–function relationships are obvious. For example, the heart is well designed to receive and pump blood, the teeth to tear and grind food, and the hingelike elbow joint to permit bending of the arm. In other situations, the interdependence of form and function is more subtle but equally important. Consider the interface between air and blood in the lungs as an example: The respiratory airways, which carry air from the outside into the lungs, branch extensively when they reach the lungs. Tiny air sacs cluster at the ends of the huge number of airway branches. The branching is so extensive that the lungs contain about 300 million air sacs. Similarly, the vessels carrying blood into the lungs branch extensively and form dense networks of small vessels that encircle each air sac (see ▌Figure 13-2, p. 448). Because of this structural relationship, the total surface area forming an interface between the air in the air sacs and the blood in the small vessels is about the size of one side of a volleyball court. This tremendous interface is crucial for the lungs' ability to efficiently carry out their function: the transfer of needed oxygen (O_2) from the air into the blood and the unloading of the waste product carbon dioxide (CO_2) from the blood into the air. The greater the surface area available for these exchanges, the faster O_2 and CO_2 can move between the air and the blood. This large functional interface packaged within the confines of your lungs is possible only because both the air-containing and blood-containing components of the lungs branch extensively.

Check Your Understanding 1.1

1. Define *physiology*.
2. The nutrient-absorbing intestinal cells have a multitude of fingerlike projections in contact with the digested food (see ▌Figure 16-20, p. 602). Based on your knowledge of structure–function relationships, explain the functional advantage of this structural feature. (Answers are in Appendix C.)

1.2 Levels of Organization in the Body

We now turn to how the body is structurally organized into a total functional unit, from the chemical level to the whole body (▌Figure 1-2). These levels of organization make possible life as we know it.

The chemical level: Various atoms and molecules make up the body.

Like all matter, both living and nonliving, the human body is a combination of specific *atoms,* which are the smallest building blocks of matter. The most common atoms in the body—oxygen, carbon, hydrogen, and nitrogen—make up approximately 96% of the total body chemistry. These common atoms and a few others combine to form the *molecules* of life, such as proteins, carbohydrates, fats, and nucleic acids (genetic material, such as deoxyribonucleic acid, or DNA). These important atoms and molecules are the inanimate raw ingredients from which all living things arise. (See Appendix A for a review of this chemical level.)

The cellular level: Cells are the basic units of life.

The mere presence of a particular collection of atoms and molecules does not confer the unique characteristics of life. Instead, these nonliving chemical components must be arranged and packaged in precise ways to form a living entity. The **cell**, the fundamental unit of both structure and function in a living being, is the smallest unit capable of carrying out the processes associated with life. Cell physiology is the focus of Chapter 2.

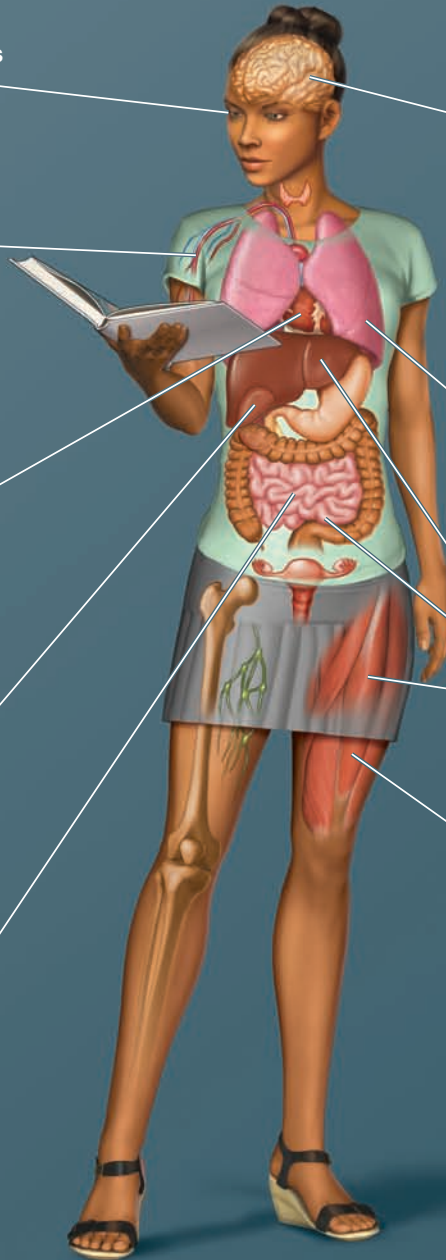
During the minute that it will take you to read this page:

Your eyes will convert the image from this page into electrical signals (nerve impulses) that will transmit the information to your brain for processing.

Approximately 150 million old red blood cells will die and be replaced by newly produced ones.

Your heart will beat 70 times, pumping 5 liters (about 5 quarts) of blood to your lungs and another 5 liters to the rest of your body.

More than 1 liter of blood will flow through your kidneys, which will act on the blood to conserve the "wanted" materials and eliminate the "unwanted" materials in the urine. Your kidneys will produce 1 mL (about a thimbleful) of urine.

Your digestive system will be processing your last meal for transfer into your bloodstream for delivery to your cells.


Besides receiving and processing information such as visual input, your brain will provide output to your muscles to help maintain your posture, move your eyes across the page as you read, and turn the page as needed. Chemical messengers will carry signals between your nerves and muscles to trigger appropriate muscle contraction.

You will breathe in and out about 12 times, exchanging 6 liters of air between the atmosphere and your lungs.

Your cells will consume 250 mL (about a cup) of oxygen and produce 200 mL of carbon dioxide.

You will use about 2 calories of energy derived from food to support your body's "cost of living," and your contracting muscles will burn additional calories.

❙Figure 1-1 A glimpse at your body functions.

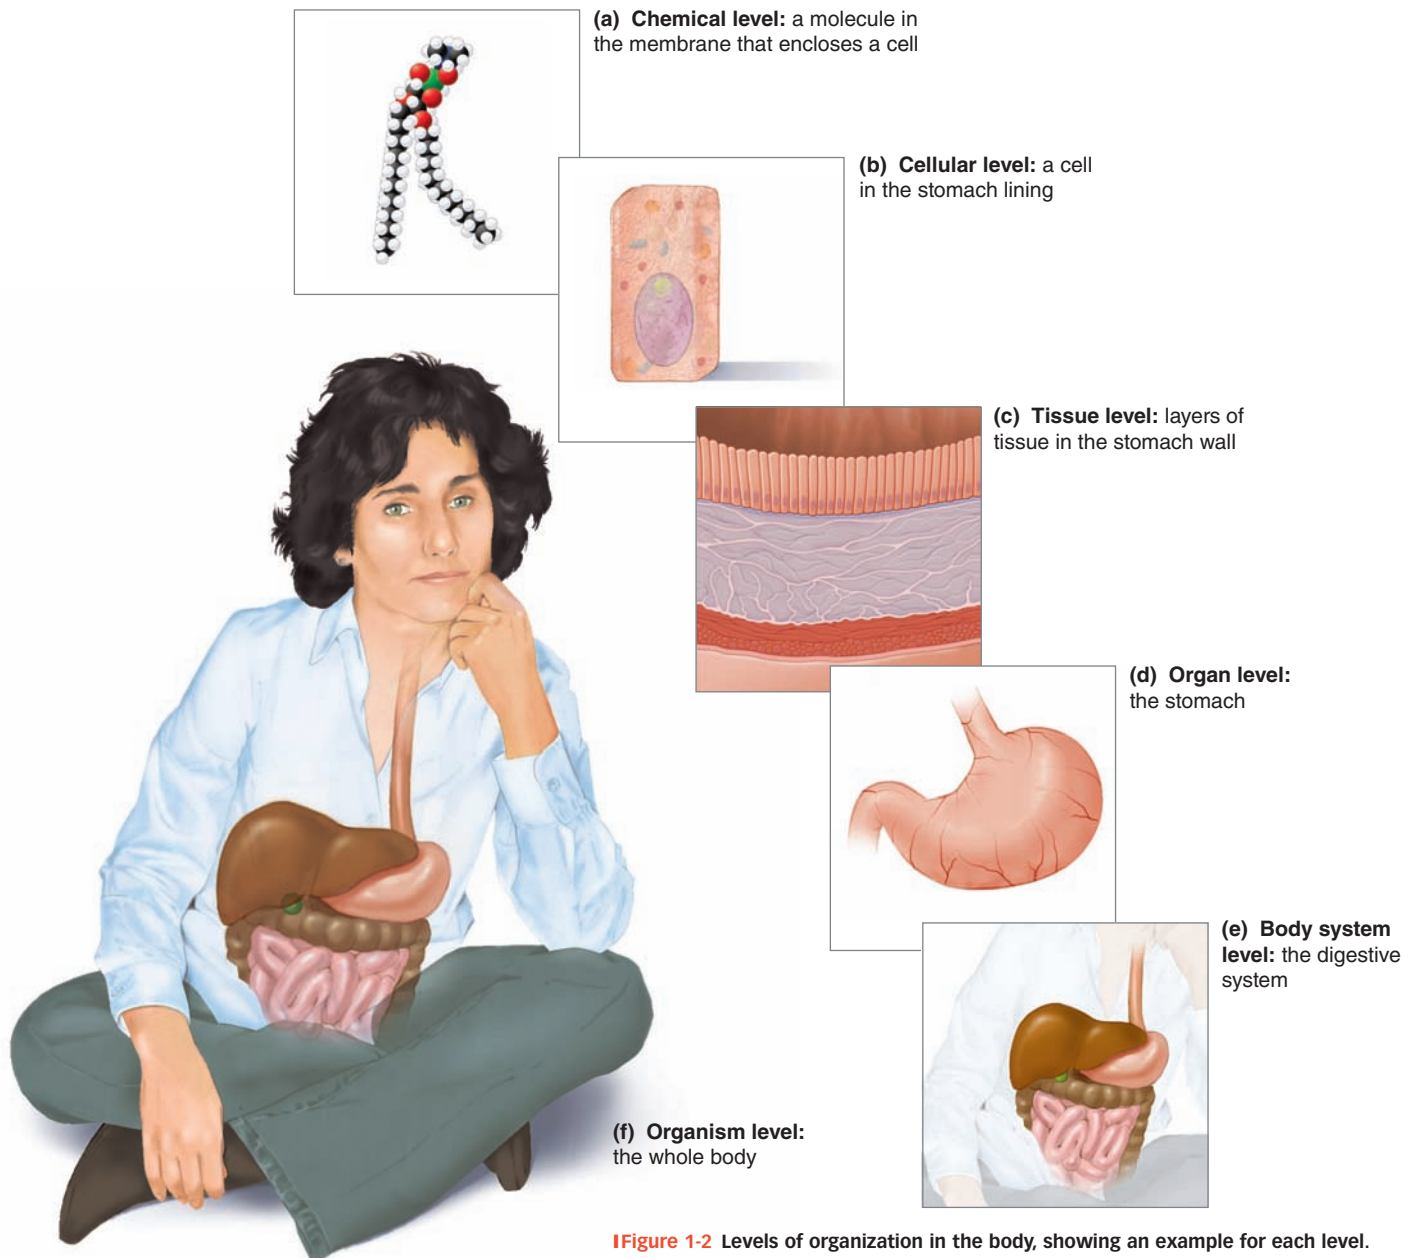
(a) **Chemical level:** a molecule in the membrane that encloses a cell

(b) **Cellular level:** a cell in the stomach lining

(c) **Tissue level:** layers of tissue in the stomach wall

(d) **Organ level:** the stomach

(e) **Body system level:** the digestive system

(f) **Organism level:** the whole body


▌Figure 1-2 **Levels of organization in the body, showing an example for each level**.

An extremely thin, oily, complex barrier, the *plasma membrane,* encloses the contents of each cell and controls movement of materials into and out of the cell. Thus, the cell's interior contains a combination of atoms and molecules that differs from the mixture of chemicals in the environment surrounding the cell. Given the importance of the plasma membrane and its associated functions for carrying out life processes, Chapter 3 is devoted entirely to this structure.

Organisms are independent living entities. The simplest forms of independent life are single-celled organisms such as bacteria and amoebas. Complex multicellular organisms, such as trees and humans, are structural and functional aggregates of trillions of cells (*multi* means "many"). In the simpler multicellular forms of life—for example, a sponge—the cells of the organism are all similar. However, more complex organisms, such as humans, have many kinds of cells, such as muscle cells, nerve cells, and gland cells.

Each human organism begins when an egg and sperm unite to form a single new cell, which multiplies and forms a growing mass through myriad cell divisions. If cell multiplication were the only process involved in development, all body cells would be essentially identical, as in the simplest multicellular life-forms. However, during development of complex multicellular organisms such as humans, each cell also **differentiates**, or becomes specialized to carry out a particular function. As a result of cell differentiation, your body is made up of about 200 specialized types of cells.

Basic Cell Functions All cells, whether they exist as solitary cells or as part of a multicellular organism, perform certain basic functions essential for their own survival, including the following:

1. Obtaining food (nutrients) and O_2 from the environment surrounding the cell.

2. Performing chemical reactions that use nutrients and O_2 to provide energy for the cells, as follows:

$$\text{Food} + O_2 \rightarrow CO_2 + H_2O + \text{energy}$$
3. Eliminating to the cell's surrounding environment CO_2 and other by-products, or wastes, produced during these chemical reactions.

4. Synthesizing proteins and other components needed for cell structure, for growth, and for carrying out particular cell functions. For example, **enzymes** are specialized proteins that speed up particular chemical reactions in the body.

5. Largely controlling the exchange of materials between the cell and its surrounding environment.

6. Moving materials internally from one part of the cell to another, with some cells also being able to move themselves through their surrounding environment.

7. Being sensitive and responsive to changes in the surrounding environment.

8. In the case of most cells, reproducing. Exceptions are nerve cells and muscle cells, which lose the ability to reproduce soon after they are formed. This is the reason strokes, which result in lost nerve cells in the brain, and heart attacks, which cause death of heart muscle cells, can be so devastating.

Because all cells are remarkably similar in the ways they carry out these basic functions, they share many common characteristics despite their specialization.

Specialized Cell Functions In multicellular organisms, each cell also performs a specialized function, which is usually a modification or elaboration of a basic cell function. Here are a few examples:

■ By taking special advantage of their protein-synthesizing ability, the gland cells of the digestive system secrete digestive enzymes that break down ingested food.

■ Certain kidney cells can selectively retain the substances needed by the body while eliminating unwanted substances in the urine because of their highly specialized ability to control exchange of materials between the cell and its environment.

■ Muscle contraction, which involves selective movement of internal structures to generate tension in the muscle cells, is an elaboration of the inherent ability of these cells to produce intracellular movement (*intra* means "within").

■ Capitalizing on the basic ability of cells to respond to changes in their surrounding environment, nerve cells generate and transmit to other body regions electrical impulses that relay information

about changes to which the nerve cells are responsive. For example, nerve cells in the ear can relay information to the brain about sounds in the body's surroundings.

Each cell performs these specialized activities in addition to carrying on the unceasing, fundamental activities required of all cells. The basic cell functions are essential for survival of individual cells, whereas the specialized contributions and interactions among the cells of a multicellular organism are essential for survival of the whole body.

Just as a machine does not function unless all its parts are properly assembled, the cells of the body must be specifically organized to carry out the life-sustaining processes of the body as a whole, such as digestion, respiration, and circulation. Cells are progressively organized into tissues, organs, body systems, and finally the whole body.

The tissue level: Tissues are groups of cells of similar specialization.

Cells of similar structure and specialized function combine to form **tissues**, of which there are four *primary types:* muscle, nervous, epithelial, and connective (❚ Figure 1-3). Each tissue consists of cells of a single specialized type, along with varying amounts of extracellular material (*extra* means "outside of ").

■ **Muscle tissue** consists of cells specialized for contracting, which generates tension and produces movement. The three types of muscle tissue include *skeletal muscle,* which moves the skeleton; *cardiac muscle,* which pumps blood out of the heart;

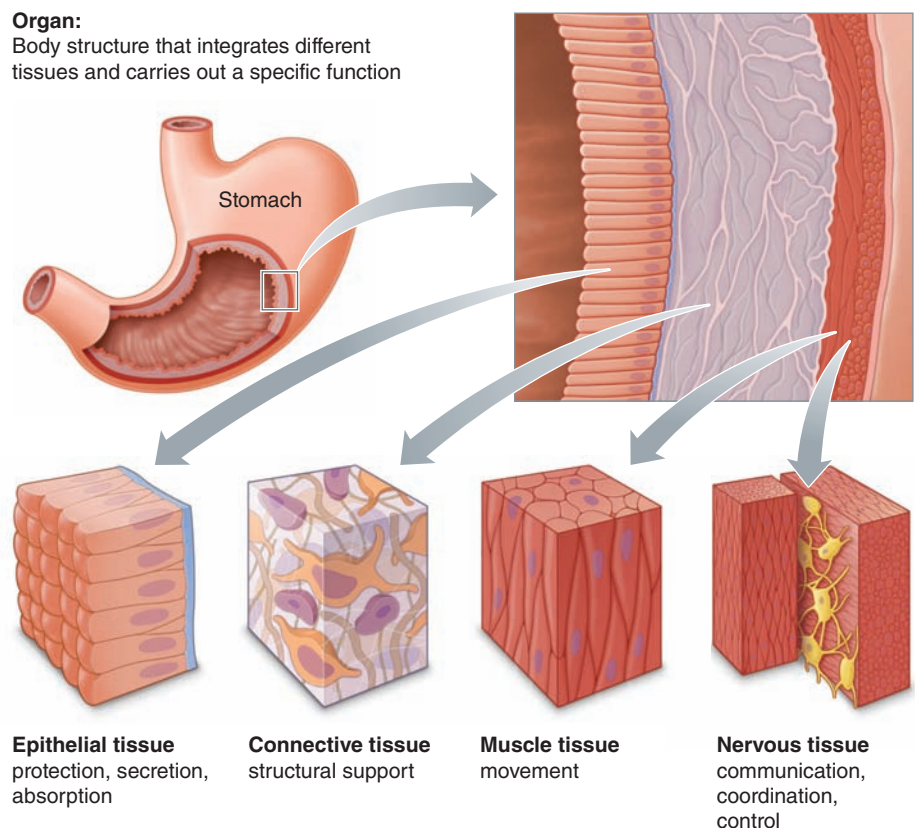
Organ:
Body structure that integrates different tissues and carries out a specific function

Stomach

Epithelial tissue
protection, secretion, absorption

Connective tissue
structural support

Muscle tissue
movement

Nervous tissue
communication, coordination, control


❚Figure 1-3 **The stomach as an organ made up of all four primary tissue types.**

and *smooth muscle,* which controls movement of contents through hollow tubes and organs, such as movement of food through the digestive tract.

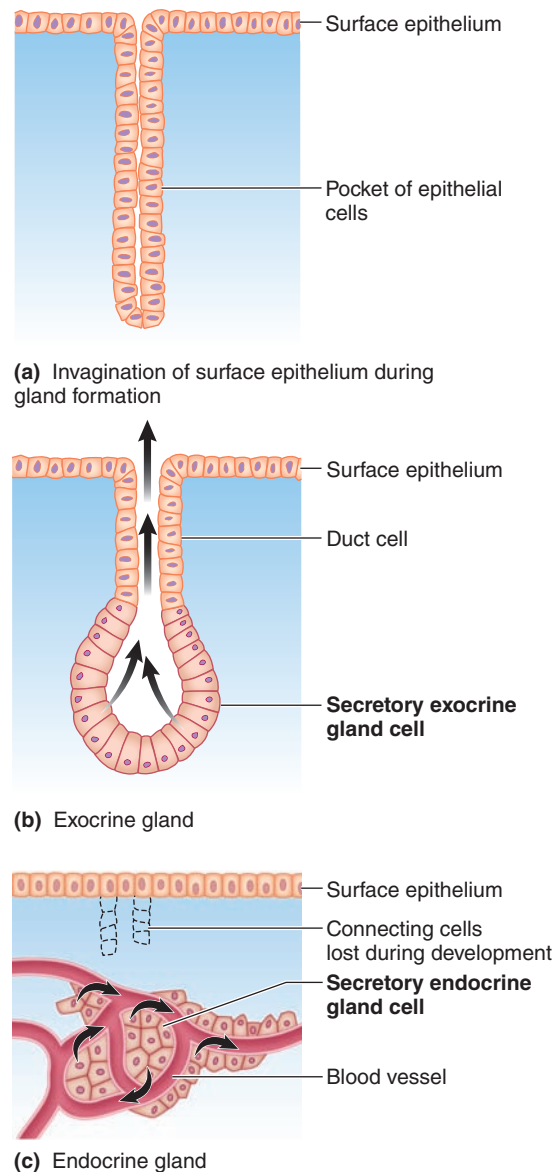
■ **Nervous tissue** consists of cells specialized for initiating and transmitting electrical impulses, sometimes over long distances. These electrical impulses act as signals that relay information from one part of the body to another. Such signals are important in communication, coordination, and control in the body. Nervous tissue is found in the brain, spinal cord, nerves, and special sense organs.

■ **Epithelial tissue** consists of cells specialized for exchanging materials between the cell and its environment. Any substance that enters or leaves the body must cross an epithelial barrier. Epithelial tissue is organized into two general types of structures: *epithelial sheets* and *secretory glands.* Epithelial sheets are layers of tightly joined cells that cover and line various parts of the body. For example, the outer layer of the skin is epithelial tissue, as is the lining of the digestive tract. In general, epithelial sheets serve as boundaries that separate the body from its surroundings and from the contents of cavities that open to the outside, such as the digestive tract lumen. (A **lumen** is the cavity within a hollow organ or tube.) Only selective transfer of materials is possible between regions separated by an epithelial barrier. The type and extent of controlled exchange vary depending on the location and function of the epithelial tissue. For example, the skin can exchange little between the body and outside environment, making it a protective barrier. By contrast the epithelial cells lining the small intestine of the digestive tract are specialized for absorbing nutrients that have come from outside the body.

Glands are epithelial tissue derivatives specialized for secreting. **Secretion** is the release from a cell, in response to appropriate stimulation, of specific products that have been produced by the cell. Glands are formed during embryonic development by pockets of epithelial tissue that dip inward from the surface and develop secretory capabilities. The two categories of glands are *exocrine* and *endocrine* (❙Figure 1-4). During development, if the connecting cells between the epithelial surface cells and the secretory gland cells within the depths of the pocket remain intact as a duct between the gland and the surface, an exocrine gland is formed. **Exocrine glands** secrete through ducts to the outside of the body (or into a cavity that opens to the outside) (*exo* means "external"; *crine* means "secretion"). Examples are sweat glands and glands that secrete digestive juices. If, in contrast, the connecting cells disappear during development and the secretory gland cells are isolated from the surface, an endocrine gland is formed. **Endocrine glands** lack ducts and release their secretory products, known as *hormones,* internally into the blood (*endo* means "internal"). For example, the pancreas secretes insulin into the blood, which transports this hormone to its sites of action throughout the body. Most cell types depend on insulin for taking up glucose (sugar).

■ **Connective tissue** is distinguished by having relatively few cells dispersed within an abundance of extracellular material. As its name implies, connective tissue connects, supports, and

(a) Invagination of surface epithelium during gland formation

(b) Exocrine gland


(c) Endocrine gland

❙Figure 1-4 **Exocrine and endocrine glands.** (a) Glands form during development from pocketlike invaginations of surface epithelial cells. (b) Exocrine gland cells release their secretory product through a duct to the outside of the body (or to a cavity in communication with the outside). (c) Endocrine gland cells release their secretory product (a hormone) into the blood.

FIGURE FOCUS: *Milk-secreting glands are surrounded by musclelike cells that squeeze out the milk in response to oxytocin secreted into the blood when a baby breast-feeds. Are milk-secreting glands exocrine or endocrine? Is oxytocin secreted by an exocrine or endocrine gland? (Answers are in Appendix C.)*

anchors various body parts. It includes such diverse structures as the loose connective tissue that attaches epithelial tissue to underlying structures; tendons, which attach skeletal muscles to bones; bone, which gives the body shape, support, and protection; and blood, which transports materials from one part of the body to another. Except for blood, the cells within connective tissue produce specific structural molecules that they release into the extracellular spaces between the cells. One such molecule is the rubber band–like protein fiber *elastin*; its presence facilitates the stretching and recoiling of structures

such as the lungs, which alternately inflate and deflate during breathing.

Muscle, nervous, epithelial, and connective tissue are the primary tissues in a classical sense—that is, each is an integrated collection of cells with the same specialized structure and function. The term *tissue* is also often used, as in clinical medicine, to mean the aggregate of various cellular and extracellular components that make up a particular organ (for example, lung tissue or liver tissue).

The organ level: An organ is a unit made up of several tissue types.

Organs consist of two or more types of primary tissue organized to perform particular functions. The stomach, an example of an organ, is made up of all four primary tissue types (see ❙Figure 1-3). The tissues of the stomach function collectively to store ingested food, move it forward into the rest of the digestive tract, and begin the digestion of protein. The stomach is lined with epithelial tissue that restricts the transfer of harsh digestive chemicals and undigested food from the stomach lumen into the blood. Epithelial gland cells in the stomach include exocrine cells, which secrete protein-digesting juices into the lumen, and endocrine cells, which secrete a hormone that helps regulate the stomach's exocrine secretion and muscle contraction. The stomach wall contains smooth muscle tissue, whose contractions mix ingested food with the digestive juices and push the mixture out of the stomach and into the intestine. The stomach wall also contains nervous tissue, which, along with hormones, controls muscle contraction and gland secretion. Connective tissue binds together all these various tissues.

The body system level: A body system is a collection of related organs.

Groups of organs are further organized into **body systems**. Each system is a collection of organs that perform related functions and interact to accomplish a common activity essential for survival of the whole body. For example, the digestive system consists of the mouth, pharynx (throat), esophagus, stomach, small intestine, large intestine, salivary glands, exocrine pancreas, liver, and gallbladder. These digestive organs cooperate to break food down into small nutrient molecules that can be absorbed into the blood for distribution to all cells.

The human body has 11 systems: circulatory, digestive, respiratory, urinary, skeletal, muscular, integumentary, immune, nervous, endocrine, and reproductive (❙Figure 1-5). Chapters 4 through 20 cover the details of these systems.

The organism level: The body systems are packaged into a functional whole body.

Each body system depends on the proper functioning of other systems to carry out its specific responsibilities. The whole body of a multicellular organism—a single, independently living individual—consists of the various body systems structurally and functionally linked as an entity that is separate from its sur-

rounding environment. Thus, the body is made up of living cells organized into life-sustaining systems.

The different body systems do not act in isolation from one another. Many complex body processes depend on the interplay among multiple systems. For example, regulation of blood pressure depends on coordinated responses among the circulatory, urinary, nervous, and endocrine systems. Even though physiologists may examine body functions at any level from cells to systems (as indicated in the title of this book), their ultimate goal is to integrate these mechanisms into the big picture of how the entire organism works as a cohesive whole.

Currently, researchers are hotly pursuing several approaches for repairing or replacing tissues or organs that can no longer adequately perform vital functions because of disease, trauma, or age-related changes. (See the boxed feature on pp. 10 and 11, ❙Concepts, Challenges, and Controversies. Each chapter has similar boxed features that explore in greater depth high-interest information on such diverse topics as environmental impact on the body, aging, ethical issues, discoveries regarding common diseases, and historical perspectives.)

We next focus on how the different body systems normally work together to maintain the internal conditions necessary for life.

Check Your Understanding 1.2

1. List and describe the levels of organization in the body.
2. State the basic cell functions.
3. Name the four primary types of tissue and give an example of each.

1.3 Concept of Homeostasis

If each cell has basic survival skills, why can't the body cells live without performing specialized tasks and being organized according to specialization into systems that accomplish functions essential for the whole organism's survival? The cells in a multicellular organism cannot live and function without contributions from the other body cells because most cells are not in direct contact with the external environment. The **external environment** is the surrounding environment in which an organism lives. A single-celled organism such as an amoeba obtains nutrients and O_2 directly from its immediate external surroundings and eliminates wastes back into those surroundings. A muscle cell or any other cell in a multicellular organism has the same need for life-supporting nutrient and O_2 uptake and waste elimination; yet, the muscle cell is isolated from the external environment surrounding the body. How can it make vital exchanges with the external environment with which it has no contact? The key is the presence of a watery internal environment. The **internal environment** is the fluid that surrounds the cells and through which they make life-sustaining exchanges.
Circulatory system	**Digestive system**	**Respiratory system**	**Urinary system**	**Skeletal system**	**Muscular system**
heart, blood vessels, blood	mouth, pharynx, esophagus, stomach, small intestine, large intestine, salivary glands, exocrine pancreas, liver, gallbladder	nose, pharynx, larynx, trachea, bronchi, lungs	kidneys, ureters, urinary bladder, urethra	bones, cartilage, joints	skeletal muscles

❙Figure 1-5 **Components of the body systems.**

Body cells are in contact with a privately maintained internal environment.

The fluid collectively contained within all body cells is called **intracellular fluid (ICF)**. The fluid outside the cells is called **extracellular fluid (ECF)**. Note that the ECF is outside the cells but inside the body. Thus, the ECF is the internal environment of the body. You live in the external environment; your cells live in the body's internal environment.

ECF is made up of two components: the **plasma**, the fluid portion of the blood, and the **interstitial fluid**, which surrounds and bathes the cells (*inter* means "between"; *stitial* means "that which stands") (❙Figure 1-6).

No matter how remote a cell is from the external environment, it can make life-sustaining exchanges with its surrounding fluid. Particular body systems accomplish the transfer of materials between the external environment and the internal environment so that the composition of the internal environment is appropriately maintained to support the life and functioning of the cells. The digestive system transfers the nutrients required by all body cells from the external environment into the plasma, and the respiratory system transfers O_2 from the external environment into the plasma. The circulatory system distributes these nutrients and O_2 throughout the body. Materials are thoroughly mixed and exchanged between the plasma and the interstitial fluid across the capillaries, the smallest and thinnest of blood vessels. As a result, the nutrients and O_2 originally obtained from the

external environment are delivered to the interstitial fluid, from which the body cells pick up these needed supplies. Similarly, wastes produced by the cells are released into the interstitial fluid, picked up by the plasma, and transported to the organs that specialize in eliminating these wastes from the internal environment to the external environment. The lungs remove CO_2 from the plasma and blow out this waste, and the kidneys remove other wastes for elimination in the urine.

Thus, a body cell takes in essential nutrients from its watery surroundings and eliminates wastes into these same surroundings, just as an amoeba does. The main difference is that each body cell must help maintain the composition of the internal environment so that this fluid continuously remains suitable to support the existence of all body cells. In contrast, an amoeba does nothing to regulate its surroundings.

Body systems maintain homeostasis, a dynamic steady state in the internal environment.

Body cells can live and function only when the ECF is compatible with their survival; thus, the chemical composition and physical state of this internal environment must be maintained within narrow limits. As cells take up nutrients and O_2 from the internal environment, these essential materials must constantly be replenished. Likewise, wastes must constantly be removed from the internal environment so that they do not reach toxic
Integumentary system
skin, hair, nails

Immune system

Female: ovaries, oviducts, uterus, vagina, breasts

levels. Other aspects of the internal environment important for maintaining life, such as temperature, also must be kept relatively constant. Maintenance of a relatively stable internal environment is termed **homeostasis** (*homeo* means "similar"; *stasis* means "to stand or stay").

The functions performed by each body system contribute to homeostasis, thereby maintaining within the body the environment required for the survival and function of all cells. Cells, in turn, make up body systems. This is the central theme of physiology and of this book: *Homeostasis is essential for the survival of each cell, and each cell, through its specialized activities as part of a body system, helps maintain the internal environment shared by all cells* (❙Figure 1-7, p. 12).

The internal environment must be kept relatively stable, but this does not mean that its composition, temperature, and other characteristics are absolutely unchanging. Both external and internal factors continuously threaten to disrupt homeostasis. When any factor starts to move the internal environment away from optimal conditions, the body systems initiate appropriate counter-reactions to minimize the change. For example, when you're exposed to a cold environmental temperature (an external factor), your body temperature tends to fall. In response, the temperature control center in your brain initiates compensatory measures, such as shivering, to raise your body temperature to normal. By contrast, when you exercise, your working muscles produce extra heat (an internal factor) that tends to increase your body temperature. In response, the temperature control

center brings about sweating and other compensatory measures to reduce your body temperature to normal.

Thus, homeostasis is not a rigid, fixed state but a dynamic steady state in which changes that occur are minimized by compensatory physiological responses. The term *dynamic* refers to each homeostatically regulated factor being marked by continuous change, whereas *steady state* implies that these changes do
❙Figure 1-6 **Components of the extracellular fluid (internal environment).**

Stem Cell Science and Regenerative Medicine: Making Defective Body Parts Like New Again

LIVER FAILURE, PARALYZING SPINAL-CORD INJURY, diabetes mellitus, damaged heart muscle, arthritis, extensive burns, a cancerous breast, an arm mangled in an accident—although our bodies are remarkable and normally serve us well, sometimes a body part is defective, injured beyond repair, or lost in such situations. In addition to the loss of quality of life for affected individuals, the cost of treating patients with lost, permanently damaged, or failing organs accounts for about half of the total health-care expenditures in the United States. Ideally, when the body suffers an irreparable loss, new, permanent replacement parts would be substituted to restore normal function and appearance. Fortunately, this possibility is moving rapidly from the realm of science fiction to the reality of scientific progress.

The Medical Promise of Stem Cells

Stem cells offer exciting medical promise for repairing or replacing organs that are diseased, damaged, or worn out. **Stem cells** are versatile cells that are not specialized for a specific function but can divide to give rise to highly specialized cells while maintaining a supply of new stem cells. Two natural categories of stem cells are under investigation: embryonic stem cells from early embryos and tissue-specific stem cells from adults. **Embryonic stem cells (ESCs)** result from the early divisions of a fertilized egg. These undifferentiated cells ultimately give rise to all mature, specialized cells of the body while simultaneously self-renewing. ESCs are *pluripotent,* meaning they have the potential to generate any of the more than 200 cell types in the body if given the appropriate cues.

During development, the undifferentiated ESCs give rise to many partially differentiated **tissue-specific stem cells**, each of which becomes committed to generating the highly differentiated, specialized cell types that compose a particular tissue. For example, tissue-specific muscle stem cells give rise to specialized muscle cells. Some tissue-specific stem cells remain in adult tissues, where they serve as a continual source of new specialized cells to maintain or repair that particular tissue. Tissue-specific stem cells are even present in adult brain and muscle tissue. Even though mature nerve and muscle cells cannot reproduce themselves, to a limited extent adult brains and muscles can grow new cells throughout life by means of these persisting stem cells. However, this process is too slow to keep pace with major losses, as in a stroke or heart attack.

In 1998, for the first time, researchers succeeded in isolating human ESCs and maintaining them indefinitely in an undifferentiated state in culture. With **cell culture**, cells isolated from a living organism continue to thrive and reproduce in laboratory dishes when supplied with appropriate nutrients and supportive materials.

The medical promise of ESCs lies in their potential to serve as an all-purpose material that can be coaxed into whatever cell types are needed to patch up the body. Studies since their discovery demonstrate that these cells have the ability to differentiate into particular cells when exposed to the appropriate chemical signals. As scientists gradually learn to prepare the right cocktail of chemical signals to direct the undifferentiated cells into the desired cell types, they will have the potential to fill deficits in damaged or dead tissues with healthy cells.

Ethical Concerns and Political Issues

Despite this potential, ESC research is fraught with controversy because of the source of these cells: They are isolated from discarded embryos from abortion clinics and in vitro fertility ("test-tube baby") clinics. Opponents of using ESCs are morally and ethically concerned because embryos are destroyed in the process of harvesting these cells. Proponents argue that these embryos were destined to be destroyed anyway—a decision already made by the parents of the embryos—and that these stem cells have great potential for alleviating human suffering. Thus, ESC science has become inextricably linked with stem cell politics.

Since the mid-1990s, federal funding in the United States for research involving cells derived from embryos has been on-and-off as presidents, Congress, and the courts have grappled with ethical, legal, and public policy challenges. In general, ESC research has been encouraged by Democratic administrations and constrained under Republican leadership. Federally funded research on human ESCs is currently legal as a result of the latest court battle that ended in 2012, but the controversy persists. In the meantime, for more than the past two decades research using ESCs has continued to move forward, funded by private and state resources along with see-saw federal funding.

The Search for Noncontroversial Stem Cells

Because of the controversies and setbacks surrounding use of ESCs, some researchers have searched for alternative ways to obtain stem cells, such as by using tissue-specific stem cells from adult tissues as a substitute for pluripotent ESCs. These adult stem cells were thought to give rise only to the specialized cells of a particular tissue. However, although these partially differentiated adult stem cells do not have the complete developmental potential of ESCs, they have been coaxed into producing a wider variety of cells than originally thought possible. To name a few examples, provided the right supportive environment, stem cells from the brain can give rise to blood cells and fat-tissue stem cells to bone, cartilage, and muscle cells. Although ESCs hold greater potential for developing treatments for a broader range of diseases, adult stem cells are more accessible than ESCs, and their use is not controversial.

Long-running political setbacks have inspired still other scientists to search for new ways to obtain more versatile stem cells without destroying embryos. The newest technique with the greatest potential involves turning back the clock on adult specialized cells, such as easily obtained skin cells, and converting them to their embryonic state.

Like ESCs, these reprogrammed cells, called **induced pluripotent stem cells (iPSCs)**, have the potential to differentiate into any cell type in the body. However, iPSCs are less responsive than ESCs to differentiation signals. iPSCs retain subtle memories of the tissue from which they came, which reduces the efficiency with which they can be converted into new cell types. More recently, investigators have directly converted skin cells into neurons without first reverting them to an embryonic state.

Other researchers have been looking for a nonembryonic source of the more versatile ESCs. One group recently succeeded in creating patient-specific human ESCs through controversial **therapeutic cloning**. With this technique, the nucleus (gene-containing part of a cell) is removed from a patient's skin cell and transferred into a healthy, unfertilized egg cell (donated by another individual) that has been stripped of its own nucleus. When properly cultivated, the egg, which now genetically matches the patient, multiplies into a mass from which ESCs that bear the identical DNA of the patient can be harvested. As a less controversial alternative, another investigator has identified embryoniclike stem cells in breast milk that appear to be pluripotent.

Through rapidly evolving new techniques such as these, soon any mature body cell likely can be converted into any other cell type. Cell reprogramming is one of the hottest areas of investigation in life sciences today.

Whatever the source of the cells, stem cell research promises to revolutionize medicine in the 21st century as profoundly as the impact of vaccines and antibiotics in the 20th century. An estimated 3000 Americans die every day from conditions that may in the future be treatable with stem cell derivatives. As examples of successes, a healthy version of a specific type of ESC-derived eye cell is currently being injected into the eyes of patients with an inherited condition that leads to blindness to save their sight, and stem cells injected into failing hearts have replaced damaged heart muscle thereby improving the hearts' pumping ability. Scientists are even working on growing customized tissues and eventually whole, made-to-order replacement organs. **Regenerative medicine** is the emerging field that involves repairing, replacing, or regenerating cells, tissues, or organs to establish normal function.

The Medical Promise of Regenerative Medicine

The era of regenerative medicine is being ushered in by advances in stem cell science, cell biology, plastic manufacturing, and computer graphics. To make lab-grown replacement parts, using computer-aided designs, *tissue engineers* shape pure, biodegradable plastics into three-dimensional molds or scaffoldings that mimic the structure of a particular tissue or organ. They then "seed" the plastic mold with the desired stem cell types, which they coax, by applying appropriate nourishing and stimulatory chemicals, into multiplying and assembling into the desired body part. After the plastic scaffolding dissolves, only the newly generated tissue remains, ready to be implanted into a patient as a permanent, living replacement part.

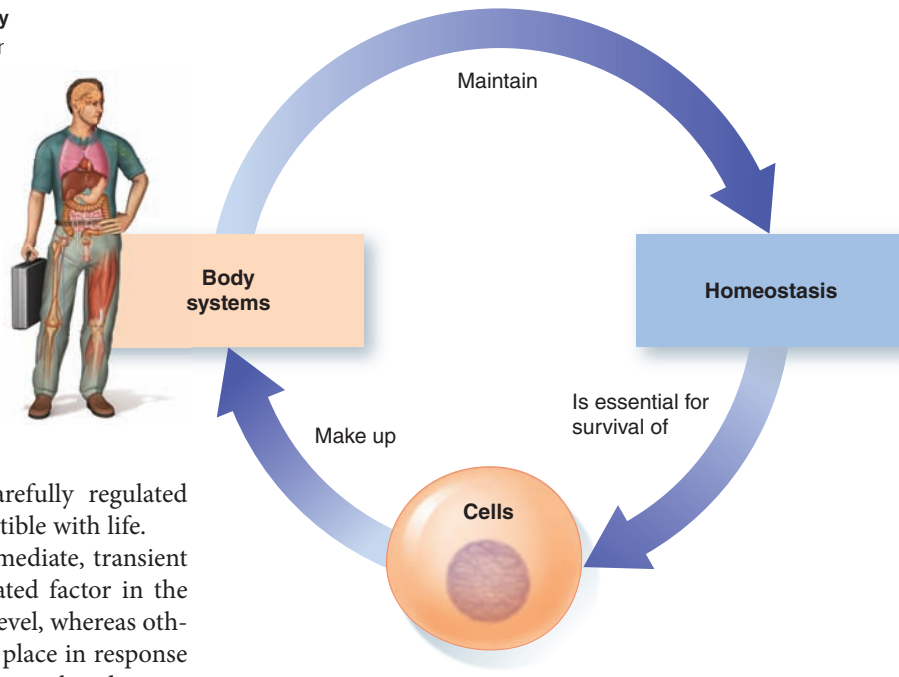
Following are some of the tissue engineers' early accomplishments. Engineered skin patches are being used to treat victims of severe burns, and engineered cartilage and bone graft substitutes are already in use. Lab-grown bladders were the first organs successfully implanted in humans, and engineered blood vessels and tracheas (windpipes) have already been built. Tissue-engineered scaffolding to promote nerve regeneration is ready for clinical trials. Progress has been made on growing more complicated organs, including liver, pancreas, heart, kidney, and lung.

Innovative scaffolds have continued to advance transplant technology in recent years. With a newer technique, some investigators are experimenting with three-dimensional *organ printing*. Based on the principle used in desktop printers, organ printing involves computer-aided layer-by-layer deposition of "biological ink." Biological ink consists of cells, scaffold materials, and supportive growth factors that are simultaneously printed in thin layers in a highly organized pattern based on the anatomy of the organ under construction. Fusion of these living layers forms a three-dimensional structure that mimics the body part the printed organ is designed to replace.

The latest scaffolding strategy uses nature's architecture instead of building an intricate scaffold from scratch. Still in the experimental stage, this technique involves chemically stripping all f esh from a donor organ, such as a pig heart, leaving behind a heart-shaped, natural scaffold consisting of collagen, a tough connective tissue fiber. When this naked heart shell is coated with tissue grown from a recipient's stem cells, the cells rebuild a beating heart complete with its blood supply that can be transplanted into the recipient. The goal is to ultimately remove all natural cells from pig hearts (or other organs) and use them as scaffolds for recreating hearts compatible for transplant into humans, thereby overcoming donor shortage and avoiding the risk of transplant rejection.

On the horizon is an emerging capability to produce iPSCs in the body to regenerate damaged parts in place, inside the body itself—the ultimate scaffolding. Another related avenue of exploration is the possibility of promoting regeneration of body parts salamander-style. Some species, including vertebrates such as salamanders and newts, have extraordinary regenerative powers. Whereas humans form scar tissue at the stump end of a severed limb, these species grow entire replacement limbs. Scientists are hopeful that by studying how salamanders regenerate lost tissue, they can duplicate these steps in humans. Most investigators in the field think that humans have the latent capacity to regenerate but have built-in brakes on the process. How to remove the brakes or stimulate the process is the challenge.

Whatever way it happens, replacing or regenerating defective body parts with "the real thing" cannot come soon enough.

Figure 1-7 Interdependent relationship of cells, body systems, and homeostasis. Homeostasis is essential for the survival of cells, cells make up body systems, and body systems maintain homeostasis. This relationship serves as the foundation for physiology.


not deviate far from a constant, or steady, level. This situation is comparable to the minor steering adjustments you make as you drive a car along a straight stretch of highway. Small fluctuations around the optimal level for each factor in the internal environment are normally kept, by carefully regulated mechanisms, within the narrow limits compatible with life.

Some compensatory mechanisms are immediate, transient responses to a situation that moves a regulated factor in the internal environment away from the desired level, whereas others are more long-term adaptations that take place in response to prolonged or repeated exposure to a situation that disrupts homeostasis. Long-term adaptations make the body more efficient in responding to an ongoing or repetitive challenge. The body's reaction to exercise includes examples of both short-term compensatory responses and long-term adaptations among the different body systems. (See the accompanying boxed feature, ▌A Closer Look at Exercise Physiology. Most chapters have a boxed feature focusing on exercise physiology. Also, we mention issues related to exercise physiology throughout the text. Appendix B will help you locate all the references to this important topic.)

Homeostatically Regulated Factors Many factors of the internal environment must be homeostatically maintained. They include the following:

1. *Concentration of nutrients.* Cells need a constant supply of nutrient molecules for energy production. Energy, in turn, is needed to support life-sustaining and specialized cell activities.

2. *Concentration of O_2 and CO_2.* Cells need O_2 to carry out energy-yielding chemical reactions. The CO_2 produced during these reactions must be removed so that acid-forming CO_2 does not increase the acidity of the internal environment.

3. *Concentration of waste products.* The end products of some chemical reactions have a toxic effect on body cells if these wastes are allowed to accumulate.

4. *pH.* Changes in the pH (relative amount of acid; see pp. 547–548 and A-8) of the ECF adversely affect nerve cell function and wreak havoc with the enzyme activity of all cells.

5. *Concentrations of water, salt, and other electrolytes.* Because the relative concentrations of salt (NaCl) and water in the ECF influence how much water enters or leaves the cells, these concentrations are carefully regulated to maintain the proper volume of the cells. Cells do not function normally when they are swollen or shrunken. Other electrolytes (chemicals that form ions in solution and conduct electricity; see p. A-3 and A-7) perform a variety of vital functions. For example, the rhythmic

beating of the heart depends on a relatively constant concentration of potassium (K^+) in the ECF.

6. *Volume and pressure.* The circulating component of the internal environment, the plasma, must be maintained at adequate volume and blood pressure to ensure bodywide distribution of this important link between the external environment and the cells.

7. *Temperature.* Body cells function best within a narrow temperature range. If cells are too cold, their functions slow down too much; if they get too hot, their structural and enzymatic proteins are impaired or destroyed.

Body System Contributions to Homeostasis The 11 body systems contribute to homeostasis in the following important ways (▌Figure 1-8):

1. The *circulatory system* (heart, blood vessels, and blood) transports materials such as nutrients, O_2, CO_2, wastes, electrolytes, and hormones from one part of the body to another.

2. The *digestive system* (mouth, esophagus, stomach, intestines, and related organs) breaks down dietary food into small nutrient molecules that can be absorbed into the plasma for distribution to the body cells. It also transfers water and electrolytes from the external environment into the internal environment. It eliminates undigested food residues to the external environment in the feces.

3. The *respiratory system* (lungs and major airways) gets O_2 from and eliminates CO_2 to the external environment. By adjusting the rate of removal of acid-forming CO_2, the respiratory system is also important in maintaining the proper pH of the internal environment.

4. The *urinary system* (kidneys and associated "plumbing") removes excess water, salt, acid, and other electrolytes from the plasma and eliminates them in the urine, along with waste products other than CO_2.

What Is Exercise Physiology?

EXERCISE PHYSIOLOGY is the study of both the functional changes that occur in response to a single session of exercise and the adaptations that occur as a result of regular, repeated exercise sessions. Exercise initially disrupts homeostasis. The changes that occur in response to exercise are the body's attempt to meet the challenge of maintaining homeostasis when increased demands are placed on the body. Exercise often requires prolonged coordination among most body systems, including the muscular, skeletal, nervous, circulatory, respiratory, urinary, integumentary (skin), and endocrine (hormone-producing) systems.

Heart rate is one of the easiest factors to monitor that shows both an immediate response to exercise and long-term adaptation to a regular exercise program. When a person begins to exercise, the active muscle cells use more O_2 to support their increased energy demands. Heart rate increases to deliver more oxygenated blood to the exercising muscles. The heart adapts to regular exercise of sufficient intensity and duration by increasing its strength and efficiency so that it pumps more blood per beat. Because of increased pumping ability, the heart does not have to beat as rapidly to pump a given quantity of blood as it did before physical training.

Exercise physiologists study the mechanisms responsible for the changes that occur as a result of exercise. Much of the knowledge gained from studying exercise is used to develop appropriate exercise programs that increase the functional capacities of people ranging from athletes to the infirm. The importance of proper and sufficient exercise in disease prevention and rehabilitation is increasingly evident.

5. The *skeletal system* (bones and joints) provides support and protection for the soft tissues and organs. It also serves as a storage reservoir for calcium (Ca^{2+}), an electrolyte whose plasma concentration must be maintained within narrow limits. Together with the muscular system, the skeletal system enables the body and its parts to move. Furthermore, the bone marrow—the soft interior portion of some types of bone—is the ultimate source of all blood cells.

6. The *muscular system* (skeletal muscles) moves the bones to which the skeletal muscles are attached. From a purely homeostatic view, this system enables a person to move toward food or away from harm. Furthermore, the heat generated by muscle contraction helps maintain body temperature. In addition, because skeletal muscles are under voluntary control, a person can use them to accomplish myriad other movements by choice. These movements, which range from the fine motor skills required for delicate needlework to the powerful movements involved in weight lifting, are not necessarily directed toward maintaining homeostasis.

7. The *integumentary system* (skin and related structures) serves as an outer protective barrier that prevents internal fluid from being lost from the body and foreign microorganisms from entering. This system is also important in regulating body temperature. The amount of heat lost from the body surface to the external environment can be adjusted by controlling sweat production and by regulating the flow of warm blood through the skin.

8. The *immune system* (white blood cells and lymphoid organs) defends against foreign invaders such as bacteria and viruses and against body cells that have become cancerous. It also paves the way for repairing or replacing injured or worn-out cells.

9. The *nervous system* (brain, spinal cord, nerves, and sense organs) is one of the body's two major regulatory systems. In general, it controls and coordinates body activities that require swift responses. It is especially important in detecting changes in the external environment and initiating reactions to them. Furthermore, it is responsible for higher functions that are not entirely directed toward maintaining homeostasis, such as consciousness, memory, and creativity.

10. The *endocrine system* (all hormone-secreting glands) is the other major regulatory system. In contrast to the nervous system, the endocrine system in general regulates activities that require duration rather than speed, such as growth. It is especially important in controlling the blood concentration of nutrients and, by adjusting kidney function, controlling the volume and electrolyte composition of the ECF.

11. The *reproductive system* (male and female gonads—testes and ovaries, respectively—and related organs) is not essential for homeostasis and therefore is not essential for survival of the individual. It is essential, however, for perpetuating the species.

As we examine each of these systems in greater detail, always keep in mind that the body is a coordinated whole even though each system provides its own special contributions. It is easy to forget that all body parts actually fit together into a functioning, interdependent whole body. Accordingly, each chapter begins with a discussion of how the body system to be described fits into the body as a whole. In addition, each chapter ends with a brief review of the homeostatic contributions of the body system. As a further tool to help you keep track of how all the pieces fit together, Figure 1-8 is duplicated on the inside front cover as a handy reference.

Also be aware that the functioning whole is greater than the sum of its separate parts. Through specialization, cooperation, and interdependence, cells combine to form an integrated, unique, single living organism with more diverse and complex capabilities than are possessed by any of the cells that make it

BODY SYSTEMS
Made up of cells organized according to specialization to maintain homeostasis
See Chapter 1.

NERVOUS SYSTEM
Acts through electrical signals to control rapid responses of the body; also responsible for higher functions—e.g., consciousness, memory, and creativity

- Volume and pressure
  See Chapters 10, 14, and 15.

Homeostasis is essential for survival of cells

CELLS
Need homeostasis for their own survival and for performing specialized functions essential for survival of the whole body
See Chapters 1, 2, and 3.
Need a continual supply of nutrients and O_2 and ongoing elimination of acid-forming CO_2 to generate the energy needed to power life-sustaining cellular activities as follows:
Food + $O_2 \rightarrow CO_2$ + H_2O + energy
See Chapters 13, 15, 16, and 17.

Cells make up body systems

up. For humans, these capabilities go far beyond the processes needed to maintain life. A cell, or even a random combination of cells, cannot create an artistic masterpiece or design a spacecraft, but body cells working together permit those capabilities in an individual.

Now that you have learned what homeostasis is and how the functions of different body systems maintain it, let us look at the regulatory mechanisms by which the body reacts to changes and controls the internal environment.

<div style="border:1px solid #000; padding:4px;">

Check Your Understanding 1.3

1. Distinguish among external environment, internal environment, intracellular f uid, extracellular f uid, plasma, and interstitial f uid.
2. Define *homeostasis.*
3. Draw a figure showing the interdependent relationship of cells, body systems, and homeostasis.

</div>

1.4 Homeostatic Control Systems

A **homeostatic control system** is a functionally interconnected network of body components that operates to maintain a given factor in the internal environment at a relatively constant optimal level. To maintain homeostasis, the control system must be able to (1) detect deviations from normal in the internal environmental factor that needs to be held within narrow limits; (2) integrate this information with any other relevant information; and (3) make appropriate adjustments in the activity of the body parts responsible for restoring this factor to its desired value.

Homeostatic control systems may operate locally or bodywide.

Homeostatic control systems can be grouped into two classes—intrinsic and extrinsic controls. **Intrinsic**, or **local, controls** are built into or are inherent in an organ (*intrinsic* means "within"). For example, as an exercising skeletal muscle rapidly uses up O_2 to generate energy to support its contractile activity, the O_2 concentration within the muscle falls. This local chemical change acts directly on the smooth muscle in the walls of the blood vessels supplying the exercising muscle, causing the smooth muscle to relax so that the vessels dilate, or open widely. As a result, increased blood flows through the dilated vessels into the exercising muscle, bringing in more O_2. This local mechanism helps maintain an optimal level of O_2 in the fluid immediately around the exercising muscle's cells.

Most factors in the internal environment are maintained, however, by **extrinsic**, or **systemic, controls**, which are regulatory mechanisms initiated outside an organ to alter the organ's activity (*extrinsic* means "outside of"). Extrinsic control of the organs and body systems is accomplished by the nervous and endocrine systems, the two major regulatory

systems. Extrinsic control permits coordinated regulation of several organs toward a common goal; in contrast, intrinsic controls serve only the organ in which they occur. Coordinated, overall regulatory mechanisms are crucial for maintaining the dynamic steady state in the internal environment as a whole. For example, to restore blood pressure to the proper level when it falls too low, the nervous system acts simultaneously on the heart and blood vessels throughout the body to increase blood pressure to normal.

To stabilize the physiological factor being regulated, homeostatic control systems must be able to detect and resist change. They resist change primarily by operating on the principle of negative feedback.

Negative feedback opposes an initial change and is widely used to maintain homeostasis.

In **negative feedback**, a change in a homeostatically controlled factor triggers a response that seeks to restore the factor to normal by moving the factor in the opposite direction of its initial change—that is, a corrective adjustment opposes the original deviation from the normal desired level.

A common example of negative feedback is control of room temperature. Room temperature is a **controlled variable**, a factor that can vary but is held within a narrow range by a control system. In our example, the control system includes a thermostat, a furnace, and all their electrical connections. The room temperature is determined by the activity of the furnace, a heat source that can be turned on or off. To switch on or off appropriately, the control system as a whole must "know" what the *actual* room temperature is, "compare" it with the *desired* room temperature, and "adjust" the output of the furnace to bring the actual temperature to the desired level. A thermometer in the thermostat provides information about the actual room temperature. The thermometer is the **sensor**, which monitors the magnitude of the controlled variable. The sensor typically converts the original information regarding a change into a "language" the control system can "understand." For example, the thermometer converts the magnitude of the air temperature into electrical impulses. This message serves as the input into the control system. The thermostat setting provides the desired temperature level, or **set point**. The thermostat acts as an **integrator**, or **control center**: It compares the sensor's input with the set point and adjusts the heat output of the furnace to bring about the appropriate response to oppose a deviation from the set point. The furnace is the **effector**, the component of the control system commanded to bring about the desired effect. These general components of a negative-feedback control system are summarized in Figure 1-9a. Carefully examine this figure and its key; the symbols and conventions introduced here are used in comparable flow diagrams throughout the text.

Let us look at a typical negative-feedback loop. For example, if the room temperature falls below the set point because it is cold outside, the thermostat, through connecting circuitry, activates the furnace, which produces heat to raise the room temperature (❙Figure 1-9b). Once the room temperature reaches the set point, the thermometer no longer detects a deviation

FIGURE FOCUS: *The hormone erythropoietin stimulates production of red blood cells. Would the rate of erythropoietin secretion go up, go down, or stay the same after you donate blood?*

from that point. As a result, the activating mechanism in the thermostat and the furnace are switched off. Thus, the heat from the furnace counteracts, or is "negative" to, the original fall in temperature. If the heat-generating pathway was not shut off once the target temperature was reached, heat production would continue and the room would get hotter and hotter. Overshooting the set point does not occur because the heat "feeds back" to shut off the thermostat that triggered its output. Thus, a negative-feedback control system detects a change away from the ideal value in a controlled variable, initiates mechanisms to correct the situation, and then shuts itself off. In this way, the controlled variable does not drift too far above or below the set point.

What if the original deviation is a rise in room temperature above the set point because it is hot outside? A heat-producing furnace is of no use in returning the room temperature to the desired level. An opposing control system involving a cooling air conditioner is needed to reduce the room temperature. In

this case, the thermostat, through connecting circuitry, activates the air conditioner, which cools the room air, the opposite effect from that of the furnace. In negative-feedback fashion, once the set point is reached, the air conditioner is turned off to prevent the room from becoming too cold. Note that if the controlled variable can be deliberately adjusted to oppose a change in one direction only, the variable can move in an uncontrolled fashion in the opposite direction. For example, if the house is equipped only with a furnace that produces heat to oppose a fall in room temperature, no mechanism is available to prevent the house from getting too hot in warm weather. However, the room temperature can be kept relatively constant through two opposing mechanisms, one that heats and one that cools the room, despite wide variations in the temperature of the external environment.

Homeostatic negative-feedback systems in the human body operate in the same way. For example, when temperature-monitoring nerve cells detect a decrease in body temperature

below the desired level, these sensors signal the temperature control center in the brain, which begins a sequence of events that ends in responses, such as shivering, that generate heat and raise the temperature to the proper level (❙ Figure 1-9c). When the body temperature reaches the set point, the temperature-monitoring nerve cells turn off the stimulatory signal to the skeletal muscles. As a result, the body temperature does not continue to increase above the set point. Conversely, when the temperature-monitoring nerve cells detect a rise in body temperature above normal, cooling mechanisms, such as sweating, are called into play to lower the temperature to normal. When the temperature reaches the set point, the cooling mechanisms are shut off. As with body temperature, opposing mechanisms can move most homeostatically controlled variables in either direction as needed.

Positive feedback amplifies an initial change.

In negative feedback, a control system's output is regulated to resist change so that the controlled variable is kept at a relatively steady set point. With **positive feedback**, by contrast, the output enhances or amplifies a change so that the controlled variable continues to move in the direction of the initial change. Such action is comparable to the heat generated by a furnace triggering the thermostat to call for even more heat output from the furnace so that the room temperature continuously rises.

Because the major goal in the body is to maintain stable, homeostatic conditions, positive feedback does not occur nearly as often as negative feedback. Positive feedback does play an important role in certain instances, however, as in the birth of a baby. The hormone oxytocin causes powerful contractions of the uterus (womb). As the contractions push the baby against the cervix (the exit from the uterus), the resultant stretching of the cervix triggers a sequence of events that brings about the release of even more oxytocin, which causes even stronger uterine contractions, triggering the release of more oxytocin, and so on. This positive-feedback cycle does not stop until the cervix is stretched sufficiently for the baby to be pushed through and born. Likewise, all other normal instances of positive-feedback cycles in the body include some mechanism for stopping the cycle.

Feedforward mechanisms initiate responses in anticipation of a change.

In addition to feedback mechanisms, which bring about a reaction to a change in a regulated variable, the body less frequently uses feedforward mechanisms, which respond in anticipation of a change in a regulated variable. For example, when a meal is still in the digestive tract, a feedforward mechanism increases secretion of a hormone (insulin) that promotes the cellular uptake and storage of ingested nutrients after they have been absorbed from the digestive tract. This anticipatory response helps limit the rise in blood nutrient concentration after nutrients have been absorbed.

Disruptions in homeostasis can lead to illness and death.

Clinical Note Despite control mechanisms, when one or more of the body's systems malfunction, homeostasis is disrupted and all cells suffer because they no longer have an optimal environment in which to live and function. Various pathophysiological states develop, depending on the type and extent of the disruption. The term **pathophysiology** refers to the abnormal functioning of the body (altered physiology) associated with disease. When a homeostatic disruption becomes so severe that it is no longer compatible with survival, death is the result.

Physiology serves as an important underpinning of clinical medicine. All health professionals must comprehend basic physiological principles to be able to understand what's happening in the body when things go wrong and to determine what needs to be done to correct the situation by whatever means, if possible. Many diagnostic tests rely heavily on principles learned by physiologists; examples include the electrocardiogram and lung function tests. Treatments for a number of pathophysiological conditions, such as high blood pressure, diabetes mellitus, and erectile dysfunction, are likewise based on knowledge acquired through physiological research. Thus physiology is at the heart of clinical practice.

Check Your Understanding 1.4

1. Distinguish between intrinsic controls and extrinsic controls.
2. Compare negative feedback and positive feedback.
3. Draw a f ow diagram showing the relationships among the components of a negative-feedback control system.

Homeostasis: Chapter in Perspective

In this chapter you learned what homeostasis is: a dynamic steady state of the constituents in the internal f uid environment (the extracellular f uid) that surrounds and exchanges materials with the cells. Maintenance of homeostasis is essential for survival and normal functioning of cells. Each cell, through its specialized activities, contributes as part of a body system to the maintenance of homeostasis.

This relationship is the foundation of physiology and the central theme of this book. We have described how cells are organized according to specialization into body systems. How homeostasis is essential for cell survival and how body systems maintain this internal constancy are the topics covered in the rest of this book. Each chapter concludes with this capstone feature to facilitate your understanding of how the system under discussion contributes to homeostasis and of the interactions and interdependency of the body systems.

Review Exercises

Reviewing Terms and Facts

1. Which of the following activities is *not* carried out by every cell in the body?
   a. obtaining O_2 and nutrients
   b. performing chemical reactions to acquire energy for the cell's use
   c. eliminating wastes
   d. largely controlling exchange of materials between the cell and its external environment
   e. reproducing

2. Which of the following is the proper progression of the levels of organization in the body?
   a. chemicals, cells, organs, tissues, body systems, whole body
   b. chemicals, cells, tissues, organs, body systems, whole body
   c. cells, chemicals, tissues, organs, whole body, body systems
   d. cells, chemicals, organs, tissues, whole body, body systems
   e. chemicals, cells, tissues, body systems, organs, whole body

3. Which of the following is *not* a type of connective tissue?
   a. bone
   b. blood
   c. the spinal cord
   d. tendons
   e. the tissue that attaches epithelial tissue to underlying structures

4. The term *tissue* can apply either to one of the four primary tissue types or to a particular organ's aggregate of cellular and extracellular components. *(True or false?)*

5. Cells in a multicellular organism have specialized to such an extent that they have little in common with single-celled organisms. *(True or false?)*

6. Cell specializations are usually a modification or elaboration of one of the basic cell functions. *(True or false?)*

7. The four primary types of tissue are _____, _____, _____, and _____.

8. The term _____ refers to the release from a cell, in response to appropriate stimulation, of specific products that have been synthesized largely by the cell.

9. _____ glands secrete through ducts to the outside of the body, whereas _____ glands release their secretory products, known as _____, internally into the blood.

10. _____ controls are inherent to an organ, whereas _____ controls are regulatory mechanisms initiated outside an organ that alter the activity of the organ.

11. Match the following:
   1. circulatory system
   2. digestive system
   3. respiratory system
   4. urinary system
   5. muscular and skeletal systems working together
   6. integumentary system
   7. immune system
   8. nervous system
   9. endocrine system
   10. reproductive system

   (a) obtains O_2 and eliminates CO_2
   (b) supports, protects, and moves body parts
   (c) controls, via hormones it secretes, processes that require duration
   (d) acts as the transport system
   (e) removes wastes and excess water, salt, and other electrolytes
   (f) perpetuates the species
   (g) obtains nutrients, water, and electrolytes
   (h) defends against foreign invaders and cancer
   (i) acts through electrical signals to control the body's rapid responses
   (j) serves as an outer protective barrier

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Compare physiology and anatomy.

2. Explain the difference between basic cell functions and specialized cell functions and indicate in what way each of these categories of functions is essential for life in a multicellular organism.

3. Distinguish between the external environment and the internal environment. What constitutes the internal environment? Distinguish between the intracellular fluid (ICF) and the extracellular fluid (ECF). Discuss the relationship between the internal environment and the ECF. What fluid compartments make up the ECF?

4. State the central theme of physiology and of this book.

5. What factors must be homeostatically maintained, and which body systems contribute to maintaining each of these factors?

6. Define and describe the components of a homeostatic control system.

7. Why is negative feedback important physiologically?

Applying Clinical Reasoning
Jennifer R. has the "stomach flu" that is going around campus and has been vomiting profusely for the past 24 hours. Not only has she been unable to keep down fluids or food, but she also has lost the acidic digestive juices secreted by the stomach that are normally reabsorbed back into the blood farther down

the digestive tract. In what ways might this condition threaten to disrupt homeostasis in Jennifer's internal environment? That is, what homeostatically maintained factors are moved away from normal by her profuse vomiting? What body systems respond to resist these changes?

Thinking at a Higher Level

1. Considering the nature of negative-feedback control and the function of the respiratory system, what effect do you predict that a decrease in CO_2 in the internal environment would have on how rapidly and deeply a person breathes?

2. Would the O_2 levels in the blood be (a) normal, (b) below normal, or (c) elevated in a patient with severe pneumonia resulting in impaired exchange of O_2 and CO_2 between the air and blood in the lungs? Would the CO_2 levels in the same patient's blood be (a) normal, (b) below normal, or (c) elevated? Because CO_2 reacts with H_2O to form carbonic acid (H_2CO_3), would the patient's blood (a) have a normal pH, (b) be too acidic, or (c) not be acidic enough (that is, be too alkaline), assuming that other compensatory measures have not yet had time to act?

3. The hormone insulin enhances the transport of glucose (sugar) from the blood into most body cells. Its secretion is controlled by a negative-feedback system between the concentration of glucose in the blood and the insulin-secreting cells. Therefore, which of the following statements is correct?

   a. A decrease in blood glucose concentration stimulates insulin secretion, which in turn further lowers blood glucose concentration.

   b. An increase in blood glucose concentration stimulates insulin secretion, which in turn lowers blood glucose concentration.

   c. A decrease in blood glucose concentration stimulates insulin secretion, which in turn increases blood glucose concentration.

   d. An increase in blood glucose concentration stimulates insulin secretion, which in turn further increases blood glucose concentration.

   e. None of the preceding is correct.

4. Given that most patients with AIDS die from overwhelming infections or rare types of cancer, what body system do you think the human immunodeficiency virus (or HIV, the AIDS virus) impairs?

5. Body temperature is homeostatically regulated around a set point. Given your knowledge of negative feedback and homeostatic control systems, predict whether narrowing or widening of the blood vessels of the skin will occur when a person exercises strenuously. (*Hints:* Muscle contraction generates heat. Narrowing of the vessels supplying an organ decreases blood flow through the organ, whereas vessel widening increases blood flow through the organ. The more warm blood flowing through the skin, the greater is the loss of heat from the skin to the surrounding environment.)

Cytosol (*green*) surrounds the organelles.

CHAPTER AT A GLANCE

Homeostasis Highlights

Cells are the highly organized, living building blocks of the body. A cell has three major parts: the **plasma membrane**, which encloses the cell; the **nucleus**, which houses the cell's genetic material; and the **cytoplasm**. The cytoplasm consists of the cytosol, organelles, and cytoskeleton. The *cytosol* is a gel-like liquid within which the organelles and cytoskeleton are suspended. *Organelles* are discrete, well-organized structures that carry out specialized functions. The *cytoskeleton* is protein scaffolding that extends throughout the cell and serves as the cell's "bone and muscle."

Through the coordinated action of these components, every cell performs certain basic functions essential to its survival and a specialized task that helps maintain homeostasis. Cells are organized according to their specialization into body systems that maintain the stable internal environment essential for the whole body's survival. All body functions ultimately depend on the activities of the individual cells that make up the body.

2.1 Cell Theory and Discovery

Although the same chemicals that make up living cells are found in nonliving matter, researchers have not been able to organize these chemicals into living cells in a laboratory. Life stems from the unique and complex organization and interactions of these inanimate chemicals within the cell. Cells, the smallest living entities, are the living building blocks for the immensely complicated whole body. Thus, cells are the bridge between chemicals and humans (and all other living organisms). All body functions of a multicellular organism ultimately depend on the collective structural and functional capabilities of its individual cells. Furthermore, all new cells and all new life arise from the division of preexisting cells, not from nonliving sources. Because of this continuity of life, the cells of all organisms are fundamentally similar in structure and function. ❙ Table 2-1 summarizes these principles, which are known collectively as the **cell theory**. By probing deeper into the molecular structure and organization of the cells that make up the body, modern physiologists are unraveling many of the broader mysteries of how the body works.

Body cells are so small they cannot be seen by the unaided eye. The smallest visible particle is 5 to 10 times larger than a typical human cell, which averages about 10 to 20 micrometers (μm) in diameter (1 μm = 1/1,000,000 of a meter). About 100 average-sized cells lined up side by side would stretch a distance of only 1 mm (1 mm = 1/1000 of a meter; 1 m = 39.37 in.).

Until the microscope was invented in the middle of the 17th century, scientists did not know that cells existed. With the development of better light microscopes in the early 19th century, they learned that all plant and animal tissues consist of individual cells. The cells of a hummingbird, a human, and a whale are all about the same size. Larger species have more cells, not larger cells. These early investigators also discovered that cells are filled with a fluid that, given the microscopic capabilities of the time, appeared to be a rather uniform, soupy mixture believed to be the elusive "stuff of life." In the 1940s, when researchers first used electron microscopes to observe living matter, they began to realize the great diversity and complexity of the internal structure of cells. (Electron microscopes are about 100 times more powerful than light microscopes.) Now that scientists have even more sophisticated microscopes, biochemical techniques, cell culture technology, and genetic engineering, the concept of the cell as a microscopic bag of formless fluid has given way to our current understanding of the cell as a complex, highly organized, compartmentalized structure.

Check Your Understanding 2.1

1. State the principles of the cell theory.
2. Compare the average size of cells in your body with those in a mouse and in an elephant.

2.2 An Overview of Cell Structure

The trillions of cells in a human body are classified into about 200 types based on specific variations in structure and function. Despite their diverse structural and functional specializations, however, different cells share many features. Most cells have three major subdivisions: the *plasma membrane,* which encloses the cells; the *nucleus,* which contains the cell's genetic material; and the *cytoplasm,* the portion of the cell's interior not occupied by the nucleus (❙ Figure 2-1).

The plasma membrane bounds the cell.

The **plasma membrane** is a thin membranous structure that encloses each cell and is composed mostly of lipid (fat) molecules and studded with proteins. This barrier separates the cell's contents from its surroundings; it keeps the *intracellular fluid (ICF)* within the cells from mingling with the *extracellular fluid (ECF)* outside the cells. The plasma membrane is not simply a mechanical barrier to hold in the cell contents; its proteins selectively control movement of molecules between the ICF and ECF. Through this structure, the cell controls entry of nutrients and other needed supplies and export of products manufactured within, while at the same time guarding against unwanted traffic into or out of the cell. The plasma membrane is discussed thoroughly in Chapter 3.

The nucleus contains the DNA.

The two major parts of the cell's interior are the nucleus and the cytoplasm. The **nucleus**, which is typically the largest single organized cell component, can be seen as a distinct spherical or oval structure, usually located near the center of the cell. It is surrounded by a double-layered membrane, the **nuclear envelope**, which separates the nucleus from the rest of the cell. The nuclear envelope is pierced by many **nuclear pores** that allow necessary traffic to move between the nucleus and the cytoplasm.

The nucleus houses the cell's genetic material, **deoxyribonucleic acid (DNA)**, which, along with associated nuclear proteins, is organized into **chromosomes**. Each chromosome con-

---

❙**TABLE 2-1** Principles of the Cell Theory

- The cell is the smallest structural and functional unit capable of carrying out life processes.

- The functional activities of each cell depend on the specific structural properties of the cell.

- Cells are the living building blocks of all multicellular organisms.

- An organism's structure and function ultimately depend on the collective structural characteristics and functional capabilities of its cells.

- All new cells and new life arise only from preexisting cells.

- Because of this continuity of life, the cells of all organisms are fundamentally similar in structure and function.

⏐Figure 2-1 Diagram of cell structures visible under an electron microscope.

sists of a different DNA molecule that contains a unique set of genes. Body cells contain 46 chromosomes that can be sorted into 23 pairs on the basis of their distinguishing features. DNA has two important functions:

1. *Serving as a genetic blueprint during cell replication.* Through this role, DNA ensures that the cell produces additional cells just like itself, thus continuing the identical type of cell line within the body. Furthermore, in the reproductive cells (eggs and sperm), the DNA blueprint passes on genetic characteristics to future generations.

2. *Directing protein synthesis.* DNA provides codes, or "instructions," for directing synthesis of specific structural and enzymatic proteins within the cell. Proteins are the main structural component of cells, and enzymes govern the rate of all chemical reactions in the body. By specifying the kinds and amounts of proteins that are produced, the nucleus indirectly governs most cell activities and serves as the cell's control center.

We next examine interactions of RNA with DNA in protein synthesis.

Roles of RNA Three types of **ribonucleic acid (RNA)** play roles in protein synthesis (see p. A-14). First, DNA's genetic code for a particular protein is transcribed into a **messenger RNA (mRNA)** molecule, which exits the nucleus through the nuclear pores. Within the cytoplasm, mRNA delivers the coded message to *ribosomes,* which "read" the code and translate it into the appropriate amino acid sequence for the designated protein being synthesized. **Ribosomal RNA (rRNA)** is an essential component of ribosomes. (We will discuss the structure and function of ribosomes in more detail later.) **Transfer RNA (tRNA)** delivers the appropriate amino acids within the cytoplasm to their designated site in the protein under construction at the ribosome. **Gene expression** refers to the multistepped process by which information encoded in a gene is used to direct the synthesis of a protein molecule. (For further

Cell Physiology | **23**

information regarding this topic, see the supplemental resource *Storage, Replication, and Expression of Genetic Information* on the text's Web site at www.cengagebrain.com.)

In addition to these three well-established forms of RNA, *microRNA (miRNA)* and *small interfering RNA (siRNA)* are recently discovered regulatory RNAs that can bind to mRNA and block the production of this mRNA's protein product, a process known as **RNA interference (RNAi)**. By silencing gene expression, these minuscule RNA snippets influence a variety of developmental, differentiation, and cellular processes throughout the body. Much of the DNA in humans is transcribed into regulatory RNA. Only 1.5% of DNA codes for protein synthesis. Scientists long thought that most of the DNA that did not code for proteins was "junk" or "nonsense" DNA because they did not understand its purpose. However, the revolutionary discovery of RNAi has changed that misperception and led to an explosion of fundamental and clinical research in this field. More than 1000 distinct miRNAs have been discovered, and each type of body cell contains a different collection of regulatory RNAs. Defects in RNAi have been connected to a variety of diseases, including cancer. For example, *chronic lymphocytic leukemia* is linked to mutations in two miRNA genes. Investigators are searching for ways to exploit RNAi for clinical application, such as by interfering with expression of genes that are misregulated in cancer.

Human Genome and Proteome The human **genome** is all of the genetic information coded in a complete single set of DNA in a typical body cell. The *Human Genome Project* identified and sequenced the entire genetic code through an international collaborative effort among public and private researchers that began in 1990 and was completed in 2003. The human genome mapped the composition and sequence of the 3.2 billion chemical units (nucleotides; see p. A-14) organized into about 20,000 protein-coding genes (representing only 1.5% of the genome), along with extensive intervening stretches of DNA that are involved in various ways with gene regulation. Noncoding regions also affect how DNA is folded and packaged into chromosomes and carry out yet-to-be determined actions. With this complete genetic map in hand, scientists are now scrambling to identify the functions and regulation of the genes and other parts of the genome.

The term **proteome** refers to the complete set of proteins that can be expressed by the protein-coding genes in the genome. Even though all body cells have an identical DNA blueprint, they do not all produce the same proteins. Because of cell-specific regulatory factors, different types of cells express different sets of genes and thus synthesize different sets of structural and enzymatic proteins. For example, only red blood cells can synthesize hemoglobin, even though all body cells carry the DNA instructions for hemoglobin synthesis. A *cellular proteome* is the collection of proteins found in a particular cell type under a particular set of environmental conditions. The cellular proteome, dictated by regulation of gene expression, determines the structure and function of a given cell at a particular time.

By studying the genome and related proteome of healthy and sick individuals, researchers are beginning to yield genome-based diagnostics and therapies. Although clinical applications

have been slow to arrive, more than 1800 disease-related genes have been identified and several thousand genetic tests are now available. The genomic revolution will continue to grow as scientists gradually decipher all of the data becoming available to them.

Epigenetics DNA and genetics are not the whole story controlling protein synthesis. In addition to the gene-determined instructions that govern synthesis of structural and enzymatic proteins, the emerging science of **epigenetics** studies environmentally induced modifications of a gene's activity that do not involve a change in the gene's DNA code (*epi* means "on top of"). Environmental factors such as smoking, high-fat diets, and stress can alter the way genes are expressed so that even identical twins are different. Epigenetic modifications arise from chemical tags added to DNA or its associated proteins that influence gene activity without altering the information the gene itself contains. For example, epigenetic tags, such as attachment of methyl groups, may limit the ability of mRNA to access DNA, thereby ultimately reducing synthesis of proteins coded by this stretch of DNA. Epigenetic modifications are dynamic and can change how genes behave over a lifetime. Furthermore, when epigenetic changes occur in the DNA of sperm or egg cells, they can get passed along to future generations.

Lipidome So as not to leave the mistaken impression that proteins are the only important structural and functional molecules in the cell, we digress briefly to mention the other major type of organic molecule in the body, lipids, which exert myriad roles in physiological and disease processes. To mention a few, lipids are the main structural component of the plasma membrane and store excess ingested food energy as body fat. Impaired lipid handling plays a central role in disorders such as heart disease and Alzheimer's disease. Tens of thousands of different types of lipids are included in the **lipidome**, the full roster of lipids in the body cells. Unlike proteins, lipids are not genetically encoded. However, lipid synthesis is governed by enzymes, which are produced under gene control. The formation of some body lipids can be altered by environmental factors such as diet and exercise. For example, differences in these lifestyle patterns affect the extent of cholesterol deposition in blood vessel linings.

The cytoplasm consists of various organelles, the cytoskeleton, and the cytosol.

The **cytoplasm** is that portion of the cell interior not occupied by the nucleus. It contains a number of discrete, specialized *organelles* (the cell's "little organs") and the *cytoskeleton* (a scaffolding of proteins) dispersed within the *cytosol* (a complex, gel-like liquid).

Organelles are distinct, highly organized structures that perform specialized functions within the cell. On average, nearly half of the total cell volume is occupied by two categories of organelles—*membranous organelles* and *nonmembranous organelles*. Each **membranous organelle** is a separate compartment within the cell that is enclosed by a membrane similar to the plasma membrane. Thus, the contents of a membranous

organelle are separated from the surrounding cytosol and from the contents of other organelles. Nearly all human cells contain five main types of membranous organelles—the *endoplasmic reticulum, Golgi complex, lysosomes, peroxisomes,* and *mitochondria.* Membranous organelles are like intracellular "specialty shops." Each is a separate internal compartment that contains a specific set of chemicals for carrying out a particular cellular function. This compartmentalization permits chemical activities that would not be compatible with one another to occur simultaneously within the cell. For example, enzymes that destroy unwanted proteins operate within the protective confines of the lysosomes without the risk of destroying essential cell proteins. The **nonmembranous organelles** are not surrounded by membrane and thus are in direct contact with the cytosol. They include *ribosomes, proteasomes, vaults,* and *centrioles.* Like membranous organelles, nonmembranous organelles are organized structures that carry out specific functions within the cell. Organelles are similar in all cells, although some variations occur depending on the specialized capabilities of each cell type. Just as each organ plays a role essential for survival of the whole body, each organelle performs a specialized activity necessary for survival of the whole cell.

The **cytoskeleton** is an interconnected system of protein fibers and tubes that extends throughout the cytosol. This elaborate protein network gives the cell its shape, provides for its internal organization, and regulates its various movements, thus serving as the cell's "bone and muscle."

The remainder of the cytoplasm not occupied by organelles and cytoskeleton consists of the **cytosol** ("cell liquid"). The cytosol is a semiliquid, gel-like mass. Many of the chemical reactions that are compatible with one another are conducted in the cytosol. (For clarification, the ICF encompasses all fluid inside the cell, including that within the cytosol, the organelles, and the nucleus.)

The rest of this chapter examines each of the cytoplasmic components in more detail, concentrating first on organelles. We begin with the endoplasmic reticulum, a membranous organelle.

<div style="border:1px solid; padding:8px;">

Check Your Understanding 2.2

1. State the functions of DNA and the different types of RNA.
2. Define *genome, proteome,* and *epigenetics.*
3. Distinguish among *cytoplasm, organelles, cytosol,* and *cytoskeleton.*

</div>

2.3 Endoplasmic Reticulum and Segregated Synthesis

The **endoplasmic reticulum (ER)** is an elaborate fluid-filled membranous system distributed extensively throughout the cytosol. It is primarily a protein- and lipid-producing factory. Two distinct types of ER—rough and smooth—can be distin-

guished. The **rough ER** consists of stacks of relatively flattened interconnected sacs, whereas the **smooth ER** is a meshwork of tiny interconnected tubules (❙Figure 2-2a and b). Even though these two regions differ considerably in appearance and function, they are connected to each other, making the ER one continuous organelle. The relative amount of rough and smooth ER varies among cells, depending on the activity of the cell.

The rough ER synthesizes proteins for secretion and membrane construction.

The outer surface of the rough ER membrane is studded with small particles that give it a "rough" or granular appearance under a light microscope. These particles are *ribosomes,* the "workbenches" where protein synthesis takes place. Not all ribosomes in the cell are attached to the rough ER. Unattached or "free" ribosomes are dispersed throughout the cytosol.

Ribosomes, nonmembranous organelles, carry out protein synthesis by translating mRNA into chains of amino acids in the ordered sequence dictated by the original DNA code. Ribosomes bring together all components that participate in protein synthesis—mRNA, tRNA, and amino acids—and provide the enzymes and energy required for linking the amino acids together. The nature of the protein synthesized by a given ribosome is determined by the mRNA being translated. Each mRNA serves as a code for only one protein.

A finished ribosome is about 20 nm in diameter and is made up of two parts of unequal size, a *large* and a *small ribosomal subunit* (❙Figure 2-2c) (1 nanometer [nm] = 1/1,000,000,000 of a meter). Each subunit is composed of rRNA and ribosomal proteins. These subunits are brought together when a protein is being synthesized. When the two subunits unite, a groove is formed. In translation, mRNA moves through this groove.

The rough ER, in association with its ribosomes, synthesizes and releases various new proteins into the ER lumen, the fluid-filled space enclosed by the ER membrane. These proteins serve one of two purposes: (1) Some proteins are destined for export to the cell's exterior as secretory products, such as protein hormones or enzymes, and (2) other proteins are used in constructing new cellular membrane (either plasma membrane or organelle membrane) or other cell structures, such as lysosomes. The plasma membrane consists mostly of proteins and lipids (fats). The membranous wall of the ER also contains enzymes essential for synthesis of the lipids needed to produce new membranes. These newly synthesized lipids enter the ER lumen along with the proteins. Predictably, the rough ER is most abundant in cells specialized for protein secretion (for example, cells that secrete digestive enzymes) or in cells that require extensive membrane synthesis (for example, rapidly growing cells such as immature egg cells).

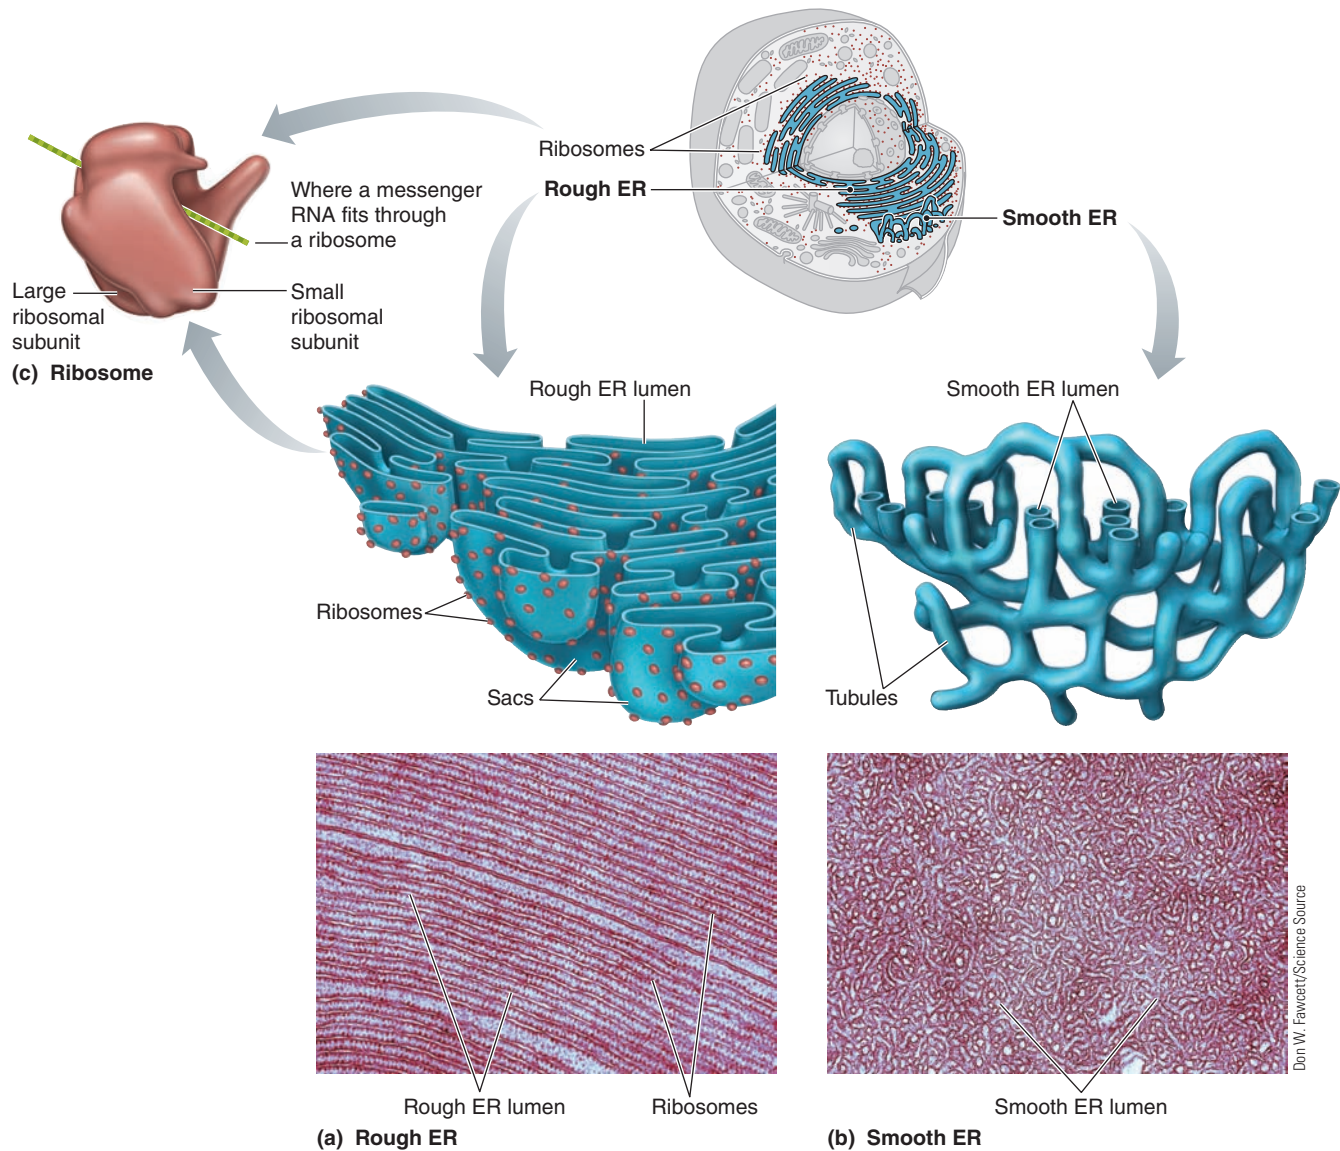
After being released into the ER lumen, a newly synthesized protein is folded into its final conformation (see p. A-14); it may also be modified in other ways, such as being pruned or having carbohydrates attached to it. After this processing, a new protein cannot pass out through the ER membrane on its own and therefore becomes permanently separated from the cytosol as soon as it has been synthesized. In contrast to the rough ER


Figure 2-2 Endoplasmic reticulum (ER). (a) Diagram and electron micrograph of the rough ER, which consists of stacks of relatively flattened interconnected sacs studded with ribosomes. (b) Diagram and electron micrograph of the smooth ER, which is a meshwork of tiny interconnected tubules. The rough ER and smooth ER are connected, making one continuous organelle. (c) Diagram of an assembled ribosome.

ribosomes, free ribosomes synthesize proteins for use within the cytosol. In this way, newly produced molecules destined for export out of the cell or for synthesis of new membrane or other cell components (those synthesized by the ER) are physically separated from those that belong in the cytosol (those produced by the free ribosomes). About one third of the proteome is typically synthesized in the ER.

How do newly synthesized molecules within the ER lumen get to their destinations if they cannot pass out through the ER membrane? They do so by action of the smooth ER.

The smooth ER packages new proteins in transport vesicles.

The smooth ER does not contain ribosomes, so it is "smooth." Lacking ribosomes, it is not involved in protein synthesis. Instead, it serves other purposes that vary in different cell types.

In most cells, the smooth ER is rather sparse and serves primarily as a central packaging and discharge site for molecules to be transported from the ER. Newly synthesized proteins and lipids move within the continuous lumen from the rough ER to gather at specialized exit sites in the smooth ER. These exit sites then "bud off" (that is, balloon outward on the surface and then are pinched off), forming **transport vesicles** that enclose the new molecules (**I**Figure 2-3). (A **vesicle** is a fluid-filled, membrane-enclosed intracellular cargo container.)

How does the ER exit site bud off? *Coat proteins* of the type known as *coat protein II (COPII)* from the cytosol bind with specific proteins facing the outer surface of the smooth ER membrane at the exit site. The linking of these coat proteins into a cagelike assembly or "coat" causes the surface membrane at the site to curve outward to form a dome-shaped bud around the newly synthesized products to be exported out of the smooth ER. Eventually the surface membrane closes and

Secretion (exocytosis)

1 The rough ER synthesizes proteins to be secreted to the exterior or to be incorporated into plasma membrane or other cell components.

2 The smooth ER packages the secretory product into transport vesicles, which bud off and move to the Golgi complex.

3 The transport vesicles fuse with the Golgi complex, open up, and empty their contents into the closest Golgi sac.

4 The newly synthesized proteins from the ER travel by vesicular transport through the layers of the Golgi complex, which modifies the raw proteins into final form and sorts and directs the finished products to their final destination by varying their wrappers.

5 Secretory vesicles containing the finished protein products bud off the Golgi complex and remain in the cytosol, storing the products until signaled to empty.

6 On appropriate stimulation, the secretory vesicles fuse with the plasma membrane, open, and empty their contents to the cell's exterior. Secretion has occurred by exocytosis, with the secretory products never having come into contact with the cytosol.

7 Lysosomes also bud from the Golgi complex.

pinches off a transport vesicle. Transport vesicles move to the Golgi complex, described in the next section, for further processing of their cargo.

In contrast to the sparseness of the smooth ER in most cells, some specialized cell types have an extensive smooth ER, which has additional functions as follows:

■ The smooth ER is abundant in cells that specialize in lipid metabolism—for example, cells that secrete lipid-derived steroid hormones. The membranous wall of the smooth ER, like that of the rough ER, contains enzymes for synthesis of lipids. These cells have an expanded smooth-ER compartment that houses the additional enzymes necessary to keep pace with demands for hormone secretion.

■ In liver cells, the smooth ER contains enzymes specialized for detoxifying harmful substances produced within the body by metabolism or substances that enter the body from the outside in the form of drugs or other foreign compounds.

■ Muscle cells have an elaborate, modified smooth ER known as the *sarcoplasmic reticulum,* which stores calcium used in the process of muscle contraction (see p. 258).

Misfolded proteins are destroyed by the ubiquitin–proteasome pathway.

Like any good factory, the rough ER has a quality control system in place to remove defective products. Misfolded proteins are tagged with **ubiquitin**, a small protein "doom tag" that labels those flawed proteins for destruction. Ubiquitin directs the tagged protein out of the ER to one of many proteasomes located throughout the cell. A **proteasome**, a nonmembranous organelle, is a protein degradation machine: It is a cylinder-shaped complex about the size of a ribosomal subunit that contains multiple protein-digesting enzymes that break down ubiquinated proteins into recyclable building blocks (❙Figure 2-4). A proteasome consists of a hollow *core particle* capped at

Proteasome and ubiquitin are recycled.

❙Figure 2-4 **Proteasome.**

each end with a *regulatory particle*. The regulatory particle recognizes the ubiquitin-tagged protein, unfolds it, and feeds it into the core. The core cavity is lined with a variety of enzymatic sites that break down the protein into peptides (small chains of amino acids). After the peptides are released from the proteasome, cytosolic enzymes finish digesting them into their component amino acids. Ubiquitin is released and recycled.

In addition to tagging misfolded proteins in the ER, ubiquitin also labels other damaged or unneeded intracellular proteins for degradation in proteasomes.

2.4 Golgi Complex and Exocytosis

The **Golgi complex**, a membranous organelle, is closely associated with the ER. Each Golgi complex consists of a stack of flattened, slightly curved, membrane-enclosed sacs (❙Figure 2-5 and chapter opener photo). The sacs within each Golgi stack do not come into physical contact with one another. Note that the

❙Figure 2-5 **Golgi complex.** Diagram and electron micrograph of a Golgi complex, which consists of a stack of slightly curved, membrane-enclosed sacs. The vesicles at the dilated edges of the sacs contain finished protein products packaged for distribution to their final destination.

flattened sacs are thin in the middle but have dilated, or bulging, edges. The number of Golgi complexes varies, depending on the cell type. Some cells have only one Golgi stack, whereas cells specialized for protein secretion may have hundreds of stacks.

Transport vesicles carry their cargo to the Golgi complex for further processing.

Most newly synthesized molecules that have just budded off from the smooth ER enter a Golgi stack. When a transport vesicle reaches a Golgi stack, the vesicle membrane fuses with the membrane of the sac closest to the center of the cell. The vesicle membrane opens up and becomes integrated into the Golgi membrane, and the contents of the vesicle are released to the interior of the sac (see ❙Figure 2-3).

These newly synthesized raw materials from the ER travel by means of vesicle formation through the layers of the Golgi

stack, from the innermost sac closest to the ER to the outermost sac near the plasma membrane. Vesicular transport from one Golgi sac to the next is accomplished through action of membrane-curving *coat protein I (COPI)*. During this transit, two important, interrelated functions take place:

1. *Processing the raw materials into finished products.* Within the Golgi complex, the "raw" proteins from the ER are modified into their final form (for example, by having a carbohydrate attached). The biochemical pathways that the proteins follow during their passage through the Golgi complex are elaborate, precisely programmed, and specific for each final product.

2. *Sorting and directing the finished products to their final destinations.* The Golgi complex is responsible for sorting and segregating products according to their function and destination, such as products to be secreted to the cell's exterior or to be used for constructing new plasma membrane.

The Golgi complex packages secretory vesicles for release by exocytosis.

How does the Golgi complex sort and direct finished proteins to the proper destinations? Finished products collect within the dilated edges of the Golgi complex's sacs. The edge of the outermost sac then pinches off to form a membrane-enclosed vesicle containing a selected product. For each type of product to reach its appropriate site of function, each distinct type of vesicle takes up a specific product before budding off (like a particular piece of mail being placed in an envelope). Vesicles with their selected cargo destined for different sites are wrapped in membranes containing distinct surface proteins. Each distinct surface protein serves as a specific **docking marker** (like an address on an envelope). A vesicle can "dock" lock-and-key fashion and "unload" its selected cargo only at the appropriate **docking-marker acceptor**, a protein located only at the proper destination within the cell (like a house address). Thus, Golgi products reach their appropriate site of function because they are sorted and delivered like addressed envelopes containing particular pieces of mail being delivered only to the appropriate house addresses.

As an example, let us look at secretory cells. **Secretion** is the release to the cell's exterior of a specific product made by the cell for a particular function (see p. 6). Specialized secretory cells include endocrine cells, which secrete protein hormones, and digestive gland cells, which secrete digestive enzymes. In secretory cells, numerous large **secretory vesicles**, which contain proteins to be secreted, bud off from the Golgi stacks. Secretory vesicles, which are about 200 times larger than transport vesicles, store the secretory proteins until the cell is stimulated by a specific signal that indicates a need for release of that particular secretory product. On the appropriate signal, a vesicle moves to the cell's periphery, fuses with the plasma membrane, opens, and empties its contents to the outside (see ❚ Figure 2-3 and Figure 2-6a). This mechanism—release to the exterior of substances originating within the cell—is referred to as **exocytosis** (*exo* means "out of"; *cyto* means "cell"). Exocytosis is the primary mechanism
(a) Exocytosis: A secretory vesicle fuses with the plasma membrane, releasing the vesicle contents to the cell exterior. The vesicle membrane becomes part of the plasma membrane.
(b) Endocytosis: Materials from the cell exterior are enclosed in a segment of the plasma membrane that pockets inward and pinches off as an endocytic vesicle.

❚ Figure 2-6   Exocytosis and endocytosis.

FIGURE FOCUS*: What happens to the surface area of the plasma membrane as a result of exocytosis and of endocytosis?*

for accomplishing secretion. Secretory vesicles fuse only with the plasma membrane and not with any organelle membranes, thereby preventing wasteful or even dangerous discharge of secretory products into organelles.

Let us now examine how secretory vesicles take up specific products in the Golgi stacks for release into the ECF and why they are able to dock only at the plasma membrane (❚ Figure 2-7):

■ The newly finished proteins destined for secretion contain a unique sequence of amino acids at one end known as a *sorting signal*, and the interior surface of the Golgi membrane contains *recognition markers,* proteins that recognize and attract specific sorting signals. Recognition of the right protein's sorting signal by the complementary membrane marker ensures that the proper cargo is captured and packaged into the secretory vesicle.

■ *Coat proteins* called *coatomer* from the cytosol bind with another specific protein on the outer surface of the Golgi membrane and cause a bud to form around the captured cargo.

■ After budding off, the vesicle sheds its coat proteins and exposes the docking markers, known as *v-SNAREs,* which face the outer surface of the vesicle membrane.

■ A v-SNARE can link lock-and-key fashion only with its docking-marker acceptor, called a *t-SNARE,* on the targeted membrane. In the case of secretory vesicles, the targeted membrane is the plasma membrane, the designated site for

Coatomer (coat protein that causes membrane to curve)

t-SNARE (docking-marker acceptor)
1 Recognition markers in the membrane of the outermost Golgi sac capture the appropriate cargo from the Golgi lumen by binding only with the sorting signals of the protein molecules to be secreted. The membrane that will wrap the vesicle is coated with coatomer, which causes the membrane to curve, forming a bud.

2 The membrane closes beneath the bud, pinching off the secretory vesicle.

3 The vesicle loses its coating, exposing v-SNARE docking markers on the vesicle surface.

4 The v-SNAREs bind only with the t-SNARE docking-marker acceptors of the targeted plasma membrane, ensuring that secretory vesicles empty their contents to the cell's exterior.

❙Figure 2-7 **Packaging, docking, and release of secretory vesicles.** The diagram series illustrates secretory vesicle formation and budding with the aid of a coat protein and docking with the plasma membrane by means of v-SNAREs and t-SNAREs. The transmission electron micrograph shows secretion by exocytosis.

secretion to take place. Thus, the v-SNAREs of secretory vesicles fuse only with the t-SNAREs of the plasma membrane. Once a vesicle has docked at the appropriate membrane by means of matching SNAREs, the two membranes completely fuse; then the vesicle opens up and empties its contents at the targeted site.

Note that the contents of secretory vesicles never come into contact with the cytosol. From the time these products are first synthesized in the ER until they are released from the cell by exocytosis, they are always wrapped in membrane and thus isolated from the remainder of the cell. By manufacturing its particular secretory protein ahead of time and storing this product in secretory vesicles, a secretory cell has a readily available reserve from which to secrete large amounts of this product on demand. If a secretory cell had to synthesize all its product on the spot as needed for export, the cell would be more limited in its ability to meet varying levels of demand.

Secretory vesicles are formed only by secretory cells. However, the Golgi complexes of these and other cell types also sort and package newly synthesized products for different destinations within the cell in a similar manner: A particular vesicle captures a specific kind of cargo from among the many proteins in the Golgi lumen, then addresses each shipping container for a distinct destination.

Check Your Understanding 2.4

1. Describe the structure and functions of a Golgi complex.
2. Define *secretion*.
3. Explain how secretory vesicles can dock only with the plasma membrane to release their contents to the cell's exterior.

2.5 Lysosomes and Endocytosis

Lysosomes are small, membrane-enclosed, degradative organelles that break down organic molecules (*lys* means "break down"; *some* means "body"). Instead of having a uniform structure, as is characteristic of all other organelles, lysosomes vary in size and shape, depending on the contents they are digesting. Most commonly, lysosomes are small (0.2 to 0.5 μm in diameter) oval or spherical bodies (❙Figure 2-8). On average, a cell contains about 300 lysosomes.

Lysosomes digest extracellular material brought into the cell by phagocytosis.

Lysosomes are formed by budding from the Golgi complex. A lysosome contains about 40 different powerful **hydrolytic enzymes** that are synthesized in the ER and then transported to

the Golgi complex for packaging in the budding lysosome (see Figure 2-3). These enzymes catalyze **hydrolysis**, reactions that break down organic molecules by the addition of water at a bond site (*hydrolysis* means "splitting with water"; see p. A-14). In lysosomes, the organic molecules are cell debris and foreign material, such as bacteria, that have been brought into the cell. Lysosomal enzymes are similar to the hydrolytic enzymes that the digestive system secretes to digest food. Thus, lysosomes serve as the intracellular "digestive system." Note that lysosomes mostly degrade extracellular proteins brought into the cell, whereas most unwanted intracellular proteins are degraded by the ubiquitin–proteasome pathway.

Extracellular material to be attacked by lysosomal enzymes is brought into the cell through the process of phagocytosis, a type of endocytosis. **Endocytosis**, the reverse of exocytosis, refers to the internalization of extracellular material within a cell (*endo* means "within") (see Figure 2-6b). Endocytosis can be accomplished in three ways—*pinocytosis, receptor-mediated endocytosis,* and *phagocytosis*—depending on the contents of the internalized material.

Pinocytosis In **pinocytosis** ("cell drinking"), a droplet of ECF is taken up nonselectively. First, the plasma membrane dips inward, forming a pouch that contains a small bit of ECF (Figure 2-9a). The plasma membrane then seals at the surface of the pouch, trapping the contents in a small, intracellular **endocytic vesicle**, or **endosome**. *Dynamin,* the protein responsible for pinching off an endocytic vesicle, forms rings that wrap around and "wring the neck" of the pouch, severing the vesicle

from the surface membrane. Besides bringing ECF into a cell, pinocytosis provides a means to retrieve extra plasma membrane that has been added to the cell surface during exocytosis.

Receptor-Mediated Endocytosis Unlike pinocytosis, which involves the nonselective uptake of the surrounding fluid, **receptor-mediated endocytosis** is a highly selective process that enables cells to import specific large molecules that it needs from its environment. Receptor-mediated endocytosis is triggered by the binding of a specific target molecule such as a protein to a surface membrane receptor specific for that molecule (Figure 2-9b). This binding causes the plasma membrane at that site to pocket inward and then seal at the surface, trapping the bound molecule inside the cell. The pouch is formed by the linkage of *clathrin* molecules, which are membrane-deforming coat proteins on the inner surface of the plasma membrane that bow inward, in contrast to the outward-curving coat proteins that form buds. The resulting pouch is known as a *coated pit* because it is coated with clathrin. Cholesterol complexes, vitamin B_{12}, the hormone insulin, and iron are examples of substances selectively taken into cells by receptor-mediated endocytosis.

Clinical Note Unfortunately, some viruses can sneak into cells by exploiting this mechanism. For instance, flu viruses and HIV, the virus that causes AIDS (see p. 426), gain entry to cells via receptor-mediated endocytosis. They do so by binding with membrane receptors normally designed to trigger the internalization of a needed molecule.

Phagocytosis During **phagocytosis** ("cell eating"), large multimolecular particles are internalized. Most body cells perform pinocytosis, many carry out receptor-mediated endocytosis, but only a few specialized cells are capable of phagocytosis, the most notable being certain types of white blood cells that play an important role in the body's defense mechanisms. When a white blood cell encounters a large particle, such as a bacterium or tissue debris, it extends surface projections known as **pseudopods** ("false feet") that surround or engulf the particle and trap it within an internalized vesicle known as a **phagosome** (Figure 2-9c). A lysosome fuses with the membrane of the phagosome and releases its hydrolytic enzymes into the vesicle, where they safely attack the bacterium or other trapped material without damaging the remainder of the cell. The enzymes largely break down the engulfed material into raw ingredients, such as amino acids, glucose, and fatty acids, which the cell can use.

Lysosomes remove worn-out organelles.

Cells typically live longer than many of their internal components. Lysosomes can fuse with aged or damaged organelles to remove these useless parts of the cell. Lysosomal enzymes degrade the dysfunctional organelle, making its building blocks available for reuse by the cell. This selective self-digestion, known as **autophagy** (*auto* means "self"; *phag* means "eating") makes way for new replacement parts. In most cells, all organelles are renewable.

When cells are starving, they often induce autophagy of healthy cellular components that can be spared. This self-

cannibalism provides an internal source of raw ingredients to provide energy and support cell survival for as long as possible. Some individuals lack the ability to synthesize one or more of the lysosomal enzymes. The result is massive accumulation within the lysosomes of the compound normally digested by the missing enzyme. Clinical manifestations often accompany such disorders because the engorged lysosomes interfere with normal cell activity. More than 50 of these so-called *lysosomal storage diseases* have been identified, and they all differ. The nature and severity of the symptoms depend on the type of substance accumulating, which in turn depends on what lysosomal enzyme is missing. An example is **Tay-Sachs disease**, which is characterized by abnormal accumulation of complex molecules found in nerve cells. As the accumulation continues, profound symptoms of progressive nervous system degeneration result.

2.6 Peroxisomes and Detoxification

Peroxisomes are membranous organelles that produce and decompose hydrogen peroxide (H_2O_2) in the process of degrading potentially toxic molecules (*peroxi* refers to "hydrogen peroxide"). Typically, several hundred small peroxisomes about one third to one half the average size of lysosomes are present in a cell (see ❚Figure 2-8). They too arise from the ER and Golgi complex.

Peroxisomes house oxidative enzymes that detoxify various wastes.

Like lysosomes, peroxisomes are membrane-enclosed sacs containing enzymes, but unlike lysosomes, which contain hydrolytic enzymes, peroxisomes house several powerful *oxidative enzymes* and contain most of the cell's *catalase*.

Oxidative enzymes, as the name implies, use oxygen (O_2), in this case to strip hydrogen from certain organic molecules. This reaction helps detoxify various wastes produced within the cell or foreign toxic compounds that have entered the cell, such as alcohol consumed in beverages.

The major product generated in the peroxisome, H_2O_2, is formed by molecular oxygen and the hydrogen atoms stripped from the toxic molecule. H_2O_2 is potentially destructive if allowed to accumulate or escape from the confines of the peroxisome. However, peroxisomes also contain an abundance of **catalase**, an enzyme that decomposes potent H_2O_2 into harmless H_2O and O_2. This latter reaction is an important safety mechanism that destroys the potentially deadly H_2O_2 at its site of production, thereby preventing its possible devastating escape into the cytosol.

2.7 Mitochondria and ATP Production

Mitochondria are the energy organelles, or "power plants," of the cell; they extract energy from the nutrients in food and transform it into a usable form for cell activities. Mitochondria generate about 90% of the energy that cells—and, accordingly, the whole body—need to survive and function. A single cell may contain as few as a hundred or as many as several thousand mitochondria, depending on the energy needs of each particular cell type.

Mitochondria are enclosed by two membranes.

Mitochondria are rod-shaped or oval structures about the size of bacteria. In fact, mitochondria are descendants of bacteria that invaded or were engulfed by primitive cells early in evolutionary history and that subsequently became permanent organelles. As part of their separate heritage, mitochondria possess their own DNA, distinct from the DNA housed in the cell's nucleus. **Mitochondrial DNA (mtDNA)** contains the genetic codes for producing many of the molecules the mitochondria need to generate energy.

Mitochondrial diseases affect an estimated 1 in 4000 people. Mitochondrial diseases primarily affect children, often because of inherited defects in mtDNA. However, adult onset of mitochondrial disease is becoming increasingly common. Flaws gradually accumulate in mtDNA over a person's lifetime; these flaws have been implicated in aging and in an array of disorders. The clinical manifestations of mitochondrial diseases are highly diverse, depending on the location and extent of mtDNA mutations. Typically several organ systems are involved. The more common symptoms of mitochondrial diseases include a mixture from among the following: chronic fatigue, incoordination, mental decline, muscle weakness and pain, digestive disturbances, heart disease, liver disease, respiratory complications, blindness, and hearing loss. Mitochondrial diseases get progressively worse and may be fatal, with the only treatments available being aimed at managing symptoms. An example of a mitochondrial disease is *Leigh syndrome*, which begins in infants and leads to early death following a rapid loss of mental and movement abilities and severe breathing problems.

Each mitochondrion, a membranous organelle, is enclosed by a double membrane—a smooth outer membrane that surrounds the mitochondrion and an inner membrane that forms a series of infoldings or shelves called **cristae**, which project into an inner cavity filled with a gel-like solution known as the **matrix** (❚Figure 2-10a and chapter opener photo). The two membranes are separated by a narrow **intermembrane space**. The cristae contain proteins that ultimately use O_2 to convert

much of the energy in food into a usable form. The generous folds of the inner membrane greatly increase the surface area available for housing these important proteins. The matrix consists of a concentrated mixture of hundreds of different dissolved enzymes that prepare nutrient molecules for final extraction of usable energy by the cristae proteins.

Mitochondria form a mitochondrial reticulum in some cell types.

In skeletal muscle and many other cell types, mitochondria rarely exist separately but instead are interconnected in a network, the **mitochondrial reticulum** (❙Figure 2-10b). This organized system efficiently distributes materials essential for generating energy—for example O_2 and food derivatives such as fatty acids—from the cell surface to deep within the cell. O_2 and fatty acids, which are poorly soluble in water, are more soluble in and thus can move more quickly through the oily membranes surrounding the interconnected mitochondria than through the watery cytosol.

The mitochondrial reticulum is dynamic; it continuously changes through ongoing rounds of fusion and fission as individual mitochondria join to or split from the network, depending on the cell's energy needs. For example, the mitochondrial network expands in response to contractile activity (exercise) in skeletal muscle.

Mitochondria play a major role in generating ATP.

The source of energy for the body is the chemical energy stored in the carbon bonds of ingested food. Body cells are not equipped to use this energy directly. Instead, the cells must extract energy from food nutrients and convert it into a form they can use—namely, the high-energy phosphate bonds of **adenosine triphosphate (ATP)**, which consists of adenosine with three phosphate groups attached (*tri* means "three") (see p. A-15). When the high-energy bond that binds the terminal phosphate to adenosine is split, a substantial amount of energy is released.

ATP is the universal energy carrier—the common energy "currency" of the body. Cells can "cash in" ATP to pay the energy "price" for running the cell machinery. To obtain immediate usable energy, cells split the terminal phosphate bond of ATP, which yields **adenosine diphosphate (ADP)**—adenosine with two phosphate groups attached (*di* means "two")—plus inorganic phosphate (P_i) plus energy:

$$ATP \xrightarrow{\text{splitting}} ADP + P_i + \text{energy for use by the cell}$$
In this energy scheme, food can be thought of as the "crude fuel" and ATP as the "refined fuel" for operating the body's machinery. Food is digested by the digestive system into small absorbable units that can be transferred from the digestive tract lumen into the blood. For example, dietary carbohydrates are broken down primarily into glucose, which is absorbed into the blood. No usable energy is released during the digestion of food. When delivered to the cells by the blood, the nutrient molecules are transported across the plasma membrane into the

IFigure 2-11 **Stages of cellular respiration.** The three stages of cellular respiration are (1) glycolysis, (2) citric acid cycle, and (3) oxidative phosphorylation.

cytosol. (Details of how materials cross the membrane are covered in Chapter 3.)

We now turn attention to the steps involved in ATP production within the cell and the role of the mitochondria in these steps. **Cellular respiration** refers collectively to the intracellular reactions in which energy-rich molecules are broken down to form ATP, using O_2 and producing carbon dioxide (CO_2) in the process. In most cells, ATP is generated from the sequential dismantling of absorbed nutrient molecules in three stages: *glycolysis* in the cytosol, the *citric acid cycle* in the mitochondrial matrix, and *oxidative phosphorylation* at the mitochondrial inner membrane (IFigure 2-11). (Muscle cells use an additional cytosolic pathway for immediately generating energy at the onset of exercise; see p. 269.) We use glucose as an example to describe these stages.

Glycolysis Among the thousands of enzymes in the cytosol are the 10 responsible for **glycolysis**, a chemical process involving 10 sequential reactions that break down glucose, a

six-carbon sugar molecule, into two **pyruvate** molecules, each with three carbons (*glyc-* means "sweet"; *lysis* means "breakdown") (IFigure 2-12). During this process, two hydrogens are released and transferred to two NADH molecules for later use. (You will learn more about NADH shortly.) Some energy from the broken chemical bonds of glucose is used directly to convert ADP into ATP. However, glycolysis is not efficient in terms of energy extraction: The net yield is only two molecules of ATP per glucose molecule processed. Much of the energy originally contained in the glucose molecule is still locked in the chemical bonds of the pyruvate molecules. The low-energy yield of glycolysis is not enough to support the body's demand for ATP. This is where the mitochondria come into play.

Citric Acid Cycle The pyruvate produced by glycolysis in the cytosol is selectively transported into the mitochondrial matrix. Here, one of its carbons is enzymatically removed in the form of CO_2 (IFigure 2-13). Also, another hydrogen is released and transferred to another NADH. The two-carbon molecule remaining after the breakdown process, an **acetyl group**, combines with coenzyme A (CoA), a derivative of pantothenic acid (a B vitamin), to produce the compound **acetyl coenzyme A (acetyl-CoA)**.

Acetyl-CoA then enters the **citric acid cycle**, a cyclical series of eight biochemical reactions that are catalyzed by the enzymes of the mitochondrial matrix. This cycle of reactions can be compared to one revolution around a Ferris wheel, except that the molecules themselves are not physically moved around in a cycle. On the top of the Ferris wheel, acetyl-CoA, a two-carbon molecule, enters a seat already occupied by oxaloacetate, which has four carbons. These two molecules link to form a six-carbon citrate molecule (at intracellular pH, citric acid exists in an ionized form, citrate), and the trip around the citric acid cycle begins. (This cycle is alternatively known as the **Krebs cycle**, in honor of its principal discoverer, or the **tricarboxylic acid cycle**, because citrate contains three carboxylic acid groups.) At each step in the cycle, matrix enzymes modify the passenger molecule to form a slightly different molecule
IFigure 2-12 **Glycolysis in the cytosol.** Glycolysis splits glucose (six carbons) into two pyruvate molecules (three carbons each), with a net yield of 2 ATP plus 2 NADH (available for further energy extraction by the electron transport system).

(shown in Figure 2-13). These molecular alterations have the following important consequences:

1. Two carbons are "kicked off the ride"—released one at a time from six-carbon citrate, converting it back into four-carbon oxaloacetate, which is now available at the top of the cycle to pick up another acetyl-CoA for another revolution through the cycle. CoA is recycled too; it is released at the beginning of the cycle, making it available to bind with a new acetyl group to form another acetyl-CoA.

2. The released carbon atoms, which were originally present in the acetyl-CoA that entered the cycle, are converted into two molecules of CO_2. Note that two carbon atoms enter the cycle in the form of acetyl-CoA and two carbon atoms leave the cycle in the form of two CO_2 molecules. This CO_2 and the CO_2 produced during the formation of an acetyl group from pyruvate pass out of the mitochondrial matrix and subsequently out of the cell to enter the blood. The blood carries the CO_2 to the lungs, where it is eliminated as a waste to the atmosphere through breathing. The oxygen used to make CO_2 from these released carbons is derived from the molecules involved in the reactions, not from free molecular oxygen supplied by breathing.

3. Hydrogens are also "bumped off" during the cycle at four of the chemical conversion steps. The key purpose of the citric
IFigure 2-13 Citric acid cycle in the mitochondrial matrix. The two carbons entering the cycle by means of acetyl-CoA are eventually converted to CO_2, with oxaloacetate, which accepts acetyl-CoA, being regenerated at the end of the cyclical pathway. The hydrogens released at specific points along the pathway bind to the hydrogen carrier molecules NAD⁺ and FAD for further processing by the electron transport system. One molecule of ATP is generated for each molecule of acetyl-CoA that enters the citric acid cycle, for a total of two molecules of ATP for each molecule of processed glucose.

FIGURE FOCUS: *How many each of NADH and FADH$_2$ molecules are generated for each "turn" of the citric acid cycle? How many of each are produced for every glucose molecule processed?*

Unless otherwise noted, all content on this page is © Cengage Learning.

acid cycle is to produce these hydrogens for entry into the electron transport system in the inner mitochondrial membrane. The hydrogens are transferred to two different hydrogen carrier molecules—**nicotinamide adenine dinucleotide (NAD$^+$)**, a derivative of the B vitamin niacin, and **flavine adenine dinucleotide (FAD)**, a derivative of the B vitamin riboflavin. The transfer of hydrogen converts these compounds to NADH and FADH$_2$, respectively. Three NADH and one FADH$_2$ are produced for each turn of the citric acid cycle.

    4. One more molecule of ATP is produced for each molecule of acetyl-CoA processed. ATP is not directly produced by the citric acid cycle. The released energy directly links inorganic phosphate to **guanosine diphosphate (GDP)**, forming **guanosine triphosphate (GTP)**, a high-energy molecule similar to ATP. The energy from GTP is then transferred to ATP as follows:

$$ADP + GTP \rightleftharpoons ATP + GDP$$

Because each glucose molecule is converted into two acetyl-CoA molecules, fueling two turns of the citric acid cycle, two more ATP molecules are produced from each glucose molecule.

    So far, the cell still does not have much of an energy profit. However, the citric acid cycle is important in preparing the hydrogen carrier molecules for their entry into the final stage, oxidative phosphorylation, which produces far more energy than the sparse amount of ATP produced by the cycle itself.

Oxidative Phosphorylation Considerable untapped energy is still stored in the released hydrogens, which contain electrons at high energy levels. **Oxidative phosphorylation** refers to the process by which ATP is synthesized using energy released by electrons as they are transferred to O$_2$. This process involves two groups of proteins at the inner mitochondrial membrane: the *electron transport system* and *ATP synthase.*

    The "big payoff" in energy capture begins when NADH and FADH$_2$ carry the hydrogens to the electron transport system. The **electron transport system** consists of electron carriers found in four large stationary protein complexes, numbered *I, II, III,* and *IV,* along with two small highly mobile electron carriers, *cytochrome c* and *ubiquinone* (also known as *coenzyme Q* or *CoQ*), which shuttle electrons between the major complexes (❙Figure 2-14).

    The high-energy electrons are extracted from the hydrogens held in NADH and FADH$_2$ and enter the electron transport chain for transfer through a series of steps from one electron-carrier molecule to another in an assembly line (step ❶). As a result of giving up hydrogen ions (H$^+$) and electrons at the electron transport system, NADH and FADH$_2$ are converted back to NAD$^+$ and FAD (step ❷), freeing them to pick up more hydrogen atoms released during glycolysis and the citric acid cycle. Thus, NAD$^+$ and FAD link the citric acid cycle and the electron transport system. The electron carriers are arranged in a specific order in the inner membrane so that the high-energy electrons fall to successively lower energy levels as they are transferred from carrier to carrier through a chain of reactions (step ❸). Ultimately, when they are in their lowest energy state, the electrons are bound to molecular oxygen derived from the air we breathe. Oxygen enters the mitochondria to serve as the final electron acceptor of the electron transport system. This

negatively charged oxygen (O$_2^-$)—negative because it has acquired additional electrons—then combines with the positively charged hydrogen ions (H$^+$)—positive because they have donated electrons at the beginning of the electron transport system—to form water, H$_2$O (step ❹).

    As electrons move through this chain of reactions, they release free energy. Part of the released energy is lost as heat, but some is harnessed by the mitochondrion to synthesize ATP. At three sites in the electron transport system (Complexes I, III, and IV), the energy released during the transfer of electrons is used to transport hydrogen ions across the inner mitochondrial membrane from the matrix to the intermembrane space between the inner and the outer mitochondrial membranes (step ❺). As a result, hydrogen ions are more heavily concentrated in the intermembrane space than in the matrix. This H$^+$ gradient generated by the electron transport system (step ❻) supplies the energy that drives ATP synthesis by the membrane-bound mitochondrial enzyme ATP synthase.

    ATP synthase consists of a *basal unit* embedded in the inner membrane, connected by a stalk to a *headpiece* located in the matrix, with the *stator* bridging the basal unit and headpiece. Because H$^+$ ions are more heavily concentrated in the intermembrane space than in the matrix, they have a strong tendency to flow back into the matrix through the inner membrane via channels formed between the basal units and stators of the ATP synthase complexes (step ❼). This flow of H$^+$ ions activates ATP synthase and powers ATP synthesis by the headpiece, a process called **chemiosmosis**. Passage of H$^+$ ions through the channel makes the headpiece and stalk spin like a top (step ❽), similar to the flow of water making a waterwheel turn. As a result of the changes in its shape and position as it turns, the headpiece is able to sequentially pick up ADP and P$_i$, combine them, and release the ATP product (step ❾).

    Oxidative phosphorylation encompasses the entire process by which ATP synthase synthesizes ATP by phosphorylating (adding a phosphate to) ADP using the energy released by electrons as they are transferred to O$_2$ by the electron transport system. The harnessing of energy into a useful form as the electrons tumble from a high-energy state to a low-energy state can be likened to a power plant converting the energy of water tumbling down a waterfall into electricity.

    When activated, ATP synthase provides a rich yield of 28 more ATP molecules for each glucose molecule processed (from the 10 NADH and 2 FADH$_2$ molecules formed during glucose processing) (❙Figure 2-15). Approximately 2.5 ATP are synthesized as a pair of electrons released by NADH travels through the entire electron transport system to oxygen, for a total of 25 ATPs from NADH. The shorter pathway followed by an electron pair released from FADH$_2$ (see ❙Figure 2-14) synthesizes about 1.5 ATP, for a total of 3 ATPs from FADH$_2$. This means a total of 32 molecules of ATP are produced when a glucose molecule is completely dismantled in cellular respiration: 2 during glycolysis, 2 during the citric acid cycle, and 28 during oxidative phosphorylation. The ATP is transported out of the mitochondrion into the cytosol for use as the cell's energy source.

    The steps leading to oxidative phosphorylation might at first seem an unnecessary complication. Why not just directly oxidize, or "burn," food molecules to release their energy?
1 The high-energy electrons extracted from the hydrogens in NADH and $FADH_2$ are transferred from one electron-carrier molecule to another.

2 The NADH and $FADH_2$ are converted to NAD^+ and FAD, which frees them to pick up more hydrogen atoms released during glycolysis and the citric acid cycle.

3 The high-energy electrons fall to successively lower energy levels as they are transferred from carrier to carrier through the electron transport system.

4 The electrons are passed to O_2, the final electron acceptor of the electron transport system. This oxygen, now negatively charged because it has acquired additional electrons, combines with H^+ ions, which are positively charged because they donated electrons at the beginning of the electron transport system, to form H_2O.

5 As electrons move through the electron transport system, they release free energy. Part of the released energy is lost as heat, but some is harnessed to transport H^+ across the inner mitochondrial membrane from the matrix to the intermembrane space at Complexes I, III, and IV.

6 As a result, H^+ ions are more heavily concentrated in the intermembrane space than in the matrix. This H^+ gradient supplies the energy that drives ATP synthesis by ATP synthase.

7 Because of this gradient, H^+ ions have a strong tendency to flow into the matrix across the inner membrane via channels between the basal units and stators of the ATP synthase complexes.

8 This flow of H^+ ions activates ATP synthase and powers ATP synthesis by the headpiece, a process called **chemiosmosis**. Passage of H^+ ions through the channel makes the headpiece and stalk spin like a top.

9 As a result of changes in its shape and position as it turns, the headpiece picks up ADP and P_i, combines them, and releases the ATP product.

Oxidative phosphorylation

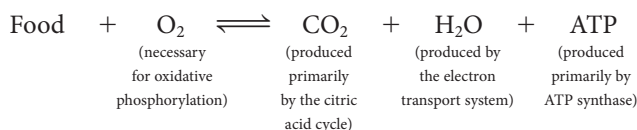
Figure 2-14 **Oxidative phosphorylation at the mitochondrial inner membrane.** Oxidative phosphorylation involves the electron transport system (steps 1–6) and chemiosmosis by ATP synthase (steps 7–9). The pink circles in the electron transport system represent specific electron carriers.

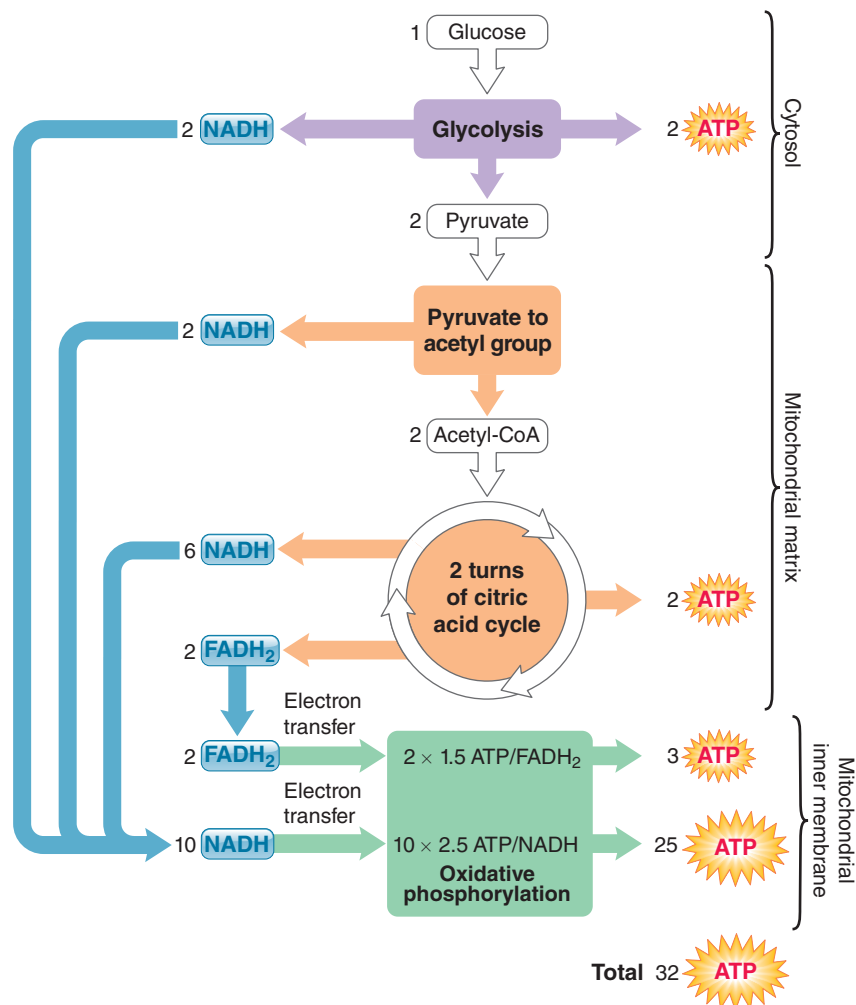
When this process occurs outside the body, all the energy stored in a food molecule is released explosively in the form of heat (▌Figure 2-16). Think about what happens when a marshmallow you are roasting accidentally catches on fire. The burning marshmallow gets hot quickly as a result of the rapid oxidation of sugar. In the body, food molecules are oxidized within the mitochondria in many small, controlled steps so that their chemical energy is gradually released in small quantities that can be more efficiently captured in ATP bonds and stored in a form that is useful to the cell. In this way, much less of the energy is converted to heat. The heat that is produced is not completely wasted energy; it is used to help maintain body temperature, with any excess heat being eliminated to the environment.

The cell generates more energy in aerobic than in anaerobic conditions.

The cell is a more efficient energy converter when O_2 is available. In an **anaerobic** ("lack of air," specifically "lack of O_2") condition, the degradation of glucose cannot proceed beyond glycolysis, which takes place in the cytosol and yields only two molecules of ATP per molecule of glucose. The untapped energy of the glucose molecule remains locked in the bonds of the pyruvate molecules, which are eventually converted to **lactate** if they do not enter the pathway that ultimately leads to oxidative phosphorylation.

When sufficient O_2 is present—an **aerobic** ("with air" or "with O_2") condition—mitochondrial processing (that is, the citric acid cycle in the matrix and the electron transport system and ATP synthase at the inner membrane) harnesses enough energy to generate 30 more molecules of ATP, for a total net yield of 32 ATPs per molecule of glucose processed. (For a description of aerobic exercise, see the boxed feature on p. 41, ▌A Closer Look at Exercise Physiology.) The overall reaction for the oxidation of food molecules to yield energy during cellular respiration is as follows:

$$\underset{\substack{\text{(necessary} \\ \text{for oxidative} \\ \text{phosphorylation)}}}{\text{Food} + \text{O}_2} \rightleftharpoons \underset{\substack{\text{(produced} \\ \text{primarily} \\ \text{by the citric} \\ \text{acid cycle)}}}{\text{CO}_2} + \underset{\substack{\text{(produced by} \\ \text{the electron} \\ \text{transport system)}}}{\text{H}_2\text{O}} + \underset{\substack{\text{(produced} \\ \text{primarily by} \\ \text{ATP synthase)}}}{\text{ATP}}$$


Note that the oxidative reactions within the mitochondria generate energy, unlike the oxidative reactions controlled by the peroxisome enzymes. Both organelles use O_2, but they do so for different purposes.


▌**Figure 2-15** **Summary of ATP production from the complete oxidation of one molecule of glucose.** The total of 32 ATP assumes that electrons carried by each NADH yield 2.5 ATP and those carried by each FADH$_2$ yield 1.5 ATP during oxidative phosphorylation.

FIGURE FOCUS: *If no O_2 is available, pyruvate is converted to lactate instead of an acetyl group. Compare the energy yield of glucose degradation with O_2 and without O_2.*

Glucose, the principal nutrient derived from dietary carbohydrates, is the fuel preference of most cells. However, nutrient molecules derived from fats (fatty acids) and, if necessary, from proteins (amino acids) can also participate at specific points in this overall chemical reaction to eventually produce energy. Amino acids are usually used for protein synthesis rather than energy production, but they can be used as fuel if insufficient glucose and fat are available (see Chapter 17). Fatty acids are sequentially broken down in the mitochondrial matrix through the process of **beta (β) oxidation**, which cleaves off blocks of two-carbon units one at a time. Each two-carbon unit is used to form an acetyl-CoA molecule that enters the citric acid cycle. Different fatty acids contain a different number of carbons. Most fatty acids in the body are between 14 and 22 carbons long. Because every two carbons in a long fatty acid chain forms an acetyl-CoA, a single fatty acid can yield 7 to 11 acetyl-CoA molecules, depending on the fatty acid length, compared to the 2 acetyl-CoA molecules resulting from the breakdown of a glucose molecule. For this

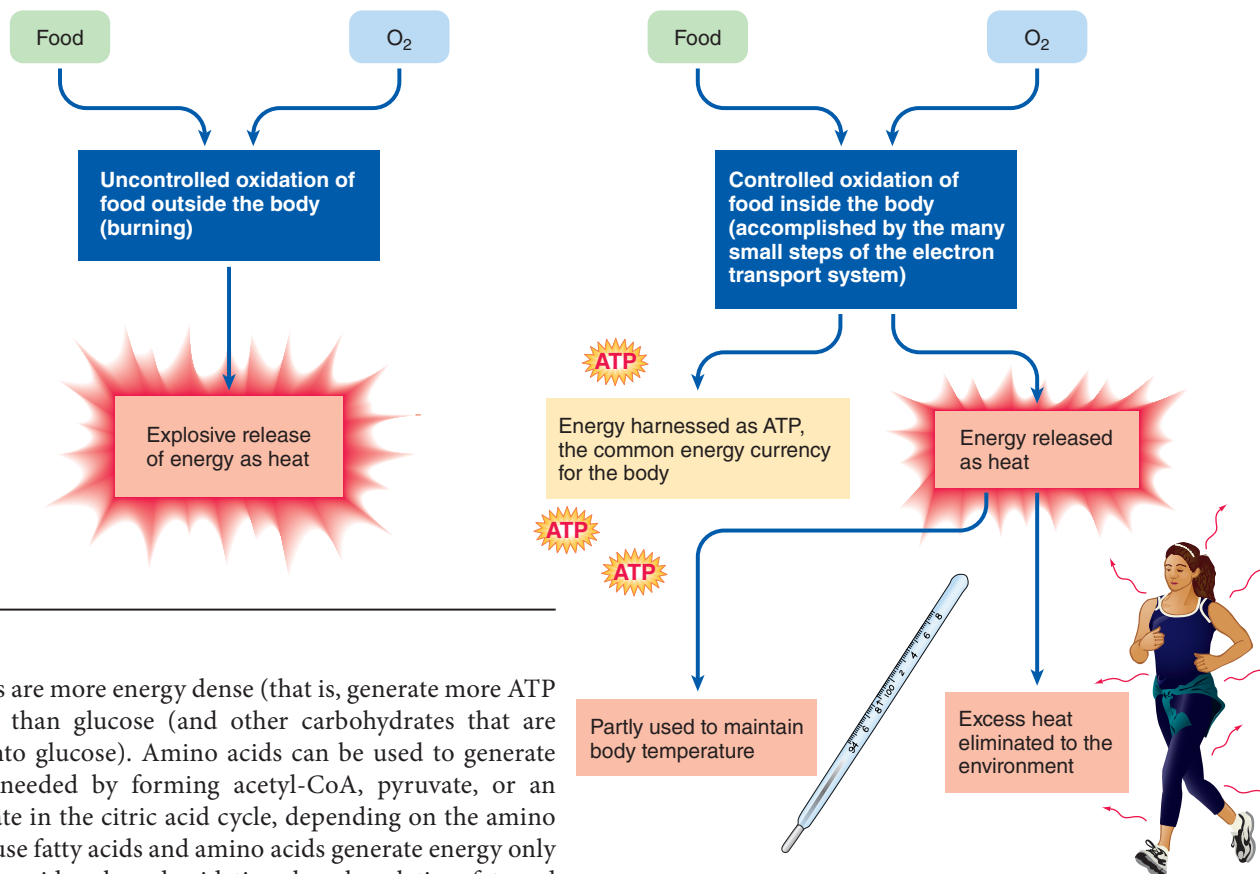
Cell Physiology | **39**


Figure 2-16 Uncontrolled versus controlled oxidation of food. Part of the energy released as heat when food undergoes uncontrolled oxidation (burning) outside the body is instead harnessed and stored in useful form when controlled oxidation of food occurs inside the body.

reason, fats are more energy dense (that is, generate more ATP per gram) than glucose (and other carbohydrates that are digested into glucose). Amino acids can be used to generate energy if needed by forming acetyl-CoA, pyruvate, or an intermediate in the citric acid cycle, depending on the amino acid. Because fatty acids and amino acids generate energy only by the citric acid cycle and oxidative phosphorylation, fats and proteins can be used only aerobically, whereas glucose can be used anaerobically (via glycolysis alone) and aerobically when the product of glycolysis (pyruvate) is further broken down via the citric acid cycle and oxidative phosphorylation.

The energy stored within ATP is used for synthesis, transport, and mechanical work.

Once formed, ATP is transported out of the mitochondria and is then available as an energy source in the cell. Cell activities that require energy expenditure fall into three main categories:

1. *Synthesis of new chemical compounds,* such as protein synthesis by the ER. Some cells, especially cells with a high rate of secretion, use up to 75% of the ATP they generate just to synthesize new chemical compounds.

2. *Membrane transport,* such as the selective transport of molecules across the kidney tubules during the process of urine formation. Kidney cells can expend as much as 80% of their ATP currency to operate their selective membrane-transport mechanisms.

3. *Mechanical work,* such as contraction of the heart muscle to pump blood or contraction of skeletal muscles to lift an object. These activities require tremendous quantities of ATP.

As a result of cell energy expenditure to support these various activities, large quantities of ADP are produced. These energy-depleted molecules enter the mitochondria for "recharging" and then cycle back into the cytosol as energy-rich ATP molecules after participating in oxidative phosphorylation. In this recharging–expenditure cycle, a single ADP/ATP molecule

may shuttle between mitochondria and cytosol thousands of times per day. On average a person recycles the equivalent of his or her body weight of ATP every day.

The high demands for ATP make glycolysis alone an insufficient, and inefficient, supplier of power for most cells. Were it not for the mitochondria, which house the metabolic machinery for oxidative phosphorylation, the body's energy capability would be limited. However, glycolysis does provide cells with a sustenance mechanism that can produce ATP under anaerobic conditions. Skeletal muscle cells in particular take advantage of this ability during short bursts of strenuous exercise, when energy demands for contractile activity outstrip the body's ability to bring adequate O_2 to the exercising muscles to support oxidative phosphorylation.

Mitochondria play a key role in programmed cell death.

In addition to their central role in generating most of the ATP for cell use, mitochondria play a key, unrelated role in deliberate cell suicide, a process called **apoptosis**. Every cell has a built-in biochemical pathway that, if triggered, causes the cell to execute itself as a result of mitochondrial leakage of cytochrome *c* (one of the components of the electron transport system), which out-

Aerobic Exercise: What For and How Much?

AEROBIC ("WITH O_2") EXERCISE involves large muscle groups and is performed at a low-enough intensity and for a long-enough period that fuel sources can be converted to adenosine triphosphate (ATP) by using the citric acid cycle and oxidative phosphorylation as the predominant metabolic pathway. Aerobic exercise can be sustained from 15 to 20 minutes to several hours at a time. Short-duration, high-intensity activities, such as weight training and the 100-meter dash, which last for a matter of seconds and rely solely on energy stored in the muscles and on glycolysis, are forms of **anaerobic** ("without O_2") **exercise**.

Inactivity is associated with increased risk of developing both hypertension (high blood pressure) and coronary artery disease (blockage of the arteries that supply the heart). The American College of Sports Medicine recommends that an individual participate in aerobic exercise a minimum of three times per week for 20 to 60 minutes to reduce the risk of hypertension and coronary artery disease and to improve physi-

cal work capacity. The same health benefits are derived whether the exercise is accomplished in one long stretch or is broken into multiple shorter stints. This is good news because many individuals find it easier to stick with brief bouts of exercise sprinkled throughout the day.

The intensity of the exercise should be based on a percentage of the individual's maximal capacity to work. The easiest way to establish the proper intensity of exercise and to monitor intensity levels is by checking the heart rate. The estimated maximal heart rate is determined by subtracting the person's age from 220. Significant benefits can be derived from aerobic exercise performed between 70% and 80% of maximal heart rate. For example, the estimated maximal heart rate for a 20 year old is 200 beats per minute. If this person exercised three times per week for 20 to 60 minutes at an intensity that increased the heart rate to 140 to 160 beats per minute, the participant should significantly improve his or her aerobic work capacity and reduce the risk of cardiovascular disease.

side the confines of the mitochondria exerts the entirely different function of activating intracellular protein-snipping enzymes that slice the cell into small, disposable pieces. Apoptosis is a natural part of the life of an organism: It eliminates cells that are no longer needed or are disordered. (The term *apoptosis* means "dropping off," in reference to the dropping off of cells that are no longer useful, much as autumn leaves drop off trees.) (See the boxed feature on pp. 42 and 43, ▌Concepts, Challenges, and Controversies, for further discussion of apoptosis.)

2.8 Vaults as Cellular Trucks

Vaults, which are nonmembranous organelles, are shaped like octagonal barrels (▌Figure 2-17, p. 44). Their name comes from their multiple arches, which reminded their discoverers of vaulted or cathedral ceilings. Just like barrels, vaults have a hollow interior. When open, they appear like pairs of unfolded flowers with each half of the vault bearing eight "petals" attached to a central ring. A cell may contain thousands of vaults, which are three times as large as ribosomes.

Vaults may serve as cellular transport vehicles.

Currently, the function of vaults is uncertain, but their octagonal shape and their hollow interior provides clues. Nuclear pores are also octagonal and the same size as vaults, leading to speculation that vaults may be cellular "trucks." According to this proposal, vaults would dock at or enter nuclear pores, pick up molecules synthesized in the nucleus, and deliver their cargo elsewhere in the cell. Ongoing research supports the role of vaults in nucleus-to-cytoplasm transport, but their cargo has not been determined. One possibility is that vaults carry mRNA from the nucleus to the ribosomal sites of protein synthesis within the cytoplasm. Another possibility is that vaults transport the two subunits that make up ribosomes from the nucleus, where they are produced, to their sites of action—either attached to the rough ER or in the cytosol. The interior of a vault is the right size to accommodate these ribosomal subunits.

Clinical Note Vaults may play an undesirable role in bringing about the multidrug resistance sometimes displayed by cancer cells. Chemotherapy drugs designed to kill cancer cells tend to accumulate in the nuclei of these cells, but some cancer cells develop resistance to a wide variety of these drugs. This broad resistance is a major cause of cancer treatment failure. Researchers have shown that some cancer cells resistant to chemotherapy produce up to 16 times more than normal quantities of the major vault protein. If further investigation confirms that vaults play a role in drug resistance—perhaps by transporting the drugs from the nucleus to sites for exocytosis from the cancer cells—the exciting possibility exists that interference with this vault activity could improve the sensitivity of cancer cells to chemotherapeutic drugs.

Apoptosis: Programmed Cell Suicide

APOPTOSIS is intentional suicide of a cell that is no longer useful. Apoptosis is a normal part of life—individual cells that have become superfluous or disordered are triggered to self-destruct for the greater good of maintaining the whole body's health.

Roles of Apoptosis

Here are examples of the vital roles played by this intrinsic sacrificial program:

■ *Predictable self-elimination of selected cells is a normal part of development.* Certain unwanted cells produced during development are programmed to kill themselves as the body is sculpted into its final form. During the development of a female, for example, apoptosis deliberately removes the embryonic ducts capable of forming a male reproductive tract. Likewise, apoptosis carves fingers from a mitten-shaped developing hand by eliminating the weblike membranes between them.

■ *Apoptosis is important in tissue turnover in the adult body.* Optimal functioning of most tissues depends on a balance between controlled production of new cells and regulated cell self-destruction. This balance maintains the proper number of cells in a given tissue while ensuring a controlled supply of fresh cells that are at their peak of performance.

■ *Programmed cell death plays an important role in the immune system.* Apoptosis provides a means to remove cells infected with harmful viruses. Furthermore, infection-fighting white blood cells that have finished their prescribed function and are no longer needed execute themselves.

■ *Undesirable cells that threaten homeostasis are typically culled from the body by apoptosis.* Included in this hit list are aged cells, cells that have suffered irreparable damage by exposure to radiation or other poisons, and cells that have somehow gone awry. Many mutated cells are eliminated by this means before they become fully cancerous.

Comparison of Apoptosis and Necrosis

Apoptosis is not the only means by which a cell can die, but it is the neatest way. Apoptosis is a controlled, intentional, tidy way of removing individual cells that are no longer needed or that pose a threat to the body. The other form of cell death, **necrosis** (meaning "making dead"), is uncontrolled, accidental, messy murder of useful cells that have been severely injured by an agent external to the cell, as by a physical blow, O_2 deprivation, or disease. For example, heart muscle cells deprived of their O_2 supply by complete blockage of the blood vessels supplying them during a heart attack die as a result of necrosis (see p. 314). Apoptosis is an energy-dependent process, whereas necrosis does not require energy.

Even though necrosis and apoptosis both result in cell death, the steps involved are different. In necrosis the dying cells are passive victims, whereas in apoptosis the cells actively participate in their deaths. In necrosis, the injured cell loses the integrity of its plasma membrane and cannot pump out Na^+ as usual. As a result, water streams in by osmosis (see p. 66), causing the cell to swell and rupture. Typically, in necrosis the insult that prompted cell death injures many cells in the vicinity, so many neighboring cells swell and rupture together. Release of intracellular contents into the surrounding tissues initiates an inflammatory response at the damaged site (see p. 408). Unfortunately, this inflammatory response may harm healthy neighboring cells.

By contrast, apoptosis targets individual cells for destruction, leaving the surrounding cells intact. A condemned cell signaled to commit suicide detaches itself from its neighbors and then shrinks instead of swelling and bursting. The cell's mitochondria become leaky, permitting cytochrome *c* to leak out into the cytosol. **Cytochrome *c***, a component of the electron transport system, usually participates in oxidative phosphorylation to produce ATP. Outside its typical mitochondrial environment, however, cytochrome *c* activates normally inactive intracellular protein-cutting enzymes, the **caspases**, which kill the cell from within. The unleashed caspases act like molecular scissors to systematically dismantle the cell. Snipping protein after protein, they chop up the nucleus, disassembling its life-essential DNA, then break down the internal shape-holding cytoskeleton, and finally fragment the cell into disposable membrane-enclosed packets (see accompanying photo). Of note, the contents of the dying cell remain wrapped by plasma membrane throughout the entire self-execution process, thus avoiding the spewing of poten-

2.9 Cytosol: Cell Gel

Occupying about 55% of the total cell volume, the cytosol is the semiliquid portion of the cytoplasm that surrounds the organelles. Its nondescript appearance under an electron microscope gives the false impression that the cytosol is a liquid mixture of uniform consistency, but it is actually a highly organized, gel-like mass with differences in composition and consistency from one part of the cell to another.

The cytosol is important in intermediary metabolism, ribosomal protein synthesis, and nutrient storage.

Three general categories of activities are associated with the cytosol: (1) enzymatic regulation of intermediary metabolism; (2) ribosomal protein synthesis; and (3) storage of fat, carbohydrate, and secretory vesicles.

tially harmful intracellular contents characteristic of necrosis. No inflammatory response is triggered, so no neighboring cells are harmed. Instead, cells in the vicinity swiftly engulf and destroy the apoptotic cell fragments by phagocytosis. The breakdown products are recycled for other purposes as needed. The tissue as a whole has continued to function normally, while the targeted cell has unobtrusively killed itself.

By comparison to apoptosis and necrosis, both means of cell death, the self-eating process of autophagy (see p. 31) actually promotes cell survival by removing outdated or damaged cell components, thus permitting the cell to refresh itself with healthy new replacement parts.

Control of Apoptosis

If every cell contains caspases, what normally keeps these powerful self-destructive enzymes under control (that is, in inactive form) in cells that are useful to the body and deserve to live? Likewise, what activates the death-wielding caspases in unwanted cells destined to eliminate themselves? Given the importance of these life-or-death decisions, it is not surprising that multiple internal control pathways tightly regulate whether a cell is "to be or not to be." A cell normally receives a constant stream of "survival signals," which reassure the cell that it is useful to the body, that all is right in the internal environment surrounding the cell, and that everything is in good working order within the cell. These signals include tissue-specific growth factors, certain hormones, and appropriate contact with neighboring cells and surrounding connective tissue. These extracellular survival signals trigger intracellular pathways that block activation of the caspases, thus restraining the cell's death ma-
A normal cell (bottom) and a cell undergoing apoptosis (top).

chinery. Most cells are programmed to commit suicide if they do not receive their normal reassuring survival signals. With the usual safeguards removed, the lethal protein-snipping enzymes are unleashed. For example, withdrawal of growth factors or detachment from the surrounding connective tissue causes a cell to promptly execute itself.

Furthermore, cells display "death receptors" in their outer plasma membrane that receive specific extracellular "death signals," such as a particular hormone or a specific chemical messenger from white blood cells that arrive at the cell via the blood. Activation of death pathways by these signals can override the life-saving pathways triggered by the survival signals. The death-signal pathway swiftly ignites the internal apoptotic machinery, driving the cell to its demise. Likewise, the self-execution machinery is set in motion when a cell suffers irreparable intracellular damage. Thus, some signals block apoptosis and others promote it. Whether a cell lives or dies depends on which of these competing signals dominates at any given time. Although all cells have the same death machinery, they vary in the specific signals that induce them to commit suicide.

Considering that every cell's life hangs in delicate balance at all times, it is not surprising that faulty control of apoptosis—resulting in either too much or too little cell suicide—appears to participate in many major diseases. Excessive apoptotic activity is believed to contribute to the brain cell death associated with Alzheimer's disease, Parkinson's disease, and stroke and to the premature demise of important infection-fighting cells in AIDS. Conversely, too little apoptosis most likely plays a role in cancer. Evidence suggests that cancer cells fail to respond to the normal extracellular signals that promote cell death. Because these cells neglect to die on cue, they grow in unchecked fashion, forming a chaotic, out-of-control mass.

Apoptosis is currently one of the hottest topics of investigation in the field. Researchers are scrambling to sort out the multiple factors involved in the mechanisms controlling this process. Their hope is to find ways to tinker with the apoptotic machinery to find badly needed new therapies for treating a variety of big killers.

Enzymatic Regulation of Intermediary Metabolism

The term **intermediary metabolism** refers collectively to the large set of chemical reactions inside the cell that involve the degradation, synthesis, and transformation of small organic molecules such as simple sugars, amino acids, and fatty acids. These reactions are critical for ultimately capturing the energy used for cell activities and for providing the raw materials needed to maintain the cell's structure, function, and growth. Intermediary metabolism occurs in the cytoplasm, with most of it being accomplished in the cytosol. The cytosol contains thousands of enzymes involved in intermediary biochemical reactions.

Ribosomal Protein Synthesis

Also dispersed throughout the cytosol are the free ribosomes, which synthesize proteins for use in the cytosol itself. In contrast, recall that the rough-ER ribosomes synthesize proteins for secretion and for construction of new cell components.

Storage of Fat, Glycogen, and Secretory Vesicles

Excess nutrients not immediately used for ATP production are converted in the cytosol into storage forms that are readily visible under a light microscope. Such nonpermanent masses of stored material are known as **inclusions**. Inclusions are not surrounded by membrane, and they may or may not be present,

depending on the type of cell and the circumstances. The largest and most important storage product is fat. Small fat droplets are present within the cytosol in various cells. In **adipose tissue**, the tissue specialized for fat storage, stored fat molecules can occupy almost the entire cytosol, where they merge to form one large fat droplet (**Figure 2-18a). The other storage product is **glycogen**, the storage form of glucose, which appears as clusters or granules dispersed throughout the cell (**Figure 2-18b). Cells vary in their ability to store glycogen, with liver and muscle cells having the greatest stores. When food is not available to provide fuel for the citric acid cycle and electron transport system, stored glycogen and fat are broken down to release glucose and fatty acids, respectively, which can feed the mitochondrial energy-producing machinery. An average adult human stores enough glycogen to provide energy for about a day of normal activities and typically has enough fat stored to provide energy for two months.

Secretory vesicles that have been processed and packaged by the ER and Golgi complex also remain in the cytosol, where they are stored until signaled to empty their contents to the outside. In addition, transport and endocytic vesicles move through the cytosol.

2.10 Cytoskeleton: Cell "Bone and Muscle"

Different cell types in the body have distinct shapes, structural complexities, and functional specializations. These unique characteristics are maintained by the **cytoskeleton**, an elaborate protein scaffolding dispersed throughout the cytosol that acts as the "bone and muscle" of the cell by supporting and organizing the cell components and controlling their movements.

The cytoskeleton has three distinct elements: (1) *microtubules,* (2) *microfilaments,* and (3) *intermediate filaments*. These elements are structurally linked and functionally coordinated to provide certain integrated functions for the cell. These functions, along with the functions of all other components of the cytoplasm, are summarized in **Table 2-2.

Cytoplasm Component	Structure	Function
Membranous organelles		
Endoplasmic reticulum	Extensive, continuous membranous network of fluid-filled tubules and flattened sacs, partially studded with ribosomes	Forms new cell membrane and other cell components and manufactures products for secretion
Golgi complex	Sets of stacked, flattened, membranous sacs	Modifies, packages, and distributes newly synthesized proteins
Lysosomes	Membranous sacs containing hydrolytic enzymes	Serve as cell's digestive system, destroying foreign substances and cellular debris
Peroxisomes	Membranous sacs containing oxidative enzymes	Perform detoxification activities
Mitochondria	Rod- or oval-shaped bodies enclosed by two membranes, with the inner membrane folded into cristae that project into an interior matrix	Act as energy organelles; major site of ATP production; contain enzymes for citric acid cycle, proteins of electron transport system, and ATP synthase
Nonmembranous organelles		
Ribosomes	Granules of RNA and proteins—some attached to rough ER, some free in cytosol	Serve as workbenches for protein synthesis
Proteasomes	Cylindrical protein complexes consisting of a hollow core particle capped on both ends by a regulatory particle	Degrade unwanted intracellular proteins that have been tagged for destruction by ubiquitin
Vaults	Shaped like hollow octagonal barrels	Serve as cellular trucks for transport from nucleus to cytoplasm
Centrioles	A pair of cylindrical structures at right angles to each other	Form and organize microtubules during assembly of the mitotic spindle during cell division and form cilia and flagella
Cytosol		
Intermediary metabolism enzymes	Dispersed within the cytosol	Facilitate intracellular reactions involving degradation, synthesis, and transformation of small organic molecules
Transport, secretory, and endocytic vesicles	Transiently formed, membrane-enclosed products synthesized within or engulfed by the cell	Transport or store products being moved within, out of, or into the cell, respectively
Inclusions	Glycogen granules, fat droplets	Store excess nutrients
Cytoskeleton		As an integrated whole, serves as the cell's "bone and muscle"
Microtubules	Long, slender, hollow tubes composed of tubulin molecules	Maintain asymmetric cell shapes and coordinate complex cell movements, specifically serving as highways for transport of secretory vesicles within cell, serving as main structural and functional component of cilia and flagella, and assembling into mitotic spindle
Microfilaments	Intertwined helical chains of actin molecules; microfilaments composed of myosin molecules also present in muscle cells	Play a vital role in various cellular contractile systems, including muscle contraction and amoeboid movement; serve as a mechanical stiffener for microvilli
Intermediate filaments	Irregular, threadlike proteins	Help resist mechanical stress
Figure 2-19 **Components of the cytoskeleton.** (a) Microtubules, the largest of the cytoskeletal elements, are long, hollow tubes formed by two slightly different variants of globular-shaped tubulin molecules. (b) Most microfilaments, the smallest of the cytoskeletal elements, consist of two chains of actin molecules wrapped around each other. (c) The intermediate filament keratin, found in skin, is made of four keratin protofibrils twisted together. A protofibril consists of two strands, each made up of two staggered rows of keratin subunits. The composition of intermediate filaments, which are intermediate in size between the microtubules and microfilaments, varies among different cell types.

(a) Microtubule   **(b)** Microfilament   **(c)** Keratin, an intermediate filament

Microtubules help maintain asymmetric cell shapes and play a role in complex cell movements.

Microtubules are the largest of the cytoskeletal elements. They are slender (22 nm in diameter), long, hollow, unbranched tubes composed primarily of **tubulin**, a small, globular, protein molecule (**I**Figure 2-19a).

Microtubules arise from the centrosome and its associated centrioles. The **centrosome**, or **cell center**, located near the nucleus, consists of the centrioles surrounded by an amorphous mass of proteins. The **centrioles**, which are nonmembranous organelles, are a pair of short cylindrical structures that lie at right angles to each other at the centrosome's center (**I**Figure 2-20). The centrosome is the cell's main microtubule organizing center. When a cell is not dividing, microtubules are formed from the amorphous mass and radiate outward in all directions from the centrosome (see **I**Figure 2-1, p. 23). Centrioles form microtubules under special circumstances, as you will see as we turn attention to microtubule functions.

Microtubules position many of the cytoplasmic organelles, such as the ER, Golgi complex, lysosomes, and mitochondria. They are also essential for maintaining the shape of asymmetric cells, such as nerve cells, whose elongated axons may extend up to a meter in length from where the cell body originates in the spinal cord to where the axon ends at a muscle (**I**Figure 2-21a).

Centrioles

Microtubule triplet
Figure 2-20 **Centrioles.** The two cylindrical centrioles lie at right angles to each other as shown in the diagram. The electron micrograph shows a centriole in cross section. Note that a centriole is made up of nine microtubule triplets that form a ring.

(b)
Figure 2-21 Two-way vesicular axonal transport facilitated by the microtubular "highway" in a neuron. (a) Secretory vesicles are transported from the site of production in the cell body along a microtubule "highway" to the terminal end for secretion. Vesicles containing debris are transported in the opposite direction for degradation in the cell body. The top enlargement depicts kinesin, a motor protein, carrying a secretory vesicle down the microtubule by using its "feet" to "step" on one tubulin molecule after another. The bottom enlargement depicts another motor protein, dynein, transporting debris up the microtubule. (b) How a kinesin "walks" along the surface of a microtubule by alternately attaching and releasing its "feet" as it cyclically swings the rear foot ahead of the front foot.

FIGURE FOCUS: *Microtubules disintegrate during the course of Alzheimer's disease. How could this breakdown lead to death of involved neurons?*

Along with specialized intermediate filaments, microtubules stabilize this asymmetric axonal extension.

Microtubules also play an important role in some complex cell movements, including (1) transport of secretory vesicles or other materials from one region of the cell to another, (2) movement of specialized cell projections such as cilia and flagella, and (3) distribution of chromosomes during cell division through formation of a mitotic spindle. Let us examine each of these roles.

Vesicle Transport Axonal transport provides a good example of the importance of an organized system for moving secretory vesicles. In a nerve cell, specific chemicals are released from the terminal end of the elongated axon to influence a muscle or another structure that the nerve cell controls. These chemicals are largely produced within the cell body where the nuclear DNA blueprint, endoplasmic reticular factory, and Golgi packaging and distribution outlet are located. If they had to diffuse on their own from the cell body to a distant axon

terminal, it would take the chemicals about 50 years to get there—obviously an impractical solution. Instead, the microtubules that extend from the beginning to the end of the axon provide a "highway" for vesicular traffic along the axon.

Motor proteins are the transporters. A **motor protein**, or **molecular motor**, is a protein that attaches to the particle to be transported and then uses energy harnessed from ATP to "walk" along the microtubule, with the particle riding "piggyback" (*motor* means "movement"). **Kinesin**, the motor protein that carries secretory vesicles to the end of the axon, consists of two "feet," a stalk, and a fanlike tail (❙Figure 2-21a). The tail binds to the secretory vesicle to be moved, and the feet swing forward one at a time, as if walking, using the tubulin molecules as stepping stones (❙Figure 2-21b).

Reverse vesicular traffic also occurs along these microtubular highways. Vesicles that contain debris are transported by a different ATP-driven motor protein, **dynein**, from the axon terminal to the cell body for degradation by lysosomes, which are confined within the cell body. The two ends of a microtubule are different, and each motor protein can travel in only one direction along the microtubule toward a specific end. Dynein always moves toward the centrosome (or "minus") end of the microtubule and kinesin always walks toward the outermost (or "plus") end, ensuring that their cargo is moved in the right direction.

Clinical Note Reverse axonal transport may also serve as a pathway for the movement of some infectious agents, such as herpes viruses (the ones that cause cold sores, genital herpes, and shingles), poliomyelitis virus, and rabies virus. These viruses travel backward along nerves from their surface site of contamination, such as a break in the skin or an animal bite, to the central nervous system (brain and spinal cord).

Movement of Cilia and Flagella Microtubules are also the dominant structural and functional components of cilia and flagella. These specialized motile protrusions from the cell surface allow a cell to move materials across its surface (in the case of a stationary cell) or to propel itself through its environment (in the case of a motile cell). **Cilia** (meaning "eyelashes"; singular, *cilium)* are short, tiny, hairlike protrusions usually found in large numbers on the surface of a ciliated cell. **Flagella** (meaning "whips"; singular, *flagellum)* are long, whiplike appendages; typically, a cell has one or a few flagella at most. Even though they project from the surface of the cell, cilia and flagella are both intracellular structures—they are covered by the plasma membrane.

Cilia beat or stroke in unison in a given direction, much like the coordinated efforts of a rowing team. In humans, ciliated cells line the respiratory tract, the oviduct of the female reproductive tract, and the fluid-filled ventricles (chambers) of the brain. The coordinated stroking of the thousands of respiratory cilia help keep foreign particles out of the lungs by sweeping outward dust and other inspired (breathed-in) particles (❙Figure 2-22). In the female reproductive tract, the sweeping action of the cilia lining the oviduct draws the egg (ovum) released from the ovary during ovulation into the oviduct and then guides it toward the uterus (womb). In the brain, the ciliated cells lining the ventricles produce cerebrospinal fluid, which

flows through the ventricles and around the brain and spinal cord, cushioning and bathing these fragile neural structures. Beating of the cilia helps promote circulation of this supportive fluid.

In addition to the multiple motile cilia found in cells in these specific locations, almost all cells in the human body possess a single nonmotile **primary cilium**. Until recently, primary cilia were considered useless vestiges, but growing evidence suggests that they act as microscopic sensory organs that sample the extracellular environment. They may be critical for receiving regulatory signals involved in controlling growth, cell differentiation, and cell proliferation (expansion of a given cell type).

Clinical Note Defects in primary and motile cilia have been implicated in a range of human disorders, including polycystic kidney disease and chronic respiratory disease, respectively.

In humans, the only cells that have a flagellum are sperm (see ❙Figure 20-9, p. 728). The whiplike motion of the flagellum or "tail" enables a sperm to move through its environment to maneuver into position to fertilize the female ovum.

Cilia and flagella have the same basic internal structure, their only difference being their length: Cilia are short, and flagella are long. Both consist of nine fused pairs of microtubules (doublets) arranged in an outer ring around two single unfused microtubules in the center (❙Figure 2-23). This characteristic "9 + 2" grouping of microtubules extends throughout the length of the motile appendage. Spokelike accessory proteins hold the structure together.

Cilia and flagella arise from centrioles. Each cylinder of the centriole pair contains a bundle of microtubules similar to the 9 + 2 complex, except that the central pair of single microtubules is missing and the outer ring has nine fused triplets rather than doublets of microtubules (see ❙Figure 2-20). During formation of a cilium or flagellum, a duplicated centriole moves to a position just under the plasma membrane, where microtubules grow

outward from the centriole in an orderly pattern to form the motile appendage. The centriole remains at the base of the developed cilium or flagellum as the **basal body** of the structure.

In addition to the accessory proteins that maintain the microtubule's organization, another accessory protein, the motor protein dynein, plays an essential part in the microtubular movement that causes the entire structure to bend. Dynein forms armlike projections from each doublet of microtubules (see ❙Figure 2-23b and c). These dynein arms walk along the adjacent microtubule doublets, causing the doublets to slide past each other, bringing about the bending and stroking (❙Figure 2-23d). Groups of cilia working together are oriented to beat in the same direction and contract in a synchronized manner through poorly understood control mechanisms involving the single microtubules at the cilium's center.

Formation of the Mitotic Spindle Cell division involves two discrete but related activities: *mitosis* (nuclear division), which depends on microtubules, and *cytokinesis* (cytoplasmic division), which depends on microfilaments and is described in the next section. During **mitosis**, the DNA-containing chromosomes of the nucleus are replicated, resulting in two identical sets. These duplicate sets of chromosomes are separated and drawn apart to opposite sides of the cell so that the genetic material is evenly distributed in the two halves of the cell.

The replicated chromosomes are pulled apart by motor proteins that move them along a cellular apparatus called the **mitotic spindle**, which is transiently assembled from microtubules only during cell division. The microtubules of the mitotic spindle are formed by the centrioles. As part of cell division, the centrioles first duplicate themselves; then, the new centriole pairs move to opposite ends of the cell and form the spindle apparatus between them through a precisely organized assemblage of microtubules.

Microfilaments are important to cellular contractile systems and as mechanical stiffeners.

Microfilaments are the smallest (6 nm in diameter) elements of the cytoskeleton. The most obvious microfilaments in most cells are those composed of **actin**, a protein molecule that has a globular shape similar to that of tubulin. Unlike tubulin, which forms a hollow tube, actin assembles into two strands, which twist around each other to form a microfilament (see ❙Figure 2-19b). In muscle cells, the protein **myosin** forms a different kind of microfilament (see ❙Figure 8-4, p. 255). In most cells, myosin is not as abundant and does not form such distinct filaments.

Microfilaments serve two functions: (1) They play a vital role in various cell contractile systems, and (2) they act as mechanical stiffeners for several specific cell projections.

Microfilaments in Cell Contractile Systems Actin-based assemblies are involved in muscle contraction, cell division, and cell locomotion. The most obvious, best-organized, and most clearly understood cell contractile system is that found in muscle. Muscle contains an abundance of actin and myosin microfilaments, which bring about muscle contraction through the ATP-powered sliding of actin microfilaments in relation to stationary myosin microfilaments. Myosin is a motor protein that has heads that walk along the actin microfilaments, pulling them inward between the myosin microfilaments. Microfilament sliding and force development are triggered by a complex sequence of electrical, biochemical, and mechanical events initiated when the muscle cell is stimulated to contract (see Chapter 8 for details).

Nonmuscle cells may also contain "musclelike" assemblies. Some of these microfilament contractile systems are transiently assembled to perform a specific function when needed. A good example is the contractile ring that forms during **cytokinesis**, the process by which the two halves of a dividing cell separate into two new daughter cells, each with a full complement of chromosomes. The ring consists of a beltlike bundle of actin filaments located just beneath the plasma membrane in the middle of the dividing cell. When this ring of fibers contracts and tightens, it pinches the cell in two (❙Figure 2-24).

Complex actin-based assemblies are also responsible for most cell locomotion. Four types of human cells are capable of moving on their own—sperm, white blood cells, fibroblasts, and skin cells. Flagella propel sperm. The other motile cells move via **amoeboid movement**, a cell-crawling process that depends on the activity of their actin filaments, in a mechanism similar to that used by amoebas to maneuver through their environment. When crawling, the motile cell forms footlike protrusions, or *pseudopods*, at the "front" or leading edge of the cell in the direction of the target. For example, the target that triggers amoeboid movement might be the proximity of food in the case of an amoeba or a bacterium in the case of a white blood cell (see ❙Figure 2-9c, p. 32). Pseudopods are formed as a result of the organized assembly and disassembly of branching actin networks. During amoeboid movement, actin filaments continuously grow at the cell's leading edge through the addition of actin molecules at the front of the actin chain. This filament growth pushes that portion of the cell forward as a pseudopod protrusion (❙Figure 2-25). Simultaneously, actin molecules at the rear of the filament are being disassembled and transferred to the front of the line. Thus, the filament does not get any longer; it stays the same length but moves forward through the continuous transfer of actin molecules from the rear to the front of the filament in what is termed *treadmilling* fashion. The cell attaches the advancing pseudopod to surrounding connective tissue and at the same time detaches from its older adhesion site at the rear. The cell uses the new adhesion site at the leading edge as a point of traction to pull the bulk of its body forward through cytoskeletal contraction.

White blood cells are the most active crawlers in the body. These cells leave the blood and travel by amoeboid movement to areas of infection or inflammation, where they engulf and destroy microorganisms and cellular debris. Amazingly, it is estimated that the total distance traveled collectively per day by all your white blood cells while they roam the tissues in their search-and-destroy tactic would circle Earth twice.

Fibroblasts ("fiber formers"), another type of motile cell, move amoeboid fashion into a wound from adjacent connective tissue to help repair the damage; they are responsible for scar formation. Skin cells, which are ordinarily stationary, can become moderately mobile and move by amoeboid motion toward a cut to restore the skin surface.

Microfilaments as Mechanical Stiffeners Besides their role in cellular contractile systems, actin filaments serve as mechanical supports or stiffeners for several cellular extensions, of which the most common are microvilli. **Microvilli** are microscopic, nonmotile, hairlike projections from the surface of epithelial cells lining the small intestine and kidney tubules (❙Figure 2-26). Their presence greatly increases the surface area available for transferring material across the plasma membrane. In the small intestine, the microvilli increase the area available for absorbing digested nutrients. In the kidney tubules, microvilli enlarge the absorptive surface that salvages useful sub-

stances passing through the kidney so that these materials are saved for the body instead of being eliminated in the urine. Within each microvillus, a core of parallel linked actin filaments forms a rigid mechanical stiffener that keeps these valuable surface projections intact.

Intermediate filaments are important in cell regions subject to mechanical stress.

Intermediate filaments are intermediate in size between microtubules and microfilaments (7 to 11 nm in diameter)— hence their name. The proteins that compose the intermediate filaments vary among cell types, but in general they appear as irregular, threadlike molecules. These proteins form tough, durable fibers that play a central role in maintaining the structural integrity of a cell and in resisting mechanical stresses externally applied to a cell.

Intermediate filaments are tailored to suit their structural or tension-bearing role in specific cell types. In general, only one class of intermediate filament is found in a particular cell type. Two important examples follow:

■ *Neurofilaments* are intermediate filaments found in nerve cell axons. Together with microtubules, neurofilaments strengthen and stabilize these elongated cellular extensions.

■ Skin cells contain irregular networks of intermediate filaments made of the protein **keratin** (see **Figure 2-19c**). These intracellular filaments connect with the extracellular filaments that tie adjacent cells together, creating a continuous filamentous network that extends throughout the skin and gives it strength. When surface skin cells die, their tough keratin skeletons persist, forming a protective, waterproof outer layer. Hair and nails are also keratin structures.

Intermediate filaments account for up to 85% of the total protein in nerve cells and keratin-producing skin cells, whereas these filaments constitute only about 1% of other cells' total protein on average.

Clinical Note Neurofilament abnormalities contribute to some neurological disorders. An important example is **amyotrophic lateral sclerosis (ALS)**, more familiarly known

as **Lou Gehrig's disease**. ALS is characterized by progressive degeneration and death of motor neurons, the type of nerve cells that control skeletal muscles. This adult-onset condition leads to gradual loss of control of skeletal muscles, including the muscles of breathing, and ultimately to death, as it did for baseball legend Lou Gehrig. One underlying problem may be an abnormal accumulation and disorganization of neurofilaments. Motor neurons, which have the most neurofilaments, are the most affected. The disorganized neurofilaments are believed to block the axonal transport of crucial materials along the microtubular highways, thus choking off vital supplies from the cell body to the axon terminal.

The cytoskeleton functions as an integrated whole and links other parts of the cell.

Collectively, the cytoskeletal elements and their interconnections support the plasma membrane and are responsible for the particular shape, rigidity, and spatial geometry of each different cell type. Furthermore, growing evidence suggests that the cytoskeleton serves as a lattice to organize groups of enzymes for many cellular activities. This internal framework thus acts as the cell's "skeleton."

New studies hint that the cytoskeleton as a whole is not merely a supporting structure that maintains the tensional integrity of the cell, but also may serve as a mechanical communications system. Various components of the cytoskeleton behave as if they are structurally connected or "hardwired" to each other and to the plasma membrane and the nucleus. This force-carrying network may serve as the mechanism by which mechanical forces acting on the cell surface reach all the way from the plasma membrane through the cytoskeleton to ultimately influence gene regulation in the nucleus.

Furthermore, as you have learned, the coordinated action of the cytoskeletal elements is responsible for directing intracellular transport and for regulating numerous cellular movements and thereby also serves as the cell's "muscle."

Check Your Understanding 2.10

1. List the three types of cytoskeletal elements and state one function of each.

2. Explain how motor proteins transport proteins along a cytoskeletal "highway."

3. Discuss the role of centrioles in the formation of cilia and flagella.

4. Describe how treadmilling forms pseudopods during amoeboid movement.

Homeostasis: Chapter in Perspective

The ability of cells to perform functions essential for their survival, in addition to specialized tasks that help maintain homeostasis within the body, ultimately depends on the successful, cooperative operation of

the intracellular components. For example, to support life-sustaining activities, all cells must generate energy, in a usable form, from nutrient molecules. Energy is generated intracellularly by chemical reactions in the cytosol and mitochondria.

In addition to being essential for basic cell survival, the organelles and cytoskeleton participate in many cells' specialized tasks that contribute to homeostasis. Here are several examples:

■ Both nerve and endocrine cells release protein chemical messengers (neurotransmitters in nerve cells and hormones in endocrine cells) that are important in regulatory activities aimed at maintaining homeostasis. For example, neurotransmitters stimulate the respiratory muscles, which accomplish life-sustaining exchanges of oxygen and carbon dioxide between the body and the atmosphere through breathing. These protein chemical messengers are all produced by the endoplasmic reticulum and Golgi complex and are released by exocytosis from the cell when needed.

■ The ability of muscle cells to contract depends on their highly developed cytoskeletal microfilaments sliding past one another. Muscle contraction is responsible for many homeostatic activities, including (1) contracting the heart muscle, which pumps life-supporting blood throughout the body; (2) contracting the muscles attached to bones, which enables the body to procure food; and (3) contracting the muscle in the walls of the stomach and intestine, which moves the food along the digestive tract so that ingested nutrients can be progressively broken down into a form that can be absorbed into the blood for delivery to the cells.

■ White blood cells help the body resist infection by making extensive use of lysosomal destruction of engulfed particles as they police the body for microbial invaders. These white blood cells are able to roam the body by means of amoeboid movement, a cell-crawling process accomplished by coordinated assembly and disassembly of actin, one of their cytoskeletal components.

As we begin to examine the various organs and systems, keep in mind that proper cell functioning is the foundation of all organ activities.

Review Exercises Answers begin on p. A-21

Reviewing Terms and Facts

1. The barrier that separates and controls movement between the cell contents and the extracellular fluid is the _____.

2. The chemical that directs protein synthesis and serves as a genetic blueprint is _____, which is found in the _____ of the cell.

3. The three major subdivisions of a cell are _____, _____, and _____.

4. The cytoplasm consists of _____, which are discrete, specialized, intracellular compartments; a gel-like mass known as _____; and elaborate protein scaffolding called the _____.

5. Transport vesicles from the _____ fuse with and enter the _____ for modification and sorting.

6. The *(what kind of)* _____ enzymes within the peroxisomes primarily detoxify various wastes produced within the cell or foreign compounds that have entered the cell.

7. The universal energy carrier of the body is _____.

8. The largest cells in the human body can be seen by the unaided eye. *(True or false?)*

9. Amoeboid movement is accomplished by the coordinated assembly and disassembly of microtubules. *(True or false?)*

10. Using the answer code on the right, indicate which form of energy production is being described:

1. takes place in the mitochondrial matrix	(a) glycolysis
2. produces H_2O as a by-product	(b) citric acid cycle
3. results in a rich yield of ATP	(c) oxidative phosphorylation
4. takes place in the cytosol	
5. processes acetyl-CoA	
6. takes place in the mitochondrial inner-membrane cristae	
7. converts glucose into two pyruvate molecules	
8. uses molecular oxygen	
9. accomplished by the electron transport system and ATP synthase	

11. Using the answer code on the right, indicate which type of ribosome is being described:

1. synthesizes proteins used to construct new cell membrane
2. synthesizes proteins used intracellularly within the cytosol
3. synthesizes secretory proteins such as enzymes or hormones
4. synthesizes the hydrolytic enzymes incorporated in lysosomes

(a) free ribosome
(b) rough ER-bound ribosome

Understanding Concepts

(Answers at www.cengagebrain.com)

1. State an advantage of organelle compartmentalization.

2. Distinguish between membranous organelles and non-membranous organelles. List the five types of membranous organelles and the four types of nonmembranous organelles.

3. Describe the structure of the endoplasmic reticulum, distinguishing between rough and smooth. What is the function of each?

4. Compare exocytosis and endocytosis. Define *secretion, pinocytosis, receptor-mediated endocytosis,* and *phagocytosis.*

5. Which organelles serve as the intracellular "digestive system"? What type of enzymes do they contain? What functions do these organelles serve?

6. Compare lysosomes with peroxisomes.

7. Distinguish among *cellular respiration, oxidative phosphorylation,* and *chemiosmosis.*

8. Describe the structure of mitochondria, and explain their role in cellular respiration.

9. Distinguish between the oxidative enzymes found in peroxisomes and those found in mitochondria.

10. Cells expend energy on what three categories of activities?

11. List and describe the functions of each component of the cytoskeleton.

Solving Quantitative Exercises

1. Each "turn" of the citric acid cycle
   a. generates 3 NAD^+, 1 $FADH_2$, and 2 CO_2
   b. generates 1 GTP, 2 CO_2, and 1 $FADH_2$
   c. consumes 1 pyruvate and 1 oxaloacetate
   d. consumes an amino acid

2. Let us consider how much ATP you synthesize in a day. Assume that you consume 1 mole of O_2 per hour or 24 moles per day. (A mole is the number of grams of a chemical equal to its molecular weight; see p. A-6.) About 6 moles of ATP are produced per mole of O_2 consumed. The molecular weight of ATP is 507. How many grams of ATP do you produce per day at this rate? Given that 1000 g equal 2.2 pounds, how many pounds of ATP do you produce per day at this rate? (This is under relatively inactive conditions!)

3. Under resting circumstances a person produces about 144 moles of ATP per day (73,000 g ATP/day). The amount of *free energy* represented by this amount of ATP can be calculated as follows: Cleavage of the terminal phosphate bond from ATP results in a decrease in free energy of approximately 7300 cal/mole. This is a crude measure of the energy available to do work that is contained in the terminal phosphate bond of the ATP molecule. How many calories, in the form of ATP, are produced per day by a resting individual, crudely speaking?

4. Calculate the number of cells in the body of an average 68-kg (150-lb) adult. (This will only be accurate to about 1 part in 10 but should give you an idea how scientists estimate this commonly quoted number.) Assume all cells are spheres 20 μm in diameter. The volume of a sphere can be determined by the equation $v = 4/3\ \pi r^3$. (*Hint:* We know that about two thirds of the water in the body is intracellular and the density of cells is nearly 1 g/mL. The proportion of the mass made up of water is about 60%.)

5. If sucrose is injected into the bloodstream, it tends to stay out of the cells (cells do not use sucrose directly). If it does not go into cells, where does it go? In other words, how much "space" is in the body that is not inside some cell? Sucrose can be used to determine this space. Suppose 150 mg of sucrose is injected into a 55-kg (121-lb) woman. If the concentration of sucrose in her blood is 0.015 mg/mL, what is the volume of her extracellular space, assuming that no metabolism is occurring and that the blood sucrose concentration is equal to the sucrose concentration throughout the extracellular space?

Applying Clinical Reasoning

Kevin S. and his wife have been trying to have a baby for the past 3 years. On seeking the help of a fertility specialist, Kevin learned that he has a hereditary form of male sterility involving nonmotile sperm. His condition can be traced to defects in the cytoskeletal components of the sperm's flagella. As a result of this finding, the physician suspected that Kevin also has a long history of recurrent respiratory tract disease. Kevin confirmed that indeed he has had colds, bronchitis, and influenza more frequently than his friends. Why would the physician suspect that Kevin probably had a history of frequent respiratory disease based on his diagnosis of sterility from nonmotile sperm?

Thinking at a Higher Level

1. The stomach has two types of exocrine secretory cells: *chief cells,* which secrete an inactive form of the protein-digesting enzyme *pepsinogen,* and *parietal cells,* which secrete *hydrochloric acid (HCl)* that activates pepsinogen. Both cell types have an abundance of mitochondria for ATP production—the chief cells need energy to synthesize pepsinogen, and the parietal cells need energy to transport hydrogen ions (H^+) and chloride ions (Cl^-) from the blood into the stomach lumen. Only one of these cell types also has an extensive rough ER and abundant Golgi stacks. Would this type be the chief cells or the parietal cells? Why?

2. The poison *cyanide* acts by binding irreversibly to one component of the electron transport system, blocking its action. As a result, the entire electron-transport process comes to a screeching halt, and the cells lose more than 94% of their ATP-producing capacity. Considering the types of cell activities that depend on energy expenditure, what would be the consequences of cyanide poisoning?

3. Hydrogen peroxide, which belongs to a class of very unstable compounds known as *free radicals,* can bring about drastic, detrimental changes in a cell's structure and function by reacting with almost any molecule with which it comes in contact, including DNA. The resultant cellular changes can lead to genetic mutations, cancer, or other serious consequences. Furthermore, some researchers speculate that cumulative effects of more subtle cellular damage resulting from free radical reactions over a period of time might contribute to the gradual deterioration associated with aging. Related to this speculation, studies have shown that longevity decreases in fruit flies in direct proportion to a decrease in a specific chemical found in one of the cellular organelles. Based on your knowledge of how the body rids itself of dangerous hydrogen peroxide, what do you think this chemical in the organelle is?

4. Why do you think a person is able to perform anaerobic exercise (such as lifting and holding a heavy weight) only briefly but can sustain aerobic exercise (such as walking or swimming) for long periods? (*Hint:* Muscles have limited energy stores.)

5. One type of the affliction *epidermolysis bullosa* is caused by a genetic defect that results in production of abnormally weak keratin. Based on your knowledge of the role of keratin, what part of the body do you think would be affected by this condition?

The Plasma Membrane and Membrane Potential
3

Peter Arnold, Inc./Alamy

A computer model of the plasma membrane. All cells are enclosed by a plasma membrane consisting of a lipid bilayer (*green*) with proteins (*blue*) embedded or attached and carbohydrates (*red*) protruding from the outer surface.

Homeostasis Highlights

All cells are enveloped by a **plasma membrane**, a thin, flexible, lipid barrier that separates the contents of the cell from its surroundings. To carry on life-sustaining and specialized activities, each cell must exchange materials across this membrane with the homeostatically maintained internal fluid environment that surrounds the cell. This discriminating barrier contains specific proteins, some of which enable selective passage of materials. Other membrane proteins are receptors for interaction with specific chemical messengers in the cell's environment. These messengers control many cell activities crucial to homeostasis.

Cells have a **membrane potential**, a slight excess of negative charges lined up along the inside of the membrane and a slight excess of positive charges on the outside. The specialization of nerve and muscle cells depends on the ability of these cells to alter their potential on appropriate stimulation. Much of nerve and muscle function is geared toward maintaining homeostasis.

3.1 Membrane Structure and Functions

To survive, every cell must maintain a specific composition of its contents unique for that cell type despite the remarkably different composition of the extracellular fluid (ECF) surrounding it. This difference in fluid composition inside and outside a cell is maintained by the **plasma membrane**, the extremely thin layer that forms the outer boundary of every cell and encloses the intracellular contents. Besides acting as a mechanical barrier that traps needed molecules within the cell, the plasma membrane helps determine the cell's composition by selectively permitting specific substances to pass between the cell and its environment. The plasma membrane controls the entry of nutrient molecules and the exit of secretory and waste products. In addition, it maintains differences in ion concentrations inside and outside the cell, which are important in the membrane's electrical activity. The plasma membrane also participates in the joining of cells to form tissues and organs. Finally, it plays a key role in enabling a cell to respond to signals from chemical messengers in the cell's environment; this ability is important in communication among cells. No matter what the cell type, these common membrane functions are crucial to the cell's survival, to its ability to perform specialized homeostatic activities, and to its ability to coordinate its functions with those of other cells. Many of the functional differences among cell types are a result of subtle variations in the composition of their plasma membranes, which in turn enable different cells to interact in different ways with essentially the same ECF environment.

The plasma membrane is a fluid lipid bilayer embedded with proteins.

The plasma membrane consists mostly of lipids and proteins plus small amounts of carbohydrate. It is too thin to be seen under an ordinary light microscope, but with an electron microscope it appears as a trilaminar structure consisting of two dark layers separated by a light middle layer (*tri* means "three"; *lamina* means "layer") (❙Figure 3-1). The specific arrangement of the molecules that make up the plasma membrane is responsible for this "sandwich" appearance.
❙**Figure 3-1 Trilaminar appearance of a plasma membrane in an electron micrograph.** Depicted are the plasma membranes of two adjacent cells. Note that each membrane appears as two dark, thin layers separated by a light middle layer.

The most abundant membrane lipids are phospholipids, with lesser amounts of cholesterol. An estimated 1 billion phospholipid molecules are present in the plasma membrane of a typical human cell. **Phospholipids** have a polar (electrically charged; see p. A-4) head containing a negatively charged phosphate group and two nonpolar (electrically neutral) fatty acid chain tails (❙Figure 3-2a). The polar end is hydrophilic (meaning "water loving") because it can interact with water molecules, which are also polar; the nonpolar end is hydrophobic (meaning "water fearing") and will not mix with water. In water, phospholipids self-assemble into a **lipid bilayer**, a double layer of lipid molecules (❙Figure 3-2b) (*bi* means "two"). The hydrophobic tails bury themselves in the center of the bilayer away from the water, and the hydrophilic heads line up on both sides in contact with the water. The outer surface of the bilayer is exposed to ECF, whereas the inner surface is in contact with the intracellular fluid (ICF) (❙Figure 3-2c).

The lipid bilayer is fluid, not rigid, with a consistency more like cooking oil than stick butter. The phospholipids, which are not held together by strong chemical bonds, are constantly moving. They can twirl, vibrate, and move around within their half of the bilayer, exchanging places millions of times a second. This phospholipid movement largely accounts for membrane fluidity.

Cholesterol contributes to both the fluidity and the stability of the membrane. Cholesterol molecules are tucked between the phospholipid molecules, where they prevent the fatty acid chains from packing together and crystallizing, a process that would drastically reduce membrane fluidity. Through their spatial relationship with phospholipid molecules, cholesterol molecules also help stabilize the phospholipids' position. Because of its fluidity, the plasma membrane has structural integrity but at the same time is flexible, enabling the cell to change shape. For example, muscle cells change shape as they contract.

Membrane proteins are inserted within or attached to the lipid bilayer (❙Figure 3-3 and chapter opener photo). **Integral proteins** are embedded in the lipid bilayer, with most extending through the entire thickness of the membrane, in which case they are alternatively called **transmembrane proteins** (*trans* means "across"). Like phospholipids, integral proteins have hydrophilic and hydrophobic regions. **Peripheral proteins** are polar molecules that do not penetrate the membrane. They only stud the membrane surface, anchored by weak chemical bonds with the polar parts of integral membrane proteins or membrane lipids. Peripheral proteins are found more commonly on the inner than on the outer surface. The plasma membrane has about 50 times more lipid molecules than protein molecules. However, proteins account for nearly half of the membrane's mass because they are much larger than lipids. The fluidity of the lipid bilayer enables many membrane proteins to float freely like "icebergs" in a moving "sea" of lipids. This view of membrane structure is known as the **fluid mosaic model**, in reference to the membrane fluidity and the ever-changing mosaic pattern of the proteins embedded in the lipid bilayer. (A mosaic is a surface decoration made by inlaying small pieces of variously colored tiles to form patterns or pictures.)

Despite the plasma membrane's generally fluid nature and randomly arranged proteins, researchers recently identified

specialized membrane patches known as **lipid rafts** made up mostly of sphingolipids (instead of phospholipids), extra cholesterol, and an abundance of particular proteins. Lipid rafts are more highly organized, more tightly packed, and a little thicker than the remainder of the plasma membrane. The rafts are

thicker because the fatty acid tails of sphingolipids are longer than those of phospholipids. The proteins are anchored in place by the sphingolipids or cytoskeletal elements in the cytoplasm.

The proteins gathered in the lipid rafts are *receptors* specialized to interact with specific *extracellular chemical messengers,* or *signal molecules,* in the cell's environment that dictate specific intracellular responses. An example of an extracellular signal is a hormone directing secretion of digestive enzymes by exocrine gland cells of the pancreas in response to food in the small intestine. Lipid rafts exist either as flat platforms on the smooth parts of the plasma membrane or in tiny (50 to 100 nm in diameter) cavelike indentations in the membrane surface aptly called **caveolae** ("tiny caves").

A small amount of **membrane carbohydrate** is located on the outer surface of cells, "sugar coating" them. Short carbohydrate chains protrude like tiny antennas from the outer surface, bound primarily to membrane proteins and, to a lesser extent, to lipids. These sugary combinations are known as *glycoproteins* and *glycolipids,* respectively (❙Figure 3-3 and chapter opener photo), and the coating they form is called the *glycocalyx* (*glyco* means "sweet"; *calyx* means "husk").

This proposed structure accounts for the trilaminar appearance of the plasma membrane. When stains are used to help visualize the plasma membrane under an electron microscope (as in ❙Figure 3-1), the two dark lines represent the hydrophilic polar regions of the lipid and protein molecules that have taken up the stain. The light space between corresponds to the poorly stained hydrophobic core formed by the nonpolar regions of these molecules.

The different components of the plasma membrane carry out a variety of functions. The lipid bilayer forms the primary barrier to diffusion, the proteins perform most of the specific membrane functions, and the carbohydrates play an important role in "self-recognition" processes and cell-to-cell interactions. We now examine these functions in more detail.

The lipid bilayer forms the basic structural barrier that encloses the cell.

The lipid bilayer serves the following functions related to its role as a barrier between a cell's contents and its surroundings:

1. It forms the basic structure of the membrane. The phospholipids can be visualized as the "pickets" that form the "fence" around the cell.

2. Its hydrophobic interior is a barrier to passage of water-soluble substances between the ICF and ECF. Water-soluble substances cannot dissolve in and pass through the lipid bilayer. By means of this barrier, the cell can maintain different mixtures and concentrations of solutes (dissolved substances) inside and outside the cell.

3. It is responsible for the fluidity of the membrane.

In addition to these barrier roles, the lipid bilayer is also a source of lipid signal molecules (although most signal molecules in the body are secreted proteins). In response to specific controlling mechanisms, a portion of specific fatty acid tails of the phospholipid molecules can be cleaved off and used for either intracellular or extracellular communication. An exam-

ple is the prostaglandin released in response to an infection that turns up the temperature-controlling thermostat in the brain to bring about a fever.

The membrane proteins perform various specific membrane functions.

Different types of membrane proteins serve the following specialized functions:

1. Some transmembrane proteins form water-filled pathways, or **channels**, through the lipid bilayer (I Figure 3-3). Water-soluble substances small enough to enter a channel can pass through the membrane by this means without coming into direct contact with the hydrophobic lipid interior. Channels are highly selective. The small diameter of channels prevents particles larger than 0.8 nm (40 billionths of an inch) in diameter from entering. Only small ions can fit through channels. Furthermore, a given channel selectively admits particular ions. For example, only sodium ions (Na^+) can pass through Na^+ channels, and only potassium ions (K^+) can pass through K^+ channels. This channel selectivity is a result of specific arrangements of chemical groups on the interior surfaces of the channels. Some channels are **leak channels** that always permit passage of their selected ion. Others are **gated channels** that may be open or closed to their specific ion as a result of changes in channel shape in response to controlling mecha-

nisms, described later. This is a good example of function depending on structural details. Cells vary in the number, kind, and activity of channels they possess.

Clinical Note Some drugs target channels—for example, Ca^{2+} *channel blockers* that are widely used in the management of high blood pressure and abnormal heart rhythms. More than 60 genetic mutations in channels have been linked to human diseases. To learn how a specific channel defect can lead to a devastating disease, see the accompanying boxed feature, I Concepts, Challenges, and Controversies.

2. Other proteins that span the membrane are **carrier**, or **transport, molecules**; they transfer across the membrane specific substances that are unable to cross on their own. The means by which carriers accomplish this transport is described later. Each carrier can transport only a particular molecule (or ion) or group of closely related molecules. Cells of different types have different kinds of carriers. As a result, they vary as to which substances they can selectively transport across their membranes. For example, thyroid gland cells are the only cells to use iodine. Appropriately, only the plasma membranes of thyroid gland cells have carriers for iodine, so only these cells can transport iodine from the blood into the cell interior.

3. Other proteins, located on the inner membrane surface, serve as **docking-marker acceptors**; they bind lock-and-key fashion with the docking markers of secretory vesicles (see p. 29). Secretion is initiated as stimulatory signals trigger fusion

Cystic Fibrosis: A Fatal Defect in Membrane Transport

CYSTIC FIBROSIS (CF), THE MOST common fatal genetic disease in the United States, strikes 1 in every 2000 Caucasian children. It is characterized by the production of abnormally thick, sticky mucus. Most dramatically affected are the respiratory airways and the pancreas.

Respiratory Problems

The presence of thick, sticky mucus in the respiratory airways makes it difficult to get adequate air in and out of the lungs. Also, because bacteria thrive in the accumulated mucus, patients with CF experience repeated respiratory infections. They are especially susceptible to *Pseudomonas aeruginosa,* an "opportunistic" bacterium that is often present in the environment but usually causes infection only when some underlying problem handicaps the body's defenses. Gradually, the involved lung tissue becomes scarred (fibrotic), making the lungs harder to inflate. This complication increases the work of breathing beyond the extra effort required to move air through the clogged airways.

Pancreatic Problems

In patients with CF, the pancreatic duct, which carries secretions from the pancreas to the small intestine, becomes plugged with thick mucus. Because the pancreas produces enzymes important in the digestion of food, malnourishment eventually results. In addition, as the pancreatic digestive secretions accumulate behind the blocked duct, fluid-filled cysts form in the pancreas, with the affected pancreatic tissue gradually degenerating and becoming fibrotic.

The name *cystic fibrosis* aptly describes long-term changes that occur in the pancreas and lungs as the result of a single genetic flaw in chloride (Cl^-) channels.

Underlying Cause

CF is caused by one of a number of genetic defects that lead to production of a flawed version of a protein known as *cystic fibrosis transmembrane conductance regulator (CFTR)*. CFTR normally forms the Cl^- channels in the plasma membrane. With CF, the defective CFTR gets "stuck" in the endoplasmic reticulum–Golgi system, which normally manufactures and processes this product and then ships it to the plasma membrane (see pp. 25–30). Thus, in patients with CF, the mutated version of CFTR is only partially processed and never makes it to the cell surface. The resultant absence of CFTR protein in the plasma membrane makes the membrane impermeable to Cl^-.

What are the consequences of this impermeability? Looking at the development of the respiratory problems as an example, because Cl^- transport across the membrane is closely linked to Na^+ transport, cells lining the respiratory airways cannot absorb NaCl (salt) properly. As a result, salt accumulates in the fluid lining the airways.

How does this Cl^- channel defect and resultant salt accumulation lead to the excess mucus problem? The following discoveries provide a plausible answer, although research into other possible mechanisms continues to be pursued. The airway cells produce a natural antibiotic, *defensin,* which normally kills most inhaled airborne bacteria. Defensin cannot function properly in a salty environment. Bathed in the excess salt associated with CF, the disabled antibiotic cannot rid the lungs of inhaled bacteria. In addition, the opportunistic *P. aeruginosa* bacteria disable the white blood cells in the lung that normally fight infectious agents. Besides causing infection, *P. aeruginosa* triggers the airway cells to produce unusually large amounts of abnormal, thick, sticky mucus, which serves as a breeding ground for even more bacterial growth. Furthermore, the mucus is thick and sticky in part because it is underhydrated (has too little water), a problem linked to the defective salt transport. To make matters worse, because the excess mucus is thick and sticky, the normal ciliary defense mechanisms of the lungs have a difficult time sweeping up the bacteria-laden mucus (see pp. 48 and 441). As a result, repeated respiratory infections occur. The vicious cycle continues as the lung-clogging mucus accumulates and lung infections become more frequent.

Treatment and New Research Directions

Treatment consists of physical therapy and mucus-thinning aerosols to help clear the airways of excess mucus and antibiotic therapy to combat respiratory infections, plus special diets and administration of pancreatic digestive enzymes to maintain adequate nutrition. Despite this supportive treatment, most people with CF do not survive beyond their late 30s, with most dying from lung complications.

Researchers are investigating gene therapy approaches to cure CF. Another treatment underway is development of drugs that induce the mutated CFTR to be "finished off" and inserted in the plasma membrane.

---

of the secretory vesicle membrane with the inner surface of the plasma membrane through interactions between these matching labels. The secretory vesicle subsequently opens up and empties its contents to the outside by exocytosis (see p. 30).

4. Some proteins located on either the inner or the outer cell surface function as **membrane-bound enzymes** that control specific chemical reactions. Cells are specialized in the types of membrane-bound enzymes they have. For example, a specialized area of the outer plasma membrane surface of skeletal muscle cells contains an enzyme that destroys the chemical messenger responsible for triggering muscle contraction, thus allowing the muscle to relax.

5. Many proteins on the outer surface are **receptors**, sites that "recognize" and bind with specific extracellular chemical messengers (signal molecules) in the cell's environment. This binding initiates a series of membrane and intracellular events (to

be described later) that alter the activity of the particular cell. In this way, chemical messengers in the blood, such as water-soluble hormones, influence only the specific cells that have receptors for a given messenger. Even though every cell is exposed to the same messenger via the circulating blood, a given messenger has no effect on cells lacking receptors for this specific messenger. To illustrate, the anterior pituitary gland secretes into the blood thyroid-stimulating hormone (TSH), which attaches only to the surface of thyroid gland cells to stimulate secretion of thyroid hormone. No other cells have receptors for TSH, so TSH influences only thyroid cells despite its widespread distribution.

6. Still other proteins are **cell adhesion molecules (CAMs)**. Many CAMs protrude from the outer membrane surface and form loops or hooks by which cells grip one another or grasp the connective tissue fibers between cells. For example, *cadherins,* a type of CAM found on the surface of adjacent cells, interlock in zipper fashion to help hold the cells within tissues and organs together. Other CAMs, such as *integrins*, span the plasma membrane, where they serve as a structural link between the outer membrane surface and its extracellular surroundings and connect the inner membrane surface to the intracellular cytoskeletal scaffolding. Besides mechanically linking the cell's external environment and intracellular components, integrins also relay regulatory signals through the plasma membrane in either direction. Some CAMs participate in signaling cells to grow or in signaling immune system cells to interact with the right kind of other cells in inflammatory responses and wound healing, among other things.

7. Still other proteins on the outer membrane surface, especially in conjunction with carbohydrates (as glycoproteins), are important in the cells' ability to recognize "self" (that is, cells of the same type).

The membrane carbohydrates serve as self-identity markers.

The short carbohydrate chains on the outer membrane surface serve as self-identity markers that enable cells to identify and interact with one another in the following ways:

1. Different cell types have different markers. The unique combination of sugar chains projecting from the membrane surface serves as the "trademark" of a particular cell type, enabling a cell to recognize others of its kind. To exemplify, differences in specific membrane carbohydrates are responsible for the variations in human blood group types (A, B, AB, and O). Membrane carbohydrate chains play an important role in recognition of "self" and in cell-to-cell interactions. Cells can recognize other cells of the same type and join to form tissues. This is especially important during embryonic development.

2. Carbohydrate-containing surface markers are also involved in tissue growth, which is normally held within certain limits of cell density. Cells do not "trespass" across the boundaries of neighboring tissues—that is, they do not overgrow their own territory. The exception is the uncontrolled spread of cancer cells, which have been shown to bear abnormal surface carbohydrate markers.

3.2 Cell-to-Cell Adhesions

In multicellular organisms such as humans, the plasma membrane not only is the outer boundary of all cells, but it also participates in cell-to-cell adhesions. These adhesions bind groups of cells together into tissues and package them further into organs. The life-sustaining activities of the body systems depend not only on the functions of the individual cells of which they are made but also on how these cells live and work together in tissue and organ communities.

Cells organized into appropriate groupings are held together by three different means: (1) CAMs, (2) the extracellular matrix, and (3) specialized cell junctions. You are already familiar with CAMs. We now examine the extracellular matrix and then specialized junctions.

The extracellular matrix serves as biological "glue."

Tissues are not made up solely of cells, and many cells within a tissue are not in direct contact with neighboring cells. Instead, they are held together by a biological "glue" called the **extracellular matrix (ECM)**. The ECM is an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates. The watery gel, usually called the interstitial fluid (see p. 8), provides a pathway for diffusion of nutrients, wastes, and other water-soluble traffic between the blood and tissue cells. The three major types of protein fibers woven through the gel are collagen, elastin, and fibronectin.

1. **Collagen** forms flexible but nonelastic fibers or sheets that provide tensile strength (resistance to being stretched lengthwise). Collagen is the most abundant protein in the body, making up nearly half of total body protein by weight.

Clinical Note In **scurvy**, a condition caused by vitamin C deficiency, collagen fibers are not properly formed. As a result, the tissues, especially those of the skin and blood vessels, become fragile. This leads to bleeding in the skin and mucous membranes, which is especially noticeable in the gums.

2. **Elastin** is a rubbery protein fiber most plentiful in tissues that must easily stretch and then recoil after the stretching force is removed. It is found, for example, in the lungs, which stretch and recoil as air moves in and out of them.

3. **Fibronectin** promotes cell adhesion and holds cells in position. Reduced amounts of this protein have been found within certain types of cancerous tissue, possibly accounting for cancer cells' inability to adhere well to one another; in-

stead, they tend to break loose and metastasize (spread elsewhere in the body).

The ECM is secreted by local cells present in the matrix. The relative amount of ECM compared to cells varies greatly among tissues. For example, the ECM is scant in epithelial tissue but is the predominant component of connective tissue. Most of this abundant matrix in connective tissue is secreted by **fibroblasts** ("fiber formers"). The exact composition of the ECM also varies for different tissues, thus providing distinct local environments for the various cell types in the body. In some tissues, the matrix becomes highly specialized to form such structures as cartilage or tendons or, on appropriate calcification, the hardened structures of bones and teeth.

Contrary to long-held belief, the ECM is not just passive scaffolding for cellular attachment; it also helps regulate the behavior and functions of the cells with which it interacts. Cells are able to function normally and indeed even to survive only when associated with their normal matrix components. The matrix is especially influential in cell growth and differentiation. In the body, only circulating blood cells are designed to survive and function without attaching to the ECM.

Some cells are directly linked by specialized cell junctions.

In tissues where the cells lie close to one another, CAMs provide some tissue cohesion as they "Velcro" adjacent cells together. In addition, some cells within given types of tissues are directly linked by one of three types of specialized cell junctions: (1) *desmosomes* (adhering junctions), (2) *tight junctions* (impermeable junctions), or (3) *gap junctions* (communicating junctions).

Desmosomes **Desmosomes** act like "spot rivets" that anchor together two adjacent but nontouching cells. A desmosome consists of two components: (1) a pair of dense, buttonlike cytoplasmic thickenings known as *plaques* located on the inner surface of each of the two adjacent cells, and (2) strong filaments containing cadherins (a type of CAM) that extend across the space between the two cells and attach to the plaque on both sides (❙ Figure 3-4). These intercellular filaments bind adjacent plasma membranes together so that they resist being pulled apart. Thus, desmosomes are adhering junctions. They are the strongest cell-to-cell connections.

Desmosomes are most abundant in tissues that are subject to considerable stretching, such as those found in the skin, the heart, and the uterus. In these tissues, functional groups of cells are riveted together by desmosomes. Furthermore, intermediate cytoskeletal filaments, such as tough keratin filaments in the skin (see p. 51), stretch across the interior of these cells and attach to the desmosome plaques located on opposite sides of the cells' interior. This arrangement forms a continuous network of strong fibers throughout the tissue, both through and between cells, much like a continuous line of people firmly holding hands. This interlinking fibrous network provides tensile strength, reducing the chances of the tissue being torn when stretched.

Tight Junctions At **tight junctions**, adjacent cells bind firmly with each other at points of direct contact to seal off the pas-
❙Figure 3-4 **Desmosome.** Desmosomes are adhering junctions that spot-rivet cells, anchoring them together in tissues subject to considerable stretching.

sageway between the two cells. Tight junctions are found primarily in sheets of epithelial tissue, which cover the surface of the body and line its internal cavities. All epithelial sheets are highly selective barriers between two compartments with considerably different chemical compositions. For example, the epithelial sheet lining the digestive tract separates the food and potent digestive juices within the inner cavity (lumen) from the blood vessels on the other side. Only completely digested food particles and not undigested food particles or digestive juices must be permitted to move across the epithelial sheet from the lumen to the blood. Accordingly, the lateral (side) edges of adjacent cells in the epithelial sheet are joined in a tight seal near their luminal border by "kiss" sites, at which strands of proteins known as *claudins* on the outer surfaces of the two interacting plasma membranes fuse directly (❙ Figure 3-5) (*claudin* means "to close," indicative of the barrier role of these proteins). These tight junctions are impermeable and thus prevent materials from passing between the cells. Passage across the epithelial barrier, therefore, must take place *through* the cells, not *between* them. This **transcellular transport** across the cell (*trans* means "across") is regulated by channel and carrier proteins. If the cells were not joined by tight junctions, uncontrolled exchange of molecules could take place between the compartments by means of unpoliced traffic through the spaces between adjacent cells. Tight junctions thus prevent undesirable leaks within epithelial sheets.

Despite their generally tight nature, some tight junctions are a bit "leaky," enabling water molecules and some small ions to

Figure 3-6 Gap junction. Gap junctions are communicating junctions made up of connexons, which form tunnels that permit movement of charge-carrying ions and small molecules between two adjacent cells.
Figure 3-5 Tight junction. Tight junctions are impermeable junctions that join the lateral edges of epithelial cells near their luminal borders, thus preventing movement of materials between the cells. Only regulated passage of materials can occur through these cells, which form highly selective barriers that separate two compartments of highly different chemical composition.

FIGURE FOCUS: *Different types of specialized membrane proteins such as channels, carriers, or enzymes are localized at the luminal membrane or at the basolateral membrane. What keeps these proteins from migrating to the wrong part of the membrane?*

pass between the cells—for example, in the small intestine during absorption of a meal. This between-cell transport is called **paracellular transport** (*para* means "beside" in reference to this transport occurring beside the adjacent cells).

Gap Junctions At a **gap junction**, as the name implies, a gap exists between adjacent cells, which are linked by small, connecting tunnels formed by connexons. A **connexon** is made up of six protein subunits (called *connexins)* arranged in a hollow, tubelike structure that extends through the thickness of the plasma membrane. Two connexons, one from each of the plasma membranes of two adjacent cells, extend outward and join end-to-end to form a connecting tunnel between the two cells (**Figure 3-6). Gap junctions are communicating junctions. The small diameter of the tunnels permits small, water-soluble particles to pass between the connected cells but precludes passage of large molecules, such as vital intracellular proteins. Ions and small molecules can be directly exchanged between interacting cells through gap junctions without ever entering the ECF.

Gap junctions are especially abundant in cardiac muscle and smooth muscle. In these tissues, movement of ions (charge-carrying particles) through gap junctions transmits electrical

activity throughout an entire muscle mass. Because this electrical activity brings about contraction, the presence of gap junctions enables synchronized contraction of a whole muscle mass, such as the pumping chamber of the heart.

Gap junctions are also found in some nonmuscle tissues, where they permit unrestricted passage of small nutrient molecules between cells. For example, glucose, amino acids, and other nutrients pass through gap junctions to a developing egg cell from surrounding cells within the ovary, thus helping the egg stockpile these essential nutrients.

Gap junctions also are avenues for the direct transfer of small signal molecules from one cell to the next. Such transfer permits cells connected by gap junctions to communicate with each other directly.

We now turn to the topic of membrane transport, focusing on how the plasma membrane selectively controls what enters and exits the cell.

Check Your Understanding 3.2

1. Describe the extracellular matrix.
2. List the three types of specialized cell junctions and indicate their primary role.
3. Draw a desmosome.

3.3 Overview of Membrane Transport

Anything that passes between a cell and the surrounding ECF must be able to penetrate the plasma membrane. If a substance can cross the membrane, the membrane is **permeable** to that substance; if a substance cannot pass, the membrane is **impermeable** to it. The plasma membrane is **selectively permeable**: It permits some particles to pass through while excluding others.

Lipid-soluble substances and small water-soluble substances can permeate the plasma membrane unassisted.

Two properties of particles influence whether they can permeate the plasma membrane without assistance: (1) the relative solubility of the particle in lipid and (2) the size of the particle. Highly lipid-soluble particles of any size can dissolve in the lipid bilayer and pass through the membrane. Uncharged or nonpolar molecules, such as oxygen (O_2), carbon dioxide (CO_2), and fatty acids, are highly lipid soluble and readily permeate the membrane. Charged particles (ions such as Na^+ and K^+) and polar molecules (such as glucose and proteins) have low lipid solubility but are very soluble in water. The lipid bilayer is an impermeable barrier to particles poorly soluble in lipid. For water-soluble (and thus lipid-insoluble) ions less than 0.8 nm in diameter, the protein channels are an alternative route for passage across the membrane. Only ions for which specific channels are available and open can permeate the membrane.

Particles that have low lipid solubility and are too large for channels cannot permeate the membrane on their own. Yet some of these particles—for example, glucose—must cross the membrane for the cell to survive and function. (Most cells use glucose as their fuel of choice to produce adenosine triphosphate, or ATP.) Cells have several means of assisted transport to move particles that must cross the membrane but cannot do so unaided, as you will learn shortly.

Active forces use energy to move particles across the membrane, but passive forces do not.

Even if a particle can permeate the membrane because of its lipid solubility or its ability to fit through a channel, some force is needed to move it across the membrane. Two general types of forces accomplish transport of substances across the membrane: (1) **passive forces**, which do not require the cell to expend energy to produce movement, and (2) **active forces**, which do require the cell to expend energy (ATP) in transporting a substance across the membrane.

We now examine the methods of membrane transport, noting whether each is an unassisted or assisted means of transport and whether each is a passive- or active-transport mechanism.

Check Your Understanding 3.3

1. Explain how both highly lipid-soluble substances of any size and small water-soluble substances are able to permeate the plasma membrane without assistance.
2. Distinguish between passive and active forces that produce movement of substances across the plasma membrane.

3.4 Unassisted Membrane Transport

Particles that can penetrate the plasma membrane on their own are passively driven across the membrane by one or both of two forces: diffusion down a concentration gradient or movement along an electrical gradient. We first examine diffusion down a concentration gradient.

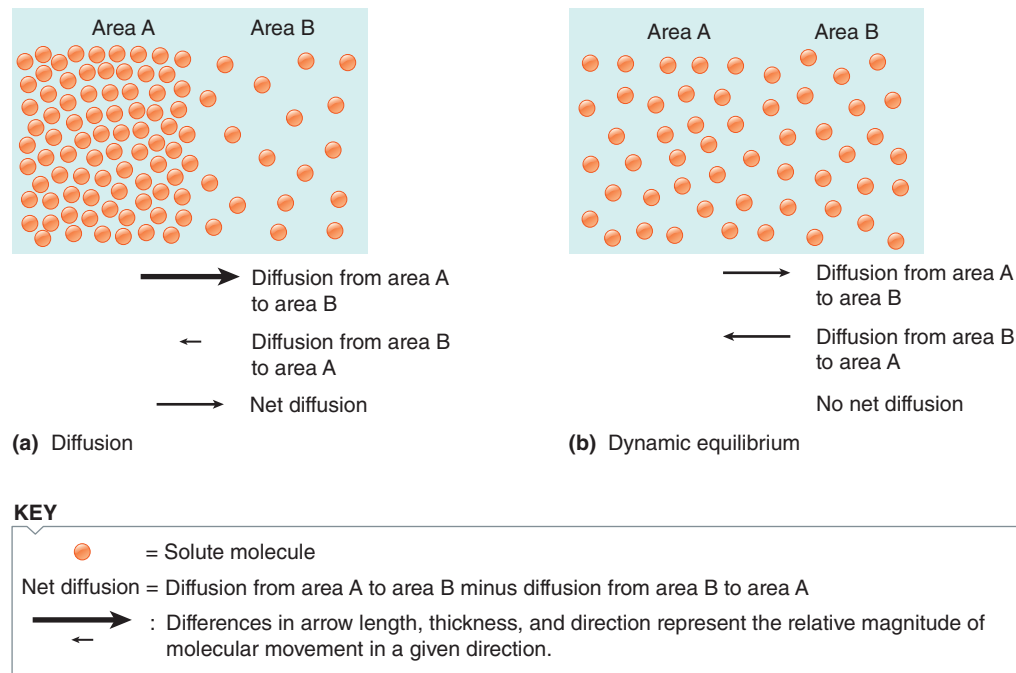
Particles that can permeate the membrane diffuse passively down their concentration gradient.

All molecules and ions are in continuous random motion at temperatures above absolute zero as a result of thermal (heat) energy. This motion is most evident in liquids and gases, where the individual molecules (or ions) have more room to move before colliding with another molecule. Each molecule moves separately and randomly in any direction. As a consequence of this haphazard movement, the molecules often collide, bouncing off one another in different directions like billiard balls striking.

KEY

- = Solute molecule

Net diffusion = Diffusion from area A to area B minus diffusion from area B to area A

: Differences in arrow length, thickness, and direction represent the relative magnitude of molecular movement in a given direction.


❙Figure 3-7 **Diffusion.** (a) Diffusion down a concentration gradient. (b) Dynamic equilibrium, with no net diffusion occurring.

Simple Diffusion **Solutions** are homogeneous mixtures containing a relatively large amount of one substance called the **solvent** (the dissolving medium, which in the body is water) and smaller amounts of one or more dissolved substances called **solutes**. The **concentration** of a solution refers to the amount of solute dissolved in a specific amount of solution. The greater the concentration of solute molecules (or ions), the greater the likelihood is of collisions. Consequently, molecules within a particular space tend to become evenly distributed over time. Such uniform spreading out of molecules as a result of their random intermingling is known as **simple diffusion**, or **diffusion** for short (*diffusere* means "to spread out").

To illustrate simple diffusion, in Figure 3-7a, the concentration of the solute in a solution differs between area A and area B. Such a difference in concentration between two adjacent areas is called a **concentration gradient** (or **chemical gradient**). Random molecular collisions occur more frequently in area A because of its greater concentration of solute molecules. For this reason, more molecules bounce from area A into area B than in the opposite direction. In both areas, individual molecules move randomly and in all directions, but the net movement of molecules by diffusion is from the area of higher concentration to the area of lower concentration.

Net Diffusion The term **net diffusion** refers to the difference between two opposing movements. If 10 molecules move from area A to area B while 2 molecules simultaneously move from B to A, the net diffusion is 8 molecules moving from A to B. Molecules spread in this way until the substance is uniformly distributed between the two areas and a concentration gradient no longer exists (❙Figure 3-7b). At this point, even though movement is still taking place, no net diffusion is occurring because the opposing movements exactly counterbalance each other—

that is, they are in **dynamic equilibrium** (*dynamic* in reference to the continuous movement, *equilibrium* in reference to the exact balance between opposing forces). Movement of molecules from area A to area B is exactly matched by movement of molecules from B to A.

What happens if a plasma membrane separates different concentrations of a substance? If the substance can permeate the membrane, net diffusion of the substance occurs through the membrane down its concentration gradient from the area of high concentration to the area of low concentration until the concentration gradient is abolished, unless there's some opposing force (❙Figure 3-8a). No energy is required for this movement, so it is a passive means of membrane transport. The process of diffusion is crucial to the survival of every cell and plays an important role in many specialized homeostatic activities. As an example, O_2 is transferred across the lung membrane by diffusion. The blood carried to the lungs is low in O_2, having given up O_2 to the body tissues for cell metabolism. The air in the lungs, in contrast, is high in O_2 because it is continuously exchanged with fresh air during breathing. Because of this concentration gradient, net diffusion of O_2 occurs from the lungs into the blood as blood flows through the lungs. Thus, as blood leaves the lungs for delivery to the tissues, it is high in O_2.

If the membrane is impermeable to the substance, no diffusion can take place across the membrane, even though a concentration gradient may exist (❙Figure 3-8b). For example, because the plasma membrane is impermeable to the vital intracellular proteins, they are unable to escape from the cell, even though they are in greater concentration in the ICF than in the ECF.

Fick's Law of Diffusion Several factors, in addition to the concentration gradient, influence the rate of net diffusion

across a membrane. The effects of these factors collectively make up **Fick's law of diffusion** (▎Table 3-1):

1. *The magnitude (or steepness) of the concentration gradient.* If a substance can permeate the membrane, its rate of simple diffusion is always directly proportional to its concentration gradient—that is, the greater the difference in concentration, the faster the rate of net diffusion (see ▎Figure 3-15, p. 71). For example, during exercise the working muscles produce CO_2 more rapidly than usual because they are burning additional fuel to produce the extra ATP they need to power the stepped-up, energy-demanding contractile activity. The increase in CO_2 level in the muscles creates a greater-than-normal difference in CO_2 between the muscles and the blood supplying the muscles. Because of this steeper gradient, more CO_2 than usual enters the blood. When this blood with its increased CO_2 load reaches the lungs, a greater-than-normal CO_2 gradient exists between the blood and the air sacs in the lungs. Accordingly, more CO_2 than normal diffuses from the blood into the air sacs. This extra CO_2 is subsequently breathed out to the environment. Thus, any additional CO_2 produced by exercising muscles is eliminated from the body through the lungs as a result of the increase in CO_2 concentration gradient.

2. *The surface area of the membrane across which diffusion is taking place.* The larger the surface area available, the greater the rate of diffusion it can accommodate. Various strategies are used throughout the body for increasing the membrane surface area across which diffusion and other types of transport take place. For example, absorption of nutrients in the small intestine is enhanced by the presence of microvilli, which greatly increase the available absorptive surface in contact with the nutrient-rich contents of the small-intestine lumen (see p. 50). Conversely, abnormal loss of membrane surface area decreases the rate of net diffusion. For example, in *emphysema,* O_2 and CO_2 exchange between air and blood in the lungs is reduced because the walls of the air sacs break down,

TABLE 3-1 Factors Influencing the Rate of Net Diffusion of a Substance across a Membrane (Fick's Law of Diffusion)	
Factor	**Effect on Rate of Net Diffusion**
↑ Concentration gradient of substance (ΔC)	↑
↑ Surface area of membrane (A)	↑
↑ Lipid solubility (β)	↑
↑ Molecular weight of substance (*MW*)	↓
↑ Distance (thickness) (ΔX)	↓

Modified Fick's equation:

$$\text{Net rate of diffusion } (Q) = \frac{\Delta C \cdot A \cdot \beta}{\sqrt{MW} \cdot \Delta X}$$

$$\left[\text{diffusion constant } (D) \propto \frac{\beta}{\sqrt{MW}} \right]$$

$$\left[\text{permeability } (P) = \frac{D}{\Delta X} \right]$$

$$\text{Restated } Q \propto \Delta C \cdot A \cdot P$$

resulting in less surface area available for diffusion of these gases.

3. *The lipid solubility of the substance.* The greater the lipid solubility of a substance, the more rapidly the substance can diffuse through the membrane's lipid bilayer down its concentration gradient.

4. *The molecular weight of the substance.* Heavier molecules do not bounce as far on collision as lighter molecules such as O_2 and CO_2 do. Consequently, O_2 and CO_2 diffuse rapidly, permitting rapid exchanges of these gases across the lung membranes. As molecular weight increases, the rate of diffusion decreases.

5. *The distance through which diffusion must take place.* The greater the distance, the slower the rate of diffusion. Accordingly, membranes across which diffusing particles must travel are normally relatively thin, such as the membranes separating air and blood in the lungs. Thickening of this air–blood interface (as in *pneumonia,* for example) slows exchange of O_2 and CO_2. Furthermore, diffusion is efficient only for short distances between cells and their surroundings. It becomes an inappropriately slow process for distances of more than a few millimeters. To illustrate, it would take months or even years for O_2 to diffuse from the surface of the body to the cells in the interior. Instead, the circulatory system provides a network of tiny vessels that deliver and pick up materi-

als at every "block" of a few cells, with diffusion accomplishing short local exchanges between blood and surrounding cells.
Ions that can permeate the membrane also move passively along their electrical gradient.

In addition to their concentration gradient, movement of ions is affected by their electrical charge. Ions with like charges (those with the same kind of charge) repel each other, and ions with opposite charges attract each other. If a relative difference in charge exists between two adjacent areas, positively charged ions (*cations*) tend to move toward the more negatively charged area and negatively charged ions (*anions*) tend to move toward the more positively charged area. A difference in charge between two adjacent areas thus produces an **electrical gradient** that promotes movement of ions toward the area of opposite charge. Because a cell does not have to expend energy for ions to move into or out of it along an electrical gradient, this method of membrane transport is passive. When an electrical gradient exists between the ICF and the ECF, only ions that can permeate the plasma membrane can move along this gradient.

Both an electrical and a concentration (chemical) gradient may be acting on a particular ion at the same time. The net effect of simultaneous electrical and concentration gradients on this ion is called an **electrochemical gradient**. Later in this chapter you will learn how electrochemical gradients contribute to the electrical properties of the plasma membrane.

Osmosis is the net diffusion of water down its own concentration gradient.

Water molecules can readily permeate the plasma membrane. Even though water molecules are strongly polar, they are small enough to slip through momentary spaces created between the phospholipid molecules' tails as they sway and move within the lipid bilayer. However, this type of water movement across the membrane is relatively slow. In many cell types, membrane proteins form **aquaporins**, which are channels specific for the passage of water (*aqua* means "water"). This avenue greatly increases membrane permeability to water. About a billion water molecules can pass in single file through an aquaporin channel in a second. Different cell types vary in their density of aquaporins and thus in their water permeability. The driving force for net movement of water across the membrane is the same as for any other diffusing molecule—namely, its concentration gradient.

The term *concentration* usually refers to the density of the solute in a given volume of water. Recognize, however, that adding a solute to pure water decreases the water concentration. In general, one molecule of a solute displaces one molecule of water. Compare the water and solute concentrations in the two containers in Figure 3-9. The container in Figure 3-9a is full of pure water, so the water concentration is 100% and the solute concentration is 0%. In Figure 3-9b, solute has replaced 10% of the water molecules. The water concentration is now 90%, and the solute concentration is 10%—a lower water concentration and a higher solute concentration than in Figure 3-9a. As the solute concentration increases, the water concentration decreases correspondingly.

❙Figure 3-9 **Relationship between solute and water concentration in a solution**.

We now examine what water movement takes place when a selectively permeable membrane separates two fluid compartments under different circumstances, beginning with pure water being separated from a solution by a membrane permeable to water but not to the solute.

Movement of Water When a Selectively Permeable Membrane Separates Pure Water from a Solution of a Nonpenetrating Solute If as in Figure 3-10 pure water (side 1) and a solution containing a nonpenetrating solute (side 2) are separated by a selectively permeable membrane that permits passage of water but not of solute, water will move passively down its own concentration gradient from the area of higher water concentration (lower solute concentration) to the area of lower water concentration (higher solute concentration). This net diffusion of water down its concentration gradient through a selectively permeable membrane is known as **osmosis**. Because solutions are always referred to in terms of concentration of solute, *water moves by osmosis to the area of higher solute concentration.* Despite the impression that the solutes are "pulling," or attracting, water, osmosis is nothing more than diffusion of water down its own concentration gradient across the membrane.

Osmosis occurs from side 1 to side 2, but the concentrations between the two compartments can never become equal. No matter how dilute side 2 becomes because of water diffusing into it, it can never become pure water, nor can side 1 ever acquire any solute. Therefore, does net diffusion of water (osmosis) continue until all the water has left side 1? No. As the volume expands in side 2, a difference in hydrostatic pressure between the two sides is created, and it opposes osmosis. **Hydrostatic (fluid) pressure** is the pressure exerted by a standing, or stationary, fluid on an object—in this case, the membrane (*hydro* means "fluid"; *static* means "standing"). The hydrostatic pressure exerted by the larger volume of fluid on side 2 is greater than the hydrostatic pressure exerted on side 1.

KEY

= Water molecule   = Nonpenetrating solute

❙Figure 3-10 **Osmosis when pure water is separated from a solution containing a nonpenetrating solute.**

This difference in hydrostatic pressure tends to push fluid from side 2 to side 1.

The **osmotic pressure** of a solution (a "pulling" pressure) is a measure of the tendency for osmotic flow of water into that solution because of its relative concentration of nonpenetrating solutes and water. Net movement of water by osmosis continues until the opposing hydrostatic pressure (a "pushing" pressure) exactly counterbalances the osmotic pressure. The magnitude of the osmotic pressure is equal to the magnitude of the opposing hydrostatic pressure necessary to completely stop osmosis. The greater the concentration of nonpenetrating solute → the lower the concentration of water → the greater the drive for water to move by osmosis from pure water into the solution → the greater the opposing pressure required to stop the osmotic

flow → the greater the osmotic pressure of the solution. Therefore, a solution with a high concentration of nonpenetrating solute exerts greater osmotic pressure than a solution with a lower concentration of nonpenetrating solute does.

Osmotic pressure is an indirect measure of solute concentration, expressed in units of pressure. A more direct means of expressing solute concentration is the **osmolarity** of a solution, which is a measure of its total solute concentration given in terms of the *number* of particles (molecules or ions). Osmolarity is expressed in *osmoles per liter* (or *Osm/L*), the number of moles of solute particles in 1 liter of solution (see p. A-7). Because glucose remains as an intact molecule when in solution, 1 mole of glucose equals 1 osmole—that is, 1 mole of solute particles. By contrast, because a molecule of NaCl dissociates (separates) into 2 ions—Na^+ and Cl^-—when in solution, 1 mole of NaCl equals 2 osmoles—1 mole of Na^+ and 1 mole of Cl^-, or 2 moles of solute particles. The osmolarity of body fluids is typically expressed in *milliosmoles per liter* (*mOsm/L*) (1/1000 of an osmole) because the solutes in body fluids are too dilute to conveniently use the osmole unit. Because osmolarity depends on the number, not the nature, of particles, any mixture of particles can contribute to the osmolarity of a solution. The normal osmolarity of body fluids is 300 mOsm/L.

Thus far in our discussion of osmosis, we have considered movement of water when pure water is separated from a solution by a membrane permeable to water but not to nonpenetrating solutes. However, in the body, the plasma membrane separates the ICF and the ECF, and both of these contain solutes, some that can and others that cannot penetrate the membrane. Let us compare the results of water movement when solutions of differing osmolarities are separated by a selectively permeable membrane that permits movement of water and only some solutes.

Movement of Water and Solute When a Membrane Separates Unequal Solutions of a Penetrating Solute

Assume that solutions of *unequal* concentration of *penetrating* solute (differing osmolarities) are separated by a membrane that is permeable to both water and solute (❙Figure 3-11). In this situation, the solute moves down its own concentration gradient in the opposite direction of the net water movement. The movement continues until both solute and water are evenly distributed across the membrane. With all concentration gradients gone, net movement ceases. The final volume of each side when dynamic equilibrium is achieved and no further net movement occurs is the same as at the onset. Water and solute molecules merely exchange places between the two sides until their distributions are equalized—that is, an equal number of water molecules move from side 1 to side 2 as solute molecules move from side 2 to side 1. Therefore, solutes that can penetrate the plasma membrane do not contribute to osmotic differences between the ICF and the ECF and do not affect cell volume.

Movement of Water When a Membrane Separates Equal or Unequal Solutions of a Nonpenetrating Solute

If solutions of *equal* concentration of *nonpenetrating* solute (the same osmolarities) are separated by a membrane that is permeable to water but impermeable to the solute, no concentration

differences exist and thus no net movement of water occurs across the membrane. Of course, the solute does not move because the membrane is impermeable to it and no concentration gradient exists for it. This is the usual situation in body fluids. Body cells normally do not experience any net gain (swelling) or loss (shrinking) of volume because the concentration of nonpenetrating solutes in the ECF is normally carefully regulated (primarily by the kidneys) so that the ECF osmolarity is the same as the osmolarity within the cells. Intracellular osmolarity is normally 300 mOsm/L, and all intracellular solutes are assumed to be nonpenetrating.

Now assume that solutions of *unequal* concentration of *nonpenetrating* solute (differing osmolarities) are separated by a membrane that is permeable to water but impermeable to the solute (❙Figure 3-12). Osmotic movement of water across the membrane is driven by the difference in osmotic pressure of the two solutions. At first, the concentration gradients are identical to those in Figure 3-11. Net diffusion of water takes place

from side 1 to side 2, but the solute cannot cross the membrane down its concentration gradient. As a result of water movement alone, the volume of side 2 increases while the volume of side 1 correspondingly decreases. Loss of water from side 1 increases the solute concentration on side 1, whereas addition of water to side 2 reduces the solute concentration on that side. If the membrane is free to move so that side 2 can expand without an opposing hydrostatic pressure developing, eventually the concentrations of water and solute on the two sides of the membrane become equal and net diffusion of water ceases. This situation is similar to what happens across plasma membranes in the body. Within the slight range of changes in ECF osmolarity that occur physiologically, if water moves by osmosis into the cells, their plasma membranes normally accommodate the increase in cell volume with no significant change in hydrostatic pressure inside the cells. Likewise, in the reverse situation, if water moves by osmosis out of the cells, the ECF compartment

expands without a change in its hydro-static pressure. Therefore, osmosis is the major force responsible for the net movement of water into or out of cells, without having to take hydrostatic pressure into consideration. At the endpoint, when osmosis ceases, the volume has increased on the side that originally had the higher solute concentration and the volume has decreased on the side with the lower solute concentration. Therefore, osmotic movement of water across the plasma membrane always results in a change in cell volume, and cells, especially brain cells, do not function properly when they swell or shrink.

Tonicity refers to the effect the concentration of nonpenetrating solutes in a solution has on cell volume.

The **tonicity** of a solution is the effect the solution has on cell volume—whether the cell remains the same size, swells, or shrinks—when the solution surrounds the cell. The tonicity of a solution has no units and is a reflection of its concentration of nonpenetrating solutes relative to the cell's concentration of nonpenetrating solutes. (By contrast, the osmolarity of a solution is a measure of its total concentration of both penetrating and nonpenetrating solutes expressed in units of osmoles per liter.) The easiest way to demonstrate this phenomenon is to place red blood cells in solutions with varying concentrations of a nonpenetrating solute (❙Figure 3-13).

Normally, the plasma in which red blood cells are suspended has the same osmotic activity as the fluid inside these cells, so the cells maintain a constant volume. An **isotonic solution** (*iso* means "equal") has the same concentration of nonpenetrating solutes as normal body cells do. When a cell is bathed in an isotonic solution, no water enters or leaves the cell by osmosis, so cell volume remains constant. For this reason, the ECF is normally maintained isotonic so that no net diffusion of water occurs into or out of body cells.

If red blood cells are placed in a dilute or **hypotonic solution** (*hypo* means "below"), a solution with a below-normal concentration of nonpenetrating solutes (and therefore a higher concentration of water), water enters the cells by osmosis. Net gain of water by the cells causes them to swell, perhaps to the point of rupturing, or *lysing*. If, in contrast, red blood cells are placed in a concentrated or **hypertonic solution** (*hyper* means "above"), a solution with an above-normal concentration of nonpenetrating solutes (and therefore a lower concentration of water), the cells shrink as they lose water by

osmosis. When a red blood cell decreases in volume, its surface area does not decrease correspondingly, so the cell assumes a *crenated,* or spiky, shape (❙Figure 3-13c). Because cells change volume when surrounded by fluid that is not isotonic, it is crucial that the concentration of nonpenetrating solutes in the ECF quickly be restored to normal should the ECF become hypotonic (as with ingesting too much water) or hypertonic (as with losing too much water through severe diarrhea). (See pp. 540–547 for further details about the important homeostatic mechanisms that maintain the normal concentration of nonpenetrating solutes in the ECF.) For the same reason, fluids injected intravenously should be isotonic to prevent unwanted movement of water into or out of the cells. For example, isotonic saline (0.9% NaCl solution) is used as a vehicle for delivering drugs intravenously or for expanding plasma volume without affecting the cells. (Sometimes hypotonic or hypertonic fluids are injected therapeutically to correct osmotic imbalances.)

3.5 Assisted Membrane Transport

All the kinds of transport we have discussed thus far—diffusion down concentration gradients, movement along electrical gradients, and osmosis—produce net movement of particles capable of permeating the plasma membrane because of their lipid solubility (nonpolar molecules of any size) or their ability to fit through channels (selected ions and water). Poorly lipid-soluble polar molecules that are too big for channels, such as proteins, glucose, and amino acids, cannot cross the plasma membrane on their own no matter what forces are acting on them. This impermeability ensures that large, polar intracellular proteins stay in the cell where they belong and can carry out their life-sustaining functions—for example, serving as metabolic enzymes.

However, because poorly lipid-soluble molecules cannot cross the plasma membrane on their own, the cell must provide mechanisms for deliberately transporting these types of molecules into or out of the cell as needed. For example, the cell must usher in essential nutrients, such as glucose for energy and amino acids for synthesis of proteins, and transport out metabolic wastes and secretory products, such as water-soluble pro-

tein hormones. Furthermore, passive diffusion alone cannot always account for the movement of ions. Some ions move through the membrane passively in one direction and actively in the other direction. Cells use two different mechanisms to accomplish these selective transport processes: *carrier-mediated transport* for transfer of small to moderate-sized water-soluble substances across the membrane and *vesicular transport* for movement of large water-soluble molecules and multimolecular particles between the ECF and the ICF. We examine each of these methods of assisted membrane transport in turn.

Carrier-mediated transport is accomplished by a membrane carrier changing its shape.

A carrier protein spans the thickness of the plasma membrane and can change its conformation (shape) so that specific binding sites within the carrier are alternately exposed to the ECF and the ICF. Figure 3-14 shows how this **carrier-mediated transport** works. Step **1** shows the carrier open to the ECF. The molecule to be transported attaches to a carrier's binding site on one side of the membrane—in this case, on the ECF side (step **2**). Then the carrier changes shape, exposing the same site to the other side of the membrane (step **3**). Having been moved in this way from one side of the membrane to the other, the bound molecule

detaches from the carrier (step **4**). Next, the carrier reverts to its original shape (back to step **1**).

Both channels and carriers are proteins that span the plasma membrane and serve as selective avenues for movement of water-soluble substances across the membrane, but there are notable differences between them: (1) Only ions fit through the narrow channels, whereas small polar molecules such as glucose and amino acids are transported across the membrane by carriers. (2) Channels can be open or closed, but carriers are always "open for business" (although the number and kinds of carriers in the plasma membrane can be regulated). (3) Movement through channels is considerably faster than carrier-mediated transport is. When open for traffic, channels are open at both sides of the membrane at the same time, permitting continuous, rapid movement of ions between the ECF and the ICF through these nonstop passageways. By contrast, carriers are never open to both the ECF and the ICF simultaneously. They must change shape to alternately pick up passenger molecules on one side and drop them off on the other side, a time-consuming process. Whereas a carrier may move up to 5000 particles per second across the membrane, 5 million ions may pass through an open channel in 1 second.

Carrier-mediated transport systems display three important characteristics that determine the kind and amount of material that can be transferred across the membrane: *specificity, saturation,* and *competition.*

1. **Specificity.** Each carrier protein is specialized to transport a specific substance or, at most, a few closely related chemical compounds. For example, amino acids cannot bind to glucose carriers, although several similar amino acids may be able to use the same carrier. Cells vary in the types of carriers they have, thus permitting transport selectivity among cells.

A number of inherited diseases involve defects in transport *Clinical Note* systems for a particular substance. *Cysteinuria* (cysteine in the urine) is such a disease involving defective cysteine carriers in the kidney membranes. This transport system normally removes cysteine from the fluid destined to become urine and returns this essential amino acid to the blood. When this carrier malfunctions, large quantities of cysteine remain in the urine, where it is relatively insoluble and tends to precipitate. This is one cause of urinary stones.

2. **Saturation.** A limited number of carrier binding sites are available within a particular plasma membrane for a specific substance. Therefore, the amount of a substance carriers can transport across the membrane in a given time is limited. This limit is known as the **transport maximum (T_m)**. Until the T_m is reached, the number of carrier binding sites occupied by a substance and, accordingly, the substance's rate of transport across the membrane is directly related to its concentration. The more of a substance available for transport, the more transported. When the T_m is reached, the carriers are saturated (all binding sites are occupied) and the rate of the substance's transport across the membrane is maximal. Further increases in the substance's concentration are no longer accompanied by

Simple diffusion down concentration gradient

T_m

Carrier-mediated transport down concentration gradient (facilitated diffusion)

Low → High

Concentration of transported molecules in ECF
❚Figure 3-15 Comparison of carrier-mediated transport and simple diffusion down a concentration gradient. With simple diffusion of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule. With carrier-mediated transport of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule until the carrier is saturated, at which time the rate of transport reaches the transport maximum (T_m). After T_m is reached, the rate of transport levels off despite further increases in the ECF concentration of the molecule.

corresponding increases in the rate of transport (❚Figure 3-15).

As an analogy, consider a ferry boat that can carry at most 100 people across a river during one trip in an hour. If 25 people are on hand to board the ferry, 25 will be transported that hour. Doubling the number of people on hand to 50 will double the rate of transport to 50 people that hour. Such a direct relationship will exist between the number of people waiting to board (the concentration) and the rate of transport until the ferry is fully occupied (its T_m is reached). Even if 150 people are waiting to board, only 100 can be transported per hour.

Saturation of carriers is a critical rate-limiting factor in the transport of selected substances across the kidney membranes during urine formation and across the intestinal membranes during absorption of digested foods. Furthermore, it is sometimes possible to regulate the rate of carrier-mediated transport by varying the affinity (attraction) of the binding site for its passenger or by varying the number of binding sites. For example, the hormone insulin greatly increases the carrier-mediated transport of glucose into most cells of the body by promoting an increase in the number of glucose carriers in the cell's plasma membrane. Deficient insulin action (*diabetes mellitus*) drastically impairs the body's ability to take up and use glucose as the primary energy source.

3. **Competition.** Several closely related compounds may compete for a ride across the membrane on the same carrier. If a given binding site can be occupied by more than one type of molecule, the rate of transport of each substance is less when both molecules are present than when either is present by itself. To illustrate, assume the ferry has 100 seats (binding sites)

The Plasma Membrane and Membrane Potential | **71**

Exercising Muscles Have a "Sweet Tooth"

CELLS TAKE UP GLUCOSE FROM the blood by facilitated diffusion via glucose carriers in the plasma membrane. The cells maintain an intracellular pool of these carriers that can be inserted into the plasma membrane as the need for glucose uptake increases. In many cells, including resting muscle cells, glucose uptake depends on the hormone insulin, which promotes the insertion of glucose carriers in the plasma membranes of insulin-dependent cells.

During exercise, muscle cells use more glucose and other nutrient fuels than usual to power their increased contractile activity. The rate of glucose transport into exercising muscle may increase more than 10-fold during moderate or intense physical activity. Insulin is not responsible for the increased transport of glucose into exercising muscles, however, because blood insulin levels fall during exercise. Instead muscle cells insert more glucose carriers in their plasma membranes in direct response to exercise.

Exercise influences glucose transport into cells in yet another way. Regular aerobic exercise (see p. 39) has been shown to increase both the affinity (degree of attraction) and number of plasma membrane receptors that bind specifically with insulin. This adaptation results in an increase in insulin sensitivity—that is, the cells are more responsive than normal to a given level of circulating insulin.

Because insulin enhances the facilitated diffusion of glucose into most cells, an exercise-induced increase in insulin sensitivity is one of the factors that makes exercise a beneficial therapy for controlling diabetes mellitus. In this disorder, glucose entry into most cells is impaired as a result of inadequate insulin action (see Chapter 19). Plasma levels of glucose become elevated because glucose remains in the plasma instead of being transported into the cells. In Type 1 diabetes, too little insulin is produced to meet the body's need for glucose uptake. Regular aerobic exercise reduces the amount of insulin that must be injected to promote glucose uptake and lower the blood glucose level toward normal. In Type 2 diabetes, insulin is produced, but insulin's target cells have decreased sensitivity to its presence. By increasing the cells' responsiveness to the insulin available, regular aerobic exercise helps drive glucose into the cells, where it can be used for energy production, instead of remaining in the plasma, where it leads to detrimental consequences for the body.

---

that can be occupied by either men or women. If only men are waiting to board, up to 100 men can be transported during each trip; the same holds true if only women are waiting to board. If both men and women are waiting to board, however, they will compete for the available seats. Fifty of each might make the trip, although the total number of people transported will still be the same, 100 people. In other words, when a carrier can transport two closely related substances, such as the amino acids glycine and alanine, the presence of both diminishes the rate of transfer for either.

Facilitated diffusion is passive carrier-mediated transport.

Carrier-mediated transport takes two forms, depending on whether energy must be supplied to complete the process: facilitated diffusion (not requiring energy) and active transport (requiring energy). **Facilitated diffusion** uses a carrier to facilitate (assist) the transfer of a particular substance across the membrane "downhill" from high to low concentration. This process is passive and does not require energy because movement occurs naturally down a concentration gradient. **Active transport**, however, requires the carrier to expend energy to transfer its passenger "uphill" against a concentration gradient, from an area of lower concentration to an area of higher concentration. An analogous situation is a car on a hill. To move the car downhill requires no energy; it will coast from the top down. Driving the car uphill, however, requires the use of energy (generated by the burning of gasoline).

The most notable example of facilitated diffusion is the transport of glucose into cells. Glucose is in higher concentration in the blood than in the tissues. Fresh supplies of this nutrient are regularly added to the blood by eating and by using reserve energy stores in the body. Simultaneously, the cells metabolize glucose almost as rapidly as it enters from the blood. As a result, a continuous gradient exists for net diffusion of glucose into the cells. However, glucose cannot cross plasma membranes on its own because it is not lipid soluble and is too large to fit through a channel. Without glucose carrier molecules (called **glucose transporters**, or **GLUTs**; see p. 691) to facilitate membrane transport of glucose, cells would be deprived of their preferred source of fuel. (The accompanying boxed feature, ■ A Closer Look at Exercise Physiology, describes the effect of exercise on glucose carriers in skeletal muscle cells.)

The binding sites on facilitated diffusion carriers can bind with their passenger molecules when exposed on either side of the membrane. As a result of thermal energy, these carriers undergo spontaneous changes in shape, alternately exposing their binding sites to the ECF or the ICF. After picking up the passenger on one side, when the carrier changes its conformation, it drops off the passenger on the opposite side of the membrane. Because passengers are more likely to bind with the carrier on the high-concentration side than on the low-concentration side, the net movement always proceeds down the concentration gradient from higher to lower concentration (see ■ Figure 3-14). As is characteristic of all types of mediated transport, the rate of facilitated diffusion is limited by saturation of the carrier binding sites—unlike the rate of simple diffu-

sion, which is always directly proportional to the concentration gradient (see ❙ Figure 3-15).

Active transport is carrier mediated and uses energy.

Active transport also uses a carrier protein to transfer a specific substance across the membrane, but in this case the carrier transports the substance uphill *against* its concentration gradient. Active transport comes in two forms. In **primary active transport**, energy is *directly* required to move a substance against its concentration gradient; the carrier splits ATP to power the transport process. In **secondary active transport**, energy is required in the entire process, but it is *not directly* used to produce uphill movement. That is, the carrier does not split ATP; instead, it moves a molecule uphill by using "secondhand" energy stored in the form of an **ion concentration gradient** (most commonly a Na^+ gradient). This ion gradient is built up by primary active transport of the ion by a different carrier.

Primary Active Transport In primary active transport, energy in the form of ATP is required for the carrier to change shape and alternately expose the carrier's binding sites for passengers (always ions) to opposite sides of the membrane, with the affinity of the binding sites for their passenger ions being different when the sites are open to the ICF side than when open to the ECF side. The binding sites have a greater affinity for the passenger ion on the low-concentration side where the ion is picked up and a lower affinity on the high-concentration side where the ion is dropped off. In this way, transported ions are moved uphill from an area of low concentration to an area of higher concentration. These active-transport mechanisms are often called "**pumps**," analogous to water pumps that require energy to lift water against the downward pull of gravity. In contrast, in facilitated diffusion, the affinity of the binding site is the same when exposed to either the outside or the inside of the cell and the transported ions are moved downhill from high to low concentration.

All primary-active transport carriers act as enzymes that have ATPase activity, which means they split the terminal phosphate from an ATP molecule to yield adenosine diphosphate (ADP) and inorganic phosphate (P_i) plus free energy (see p. 34). (Do not confuse *ATPase,* which splits ATP, with *ATP synthase,* which synthesizes ATP.) Let us see how ATP is used by primary-active transport carriers to move transported ions against their concentration gradients by considering one of the most important pumps, the **Na^+–K^+ ATPase pump** (**Na^+–K^+ pump** for short) found in the plasma membrane of all cells. This carrier transports Na^+ out of the cell, concentrating it in the ECF, and picks up K^+ from the outside, concentrating it in the ICF. The Na^+–K^+ pump has three binding sites for Na^+ and two binding sites for K^+. When exposed to the cell interior, the pump has high affinity for Na^+ and low affinity for K^+ (❙ Figure 3-16, step ❶). Attachment of three Na^+ to the carrier's high-affinity Na^+ binding sites on the ICF side (where Na^+ is in low concentration) activates the pump's ATPase activity, triggering the splitting of ATP and subsequent *phosphorylation* of the carrier (that is, binding of the inorganic phosphate resulting from ATP splitting) on the intracellular side

(step ❷). This phosphorylation causes the carrier to change shape, which exposes the bound Na^+ to the exterior. The change in carrier shape sharply reduces the affinity of the binding sites for Na^+, so this ion is released to its high concentration side in the ECF (step ❸). Simultaneously, the change in shape increases the carrier's affinity for K^+ on the ECF side (where this ion is in low concentration) (step ❹). Binding of two K^+ leads to *dephosphorylation* of the carrier (that is, the inorganic phosphate detaches from the carrier), inducing a second change in carrier shape, reverting the carrier back to its original conformation, and exposing the bound K^+ to the cell's interior (step ❺). On this side, the affinity of the K^+ binding sites markedly decreases, so K^+ is released to its high concentration side in the ICF (step ❻). Simultaneously, the affinity of the Na^+ binding sites greatly increases as they are exposed to the cell interior once again, so the pump is ready to repeat the cycle (back to step ❶). Thus, the Na^+–K^+ pump moves three Na^+ out of the cell for every two K^+ it pumps in, with both ions moving against their concentration gradients at the expense of energy (ATP splitting). (To appreciate the magnitude of active Na^+–K^+ pumping, consider that a single nerve cell membrane contains roughly 1 million Na^+–K^+ pumps capable of transporting about 200 million ions per second.)

The Na^+–K^+ pump plays three important roles:

1. It establishes Na^+ and K^+ concentration gradients across the plasma membrane of all cells; these gradients are critically important in the ability of nerve and muscle cells to generate electrical signals essential to their functioning (a topic discussed more thoroughly later).

2. It helps regulate cell volume by controlling the concentrations of solutes inside the cell and thus minimizing osmotic effects that would induce swelling or shrinking of the cell.

3. The energy used to run the Na^+–K^+ pump also indirectly serves as the energy source for secondary active transport.

The Na^+–K^+ pump is not the only primary active-transport carrier. Primary active-transport pumps all move positively charged ions—namely, Na^+, K^+, hydrogen ion (H^+), or calcium ion (Ca^{2+})—across the membrane. The simplest primary active-transport systems pump a single type of passenger. For example, the **Ca^{2+} pump** in the plasma membrane transports Ca^{2+} out of the cell, keeping the Ca^{2+} concentration in the cytosol low. These Ca^{2+} transporters are particularly abundant in the plasma membrane of neuron (nerve cell) terminals that store chemical messengers (neurotransmitters) in secretory vesicles (see p. 103). An electrical signal in a neuron terminal triggers the opening of Ca^{2+} channels in the terminal's plasma membrane. Entry of Ca^{2+} down its concentration gradient through these open channels promotes the secretion of neurotransmitter by exocytosis of the secretory vesicles. By keeping the intracellular Ca^{2+} concentration low, the active Ca^{2+} pump helps maintain a large concentration gradient for the entry of secretion-inducing Ca^{2+} from the ECF into the neuron terminal.

More complicated primary active-transport mechanisms involve the transfer of two different passengers in opposite directions, the most important example being the Na^+–K^+ pump. Let us now turn attention to how this primary pump indirectly serves as the energy source for secondary active transport.

Secondary Active Transport With secondary active transport, the carrier does not directly split ATP to move a substance against its concentration gradient. Instead, the movement of Na^+ into the cell down its concentration gradient (established by the ATP-splitting Na^+–K^+ pump) drives the uphill transport of another solute by a secondary active-transport carrier. This is efficient because Na^+ must be pumped out anyway to maintain the electrical and osmotic integrity of the cell.

In secondary active transport, the transfer of the solute across the membrane is always coupled (occurs together) with the transfer of the ion that supplies the driving force. We use Na^+ as the main example. Secondary active transport carriers have two binding sites: one for the solute being moved and one for Na^+. Secondary active transport occurs by two mechanisms—symport and antiport—depending on the direction the transported solute moves in relation to Na^+ movement. In **symport** (also called **cotransport**), the solute and Na^+ move through the membrane in the same direction—that is, into the cell (*sym* means "together"; *co* means "with"). Glucose and amino acids are examples of molecules transported by symport in intestinal and kidney cells. We discuss the importance of these carriers in more detail shortly. In **antiport** (also known as **countertransport** or **exchange**), the solute and Na^+ move through the membrane in opposite directions—that is, Na^+ into and the solute out of the cell (*anti* means "opposite"; *counter* means "against") (Figure 3-17). For example, cells exchange Na^+ and H^+ by means of anti-

3 Phosphorylation causes pump to change conformation so that Na^+ binding sites are exposed to opposite side of membrane and 3 Na^+ are released to ECF (where Na^+ concentration is high) as affinity of Na^+ binding sites greatly decreases.

5 When 2 K^+ from ECF (where K^+ concentration is low) bind to pump, it releases phosphate group. Dephosphorylation causes pump to revert to its original conformation.

Figure 3-16 Na^+–K^+ pump, an example of primary active transport. The plasma membrane of all cells contains an active-transport carrier, the Na^+–K^+ pump, which uses energy in the carrier's phosphorylation–dephosphorylation cycle to sequentially transport Na^+ out of the cell and K^+ into the cell against these ions' concentration gradient. This pump moves three Na^+ out and two K^+ in for each ATP split.

FIGURE FOCUS: *If ATP production was to sharply fall, what would happen to the Na^+ and K^+ concentrations in the ECF and the ICF?*

port. This carrier plays an important role in maintaining the appropriate pH inside the cells (a fluid becomes more acidic as its H$^+$ concentration rises).

Let us examine Na$^+$ and glucose symport in more detail as an example of secondary active transport. Unlike most body cells, the intestinal and kidney cells actively transport glucose by moving it uphill from low to high concentration. The intestinal cells transport this nutrient from the intestinal lumen into the blood, concentrating it there, until none is left in the lumen to be lost in the feces. The kidney cells save this nutrient for the body by transporting it out of the fluid that is to become urine, moving it against a concentration gradient into the blood. The symport carriers that transport glucose against its concentration gradient from the lumen in the intestine and kidneys are distinct from the glucose facilitated-diffusion carriers that transport glucose down its concentration gradient into most cells.

Here, we focus specifically on the symport carrier that cotransports Na$^+$ and glucose in intestinal epithelial cells. This carrier, known as the **sodium and glucose cotransporter** or **SGLT**, is located in the luminal membrane (the membrane facing the intestinal lumen) (▮Figure 3-18). The Na$^+$–K$^+$ pump in these cells is located in the basolateral membrane (the membrane on the side of the cell opposite the lumen and along the lateral edge of the cell below the tight junction; see Figure 3-5, p. 62). More Na$^+$ is present in the lumen than inside the cells because the energy-requiring Na$^+$–K$^+$ pump transports Na$^+$ out of the cell at the basolateral membrane, keeping the intracellular Na$^+$ concentration low (▮Figure 3-18, step **1**). Because of this Na$^+$ concentration difference, more Na$^+$ binds to the SGLT when it is exposed to the lumen than when it is exposed to the ICF. Binding of Na$^+$ to this carrier increases the carrier's affinity for glucose, so glucose binds to the SGLT when it is open to the lumen side where glucose concentration is low (step **2a**). When both Na$^+$ and glucose are bound to it, the SGLT changes shape and opens to the inside of the cell (step **2b**). Both Na$^+$ and glucose are released to the interior— Na$^+$ because of the lower intracellular Na$^+$ concentration and glucose because of the reduced affinity of the binding site on release of Na$^+$ (step **2c**). The movement of Na$^+$ into the cell by this cotransport carrier is downhill because the intracellular Na$^+$ concentration is low, but the movement of glucose is uphill because glucose becomes concentrated in the cell.

The released Na$^+$ is quickly pumped out by the active Na$^+$–K$^+$ transport mechanism, keeping the level of intracellular Na$^+$ low. The energy expended in this process is not used directly to run the SGLT because phosphorylation is not required to alter the affinity of the binding site to glucose. Instead, the establishment of a Na$^+$ concentration gradient by the Na$^+$–K$^+$ pump (a primary active-transport mechanism) drives the SGLT (a secondary active-transport mechanism) to move glucose against its concentration gradient.

The glucose carried across the luminal membrane into the cell by secondary active transport then moves passively out of

(a) **Symport**

(b) **Antiport**
▮Figure 3-17 **Secondary active transport.** With secondary active transport, an ion concentration gradient (established by primary active transport) is used as the energy source to transport a solute against its concentration gradient. (Usually the driving ion is Na$^+$, whose concentration gradient is established by the Na$^+$–K$^+$ pump.) Note that for convenience in using arrows to depict the direction in which the carrier moves the transported solute and driving ion, the carrier is shown as being open to both sides of the membrane at the same time, which is never the case in reality. (a) In symport, the transported solute moves in the same direction as the gradient of the driving ion. (b) In antiport, the transported solute moves in the direction opposite from the gradient of the driving ion.

the cell by facilitated diffusion across the basolateral membrane and into the blood (step **3**). This facilitated diffusion, which moves glucose down its concentration gradient, is mediated by a passive GLUT identical to the one that transports glucose into other cells, but in intestinal and kidney cells it transports glucose out of the cell. The difference depends on the direction of the glucose concentration gradient. In the case of intestinal and kidney cells, the glucose concentration is higher inside the cells. Note that in this sequence of events, secondary active transport refers only to the cotransport of glucose uphill across the luminal membrane driven by the Na$^+$ concentration gradient—that is, the transport accomplished by SGLT.

Before leaving the topic of carrier-mediated transport, think about all the activities that rely on carrier assistance. All cells depend on carriers for the uptake of glucose and amino acids, which serve as the major energy source and the structural building blocks, respectively. Na$^+$–K$^+$ pumps are essential for generating cellular electrical activity and for ensuring that cells have an appropriate intracellular concentration of osmotically active solutes. Both primary active transport and secondary active transport are used extensively to accomplish the specialized functions of the nervous and digestive systems and those of the kidneys and all types of muscle.

With vesicular transport, material is moved into or out of the cell wrapped in membrane.

The special carrier-mediated transport systems embedded in the plasma membrane selectively transport ions and small polar molecules. But how do large polar molecules, such as the protein hormones secreted by endocrine cells, or even multimolecular

materials, such as the bacteria ingested by white blood cells, leave or enter the cell? These materials are unable to cross the plasma membrane, even with assistance: They are much too big for channels, and no carriers exist for them (they would not even fit into a carrier molecule). These large particles are transferred between the ICF and the ECF not by crossing the membrane but by being wrapped in a membrane-enclosed vesicle, a process known as **vesicular transport**. Vesicular transport requires energy expenditure by the cell, so this is an active method of membrane transport. Energy is needed to accomplish vesicle

formation and vesicle movement within the cell. Transport into the cell in this manner is termed *endocytosis,* whereas transport out of the cell is called *exocytosis* (see ❙Figure 2-6, p. 29).

Endocytosis To review, in **endocytosis** the plasma membrane surrounds the substance to be ingested and then fuses over the surface, pinching off a membrane-enclosed vesicle so that the engulfed material is trapped within the cell. Recall that there are three forms of endocytosis, depending on the material internalized: *pinocytosis* (nonselective uptake of a sample of ECF), *receptor-mediated endocytosis* (selective uptake of a large molecule)*,* and *phagocytosis* (selective uptake of a multimolecular particle) (see ❙Figure 2-9, p. 32). Once inside the cell, an engulfed vesicle has two possible destinies:

1. In most instances, lysosomes fuse with the vesicle, degrading and releasing its contents into the intracellular fluid.
2. In some cells, the endocytic vesicles bypass the lysosomes where they are normally degraded and instead travel to the opposite side of the cell, where they release their contents by exocytosis. This provides a pathway, termed **transcytosis,** to shuttle large intact molecules through the cell. Such vesicular traffic is one means by which materials are transferred through the thin cells lining the capillaries, the smallest of blood vessels, across which exchanges are made between the blood and the surrounding tissues.

Exocytosis In exocytosis, almost the reverse of endocytosis occurs. A membrane-enclosed vesicle formed within the cell fuses with the plasma membrane, then opens up and releases its contents to the exterior. Materials packaged for export by the endoplasmic reticulum and Golgi complex are externalized by exocytosis.

Exocytosis serves two different purposes:

1. It provides a mechanism for secreting large polar molecules, such as protein hormones and enzymes that are unable to cross the plasma membrane. In this case, the vesicular contents are highly specific and are released only on receipt of appropriate signals.
2. It enables the cell to add specific components to the membrane, such as selected carriers, channels, or receptors, depending on the cell's needs. In such cases, the composition of the membrane surrounding the vesicle is important and the contents may be merely a sampling of ICF.

Balance Between Endocytosis and Exocytosis The rates of endocytosis and exocytosis must be kept in balance to maintain a constant membrane surface area. In a cell actively involved in endocytosis, more than 100% of the plasma membrane may be used in an hour to wrap internalized vesicles, necessitating rapid replacement of surface membrane by exocytosis. In contrast, when a secretory cell is stimulated to secrete, it may temporarily insert up to 30 times its surface membrane through exocytosis. This added membrane must be specifically retrieved by an equivalent level of endocytic activity. Thus, through exocytosis and endocytosis, portions of the membrane are constantly being restored, retrieved, and generally recycled.

Our discussion of membrane transport is now complete; ❙Table 3-2 summarizes the pathways by which materials can pass between the ECF and the ICF. Cells are differentially selective in what enters or leaves because they have varying numbers and kinds of channels, carriers, and mechanisms for vesicular transport. Large polar molecules (too large for channels and not lipid soluble) that have no special transport mechanisms are unable to permeate.

The selective transport of K^+ and Na^+ is responsible for the electrical properties of cells. We turn to this topic next.

Check Your Understanding 3.5

1. Draw a graph comparing simple diffusion down a concentration gradient and carrier-mediated transport.
2. Describe what causes the carrier to change shape to expose binding sites for passengers to opposite sides of the membrane in facilitated diffusion, primary active transport, and secondary active transport.
3. Distinguish between symport and antiport.

</div>

3.6 Membrane Potential

The plasma membranes of all living cells have a membrane potential, or are polarized electrically.

Membrane potential is a separation of opposite charges across the plasma membrane.

The term **membrane potential** refers to a separation of opposite charges across the membrane or to a difference in the relative number of cations and anions in the ICF and ECF. Recall that opposite charges tend to attract each other and like charges tend to repel each other. Work must be performed (energy expended) to separate opposite charges after they have come together. Conversely, when oppositely charged particles have been separated, the electrical force of attraction between them can be harnessed to perform work when the charges are permitted to come together again. This is the basic principle underlying electrically powered devices. A separation of charges across the membrane is called a *membrane potential* because separated charges have the potential to do work. Potential is measured in volts (the same unit used for the voltage in electrical devices), but because the membrane potential is relatively low, the unit used is the **millivolt** (**mV;** 1/1000 of a volt).

Because the concept of potential is fundamental to understanding much of physiology, especially nerve and muscle physiology, it is important to understand clearly what this term means. The membrane in ❙Figure 3-19a is electrically neutral; with an equal number of positive (+) and negative (−) charges on each side of the membrane, no membrane potential exists. In ❙Figure 3-19b, some of the positive charges from the right side have been moved to the left. Now the left side has an excess of positive charges, leaving an excess of negative charges on the right. In other words, opposite charges are separated across the

Method of Transport	Substances Involved	Energy Requirements and Force Producing Movement	Limit to Transport
Simple Diffusion			
Diffusion through lipid bilayer	Nonpolar molecules of any size (e.g., O_2, CO_2, fatty acids)	Passive; molecules move down concentration gradient (from high to low concentration)	Continues until gradient is abolished (dynamic equilibrium with no net diffusion)
Diffusion through protein channel	Specific small ions (e.g., Na^+, K^+, Ca^{2+}, Cl^-)	Passive; ions move down electrochemical gradient through open channels (from high to low concentration and by attraction of ion to area of opposite charge)	Continues until there is no net movement and dynamic equilibrium is established
Osmosis	Water only	Passive; water moves down its own concentration gradient (to area of lower water concentration—that is, higher solute concentration)	Continues until concentration difference is abolished or until stopped by opposing hydrostatic pressure or until cell is destroyed
Carrier-Mediated Transport			
Facilitated diffusion	Specific polar molecules for which carrier is available (e.g., glucose)	Passive; molecules move down concentration gradient (from high to low concentration)	Displays a transport maximum (T_m); carrier can become saturated
Primary active transport	Specific cations for which carriers are available (e.g., Na^+, K^+, H^+, Ca^{2+})	Active; ions move against concentration gradient (from low to high concentration); requires ATP	Displays a transport maximum; carrier can become saturated
Secondary active transport (symport or antiport)	Specific polar molecules and ions for which coupled transport carriers are available (e.g., glucose, amino acids for symport; some ions for antiport)	Active; substance moves against concentration gradient (from low to high concentration); driven directly by ion gradient (usually Na^+) established by ATP-requiring primary pump. In symport, cotransported molecule and driving ion move in same direction; in antiport, transported solute and driving ion move in opposite directions	Displays a transport maximum; coupled transport carrier can become saturated
Vesicular Transport			
Endocytosis			
Pinocytosis	Small volume of ECF fluid; also important in membrane recycling	Active; plasma membrane dips inward and pinches off at surface, forming internalized vesicle	Control poorly understood
Receptor-mediated endocytosis	Specific large polar molecule (e.g., protein)	Active; plasma membrane dips inward and pinches off at surface, forming internalized vesicle	Necessitates binding to specific receptor on membrane surface
Phagocytosis	Multimolecular particles (e.g., bacteria and cellular debris)	Active; cell extends pseudopods that surround particle, forming internalized vesicle	Necessitates binding to specific receptor on membrane surface
Exocytosis	Secretory products (e.g., hormones and enzymes) as well as large molecules that pass through cell intact; also important in membrane recycling	Active; increase in cytosolic Ca^{2+} induces fusion of secretory vesicle with plasma membrane; vesicle opens up and releases contents to outside	Secretion triggered by specific neural or hormonal stimuli; other controls involved in transcellular traffic and membrane recycling not known

---

membrane, or the relative number of positive and negative
charges differs between the two sides. A membrane potential
now exists. The attractive force between the separated charges
causes them to accumulate in a thin layer along the outer and
inner surfaces of the plasma membrane (❙Figure 3-19c). These
separated charges represent only a fraction of the total number
of charged particles (ions) present in the ICF and ECF, however,
and most fluid inside and outside the cells is electrically neutral
(❙Figure 3-19d). The electrically balanced ions can be ignored
because they do not contribute to membrane potential. Thus, an
almost insignificant fraction of the total number of charged
particles present in the body fluids is responsible for the mem-
brane potential.

Note that the membrane itself is not charged. The term
membrane potential refers to the difference in charge between
the wafer-thin regions of ICF and ECF lying next to the inside
and outside of the membrane, respectively. The magnitude of
the potential depends on the number of opposite charges sepa-
rated: The greater the number of charges separated, the larger

the potential. Therefore, in ❙Figure 3-19e membrane B has more
potential than A and less potential than C.

Membrane potential results from differences in the concentration and permeability of key ions.

All cells have membrane potential. The cells of **excitable
tissues**—namely, nerve cells and muscle cells—have the ability
to produce rapid, transient changes in their membrane poten-
tial when excited. These brief fluctuations in potential serve as
electrical signals. The constant membrane potential present in
the cells of nonexcitable tissues and those of excitable tissues
when they are at rest—that is, when they are not producing
electrical signals—is known as the **resting membrane poten-
tial**. Here, we concentrate on the generation and maintenance
of the resting membrane potential; in later chapters, we exam-
ine the changes that take place in excitable tissues during elec-
trical signaling.

The unequal distribution of a few key ions between the ICF and the ECF and their selective movement through the plasma membrane are responsible for the electrical properties of the membrane. In the body, electrical charges are carried by ions. The ions directly responsible for generating the resting membrane potential are Na^+ and K^+. The presence of large, negatively charged (anionic) intracellular proteins, written as A^-, is also important. Other ions (calcium, magnesium, and chloride, to name a few) do not contribute to the resting electrical properties of the plasma membrane in most cells, even though they play other important roles in the body.

The concentrations and relative permeabilities of the ions critical to membrane electrical activity are compared in ▮Table 3-3. Note that *Na^+ is more concentrated in the ECF and K^+ is more concentrated in the ICF*. These concentration differences are maintained by the Na^+–K^+ pump at the expense of energy. Because the plasma membrane is virtually impermeable to A^-, these large, negatively charged proteins are found only inside the cell. After they have been synthesized from amino acids transported into the cell, they remain trapped within the cell.

In addition to the active carrier mechanism, Na^+ and K^+ can passively cross the membrane through protein channels specific for them. It is usually much easier for K^+ than for Na^+ to get through the membrane because the membrane typically has many more leak channels always open for passive K^+ traffic than channels open for passive Na^+ traffic. At resting potential in a nerve cell, the membrane is typically about 25 to 30 times more permeable to K^+ than to Na^+.

Armed with knowledge of the relative concentrations and permeabilities of these ions, we can analyze the forces acting across the plasma membrane. We consider (1) the direct contributions of the Na^+–K^+ pump to membrane potential, (2) the effect that the movement of K^+ alone would have on membrane potential, (3) the effect of Na^+ alone, and (4) the situation that exists in the cells when both K^+ and Na^+ effects are taking place concurrently. Remember throughout this discussion that *the concentration gradient for K^+ will always be outward* and *the concentration gradient for Na^+ will always be inward* because the Na^+–K^+ pump maintains a higher concentration of K^+ inside the cell and a higher concentration of Na^+ outside the cell. Also, note that because K^+ and Na^+ are both cations (positively charged), *the electrical gradient for both of these ions will always be toward the negatively charged side of the membrane.*

▮**TABLE 3-3** Concentration and Permeability of Ions Responsible for Membrane Potential in a Resting Nerve Cell

Ion	Extracellular Concentration*	Intracellular Concentration*	Relative Permeability
Na^+	150	15	1
K^+	5	150	25–30
A^-	0	65	0

*Concentration expressed in millimoles per liter, mM

Effect of Na^+–K^+ Pump on Membrane Potential The Na^+–K^+ pump transports three Na^+ out for every two K^+ it transports in. Because Na^+ and K^+ are both positive ions, this unequal transport separates charges across the membrane, with the outside becoming relatively more positive and the inside becoming relatively more negative as more positive ions are transported out than in. However, this active-transport mechanism only separates enough charges to generate a small membrane potential of 1 mV to 3 mV, with the interior negative to the exterior of the cell. Most of the membrane potential results from the passive diffusion of K^+ and Na^+ down concentration gradients. Thus, the main role of the Na^+–K^+ pump in producing membrane potential is indirect, through its critical contribution to maintaining the concentration gradients directly responsible for the ion movements that generate most of the potential.

Effect of Movement of K^+ Alone on Membrane Potential: Equilibrium Potential for K^+ Consider a hypothetical situation characterized by (1) the concentrations that exist for K^+ and A^- across the plasma membrane, (2) free permeability of the membrane to K^+ but not to A^-, and (3) no potential as yet present. The concentration gradient for K^+ would tend to move these ions out of the cell (▮Figure 3-20). Because the membrane is permeable to K^+, these ions would readily pass through, carrying their positive charge with them, so more positive charges would be on the outside. At the same time, negative charges in the form of A^- would be left behind on the inside, similar to the situation shown in Figure 3-19b. (Remember that A^- cannot diffuse out, despite a tremendous concentration gradient.) A membrane potential would now exist. Because an electrical gradient would also be present, K^+ would be attracted toward the negatively charged interior and repelled by the positively charged exterior. Thus, two opposing forces would now be acting on K^+: the concentration gradient tending to move K^+ out of the cell and the electrical gradient tending to move these same ions into the cell.

Initially, the concentration gradient would be stronger than the electrical gradient, so net movement of K^+ out of the cell would continue and the membrane potential would increase. As more and more K^+ moved out of the cell, however, the opposing electrical gradient would become stronger as the outside became increasingly positive and the inside became increasingly negative. One might think that the outward concentration gradient for K^+ would gradually decrease as K^+ leaves the cell down this gradient. It is surprising, however, that the K^+ concentration gradient would remain essentially constant despite the outward movement of K^+. The reason is that even infinitesimal movement of K^+ out of the cell would bring about rather large changes in membrane potential. Accordingly, such an extremely small number of K^+ ions would have to leave the cell to establish an opposing electrical gradient that the K^+ concentration inside and outside the cell would remain essentially unaltered. As K^+ continued to move out down its unchanging concentration gradient, the inward electrical gradient would continue to increase in strength. Net outward movement would gradually be reduced as the strength of the electrical gradient approached that of the concentration gradient.

Concentration gradient for K$^+$

K$^+$

Electrical gradient for K$^+$

A$^-$

$E_{K^+} = -90$ mV
1　The concentration gradient for K$^+$ tends to move this ion out of the cell.

2　The outside of the cell becomes more positive as K$^+$ moves to the outside down its concentration gradient.

3　The membrane is impermeable to the large intracellular protein anion (A$^-$). The inside of the cell becomes more negative as K$^+$ moves out, leaving behind A$^-$.

4　The resulting electrical gradient tends to move K$^+$ into the cell.

5　No further net movement of K$^+$ occurs when the inward electrical gradient exactly counterbalances the outward concentration gradient. The membrane potential at this equilibrium point is the equilibrium potential for K$^+$ (E_{K^+}) at -90 mV.

IFigure 3-20　**Equilibrium potential for K$^+$.**

FIGURE FOCUS: *If the ECF concentration of K$^+$ decreases, does E_{K^+} become more negative, less negative, or stay the same?*

Finally, when these two forces exactly balanced each other (that is, when they were in dynamic equilibrium), no further net movement of K$^+$ would occur. The potential that would exist at this equilibrium is known as the **equilibrium potential for K$^+$** (**E_{K^+}**). At this point, a large concentration gradient for K$^+$ would still exist, but no more net movement of K$^+$ out of the cell would occur down this concentration gradient because of the exactly equal opposing electrical gradient (**I**Figure 3-20).

The membrane potential at E_{K^+} is -90 mV. By convention, *the sign always designates the polarity of the excess charge on the inside of the membrane.* A membrane potential of -90 mV means that the potential is of a magnitude of 90 mV, with the inside being negative relative to the outside. A potential of $+90$ mV would have the same strength, but the inside would be more positive than the outside. For convenience in depicting the charge separation responsible for potential, each pair of separated charges in a figure represents 10 mV of potential. (This is not technically correct because in reality many separated charges must be present to account for a potential of 10 mV.) Thus E_{K^+} in Figure 3-20 is represented by nine separated pairs of charges, with the negative charges lined up along the intracellular side of the membrane.

The equilibrium potential for a given ion with differing concentrations across a membrane can be calculated by means of the **Nernst equation** as follows:

$$E_{ion} = \frac{61}{z} \log \frac{C_o}{C_i}$$

where

$E_{ion} =$ equilibrium potential for ion in mV

　61 = a constant that incorporates the universal gas constant (R), absolute temperature (T), and an electrical constant known as Faraday (F), along with the conversion of the natural logarithm (*ln*) to the logarithm to base 10 (*log*); 61 = RT/F.

　　$z =$ the ion's valence; $z = 1$ for K$^+$ and Na$^+$, the ions that contribute to membrane potential

　$C_o =$ concentration of the ion outside the cell in millimoles/liter (millimolars; mM)

　$C_i =$ concentration of the ion inside the cell in mM

Given that the ECF concentration of K$^+$ is 5 mM and the ICF concentration is 150 mM (see **I**Table 3-3),

$$E_{K^+} = 61 \log \frac{5 \text{ mM}}{150 \text{ mM}}$$

$$= 61 \log \frac{1}{30}$$

Because the log of $1/30 = -1.477$,

$$E_{K^+} = 61(-1.477) = -90 \text{ mV}$$

Because 61 is a constant, the equilibrium potential is essentially a measure of the membrane potential (that is, the magnitude of the electrical gradient) that exactly counterbalances the concentration gradient for the ion (that is, the ratio between the ion's concentration outside and inside the cell). The larger the concentration gradient is for an ion, the greater the ion's equilibrium potential. A comparably greater opposing electrical gradient would be required to counterbalance the larger concentration gradient.

Effect of Movement of Na$^+$ Alone on Membrane Potential: Equilibrium Potential for Na$^+$ A similar hypothetical situation could be developed for Na$^+$ alone (**I**Figure 3-21). The concentration gradient for Na$^+$ would move these ions into the cell, producing a buildup of positive charges on the interior of the membrane and leaving negative charges unbalanced outside (primarily in the form of chloride, Cl$^-$; Na$^+$ and Cl$^-$—that is, salt—are the predominant ECF ions). Net inward movement would continue until equilib-

Plasma membrane

1 The concentration gradient for Na⁺ tends to move this ion into the cell.

2 The inside of the cell becomes more positive as Na⁺ moves to the inside down its concentration gradient.

3 The outside becomes more negative as Na⁺ moves in, leaving behind in the ECF unbalanced negatively charged ions, mostly Cl⁻.

4 The resulting electrical gradient tends to move Na⁺ out of the cell.

5 No further net movement of Na⁺ occurs when the outward electrical gradient exactly counterbalances the inward concentration gradient. The membrane potential at this equilibrium point is the equilibrium potential for Na⁺ (E_{Na^+}) at +60 mV.

E_{Na^+} = +60 mV

❚Figure 3-21 Equilibrium potential for Na⁺.

rium was established by the development of an opposing electrical gradient that exactly counterbalanced the concentration gradient. At this point, given the concentrations for Na⁺, the **equilibrium potential for Na⁺ (E_{Na^+})** as calculated by the Nernst equation would be +61 mV. Given that the ECF concentration of Na⁺ is 150 mM and the ICF concentration is 15 mM,

$$E_{Na^+} = 61 \log \frac{150 \text{ mM}}{15 \text{ mM}}$$

$$= 61 \log 10$$

Because the log of 10 = 1,

$$E_{Na^+} = 61(1) = 61 \text{ mV}$$

In this case, the inside of the cell would be positive, in contrast to the equilibrium potential for K⁺. The magnitude of E_{Na^+} is somewhat less than that for E_{K^+} (61 mV compared to 90 mV) because the concentration gradient for Na⁺ is not as large (see ❚Table 3-3); thus, the opposing electrical gradient (membrane potential) is not as great at equilibrium. (For convenience in representing the magnitude of separated charges in figures, we round E_{Na^+} to +60 mV.)

Simultaneous K⁺ and Na⁺ Effects on Membrane Potential Neither K⁺ nor Na⁺ exists alone in the body fluids, so equilibrium potentials are not present in body cells. They exist only in hypothetical or experimental conditions. In a living cell, the effects of both K⁺ and Na⁺ must be taken into account. *The greater the permeability of the plasma membrane for a given ion, the greater the tendency for that ion to drive the membrane potential toward the ion's equilibrium potential.* Because the membrane at rest is 25 to 30 times more permeable to K⁺ than to Na⁺, K⁺ passes through more readily than Na⁺; thus, K⁺ influences the resting membrane potential to a much greater extent than Na⁺ does. Recall that K⁺ acting

alone would establish an equilibrium potential of −90 mV. The membrane is somewhat permeable to Na⁺, however, so some Na⁺ enters the cell in a limited attempt to reach its equilibrium potential. This Na⁺ entry neutralizes, or cancels, some of the potential that would have been produced by K⁺ alone if Na⁺ were not present.

To better understand this concept, examine Figure 3-22, where nine separated pluses and minuses, with the minuses on the inside, represent the E_{K^+} of −90 mV. Superimposing the slight influence of Na⁺ on this K⁺-dominated membrane, assume that two Na⁺ enter the cell down the Na⁺ concentration and electrical gradients. (Note that the electrical gradient for Na⁺ is now inward in contrast to the outward electrical gradient for Na⁺ at E_{Na^+}. At E_{Na^+}, the inside of the cell is positive as a result of the inward movement of Na⁺ down its concentration gradient. In a resting nerve cell, however, the inside is negative because of the dominant influence of K⁺ on membrane potential. Thus, both the concentration and the electrical gradients now favor the inward movement of Na⁺.) The inward movement of these two positively charged Na⁺ neutralizes some of the potential established by K⁺, so now only seven pairs of charges are separated and the potential is −70 mV. This is the resting membrane potential of a typical nerve cell. The resting potential is much closer to E_{K^+} than to E_{Na^+} because of the greater permeability of the membrane to K⁺, but it is slightly less than E_{K^+} (−70 mV is a lower potential than −90 mV) because of the weak influence of Na⁺.

Membrane potential can be measured directly in experimental conditions by recording the voltage difference between the inside and outside of the cell, or it can be calculated using the **Goldman-Hodgkin-Katz equation (GHK equation)**, which takes into account the relative permeabilities and concentration gradients of all permeable ions. The stable, resting membrane is permeable to K⁺, Na⁺, and Cl⁻, but for reasons to be described later Cl⁻ does not directly contribute to potential

1 The Na⁺–K⁺ pump actively transports Na⁺ out of and K⁺ into the cell, keeping the concentration of Na⁺ high in the ECF and the concentration of K⁺ high in the ICF.

2 Given the concentration gradients that exist across the plasma membrane, K⁺ tends to drive membrane potential to the equilibrium potential for K⁺ (–90 mV), whereas Na⁺ tends to drive membrane potential to the equilibrium potential for Na⁺ (+60 mV).

3 However, K⁺ exerts the dominant effect on resting membrane potential because the membrane is more permeable to K⁺. As a result, resting potential (–70 mV) is much closer to E_{K^+} than to E_{Na^+}.

4 During the establishment of resting potential, the relatively large net diffusion of K⁺ outward does not produce a potential of –90 mV because the resting membrane is slightly permeable to Na⁺ and the relatively small net diffusion of Na⁺ inward neutralizes (in *gray* shading) some of the potential that would be created by K⁺ alone, bringing resting potential to –70 mV, slightly less than E_{K^+}.

5 The negatively charged intracellular proteins (A⁻) that cannot cross the membrane remain unbalanced inside the cell during the net outward movement of the positively charged ions, so the inside of the cell is more negative than the outside.
Resting membrane potential = −70 mV

❚Figure 3-22 **Effect of concurrent K⁺ and Na⁺ movement on establishing the resting membrane potential.**

in most cells. Therefore, we can ignore it when calculating membrane potential, making the simplified GHK equation:

$$V_m = 61 \log \frac{P_{K^+}[K^+]_o + P_{Na^+}[Na^+]_o}{P_{K^+}[K^+]_i + P_{Na^+}[Na^+]_i}$$

where

V_m = membrane potential in mV
61 = a constant representing RT/zF, when z = 1, as it does for K⁺ and Na⁺
P_{K^+}, P_{Na^+} = permeabilities for K⁺ and Na⁺, respectively
$[K^+]_o, [Na^+]_o$ = concentration of K⁺ and Na⁺ outside the cell in mM, respectively
$[K^+]_i, [Na^+]_i$ = concentration of K⁺ and Na⁺ inside the cell in mM, respectively.

The GHK equation is basically an expanded version of the Nernst equation. The Nernst equation can only be used to calculate the potential generated by a specific ion, but the GHK equation takes into account the combined contributions to potential of all ions moving across the membrane. Assuming the resting membrane is 25 times more permeable to K⁺ than to Na⁺, then the relative permeabilities are $P_{K^+} = 1.0$ and $P_{Na^+} = 0.04$ (1/25 of 1.0). Given these permeabilities and the concentrations for K⁺ and Na⁺ in the ECF and ICF listed in ❚Table 3-3,

$$V_m = 61 \log \frac{(1)(5) + (0.04)(150)}{(1)(150) + (0.04)(15)}$$

$$= 61 \log \frac{5 + 6}{150 + 0.6}$$

$$= 61 \log 0.073$$

Because the log of 0.073 is − 1.137,

$$V_m = 61 (−1.137) = −69 \text{ mV}$$

Adding −1 mV of potential generated directly by the Na⁺–K⁺ pump to this value totals −70 mV for the resting membrane potential.

Balance of Passive Leaks and Active Pumping at Resting Membrane Potential At resting potential, neither K⁺ nor Na⁺ is at equilibrium. A potential of −70 mV does not exactly counterbalance the concentration gradient for K⁺; it takes a potential of −90 mV to do that. Thus, K⁺ slowly continues to passively exit through its leak channels down this small concentration gradient. In the case of Na⁺, the concentration and electrical gradients do not even oppose each other; they both favor the inward movement of Na⁺. Therefore, Na⁺ continually leaks inward down its electrochemical gradient, but only slowly, because of its low permeability—that is, because of the scarcity of Na⁺ leak channels.

Such leaking goes on all the time, so why doesn't the intracellular concentration of K⁺ continue to fall and the concentration of Na⁺ inside the cell progressively increase? The reason is that the Na⁺–K⁺ pump counterbalances the rate of passive leakage. At resting potential, this pump transports back into the cell essentially the same number of potassium ions that have leaked out and simultaneously transports to the outside the sodium ions that have leaked in. At this point, a **steady state** exists: No net movement of any ions takes place because all passive leaks are exactly balanced by active pumping. No net change takes place in either a steady state or a dynamic equilibrium, but in a *steady state* energy must be used to maintain the constancy, whereas in a *dynamic equilibrium* no energy is needed to maintain the con-

The Plasma Membrane and Membrane Potential | **83**

stancy. That is, opposing passive and active forces counterbalance each other in a steady state and opposing passive forces counterbalance each other in a dynamic equilibrium. Because in the steady state across the membrane the active pump offsets the passive leaks, the concentration gradients for K^+ and Na^+ remain constant. Thus, the Na^+–K^+ pump not only is initially responsible for the Na^+ and K^+ concentration differences across the membrane but also maintains these differences.

As just discussed, the magnitude of these concentration gradients, together with the difference in permeability of the membrane to these ions, accounts for the magnitude of the membrane potential. Because the concentration gradients and permeabilities for Na^+ and K^+ remain constant in the resting state, the resting membrane potential established by these forces remains constant.

Chloride Movement at Resting Membrane Potential

Thus far, we have largely ignored one other ion present in high concentration in the ECF: Cl^-. Chloride is the principal ECF anion. Its equilibrium potential is -70 mV, exactly the same as the resting membrane potential. Movement alone of negatively charged Cl^- into the cell down its concentration gradient would produce an opposing electrical gradient, with the inside negative compared to the outside. When physiologists were first examining the ionic effects that could account for the membrane potential, they were tempted to think that Cl^- movements and establishment of the Cl^- equilibrium potential could be solely responsible for producing the identical resting membrane potential. Actually, the reverse is the case. The membrane potential is responsible for driving the distribution of Cl^- across the membrane.

Most cells are highly permeable to Cl^- but have no active-transport mechanisms for this ion. With no active forces acting on it, Cl^- passively distributes itself to achieve an individual state of equilibrium. In this case, Cl^- is driven out of the cell, establishing an inward concentration gradient that exactly counterbalances the outward electrical gradient (that is, the resting membrane potential) produced by K^+ and Na^+ movement. Thus, the concentration difference for Cl^- between the ECF and ICF is brought about passively by the presence of the membrane potential rather than maintained by an active pump, as is the case for K^+ and Na^+. Therefore, in most cells Cl^- does not influence resting membrane potential; instead, membrane potential passively influences the Cl^- distribution.

Specialized Use of Membrane Potential in Nerve and Muscle Cells

Nerve and muscle cells have developed a specialized use for membrane potential. They can rapidly and transiently alter their membrane permeabilities to the involved ions in response to appropriate stimulation, thereby bringing about fluctuations in membrane potential. The rapid fluctuations in potential are responsible for producing nerve impulses in nerve cells and for triggering contraction in muscle cells. These activities are the focus of the next five chapters. Even though all cells display a membrane potential, its significance in most other cells is uncertain; however, changes in membrane potential of some secretory cells—for example, insulin-secreting cells—have been linked to their level of secretory activity.

Homeostasis: Chapter in Perspective

All body cells must obtain vital materials, such as nutrients and O_2, from the surrounding ECF; they must also eliminate wastes to the ECF and release secretory products, such as chemical messengers and digestive enzymes. Thus, transport of materials across the plasma membrane between the ECF and the ICF is essential for cell survival, and the constituents of the ECF must be homeostatically maintained to support these life-sustaining exchanges.

Many cell types use membrane transport to carry out their specialized activities geared toward maintaining homeostasis. Here are several examples:

1. Absorption of nutrients from the digestive tract lumen involves the transport of these energy-giving molecules across the membranes of the cells lining the tract.

2. Exchange of O_2 and CO_2 between air and blood in the lungs involves the transport of these gases across the membranes of the cells lining the air sacs and blood vessels of the lungs.

3. Urine is formed by the selective transfer of materials between the blood and the fluid within the kidney tubules across the membranes of the cells lining the tubules.

4. The beating of the heart is triggered by cyclic changes in the transport of Na^+, K^+, and Ca^{2+} across the heart cells' membranes.

5. Secretion of chemical messengers such as neurotransmitters from nerve cells and hormones from endocrine cells involves the transport of these regulatory products to the ECF on appropriate stimulation.

In addition to providing selective transport of materials between the ECF and the ICF, the plasma membrane contains receptors for binding with specific chemical messengers that regulate various cell activities, many of which are specialized activities aimed toward maintaining homeostasis. For example, the hormone vasopressin, which is secreted in response to a water deficit in the body, binds with receptors in the plasma membrane of a specific type of kidney cell. This binding triggers the cells to conserve water during urine formation by promoting the insertion of additional aquaporins (water

channels) in the plasma membrane of these cells, thus helping alleviate the water deficit that initiated the response.

All living cells have a membrane potential, with the cell's interior being slightly more negative than the fluid surrounding the cell when the cell is electrically at rest. The specialized activities of nerve and muscle cells depend on these cells' ability to change their membrane potential rapidly on appropriate stimulation. The transient, rapid changes in potential in nerve cells serve as electrical signals or nerve impulses, which provide a means to transmit information along nerve pathways. This information is used to accomplish homeostatic adjustments, such as restoring blood pressure to normal when signaled that it has fallen too low.

Rapid changes in membrane potential in muscle cells trigger muscle contraction, the specialized activity of muscle. Muscle contraction contributes to homeostasis in many ways, including the pumping of blood by the heart and the movement of food through the digestive tract.

Review Exercises Answers begin on p. A-22

Reviewing Terms and Facts

1. The nonpolar tails of the phospholipid molecules bury themselves in the interior of the plasma membrane. *(True or false?)*

2. Cells shrink when in contact with a hypertonic solution. *(True or false?)*

3. Channels are open to both sides of the membrane at the same time, but carriers are open to only one side of the membrane at a time. *(True or false?)*

4. At resting membrane potential, there is a slight excess of _____ *(positive/negative)* charges on the inside of the membrane, with a corresponding slight excess of _____ *(positive/ negative)* charges on the outside.

5. Using the answer code on the right, indicate which membrane component is responsible for the function in question:

    1. channel formation   (a) lipid bilayer
    2. barrier to passage of water-   (b) proteins
        soluble substances   (c) carbohydrates
    3. receptor sites
    4. membrane fluidity
    5. recognition of "self"
    6. membrane-bound enzymes
    7. structural boundary
    8. carriers

6. Using the answer code on the right, indicate the direction of net movement in each case:

    1. simple diffusion   (a) movement from high
    2. facilitated diffusion   to low concentration
    3. primary active transport   (b) movement from low
    4. Na^+ during symport or   to high concentration
        antiport
    5. transported solute during
        symport or antiport
    6. water with regard to the
        water concentration gradient
        during osmosis
    7. water with regard to the
        solute concentration
        gradient during osmosis

7. Using the answer code on the right, indicate the type of cell junction described:

    1. adhering junction   (a) gap junction
    2. impermeable junction   (b) tight junction
    3. communicating junction   (c) desmosome
    4. made up of connexons, which
        permit passage of ions and small
        molecules between cells
    5. consisting of interconnecting fibers,
        which spot-rivet adjacent cells
    6. formed by an actual fusion of
        proteins on the outer surfaces of
        two interacting cells
    7. important in tissues subject to
        mechanical stretching
    8. important in synchronizing
        contractions within heart and
        smooth muscle by allowing spread
        of electrical activity between the
        cells composing the muscle mass
    9. important in preventing passage
        between cells in epithelial sheets
        that separate compartments of two
        different chemical compositions

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Describe the fluid mosaic model of membrane structure.

2. Discuss the functions of the three major types of protein fibers in the extracellular matrix.

3. What two properties of a particle influence whether it can permeate the plasma membrane?

4. List and describe the methods of membrane transport. Indicate what types of substances are transported by each method, and state whether each means of transport is passive or active and unassisted or assisted.

5. According to Fick's law of diffusion, what factors influence the rate of net diffusion across a membrane?

6. State three important roles of the Na^+–K^+ pump.

7. Describe the contribution of each of the following to establishing and maintaining membrane potential: (a) the Na^+–K^+ pump, (b) passive movement of K^+ across the membrane, (c) passive movement of Na^+ across the membrane, and (d) the large intracellular anions.

Solving Quantitative Exercises

1. Using the Nernst equation, calculate the equilibrium potential for Ca^{2+} and for Cl^- from the following sets of data:

   a. Given $[Ca^{2+}]_o = 1$ mM, $[Ca^{2+}]_i = 100$ nM, find $E_{Ca^{2+}}$

   b. Given $[Cl^-]_o = 110$ mM, $[Cl^-]_i = 10$ mM, find E_{Cl^-}

2. One of the important uses of the Nernst equation is in describing the flow of ions across plasma membranes. Ions move under the influence of two forces: the concentration gradient (given in electrical units by the Nernst equation) and the electrical gradient (given by the membrane voltage). This is summarized by *Ohm's law*:

$$I_x = G_x (V_m - E_x)$$

which describes the movement of ion x across the membrane. I is the current in amperes (A); G is the conductance, a measure of the permeability of x, in Siemens (S), which is $\Delta I/\Delta V$; V_m is the membrane voltage; and E_x is the equilibrium potential of ion x. Not only does this equation tell how large the current is, but it also tells what direction the current is flowing. By convention, a negative value of the current represents either a positive ion entering the cell or a negative ion leaving the cell. The opposite is true of a positive value of the current.

   a. Using the following information, calculate the magnitude of I_{Na^+}.

   $[Na^+]_o = 145$ mM, $[Na^+]_i = 15$ mM, $G_{Na^+} = 1$ nS, $V_m = -70$ mV

   b. Is Na^+ entering or leaving the cell?

   c. Is Na^+ moving with or against the concentration gradient? Is it moving with or against the electrical gradient?

3. Using the Goldman-Hodgkin-Katz equation, determine what happens to the resting membrane potential if the ECF K^+ concentration doubles to 10 mM.

Applying Clinical Reasoning

When William H. was helping victims after a devastating earthquake in a region not prepared to swiftly set up adequate temporary shelter, he developed severe diarrhea. He was diagnosed as having *cholera,* a disease transmitted through unsanitary water supplies contaminated by fecal material from infected individuals. The toxin produced by cholera bacteria causes Cl^- channels in the luminal membranes of the intestinal cells to stay open, thereby increasing the secretion of Cl^- from the cells into the intestinal tract lumen. By what mechanisms would Na^+ and water be secreted into the lumen in conjunction with Cl^- secretion? How does this secretory re-

sponse account for the severe diarrhea that is characteristic of cholera?

Thinking at a Higher Level

1. Which of the following methods of transport is being used to transfer the substance into the cell in the accompanying graph?
   a. diffusion down a concentration gradient

   b. osmosis

   c. facilitated diffusion

   d. active transport

   e. vesicular transport

   f. It is impossible to tell with the information provided.

2. Assume that a membrane permeable to Na^+ but not to Cl^- separates two solutions. The concentration of sodium chloride on side 1 is higher than on side 2. Which of the following ionic movements would occur?

   a. Na^+ would move until its concentration gradient is dissipated (until the concentration of Na^+ on side 2 is the same as the concentration of Na^+ on side 1).

   b. Cl^- would move down its concentration gradient from side 1 to side 2.

   c. A membrane potential, negative on side 1, would develop.

   d. A membrane potential, positive on side 1, would develop.

   e. None of the preceding is correct.

3. A solution may have the same osmolarity as normal body fluids yet it may not be isotonic. Explain why.

4. Compared to resting potential, would the membrane potential become more negative or more positive if the membrane were more permeable to Na^+ than to K^+?

5. Colostrum, the first milk that a mother produces, contains an abundance of antibodies, large protein molecules. These maternal antibodies help protect breast-fed infants from infections until the babies are capable of producing their own antibodies. By what means would you suspect these maternal antibodies are transported across the cells lining a newborn's digestive tract into the bloodstream?

Principles of Neural and Hormonal Communication
Science Source

A transmission electron micrograph of two adjacent synapses. A synapse is a junction between two neurons separated by a narrow space (*highlighted in purple*). The presynaptic neuron (*light blue, top left or right*) transmits information across the space to the postsynaptic neuron (*darker blue, middle*) by means of a chemical messenger (a neurotransmitter) released from synaptic vesicles (*small orange spheres*).

CHAPTER AT A GLANCE

Homeostasis Highlights

To maintain homeostasis, cells must work in a coordinated fashion toward common goals. The two major regulatory systems of the body that help ensure life-sustaining coordinated responses are the nervous and endocrine systems. **Neural communication** is accomplished by means of nerve cells, or neurons, which are specialized for rapid electrical signaling and for secreting neurotransmitters, short-distance chemical messengers that act on nearby target organs. The nervous system exerts rapid control over most of the body's muscles and exocrine secretions. **Hormonal communication** is accomplished by hormones, which are long-distance chemical messengers secreted by the endocrine glands into the blood. The blood carries the hormones to distant target sites, where they regulate processes that require duration rather than speed, such as metabolic activities, water and electrolyte balance, and growth.

4.1 Introduction to Neural Communication

All body cells display a membrane potential, which is a separation of positive and negative charges across the membrane, as discussed in the preceding chapter (see pp. 77–84). This potential is related to the uneven distribution of sodium (Na^+), potassium (K^+), and large intracellular protein anions between the intracellular fluid (ICF) and the extracellular fluid (ECF) and to the differential permeability of the plasma membrane to these ions.

Figure 4-1 Types of changes in membrane potential.

Nerve and muscle are excitable tissues.

The constant membrane potential present when a cell is electrically at rest—that is, not producing electrical signals—is referred to as the *resting membrane potential.* Two types of cells, *neurons (nerve cells)* and *muscle cells,* have developed a specialized use for membrane potential. They can undergo transient, rapid fluctuations in their membrane potentials, which serve as electrical signals.

Nerve and muscle are considered **excitable tissues** because they produce electrical signals when excited. Neurons use these electrical signals to receive, process, initiate, and transmit messages. In muscle cells, these electrical signals initiate contraction. Thus, electrical signals are critical to the function of the nervous system and all muscles. In this chapter, we examine how neurons undergo changes in potential to accomplish their function. Muscle cells are discussed in later chapters.

Membrane potential becomes less negative during depolarization and more negative during hyperpolarization.

Before you can understand what electrical signals are and how they are created, you must become familiar with several terms used to describe changes in potential, which are graphically represented in ❙Figure 4-1:

1. **Polarization.** Charges are separated across the plasma membrane, so the membrane has potential. Any time membrane potential is other than 0 millivolts (mV), in either the positive or the negative direction, the membrane is in a state of polarization. Recall that the magnitude of the potential is directly proportional to the number of positive and negative charges separated by the membrane and that the sign of the potential ($+$ or $-$) always designates whether excess positive or excess negative charges are present, respectively, on the inside of the membrane. At resting potential, the membrane is polarized at -70 mV in a typical neuron (see p. 82).

2. **Depolarization.** The membrane becomes less polarized; the inside becomes less negative than at resting potential, with the potential moving closer to 0 mV (for example, a change from -70 to -60 mV); fewer charges are separated than at resting potential. This term also refers to the inside even becoming positive as it does during an action potential (a major type of electrical signal) when the membrane potential reverses itself (for example, becoming $+30$ mV).
3. **Repolarization.** The membrane returns to resting potential after having been depolarized.

4. **Hyperpolarization.** The membrane becomes more polarized; the inside becomes more negative than at resting potential, with the potential moving even farther from 0 mV (for instance, a change from -70 to -80 mV); more charges are separated than at resting potential.

One possibly confusing point should be clarified. On the device used for recording rapid changes in potential, during a depolarization, when the inside becomes less negative than at resting, this *decrease* in the magnitude of the potential is represented as an *upward* deflection. By contrast, during a hyperpolarization, when the inside becomes more negative than at resting, this *increase* in the magnitude of the potential is represented by a *downward* deflection.

Electrical signals are produced by changes in ion movement across the plasma membrane.

Changes in membrane potential are brought about by changes in ion movement across the membrane. For example, if the net inward flow of positively charged ions increases compared to the resting state (such as more Na^+ moves in), the membrane depolarizes (becomes less negative inside). By contrast, if the net outward flow of positively charged ions increases compared to the resting state (such as more K^+ moves out), the membrane hyperpolarizes (becomes more negative inside).

Changes in ion movement are brought about by changes in membrane permeability in response to triggering events. A **triggering event** triggers a change in membrane potential by altering membrane permeability and consequently altering ion flow across the membrane. These ion movements redistribute charge, thus changing the potential.

Because the water-soluble ions responsible for carrying charges cannot penetrate the plasma membrane's lipid bilayer, these charges can cross the membrane only through channels specific for them or by carrier-mediated transport. Membrane channels may be either *leak channels* or *gated channels.* As described in Chapter 3, leak channels, which are open all the time, permit unregulated leakage of their specific ion across the membrane through the channels. **Gated channels**, in contrast, have gates that can be open or closed, permitting ion passage through the channels when open and preventing

ion passage through the channels when closed. Gate opening and closing occurs in response to a triggering event that causes a change in the conformation (shape) of the protein that forms the gated channel. There are four kinds of gated channels, depending on the factor that causes the channel to change shape: (1) **Voltage-gated channels** open or close in response to changes in membrane potential, (2) **chemically gated channels** change shape in response to binding of a specific extracellular chemical messenger to a surface membrane receptor, (3) **mechanically gated channels** respond to stretching or other mechanical deformation, and (4) **thermally gated channels** respond to local changes in temperature (heat or cold).

There are two basic forms of electrical signals: (1) *graded potentials,* which serve as short-distance signals, and (2) *action potentials,* which signal over long distances. We next examine these types of signals in more detail.

4.2 Graded Potentials

Graded potentials are local changes in membrane potential that occur in varying grades or degrees of magnitude or strength. For example, membrane potential could change from −70 to −60 mV (a 10-mV graded potential) or from −70 to −50 mV (a 20-mV graded potential).

The stronger a triggering event, the larger the resultant graded potential.

Graded potentials are usually produced by a specific triggering event that causes gated ion channels to open in a specialized region of the excitable cell membrane. The resultant ion movement produces the graded potential, which most commonly is a depolarization resulting from net Na$^+$ entry. The graded potential is confined to this small, specialized region of the total plasma membrane.

The magnitude of the initial graded potential (that is, the difference between the new potential and the resting potential) is related to the magnitude of the triggering event. *The stronger the triggering event, the larger the resultant graded potential.* Here's why, using gated channels that permit net Na$^+$ entry as a common example: The stronger the triggering event is, the more gated Na$^+$ channels open. As more gated Na$^+$ channels open, more positive charges in the form of Na$^+$ enter the cell. The more positive charges that enter the cell, the less negative (more depolarized) the inside becomes at this specialized region. This depolarization is the graded potential.

Also, the duration of the graded potential varies, depending on how long the triggering event keeps the gated channels open. *The longer the duration of the triggering event, the longer the duration of the graded potential.*

Graded potentials spread by passive current flow.

When a graded potential occurs locally in a nerve or muscle cell membrane, the rest of the membrane remains at resting potential. The temporarily depolarized region is called an *active area*. Note from ❚ Figure 4-2b that, inside the cell, the active area is relatively more positive than the neighboring *inactive areas* that are still at resting potential. Outside the cell, the active area is relatively less positive than adjacent inactive areas. Because of this difference in potential, electrical charges, which are carried by ions, passively flow between the active and the adjacent resting regions on both the inside and the outside of the membrane. Any flow of electrical charges is called a **current**. By convention, the direction of current flow is always expressed as the direction in which the positive charges are moving (❚ Figure 4-2c). Inside the cell, positive charges flow through the ICF away from the relatively more positive depolarized active region toward the more negative adjacent resting regions. Outside the cell, positive charges flow through the ECF from the more positive adjacent inactive regions toward the relatively more negative active region. Ion movement (that is, current) is occurring *along* the membrane between regions next to each other on the same side of the membrane. This flow is in contrast to ion movement *across* the membrane through ion channels or by means of carriers.

As a result of local current flow between an active area and an adjacent inactive area, the potential changes in the previously inactive area. Because positive charges have flowed simultaneously into the adjacent inactive area on the inside and out of this area on the outside, the adjacent area is now more positive (or less negative) on the inside than before and less positive (or more negative) on the outside (❚ Figure 4-2c). Stated differently, the previously inactive adjacent area has been depolarized, so the graded potential has spread. This area's potential now differs from that of the inactive region immediately next to it on the other side, inducing further current flow at this new site, and so on. In this manner, current spreads in both directions away from the initial site of the change in potential.

The amount of current that flows between two areas depends on the difference in potential between the areas and on the resistance of the material through which the charges are moving. **Resistance** is the hindrance to electrical charge movement. The *greater* the difference in potential, the *greater* the current flow; by contrast, the *lower* the resistance, the *greater* the current flow. *Conductors* have low resistance, providing little hindrance to current flow. Electrical wires and the ICF and ECF are all good conductors, so current readily flows through them. *Insulators* have high resistance and greatly hinder movement of charge. The plastic surrounding electrical wires has high resistance, as do body lipids. Thus, current does not flow directly through the plasma membrane's lipid bilayer. Current, carried by ions, can move across the membrane only through ion channels.
(a) Entire membrane at resting potential
(b) Inward movement of Na⁺ depolarizes membrane, producing a graded potential
(c) Depolarization spreads by local current flow to adjacent inactive areas, away from point of origin

❙Figure 4-2 **Current flow during a graded potential.** (a) The membrane of an excitable cell at resting potential. (b) A triggering event opens ion channels, usually leading to net Na⁺ entry that depolarizes the membrane at this site. The adjacent inactive areas are still at resting potential. (c) Local current flows between the active and adjacent inactive areas, resulting in depolarization of the previously inactive areas. In this way, the depolarization spreads away from its point of origin.

Graded potentials die out over short distances.

The passive current flow between active and adjacent inactive areas is similar to the means by which current is carried through electrical wires. We know from experience that current leaks out of an electrical wire with dangerous results unless the wire is covered with an insulating material such as plastic. (People can get an electric shock if they touch a bare wire.) Likewise, current is lost across the plasma membrane as

charge-carrying ions in the form of K⁺ leak out through the "uninsulated" parts of the membrane— that is, by diffusing outward down their electrochemical gradient through open K⁺ leak channels. Because of this current loss, the magnitude of the local current—and thus the magnitude of the graded potential— progressively diminishes the farther it moves from the initial active area (❙Figure 4-3a). Another way of saying this is that the spread of a graded potential is *decremental* (gradually decreases) (❙Figure 4-3b). Note that in this example the magnitude of the initial change in potential is 15 mV (a change from the resting state of −70 to −55 mV); the change in potential decreases as it moves along the membrane to a potential of 10 mV (from −70 to −60 mV) and continues to diminish the farther it moves away from the initial active area until there is no longer a change in potential. In this way, local currents die out within micrometers (less than 1 mm) as they move away from the initial site of change in potential and consequently can function as signals for only very short distances.

Although graded potentials have limited signaling distance, they are critically important to the body's function, as explained in later chapters. The following are all graded potentials: *postsynaptic potentials, receptor potentials, end-plate potentials, pacemaker potentials,* and *slow-wave potentials.* These terms are unfamiliar to you now, but you will become well acquainted with them as we continue discussing nerve and muscle physiology. We are including this list here because it is the only place all these types of graded potentials are listed together. For now it's enough to say that most excitable cells produce one of these types of graded potentials in response to a triggering event. In turn, graded potentials can initiate action potentials, the long-distance signals, in an excitable cell.

2. Compare how an increase in the difference in potential and an increase in resistance would affect current flow.

3. Explain why the spread of graded potentials is decremental.

4.3 Action Potentials

Action potentials are brief, rapid, large (100-mV) changes in membrane potential during which the potential actually reverses so that the inside of the excitable cell transiently becomes more positive than the outside. As with a graded potential, a single action potential involves only a small portion of the total excitable cell membrane. Unlike graded potentials, however, action potentials are conducted, or propagated, throughout the entire membrane *nondecrementally*—that is, they do not diminish in

strength as they travel from their site of initiation throughout the remainder of the cell membrane. Thus, action potentials can serve as faithful long-distance signals.

Think about the neuron that causes the muscle cells in your big toe to contract (see ❙Figure 4-7, p. 95). If you want to wiggle your big toe, commands are sent from your brain down your spinal cord to initiate an action potential at the beginning of this neuron, which is located in the spinal cord. The action potential travels all the way down the neuron's long axon, which runs through your leg to terminate on your big-toe muscle cells. The signal does not weaken or die off, being instead preserved at full strength from beginning to end.

Let us now consider the changes in potential during an action potential before we see how action potentials spread throughout the cell membrane without diminishing.

During an action potential, the membrane potential rapidly, transiently reverses.

If a graded potential is large enough, it can initiate an action potential before the graded change dies off. (Later you will discover how this initiation is accomplished for the various types of graded potentials.) Typically, the region of the excitable membrane where graded potentials are produced in response to a triggering event does not undergo action potentials. Instead, passive current flow from the region where a graded potential is taking place depolarizes adjacent portions of the membrane where action potentials can occur.

Depolarization from the resting potential of −70 mV proceeds slowly until it reaches a critical level known as **threshold potential**, typically between −50 and −55 mV (❙Figure 4-4). At threshold potential, an explosive depolarization takes place. A recording of the potential at this time shows a sharp upward

deflection as the potential rapidly reverses itself so that the inside of the cell becomes positive compared to the outside. Peak potential is usually +30 to +40 mV, depending on the excitable cell. Just as rapidly, the membrane repolarizes, dropping back to resting potential. Often, the forces that repolarize the membrane push the potential too far, causing a brief **after hyperpolarization**, during which the inside of the membrane briefly becomes even more negative than normal (for example, −80 mV) before resting potential is restored.

The action potential is the entire rapid change in potential from threshold to peak and then back to resting. If the initial triggered depolarization does not reach threshold potential, no action potential takes place. Therefore, threshold is a critical point: Either the membrane is depolarized to threshold and an action potential takes place, or threshold is not reached in response to the depolarizing event and no action potential occurs.

Unlike the variable duration of a graded potential, the duration of an action potential is always the same in a given excitable cell. In a neuron, an action potential lasts for only 1 msec (0.001 second). It lasts longer in muscle, with the duration depending on the muscle type.

Often an action potential is referred to as a **spike** because of its spikelike recorded appearance. Alternatively, when an excitable membrane is triggered to undergo an action potential, it is said to **fire**. Thus, the terms *action potential, spike,* and *firing* all refer to the same phenomenon of rapid reversal of membrane potential.

Marked changes in membrane permeability and ion movement lead to an action potential.

How is the membrane potential, which is usually maintained at a constant resting level, altered to such an extent as to produce an action potential? Recall that K^+ makes the greatest contribution to the establishment of the resting potential because the membrane at rest is considerably more permeable to K^+ than to Na^+ (see pp. 80 and 82). During an action potential, marked changes in membrane permeability to Na^+ and K^+ take place, permitting rapid fluxes of these ions down their electrochemical

gradients. These ion movements carry the current responsible for the potential changes that occur during an action potential. Action potentials take place as a result of the triggered opening and subsequent closing of two specific types of channels: voltage-gated Na^+ channels and voltage-gated K^+ channels.

Voltage-Gated Na^+ and K^+ Channels Voltage-gated membrane channels consist of proteins that have many charged groups. The electrical field (potential) surrounding the channels can distort the channel structure as charged portions of the channel proteins are electrically attracted or repelled by charges in the fluids around the membrane. Unlike most membrane proteins, which remain stable despite fluctuations in membrane potential, voltage-gated channel proteins are especially sensitive to voltage changes. Small distortions in shape induced by changes in potential can cause channel gates to open or close. Here, again, is an example of how subtle changes in structure can profoundly influence function.

The voltage-gated Na^+ channel has two gates: an activation gate and an inactivation gate (❙Figure 4-5). The *activation gate* guards the channel interior by opening and closing like a sliding door. The *inactivation gate* consists of a ball-and-chain-like sequence of amino acids at the channel opening facing the ICF. This gate is open when the ball is hanging free on the end of its chain and closed when the ball binds to the channel opening, thus blocking the opening. Both gates must be open to permit passage of Na^+ through the channel, and closure of either gate prevents passage. This voltage-gated Na^+ channel can exist in three conformations: (1) *closed but capable of opening* (activation gate closed, inactivation gate open; ❙Figure 4-5a); (2) *open, or activated* (both gates open, ❙Figure 4-5b); and (3) *closed and not capable of opening,* or *inactivated* (activation gate open, inactivation gate closed, ❙Figure 4-5c). The channel moves through these various conformations as a result of voltage changes that take place during an action potential, as described shortly. When the action potential is over and the membrane has returned to resting potential, the channel reverts back to its "closed but capable of opening" conformation.

The voltage-gated K^+ channel is simpler. It has only an activation gate, which can be either closed (❙Figure 4-5d) or open

❙Figure 4-5 **Conformations of voltage-gated sodium and potassium channels.**

(❙Figure 4-5e). These voltage-gated Na^+ and K^+ channels exist in addition to the Na^+–K^+ pump and the leak channels for these ions (described in Chapter 3).

Changes in Permeability and Ion Movement During an Action Potential At resting potential (-70 mV), all voltage-gated channels for both Na^+ and K^+ are closed, with the activation gates of the Na^+ channels being closed and their inactivation gates being open—that is, the voltage-gated Na^+ channels are in their "closed but capable of opening" conformation. Therefore, Na^+ and K^+ cannot pass through these voltage-gated channels at resting potential. However, because many K^+ leak channels and few Na^+ leak channels are present, the resting membrane is 25 to 30 times more permeable to K^+ than to Na^+.

When current spreads passively from an adjacent site already depolarized (such as from a site undergoing a graded potential) into a new region still at resting potential, the new region of membrane starts to depolarize toward threshold. This depolarization causes the activation gates of some voltage-gated Na^+ channels in the new region to open so that both gates of these activated channels are now open. Because both the concentration and the electrical gradients for Na^+ favor its movement into the cell, Na^+ starts to move in. The inward movement of positively charged Na^+ depolarizes the membrane further, opening even more voltage-gated Na^+ channels and allowing more Na^+ to enter, and so on, in a positive-feedback cycle.

At threshold potential, Na^+ permeability, which is symbolized as P_{Na^+}, increases explosively as the membrane swiftly becomes about 600 times more permeable to Na^+ than to K^+. Each channel is either closed or open and cannot be partially open. However, the delicately poised gating mechanisms of the various voltage-gated Na^+ channels are jolted open by slightly different voltage changes. During the early depolarizing phase, more and more Na^+ channels open as the potential progressively decreases. At threshold, enough Na^+ gates have opened to set off the positive-feedback cycle that rapidly causes the remaining Na^+ gates to open. Now Na^+ permeability dominates the membrane, in contrast to the K^+ domination at resting potential. Thus, at threshold Na^+ rushes into the cell, rapidly eliminating the internal negativity and even making the inside of the cell more positive than the outside in an attempt to drive the membrane potential to the Na^+ equilibrium potential (which is $+61$ mV; see p. 82). The potential reaches $+30$ mV, close to the Na^+ equilibrium potential. The potential does not become any more positive because, at the peak of the action potential, the Na^+ channels start to close to the inactivated state and P_{Na^+} starts to fall to its low resting value (❙Figure 4-6).

What causes the Na^+ channels to close? When the membrane potential reaches threshold, two closely related events take place in each Na^+ channel's gates. First, the activation gate is triggered to *open rapidly* in response to the depolarization, converting the channel to its open (activated) conformation. Surprisingly, the conformational change that opens the channel also allows the inactivation gate's ball to bind to the channel opening, thereby physically blocking the mouth of the channel. However, this closure process takes time, so the inactivation gate *closes*

slowly compared to the rapidity of channel opening (see ❙Figure 4-5c). Meanwhile, during the 0.5-msec delay after the activation gate opens and before the inactivation gate closes, both gates are open and Na^+ rushes into the cell through these open channels, bringing the action potential to its peak. Then the inactivation gate closes, membrane permeability to Na^+ plummets to its low resting value, and further Na^+ entry is prevented. The channel remains in this inactivated conformation until the membrane potential has been restored to resting.

Simultaneous with inactivation of Na^+ channels, the voltage-gated K^+ channels start to slowly open at the peak of the action potential. Opening of the K^+ channel gate is a delayed voltage-gated response triggered by the initial depolarization to threshold (see ❙Figures 4-5e and 4-6). Thus, three action potential–related events occur at threshold: (1) rapid opening of the Na^+ activation gates, which permits Na^+ to enter, moving the potential from threshold to its positive peak; (2) slow closing of the Na^+ inactivation gates, which halts further Na^+ entry after a brief time delay, thus keeping the potential from rising any further; and (3) slow opening of the K^+ gates, which is in large part responsible for the potential plummeting from its peak back to resting.

The membrane potential would gradually return to resting after closure of the Na^+ channels as K^+ continued to leak out but no further Na^+ entered. However, the return to resting is hastened by the opening of K^+ gates at the peak of the action potential. Opening of the voltage-gated K^+ channels greatly increases K^+ permeability (designated P_{K^+}) to about 300 times the resting P_{Na^+}. This marked increase in P_{K^+} causes K^+ to rush out of the cell down its electrochemical gradient, carrying positive charges back to the outside. Note that at the peak of the action potential, the positive potential inside the cell tends to repel the positive K^+ ions, so the electrical gradient for K^+ is outward, unlike at resting potential. Of course, the concentration gradient for K^+ is always outward. The outward movement of K^+ rapidly restores the negative resting potential.

To review (see ❙Figure 4-6), *the rising phase of the action potential* (from threshold to $+30$ mV) *is due to Na^+ influx* (Na^+ entering the cell) induced by an explosive increase in P_{Na^+} at threshold. The *falling phase* (from $+30$ mV to resting potential) *is brought about largely by K^+ efflux* (K^+ leaving the cell) caused by the marked increase in P_{K^+} occurring at the peak of the action potential.

As the potential returns to resting, the changing voltage shifts the Na^+ channels to their "closed but capable of opening" conformation, with the activation gate closed and the inactivation gate open. Now the channel is reset, ready to respond to another triggering event. The newly opened voltage-gated K^+ channels also close, so the membrane returns to the resting number of open K^+ leak channels. Typically, the voltage-gated K^+ channels are slow to close. As a result of this persistent increased permeability to K^+, more K^+ may leave than is necessary to bring the potential to resting. This slightly excessive K^+ efflux makes the interior of the cell transiently even more negative than resting potential, causing the after hyperpolarization. When the voltage-gated K^+ channels all close, the membrane returns to resting potential, where it remains until another triggering event alters the gated Na^+ and K^+ channels.

1 Resting potential: all voltage-gated channels closed.

2 At threshold, Na+ activation gate opens and P_{Na^+} rises.

3 Na+ enters cell, causing explosive depolarization to +30 mV, which generates rising phase of action potential.

4 At peak of action potential, Na+ inactivation gate closes and P_{Na^+} falls, ending net movement of Na+ into cell. At the same time, K+ activation gate opens and P_{K^+} rises.

5 K+ leaves cell, causing its repolarization to resting potential, which generates falling phase of action potential.

6 On return to resting potential, Na+ activation gate closes and inactivation gate opens, resetting channel to respond to another depolarizing triggering event.

7 Further outward movement of K+ through still-open K+ channel briefly hyperpolarizes membrane, which generates after hyperpolarization.

8 K+ activation gate closes, and membrane returns to resting potential.

Figure 4-6 **Permeability changes and ion fluxes during an action potential.**
FIGURE FOCUS: *Compare the status of the voltage-gated Na+ and K+ channels during the rising and falling phases of an action potential.*

The Na+–K+ pump gradually restores the concentration gradients disrupted by action potentials.

At the completion of an action potential, the membrane potential has been restored to resting, but the ion distribution has been altered slightly. Na+ entered the cell during the rising phase, and K+ left during the falling phase. The Na+–K+ pump restores these ions to their original locations in the long run, but not after each action potential.

The active pumping process takes much longer to restore Na+ and K+ to their original locations than it takes for the passive fluxes of these ions during an action potential. However, the membrane does not need to wait until the concentration gradients are slowly restored before it can undergo another action potential. Actually, the movement of relatively few Na+

and K^+ ions causes the large swings in membrane potential that occur during an action potential. Only about 1 out of 100,000 K^+ ions present in the cell leaves during an action potential, while a comparable number of Na^+ ions enter from the ECF. The movement of this extremely small proportion of the total Na^+ and K^+ during a single action potential produces dramatic 100-mV changes in potential (between -70 and $+30$ mV) but only infinitesimal changes in the ICF and ECF concentrations of these ions. Much more K^+ is still inside the cell than outside, and Na^+ is still predominantly extracellular. Consequently, the Na^+ and K^+ concentration gradients still exist, so repeated action potentials can occur without the pump having to keep pace restoring the gradients.

Were it not for the pump, even tiny fluxes accompanying repeated action potentials would eventually "run down" the concentration gradients so that further action potentials would be impossible. If the concentrations of Na^+ and K^+ were equal between the ECF and the ICF, changes in permeability to these ions would not bring about ion fluxes, so no change in potential would occur. Thus, the Na^+–K^+ pump is critical to maintaining the concentration gradients in the long run. However, it does not have to perform its role between action potentials, nor is it directly involved in the ion fluxes or potential changes that occur during an action potential.

Action potentials are propagated from the axon hillock to the axon terminals.

A single action potential involves only a small patch of the total surface membrane of an excitable cell. But if action potentials are to serve as long-distance signals, they cannot be merely isolated events occurring in a limited area of a nerve or muscle cell membrane. Mechanisms must exist to conduct or spread the action potential throughout the entire cell membrane. Furthermore, the signal must be transmitted from one cell to the next (for example, along specific nerve pathways). To explain these mechanisms, we begin with a brief look at neuronal structure. Then we examine how an action potential (nerve impulse) is conducted throughout a neuron before we turn to how the signal is passed to another cell.

A single **neuron** typically consists of three basic parts—the *cell body,* the *dendrites,* and the *axon*—although the structure varies depending on the location and function of the neuron (❙Figure 4-7). The nucleus and organelles are housed in the **cell body**, from which numerous extensions known as **dendrites** typically project like antennae to increase the surface area available for receiving signals from other neurons. Often tiny spike-like or knoblike projections. known as *dendritic spines* arise from the dendrites, increasing even further the surface area available

for reception of incoming signals (❙Figure 4-7c). Some neurons have up to 400,000 dendrites, which carry signals *toward* the cell body. In most neurons, the plasma membrane of the dendrites and cell body contains protein receptors that bind chemical messengers from other neurons. Therefore, the dendrites and cell body are the neuron's *input zone* because these components receive and integrate incoming signals. This is the region where graded potentials are produced in response to triggering events, in this case, incoming chemical messengers.

The **axon**, or **nerve fiber**, is a single, elongated, tubular extension that conducts action potentials *away from* the cell body and eventually terminates at other cells. Axons vary in length from less than a millimeter in neurons that communicate only with neighboring cells to longer than a meter in neurons that communicate with distant parts of the nervous system or with peripheral organs. For example, the axon of the neuron innervating your big toe must traverse the distance from the origin of its cell body within the spinal cord of your lower back all the way down your leg to your toe.

The first portion of the axon plus the region of the cell body from which the axon leaves are known collectively as the **axon hillock** or **initial segment**. The axon hillock is the neuron's *trigger zone* because it is the site where action potentials are triggered, or initiated, by a graded potential of sufficient magnitude. The action potentials are then conducted along the axon from the axon hillock to what is typically the highly branched ending at the **axon terminals**. These terminals release chemical messengers that simultaneously influence numerous other cells with which they come into close association. Functionally, therefore, the axon is the *conducting zone* of the neuron, and the axon terminals constitute its *output zone.* (The major exceptions to this typical neuronal structure and functional organization are neurons specialized to carry sensory information, a topic described in a later chapter.)

Action potentials can be initiated only in portions of the membrane with abundant voltage-gated Na^+ channels that can be triggered to open by a depolarizing event. Typically, regions of excitable cells where graded potentials take place do not undergo action potentials because voltage-gated Na^+ channels are sparse there. Therefore, sites specialized for graded potentials do not undergo action potentials, even though they might be considerably depolarized. However, before dying out, graded potentials can trigger action potentials in adjacent portions of the membrane by bringing these more sensitive regions to threshold through local current flow spreading from the site of the graded potential. In a typical neuron, for example, graded potentials are generated in the dendrites and cell body in response to incoming chemical signals. If these graded potentials have sufficient magnitude by the time they have spread to the axon hillock, they initiate an action potential at this trigger zone. The axon hillock has the lowest threshold in the neuron because this region has a much higher density of voltage-gated Na^+ channels than anywhere else in the neuron. For this reason, the axon hillock is considerably more responsive than the dendrites or remainder of the cell body to changes in potential and is the first to reach threshold (the dendrites and cell body at the same potential are still considerably below their much higher thresholds). Therefore, an action potential originates in

the axon hillock and is propagated from there to the end of the axon.

Once initiated, action potentials are conducted throughout a nerve fiber.

Once an action potential is initiated at the axon hillock, no further triggering event is necessary to activate the remainder of the nerve fiber. The impulse is automatically conducted throughout the neuron without further stimulation by one of two methods of propagation: *contiguous conduction* or *saltatory conduction.* Here, we discuss contiguous conduction. Saltatory conduction is discussed later.

Contiguous conduction involves the spread of the action potential along every patch of membrane down the length of the axon (*contiguous* means "touching" or "next to in sequence"). This process is illustrated in ❙Figure 4-8, which represents a longitudinal section of the axon hillock and the portion of the axon immediately beyond it. The membrane at the axon hillock is at the peak of an action potential. The inside of the cell is positive in this active area because Na^+ has already rushed in here. The remainder of the axon, still at resting potential and negative inside, is considered inactive. For the action potential to spread from the active to the inactive areas, the inactive areas must somehow be depolarized to threshold. This depolarization is accomplished by local current flow between the area already undergoing an action potential and the adjacent inactive area, similar to the current flow responsible for the spread of graded potentials. Because opposite charges attract, current can flow locally between the active area and the neighboring inactive area on both the inside and the outside of the membrane. This local current flow neutralizes or eliminates some of the unbalanced charges in the inactive area; that is, it reduces the number of opposite charges separated across the membrane, reducing the potential in this area. This depolarizing effect quickly brings the involved inactive area to threshold, at which time the voltage-gated Na^+ channels in this region of the membrane are all thrown open, leading to an action potential in this previously inactive area. Meanwhile, the original active area returns to resting potential as a result of K^+ efflux.

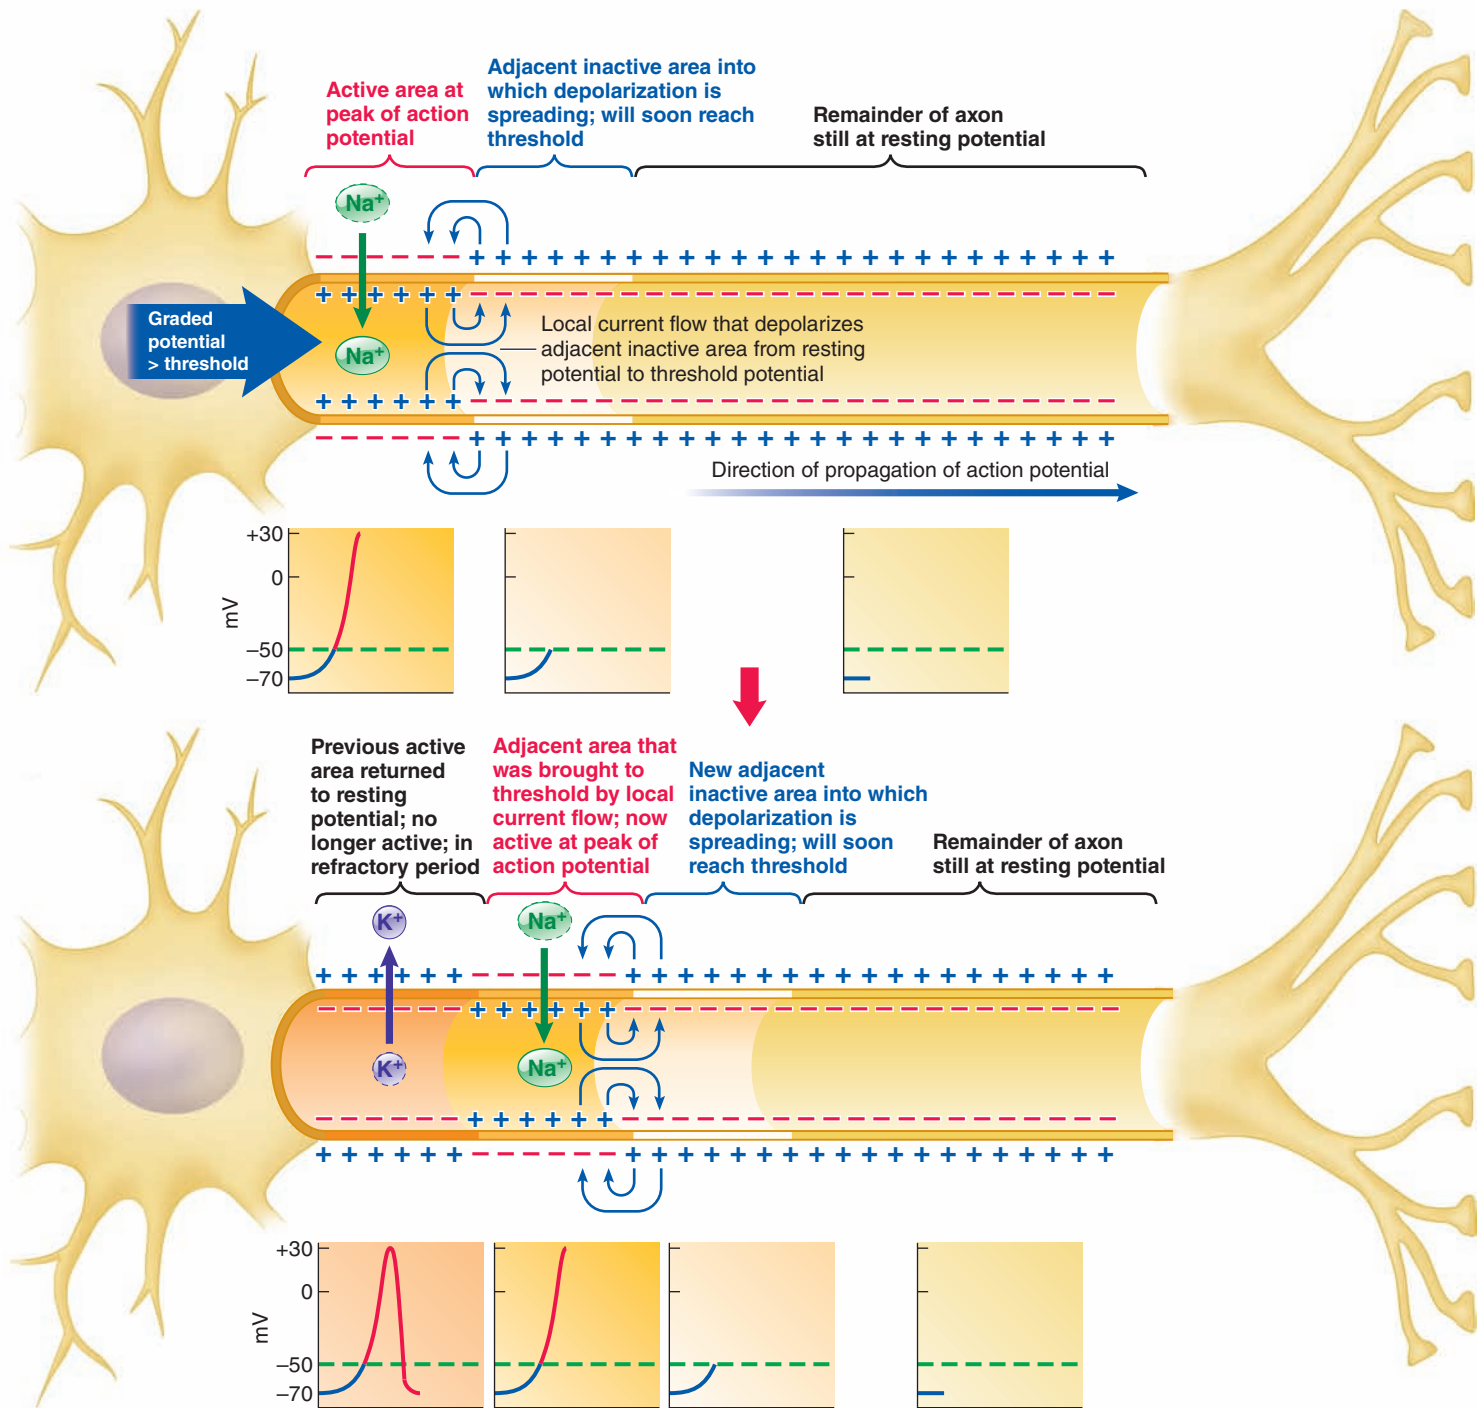
Beyond the new active area is another inactive area, so the same thing happens again. This cycle repeats itself in a chain reaction until the action potential has spread to the end of the axon. *Once an action potential is initiated in one part of a neuron's cell membrane, a self-perpetuating cycle is initiated so that the action potential is propagated along the rest of the fiber automatically.* In this way, the axon is like a firecracker fuse that needs to be lit at only one end. Once ignited, the fire spreads down the fuse; it is not necessary to hold a match to every separate section of the fuse. Note that the original action potential does not travel along the membrane. Instead, it triggers an identical new action potential in the bordering area of the membrane, with this process being repeated along the axon's length. An analogy is the "wave" at a stadium. Each section of spectators stands up (the rising phase of an action potential) and then sits down (the falling phase) in sequence one after another as the wave moves around the stadium. The wave, not individual spectators, travels around the stadium. Similarly,


Figure 4-8 **Contiguous conduction.** Local current flow between the active area at the peak of an action potential and the adjacent inactive area still at resting potential reduces the potential in this contiguous inactive area to threshold, which triggers an action potential in the previously inactive area. The original active area returns to resting potential, and the new active area induces an action potential in the next adjacent inactive area by local current flow as the cycle repeats itself down the length of the axon.

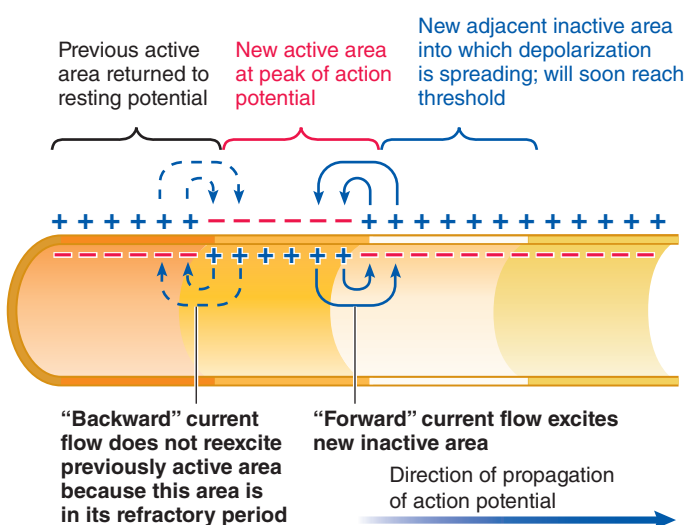
FIGURE FOCUS: *What initiates an action potential at the axon hillock? What initiates the action potential at each subsequent adjacent inactive area as the action potential propagates along the axon?*

new action potentials arise sequentially down the axon. Each new action potential is a fresh local event that depends on induced permeability changes and electrochemical gradients that are virtually identical down the length of the axon. Therefore, the last action potential at the end of the axon is identical to the original one, no matter how long the axon is. In this way, action potentials can serve as long-distance signals without weakening or distortion.

This nondecremental propagation of an action potential contrasts with the decremental spread of a graded potential,

TABLE 4-1 Comparison of Graded Potentials and Action Potentials

Property	Graded Potentials	Action Potentials
Triggering events	Stimulus, combination of neurotransmitter with receptor, or self-induced changes in channel permeability	Depolarization to threshold, usually through passive spread of depolarization from an adjacent area undergoing a graded potential or an action potential
Ion movement producing a change in potential	Net movement of Na^+, K^+, Cl^-, or Ca^{2+} across the plasma membrane by various means	Sequential movement of Na^+ into and K^+ out of the cell through voltage-gated channels
Coding of the magnitude of the triggering event	Graded potential change; magnitude varies with the magnitude of the triggering event	All-or-none membrane response; magnitude of the triggering event is coded in the frequency rather than the amplitude of action potentials
Duration	Varies with the duration of the triggering event	Constant
Magnitude of the potential change with distance from the initial site	Decremental conduction; magnitude diminishes with distance from the initial site	Propagated throughout the membrane in an undiminishing fashion; self-regenerated in neighboring inactive areas of the membrane
Refractory period	None	Relative, absolute
Summation	Temporal, spatial	None
Direction of potential change	Depolarization or hyperpolarization	Always depolarization and reversal of charges
Location	Specialized regions of the membrane designed to respond to the triggering event	Regions of the membrane with an abundance of voltage-gated channels

which dies out over a short distance because it cannot regenerate itself. ▌Table 4-1 summarizes the differences between graded potentials and action potentials, some of which we have yet to discuss.


▌**Figure 4-9** **Value of the refractory period.** The refractory period prevents "backward" current flow. During an action potential and slightly afterward, an area cannot be restimulated by normal events to undergo another action potential. Thus, the refractory period ensures that an action potential can be propagated only in the forward direction along the axon.

The refractory period ensures one-way propagation of action potentials and limits their frequency.

What ensures the one-way propagation of an action potential away from the initial site of activation? Note from ▌Figure 4-9 that once the action potential has been regenerated at a new neighboring site (now positive inside) and the original active area has returned to resting (again negative inside), the proximity of opposite charges between these two areas is conducive to local current flow in the backward direction as well as in the forward direction into as-yet-unexcited portions of the membrane. If such backward current flow were able to bring the previous active area to threshold again, another action potential would be initiated here, which would spread both forward and backward, initiating still other action potentials, and so on. But if action potentials were to move in both directions, the situation would be chaotic, with numerous action potentials bouncing back and forth along the axon until the neuron eventually fatigued. Fortunately, neurons are saved from this fate of oscillating action potentials by the **refractory period**, during which a new action potential cannot be initiated in a region that has just undergone an action potential.

Because of the changing status of the voltage-gated Na^+ and K^+ channels during and after an action potential, the refractory period has two components: the *absolute refractory period* and the *relative refractory period* (▌Figure 4-10). When a particular
Figure 4-10 Absolute and relative refractory periods. During the absolute refractory period, the portion of the membrane that has just undergone an action potential cannot be restimulated. This period corresponds to the time during which the Na^+ gates are not in their resting conformation. During the relative refractory period, the membrane can be restimulated only by a stronger stimulus than is usually necessary. This period corresponds to the time during which the K^+ gates opened during the action potential have not yet closed, coupled with lingering inactivation of the voltage-gated Na^+ channels.

patch of axonal membrane is undergoing an action potential, it cannot initiate another action potential, no matter how strong the depolarizing triggering event is. This period when a recently activated patch of membrane is completely refractory (meaning "stubborn" or "unresponsive") to further stimulation is known as the **absolute refractory period**. Once the voltage-gated Na^+ channels are triggered to open at threshold, they cannot open again in response to another depolarizing triggering event, no matter how strong, until they pass through their "closed and not capable of opening" conformation and then are reset to their "closed and capable of opening" conformation when resting potential is restored. Accordingly, the absolute refractory period lasts the entire time from threshold, through the action potential, and until return to resting potential. Only then can the voltage-gated Na^+ channels respond to another depolarization with an explosive increase in P_{Na^+} to initiate another action potential. Because of the absolute refractory period, one action potential must be over before another can be initiated at the same site. Action potentials cannot overlap or be added one on top of another "piggyback" fashion.

Following the absolute refractory period is a **relative refractory period**, during which a second action potential can be produced only by a triggering event considerably stronger than usual. The relative refractory period occurs after the action potential is completed because of a twofold effect. First, the voltage-gated Na^+ channels that opened during the action potential do not all reset at once when resting potential is reached. Some take a little longer to be restored to their capable of opening conformation. As a result, fewer voltage-gated Na^+ channels are in a position to be jolted open in

response to another depolarizing triggering event. Second, the voltage-gated K^+ channels that opened at the peak of the action potential are slow to close. During this time, the resultant less-than-normal Na^+ entry in response to another triggering event is opposed by K^+ still leaving through its slow-to-close channels during the after hyperpolarization. Thus, a greater depolarizing triggering event than normal is needed to offset the persistent hyperpolarizing outward movement of K^+ and bring the membrane to threshold during the relative refractory period.

By the time the original site has recovered from its refractory period and is capable of being restimulated by normal current flow, the action potential has been propagated in the forward direction only and is so far away that it can no longer influence the original site. Thus, *the refractory period ensures the one-way propagation of the action potential down the axon away from the initial site of activation.*

The refractory period is also responsible for setting an upper limit on the frequency of action potentials—that is, it determines the maximum number of new action potentials that can be initiated and propagated along a fiber in a given period. The original site must recover from its refractory period before a new action potential can be triggered to follow the preceding action potential. The length of the refractory period varies for different types of neurons. The longer the refractory period, the greater the delay before a new action potential can be initiated and the lower the frequency with which a neuron can respond to repeated or ongoing stimulation.

Action potentials occur in all-or-none fashion.

If any portion of the neuronal membrane is depolarized to threshold, an action potential is initiated and relayed along the membrane in an undiminished fashion. Furthermore, once threshold has been reached, the resultant action potential always goes to maximal height. The reason for this effect is that the changes in voltage during an action potential result from ion movements down concentration and electrical gradients, and these gradients are not affected by the strength of the depolarizing triggering event. A triggering event stronger than necessary to bring the membrane to threshold (a **suprathreshold** event) does not produce a larger action potential. However, a triggering event that fails to depolarize the membrane to threshold (a **subthreshold** event) does not trigger an action potential at all. Thus, *an excitable membrane either responds to a triggering event with a maximal action potential that spreads nondecrementally throughout the membrane or does not respond with an action potential at all.* This property is called the **all-or-none law**.

The all-or-none concept is analogous to firing a gun. Either the trigger is not pulled sufficiently to fire the bullet (threshold is not reached), or it is pulled hard enough to elicit the full firing response of the gun (threshold is reached). Squeezing the trigger harder does not produce a greater explosion. Just as it is not possible to fire a gun halfway, it is not possible to cause a halfway action potential.

The threshold phenomenon allows some discrimination between important and unimportant stimuli or other triggering events. Stimuli too weak to bring the membrane to threshold do

The strength of a stimulus is coded by the frequency of action potentials.

How is it possible to differentiate between two stimuli of varying strengths when both stimuli bring the membrane to threshold and generate action potentials of the same magnitude? For example, how can we distinguish between touching a warm object and touching a hot object if both trigger identical action potentials in a nerve fiber relaying information about skin temperature to the central nervous system (CNS) (the brain and spinal cord)? The answer partly lies in the *frequency* with which the action potentials are generated. A stronger stimulus does not produce a *larger* action potential, but it does trigger a greater *number* of action potentials per second. For an illustration, see ❙Figure 10-31, p. 367, in which changes in blood pressure are coded by corresponding changes in the frequency of action potentials generated in the neurons monitoring blood pressure.

In addition, a stronger stimulus in a region causes more neurons to reach threshold, increasing the total information sent to the CNS. For example, lightly touch this page with your finger and note the area of skin in contact with the page. Now, press down more firmly and note that a larger surface area of skin is in contact with the page. Therefore, more neurons are brought to threshold with this stronger touch stimulus.

Once initiated, the velocity, or speed, with which an action potential travels down the axon depends on two factors: (1) whether the fiber is myelinated and (2) the diameter of the fiber. Contiguous conduction occurs in unmyelinated fibers. In this case, as you just learned, each action potential initiates an identical new action potential in the next contiguous segment of the axon membrane so that every portion of the membrane undergoes an action potential as this electrical signal is conducted from the beginning to the end of the axon. A faster method of propagation, saltatory conduction, takes place in myelinated fibers. We show next how a myelinated fiber compares with an unmyelinated fiber and then how saltatory conduction compares with contiguous conduction.

Myelination increases the speed of conduction of action potentials.

Myelinated fibers are axons covered with **myelin**, a thick layer composed primarily of lipids, at regular intervals along their length (❙Figure 4-11a). Because the water-soluble ions responsible for carrying current across the membrane cannot permeate this myelin coating, it acts as an insulator, just like plastic around an electrical wire, to prevent leakage of current across the myelinated portion of the membrane. Myelin is not actually a part of the neuron but consists of separate myelin-forming cells that wrap themselves around the axon in jelly-roll fashion. These myelin-forming cells are **Schwann cells** in the peripheral nervous system (PNS) (❙Figure 4-11b) (the nerves running between the CNS and the various regions of the body), and **oligodendrocytes** in the CNS (❙Figure 4-11c). Each patch of lipid-rich myelin consists of multiple layers of the myelin-forming cell's plasma membrane (predominantly the lipid bilayer) as the cell repeatedly wraps itself around the axon. A patch of myelin might be made up of as many as 300 wrapped lipid bilayers.

Between the myelinated regions, at the **nodes of Ranvier**, the axonal membrane is bare and exposed to the ECF. Current can flow across the membrane only at these bare spaces to produce action potentials. Voltage-gated Na^+ and K^+ channels are concentrated at the nodes, whereas the myelin-covered regions are almost devoid of these special passageways (❙Figure 4-11d). By contrast, an unmyelinated fiber has a high density of these voltage-gated channels along its entire length. As you now know, action potentials can be generated only at portions of the membrane furnished with an abundance of these channels.

The distance between the nodes is short enough that local current can flow between an active node and an adjacent inactive node before dying off. When an action potential occurs at one node, local current flow between this node and the oppositely charged adjacent resting node reduces the adjacent node's potential to threshold so that it undergoes an action potential, and so on. Consequently, in a myelinated fiber, the impulse "jumps" from node to node, skipping over the myelinated sections of the axon (❙Figure 4-12); this process is called **saltatory conduction** (*saltare* means "to jump"). Saltatory conduction propagates action potentials more rapidly than contiguous conduction does, because the action potential does not have to be regenerated at myelinated sections but must be regenerated within every section of an unmyelinated axon from beginning to end. Myelinated fibers conduct impulses about 50 times faster than unmyelinated fibers of comparable size. You can think of myelinated fibers as the "superhighways" and unmyelinated fibers as the "back roads" of the nervous system when it comes to the speed with which information can be transmitted.

Besides permitting action potentials to travel faster, myelination also conserves energy. Because the ion fluxes associated with action potentials are confined to the nodal regions, the energy-consuming Na^+–K^+ pump must restore fewer ions to their respective sides of the membrane following propagation of an action potential.

The boxed feature on p. 103, ❙Concepts, Challenges, and Controversies, examines the myelin-destroying disease *multiple sclerosis*.

Fiber diameter also influences the velocity of action potential propagation.

Besides the effect of myelination, fiber diameter influences the speed with which an axon can conduct action potentials. The magnitude of current flow (that is, the amount of charge that moves) depends not only on the difference in potential between two adjacent electrically charged regions, but also on the resistance to electrical charge movement between the two regions. When fiber diameter increases, the resistance to local current decreases. Thus, the larger the fiber diameter, the faster action potentials can be propagated.

Large myelinated fibers, such as those supplying skeletal muscles, can conduct action potentials at a velocity of up to 120 meters/second (268 miles/hour), compared with a conduction velocity of 0.7 meters/second (2 miles/hour) in small unmy-
Figure 4-11 Myelinated fibers. (a) A myelinated fiber is surrounded by myelin at regular intervals. The intervening bare, unmyelinated regions are known as nodes of Ranvier. The electron micrograph shows a myelinated fiber in cross section at a myelinated region. (b) In the PNS each patch of myelin is formed by a separate Schwann cell that wraps itself jelly-roll fashion around the nerve fiber. (c) In the CNS each of several processes ("arms") of a myelin-forming oligodendrocyte forms a patch of myelin around a separate nerve fiber.

elinated fibers such as those supplying the digestive tract. This difference in speed of propagation is related to the urgency of the information being conveyed. A signal to skeletal muscles to execute a particular movement (for example, to prevent you from falling as you trip on something) must be transmitted more rapidly than a signal to modify a slow-acting digestive process. Without myelination, axon diameters within urgent nerve pathways would have to be very large and cumbersome to achieve

the necessary conduction velocities. Indeed, many invertebrates have large axons. In the course of vertebrate evolution, an efficient alternative to very large nerve fibers was development of the myelin sheath, which allows economic, rapid, long-distance signaling. For example, in humans the optic nerve leading from the eye to the brain is only 3 mm in diameter but is packed with more than a million myelinated axons. If those axons were unmyelinated, each would have to be about 100 times thicker to

4.4 Synapses and Neuronal Integration

When an action potential reaches the axon terminals, they release a chemical messenger that alters the activity of the cells on which the neuron terminates. A neuron may terminate on one of three structures: a muscle, a gland, or another neuron. Therefore, depending on where a neuron terminates, it can cause a muscle cell to contract, a gland cell to secrete, another neuron to convey an electrical message along a nerve pathway, or some other function. When a neuron terminates on a muscle or a gland, the neuron is said to **innervate**, or supply, the structure. The junctions between the nerves and the muscles and glands that they innervate are described later. For now, we concentrate on the junction between two neurons—a **synapse** (*synapsis* means "juncture"). (Sometimes the term *synapse* is used to describe a junction between any two excitable cells, but we reserve this term for the junction between two neurons.)

conduct impulses at the same velocity, resulting in an optic nerve about 300 mm (12 inches) in diameter.

The presence of myelinating cells can be either a tremendous benefit or a tremendous detriment when an axon is cut, depending on whether the damage occurs in a peripheral nerve or in the CNS. See the boxed feature on p. 104, ❙Concepts, Challenges, and Controversies, to learn more about the regeneration of damaged nerve fibers, a matter of crucial importance in spinal-cord injuries.

You have now seen how an action potential is propagated along the axon and learned about the factors influencing the speed of this propagation. But what happens when an action potential reaches the end of the axon?

Check Your Understanding 4.3

1. Draw and label an action potential, indicating the ion movements responsible for the rising phase and the falling phase.
2. Describe the three conformations of a voltage-gated Na⁺ channel and indicate the membrane potential at which each of these conformations exists.
3. Draw and label the most common type of neuron and identify its four functional zones.
4. Explain why saltatory conduction propagates action potentials more rapidly than contiguous conduction does.

Synapses are typically junctions between presynaptic and postsynaptic neurons.

There are two types of synapses: *electrical synapses* and *chemical synapses*, depending on how information is transferred between the two neurons.

Electrical Synapses In an **electrical synapse**, two neurons are connected by gap junctions (see p. 62), which allow charge-carrying ions to flow directly between the two cells in either direction. Although electrical synapses lead to unbroken transmission of electrical signals and are extremely rapid, this type of connection is essentially "on" or "off" and is unregulated. At an electrical synapse, an action potential in one neuron always leads to an action potential in the connected neuron.

Electrical synapses are not as common as chemical synapses in the human nervous system. Gap junctions are more numerous in smooth muscle and cardiac muscle, where their function is better understood. Until recently electrical synapses in the nervous system were thought to be confined to specialized locations such as the retina of the eye and the pulp of a tooth. Neuroscientists now know that these synapses are present in widespread locations within the CNS. Electrical synapses are typically found among populations of neurons

Multiple Sclerosis: Myelin—Going, Going, Gone

MULTIPLE SCLEROSIS (MS) IS A pathophysiologic condition in which nerve fibers in various locations throughout the nervous system lose their myelin. MS is an autoimmune disease (*auto* means "self"; *immune* means "defense against") in which the body's defense system erroneously attacks the myelin sheath surrounding myelinated nerve fibers. The condition afflicts about 1 in 1000 people in the United States. MS typically begins between the ages of 20 and 40.

Many investigators believe that MS arises from a combination of genetic and environmental factors. Relatives of those with MS have a 6 to 10 times greater chance of developing the disease themselves than the general population does. Because of their genetic predisposition, these relatives have increased susceptibility to environmental factors that may trigger the disease. Various environmental triggers have been proposed, including viral infections, environmental toxins, and vitamin D deficiency, but no evidence has been conclusive.

Loss of myelin as a result of a misguided immune attack slows transmission of impulses in the affected neurons. A hardened scar known as a *sclerosis* (meaning "hard") forms at the multiple sites of myelin damage. These scars interfere with and can eventually block the propagation of action potentials in the underlying axons. Furthermore, the inflammatory phase characterized by myelin destruction sets off a subsequent degenerative phase characterized by deterioration of the affected axons.

The symptoms of MS vary considerably, depending on the extent and location of myelin damage and axon degeneration. The most common symptoms include fatigue, visual problems, tingling and numbness, muscle weakness, impaired balance and coordination, and gradual paralysis. The early stage of the disease is often characterized by cycles of relapse and recovery, whereas the later chronic stage is marked by slow, progressive worsening of symptoms. MS can be debilitating, but is not generally fatal, although the life expectancy of those with the condition averages 5 to 10 years less than the unaffected population.

Currently there is no cure for MS, but researchers have been scrambling to find means to treat attacks, reduce debilitating symptoms, and improve the course of the disease. The symptoms are so mild in some people that no treatment is necessary. For those with more pronounced symptoms, current treatments include drugs that suppress the immune attack on myelin in various ways, along with physical therapy and muscle relaxants. Some patients respond better than others to current drug therapies. Among recent efforts to thwart MS are development of an experimental vaccine that calms the myelin-attacking immune cells, strategies to promote remyelination, and use of neuroprotective drugs.

---

where synchronization of activity is paramount. For example, electrical synapses interconnect a cluster of neurosecretory neurons in the brain that all secrete the same neurohormone, *GnRH,* which is at the head of an endocrine chain of command that governs reproductive function. Because of these electrical synapses, these neurons all fire and secrete GnRH in synchrony, resulting in coordinated bursts of secretion once every 2 to 3 hours, with no secretion occurring between these bursts. The target cells of GnRH in the chain of command are programmed to respond only to the normal pulsatile pattern of GnRH, so control of the reproductive system ultimately depends on electrical synapses enabling this synchronized secretion.

Chemical Synapses Most synapses in the human nervous system are **chemical synapses** at which a chemical messenger transmits information one way across a space separating the two neurons. A chemical synapse typically involves a junction between an axon terminal of one neuron, known as the *presynaptic neuron,* and the dendrites or cell body of a second neuron, known as the *postsynaptic neuron.* (*Pre* means "before," and *post* means "after"; the presynaptic neuron lies before the synapse, and the postsynaptic neuron lies after the synapse.) The dendrites and, to a lesser extent, the cell body of most neurons receive thousands of synaptic inputs, which are axon terminals from many other neurons. Some neurons in the CNS receive as many as 100,000 synaptic inputs (❙Figure 4-13).

The anatomy of a chemical synapse is shown in ❙Figure 4-14 and in the chapter opener photo. The axon terminal of the **presynaptic neuron**, which conducts its action potentials *toward* the synapse, ends in a slight swelling, the **synaptic knob**. The synaptic knob contains **synaptic vesicles**, which store a specific chemical messenger, a **neurotransmitter** that has been synthesized and packaged by the presynaptic neuron. The synaptic knob comes close to, but does not touch, the **postsynaptic neuron**, whose action potentials are propagated *away from* the synapse. The space between the presynaptic and postsynaptic neurons is called the **synaptic cleft**. Fingerlike CAMs (see p. 60) extend partway across the synaptic cleft from the surfaces of both the presynaptic and postsynaptic neurons. These projections are "Velcroed" together where they meet and overlap in the middle of the cleft, much as if you interlock the extended fingers from both hands together. This physical tethering stabilizes the close proximity of the presynaptic and postsynaptic neurons at the synapse.

Regeneration: PNS Axons Can Do It, But CNS Axons Cannot

NERVE FIBERS MAY BE DAMAGED by being severed or crushed (as during a traumatic event, such as a vehicle wreck, a gunshot wound, or a diving accident) or by being deprived of their blood supply (as during a stroke). When damaged, the affected axons can no longer conduct action potentials to convey messages. Using a severed axon as an example, the portion of the axon farthest from the cell body degenerates. Whether the lost portion of the axon regenerates depends on its location. Cut axons in the peripheral nervous system (PNS) can regenerate, whereas those in the central nervous system (CNS) cannot.

Regeneration of Peripheral Axons

In the case of a cut axon in a peripheral nerve, when the detached part of the axon degenerates, the surrounding Schwann cells phagocytize the debris. The Schwann cells themselves remain, then form a **regeneration tube** that guides the regenerating nerve fiber to its proper destination. The remaining portion of the axon connected to the cell body starts to grow and move forward within the Schwann cell column by amoeboid movement (see p. 50). The growing axon tip "sniffs" its way forward in the proper direction, guided by a chemical secreted into the regeneration tube by the Schwann cells. Successful fiber regeneration is responsible for the eventual return of sensation and movement after traumatic peripheral nerve injuries, although regeneration is not always successful.

Inhibited Regeneration of Central Axons

Fibers in the CNS, which are myelinated by oligodendrocytes, do not have this regenerative ability. Actually, the axons themselves have the ability to regenerate, but the oligodendrocytes surrounding them synthesize proteins that inhibit axonal growth, in sharp contrast to the nerve growth–promoting action of the Schwann cells that myelinate peripheral axons. Nerve growth in the brain and spinal cord is controlled by a delicate balance between *nerve growth–enhancing* and *nerve growth–inhibiting proteins.* During fetal development, nerve growth in the CNS is possible as the brain and spinal cord are being formed. Researchers speculate that nerve growth inhibitors, which are produced late in fetal development in the myelin sheaths surrounding central nerve fibers, may normally serve as "guardrails" that keep new nerve endings from straying outside their proper paths. The growth-inhibiting action of oligodendrocytes may thus serve to stabilize the enormously complex structure of the CNS.

The synaptic cleft is too wide for the direct spread of current from one cell to the other and therefore prevents action potentials from electrically passing between the neurons. Instead, an action potential in the presynaptic neuron alters the postsynaptic neuron's potential by chemical means. Synapses operate in one direction only—that is, the presynaptic neuron brings about changes in the membrane potential of the postsynaptic neuron, but the postsynaptic neuron does not directly influence the potential of the presynaptic neuron. The reason for this becomes readily apparent when you examine the events that occur at a synapse.
Figure 4-13 Synaptic inputs (presynaptic axon terminals) to the cell body and dendrites of a single postsynaptic neuron. The drying process used to prepare the neuron for the electron micrograph has toppled the presynaptic axon terminals and pulled them away from the postsynaptic cell body.

Growth inhibition is a disadvantage, however, when CNS axons need to be mended, as when the spinal cord has been severed accidentally. Damaged central fibers show immediate signs of repairing themselves after an injury, but within several weeks they start to degenerate, and scar tissue forms at the site of injury, halting any recovery. Therefore, damaged neuronal fibers in the brain and spinal cord never regenerate.

Research on Regeneration of Central Axons

In the future, however, it may be possible to promote significant regeneration of damaged fibers in the CNS. Investigators are exploring several promising ways of spurring repair of central axonal pathways, with the goal of enabling victims of spinal-cord injuries to walk again and to regain control of bladder emptying. Here are some current lines of research:

■ Scientists have been able to induce significant nerve regeneration in rats with severed spinal cords by *chemically blocking the nerve growth inhibitor* dubbed *Nogo,* thereby allowing nerve growth enhancers to promote abundant sprouting of new nerve fibers at the site of injury.

■ Other researchers are experimentally *using peripheral nerve grafts* to bridge the defect at an injured spinal-cord site. These grafts contain the nurturing Schwann cells, which release nerve growth–enhancing proteins.

■ Another avenue of hope is the discovery of *neural stem cells* (see pp. 10 and 138). These cells might someday be implanted into a damaged spinal cord and coaxed into multiplying and differentiating into mature, functional neurons that will replace those lost.

■ Yet another new strategy under investigation is *enzymatically breaking down inhibitory components in the scar tissue* that naturally forms at the injured site and prevents sprouting nerve fibers from crossing this barrier.

■ Other researchers are taking a *bionic approach,* trying to create electronic devices that plug into the nervous system to bypass a broken connection in the spinal cord. The idea is to ultimately implant brain chips that could pick up the electrical message intended to command muscle movement, then to relay this message to a second device implanted in the spinal cord below the level of damage. This second device would stimulate the motor neurons to produce the commanded movement.
1 Action potential reaches axon terminal of presynaptic neuron.

2 Ca^{2+} enters synaptic knob (presynaptic axon terminal).

3 Neurotransmitter is released by exocytosis into synaptic cleft.

4 Neurotransmitter binds to receptors that are an integral part of chemically gated channels on subsynaptic membrane of postsynaptic neuron.

5 Binding of neurotransmitter to receptor-channel opens that specific channel.

The blowup depicts the release by exocytosis of neurotransmitter from the presynaptic axon terminal and its subsequent binding with receptor-channels specific for it on the subsynaptic membrane of the postsynaptic neuron.

Principles of Neural and Hormonal Communication

A neurotransmitter carries the signal across a synapse.

When an action potential in a presynaptic neuron has been propagated to the axon terminal (❙Figure 4-14, step ❶), this local change in potential triggers the opening of voltage-gated calcium (Ca^{2+}) channels in the synaptic knob. Because Ca^{2+} is more highly concentrated in the ECF (see p. 73), this ion flows into the synaptic knob through the open channels (step ❷). Ca^{2+} promotes the release of a neurotransmitter from some synaptic vesicles into the synaptic cleft (step ❸). The release is accomplished by exocytosis (see p. 29). The released neurotransmitter diffuses across the cleft and binds with specific protein receptors on the **subsynaptic membrane**, the portion of the postsynaptic membrane immediately underlying the synaptic knob (*sub* means "under") (step ❹). These receptors are an integral part of specific ion channels. These combined receptor and channel units are appropriately known as **receptor-channels**. Binding of neurotransmitter to the receptor-channels causes the channels to open, changing the ion permeability and thus the potential of the postsynaptic neuron (step ❺). These are chemically gated channels, in contrast to the voltage-gated channels responsible for the action potential and for Ca^{2+} influx into the synaptic knob. Because the presynaptic terminal releases the neurotransmitter and the subsynaptic membrane of the postsynaptic neuron has receptor-channels for the neurotransmitter, the synapse can operate only in the direction from presynaptic to postsynaptic neuron.

Conversion of the electrical signal in the presynaptic neuron (an action potential) to an electrical signal in the postsynaptic neuron by chemical means (via the neurotransmitter–receptor combination) takes time. This **synaptic delay** is usually about 0.5 to 1 msec. In a neural pathway, chains of neurons often must be traversed. The more complex the pathway, the more synaptic delays and the longer the *total reaction time* (the time required to respond to a particular event).

Some synapses excite, whereas others inhibit, the postsynaptic neuron.

Each presynaptic neuron typically releases only one neurotransmitter; however, different neurons vary in the neurotransmitter they release. On binding with their subsynaptic receptor-channels, different neurotransmitters cause different ion permeability changes. There are two types of synapses, depending on the resultant permeability changes: *excitatory synapses* and *inhibitory synapses*.

Excitatory Synapses   At an **excitatory synapse**, the receptor-channels to which the neurotransmitter binds are nonspecific cation channels that permit simultaneous passage of Na^+ and K^+ through them. (These are a different type of channel from those you have encountered before.) When these channels open in response to neurotransmitter binding, permeability to both these ions is increased at the same time. How much of each ion diffuses through an open nonspecific cation channel depends on the ions' electrochemical gradients. At resting potential, both the concentration and the electrical gradients for Na^+ favor its movement

into the postsynaptic neuron, whereas only the concentration gradient for K^+ favors its movement outward. Therefore, the permeability change induced at an excitatory synapse results in the movement of a few K^+ ions out of the postsynaptic neuron, whereas a larger number of Na^+ ions simultaneously enter this neuron. The result is net movement of positive ions into the cell. This makes the inside of the membrane slightly less negative than at resting potential, thus producing a *small depolarization* of the postsynaptic neuron.

Activation of one excitatory synapse cannot depolarize the postsynaptic neuron enough to bring it to threshold. Too few channels are involved at a single synaptic site to permit adequate ion flow to reduce the potential to threshold. This small depolarization, however, does bring the postsynaptic neuron's membrane closer to threshold, increasing the likelihood that threshold will be reached (in response to further excitatory input) and that an action potential will occur—that is, the membrane is now more excitable (easier to bring to threshold) than when at rest. Accordingly, the change in postsynaptic potential occurring at an excitatory synapse is called an **excitatory postsynaptic potential**, or **EPSP** (❙Figure 4-15a).
(a) Excitatory synapse
(b) Inhibitory synapse

❙**Figure 4-15 Postsynaptic potentials.** (a) An excitatory postsynaptic potential (EPSP) brought about by activation of an excitatory presynaptic input brings the postsynaptic neuron closer to threshold potential. (b) An inhibitory postsynaptic potential (IPSP) brought about by activation of an inhibitory presynaptic input moves the postsynaptic neuron farther from threshold potential.

Inhibitory Synapses At an **inhibitory synapse**, binding of a neurotransmitter with its receptor-channels increases the permeability of the subsynaptic membrane to either K^+ or chloride (Cl^-), depending on the synapse. The resulting ion movements bring about a *small hyperpolarization* of the postsynaptic neuron—that is, greater internal negativity. In the case of increased P_{K^+}, more positive charges leave the cell via K^+ efflux, leaving more negative charges behind on the inside. In the case of increased P_{Cl^-}, because the concentration of Cl^- is higher in the ECF, negative charges enter the cell in the form of Cl^-. In either case, this small hyperpolarization moves the membrane potential even farther from threshold (Figure 4-15b), reducing the likelihood that the postsynaptic neuron will reach threshold (in response to excitatory input) and undergo an action potential—that is, the membrane is now less excitable (harder to bring to threshold by excitatory input) than when it is at resting potential. The membrane is said to be inhibited under these circumstances, and the small hyperpolarization of the postsynaptic cell is called an **inhibitory postsynaptic potential**, or **IPSP**.

In cells where the equilibrium potential for $Cl-$ exactly equals the resting potential (see p. 84), an increased P_{Cl^-} does not result in a hyperpolarization because there is no driving force to produce Cl^- movement. Opening of Cl^- channels in these cells tends to hold the membrane at resting potential, reducing the likelihood that threshold will be reached.

Note that EPSPs and IPSPs are produced by opening of chemically gated channels, unlike action potentials, which are produced by opening of voltage-gated channels.

Each neurotransmitter–receptor combination always produces the same response.

Many different molecules serve as neurotransmitters. The chemical classes and functions of the major neurotransmitters are found in Table 4-2. You will learn about the details of these neurotransmitter actions as we discuss their roles later on.

Even though neurotransmitters vary from synapse to synapse, the same neurotransmitter is always released at a particular synapse. Furthermore, at a given synapse, binding of a neurotransmitter with its appropriate subsynaptic receptor-channels always leads to the same change in permeability and resultant change in potential of the postsynaptic membrane. Thus, the response to a given neurotransmitter–receptor combination is always the same; the combination does not generate an EPSP under one circumstance and an IPSP under another. Some neurotransmitters (for example, *glutamate,* the most common excitatory neurotransmitter in the brain) typically bring about EPSPs, whereas others (for

TABLE 4-2 Major Neurotransmitters

Classes and Examples of Neurotransmitters	Chemical Structure	Functions
Choline derivative		
Acetylcholine	Synthesized from choline and acetyl CoA	Major neurotransmitter in PNS*: released from motor nerves that supply skeletal muscle and from parasympathetic nerves that supply smooth muscle, cardiac muscle, and exocrine glands; also acts in CNS**
Biogenic amines (Monoamines)	Amines each derived from a single amino acid	
Norepinephrine	Made from tyrosine; is a catecholamine	Important neurotransmitter in PNS: released from sympathetic nerves that supply smooth muscle, cardiac muscle, and exocrine glands; also acts in CNS in pathways involved with memory, mood, emotions, behavior, sensory perception, sleep, and muscle movements
Dopamine	Made from tyrosine; is a catecholamine	Acts in CNS in many pathways similar to norepinephrine; especially important in "pleasure" pathways and muscle movements
Serotonin	Made from tryptophan; is an indoleamine	Acts in CNS in pathways involving mood, emotions, behavior, appetite, states of consciousness, and muscle movements
Amino acids	Are single amino acids	Most abundant neurotransmitters
Glutamate		Primary excitatory neurotransmitter in CNS; important in pathways involved with memory and learning
Gamma-aminobutyric acid (GABA)		Primary inhibitory neurotransmitter in brain; often acts in same circuits as glutamate
Glycine		Primary inhibitory neurotransmitter in spinal cord and brain stem

*PNS refers to the peripheral nervous system.
**CNS refers to the central nervous system.

example, *gamma-aminobutyric acid,* or GABA, the brain's main inhibitory neurotransmitter) always produce IPSPs. Still other neurotransmitters (for example, *norepinephrine*) can produce EPSPs at one synapse and IPSPs at a different synapse, because different permeability changes occur in response to the binding of this same neurotransmitter to different postsynaptic neurons. Yet the response at a given norepinephrine-influenced synapse is always either excitatory or inhibitory.

Most of the time, each axon terminal releases only one neurotransmitter. However, in some cases two different neurotransmitters can be released simultaneously from a single axon terminal. For example, *glycine* and GABA, both of which produce inhibitory responses, can be packaged and released from the same synaptic vesicles. Scientists speculate that the fast-acting glycine and more slowly acting GABA may complement each other in the control of activities that depend on precise timing—for example, coordination of complex movements.

Neurotransmitters are quickly removed from the synaptic cleft.

As long as the neurotransmitter remains bound to the receptor-channels, the alteration in membrane permeability responsible for the EPSP or IPSP continues. For the postsynaptic neuron to be ready to receive additional messages from the same or other presynaptic inputs, the neurotransmitter must be inactivated or removed from the postsynaptic cleft after it has produced the appropriate response in the postsynaptic neuron—that is, the postsynaptic "slate" must be "wiped clean." Thus, after combining with the postsynaptic receptor-channel, chemical transmitters are removed and the response is terminated.

Several mechanisms can remove the neurotransmitter: It may diffuse away from the synaptic cleft, be inactivated by specific enzymes within the subsynaptic membrane, or be actively taken back up into the axon terminal by transport mechanisms in the presynaptic membrane. Once the neurotransmitter is taken back up, it can be stored and released another time (recycled) in response to a subsequent action potential or destroyed by enzymes within the synaptic knob. The method used depends on the particular synapse.

Clinical Note Some drugs work by interfering with removal of specific neurotransmitters from synapses. For example, **selective serotonin reuptake inhibitors (SSRIs)**, as their name implies, selectively block the reuptake of *serotonin* into presynaptic axon terminals, thereby prolonging the action of this neurotransmitter at synapses that use this messenger. SSRIs, such as *Prozac,* are prescribed to treat depression, which is characterized by a deficiency of serotonin, among other things. Serotonin is involved in neural pathways that regulate mood and behavior.

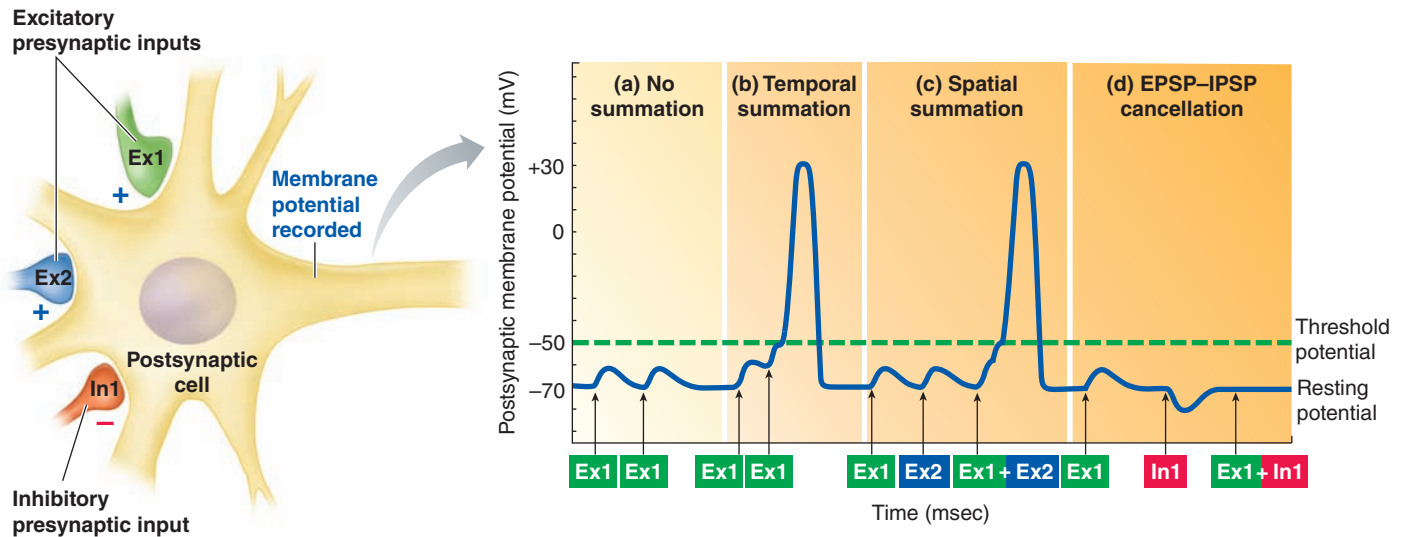
The grand postsynaptic potential depends on the sum of the activities of all presynaptic inputs.

EPSPs and IPSPs are graded potentials. Unlike action potentials, which behave according to the all-or-none law, graded potentials can be of varying magnitude, have no refractory period, and can be summed (added on top of one another). What are the mechanisms and significance of summation?

The events that occur at a single synapse result in either an EPSP or an IPSP at the postsynaptic neuron. But if a single EPSP is inadequate to bring the postsynaptic neuron to threshold and an IPSP moves it even farther from threshold, how can an action potential be initiated in the postsynaptic neuron? The answer lies in the thousands of presynaptic inputs that a typical neuronal cell body receives from many other neurons. Some of these presynaptic inputs may be carrying sensory information from the environment; some may be signaling internal changes in homeostatic balance; others may be transmitting signals from control centers in the brain; and still others may arrive carrying other bits of information. At any given time, any number of these presynaptic neurons (probably hundreds) may be firing and thus influencing the postsynaptic neuron's level of activity. The total potential in the postsynaptic neuron, the **grand postsynaptic potential (GPSP)**, is a composite of all EPSPs and IPSPs occurring around the same time.

The postsynaptic neuron can be brought to threshold by either *temporal summation* or *spatial summation.* To illustrate these methods of summation, we examine the possible interactions of three presynaptic inputs—two excitatory inputs (Ex1 and Ex2) and one inhibitory input (In1)—on a hypothetical postsynaptic neuron (❙Figure 4-16). The recording shown in the figure represents the potential in the postsynaptic cell. Bear in mind during our discussion of this simplified version that many thousands of synapses are actually interacting in the same way on a single cell body and its dendrites.

Temporal Summation Suppose that Ex1 has an action potential that causes an EPSP in the postsynaptic neuron. After this EPSP has died off, if another action potential occurs in Ex1, an EPSP of the same magnitude takes place before dying off (❙Figure 4-16a). Next, suppose that Ex1 has two action potentials in close succession (❙Figure 4-16b). The first action potential in Ex1 produces an EPSP in the postsynaptic membrane. While the postsynaptic membrane is still partially depolarized from this first EPSP, the second action potential in Ex1 produces a second EPSP. Because graded potentials do not have a refractory period, the second EPSP can add to the first, bringing the membrane to threshold and initiating an action potential in the postsynaptic neuron. EPSPs can add together or sum because an EPSP lasts longer than the action potential that caused it. The presynaptic neuron (Ex1) can recover from its refractory period following the first action potential and have a second action potential, causing a second EPSP in the postsynaptic neuron, before the first EPSP is finished.

The summing of several EPSPs occurring very close together in time because of successive firing of a single presynaptic neuron is known as **temporal summation** (*tempus* means "time"). In reality, up to 50 EPSPs might be needed to bring the postsynaptic membrane to threshold. Each action potential in a single presynaptic neuron triggers the emptying of a certain number of synaptic vesicles. The amount of neurotransmitter released and the resultant magnitude of the change in postsynaptic potential are thus directly related to the frequency of presynaptic action potentials. One way in which the postsynaptic mem-


(a) If an excitatory presynaptic input (Ex1) is stimulated a second time after the first EPSP in the postsynaptic cell has died off, a second EPSP of the same magnitude will occur.

(b) If, however, Ex1 is stimulated a second time before the first EPSP has died off, the second EPSP will add onto, or sum with, the first EPSP, resulting in *temporal summation*, which may bring the postsynaptic cell to threshold.

(c) The postsynaptic cell may also be brought to threshold by *spatial summation* of EPSPs that are initiated by simultaneous activation of two (Ex1 and Ex2) or more excitatory presynaptic inputs.

(d) Simultaneous activation of an excitatory (Ex1) and inhibitory (In1) presynaptic input does not change the postsynaptic potential, because the resultant EPSP and IPSP cancel each other out.

❙Figure 4-16 **Determination of the grand postsynaptic potential by the sum of activity in the presynaptic inputs.** Two excitatory (Ex1 and Ex2) and one inhibitory (In1) presynaptic inputs terminate on this hypothetical postsynaptic neuron. The potential of the postsynaptic neuron is being recorded. For simplicity in the figure, summation of two EPSPs brings the postsynaptic neuron to threshold, but in reality many EPSPs must sum to reach threshold.

brane can be brought to threshold, then, is through rapid, repetitive excitation from a single persistent input.

Spatial Summation Let us now see what happens in the postsynaptic neuron if both excitatory inputs are stimulated simultaneously (❙Figure 4-16c). An action potential in either Ex1 or Ex2 produces an EPSP in the postsynaptic neuron; however, neither of these alone brings the membrane to threshold to elicit a postsynaptic action potential. But simultaneous action potentials in Ex1 and Ex2 produce EPSPs that add to each other, bringing the postsynaptic membrane to threshold, so an action potential does occur. The summation of EPSPs originating simultaneously from several presynaptic inputs (that is, from different points in "space") is known as **spatial summation**. A second way to elicit an action potential in a postsynaptic cell, therefore, is through concurrent activation of several excitatory inputs. Again, in reality, up to 50 simultaneous EPSPs are required to bring the postsynaptic membrane to threshold.

Similarly, IPSPs can undergo both temporal and spatial summation. As IPSPs add together, however, they progressively move the potential farther from threshold.

Cancellation of Concurrent EPSPs and IPSPs If an excitatory and an inhibitory input are simultaneously activated, the concurrent EPSP and IPSP more or less cancel each other

out. The extent of cancellation depends on their respective magnitudes. In most cases, the postsynaptic membrane potential remains close to resting potential (❙Figure 4-16d).

Importance of Postsynaptic Integration The magnitude of the GPSP depends on the sum of activity in all presynaptic inputs and, in turn, determines whether or not the postsynaptic neuron will undergo an action potential to pass information on to the cells on which the neuron terminates. The following oversimplified real-life example demonstrates the benefits of this neuronal integration. The explanation is not completely accurate technically, but the principles of summation are accurate.

Assume for simplicity's sake that urination is controlled by a postsynaptic neuron that innervates the urinary bladder. When this neuron fires, the bladder contracts. (Actually, voluntary control of urination is accomplished by postsynaptic integration at the neuron controlling the external urethral sphincter rather than the bladder itself.) As the bladder fills with urine and becomes stretched, a reflex is initiated that ultimately produces EPSPs in the postsynaptic neuron responsible for causing bladder contraction. Partial filling of the bladder does not cause enough excitation to bring the neuron to threshold, so urination does not take place—that is, action potentials do not occur frequently enough in presynaptic neuron Ex1, which fires reflexly in response to the degree of bladder stretching, to gen-

Principles of Neural and Hormonal Communication | **109**

erate EPSPs close enough together in the postsynaptic neuron to bring the latter to threshold (❙Figure 4-16a). As the bladder progressively fills, the frequency of action potentials progressively increases in presynaptic neuron Ex1, leading to more rapid formation of EPSPs in the postsynaptic neuron. Thus, the frequency of EPSP formation arising from Ex1 activity signals the postsynaptic neuron of the extent of bladder filling. When the bladder becomes sufficiently stretched that the Ex1-generated EPSPs are temporally summed to threshold, the postsynaptic neuron undergoes an action potential that stimulates bladder contraction (❙Figure 4-16b).

What if the time is inopportune for urination to take place? Presynaptic inputs originating in higher levels of the brain responsible for voluntary control can produce IPSPs at the bladder postsynaptic neuron (In1 in ❙Figure 4-16d). These "voluntary" IPSPs in effect cancel out the "reflex" EPSPs triggered by stretching of the bladder. Thus, the postsynaptic neuron remains at resting potential and does not have an action potential, so the bladder is prevented from contracting and emptying even though it is full.

What if a person's bladder is only partially filled, so that the presynaptic input from this source (Ex1) is insufficient to bring the postsynaptic neuron to threshold to cause bladder contraction, yet the individual needs to supply a urine specimen for laboratory analysis? The person can voluntarily activate another excitatory presynaptic neuron originating in higher brain levels (Ex2 in ❙Figure 4-16c). The "voluntary" EPSPs arising from Ex2 activity and the "reflex" EPSPs arising from Ex1 activity are spatially summed to bring the postsynaptic neuron to threshold. This achieves the action potential necessary to stimulate bladder contraction, even though the bladder is not full.

This example illustrates the importance of postsynaptic neuronal integration. Each postsynaptic neuron in a sense "computes" all the input it receives and "decides" whether to pass the information on (that is, whether threshold is reached and an action potential is transmitted down the axon). In this way, neurons serve as complex computational devices, or integrators. The dendrites function as the primary processors of incoming information. They receive and tally the signals from all presynaptic neurons. Each neuron's output in the form of frequency of action potentials to other cells (muscle cells, gland cells, or other neurons) reflects the balance of activity in the inputs it receives via EPSPs or IPSPs from the thousands of other neurons that terminate on it. Each postsynaptic neuron filters out information that is not significant enough to bring it to threshold and does not pass it on. If every action potential in every presynaptic neuron that impinges on a particular postsynaptic neuron were to cause an action potential in the postsynaptic neuron, the neuronal pathways would be overwhelmed with trivia. Only if an excitatory presynaptic signal is reinforced by other supporting signals through summation will the information be passed on. Furthermore, interaction of EPSPs and IPSPs provides a way for one set of signals to offset another, allowing a fine degree of discrimination and control in determining what information will be passed on. Thus, unlike an electrical synapse, a chemical synapse is more than a simple on–off switch because many factors can influence the generation of a new action potential in the postsynaptic cell. Whether the postsynaptic neuron has an action potential depends on the relative balance of information coming in via presynaptic neurons at all of its excitatory and inhibitory synapses.

Some neurons secrete neuromodulators in addition to neurotransmitters.

In addition to the classical neurotransmitters released at synapses, some neurons also release *neuromodulators*. **Neuromodulators** are chemical messengers that do not cause the formation of EPSPs or IPSPs but instead act slowly to bring about long-term changes that subtly *modulate* (that is, depress or enhance) the action of the synapse. The neuronal receptors to which neuromodulators bind are not located on the subsynaptic membrane, and they do not directly alter membrane permeability and potential. Neuromodulators may act at either presynaptic or postsynaptic sites. For example, a neuromodulator may influence the level of an enzyme involved in the synthesis of a neurotransmitter by a presynaptic neuron, or it may alter the sensitivity of the postsynaptic neuron to a particular neurotransmitter by causing long-term changes in the number of subsynaptic receptors for the neurotransmitter. Thus, neuromodulators delicately fine-tune the synaptic response. The effect may last for days, months, or even years. Whereas neurotransmitters are involved in rapid communication between neurons, neuromodulators are involved with more long-lasting events, such as learning and motivation.

A variety of chemicals serve as neuromodulators. (1) *Neuropeptides* are the largest class of neuromodulators. Other neuromodulators include some novel chemical messengers such as (2) *adenosine triphosphate (ATP)*, which normally serves as the primary energy carrier but can be released into the synaptic cleft; (3) the short-lived gas *nitric oxide (NO),* which serves multiple other roles in the body (see p. 346); and (4) *endocannabinoids,* a group of lipid messengers that act in a way similar to the active component of *cannabis,* or *marijuana.* Let us examine the most abundant of the neuromodulators, neuropeptides, in more detail.

Neuropeptides differ from classical neurotransmitters in several important ways. Classical neurotransmitters are small, rapid-acting molecules that typically trigger the opening of specific ion channels to bring about a change in potential in the postsynaptic neuron (an EPSP or an IPSP) within a few milliseconds or less. Most classical neurotransmitters are synthesized and packaged locally in synaptic vesicles in the cytosol of the axon terminal. These chemical messengers are primarily amino acids or closely related compounds. By contrast, neuropeptides are larger molecules made up of anywhere from 2 to about 40 amino acids. They are synthesized in the endoplasmic reticulum and Golgi complex (see ❙Figure 2-3, p. 27) of the neuronal cell body and are moved by axonal transport along the microtubular highways to the axon terminal (see p. 47). Neuropeptides are not stored in small synaptic vesicles with the classical neurotransmitters but instead are packaged in large **dense-core vesicles**, which are also present in the axon terminal [see the chapter opener photo on p. 87. A dense-core vesicle is larger deep blue vesicle among the smaller orange synaptic vesicles in the synaptic knob on the top left. (The large green spheres are mitochon-

dria.)]. Dense-core vesicles undergo Ca^{2+}-induced exocytosis and release neuropeptides at the same time that neurotransmitter is released from synaptic vesicles. An axon terminal typically releases only a single classical neurotransmitter, but the same terminal may also contain one or more neuropeptides that are co-secreted simultaneously with the neurotransmitter.

Most but not all neuropeptides function as neuromodulators. (An example of a neuropeptide that has no effect on neuronal activity and thus does not function as a neuromodulator is a neurohormone, which is secreted by specialized neurons into the blood instead of being released into a synaptic cleft.) *Endogenous opioids* are examples of neuropeptides that do function as neuromodulators. Endogenous opioids are internally produced morphinelike substances that dampen the sensation of pain by exerting effects similar to the opiate drugs morphine and codeine (see p. 192). Neuropeptides that serve as neuromodulators also include many substances that in addition function as hormones released into the blood from endocrine tissues. *Cholecystokinin (CCK)* is an example. As a hormone, CCK is released from the small intestine following a meal and causes the gallbladder to contract and release bile into the intestine, among other digestive actions (see Chapter 16). CCK also functions in the brain as a neuromodulator, causing the sensation of no longer being hungry. A number of chemical messengers are versatile and can assume different roles, depending on their source, distribution, and interaction with different cell types.

Presynaptic inhibition or facilitation can selectively alter the effectiveness of a presynaptic input.

Besides neuromodulation, another means of depressing or enhancing synaptic effectiveness is presynaptic inhibition or facilitation. Sometimes, a third neuron influences activity between a presynaptic ending and a postsynaptic neuron. The presynaptic axon terminal (labeled A in ❙Figure 4-17) may itself be innervated by another axon terminal (labeled B). Note that this axon-to-axon synapse is different than the usual axon-to-dendrite (or cell body) synapse. The neurotransmitter released from modulatory terminal B binds with receptors on terminal A. This binding alters the amount of neurotransmitter released from terminal A in response to action potentials. If the amount of neurotransmitter released from A is reduced, the phenomenon is known as **presynaptic inhibition**. If the release of neurotransmitter is enhanced, the effect is called **presynaptic facilitation**.

Let us look more closely at how this process works. You know that Ca^{2+} entry into an axon terminal causes the release of neurotransmitter by exocytosis of synaptic vesicles. The amount of neurotransmitter released from terminal A depends on how much Ca^{2+} enters this terminal in response to an action potential. Ca^{2+} entry into terminal A, in turn, can be influenced by activity in modulatory terminal B. We will use presynaptic inhibition to illustrate (❙Figure 4-17). The amount of neurotransmitter released from presynaptic terminal A, an excitatory input in our example, influences the potential in the postsynaptic neuron at which it terminates (labeled C in the figure). Firing of A by itself generates an EPSP in postsynaptic neuron C. Now consider that B is stimulated simultaneously with A. Neurotransmitter from terminal B binds on terminal A, reducing Ca^{2+} entry into terminal A. Less Ca^{2+} entry means less neurotransmitter release from A. Note that modulatory neuron B can suppress neurotransmitter release from A only when A is firing. If this presynaptic inhibition by B prevents A from releasing its neurotransmitter, the formation of EPSPs on postsynaptic membrane C from input A is specifically prevented. As a result, no change in the potential of the postsynaptic neuron occurs despite action potentials in A.

Would the simultaneous production of an IPSP through activation of an inhibitory input to negate an EPSP produced by excitatory input A achieve the same result? Not quite. Activation of an inhibitory input to cell C would produce an IPSP in cell C, but this IPSP could cancel out not only an EPSP from excitatory input A but also any EPSPs produced by other excitatory terminals, such as terminal D in the figure. The entire postsynaptic membrane is hyperpolarized by IPSPs, thereby negating (canceling) excitatory information fed into any part of the cell from any presynaptic input. By contrast, presynaptic inhibition (or presynaptic facilitation) works in a much more specific way. Presynaptic inhibition provides a means by which certain inputs to the postsynaptic neuron can be *selectively*
❙**Figure 4-17 Presynaptic inhibition.** A, an excitatory terminal ending on postsynaptic cell C, is itself innervated by inhibitory terminal B. Stimulation of terminal A alone produces an EPSP in cell C, but simultaneous stimulation of terminal B prevents the release of excitatory neurotransmitter from terminal A. Consequently, no EPSP is produced in cell C despite the fact that terminal A has been stimulated. Such presynaptic inhibition selectively depresses activity from terminal A without suppressing any other excitatory input to cell C. Stimulation of excitatory terminal D produces an EPSP in cell C even though inhibitory terminal B is simultaneously stimulated because terminal B only inhibits terminal A.

FIGURE FOCUS: *Assume excitatory terminal D is itself innervated by an excitatory terminal E. What would happen to the potential in postsynaptic cell C if terminal D and terminal E were simultaneously stimulated?*

Principles of Neural and Hormonal Communication | **111**

inhibited without affecting the contributions of any other inputs. For example, firing of B specifically prevents the formation of an EPSP in the postsynaptic neuron from excitatory presynaptic neuron A but does not influence other excitatory presynaptic inputs. Excitatory input D can still produce an EPSP in the postsynaptic neuron even when B is firing. This type of neuronal integration is another means by which electrical signaling between neurons can be carefully fine-tuned.

Drugs and diseases can modify synaptic transmission.

Clinical Note Most drugs that influence the nervous system function by altering synaptic mechanisms. Synaptic drugs may block an undesirable effect or enhance a desirable effect. Possible drug actions include (1) altering the synthesis, storage, or release of a neurotransmitter; (2) modifying neurotransmitter interaction with the postsynaptic receptor; (3) influencing neurotransmitter reuptake or destruction; and (4) replacing a deficient neurotransmitter with a substitute transmitter.

You already learned about SSRIs. As another example, the socially abused drug **cocaine** blocks the reuptake of the neurotransmitter *dopamine* at presynaptic terminals. It does so by binding competitively with the dopamine reuptake transporter, which is a protein molecule that picks up released dopamine from the synaptic cleft and shuttles it back to the axon terminal. With cocaine occupying the dopamine transporter, dopamine remains in the synaptic cleft longer than usual and continues to interact with its postsynaptic receptors. The result is prolonged activation of neural pathways that use this chemical as a neurotransmitter, especially pathways that play a role in feelings of pleasure. In essence, when cocaine is present, the neural switches in the pleasure pathway are locked in the "on" position.

Cocaine is addictive because the involved neurons become *desensitized* to the drug. After the postsynaptic cells are incessantly stimulated for an extended time, they can no longer transmit normally across synapses without increasingly larger doses of the drug. Specifically, with prolonged use of cocaine, the number of dopamine receptors in the brain is reduced in response to the glut of the abused substance. As a result of this desensitization, the user must steadily increase the dosage of the drug to get the same "high," or sensation of pleasure, a phenomenon known as *drug tolerance*. When the cocaine molecules diffuse away, the sense of pleasure evaporates because the normal level of dopamine activity no longer "satisfies" the overly needy demands of the postsynaptic cells for stimulation. Cocaine users reaching this low become frantic and profoundly depressed. Only more cocaine makes them feel good again. But repeated use of cocaine often modifies responsiveness to the drug; the user no longer derives pleasure from the drug but suffers unpleasant *withdrawal symptoms* once its effect has worn off. The user typically becomes **addicted** to the drug, compulsively seeking it out, first to experience the pleasurable sensations and later to avoid the negative withdrawal symptoms. Cocaine is abused by millions who have become addicted to its mind-altering properties, with devastating social and economic effects.

Synaptic transmission is also vulnerable to neural toxins, which may cause nervous system disorders by acting at either presynaptic or postsynaptic sites. For example, two different neural poisons, tetanus toxin and strychnine, act at different synaptic sites to block inhibitory impulses while leaving excitatory inputs unchecked. Tetanus toxin prevents the presynaptic release of a specific inhibitory neurotransmitter, whereas strychnine blocks specific postsynaptic inhibitory receptors.

Tetanus toxin prevents release of GABA from inhibitory presynaptic inputs terminating at neurons that supply skeletal muscles. Unchecked excitatory inputs to these neurons result in uncontrolled muscle spasms. These spasms occur especially in the jaw muscles early in the disease, giving rise to the common name of *lockjaw* for this condition. Later, they progress to the muscles responsible for breathing, at which point death occurs.

Strychnine competes with another inhibitory neurotransmitter, glycine, at the postsynaptic receptor. This poison combines with the receptor but does not directly alter the potential of the postsynaptic cell in any way. Instead, it blocks the receptor so that it is not available for interaction with glycine when the latter is released from the inhibitory presynaptic ending. Thus, strychnine abolishes postsynaptic inhibition (formation of IPSPs) in nerve pathways that use glycine as an inhibitory neurotransmitter. Unchecked excitatory pathways lead to convulsions, muscle spasticity, and death.

Many other drugs and diseases influence synaptic transmission, but as these examples illustrate, any site along the synaptic pathway is vulnerable to interference.

Neurons are linked through complex converging and diverging pathways.

Two important relationships exist between neurons: convergence and divergence. A given neuron may have many other neurons synapsing on it. Such a relationship is known as **convergence** (❚Figure 4-18). Through converging input, a single cell is influenced by thousands of other cells. This single cell, in turn, influences the level of activity in many other cells by divergence of output. The term **divergence** refers to the branching of axon terminals so that a single cell synapses with and influences many other cells.

Note that a particular neuron is postsynaptic to the neurons converging on it but presynaptic to the other cells at which it terminates. Thus, the terms *presynaptic* and *postsynaptic* refer only to a single synapse. Most neurons are presynaptic to one group of neurons and postsynaptic to another group.

An estimated 100 billion neurons and 10^{14} (100 quadrillion) synapses are found in the brain alone! A single neuron may be connected to between 5000 and 10,000 other neurons. When you consider the vast and intricate interconnections possible among these neurons through converging and diverging pathways, you can begin to imagine the complexity of the wiring mechanism of our nervous system. Even the most sophisticated computers are far less complex than the human brain. The "language" of the nervous system—that is, all communication among neurons—is in the form of graded potentials, action potentials, neurotransmitter signaling across synapses, and other nonsynaptic forms of chemical chatter. All activities for which the nervous system is responsible—every sensation, every command to move a muscle, every thought, every emo-

tion, every memory, every spark of creativity—depend on the patterns of electrical and chemical signaling among neurons along these complexly wired neural pathways.

A neuron communicates with the cells it influences by releasing a neurotransmitter, but this is only one means of intercellular ("between cell") communication. We now consider all the ways by which cells can "talk" with one another.

4.5 Intercellular Communication and Signal Transduction

Coordination of the diverse activities of cells throughout the body to accomplish life-sustaining and other desired responses depends on the ability of cells to communicate with one another.

Communication among cells is largely orchestrated by extracellular chemical messengers.

Intercellular communication can take place either directly or indirectly (Figure 4-19). *Direct* intercellular communication involves physical contact between the interacting cells:

1. *Through gap junctions and possibly through tunneling nanotubes.* The most intimate means of intercellular communication is through gap junctions, the minute tunnels that bridge the cytoplasm of neighboring cells in some types of tissues. Through gap junctions, ions and small molecules are directly exchanged between closely associated interacting cells without ever entering the ECF.

Scientists recently discovered a possible new route for direct exchange of materials between cells—long, thin, hollow filaments called **tunneling nanotubes (TNTs)**—

that transiently form between laboratory-grown cells of a variety of types (Figure 4-20) and have now been confirmed to exist in living tissue. Studies suggest that these intercellular bridges serve as a route for selective, relatively long transfer from one cell to another of rather large cargo, including proteins or even organelles such as mitochondria. Whereas cells connected by gap junctions are in close proximity (being 2 to 4 nm apart), TNTs may extend up to 150 μm (150,000 nm) between cells. Furthermore, the opening in a gap junction is 1.5 nm in diameter compared to the much larger 50 to 200 nm diameter opening in a TNT. Because of these major differences between gap junctions and TNTs, TNTs can transfer larger cargo considerably longer distances than gap junctions can. Researchers have identified motor proteins (see p. 48) in TNTs that are believed to help move substances through these long connecting tunnels. Evidence further suggests that viruses, including HIV, the AIDS virus, can hijack TNTs to move directly between cells without entering the ECF.

2. *Through transient direct linkup of surface markers.* Some cells, such as those of the immune system, have specialized markers on the surface membrane that allow them to directly link with certain other cells that have compatible markers for transient interactions. This is how cell-destroying immune cells specifically recognize and selectively destroy only undesirable cells, such as cancer cells, while leaving the body's healthy cells alone (see p. 423).

The most common means by which cells communicate with one another is *indirectly* through **extracellular chemical messengers**, or **signal molecules**, of which there are four types: *paracrines/autocrines, neurotransmitters, hormones,* and *neurohormones.* In each case, a specific chemical messenger, the signal molecule, is synthesized by specialized controlling cells to serve a designated purpose. On being released into the ECF by appropriate stimulation, these extracellular chemical messengers act on other particular cells, the messenger's **target cells**, in a prescribed manner. To exert its effect, an extracellular chemi-

▌**Figure 4-19 Types of intercellular communication.** Gap junctions and transient direct linkup of cells by means of complementary surface markers are both means of direct communication between cells. Paracrines, neurotransmitters, hormones, and neurohormones are all extracellular chemical messengers that accomplish indirect communication between cells. These chemical messengers differ in their source and the distance they travel to reach their target cells.

Emil Lou

cal messenger must bind with target cell receptors specific for it. A given cell may have thousands to as many as a few million receptors, of which hundreds to as many as 100,000 may be for the same chemical messenger. Different cell types have distinct combinations of receptors, allowing them to react individually to various regulatory extracellular chemical messengers. Nearly 5% of all genes in humans code for synthesis of these membrane receptors, indicative of the importance of this means of intercellular communication.

The four types of extracellular chemical messengers differ in their source and the distance to and means by which they get to their site of action.

1. **Paracrines** are local chemical messengers whose effect is exerted only on neighboring cells in the immediate environment of their site of secretion. An **autocrine** is even more localized—after being secreted, it acts only on the cell that secreted it. For convenience, we implicitly include autocrines in

Unless otherwise noted, all content on this page is © Cengage Learning.

future discussions regarding paracrines. Because paracrines are distributed by simple diffusion within the interstitial fluid, their action is restricted to short distances. They do not gain entry to the blood in any significant quantity because they are rapidly inactivated by locally existing enzymes. One example of a paracrine is *histamine,* which is released from a specific type of connective tissue cell during an inflammatory response within an invaded or injured tissue (see p. 409). Among other things, histamine dilates (opens more widely) the blood vessels in the vicinity to increase blood flow to the tissue. This action brings additional blood-borne combat supplies into the affected area.

2. As you just learned, neurons communicate directly with the cells they innervate (their target cells) by releasing **neurotransmitters**, which are short-range chemical messengers, in response to electrical signals (action potentials). Like paracrines, neurotransmitters diffuse from their site of release across a narrow extracellular space to act locally on an adjoining target cell, which may be another neuron, a muscle, or a gland. Neurons themselves may carry electrical signals long distances (the length of the axon), but the chemical messenger released at the axon terminal acts at short range—just across the synaptic cleft.

3. **Hormones** are long-range chemical messengers specifically secreted into the blood by endocrine glands in response to an appropriate signal. The blood carries the messengers to other sites in the body, where they exert their effects on their target cells some distance from their site of release. Only the target cells of a particular hormone have membrane receptors for binding with this hormone. Nontarget cells are not influenced by any blood-borne hormones that reach them.

4. **Neurohormones** are hormones released into the blood by *neurosecretory neurons.* Like ordinary neurons, neurosecretory neurons can respond to and conduct electrical signals. Instead of directly innervating target cells and releasing a neurotransmitter into the synaptic cleft, however, a neurosecretory neuron releases its chemical messenger, a neurohormone, into the blood when an action potential reaches the axon terminals. The neurohormone is then distributed through the blood to distant target cells. An example is *vasopressin,* a neurohormone produced by nerve cells in the brain that promotes water conservation by the kidneys during urine formation. In the future, the general term *hormone* will tacitly include both blood-borne hormonal and neurohormonal messengers.

We now turn to how these chemical messengers cause the right cellular response.

Extracellular chemical messengers bring about cell responses by signal transduction.

The term **signal transduction** refers to the process by which incoming signals (instructions from extracellular chemical messengers) are conveyed into the target cell, where they are transformed into the dictated cellular response. Binding of the extracellular chemical messenger amounts to a signal for the cell to get a certain job done. During signal transduction, the extracellular signal is transduced, or changed into a form

necessary to modify intracellular activities to accomplish the desired outcome. (A *transducer* is a device that receives energy from one system and transmits it in a different form to another system. For example, your radio receives radio waves sent out from the broadcast station and transmits these signals in the form of sound waves that can be detected by your ears.)

Signal transduction occurs by different mechanisms, depending on the messenger and the receptor type (▮Table 4-3):

1. *Lipid-soluble extracellular chemical messengers,* such as cholesterol-derived steroid hormones, gain entry into the cell by dissolving in and passing through the lipid bilayer of the target cell's plasma membrane. Thus, these extracellular chemical messengers bind to receptors inside the target cell to initiate the desired intracellular response themselves, usually by *changing gene activity,* either turning on or suppressing transcription of specific genes. In this way the messenger controls the level of activity of the transcribed protein, such as an enzyme.

2. *Water-soluble extracellular chemical messengers,* by contrast, cannot gain entry to the target cell because they are poorly soluble in lipid and cannot dissolve in the plasma membrane. The major water-soluble extracellular messengers are peptide (protein) hormones delivered by the blood, neurotransmitters released from nerve endings, and paracrines released locally. These water-soluble messengers signal the target cell to perform a certain response by first binding with receptors specific for that given messenger on the outer surface of the plasma membrane. This binding triggers a sequence of intracellular events that controls a particular cellular activity,

▮TABLE 4-3 Signal Transduction Pathways Used by Extracellular Chemical Messengers

I. Pathway used by lipid-soluble extracellular messengers that bind to intracellular receptors

A. Function in nucleus to change specific gene activity (example: steroid hormones)

II. Pathways used by water-soluble extracellular messengers that bind to surface membrane receptors

A. Bind to and open or close chemically gated receptor-channels (example: neurotransmitters)

B. Bind to and activate receptor–enzyme complexes

   1. Use tyrosine kinase pathway, where the receptor itself functions as an enzyme (examples: insulin, growth factors)

   2. Use JAK/STAT pathway, where the receptor and attached enzymes function as a unit (examples: prolactin, immune cytokines)

C. Bind to G-protein-coupled receptors (GPCRs) and activate second-messenger pathways (examples: eicosanoids and most peptide hormones)

such as membrane transport, secretion, metabolism, or contraction.

Despite the wide range of possible responses, binding of a water-soluble extracellular messenger (also known as the **first messenger**) to its matching surface membrane receptor brings about the desired intracellular response by one of three general means, depending on receptor type.

1. Messenger binding to a *chemically gated receptor-channel* opens or closes the channel, with the resultant ion movement leading to the cell's response.
2. Messenger binding to a *receptor–enzyme complex* activates tyrosine kinase, which phosphorylates designated proteins that lead to the cell's response.
3. Messenger binding to a *G-protein-coupled receptor* activates a second-messenger pathway that carries out the cell's response.

Because of the universal nature of these events, let us examine each more closely.

Some water-soluble extracellular messengers open chemically gated receptor-channels.

Some extracellular messengers carry out the assigned task by opening or closing specific chemically gated receptor-channels to regulate movement of particular ions across the membrane. In this case, *the receptor itself serves as an ion channel.* When the appropriate extracellular messenger binds to the **receptor-channel**, the channel opens or closes, depending on the signal. (In the future, for convenience when discussing receptor-channels in general we refer only to the more common opening of channels.) An example is the opening of chemically gated receptor-channels in the subsynaptic membrane in response to neurotransmitter binding (see ❙ Figure 4-14). The resultant small, short-lived movement of given charge-carrying ions across the membrane through these open channels generates electrical signals—in this example, EPSPs and IPSPs.

On completion of the response, the extracellular messenger is removed from the receptor site and the chemically gated channels close once again. The ions that moved across the membrane through opened channels to trigger the response are returned to their original location by special membrane carriers.

Some water-soluble extracellular messengers activate receptor-enzymes.

Most water-soluble extracellular messengers that cannot enter their target cells issue their orders by triggering a "Psst, pass it on" process. In most instances, on binding to a surface membrane receptor, the extracellular messenger relays its message inside the cell by activating intracellular **protein kinases**, the name for any enzyme that transfers a phosphate group from ATP to a particular intracellular protein. As a result of phosphorylation, these proteins alter their shape and function, that is, are activated, to ultimately accomplish the cellular response dictated by the first messenger. Transduction may occur in a single step, although typically phosphorylation of a single kind of protein does not get the job done. Usually, protein kinases act in a chain of reactions, called a **cascade**, to pass along the signal to the final designated proteins capable of carrying out the desired effect. A body cell contains an estimated 1 billion protein molecules. The ultimate cellular response to receptor binding by an extracellular messenger hinges on which of these proteins are activated by phosphorylation, which depends on the messenger.

Protein kinases are activated on binding of the signal molecule to the surface receptor in one of two ways: by activating tyrosine kinase on binding to a receptor–enzyme complex or by activating a second-messenger pathway on binding to a G-protein-coupled receptor. We next describe these mechanisms.

The protein kinase **tyrosine kinase** is a key participant in two different signaling pathways—the tyrosine kinase pathway and the JAK/STAT pathway (❙ Table 4-3). In both of these pathways, protein activation on binding of the extracellular messenger to a receptor–enzyme complex is accomplished by specifically phosphorylating tyrosine, a type of amino acid within the protein, hence the name *tyrosine kinase.*

Tyrosine Kinase Pathway In the **tyrosine kinase pathway**, the simplest of the pathways, the *receptor itself functions as an enzyme,* a so-called **receptor-enzyme**, which has a receptor portion facing the ECF and protein kinase (tyrosine kinase) site on its portion that faces the cytosol (❙ Figure 4-21). To activate tyrosine kinase, appropriate extracellular messengers must bind with two of these receptor-enzymes, which assemble into a pair. On activation, the tyrosine kinase site adds phosphate groups to the tyrosines on the cytosolic side of the receptor-enzyme. Designated proteins inside the cell recognize and bind to the phosphorylated receptor-enzyme. Then the receptor-enzyme's tyrosine kinase adds phosphate groups to the tyrosines in the bound proteins. As a result of phosphorylation, the designated proteins change shape and function (are activated), enabling them to bring about the desired cellular response. The hormone insulin, which plays a major role in maintaining glucose homeostasis, exerts its effects via the tyrosine kinase pathway. Also, many growth factors that help regulate cell growth and division, such as *nerve growth factor* and *epidermal growth factor,* act via this pathway.

JAK/STAT Pathway In the **JAK/STAT pathway**, instead of the receptor itself having tyrosine kinase activity, the tyrosine kinase activity resides in a family of separate cytosolic enzymes called *Janus family tyrosine kinases,* better known as *JAKs,* two of which are attached, one on each side, to the receptor. *The receptor and attached enzymes function as a unit.* Binding of an extracellular messenger to the receptor on the ECF side causes a conformational change in the receptor that activates the JAKs bound to the cytosolic side of the receptor. Activated JAKs phosphorylate *signal transducers and activators of transcription (STAT)* within the cytosol. Phosphorylated STAT moves to the nucleus and turns on transcription of selected genes, resulting in synthesis of new proteins that carry out the cellular response. Some hormones, for example prolactin, the hormone that

1 Two extracellular messengers bind to two tyrosine kinase receptor-enzymes, which pair, activating receptor-enzyme's protein kinase (tyrosine kinase) site that faces the cytoplasm.

2 Tyrosine kinase site self-phosphorylates receptor-enzyme's tyrosines.

3 Inactive designated protein binds to phosphorylated receptor-enzyme, which phosphorylates protein, activating it.

4 Active designated protein brings about desired response.

stimulates milk secretion in lactating mothers, as well as cytokines, chemical mediators of the immune system, use this JAK/STAT signal transduction pathway.

Most water-soluble extracellular chemical messengers activate second-messenger pathways via G-protein-coupled receptors.

The **second-messenger pathway** is initiated by binding of the first messenger (alias the extracellular chemical messenger, alias the signal molecule) to a surface membrane receptor specific for it. In this pathway, *the receptor is coupled with a G protein,* appropriately called a **G-protein-coupled receptor (GPCR)**, which snakes through the membrane (**I** Figure 4-22). Binding of the first messenger to the receptor activates the **G protein**, which is a membrane-bound intermediary. On activation, a portion of the G protein shuttles along the membrane to alter the activity of a nearby membrane protein called the **effector protein**. Once altered, the effector protein leads to an increased concentration of an intracellular messenger, known as the **second messenger**. The second messenger relays the orders through a cascade of chemical reactions inside the cell that cause a change in the shape and function of designated proteins. Once activated, these designated proteins accomplish the cellular response dictated by the first messenger. Most commonly,
I Figure 4-22 **Activation of a second-messenger pathway via binding of a first messenger to a G-protein-coupled receptor.** Binding of an extracellular (first) messenger to the extracellular side of a G-protein-coupled receptor activates a membrane-bound effector protein by means of a G-protein intermediary. The effector protein produces an intracellular second messenger, which ultimately leads to the cellular response.

the second messenger activates an intracellular protein kinase, which leads to phosphorylation and thereby altered function of designated proteins. The intracellular pathways activated by a second messenger are remarkably similar among different cells despite the diversity of ultimate responses. The variability in response depends on the specialization of the cell, not on the mechanism used.

Clinical Note About half of all drugs prescribed today act on G-protein-coupled receptors. These receptors participate in some way in most body functions, so they are important targets for a variety of drugs used to treat diverse disorders. For example, they include drugs used to reduce high blood pressure, to treat congestive heart failure, to suppress stomach acid, to open airways in asthmatics, to ease symptoms of enlarged pros-

tate, to block histamine-induced allergic responses, to relieve pain, and to treat hormone-dependent cancers.

The effects of protein kinases in the tyrosine kinase, JAK/STAT, and second-messenger signal transduction pathways are reversed by another group of enzymes called **protein phosphatases**, which remove phosphate groups from the designated proteins. Unlike protein kinases, which are active only when an extracellular messenger binds to a surface membrane receptor, most protein phosphatases are continuously active in cells. By continually removing phosphate groups from designated proteins, protein phosphatases quickly shut off a signal transduction pathway if its signal molecule is no longer bound at the cell surface. Thus, kinases activate a signaling pathway by phosphorylating designated proteins, whereas phosphatases inactivate the pathway by dephosphorylating these proteins. Protein phosphorylation/dephosphorylation plays a central role in regulating the activity of proteins and thus their extensive roles in cellular physiology.

Some neurotransmitters function through intracellular second-messenger systems. Most, but not all, neurotransmitters function by changing the conformation of chemically gated receptor-channels, thereby altering membrane permeability and ion fluxes across the postsynaptic membrane, a process with which you are already familiar. Synapses involving these rapid responses are considered **"fast" synapses**. However, another mode of synaptic transmission used by some neurotransmitters, such as *serotonin,* involves the activation of intracellular second messengers. Synapses that lead to responses mediated by second messengers are known as **"slow" synapses** because these responses take longer and often last longer than those accomplished by fast synapses. For example, neurotransmitter-activated second messengers may trigger long-term postsynaptic cellular changes believed to be linked to neuronal growth and development and possibly play a role in learning and memory.

Depending on the cell type, the first messenger either can be released from the target cell and ultimately degraded by the liver and excreted in the urine, or alternatively the first messenger and receptor complex can be removed from action by receptor-mediated endocytosis, in which both the receptor and extracellular chemical messenger are internalized by the target cell (see p. 31).

Second-messenger pathways are widely used throughout the body, including being the key means by which paracrines and most water-soluble hormones ultimately bring about their effects. Let us now turn attention to paracrine communication before focusing on hormonal communication, where we will examine specific second-messenger systems in more detail.

4.6 Introduction to Paracrine Communication

Most paracrines are either cytokines or eicosanoids. **Cytokines** are a collection of *protein* signal molecules secreted by cells of the immune system and other cell types that largely act locally to regulate immune responses. **Eicosanoids** (eye-KOH-sah-noydz) are a group of *lipid* signal molecules derived from a fatty acid in the plasma membrane of most cell types that act locally to regulate diverse cellular processes throughout the body.

Cytokines act locally to regulate immune responses.

Cytokines are intercellular regulatory proteins secreted primarily by white blood cells and other cells of the immune system but also by some nonimmune cells. The nonimmune cells that are the most prolific producers of cytokines are endothelial cells that line the blood vessels (see p. 346), fibroblasts that form the extracellular matrix in connective tissue (see p. 61), and adipose tissue cells that store excess fat (see p. 623). The primary function of cytokines is to regulate numerous activities of the immune system, such as mediating inflammation and enhancing the activity of antibody-producing cells and virus-fighting cells. Some cytokines exert nonimmune effects as well, such as by influencing cell growth and cell differentiation during embryonic development. Cytokines important in development are typically referred to specifically as various **growth factors**, but growth factors have other functions not related to development as well. For example, growth factors as well as other cytokines both help regulate wound healing. More than 100 cytokines have been identified. You will learn about the specific functions of major cytokines in later chapters.

Cytokines typically act locally as paracrines but some travel in the blood, similar to hormones, to distant target cells to produce systemic (bodywide) responses. For example, specific cytokines are responsible for the generally miserable way you feel when you have the "flu." The boundary between whether a given signal molecule should be classified as a cytokine, a growth factor, or a hormone sometimes gets blurry.

Cytokines function primarily by binding to receptor–enzyme complexes, with immune cytokines largely employing the JAK/STAT pathway and growth factors mainly using the tyrosine kinase pathway.

Eicosanoids are locally acting chemical messengers derived from plasma membrane.

Eicosanoids are a group of lipid signal molecules that act locally as paracrines to regulate a plethora of physiological processes. Eicosanoids are modified 20-carbon fatty acids derived from **arachidonic acid**, a 20-carbon polyunsaturated fatty acid constituent of the phospholipids within the plasma membrane (see p. 56) (*eikos* means "20" in Greek). On appropriate stimulation, arachidonic acid is split from the plasma membrane by a membrane-bound enzyme, **phospholipase A_2,** and then is converted

❚Figure 4-23 Structure and nomenclature of prostaglandins.

into one of three main classes of eicosanoids—**prostaglandins**, **thromboxanes**, and **leukotrienes**—depending on how it is further processed. The enzyme **cyclooxygenase (COX)** initiates a pathway leading to formation of prostaglandins and thromboxanes, whereas the enzyme **lipooxygenase (LOX)** sets off another pathway that results in generation of leukotrienes.

Each eicosanoid class has multiple members, depending on slight structural variations driven by further enzymatic processing. Using prostaglandins as an example, prostaglandins are designated as belonging to one of three groups—PGA, PGE, or PGF—according to structural variations in the five-carbon ring that they contain at one end (❚Figure 4-23). Within each group, prostaglandins are further identified by the number of double bonds present in the two side chains that project from the ring structure (for example, PGE₁ has one double bond and PGE₂ has two double bonds). Which eicosanoids are produced by a particular cell depends on what specific enzymes the cell has at its disposal for processing arachidonic acid.

Once synthesized, eicosanoids diffuse out of the cell to serve as local extracellular messengers. They exert their effects by binding with surface membrane receptors of their neighboring target cells and initiating second messenger pathways. After eicosanoids act, they are rapidly inactivated by local enzymes before they gain access to the blood; if they do reach the circulatory system, they are swiftly degraded on their first pass through the lungs so that they are not dispersed through the systemic arterial system.

Eicosanoids are the most ubiquitous extracellular chemical messengers and are among the most biologically active compounds known. They exert a tremendous number of very specific actions in almost every tissue of the body, as made evident by the following discussion of the functions of each of the main classes of eicosanoids:

1. *Prostaglandins* were first identified in the semen and were believed to be of prostate gland origin (hence their name, even though they are actually secreted into the semen by another male accessory sex gland; see p. 731). Thus they were first known for enhancing sperm transport in the male and female reproductive systems. However, their production and actions are not limited to the reproductive system. Prostaglandins also are produced by and exert a bewildering variety of effects in the respiratory, urinary, digestive, nervous, endocrine, circulatory, and immune systems, in addition to affecting fat metabolism, as can be seen in ❚Table 4-4. Slight variations in prostaglandin structure are accompanied by profound differences in biological action.

❚TABLE 4-4 Actions of Prostaglandins

Body System Affected	Actions of Prostaglandins
Reproductive system	Promote sperm transport by action on smooth muscle in the male and female reproductive tracts
	Play a role in ovulation
	Play important role in menstruation
	Contribute to preparation of the maternal portion of the placenta
	Promote contractions of the uterus
Respiratory system	Some promote dilation, others constriction, of respiratory airways
Urinary system	Increase renal blood flow
	Increase excretion of water and salt
Digestive system	Inhibit HCl secretion by the stomach
	Stimulate intestinal motility
Nervous system	Influence neurotransmitter release and action
	Act at the hypothalamic "thermostat" to increase body temperature
	Intensify the sensation of pain
Endocrine system	Enhance cortisol secretion
	Influence tissue responsiveness to hormones in many instances
Circulatory system	Influence platelet aggregation
	Some decrease, others increase, blood pressure
Immune system	Promote many aspects of inflammation, including development of fever
Fat metabolism	Inhibit fat breakdown

Clinical Note Prostaglandins' various actions can be manipulated therapeutically. A classic example is the use of *aspirin* and other *nonsteroidal anti-inflammatory drugs (NSAIDs),* such as *ibuprofen,* which all inhibit COX, thus blocking the conversion of arachidonic acid into prostaglandins, for pain relief and fever reduction. (Note in ❚Table 4-4 that prostaglandins intensify pain and play a key role in development of a fever.)

2. *Thromboxanes* were originally discovered as secretory products of thrombocytes (alias blood platelets), accounting for their name. Thromboxanes promote platelet aggregation (to help stop bleeding) and constrict blood vessels.

3. *Leukotrienes* were initially encountered as secretory products from leukocytes (white blood cells), thus their name. These local messengers are involved in inflammatory responses and cause the profound airway constriction characteristic of asthma.

1. Distinguish between cytokines and eicosanoids.
2. Discuss the roles of phospholipase A_2, cyclooxygenase, and lipooxygenase.
3. Explain how NSAIDs provide pain relief.

4.7 Introduction to Hormonal Communication

Endocrinology is the study of homeostatic chemical adjustments and other activities accomplished by hormones, which are secreted into the blood by endocrine glands. Earlier we described the underlying molecular and cellular mechanisms of the nervous system—electrical signaling within neurons and chemical transmission of signals between neurons. We now focus on the molecular and cellular features of hormonal action and compare the similarities and differences in how neurons and endocrine cells communicate with other cells in carrying out their regulatory actions.

Hormones are classified chemically as hydrophilic or lipophilic.

Hormones fall into two chemical groups based on their solubility: *hydrophilic* and *lipophilic* hormones. Hormones can also be classified according to their chemical structure (namely, *peptides, amines,* and *steroids*) as follows (❙Table 4-5):

1. **Hydrophilic** ("water-loving") **hormones** are highly water soluble and have low lipid solubility. Most hydrophilic hormones are peptide or protein hormones consisting of specific amino acids arranged in a chain of varying length. The shorter chains are peptides, and the longer ones are proteins. For convenience, we refer to this entire category as **peptides**. Insulin from the pancreas is a peptide hormone. The **amines** are so called because they are amino acid derivatives. The amine hor-

❙**TABLE 4-5** Chemical Classification of Hormones

| Properties | Peptides | AMINES | | Steroids |
		Catecholamines and Indoleamines	Thyroid Hormone	
Solubility	Hydrophilic	Hydrophilic	Lipophilic	Lipophilic
Structure	Chains of specific amino acids	Tyrosine derivative (catecholamines) or tryptophan derivative (indoleamines)	Iodinated tyrosine derivative	Cholesterol derivative
Synthesis	In rough endoplasmic reticulum; packaged in Golgi complex	In cytosol	In colloid within thyroid gland (see p. 666)	Stepwise modification of cholesterol molecule in various intracellular compartments
Storage	Large amounts in secretory vesicles	In secretory vesicles	In colloid	Not stored; cholesterol precursor stored in lipid droplets

Hormones of this type	Most hormones	Catecholamines: hormones from the adrenal medulla, dopamine from hypothalamus. Indoleamines: melatonin from pineal gland	Only hormones from the follicular cells of the thyroid gland	Hormones from the adrenal cortex and gonads and some placental hormones; vitamin D (a hormone) is steroidlike

mones include two types of hydrophilic hormones (catecholamines and indoleamines) and one type of lipophilic hormone (thyroid hormone). *Catecholamines* are derived from the amino acid tyrosine and are largely secreted by the adrenal medulla. The adrenal gland consists of an inner adrenal medulla surrounded by an outer adrenal cortex. (You will learn more about the location and structure of the endocrine glands and the functions of specific hormones in later chapters.) Epinephrine is the major catecholamine hormone. *Indoleamines* are derived from the amino acid tryptophan and are secreted by the pineal gland. Melatonin is the only indoleamine hormone. Some neurotransmitters are also amines, such as dopamine (a catecholamine) and serotonin (an indoleamine). Dopamine also acts as a neurohormone, and serotonin is the precursor for melatonin, serving as examples of the overlapping activities of the nervous and endocrine systems.

2. **Lipophilic** ("lipid-loving") **hormones** have high lipid solubility and are poorly soluble in water. Lipophilic hormones include thyroid hormone and the steroid hormones. *Thyroid hormone,* as its name implies, is secreted exclusively by the thyroid gland; it is an iodinated tyrosine derivative. Even though catecholamines and thyroid hormone are both derived from tyrosine, they behave differently because of their solubility properties. **Steroids** are neutral lipids derived from cholesterol. They include hormones secreted by the adrenal cortex, such as cortisol, and the sex hormones (testosterone in males and estrogen in females) secreted by the reproductive organs.

Minor differences in chemical structure among hormones within each category often result in profound differences in biological response. For example, in ❙Figure 4-24, note the subtle difference between the steroid hormone testosterone, the male sex hormone responsible for inducing the development of masculine characteristics, and the steroid hormone estradiol, a form of estrogen, which is the feminizing female sex hormone.

The mechanisms of synthesis, storage, and secretion of hormones vary according to their chemical differences.

The solubility properties of a hormone determine (1) how the hormone is synthesized, stored, and secreted by the endocrine cell; (2) how the hormone is transported in the blood; and (3) how the hormone exerts its effects at the target cell. We first consider the different ways in which hydrophilic and lipophilic hormones are processed at their site of origin, the endocrine cell, before comparing their means of transport and their mechanisms of action.

Processing of Hydrophilic Peptide Hormones Peptide hormones are synthesized and secreted by an endocrine cell via the same steps used for manufacturing any protein that is exported from a cell (see ❙Figure 2-3, p. 27). From the time peptide hormones are synthesized until they are secreted, they are always segregated from intracellular proteins within membrane-enclosed compartments. Here is a brief outline of these steps:

1. Large precursor proteins, or **preprohormones**, are synthesized by ribosomes on the rough endoplasmic reticulum (ER).

Testosterone, a masculinizing hormone

Estradiol, a feminizing hormone
❙Figure 4-24 **Comparison of two steroid hormones: testosterone and estradiol.**

They then migrate to the Golgi complex in membrane-enclosed transport vesicles that pinch off from the smooth ER.

2. During their journey through the ER and Golgi complex, the preprohormones are pruned to active hormones.

3. The Golgi complex packages the finished hormones into secretory vesicles that are pinched off and stored in the cytoplasm until an appropriate signal triggers their secretion.

4. On appropriate stimulation, the secretory vesicles fuse with the plasma membrane and release their contents to the outside by exocytosis. Such secretion usually does not go on continuously; it is triggered only by specific stimuli. The blood then picks up the secreted hormones for distribution.

Processing of Lipophilic Steroid Hormones All steroidogenic (steroid-producing) endocrine cells perform the following steps to produce and release their hormonal product:

1. Cholesterol is the precursor for all steroid hormones.

2. Synthesis of the various steroid hormones requires a series of enzymatic reactions that modify the basic cholesterol molecule—for example, by varying the type and position of side groups attached to the cholesterol framework. Each conversion from cholesterol to a specific steroid hormone requires the help of particular enzymes limited to certain steroidogenic organs. Thus, each steroidogenic organ can produce only the steroid hormone or hormones for which it has a complete set of appropriate enzymes. For example, a key enzyme necessary for producing cortisol is found only in the adrenal cortex, so no other steroidogenic organ can produce this hormone.

3. Unlike peptide hormones, steroid hormones are not stored. Once formed, the lipid-soluble steroid hormones immediately diffuse through the steroidogenic cell's lipid plasma membrane to enter the blood. Only the hormone precursor cholesterol is stored within steroidogenic cells. Accordingly, the rate of steroid hormone secretion is controlled entirely by the rate of hormone synthesis. In contrast, peptide hormone secretion is controlled primarily by regulating the release of presynthesized stored hormone.

4. Following their secretion into the blood, some steroid hormones (and thyroid hormone) undergo further interconversions within the blood or other organs, where they are changed into more potent or different hormones.

The adrenomedullary catecholamines and thyroid hormone have unique synthetic and secretory pathways that are

described when we address each of these hormones specifically in the endocrine chapters (Chapters 18 and 19).

Hydrophilic hormones dissolve in the plasma; lipophilic hormones are transported by plasma proteins.

All hormones are carried by the blood, but they are not all transported in the same manner:

1. The hydrophilic peptide hormones simply dissolve in the blood.
2. Lipophilic steroids and thyroid hormone, which are poorly soluble in water, cannot dissolve to any extent in the watery blood. Instead, most lipophilic hormones circulate to their target cells reversibly bound to plasma proteins in the blood. Some plasma proteins carry only one type of hormone, whereas others, such as albumin, indiscriminately pick up any "hitchhiking" hormone.

Only the small, unbound, freely dissolved fraction of a lipophilic hormone is biologically active (that is, free to cross capillary walls and bind with target cell receptors to exert an effect). The bound form of steroid and thyroid hormones provides a large reserve of these lipophilic hormones that can be used to replenish the active free pool. To maintain normal endocrine function, the magnitude of the small, free, effective pool, rather than the total blood concentration of a particular lipophilic hormone, is monitored and adjusted.

3. Catecholamines are unusual in that only about 50% of these hydrophilic hormones circulate as free hormone; the other 50% are loosely bound to albumin. Because catecholamines are water soluble, the importance of this binding to plasma proteins is unclear.

Clinical Note The chemical properties of a hormone dictate not only how it is transported in the blood, but also the way in which it can be artificially introduced into the blood for therapeutic purposes. Because the digestive system does not secrete enzymes that can digest steroid and thyroid hormones, hormones such as the sex steroids contained in birth control pills can, when swallowed, be absorbed intact from the digestive tract into the blood. No other type of hormones can be taken orally (by mouth) because protein-digesting enzymes would attack and convert them into inactive fragments. Therefore, these hormones must be administered by non-oral routes; for example, insulin deficiency is treated with daily injections of insulin.

Next, we examine how the hydrophilic and lipophilic hormones vary in their mechanisms of action at their target cells.

Hormones generally produce their effect by altering intracellular proteins.

To induce their effect, hormones must bind with target cell receptors specific for them. Each interaction between a particular hormone and a target cell receptor produces a highly characteristic response that differs among hormones and among different target cells influenced by the same hormone. Both the location of the receptors within the target cell and the mechanism by which binding of the hormone with the receptors brings about a response vary, depending on the hormone's solubility characteristics.

Location of Receptors for Hydrophilic and Lipophilic Hormones Hormones can be grouped into two categories based on the location of their receptors:

1. The hydrophilic peptides and catecholamines, which are poorly soluble in lipid, cannot pass through the lipid membrane barriers of their target cells. Instead, they bind with specific receptors on the outer plasma membrane surface of the target cell.
2. The lipophilic steroids and thyroid hormone easily pass through the surface membrane to bind with specific receptors located inside the target cell.

General Means of Hydrophilic and Lipophilic Hormone Action Even though hormones cause a wide variety of responses, they ultimately influence their target cells by altering the cell's proteins in one of two major ways:

1. Surface-binding hydrophilic hormones function largely by activating second-messenger pathways within the target cell. This activation directly *alters the activity of preexisting intracellular proteins,* usually enzymes, to produce the desired effect.
2. Lipophilic hormones function mainly by activating specific genes in the target cell to cause *formation of new intracellular proteins,* which in turn produce the desired effect. The new proteins may be enzymatic or structural.

Let us examine the two major mechanisms of hormonal action (activation of second-messenger pathways and activation of genes) in more detail.

Hydrophilic hormones alter preexisting proteins via second-messenger systems.

Most hydrophilic hormones (peptides and catecholamines) bind to G-protein-coupled surface membrane receptors and produce their effects in their target cells by acting through a second-messenger pathway to alter the activity of preexisting proteins. There are two major second-messenger pathways: One uses **cyclic adenosine monophosphate (cyclic AMP**, or **cAMP)** as a second messenger, and the other uses Ca^{2+} in this role.

Both pathways use a G protein, which is found on the inner surface of the plasma membrane, as an intermediary between the receptor and the effector protein (see ❙ Figure 4-22). G proteins are so named because they are bound to guanine nucleotides—*guanosine triphosphate (GTP)* when active or *guanosine diphosphate (GDP)* when inactive. An inactive G protein consists of a complex of alpha (α), beta (β), and gamma (γ) subunits, with a GDP molecule bound to the α subunit. A number of different G proteins with varying α subunits have been identified. The different G proteins are activated in response to binding of various first messengers to surface receptors. When an appropriate extracellular messenger (a first messenger) binds with its receptor, the receptor attaches to the associated G pro-

▌Figure 4-25 Mechanism of action of hydrophilic hormones via activation of the cyclic AMP second-messenger pathway.

FIGURE FOCUS: *Does active protein kinase A phosphorylate the same inactive designated proteins in all cells that use the cAMP second-messenger pathway?*

tein, resulting in release of GDP from the G-protein complex. GTP then attaches to the α subunit, an action that activates the G protein. Once activated, the α subunit breaks away from the G-protein complex and moves along the inner surface of the plasma membrane until it reaches an effector protein, which is typically either an enzyme or an ion channel within the membrane. The a subunit links up with the effector protein and alters its activity. Researchers have identified more than 300 different receptors that convey instructions of extracellular messengers through the membrane to various effector proteins by means of G proteins. We next examine the cAMP pathway in more detail as an example of what happens after an effector protein is activated.

Cyclic AMP Second-Messenger Pathway

Cyclic AMP is the most widely used second messenger. In the following description of the cAMP pathway, the numbered steps correlate to the numbered steps in ▌Figure 4-25. When the appropriate extracellular messenger binds to its surface membrane receptor and activates the associated G protein, the G protein in turn activates the effector protein—in this case, the enzyme **adenylyl cyclase** (step **1**), which is located on the cytoplasmic side of the plasma membrane. Adenylyl cyclase converts intracellular ATP to cAMP by cleaving off two of the phosphates (step **2**). (This is the same ATP used as energy currency in the body.) Acting as the intracellular second messenger, cAMP triggers a preprogrammed series of chemical steps within the cell to bring about the response dictated by the first messenger. To begin, cAMP activates the intracellular enzyme, **protein kinase A (PKA)** (step **3**). Protein kinase A, in turn, phosphorylates a designated preexisting intracellular protein, such as an enzyme important in a particular metabolic pathway. Phosphorylation causes the protein to change its shape and function, thereby activating it (step **4**). This activated protein brings about the target cell's ultimate response to the first messenger (step **5**). For example, the activity of a particular enzymatic protein that regulates a specific metabolic event may be increased or decreased.

Note that in this signal transduction pathway the steps involving the extracellular first messenger, the receptor, the G-protein complex, and the effector protein occur *in the plasma membrane* and lead to activation of the second messenger. The extracellular messenger cannot enter the cell to "personally"
deliver its message to the proteins that carry out the desired response. Instead, it initiates membrane events that activate an intracellular second messenger, cAMP. The second messenger then triggers a chain reaction of biochemical events *inside the cell* that leads to the cellular response.

Different types of cells have different designated proteins available for phosphorylation and modification by PKA. Therefore, a *common second messenger such as cAMP can cause widely differing responses in different cells,* depending on what proteins are modified. Cyclic AMP can be thought of as an intracellular molecular "switch" that can "turn on" (or "turn off") different cell events, depending on the kinds of protein activity ultimately modified in the various target cells. The type of proteins altered by a second messenger depends on the unique specialization of a particular cell type. This can be likened to being able to either illuminate or cool a room depending on whether the wall switch you flip on is wired to a device specialized to shed light (a chandelier) or one specialized to create air movement (a

Principles of Neural and Hormonal Communication | **123**

ceiling fan). In the body, the variable responsiveness once the switch is turned on results from genetically programmed differences in the sets of proteins within different cells. For example, depending on its cellular location, activating the cAMP pathway can modify heart rate in the heart, stimulate the formation of female sex hormones in the ovaries, break down stored glucose in the liver, control water conservation during urine formation in the kidneys, create simple memory traces in the brain, or cause perception of a sweet taste by a taste bud.

After the response is completed, the α subunit cleaves off a phosphate, converting GTP to GDP, in essence shutting itself off, then rejoins the β and γ subunits to restore the inactive G-protein complex. Cyclic AMP and the other participating chemicals are inactivated so that the intracellular message is "erased" and the response can be terminated. For example, cAMP is quickly degraded by **phosphodiesterase**, a cytosolic enzyme that is continuously active. This action provides another highly effective means of turning off the response when it is no longer needed. Other complementary means of terminating the response are removal of the added phosphates from the designated proteins by protein phosphatase or removal of the first messenger.

Ca^{2+} Second-Messenger Pathway Some cells use Ca^{2+} instead of cAMP as a second messenger. In such cases, binding of the first messenger to the surface receptor eventually leads by means of G proteins to activation of the enzyme **phospholipase C**, an effector protein bound to the inner side of the membrane (step **1** in ❙ Figure 4-26). This enzyme breaks down **phosphatidylinositol bisphosphate** (abbreviated **PIP$_2$**), a component of the tails of the phospholipid molecules within the membrane itself. The products of PIP$_2$ breakdown are **diacylglycerol (DAG)** and **inositol trisphosphate (IP$_3$)** (step **2**). Lipid-soluble DAG remains in the lipid bilayer of the plasma membrane, but water-soluble IP$_3$ diffuses into the cytosol. IP$_3$ mobilizes intracellular Ca^{2+} stored in the endoplasmic reticulum to increase cytosolic Ca^{2+} by binding with IP$_3$-gated receptor-channels in the ER membrane (step **3a**). Ca^{2+} then takes on the role of second messenger, ultimately bringing about the response commanded by the first messenger. Many of the Ca^{2+}-dependent cellular events are triggered by activation of **calmodulin**, an intracellular Ca^{2+}-binding protein (step **4a**). The Ca^{2+}–calmodulin complex activates **Ca^{2+}–calmodulin dependent protein kinase (CaM kinase)** (or activates another kinase) (step **5a**). Activation of CaM kinase by the Ca^{2+}–calmodulin complex is similar to activation of PKA by cAMP. From here the patterns of the two pathways are similar. The activated CaM kinase phosphorylates the designated proteins (perhaps through multiple steps), thereby causing these proteins to change their shape and function (activating them) (step **6a**). The active designated proteins bring about the ultimate desired cellular response (step **7a**). For example, the Ca^{2+}–calmodulin pathway is the means by which chemical messengers can activate smooth muscle contraction.

Simultaneous to the IP$_3$ pathway, the other PIP$_2$ breakdown product, DAG, sets off another second-messenger pathway. (IP$_3$ and DAG themselves are sometimes considered to be second messengers.) DAG activates **protein kinase C (PKC)** (step **3b**), which phosphorylates designated proteins, different from

those phosphorylated by calmodulin (step **4b**). The resultant change in shape and function of these proteins activates them. These active proteins produce another cellular response (step **5b**). Although currently the subject of considerable investigation, the DAG pathway is not yet understood as well as the other signaling pathways. IP$_3$ and DAG typically trigger complementary actions inside a target cell to accomplish a common goal because both of these products are formed at the same time in response to the same first messenger. For example, extracellular chemical messengers promote increased contractile activity of blood-vessel smooth muscle via the IP$_3$–intracellular Ca^{2+}–calmodulin pathway, and the DAG pathway enhances the sensitivity of the contractile apparatus to Ca^{2+}.

The IP$_3$ pathway is not the only means of increasing intracellular Ca^{2+}. Intracellular Ca^{2+} can be increased by entry from the ECF or by release from Ca^{2+} stores in the endoplasmic reticulum via means other than the IP$_3$ pathway. Ca^{2+} channels in both the surface membrane and in the ER may be opened by either electrical or chemical means. For example, Ca^{2+} entry on the opening of voltage-gated surface-membrane Ca^{2+} channels is responsible for exocytosis of neurotransmitter from the axon terminal. Alternatively, surface-membrane Ca^{2+} channels may be opened via activation of receptors that serve as channels themselves or via activation of GPCRs. In yet another pathway, the opening of surface-membrane Na$^+$ and K$^+$ channels by means of receptor-channels leads to electrical signals that open Ca^{2+} channels in the endoplasmic reticulum. The latter pathway is how neurotransmitter released from neuron terminals triggers skeletal muscle contraction. The resultant rise in intracellular Ca^{2+} turns on the contractile apparatus. The pathways get even more complex than this. Ca^{2+} entering from the ECF can serve as a second messenger to trigger an even larger release of Ca^{2+} from intracellular stores, as it does to bring about contraction in cardiac muscle. This all sounds confusing, but these examples are meant to illustrate the complexity of Ca^{2+} signaling, not to overwhelm. You will learn more about the details of these pathways when appropriate in later chapters.

Although the cAMP and Ca^{2+} pathways are the most prevalent second-messenger systems, they are not the only ones. For example, a few cells use **cyclic guanosine monophosphate (cyclic GMP)** as a second messenger in a system analogous to the cAMP system. In other cells, the second messenger is still unknown. Remember that activation of second messengers is a universal mechanism used by a variety of extracellular messengers in addition to hydrophilic hormones.

Amplification by a Second-Messenger Pathway Several remaining points about receptor activation and the ensuing events merit attention. First, considering the number of steps in a second-messenger relay chain, you might wonder why so many cell types use the same complex system to accomplish such a wide range of functions. The multiple steps of a second-messenger pathway are actually advantageous because the cascading (multiplying) effect of these pathways greatly amplifies the initial signal (❙ Figure 4-27). *Amplification* means that the output of a system is much greater than the input. Using the cAMP pathway as an example, binding of one extracellular messenger molecule to a receptor activates a number of

adenylyl cyclase molecules (let's arbitrarily say 10), each of which activates many (in our hypothetical example, let's say 100) cAMP molecules. Each cAMP molecule then acts on a single protein kinase A, which phosphorylates and thereby influences many (again, let's say 100) specific proteins, such as enzymes. Each enzyme, in turn, is responsible for producing many (perhaps 100) molecules of a particular product, such as

a secretory product. The result of this cascade, with one event triggering the next in sequence, is a tremendous amplification of the initial signal. In our hypothetical example, one extracellular messenger molecule has been responsible for inducing a yield of 10 million molecules of a secretory product. In this way, very low concentrations of hormones and other chemical messengers can trigger pronounced cell responses.

Molecules in second-messenger system		Total number of molecules
Extracellular chemical messenger bound to membrane receptor		1

Products of activated enzyme	Amplification (100)	10,000,000

❘Figure 4-27 **Amplification of the initial signal by a second-messenger pathway.** Through amplification, very low concentrations of extracellular chemical messengers, such as hormones, can trigger pronounced cellular responses.

Regulation of Receptors Although membrane receptors are links between extracellular first messengers and intracellular second messengers in the regulation of specific cellular activities, the receptors themselves are also often subject to regulation. In many instances, receptor number and affinity (attraction of a receptor for its extracellular chemical messenger) can be altered, depending on the circumstances. For example, a chronic elevation in blood insulin levels leads to a reduction in the number of insulin receptors, thus reducing the responsiveness of this hormone's target cells to its high levels. *Clinical Note* Many diseases can be linked to malfunctioning receptors or to defects in the ensuing signal transduction pathways. For example, defective receptors are responsible for **Laron dwarfism**. In this condition, the person is abnormally short, despite having normal levels of growth hormone, because the tissues cannot respond normally to growth hormone. This is in contrast to the more usual type of dwarfism in which the person is abnormally short because of growth hormone deficiency. As another example, the toxins released by some infecting bacteria, such as those that cause cholera and whooping cough, keep second-messenger pathways "turned on" at a high level. **Cholera toxin** prevents the involved G protein from converting GTP to GDP, thus keeping the G protein in its active state. **Pertussis (whooping cough) toxin** blocks the inhibition of adenylyl cyclase, thereby keeping the ensuing second-messenger pathway continuously active.

Having examined the means by which hydrophilic hormones alter their target cells, we now focus on the mechanism of lipophilic hormone action.

By stimulating genes, lipophilic hormones promote synthesis of new proteins.

All lipophilic hormones (steroids and thyroid hormone) bind with intracellular receptors and primarily produce effects in their target cells by activating specific genes that cause the synthesis of new proteins, as summarized in ❘Figure 4-28.

Free lipophilic hormone (hormone not bound with its plasma–protein carrier) diffuses through the plasma membrane of the target cell (step ❶ in ❘Figure 4-28) and binds with its specific receptor inside the cell, either in the cytoplasm or in the nucleus (step ❷). Each receptor has a specific region for binding with its hormone and another region for binding with DNA. The receptor cannot bind with DNA unless it first binds with the hormone. Once the hormone is bound to the receptor, the hormone receptor complex binds with DNA at a specific attachment site on the DNA known as the **hormone response element (HRE)** (step ❸). Different steroid hormones and thyroid hormone, once bound with their respective receptors, attach at different HREs on DNA. For example, the estrogen receptor complex binds at DNA's *estrogen response element*.

Binding of the hormone receptor complex with DNA "turns on" or activates a specific gene within the target cell (step ❹). This gene contains a code for synthesizing a given protein. The code of the activated gene is transcribed into complementary messenger RNA (mRNA) (step ❺). The new mRNA leaves the nucleus and enters the cytoplasm (step ❻), where it binds to a ribosome, the "workbench" that mediates the assembly of new proteins (see pp. 23 and 25). Here, mRNA directs the synthesis

of the designated new proteins according to the DNA code in the activated genes (step **7**). The newly synthesized protein, either enzymatic or structural, is released from the ribosome (step **8**) and produces the target cell's ultimate response to the hormone (step **9**). Different genes are activated by different lipophilic hormones, resulting in different biological effects.

Even though most steroid actions are accomplished by hormonal binding with intracellular receptors that leads to gene activation, recent studies have unveiled another mechanism by which steroid hormones induce effects that occur too rapidly to be mediated by gene transcription. Some steroid hormones, most notably some of the sex hormones, bind with unique steroid receptors in the plasma membrane, in addition to binding with the traditional steroid receptors in the nucleus. This membrane binding leads to **nongenomic steroid receptor actions**—that is, actions accomplished by something other than altering gene activity, such as by inducing changes in ionic flux across the membrane or by altering activity of cellular enzymes.

Next, we compare the similarities and differences between neural and hormonal responses at the system level.

Check Your Understanding 4.7

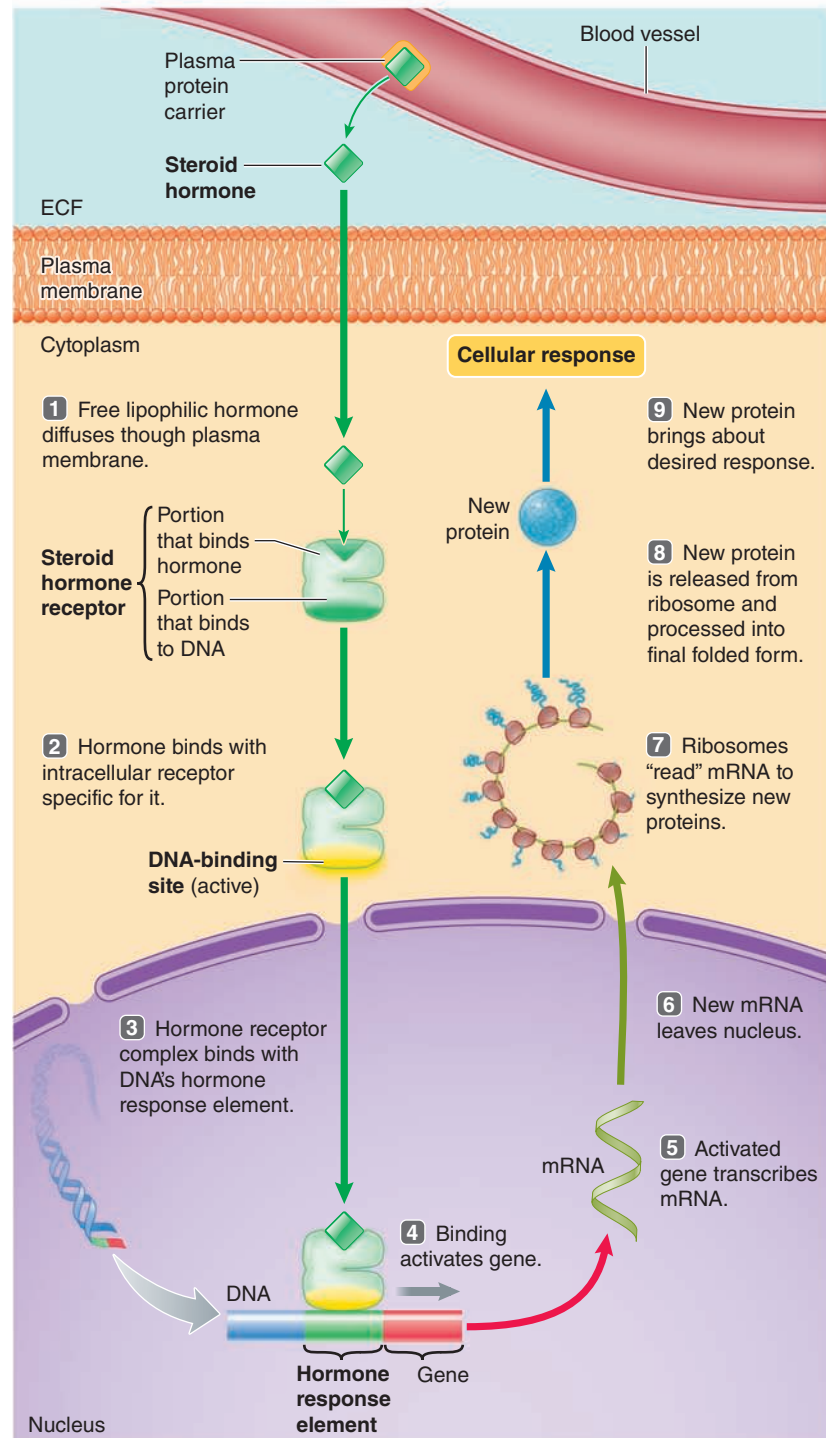
1. Prepare a chart comparing the synthesis, storage, secretion, and transport in the blood of peptide hormones and steroid hormones.

2. Explain how a common second messenger such as cAMP can induce widely differing responses in different cells.

3. Describe the role of a hormone response element.

4.8 Comparison of the Nervous and Endocrine Systems

The nervous and endocrine systems are the two main regulatory systems of the body. The nervous system swiftly transmits electrical impulses to the skeletal muscles and the exocrine glands that it innervates. The endocrine system secretes hor-

mones into the blood for delivery to distant sites of action. Although these two systems differ in many respects, they have much in common (ITable 4-6). They both alter their target cells (their sites of action) by releasing chemical messengers (neurotransmitters in the case of neurons, hormones in the case of endocrine cells) that bind with specific receptors of the target cells. This binding triggers the cellular response dictated by the regulatory system.


Now let us examine the anatomic distinctions between these two systems and the different ways in which they accomplish specificity of action.

■TABLE 4-6 Comparison of the Nervous System and the Endocrine System

Property	Nervous System	Endocrine System
Anatomic arrangement	A "wired" system: A specific structural arrangement exists between neurons and their target cells, with structural continuity in the system	A "wireless" system: Endocrine glands are widely dispersed and not structurally related to one another or to their target cells
Type of chemical messenger	Neurotransmitters released into the synaptic cleft	Hormones released into the blood
Distance of action of the chemical messenger	Short distance (diffuses across the synaptic cleft)	Long distance (carried by the blood)
Specificity of action on the target cell	Dependent on the close anatomic relationship between neurons and their target cells	Dependent on the specificity of target cell binding and responsiveness to a particular hormone
Speed of response	Generally rapid (milliseconds)	Generally slow (minutes to hours)
Duration of action	Brief (milliseconds)	Long (minutes to days or longer)
Major functions	Coordinates rapid, precise responses	Controls activities that require long duration rather than speed

The nervous system is "wired," and the endocrine system is "wireless."

Anatomically, the nervous and endocrine systems are different. In the nervous system, each neuron terminates directly on its specific target cells—that is, the nervous system is "wired" into highly organized, distinct anatomic pathways for transmission of signals from one part of the body to another. Information is carried along chains of neurons to the desired destination through action potential propagation coupled with synaptic transmission. In contrast, the endocrine system is a "wireless" system in that the endocrine glands are not anatomically linked with their target cells. Instead, the endocrine chemical messengers are secreted into the blood and delivered to distant target sites. In fact, the components of the endocrine system itself are not anatomically interconnected; the endocrine glands are scattered throughout the body (see ▮Figure 18-1, p. 639). These glands constitute a system in a functional sense, however, because they all secrete hormones and many interactions take place among various endocrine glands.

Neural specificity is a result of anatomic proximity, and endocrine specificity is a result of receptor specialization.

Because of their anatomic differences, the nervous and endocrine systems accomplish specificity of action by distinctly different means. Specificity of neural communication depends on neurons having a close anatomic relationship with their target cells, so each neuron has a narrow range of influence. A neurotransmitter is released only to specific adjacent target cells and then is swiftly inactivated or removed before it can enter the blood. The target cells for a particular neuron have receptors for the neurotransmitter, but so do many other cells in other locations, and they could respond to this same mediator if it were delivered to them. For example, the entire system of neurons (called motor neurons) supplying your skeletal muscles uses the same neurotransmitter, *acetylcholine (ACh)*, and all your skeletal muscles bear complementary ACh receptors. Yet you can wiggle your big toe without influencing any of your other muscles because ACh can be discretely released from the motor neurons specifically wired to the muscles controlling your toe. If ACh were indiscriminately released into the blood, as are hormones, all the skeletal muscles would simultaneously respond by contracting because they all have identical receptors for ACh. This does not happen because of the precise wiring patterns that provide direct lines of communication between motor neurons and their target cells.

This specificity sharply contrasts to the way specificity of communication is built into the endocrine system. Because hormones travel in the blood, they reach virtually all tissues. Yet only specific target cells can respond to each hormone. Specificity of hormonal action depends on specialization of target cell receptors. For a hormone to exert its effect, the hormone must first bind with receptors specific for it that are located only on or in the hormone's target cells. Target cell receptors are highly selective in their binding function. A receptor recognizes a specific hormone because a portion of its conformation matches a unique portion of its binding hormone in "lock-and-key" fashion. Binding of a hormone with target cell receptors initiates a reaction that culminates in the hormone's final effect. The hormone cannot influence any other cells because nontarget cells lack the right binding receptors. Likewise, a given target cell has receptors that are "tuned" to recognize only one or a few of the many hormones that circulate in its vicinity. Other signals pass by without effect because the cell has no receptors for them.

The nervous and endocrine systems have their own realms of authority but interact functionally.

The nervous and endocrine systems are specialized for controlling different types of activities. In general, the nervous system governs the coordination of rapid, precise responses. It is especially important in the body's interactions with the external environment. Neural signals in the form of action potentials are rapidly propagated along neuronal fibers, resulting in the release at the axon terminal of a neurotransmitter that must diffuse only a microscopic distance to its target cell before a response is affected. A neurally mediated response is rapid but brief; the action is quickly halted as the neurotransmitter is swiftly removed from the target site. This permits ending the response, almost immediately repeating the response, or rapidly initiating an alternate response as circumstances demand (for example, the swift changes in commands to muscle groups needed to coordinate walking). This mode of action makes neural communication extremely rapid and precise. The target tissues of the nervous system are the muscles and glands, especially exocrine glands, of the body.

The endocrine system, in contrast, is specialized to control activities that require duration rather than speed, such as regulating organic metabolism; maintaining water and electrolyte balance; promoting smooth, sequential growth and development; and controlling reproduction. The endocrine system responds more slowly to its triggering stimuli than the nervous system does for several reasons. First, the endocrine system must depend on blood flow to convey its hormonal messengers over long distances. Second, hormones typically have a more complex mechanism of action at their target cells than neurotransmitters do; thus, they require more time before a response occurs. The ultimate effect of some hormones cannot be detected until a few hours after they bind with target cell receptors. Also, because of the receptors' high affinity for their respective hormone, the hormones often remain bound to receptors for some time, thus prolonging their biological effectiveness. Furthermore, unlike the brief, neurally induced responses that stop almost immediately after the neurotransmitter is removed, endocrine effects usually last for some time after the hormone's withdrawal. Neural responses to a single burst of neurotransmitter release usually last only milliseconds to seconds, whereas the alterations that hormones induce in target cells range from minutes to days or, in the case of growth-promoting effects, even a lifetime. Thus, hormonal action is relatively slow and prolonged, making endocrine control particularly suitable for regulating metabolic activities that require long-term stability.

Although the endocrine and nervous systems have their areas of specialization, they are intimately interconnected functionally. Some neurons do not release neurotransmitters at synapses but instead end at blood vessels and release their chemical messengers (neurohormones) into the blood, where these chemicals act as hormones. A given messenger may even be a neurotransmitter when released from a nerve ending and a hormone when secreted by an endocrine cell. An example is *norepinephrine* (see p. 640). The nervous system directly or indirectly controls the secretion of many hormones (see Chapter 18). At the same time, many hormones act as neuromodulators, altering synaptic effectiveness and thereby influencing the excitability of the nervous system. The presence of certain key hormones is even essential for the proper development and maturation of the brain during fetal life. Furthermore, in many instances the nervous and endocrine systems both influence the same target cells in supplementary fashion. For example, these two major regulatory systems both help regulate the circulatory and digestive systems. Thus, many important regulatory interfaces exist between the nervous and the endocrine systems. The study of these relationships is known as **neuroendocrinology**.

In the next three chapters, we concentrate on the nervous system. We examine the endocrine system in more detail in later chapters. Throughout the text, we continue to point out the numerous ways in which these two regulatory systems interact so that the body is a coordinated whole, even though each system has its own realm of authority.

Check Your Understanding 4.8

1. Compare how neural and endocrine specificity of action is accomplished.

2. What regulatory system enables you to turn the pages of this book and what regulatory system is maintaining your blood glucose (sugar) level?

Homeostasis: Chapter in Perspective

To maintain homeostasis, cells must communicate so that they work together to accomplish life-sustaining activities. To bring about desired responses, the two major regulatory systems of the body, the nervous system and the endocrine system, must communicate with the target cells they are controlling. Neural and hormonal communication is therefore critical in maintaining a stable internal environment and in coordinating nonhomeostatic activities.

Neurons are specialized to receive, process, encode, and rapidly transmit information from one part of the body to another. The information is transmitted over intricate neuronal pathways by propagation of action potentials along the neuron's length and by chemical transmission of the signal from neuron to neuron at synapses and from neuron to muscles and glands through other neurotransmitter–receptor interactions at these junctions.

Neurons are the key functional components of the nervous system. Many activities controlled by the nervous system are geared toward maintaining homeostasis. Some neuronal electrical signals convey information about changes to which the body must rapidly respond to maintain homeostasis—for example, information about a fall in blood pressure. Other neuro-

nal electrical signals swiftly convey messages to muscles and glands stimulating appropriate responses to counteract these changes—for example, adjustments in heart and blood vessel activity that restore blood pressure to normal when it starts to fall. Furthermore, the nervous system directs many activities not geared toward maintaining homeostasis, many of which are subject to voluntary control, such as playing basketball or browsing the Internet.

The endocrine system secretes hormones into the blood, which carries these chemical messengers to distant target cells where they bring about their effect by changing the activity of enzymatic or structural proteins within these cells. Through its relatively slow-acting hormonal messengers, the endocrine system generally regulates activities that require

duration rather than speed. Most of these activities are directed toward maintaining homeostasis. For example, hormones help maintain the proper concentration of nutrients in the internal environment by directing chemical reactions involved in the cellular uptake, storage, release, and use of these molecules. Also, hormones help maintain the proper water and electrolyte balance in the internal environment. Unrelated to homeostasis, hormones direct growth and control most aspects of the reproductive system.

Together, the nervous and the endocrine systems orchestrate a range of adjustments that help the body maintain homeostasis in response to stress. Likewise, these systems work in concert to control the circulatory and digestive systems, which carry out many homeostatic activities.

Review Exercises Answers begin on p. A-24

Reviewing Terms and Facts

1. Conformational changes in channel proteins brought about by voltage changes are responsible for opening and closing Na^+ and K^+ gates during the generation of an action potential. *(True or false?)*

2. The Na^+–K^+ pump restores the membrane to resting potential after it reaches the peak of an action potential. *(True or false?)*

3. After an action potential, the K^+ concentration is greater outside the cell than inside the cell because of the efflux of K^+ during the falling phase. *(True or false?)*

4. Postsynaptic neurons can either excite or inhibit presynaptic neurons. *(True or false?)*

5. Second-messenger systems ultimately bring about the desired cell response by inducing a change in the shape and function of particular designated intracellular proteins. *(True or false?)*

6. Each steroidogenic organ has all the enzymes necessary to produce any steroid hormone. *(True or false?)*

7. The two types of excitable tissue are _____ and _____.

8. The one-way propagation of action potentials away from the original site of activation is ensured by the _____.

9. The _____ is the site of action potential initiation in most neurons because it has the lowest threshold.

10. A junction in which electrical activity in one neuron influences the electrical activity in another neuron by means of a neurotransmitter is called a _____.

11. Summing of EPSPs occurring very close together in time as a result of repetitive firing of a single presynaptic input is known as _____.

12. Summing of EPSPs occurring simultaneously from several different presynaptic inputs is known as _____.

13. The neuronal relationship in which synapses from many presynaptic inputs act on a single postsynaptic cell is called _____, whereas the relationship in which a single presynaptic neuron synapses with and thereby influences the activity of many postsynaptic cells is known as _____.

14. A common membrane-bound intermediary between the receptor and the effector protein within the plasma membrane is the _____.

15. The three types of receptors with regard to mode of action in signal transduction pathways are _____, _____, and _____.

16. The three classes of eicosanoids are _____, _____, and _____.

17. Using the answer code on the right, indicate which potential is being described:

1. behaves in all-or-none fashion	(a) graded potential
2. has a magnitude of potential change that varies with the magnitude of the triggering event	(b) action potential
3. spreads decrementally away from the original site	
4. spreads nondecrementally throughout the membrane	
5. serves as a long-distance signal	
6. serves as a short-distance signal	

18. Using the answer code on the right, indicate which characteristics apply to peptide and steroid hormones:

1. are hydrophilic
2. are lipophilic
3. are synthesized by the ER
4. are synthesized by modifying cholesterol
5. include epinephrine from the adrenal medulla
6. include cortisol from the adrenal cortex
7. bind to plasma proteins
8. bind to intracellular receptors
9. bind to surface membrane receptors
10. activate genes to promote synthesis of new proteins
11. act via second messenger to alter preexisting proteins
12. are secreted into blood by endocrine glands and carried to distant target sites

(a) peptide hormones
(b) steroid hormones
(c) both peptide and steroid hormones
(d) neither peptide nor steroid hormones

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Define the following terms: *polarization, depolarization, hyperpolarization, repolarization, resting membrane potential, threshold potential, action potential, refractory period,* and *all-or-none law*.

2. Describe the permeability changes and ion fluxes that occur during an action potential.

3. Compare contiguous conduction and saltatory conduction.

4. Compare the events at excitatory and inhibitory synapses.

5. Compare the four kinds of gated channels in terms of the factor that opens or closes them.

6. Distinguish among a neurotransmitter, a neuromodulator, and a neurohormone.

7. Discuss the possible outcomes of the GPSP brought about by interactions between EPSPs and IPSPs.

8. Distinguish between presynaptic inhibition and an inhibitory postsynaptic potential.

9. List and describe the types of intercellular communication.

10. Define *signal transduction*.

11. Compare the tyrosine kinase and JAK/STAT pathways.

12. Distinguish between first and second messengers.

13. Compare cytokines and hormones.

14. Describe how arachidonic acid is converted into prostaglandins, thromboxanes, and leukotrienes.

15. Describe the sequence of events in the cAMP second-messenger pathway.

16. Describe the sequence of events in the Ca^{2+} second-messenger pathway.

17. Explain how the cascading effect of hormonal pathways amplifies the response.

18. Compare the nervous and endocrine systems.

Solving Quantitative Exercises

1. Answer the following questions regarding conduction of action potentials using the velocities given on p. 100:

a. How long would it take for an action potential to travel 0.6 m along the axon of an unmyelinated neuron of the digestive tract?

b. How long would it take for an action potential to travel the same distance along the axon of a large myelinated neuron innervating a skeletal muscle?

c. Suppose there were two synapses in a 0.6 m nerve tract and the delay at each synapse is 1 msec. How long would it take an action potential and chemical signal to travel the 0.6 m now, for both the myelinated and unmyelinated neurons?

d. What if there were five synapses?

2. Suppose point A is 1 m from point B. Compare the following situations:

i. A single axon spans the distance from A to B, and its conduction velocity is 60 m/sec.

ii. Three neurons span the distance from A to B, all three neurons have the same conduction velocity, and the synaptic delay at both synapses (draw a picture) is 1 msec. What are the conduction velocities of the three neurons in this second situation if the total conduction time in both cases is the same?

3. One can predict what the Na^+ current produced by the Na^+–K^+ pump is with the following equation:[1]

$$p = \frac{kT}{q}\left(\frac{G_{Na^+}G_{K^+}}{G_{Na^+}+G_{K^+}}\right)\log\frac{G_{K^+}[Na^+]_o}{G_{Na^+}[K^+]_i}$$

where p is the Na^+ pump current; G is membrane conductance to the indicated ion expressed in $\mu S/cm^2$ (S = Siemens); $[x]_o$ and $[x]_i$ are the concentrations of ion x outside and inside the cell, respectively; k is Boltzmann's constant; T is the temperature in kelvins; and q is the elementary charge constant. Suppose kT/q = 25 mV, G_{Na^+} = 3.3 $\mu S/cm^2$, G_{K^+} = 240 $\mu S/cm^2$, $[Na^+]_o$ = 145 mM, and $[K^+]_i$ = 4 mM. What is the pump current for Na^+, in $\mu A/cm^2$ (A = amperes, an expression of current)?

Applying Clinical Reasoning

Becky N. was apprehensive as she sat in the dentist's chair awaiting the placement of her first silver amalgam (the "filling" in a cavity in a tooth). Before preparing the tooth for the amalgam by drilling away the decayed portion of the tooth, the dentist injected a local anesthetic in the nerve pathway

---

[1]F. C. Hoppensteadt and C. S. Peskin, *Mathematics in Medicine and the Life Sciences* (New York: Springer, 1992), equation 7.4.35, p. 178.

supplying the region. As a result, Becky, much to her relief, did not feel any pain during the drilling and filling procedure. Local anesthetics block voltage-gated Na^+ channels. Explain how this action prevents the transmission of pain impulses to the brain.

Thinking at a Higher Level

1. The rate at which the Na^+–K^+ pump operates is not constant but is controlled by a combined effect of changes in ICF Na^+ concentration and ECF K^+ concentration. Do you think the changes in both ICF Na^+ and ECF K^+ concentration following a series of action potentials in a neuron would accelerate, slow down, or have no effect on the Na^+–K^+ pumps in this cell?

2. Which of the following would occur if a neuron were experimentally stimulated simultaneously at both ends?
   a. The action potentials would pass in the middle and travel to the opposite ends.
   b. The action potentials would meet in the middle and then be propagated back to their starting positions.
   c. The action potentials would stop as they met in the middle.
   d. The stronger action potential would override the weaker action potential.
   e. Summation would occur when the action potentials met in the middle, resulting in a larger action potential.

3. Assume you touched a hot stove with your finger. Contraction of the biceps muscle causes flexion (bending) of the elbow, whereas contraction of the triceps muscle causes extension (straightening) of the elbow. What pattern of postsynaptic potentials would you expect to be initiated as a reflex in the cell bodies of the neurons controlling these muscles to pull your hand away from the painful stimulus: excitatory postsynaptic potentials (EPSPs) or inhibitory postsynaptic potentials (IPSPs)?

Now assume your finger is being pricked to obtain a blood sample. The same withdrawal reflex would be initiated. What pattern of postsynaptic potentials would you voluntarily produce in the neurons controlling the biceps and triceps to keep your arm extended despite the painful stimulus?

4. Assume presynaptic excitatory neuron A terminates on a postsynaptic cell near the axon hillock and presynaptic excitatory neuron B terminates on the same postsynaptic cell on a dendrite located on the side of the cell body opposite the axon hillock. Explain why rapid firing of presynaptic neuron A could bring the postsynaptic neuron to threshold through temporal summation, thus initiating an action potential, whereas firing of presynaptic neuron B at the same frequency and the same magnitude of EPSPs may not bring the postsynaptic neuron to threshold.

5. Sometimes patients are treated for a number of years following surgical removal of a breast because of estrogen-dependent breast cancer with *selective estrogen receptor modulators (SERMs)*. Speculate how this drug might be beneficial. Indicate by what route this drug would be administered and explain why.

The Central Nervous System
Tom Barrick, Chris Clark, SGHMS/Science Source

A diffusion magnetic resonance image (dMRI) scan of the white matter pathways of the brain. White matter is composed of myelinated nerve fibers that carry information between neurons in different parts of the brain. Blue represents neural pathways from top to bottom, green delineates pathways between front (left) and back, and red shows pathways between the left and right halves of the brain.

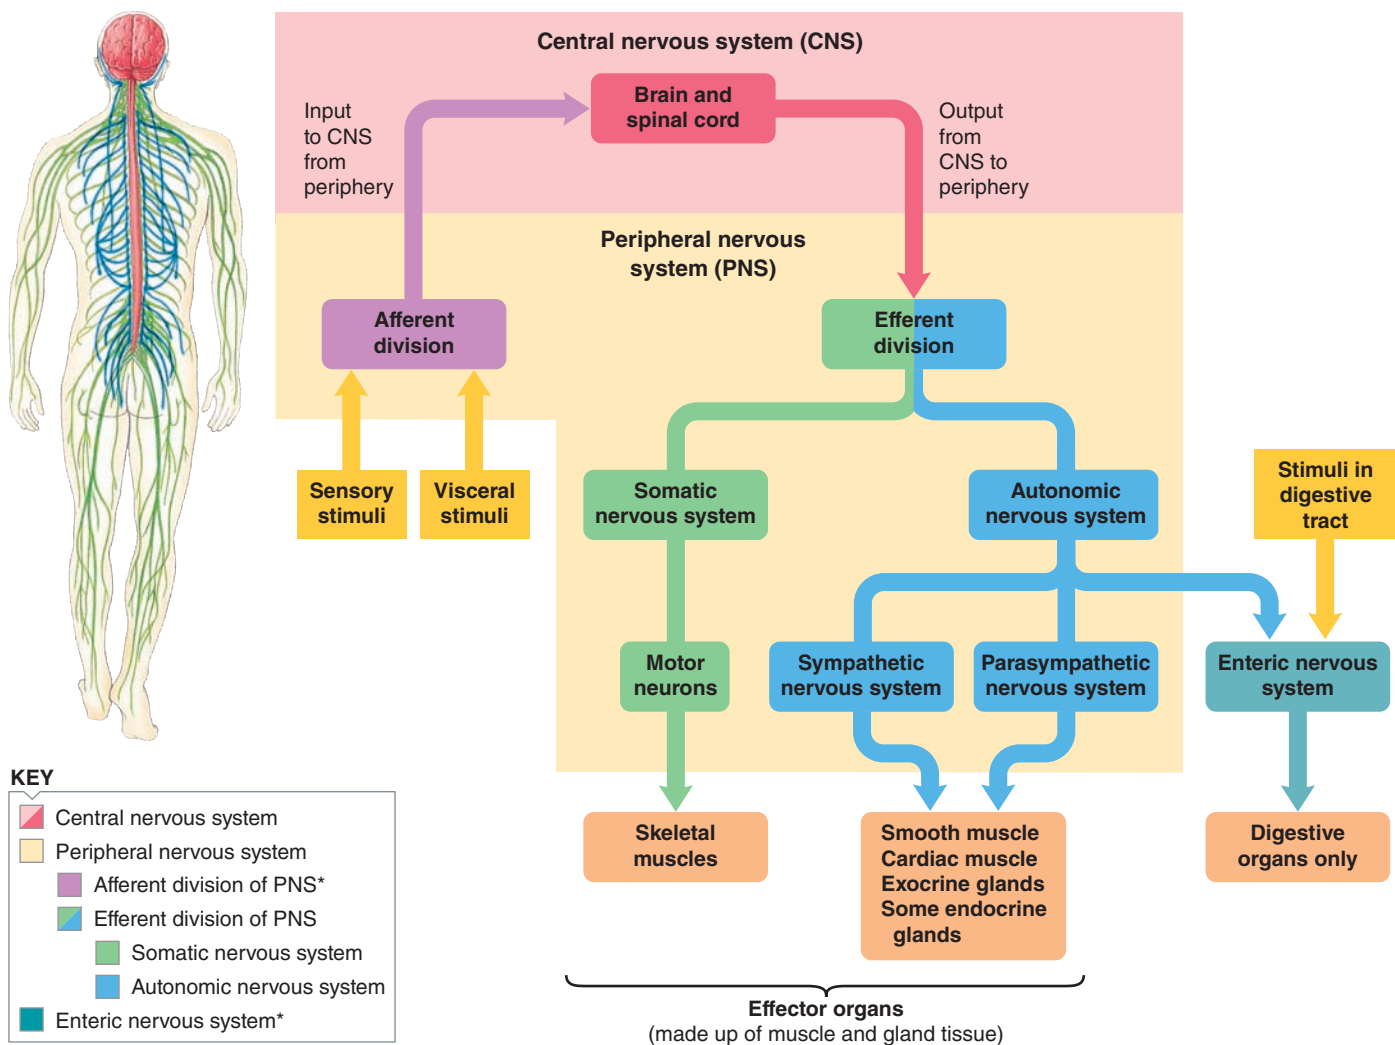
Homeostasis Highlights

The nervous system is one of the two major regulatory systems of the body; the other is the endocrine system. The three basic functional types of neurons—afferent neurons, efferent neurons, and interneurons—form a complex interactive network of excitable cells. Ninety percent of the cells of the nervous system are nonexcitable glial cells, which interact extensively both structurally and functionally with neurons. The **central nervous system (CNS)**, which consists of the brain and spinal cord, receives input about the external and internal environment from the afferent neurons. The CNS sorts and processes this input via interneurons and then initiates appropriate directions in the efferent neurons, which carry the instructions to glands or muscles to bring about the desired response—some type of secretion or movement. Many of these neurally controlled activities are directed toward maintaining homeostasis. In general, the nervous system acts by means of its electrical signals (action potentials) and neurotransmitter release to control the rapid responses of the body.

5.1 Organization and Cells of the Nervous System

The way humans act and react depends on complex, organized, discrete neuronal processing. Many basic life-supporting neuronal patterns, such as those controlling respiration and circulation, are similar in all individuals. However, there must be subtle differences in neuronal integration between someone who is a talented composer and someone who cannot carry a tune or between someone who is a math wizard and someone who struggles with long division. Some differences in the nervous systems of individuals are genetically endowed. The rest, however, are a result of environmental encounters and experiences. When the immature nervous system develops according to its genetic plan, an overabundance of neurons and synapses is formed. Depending on external stimuli and the extent to which these pathways are used, some are retained, firmly established, and even enhanced, whereas others are eliminated.

Clinical Note A case in point is **amblyopia** (lazy eye), in which the weaker of the two eyes is not used for vision. A lazy eye that does not get appropriate visual stimulation during a critical developmental period will almost completely and permanently lose the power of vision. The functionally blind eye itself is normal; the defect lies in the lost neuronal connections in the brain's visual pathways. However, if the weak eye is forced to work by covering the stronger eye with a patch during the sensitive developmental period, the weaker eye will retain full vision.

Maturation of the nervous system involves many instances of "use it or lose it." Once the nervous system has matured, modifications still occur as we continue to learn from our unique set of experiences. For example, the act of reading this page is somehow altering the neuronal activity of your brain as you (it is hoped) tuck the information away in your memory.


‖Figure 5-1 Organization of the nervous system. *The afferent division of the peripheral nervous system (PNS) and enteric nervous system are not shown in the human figure. Afferent fibers travel within the same nerves as efferent fibers but in the opposite direction. The enteric nervous system lies entirely within the wall of the digestive tract.

FIGURE FOCUS: *What parts of the nervous system come into play when you are taking a walk? How about when you are digesting a meal?*

Unless otherwise noted, all content on this page is © Cengage Learning.

The nervous system is organized into the central nervous system and the peripheral nervous system.

The nervous system is organized into the **central nervous system (CNS)**, consisting of the brain and spinal cord, and the **peripheral nervous system (PNS)**, consisting of nerve fibers that carry information between the CNS and the other parts of the body (the periphery) (▮Figure 5-1). The PNS is further subdivided into afferent and efferent divisions. The **afferent division** carries information *to* the CNS, apprising it of the external environment and providing status reports on internal activities being regulated by the nervous system (*a* is from *ad,* meaning "toward," as in *advance; ferent* means "carrying"); thus, *afferent* means "carrying toward"). Instructions *from* the CNS are transmitted via the **efferent division** to **effector organs**—the muscles or glands that carry out the orders to bring about the desired effect (*e* is from *ex,* meaning "from," as in *exit;* thus, *efferent* means "carrying from"). The efferent nervous system is divided into the **somatic nervous system**, which consists of the fibers of the motor neurons that supply the skeletal muscles; and the **autonomic nervous system**, which consists of fibers that innervate smooth muscle, cardiac muscle, and glands. The latter system is further subdivided into the **sympathetic nervous system** and the **parasympathetic nervous system**, both of which innervate most of the organs supplied by the autonomic system. In addition to the CNS and PNS, the **enteric nervous system** is an extensive nerve network in the wall of the digestive tract. Digestive activities are controlled by the autonomic nervous system, the enteric nervous system, and by hormones. The enteric nervous system can act independently of the rest of the nervous system but is also influenced by autonomic fibers that terminate on the enteric neurons. Sometimes the enteric nervous system is considered a third component of the autonomic nervous system, one that supplies the digestive organs only.

All these "nervous systems" are really subdivisions of a single, integrated nervous system. These subdivisions are based on differences in the structure, location, and functions of the various diverse parts of the whole nervous system.

The three functional classes of neurons are afferent neurons, efferent neurons, and interneurons.

Three functional classes of neurons make up the nervous system: *afferent neurons, efferent neurons,* and *interneurons.* The afferent division of the PNS consists of **afferent neurons**, which are shaped differently from efferent neurons and interneurons (▮Figure 5-2). At its peripheral ending, a typical afferent neuron has a **sensory receptor** that generates action potentials in response to a particular type of stimulus (a change detectable by the neuron). (This stimulus-sensitive afferent neuronal receptor should not be confused with the special

protein receptors that bind chemical messengers and are found in the plasma membrane of all cells.) The afferent neuron cell body, which is devoid of dendrites and presynaptic inputs, is adjacent to the spinal cord. A long *peripheral axon,* commonly called the *afferent fiber,* extends from the receptor to the cell body, and a short *central axon* passes from the cell body into the spinal cord. Action potentials are initiated at the receptor end of the peripheral axon in response to a stimulus and are propagated along the peripheral axon and the central axon toward the spinal cord. The terminals of the central axon diverge and synapse with other neurons within the spinal cord, thus disseminating information about the stimulus. Afferent neurons lie primarily within the PNS. Only a small portion of their central axon endings projects into the spinal cord to relay signals from the periphery to the CNS.

Efferent neurons also lie primarily in the PNS. Efferent neuron cell bodies originate in the CNS, where many centrally located presynaptic inputs converge on them to influence their outputs to the effector organs. Efferent axons (*efferent fibers*) leave the CNS to course their way to the muscles or glands they innervate, conveying their integrated output for the effector organs to put into effect. (An autonomic nerve pathway consists of a two-neuron chain between the CNS and the effector organ.)

About 99% of all neurons are **interneurons**, which lie entirely within the CNS. As their name implies, interneurons lie between the afferent and the efferent neurons and are important in integrating peripheral information to peripheral responses (*inter* means "between"). For example, on receiving information through afferent neurons that you are touching a hot object, appropriate interneurons signal efferent neurons that transmit
* Efferent autonomic nerve pathways consist of a two-neuron chain between the CNS and the effector organ.

▮Figure 5-2 **Structure and location of the three functional classes of neurons.**

to your hand and arm muscles the message, "Pull the hand away from the hot object!" The more complex the required action, the greater the number of interneurons interposed between the afferent message and the efferent response. In addition, interconnections between interneurons themselves are responsible for the abstract phenomena associated with the "mind," such as thoughts, emotions, memory, creativity, intellect, and motivation. These activities are the least understood functions of the nervous system.

Glial cells support the interneurons physically, metabolically, and functionally.

About 90% of the cells within the CNS are not neurons but **glial cells** or **neuroglia**. Despite their large numbers, glial cells occupy only about half the volume of the brain because they do not branch as extensively as neurons do.

Unlike neurons, glial cells do not initiate or conduct nerve impulses. However, they do communicate with neurons and among themselves by means of chemical signals. For much of the time since glial cells were discovered in the 19th century, they were considered passive "mortar" that physically supported the functionally important neurons. In the past three decades, however, the varied and important roles of these dynamic cells have become apparent. Glial cells help support the neurons both physically and metabolically. They also maintain the composition of the specialized extracellular environment surrounding the neurons within the narrow limits optimal for normal neuronal function. Furthermore, they actively modulate (depress or enhance) synaptic function and are considered nearly as important as neurons to learning and memory. There are four major types of glial cells in the CNS—*astrocytes, oligodendrocytes, microglia,* and *ependymal cells*—each with specific roles (❙Figure 5-3).

Astrocytes Named for their starlike shape (*astro* means "star"; *cyte* means "cell") (❙Figure 5-4), **astrocytes** are the most abundant glial cells. They fill several critical functions:

1. As the main "glue" (*glia* means "glue") of the CNS, astrocytes hold the neurons together in proper spatial relationships.
2. Astrocytes serve as a scaffold that guides neurons to their proper final destination during fetal brain development.
3. These glial cells induce the small blood vessels (capillaries) of the brain to undergo the anatomic and functional changes that establish the blood–brain barrier, a highly selective, protective barricade between the blood and brain.
4. They help transfer nutrients from the blood to the neurons.
5. Astrocytes form neural scars to help repair brain injuries.
6. They take up and degrade some locally released neurotransmitters, thus bringing the actions of these chemical messengers to a halt.
❙Figure 5-3 **Glial cells of the central nervous system**. The glial cells include the astrocytes, oligodendrocytes, microglia, and ependymal cells.
Figure 5-4 Astrocytes. Note the starlike shape of these astrocytes, which have been grown in tissue culture.

7. Astrocytes take up excess K^+ from the brain extracellular fluid (ECF) when high action potential activity outpaces the ability of the Na^+–K^+ pump to return to the neurons the K^+ that leaves during the falling phase of an action potential. By taking up excess K^+, astrocytes help maintain the optimal ion conditions around neurons to sustain normal neural excitability.

8. Astrocytes along with other glial cells enhance synapse formation and modify synaptic transmission.

9. Astrocytes communicate with neurons and with one another by means of chemical signals passing locally in both directions between these cells in two ways. First, chemical signals pass directly among astrocytes and between astrocytes and neurons through gap junctions (see p. 62) without entering the ECF. Second, chemical signals pass extracellularly between these cells. Astrocytes have receptors for the common neurotransmitter glutamate. Furthermore, firing of neurons in the brain in some instances triggers the release of adenosine triphosphate (ATP) along with the classical neurotransmitter from the axon terminal. Binding of glutamate to an astrocyte's receptors or detection of extracellular ATP by the astrocyte leads to Ca^{2+} influx into this glial cell. The resultant rise in intracellular Ca^{2+} prompts the astrocyte itself to release ATP, thereby activating adjacent glial cells. In this way, astrocytes can share information about action potential activity in a nearby neuron. In addition, astrocytes and other glial cells can also release glutamate and other chemical signals. These extracellular chemical signals from glial cells, collectively called **gliotransmitters**, can affect neuronal excitability and strengthen synaptic activity, such as by increasing neuronal release of neurotransmitter or promoting the formation of new synapses. Glial modulation of synaptic activity is likely important in memory and learning. Also, astrocytes are thought to coordinate and integrate synaptic activity among networks of neurons working together.

Scientists are trying to sort out the two-directional chatter that takes place between and among these glial cells and neurons because this dialogue plays an important role in information processing in the brain. In fact, some neuroscientists suggest that synapses should be considered "three-party" junctures involving the glial cells and the presynaptic and postsynaptic neurons. This point of view is indicative of the increasingly important role being placed on astrocytes in synapse function. Thus, astrocytes have come a long way from their earlier reputation as "support staff" for neurons; these glial cells might turn out to be the "board members" commanding the neurons.

10. The most recently identified role of astrocytes is their role in clearing toxic metabolic byproducts from the brain by means of the **glymphatic system**, a glia substitute for the lymphatic system (hence, this system is dubbed "glymphatic.") The brain is not supplied by the lymphatic system, a system of lymph-carrying vessels that transports excess interstitial fluid from the tissues into the blood, proteins that have leaked into the interstitial fluid, and toxic metabolic wastes that have accumulated in the interstitial fluid (see p. 358). The glymphatic system serves as a functional waste clearance pathway in the brain, similar to the lymphatic system in peripheral tissues. Astrocytes facilitate a cleansing fluid exchange within spaces that lie between microscopic brain blood vessels and the long astrocyte projections. This "brainwashing" increases during sleep.

Oligodendrocytes **Oligodendrocytes** form the insulative myelin sheaths around axons in the CNS. An oligodendrocyte has several elongated projections, each of which wraps jelly-roll fashion around a section of an interneuronal axon to form a patch of myelin (see Figure 4-11c, p. 101; and Figure 5-3).

Microglia **Microglia** are the immune defense cells of the CNS. These scavengers are similar to monocytes, a type of white blood cell that leaves the blood and sets up residence as a front-line defense agent in various tissues throughout the body. Microglia are derived from the same bone-marrow tissue that gives rise to monocytes. During embryonic development, microglia migrate to the CNS, where they remain stationary until activated by an infection or injury.

In the resting state, microglia are wispy cells with many long branches that radiate outward. Resting microglia are not just waiting watchfully, however. In addition to providing surveillance, they release low levels of growth factors, such as *nerve growth factor,* which help neurons and other glial cells survive and thrive. Also, emerging evidence suggests that microglia may play an important role in synaptic pruning (eliminating unneeded synapses) during development and memory processing. When trouble occurs in the CNS, microglia retract their branches, round up, and become highly mobile and move toward the affected area to remove any foreign invaders or tissue debris by phagocytosis (see p. 31). Activated microglia also release destructive chemicals for assault against their target.

Clinical Note Microglia are the only CNS cell type that can be infected by HIV, the virus that causes AIDS. Microglia dysfunction ultimately leads to AIDS-related
(a) Lateral view of ventricles
(b) Anterior view of ventricles

❙Figure 5-5 **The ventricles of the brain**.

dementia (mental failing). Furthermore, researchers suspect that excessive release of destructive chemicals from overzealous microglia may damage the neurons they are meant to protect, thus contributing to the insidious neuronal damage seen in stroke, Alzheimer's disease, multiple sclerosis, and other **neurodegenerative diseases** in which nerve cells are destroyed.

Ependymal Cells **Ependymal cells** line the internal, f uid-filled cavities of the CNS. As the nervous system develops embryonically from a hollow neural tube, the original central cavity of this tube is maintained and modif ed to form the ventricles and central canal. The four **ventricles** are interconnected chambers within the brain that are continuous with the narrow, hollow **central canal** through the middle of the spinal cord (❙Figure 5-5). The ependymal cells lining the ventricles help form cerebrospinal f uid, a topic to be discussed shortly. Ependymal cells are one of the few cell types with cilia (see p. 48). Beating of ependymal cilia contributes to the f ow of cerebrospinal f uid through the ventricles.

Ependymal cells also have a different role: They serve as neural stem cells with the potential of forming not only other glial cells, but also new neurons, especially after injury (see p. 10). The long held traditional view was that new neurons are not produced in the mature brain. Then, in the late 1990s, scientists discovered that new neurons are produced in the **hippocampus**, a brain structure important for learning and memory (see ❙Figure 5-16, p. 155). Astrocyte-like neural stem cells continuously renew a subpopulation of hippocampal neurons, whereas the rest of the neurons in this structure do not turn over. The nonrenewable neurons are produced during embryonic development, and most of them survive the life of the individual, although some succumb to head trauma, stroke, or neurodegenerative disease. In contrast, the new neurons generated in adults "grow up," function as mature cells for a period of time, then die and are exchanged for new neurons, thus maintaining a mix of young and old cells in the renewable hippocampal subpopulation. Young and mature neurons process

information in different ways, both of which are critical for hippocampal function. Ongoing **neurogenesis** (production of new neurons) is crucial for maintaining the forever-young pool of neurons. The rate of hippocampal neurogenesis declines with age and chronic stress and is increased in response to physical exercise.

Neurons in the rest of the brain are considered irreplaceable. But the discovery of ependymal cells as a reservoir of precursors for new neurons suggests that the adult brain has more potential for repairing damaged regions than previously assumed. Currently, no evidence shows that the brain spontaneously repairs itself following neuron-losing insults. Apparently, most brain regions cannot activate this mechanism for replenishing neurons, probably because the appropriate "cocktail" of supportive chemicals is not present. Researchers hope that probing into why these ependymal cells are dormant and how they might be activated will lead to the possibility of unlocking the brain's undeveloped capacity for self-repair.

Clinical Note Unlike neurons, glial cells do not lose the ability to undergo cell division, so most brain tumors of neural origin consist of glial cells (**gliomas**). Neurons themselves do not form tumors because they are unable to divide and multiply. Brain tumors of non-neural origin are of two types: (1) those that metastasize (spread) to the brain from other sites and (2) **meningiomas**, which originate from the meninges, the protective membranes covering the CNS. We next examine the meninges and other means by which the CNS is protected.

Check Your Understanding 5.1

5.2 Protection and Nourishment of the Brain

Central nervous tissue is delicate. Because of this characteristic, and because damaged nerve cells cannot be replaced, this fragile, irreplaceable tissue must be well protected. Four major features help protect the CNS from injury:

1. It is enclosed by hard, bony structures. The *cranium (skull)* encases the brain, and the *vertebral column* surrounds the spinal cord.

2. Three protective and nourishing membranes, the *meninges,* lie between the bony covering and the nervous tissue.

3. The brain "f oats" in a special cushioning f uid, the *cerebrospinal fluid (CSF).*

4. A highly selective *blood–brain barrier* limits access of blood-borne materials into the vulnerable brain tissue.

The role of the first of these protective devices, the bony covering, is self-evident. The latter three protective mechanisms warrant further discussion.

Three meningeal membranes wrap, protect, and nourish the central nervous system.

Three membranes, the **meninges**, wrap the CNS. From the outermost to the innermost layer, they are the *dura mater,* the *arachnoid mater,* and the *pia mater* (❚Figure 5-6). (*Mater* means "mother," indicative of these membranes' protective and supportive role.)

The **dura mater** is a tough, inelastic covering that consists of two layers (*dura* means "tough"). Usually, these layers adhere closely, but in some regions they are separated to form blood-filled cavities, **dural sinuses**, or in the case of the larger cavities, **venous sinuses**. Venous blood draining from the brain empties into these sinuses to be returned to the heart. CSF also reenters the blood at these sinus sites.

The **arachnoid mater** is a delicate, richly vascularized layer with a "cobwebby" appearance (*arachnoid* means "spiderlike"). The space between the arachnoid layer and the underlying pia mater, the **subarachnoid space**, is filled with CSF. Protrusions of arachnoid tissue, the **arachnoid villi**, penetrate through gaps in the overlying dura and project into the dural sinuses (❚Figure 5-6b). CSF is reabsorbed across the surfaces of these villi into the blood circulating within the sinuses.

The innermost meningeal layer, the **pia mater**, is the most fragile (*pia* means "gentle"). It is highly vascular and closely adheres to the surfaces of the brain and spinal cord, following every ridge and valley. In certain areas, the pia mater and ependymal cells form a special relationship important in the formation of CSF, a topic to which we now turn attention.

The brain floats in its own special cerebrospinal fluid.

Cerebrospinal fluid (CSF) surrounds and cushions the brain and spinal cord. The CSF has about the same density as the brain itself, so the brain essentially f oats or is suspended in this special f uid environment. The major function of CSF is to be a shock-absorbing f uid to prevent the brain from bumping against the interior of the hard skull when the head is subjected to sudden, jarring movements.

In addition to protecting the delicate brain from mechanical trauma, the CSF plays an important role in the exchange of materials between the neural cells and the interstitial f uid surrounding the brain. Only the brain interstitial f uid—not the blood or CSF—comes into direct contact with the neurons and glial cells. Because the brain interstitial f uid directly bathes the neural cells, its composition is critical. The composition of the brain interstitial f uid is inf uenced more by changes in the composition of the CSF than by alterations in the blood. Materials are exchanged fairly freely between the CSF and brain interstitial f uid, whereas only limited exchange occurs between the blood and brain interstitial f uid. Thus, the composition of the CSF must be carefully regulated.

CSF is formed primarily by the **choroid plexuses**, which are specialized structures in the walls of the ventricles that protrude into the ventricular cavity in particular regions (❚Figure 5-6a). Choroid plexuses consist of richly vascularized, cauliflowerlike masses of pia mater tissue that dip into pockets formed by ependymal cells (❚Figure 5-6c). CSF forms as the ependymal cells of the choroid plexuses selectively transport materials from the pia capillary blood into the ventricular cavity. The composition of CSF differs from that of blood. For example, CSF is lower in K^+ and slightly higher in Na^+, making the brain interstitial fluid an ideal environment for movement of these ions down concentration gradients, a process essential for conduction of nerve impulses (see p. 96). The biggest difference is the presence of plasma proteins in the blood but almost no proteins normally present in the CSF. Plasma proteins cannot exit the brain capillaries to leave the blood during formation of CSF.

Once CSF is formed, it f ows through the four interconnected ventricles of the brain and through the spinal cord's narrow central canal, which is continuous with the last ventricle. CSF also escapes through small openings from the fourth ventricle at the base of the brain to enter the subarachnoid space and subsequently f ows between the meningeal layers over the entire surface of the brain and spinal cord (❚Figure 5-6). When the CSF reaches the upper regions of the brain, it is reabsorbed from the subarachnoid space into the venous blood through the arachnoid villi. Flow of CSF through this system is facilitated by ciliary beating along with circulatory and postural factors that result in a CSF pressure of about 10 mm Hg. Reduction of this pressure by removal of even a few milliliters (mL) of CSF during a spinal tap for laboratory analysis may produce severe headaches.

Clinical Note Through the ongoing processes of formation, circulation, and reabsorption, the entire CSF volume of about 125 to 150 mL is replaced more than three times a day. If any one of these processes is defective so that excess CSF accumulates (for example, as with obstruction of the CSF pathways by a malformation or a tumor), **hydrocephalus** ("water on the brain") occurs. The resulting increase in CSF pressure can lead to brain damage if untreated.

A highly selective blood–brain barrier regulates exchanges between the blood and brain.

The brain is carefully shielded from harmful changes in the blood by a highly selective **blood–brain barrier (BBB)** that limits access of blood-borne materials into the vulnerable brain tissue. Throughout the body, materials can be exchanged between the blood and the interstitial fluid only across the walls of capillaries. Capillary walls are formed by a single layer of *endothelial cells*. The holes or pores usually present between the endothelial cells permit rather free exchange across capillaries elsewhere. However, the cells that form the walls of a brain capillary are joined by tight junctions (see p. 61). These impermeable junctions seal the capillary wall so that nothing can be exchanged across the wall by passing between the cells. The only permissible exchanges occur through the endothelial cells themselves. Lipid-soluble substances such as O_2, CO_2, alcohol, and steroid hormones penetrate these cells easily by dissolving in their lipid plasma membrane. Small water molecules also readily diffuse through by passing between the phospholipid molecules of the plasma membrane or through aquaporins (water channels) (see p. 66). All other substances exchanged between the blood and brain interstitial fluid, including such essential materials as glucose, amino acids, and ions, are transported by highly selective membrane-bound carriers. Thus, transport across brain capillary walls *between* the wall-forming cells is *anatomically prevented* and transport *through* the cells is *physiologically restricted*. Together, these mechanisms constitute the BBB. By strictly limiting exchange between the blood and brain, the BBB protects the delicate brain from chemical fluctuations in the blood. For example, even if the K^+ level in the blood is doubled, little change occurs in the K^+ concentration of the fluid bathing the central neurons. This is beneficial because alterations in interstitial fluid K^+ would be detrimental to neuronal function. Also, the BBB minimizes the possibility that potentially harmful blood-borne substances might reach the central neural tissue. It further prevents certain circulating hormones that could act as neurotransmitters from reaching the brain, where they could produce uncontrolled nervous activity.

Clinical Note On the negative side, the BBB limits the use of drugs for the treatment of brain and spinal cord disorders because many drugs cannot penetrate this barrier. Researchers are seeking ways to safely and temporarily breech the barrier to permit drugs to get through, such as by sneaking them through normal gateways for entry of essentials such as iron; by temporarily shrinking the endothelial cells via injection of hyperosmotic solutions that draw water out of the cells, thus creating minuscule gaps in the BBB by pulling apart the tight junctions between the cells; or by injecting microscopic gas bubbles and using ultrasound to vibrate them against a precise location of the BBB, thereby briefly forcing open the tight junctions in the bombarded section.

Pericytes and astrocytes both contribute to formation and maintenance of the BBB. **Pericytes** are contractile cells that wrap around capillary endothelial cells throughout the body. The precise roles of brain pericytes in BBB function are still being investigated. Highly complex signaling cascades take place among pericytes, brain capillary endothelial cells, and astrocytes. Brain capillaries are surrounded by astrocyte processes, which lie outside of the pericytes. Astrocytes play three roles in the BBB: (1) They signal the cells forming the brain capillaries to "get tight." Endothelial cells do not have an inherent ability to form tight junctions; they do so only at the command of a signal within their neural environment. (2) Astrocytes promote the production of specific carrier proteins and ion channels that regulate the transport of selected substances through the endothelial cells. (3) These glial cells participate in the cross-cellular transport of some substances, such as K^+.

Certain areas of the brain, most notably a portion of the hypothalamus, are not subject to the BBB. Functioning of the hypothalamus depends on its "sampling" the blood and adjusting its controlling output accordingly to maintain homeostasis. Part of this output is in the form of water-soluble hormones that must enter hypothalamic capillaries to be transported to their sites of action. Appropriately, these hypothalamic capillaries are not sealed by tight junctions, the presence of which would prevent entry of these hormones into the blood.

The brain depends on constant delivery of oxygen and glucose by the blood.

Even though many substances in the blood never come in contact with the brain tissue, the brain depends more than any other tissue on a constant blood supply. Unlike most tissues, which can resort to anaerobic metabolism to produce ATP in the absence of O_2 for at least short periods (see p. 39), the brain cannot produce ATP without O_2. Scientists recently discovered an O_2-binding protein, **neuroglobin**, in the brain. This molecule, which is similar to hemoglobin, the O_2-carrying protein in red blood cells (see p. 383), is thought to play a key role in O_2 handling in the brain, although its exact function remains to be determined. Also in contrast to most tissues, which can use other sources of fuel for energy production in lieu of glucose, the brain normally uses only glucose but does not store any of this nutrient. Because of its high rate of demand for ATP, under resting conditions the brain uses 20% of the O_2 and 50% of the glucose consumed in the body. Therefore, the brain depends on a continuous, adequate blood supply of O_2 and glucose. Although it constitutes only 2% of body weight, the brain receives 15% of the blood pumped out by the heart. (Instead of using glucose during starvation, the brain can resort to using ketone bodies produced by the liver, but this alternate nutrient source also must be delivered by the blood to the brain.)

Clinical Note Brain damage results if this organ is deprived of its critical O_2 supply for more than 4 to 5 minutes or if its glucose supply is cut off for more than 10 to 15 minutes. The most common cause of inadequate blood supply to the brain is a stroke. (See the accompanying boxed feature, ▌Concepts, Challenges, and Controversies, for details.)

Check Your Understanding 5.2

1. Name the meninges, from outermost to innermost.
2. Discuss the function of cerebrospinal fluid.

Strokes: A Deadly Domino Effect

THE MOST COMMON CAUSE OF brain damage is a **cerebrovascular accident (CVA** or **stroke)**. When a cerebral (brain) blood vessel is blocked by a clot (which accounts for more than 80% of strokes) or ruptures, the brain tissue supplied by that vessel loses its vital O_2 and glucose supply. The result is damage and usually death of the deprived tissue. Furthermore, neural damage (and the subsequent loss of neural function) extends well beyond the blood-deprived area as a result of a neurotoxic effect that leads to the death of additional nearby cells. The initial blood-deprived cells die by necrosis (unintentional cell death), but the doomed neighbors undergo apoptosis (deliberate cell suicide; see p. 40). In a process known as **excitotoxicity**, the initial O_2-starved cells release excessive amounts of glutamate, a common excitatory neurotransmitter. The excitatory overdose of glutamate from the damaged brain cells binds with and overexcites surrounding neurons. Specifically, glutamate binds with excitatory receptors known as NMDA receptors, which function as calcium (Ca^{2+}) channels. As a result of toxic activation of these receptor-channels, they remain open for too long, permitting too much Ca^{2+} to rush into the affected neighboring neurons. This elevated intracellular Ca^{2+} triggers these cells to self-destruct. Cell-damaging **free radicals** are produced during this process. These highly reactive, electron-deficient particles cause further cell damage by snatching electrons from other molecules. Adding to the injury, researchers speculate that the Ca^{2+} apoptotic signal may spread from these dying cells to abutting healthy cells through gap junctions, cell-to-cell conduits that allow Ca^{2+} and other small ions to diffuse freely between cells (see p. 62). This action kills even more neuronal victims. Thus, most neurons that die following a stroke are originally unharmed cells that commit suicide in response to the chain of reactions unleashed by the toxic release of glutamate from the initial site of O_2 deprivation.

Until late last century, physicians could do nothing to halt the inevitable neuronal loss following a stroke, leaving patients with an unpredictable mix of neural deficits. Treatment was limited to rehabilitative therapy after the damage was already complete. In recent years, armed with new knowledge about the underlying factors in stroke-related neuronal death, the medical community has been seeking ways to halt the cell-killing domino effect. The goal is to limit the extent of neuronal damage and thus minimize or even prevent clinical symptoms such as paralysis. If a stroke is caught in time, doctors now administer clot-dissolving drugs within the first 3 hours after onset to restore blood flow through blocked cerebral vessels. Clot busters were the first drugs used to treat strokes, but they are only the beginning of new stroke therapies. Other methods are under investigation to prevent adjacent neurons from succumbing to the neurotoxic release of glutamate. These include blocking the NMDA receptor-channels that initiate the death-wielding chain of events in response to glutamate, halting the apoptosis pathway that results in self-execution, and blocking the gap junctions that permit the Ca^{2+} death messenger to spread to adjacent cells. Evidence in a recent rat study even suggests that sensory stimulation, such as rubbing a stroke victim's face or fingers, may represent a cheap, simple way to help minimize disability while the person is on the way to medical attention. These tactics hold much promise for treating strokes, which are the most common cause of adult disability and the third leading cause of death in the United States. However, to date, no new neuroprotective drugs have been found that do not cause serious side effects.

3. Explain by what means the blood–brain barrier anatomically prevents transport between the cells that form the walls of brain capillaries and physiologically restricts transport through these cells.

5.3 Overview of the Central Nervous System

The CNS consists of the brain and spinal cord. The human brain is the consistency of tofu and weighs just three pounds. The estimated 85 billion neurons in your brain are joined together by an estimated quadrillion synaptic connections and are assembled into complex networks that enable you to (1) subconsciously regulate your internal environment by neural means, (2) experience emotions, (3) voluntarily control your movements, (4) perceive (be consciously aware of) your body and your surroundings, and (5) engage in other higher cognitive processes such as thought and memory. The term **cognition** refers to the act or process of "knowing," including both awareness and judgment.

No part of the brain acts in isolation from other brain regions because networks of neurons are anatomically linked by synapses and neurons throughout the brain communicate extensively with one another by electrical and chemical means. However, neurons that work together to ultimately accomplish a given function tend to be organized within a discrete location. Therefore, even though the brain operates as a whole, it is organized into regions. The parts of the brain can be grouped in various ways based on anatomic distinctions, functional specialization, and evolutionary development. We use the following grouping:

1. Brain stem
2. Cerebellum

Left cerebral hemisphere   Right cerebral hemisphere

Longitudinal fissure

(a) Brain, superior (top) view

      (1) Hypothalamus

      (2) Thalamus

   b. Cerebrum

      (1) Basal nuclei

      (2) Cerebral cortex

The order in which these components are listed generally represents both their anatomic location (from bottom to top) and their complexity and sophistication of function (from the least specialized, oldest evolutionary level to the newest, most specialized level).

A primitive nervous system consists of comparatively few interneurons interspersed between afferent and efferent neurons. During evolutionary development, the interneuronal component progressively expanded, formed more complex interconnections, and became localized at the head end of the nervous system, forming the brain. Newer, more sophisticated layers of the brain were added on to the older, more primitive layers. The human brain represents the present peak of development.

The *brain stem,* the oldest region of the brain, is continuous with the spinal cord (❘Table 5-1 and ❘Figure 5-7b). It consists of the midbrain, pons, and medulla. The brain stem controls many life-sustaining processes, such as respiration, circulation, and digestion, common to all vertebrates. These processes are often referred to as *vegetative functions,* meaning functions performed unconsciously or involuntarily. With the loss of higher brain functions, these lower brain levels, in conjunction with

appropriate supportive therapy such as providing adequate nourishment, can still sustain the functions essential for survival, but the person has no awareness or control of that life.

Attached at the top rear portion of the brain stem is the *cerebellum,* which is concerned with maintaining proper position of the body in space and subconscious coordination of motor activity (movement). The cerebellum also plays a key role in learning skilled motor tasks, such as a dance routine.

On top of the brain stem, tucked within the interior of the cerebrum, is the *diencephalon.* It houses two brain components: the *hypothalamus,* which controls many homeostatic functions important in maintaining stability of the internal environment; and the *thalamus,* which begins sensory processing.

Using an ice cream cone as an analogy, on top of this "cone" of lower brain regions is the *cerebrum,* whose "scoop" gets progressively larger and more highly convoluted (that is, has tortuous ridges delineated by deep grooves or folds) the more evolutionarily advanced the vertebrate species is. The cerebrum is most highly developed in humans, where it constitutes about 80% of the total brain weight. The outer layer of the cerebrum is the highly convoluted *cerebral cortex,* which caps an inner core that houses the *basal nuclei.* The myriad convolutions of the human cerebral cortex give it the appearance of a much-folded walnut (❘Figure 5-7a). In more ancestral mammal groups, the cortex is smooth. Without these surface wrinkles, the human cortex would take up to three times the area it does and, thus, would not fit like a cover over the underlying structures. The increased neural circuitry housed in the extra cerebral cortical area not found in less highly developed species is responsible for many of our unique human abilities. The cerebral cortex plays a key role in the most sophisticated neural functions, such as voluntary initiation of movement, final sen-

The Central Nervous System   **143**

TABLE 5-1 Overview of Structures and Functions of the Major Components of the Brain
sory perception (the brain's interpretation of the body and its surroundings based on sensory input), conscious thought, language, personality traits, and other factors we associate with the mind or intellect. It is the highest, most complex, integrating area of the brain.

Each of these regions of the CNS is now discussed in turn, starting with the highest level, the cerebral cortex, and moving down to the lowest level, the spinal cord.

Check Your Understanding 5.3

1. Define *cognition.*
2. Outline the components of the brain from the least specialized, oldest evolutionary level to the newest, most specialized level.
3. Discuss the significance of the human cerebral cortex being highly convoluted.

5.4 Cerebral Cortex

The **cerebrum** is divided into two halves, the right and left **cerebral hemispheres** (▌Figure 5-7a). They are connected to each other by the **corpus callosum**, a thick band consisting of an

estimated 300 million neuronal axons that connect the two hemispheres (▌Figure 5-7b; also see Figure 5-14, p. 153). The corpus callosum is the body's "information superhighway." The two hemispheres communicate and cooperate with each other by means of constant information exchange through this neural connection.

The cerebral cortex is an outer shell of gray matter covering an inner core of white matter.

Each hemisphere is composed of a thin outer shell of *gray matter,* the **cerebral cortex**, covering a thick central core of *white matter* (see ▌Figure 5-14). Several other masses of gray matter that collectively constitute the basal nuclei are located deep within the white matter. Throughout the entire CNS, **gray matter** consists mostly of densely packed neuronal cell bodies and their dendrites, in addition to most glial cells. Bundles or tracts of myelinated nerve fibers (axons) constitute **white matter**; its white appearance is a result of the lipid composition of the myelin. Gray matter and white matter each make up about half of the brain.

Gray matter can be viewed as the "computers" of the CNS and white matter as the "wires" that connect the computers to

1. Sensory perception
2. Voluntary control of movement
3. Language
4. Personality traits
5. Sophisticated mental events, such as thinking, memory, decision making, creativity, and self-consciousness

1. Inhibition of muscle tone
2. Coordination of slow, sustained movements
3. Suppression of useless patterns of movement

1. Relay station for all synaptic input
2. Crude awareness of sensation
3. Some degree of consciousness
4. Role in motor control

1. Regulation of many homeostatic functions, such as temperature control, thirst, urine output, and food intake
2. Important link between nervous and endocrine systems
3. Extensive involvement with emotion and basic behavioral patterns
4. Role in sleep–wake cycle

1. Maintenance of balance
2. Enhancement of muscle tone
3. Coordination and planning of skilled voluntary muscle activity

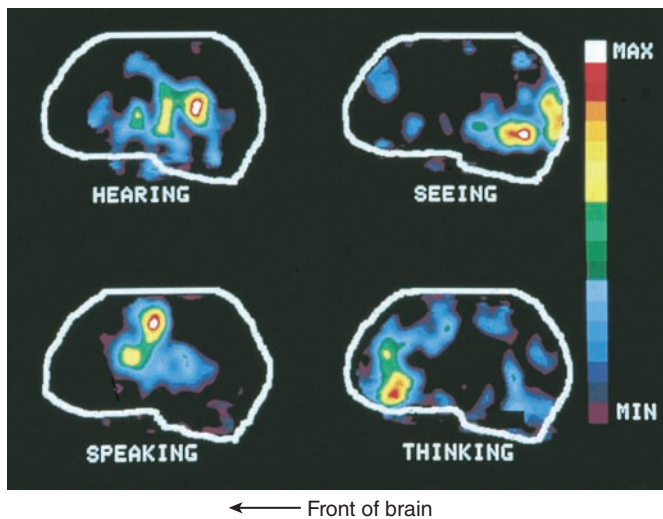
1. Origin of majority of peripheral cranial nerves
2. Cardiovascular, respiratory, and digestive control centers
3. Regulation of muscle reflexes involved with equilibrium and posture
4. Reception and integration of all synaptic input from spinal cord; arousal and activation of cerebral cortex
5. Role in sleep–wake cycle

one another. White matter contains collectively an estimated quarter million miles of fibers, enough that if lined up end to end, they would stretch from Earth to the moon. Integration of neural input and initiation of neural output take place at synapses within gray matter. The fiber tracts in white matter transmit signals from one part of the cerebral cortex to another or between the cortex and other regions of the CNS. Such communication between different areas of the cortex and elsewhere facilitates integration of their activity. This integration is essential for even a relatively simple task such as picking a fower. Vision of the fower is received by one area of the cortex, reception of its fragrance takes place in another area, and movement is initiated by still another area. More subtle neuronal responses, such as appreciation of the fower's beauty and the urge to pick it, are poorly understood but undoubtedly involve extensive interconnection of fibers among different cortical regions.

Our knowledge about the complex connections that underlie brain function is expanding at a rapid rate owing to the **Human Connectome Project** launched by the National Institutes of Health in 2009. Through this ambitious project, scientists across the country are collecting and sharing data using cutting-edge brain imaging techniques on healthy adults to map the entire white matter fiber circuitry in the human brain. One imaging tool being used is **diffusion magnetic resonance imaging (dMRI)**, which maps the orientation in space of the brain's white matter tracts by tracking how the organized bundles of fibers affect the diffusion of water. Because diffusion is faster in the direction parallel to the fibers than in the perpendicular direction, the technique can be used to reveal the patterns of white matter connectivity (see chapter opener photo).

Our knowledge about gray matter function has been leaping forward in recent decades too through use of modern technologies. In the early 1980s, new minuscule glass electrodes made it possible to directly record electrical activity of individual neurons in experimental animals engaged in particular motor tasks or encountering various sensations. The first pictures of the human brain at work were also snapped in the 1980s through use of **positron emission tomography (PET) scans** that depend on injection of small amounts of radioactive material that accumulates in the part of the body under study and leads to release of a tiny burst of gamma-ray energy that can be detected by the PET equipment. Increased gamma activity can be correlated with increased neural activity in the brain region under study (❙ Figure 5-8). In the 1990s, **functional magnetic resonance imaging (fMRI)** was used for the first time to detect functionally induced changes in regional cerebral blood f ow and O_2 use by taking advantage of the fact that the magnetic properties of hemoglobin, the O_2-carrying molecule in the blood, are affected by the amount of O_2 it is carrying. By using a *blood oxygen-level dependent (BOLD)* signal, the fMRI method highlights neural areas that are more active. The latest technology for studying neurons, **optogenetics**, debuted in the naughts (*opto* refers to "light," *genetics* refers to the genetic engineering involved in the technique). By inserting genes that code for light-responsive molecules into experimental animals' neurons, scientists can use f ashes of light to turn the neurons on or off at will (by depolarizing or hyperpolarizing these cells via light-induced changes in ion channels). By being able to manipulate neurons on command in living animals going about their routine activities, scientists hope to shed further light on complex information processing in the brain.

Neurons in different regions of the cerebral cortex may fire in rhythmic synchrony.

Neither whole-brain imaging techniques or single-neuron recordings can identify concurrent changes in electrical activity in a group of neurons working together to accomplish a particular activity. As an analogy, imagine trying to record a concert by using a single microphone that could pick up only the sounds produced by one musician. You would get a very limited impression of the performance by hearing only the changes in notes and tempo as played by this one individual. You would miss the richness of the melody and rhythm being performed in synchrony by the entire orchestra. Similarly, in recording from single neurons, scientists have overlooked a parallel informa-


Courtesy of Washington University School of Medicine, St. Louis.

← Front of brain

Figure 5-8 **PET scans of cerebral cortex during different tasks.** Different areas of the brain "light up" on positron emission tomography (PET) scans as a person performs different tasks. PET scans detect the magnitude of blood flow in various regions of the brain. Because more blood flows into a particular region of the brain when it is more active, neuroscientists can use PET scans to "take pictures" of the brain at work on various tasks.

tion mechanism involving changes in the relative timing of action potential discharges among a functional group of neurons, called a **neural network** or **assembly**. Studies involving simultaneous recordings from multiple neurons show that interacting neurons may transiently fire together for fractions of a second. Many neuroscientists believe that the brain encodes information not just by changing the firing rates of individual neurons but also by changing the patterns of these brief neural synchronizations. That is, groups of neurons communicate, or send messages about what is happening, by changing their pattern of synchronous firing. Recall that astrocytes also help coordinate synaptic activity among neural networks.

For example, when you view a bouncing ball, different visual units initially process different aspects of this object—its shape, its color, its movement, and so on. Somehow all these separate processing pathways must be integrated, or "bound together," for you to "see" the bouncing ball as a whole unit without stopping to contemplate its many separate features. The solution to the longtime mystery of how the brain accomplishes this integration might lie in the synchronous firing of neurons in separate regions of the brain that are functionally linked by virtue of being responsive to different aspects of the same objects, such as the bouncing ball.

Two new ambitious projects, both launched in 2013, will greatly expand our knowledge of brain function by studying via different approaches how neurons are functionally linked. The **BRAIN Initiative (Brain Research through Advancing Innovative Neurotechnologies)**, commonly referred to as the **Brain Activity Map Project**, is a United States–led collaborative 10-year research project with the goal of developing new technologies to advance our understanding of brain activity by real-time mapping of thousands or millions of neurons working together in coordinated networks. The European Commission launched the **Human Brain Project**, a 10-year initiative involv-

ing about 130 universities around the world to create a super-computer simulation of the human brain. To mimic the complexity of the human brain, this digital brain will eventually require computers thousands of times more powerful than those available today.

The cerebral cortex is organized into layers and functional columns.

The cerebral cortex is organized into six well-defined layers based on varying distributions of several distinctive cell types (**Figure 5-9**). These layers are organized into functional vertical columns that extend perpendicularly about 2 mm from the cortical surface down through the thickness of the cortex to the underlying white matter. The neurons within a given column function as a "team," with each cell being involved in different aspects of the same specific activity—for example, perceptual processing of the same stimulus from the same location.

The functional differences between various areas of the cortex result from different layering patterns within the columns and from different input–output connections, not from the presence of unique cell types or different neuronal mechanisms. For example, those regions of the cortex responsible for sensory perception have an expanded layer IV, a layer rich in **stellate cells**, which are neurons responsible for initial processing of sensory input to the cortex. In contrast, cortical areas that control output to skeletal muscles have a thickened layer V, which contains an abundance of large neurons known as **pyramidal cells**. These nerve cells send fibers down the spinal cord from the cortex to terminate on efferent motor neurons that innervate skeletal muscles (**Figure 5-9**).

The four pairs of lobes in the cerebral cortex are specialized for different activities.

We now consider the locations of the major functional areas of the cerebral cortex. Throughout this discussion, keep in mind that even though a discrete activity is ultimately attributed to a particular region of the brain, each part depends on complex interplay among numerous other regions for both incoming and outgoing messages.

The anatomic landmarks used in cortical mapping are specific deep folds that divide each half of the cortex into four major lobes: the *occipital, temporal, parietal,* and *frontal lobes* (**Figure 5-10**). The **occipital lobes**, located posteriorly (at the back of the head), carry out initial processing of visual input. Auditory (sound) sensation is initially received by the **temporal lobes**, located laterally (on the sides of the head) (see **Figures 5-8 and 5-11**). You will learn more about the functions of these regions in Chapter 6 when we discuss vision and hearing. The parietal lobes and frontal lobes, located on the top of the head, are separated by a deep infolding, the **central sulcus**, which runs roughly down the middle of the lateral surface of each hemisphere. The **parietal lobes** lie to the rear of the central sulcus on each side, and the **frontal lobes** lie in front of it. The parietal lobes are primarily responsible for receiving and processing sensory input. The frontal lobes are responsible for three main functions: (1) voluntary motor activity, (2) speaking
Figure 5-9 Layers of the cerebral cortex. Layer I is mostly glial cells and axons that run laterally. Layers II through VI contain different proportions of two main classes of cortical neurons: *pyramidal cells,* which are shaped like upside down pyramids and are the major output neurons, and *stellate cells,* which are shaped like stars. Stellate cells primarily receive input to the cortex and process local information.

FIGURE FOCUS*: (1) Which type of cortical neuron is most abundant in regions of the cortex that control output to skeletal muscles? (2) Which type is most abundant in cortical regions responsible for sensory perception?*

body. This distribution of cortical sensory processing is depicted in ❙Figure 5-12b. Note that on this **sensory homunculus** (*homunculus* means "little man") the different parts of the body are not equally represented. The size of each body part in this homunculus indicates the relative proportion of the somatosensory cortex devoted to that area. The exaggerated size of the face, tongue, hands, and genitalia indicates the high degree of sensory perception associated with these body parts.

The somatosensory cortex on each side of the brain mostly receives sensory input from the opposite side of the body because most ascending pathways that carry sensory information up the spinal cord cross over to the opposite side before eventually terminating in the cortex (see ❙Figure 5-26a, p. 175). Thus, damage to the somatosensory cortex in the left hemisphere produces sensory deficits on the right side of the body, whereas sensory losses on the left side are associated with damage to the right half of the cortex.

Simple awareness of touch, pressure, temperature, or pain is detected by the thalamus, a lower level of the brain, but the somatosensory cortex goes beyond mere recognition of sensations to fuller sensory perception. The thalamus makes you aware that something hot versus something cold is touching your body, but it does not tell you where or of what intensity. The somatosensory cortex localizes the source of sensory input and perceives the level of intensity of the stimulus. It also is capable of spatial discrimination, so it can discern shapes of objects being held and can distinguish subtle differences in similar objects that come into contact with the skin.

The somatosensory cortex, in turn, projects this sensory input via white matter fibers to adjacent higher sensory areas for even further elaboration, analysis, and integration of sensory information. These higher areas are important in perceiving com-

ability, and (3) elaboration of thought. We next examine the role of the parietal lobes in sensory perception and then turn to the functions of the frontal lobes in more detail.

The parietal lobes accomplish somatosensory processing.

Sensations from the surface of the body, such as touch, pressure, heat, cold, and pain, are collectively known as **somesthetic sensations** (*somesthetic* means "body feelings"). Somesthetic information is detected by sensory receptors in the skin and relayed along afferent fibers to the CNS. Within the CNS, this information is **projected** (transmitted along specific neural pathways to higher brain levels) to the **somatosensory cortex**. The somatosensory cortex is located in the front portion of each parietal lobe immediately behind the central sulcus (❙Figures 5-11 and 5-12a). It is the site for initial cortical processing and perception of both somesthetic and proprioceptive input. **Proprioception** is the awareness of body position.

Each region within the somatosensory cortex receives somesthetic and proprioceptive input from a specific area of the

Figure 5-10 Cortical lobes. Each half of the cerebral cortex is divided into the occipital, temporal, parietal, and frontal lobes, as depicted in this lateral view of the left side of the brain.
Figure 5-11 Functional areas of the cerebral cortex. Various regions of the cerebral cortex are primarily responsible for various aspects of neural processing, as indicated in this lateral view of the left side of the brain.

FIGURE FOCUS: *Assume you are petting a cat. Indicate which cortical lobe processes each of the following parts of this action: (1) seeing the cat, (2) commanding hand and arm movements, (3) feeling the soft fur, and (4) hearing the cat purr.*

plex patterns of somatosensory stimulation—for example, simultaneous appreciation of the texture, firmness, temperature, shape, position, and location of an object you are holding.

The primary motor cortex located in the frontal lobes controls the skeletal muscles.

The area in the rear portion of the frontal lobe immediately in front of the central sulcus and next to the somatosensory cortex is the **primary motor cortex** (see ❙Figures 5-11 and 5-12a). It confers voluntary control over movement produced by skeletal muscles. As in sensory processing, the motor cortex on each side of the brain primarily controls muscles on the opposite side of the body. Neuronal tracts originating in the motor cortex of the left hemisphere cross over before passing down the spinal cord to terminate on efferent motor neurons that trigger skeletal muscle contraction on the right side of the body (see ❙Figure 5-26b, p. 175). Accordingly, damage to the motor cortex on the left side of the brain produces paralysis on the right side of the body; the converse is also true.

Stimulation of different areas of the primary motor cortex brings about movement in different regions of the body. Like the sensory homunculus for the somatosensory cortex, the **motor homunculus**, which depicts the location and relative

amount of motor cortex devoted to output to the muscles of each body part, is distorted (❙Figure 5-12c). The fingers, thumbs, and muscles important in speech, especially those of the lips and tongue, are grossly exaggerated, indicating the fine degree of motor control these body parts have. Compare this to how little brain tissue is devoted to the trunk, arms, and lower extremities, which are not capable of such complex movements. Thus, the extent of representation in the motor cortex is proportional to the precision and complexity of motor skills required of the respective part.

Higher motor areas are also important in motor control.

Even though signals from the primary motor cortex terminate on the efferent neurons that trigger voluntary skeletal muscle contraction, the motor cortex is not the only region of the brain involved with motor control. First, lower brain regions and the spinal cord control involuntary skeletal muscle activity, such as in maintaining posture. Some of these same regions play an important role in monitoring and coordinating voluntary motor activity that the primary motor cortex has set in motion. Second, although fibers originating from the motor cortex can activate motor neurons to bring about muscle contraction, the

motor cortex itself does not *initiate* voluntary movement. The motor cortex is activated by a widespread pattern of neuronal discharge, the **readiness potential**, which occurs about 750 msec before specific electrical activity is detectable in the motor cortex. Three higher motor areas of the cortex are involved in this voluntary decision-making period. These higher areas, which all command the primary motor cortex, include the *supplementary motor area,* the *premotor cortex,* and the *posterior parietal cortex* (see ❙Figure 5-11). Furthermore, a subcortical region of the brain, the *cerebellum,* plays an important role in planning, initiating, and timing certain kinds of movement by sending input to the motor areas of the cortex.

The three higher motor areas of the cortex and the cerebellum carry out different, related functions that are all important in programming and coordinating complex movements that involve simultaneous contraction of many muscles. Even though electrical stimulation of the primary motor cortex brings about contraction of particular muscles, no purposeful coordinated movement can be elicited, just as pulling on isolated strings of a puppet does not produce any meaningful movement. A puppet displays purposeful movements only when a skilled puppeteer manipulates the strings in a coordinated manner. In the same way, these four regions (and perhaps other areas as yet undetermined) develop a **motor program** for the specific voluntary task and then "pull" the appropriate pattern of "strings" in the primary motor cortex to produce the sequenced contraction of appropriate muscles that accomplishes the desired complex movement.

The **supplementary motor area** lies on the medial (inner) surface of each hemisphere anterior to (in front of) the primary motor cortex. It plays a preparatory role in programming complex sequences of movement. Stimulation of various regions of this motor area brings about complex patterns of movement, such as opening or closing the hand. Lesions here do not result in paralysis, but they do interfere with performance of more complex, useful integrated movements.

The distorted graphic representation of the body parts indicates the relative proportion of the primary motor cortex devoted to controlling skeletal muscles in each area.

The Central Nervous System | **149**

The **premotor cortex**, located on the lateral surface of each hemisphere in front of the primary motor cortex, is important in orienting the body and arms toward a specific target. To command the primary motor cortex to produce the appropriate skeletal muscle contraction for accomplishing the desired movement, the premotor cortex must be informed of the body's momentary position in relation to the target. The premotor cortex is guided by sensory input processed by the **posterior parietal cortex**, a region that lies posterior to (in back of) the primary somatosensory cortex. These two higher motor areas have many anatomic interconnections and are closely related functionally. When either of these areas is damaged, the person cannot process complex sensory information to accomplish purposeful movement in a spatial context; for example, the person cannot successfully manipulate eating utensils.

Even though these higher motor areas command the primary motor cortex and are important in preparing for execution of deliberate, meaningful movement, researchers cannot say that voluntary movement is actually initiated by these areas. This pushes the question of how and where voluntary activity is initiated one step further. Probably no single area is responsible; undoubtedly, numerous pathways can ultimately bring about deliberate movement.

Think about the neural systems called into play, for example, during the simple act of picking up an apple to eat. Your memory tells you the fruit is in a bowl on the kitchen counter. Sensory systems, coupled with your knowledge based on past experience, enable you to distinguish the apple from the other kinds of fruit in the bowl. On receiving this integrated sensory information, motor systems issue commands to the exact muscles of the body in the proper sequence to enable you to move to the fruit bowl and pick up the targeted apple. During execution of this act, minor adjustments in the motor command are made as needed, based on continual updating provided by sensory input about the position of your body relative to the goal. Then there is the issue of motivation and behavior. Are you reaching for the apple because you are hungry (detected by a neural system in the hypothalamus) or because of a more complex behavioral scenario (for example, you started to think about food because you just saw someone eating on television)? Why did you choose an apple rather than a banana when both are in the fruit bowl and you like the taste of both, and so on? Thus, initiating and executing purposeful voluntary movement actually include a complex neuronal interplay that involves output from the motor regions guided by integrated sensory information and ultimately depends on motivational systems and elaboration of thought. All this plays against a background of memory stores from which you can make meaningful decisions about desirable movements.

Somatotopic maps vary slightly between individuals and are dynamic, not static.

Although the general organizational pattern of sensory and motor somatotopic ("body representation") maps of the cortex is similar in all people, the precise distribution is unique for each individual. Just as each of us has two eyes, a nose, and a mouth and yet no two faces have these features arranged in exactly the same way, so it is with brains. Furthermore, an individual's somatotopic mapping is not "carved in stone" but is subject to constant subtle modifications based on use. The general pattern is governed by genetic and developmental processes, but the individual cortical architecture can be influenced by **use-dependent competition** for cortical space. For example, when monkeys were encouraged to use their middle fingers instead of their other fingers to press a bar for food, after only several thousand bar presses the "middle finger area" of the motor cortex was greatly expanded and encroached on territory previously devoted to the other fingers. Similarly, modern neuroimaging techniques reveal that the left hand of a right-handed string musician is represented by a larger area of the somatosensory cortex than is the left hand of a person who does not play a string instrument. In this way, the musician's left-hand fingers develop a greater "feel" for the instrument as they skillfully manipulate the strings.

Other regions of the brain besides the somatosensory cortex and motor cortex can also be modified by experience. We now turn our attention to this plasticity of the brain.

Because of its plasticity, the brain can be remodeled in response to varying demands.

The brain displays a degree of **plasticity**—that is, an ability to change or be functionally remodeled in response to the demands placed on it. The ability of the brain to modify as needed is more pronounced in the early developmental years, but even adults retain some plasticity. When one area of the brain associated with a particular activity is destroyed, other areas may gradually assume some or all of the functions of the damaged region. Researchers are only beginning to unravel the molecular mechanisms responsible for the brain's plasticity. Current evidence suggests that the formation of new neural pathways (not new neurons, but new connections between existing neurons) in response to changes in experience are mediated in part by alterations in dendritic shape resulting from modifications in certain cytoskeletal elements (see p. 44). As its dendrites become more branched and elongated and more dendritic spines form (see ❚Figure 4-7, p. 95), a neuron becomes able to receive and integrate more signals from other neurons. Thus, the precise synaptic connections between neurons are not fixed but can be modified by experience. The gradual modification of each person's brain by a unique set of experiences provides a biological basis for individuality. Even though the particular architecture of your own rather plastic brain has been and continues to be influenced by your unique experiences, it is important to realize that what you do and do not do cannot totally shape the organization of your cortex and other parts of the brain. Some limits are genetically established, and others are developmental limits on the extent to which modeling can be influenced by patterns of use. For example, some cortical regions maintain their plasticity throughout life, especially the ability to learn and to add new memories, but other cortical regions can be modified by use for only a specified time after birth before becoming permanently fixed. The length of this critical developmental period varies for different cortical regions.

Different regions of the cortex control different aspects of language.

Language ability is an excellent example of early cortical plasticity coupled with later permanence. Unlike the sensory and motor regions of the cortex, which are present in both hemispheres, in most people the areas of the brain responsible for language ability are found in only one hemisphere—the left hemisphere.

Clinical Note However, if a child younger than the age of two accidentally suffers damage to the left hemisphere, language functions are transferred to the right hemisphere with no delay in language development but at the expense of less obvious nonverbal abilities for which the right hemisphere is normally responsible. Up to about the age of 10, after damage to the left hemisphere, language ability can usually be reestablished in the right hemisphere following a temporary period of loss. If damage occurs beyond the early teens, however, language ability is permanently impaired, even though some limited restoration may be possible. The regions of the brain involved in comprehending and expressing language apparently are permanently assigned before adolescence.

Even in normal individuals, there is evidence for early plasticity and later permanence in language development. Infants can distinguish between and articulate the entire range of speech sounds, but each language uses only a portion of these sounds. As children mature, they often lose the ability to distinguish between or express speech sounds that are not important in their native language. For example, Japanese children can distinguish between the sounds of *r* and *l*, but many Japanese adults cannot perceive the difference between them.

Roles of Broca's Area and Wernicke's Area **Language** is a complex form of communication in which written or spoken words (or hand gestures in the case of sign language) symbolize objects and convey ideas. It involves the integration of two distinct capabilities—namely, *expression* (speaking ability) and *comprehension*—each of which is related to a specific area of the cortex. The primary areas of cortical specialization for language are Broca's area and Wernicke's area. **Broca's area**, which governs speaking ability, is located in the left frontal lobe in close association with the motor areas of the cortex that control the muscles necessary for speaking (see ❙Figures 5-8, 5-11, and 5-13). **Wernicke's area**, located in the left cortex at the juncture of the parietal, temporal, and occipital lobes, is concerned with language comprehension. It plays a critical role in understanding both spoken and written messages. Furthermore, it is responsible for formulating coherent patterns of speech that are transferred via a bundle of fibers to Broca's area, which in turn controls the act of speaking. Wernicke's area receives input from the visual cortex in the occipital lobe, a pathway important in reading comprehension and in describing objects seen, and from the auditory cortex in the temporal lobe, a pathway essential for understanding spoken words. Wernicke's area also receives input from the somatosensory cortex, a pathway important in the ability to read Braille. Precise interconnecting pathways between these localized cortical areas are involved in the various aspects of speech (❙Figure 5-13).

Wernicke's area (plans content of spoken words)

Angular gyrus of parietal–temporal–occipital association cortex (integrates sensory input)

Primary motor cortex (commands facial and tongue muscles to speak words)

Broca's area (programs sound pattern of speech)

Primary auditory cortex (perceives sound)

Primary visual cortex (perceives sight)

Hear words

See words

1a To speak about something seen, the brain transfers the visual information from the primary visual cortex to the angular gyrus of the parietal–temporal–occipital association cortex, which integrates inputs such as sight, sound, and touch.

1b To speak about something heard, the brain transfers the auditory information from the primary auditory cortex to the angular gyrus.

2 The information is transferred to Wernicke's area, where the choice and sequence of words to be spoken are formulated.

3 This language command is then transmitted to Broca's area, which translates the message into a programmed sound pattern.

4 This sound program is conveyed to the precise areas of the primary motor cortex that activate the appropriate facial and tongue muscles for causing the desired words to be spoken.

❙Figure 5-13 **Cortical pathway for speaking a word seen or heard.** The arrows and numbered steps describe the pathway used to speak about something seen or heard. Similarly, appropriate muscles of the hand can be commanded to write the desired words.

FIGURE FOCUS: *(1) Will a person who has damage to Broca's area be able to speak clearly? (2) Will the person still be able to comprehend spoken messages and write coherent responses?*

Language Disorders Because various aspects of language are localized in different regions of the cortex, damage to specific regions of the brain can result in selective disturbances of language. Damage to Broca's area results in a failure of word formation, although the patient can still understand the spoken and written word. Such people know what they want to say but cannot express themselves. Even though they can move their lips and tongue, they cannot establish the proper motor command to say the desired words. In contrast, patients with a lesion in Wernicke's area cannot understand words they see or hear. They can speak fluently, but their perfectly spoken words make no sense. They cannot attach meaning to words or choose appropriate words to convey their thoughts. Such language disorders caused by damage to specific cortical areas are known as **aphasias**, most of which result from strokes. Aphasias should not be confused with **speech impediments**, which are caused by a defect in the mechanical aspect of speech, such as weakness or incoordination of the muscles controlling the vocal apparatus.

Dyslexia, another language disorder, is a difficulty in learning to read despite normal intelligence. Emerging evidence suggests that dyslexia stems from a deficit in phonological processing, meaning an impaired ability to break down written words into their underlying phonetic components. People with dyslexia have difficulty decoding and thus identifying and assigning meaning to words.

The association areas of the cortex are involved in many higher functions.

The motor, sensory, and language areas account for only about half of the total cerebral cortex. The remaining areas, called **association areas**, are involved in higher functions. There are three association areas: (1) the *prefrontal association cortex,* (2) the *parietal–temporal–occipital association cortex,* and (3) the *limbic association cortex* (see ❙ Figure 5-11). At one time the association areas were called "silent" areas, because stimulation does not produce any observable motor response or sensory perception. (During brain surgery, typically the patient remains awake and only local anesthetic is used along the cut scalp. This is possible because the brain itself is insensitive to pain. Before cutting into this nonregenerative tissue, the neurosurgeon explores the exposed region with a tiny stimulating electrode. The patient is asked to describe what happens with each stimulation—the flick of a finger, a prickly feeling on the bottom of the foot, nothing? In this way, the surgeon can ascertain the appropriate landmarks on the neural map before making an incision.)

The **prefrontal association cortex** is the front portion of the frontal lobe just anterior to the premotor cortex. This is the part of the brain that "brainstorms" or thinks (see ❙ Figure 5-8). Specifically, the roles attributed to this region are (1) planning for voluntary activity, (2) decision making (that is, weighing consequences of future actions and choosing among options for various social or physical situations), (3) creativity, and (4) personality traits. To carry out these highest of neural functions, the prefrontal cortex is the site of operation of *working memory,* where the brain temporarily stores and actively manipulates information used in reasoning and planning. You will learn more about working memory later.

The **parietal–temporal–occipital association cortex** lies at the interface of the three lobes for which it is named. In this strategic location, it pools and integrates somatic, auditory, and visual sensations projected from these three lobes for complex perceptual processing. It enables you to "get the complete picture" of the relationship of various parts of your body with the external world. For example, it integrates visual information with proprioceptive input to let you place what you are seeing in proper perspective, such as realizing that a bottle is in an upright position despite the angle from which you view it (that is, whether you are standing up, lying down, or hanging upside down from a tree branch). This region is also involved in the language pathway connecting Wernicke's area to the visual and auditory cortices.

The **limbic association cortex** is located mostly on the bottom and adjoining inner portion of each temporal lobe. This area is concerned primarily with motivation and emotion and is extensively involved in memory.

The association areas are all interconnected by bundles of fibers within the cerebral white matter. Collectively, they integrate diverse information for purposeful action.

The cerebral hemispheres have some degree of specialization.

The cortical areas described thus far appear to be equally distributed in both the right and the left hemispheres, except for the language areas, which are found only on one side, usually the left. The left side is also most commonly the dominant hemisphere for fine motor control. Thus, most people are right handed, because the left side of the brain controls the right side of the body. Furthermore, each hemisphere is somewhat specialized in the types of mental activities it carries out best. The **left cerebral hemisphere** excels in logical, analytical, sequential, and verbal tasks, such as math, language forms, and philosophy. In contrast, the **right cerebral hemisphere** excels in nonlanguage skills, especially spatial perception and artistic and musical talents. The left hemisphere tends to process information in a fine-detail, fragmentary way, whereas the right hemisphere views the world in a big-picture, holistic way. This specialization is known as **cerebral lateralization**. Normally, the two hemispheres share so much information that they complement each other, but in many individuals the skills associated with one hemisphere are more strongly developed. Left cerebral hemisphere dominance tends to be associated with "thinkers," whereas right hemispheric skills dominate in "creators."

The cortex has a default mode network that is most active when the mind wanders.

New imaging techniques such as PET scans and fMRIs have not only helped researchers identify the brain regions involved with performing specific tasks. These cutting-edge technologies also led to discovery of a previously unrecognized brain system, the **default mode network (DMN)**, which is more active during resting states such as when you're daydreaming than during

focused tasks such as when you're reading this page. Surprisingly, an estimated 60% to 80% of the brain's energy expenditure is used by the DMN circuits unrelated to any externally cued tasks. Most people spend an estimated 30% of their waking hours lost in spontaneous thoughts or "spacing out." The major DMN brain hubs lay midline in the medial prefrontal cortex and the medial parietal cortex. Evidence suggests that these areas communicate with one another and have functional connectivity while the brain is focused on internal signals rather than on external stimuli. Neuroscientists are unsure what purpose this DMN activity serves. Alternative proposed roles include enabling creativity, preparing the brain for conscious activity, constituting internally generated thoughts, retrieving and manipulating memories, or establishing a sense of self.

We now shift attention to the **subcortical regions** of the brain, which interact extensively with the cortex in the performance of their functions (*subcortical* means "under the cortex"). These regions include the *basal nuclei*, located in the cerebrum, and the *thalamus* and *hypothalamus*, located in the diencephalon.

5.5 Basal Nuclei, Thalamus, and Hypothalamus

The **basal nuclei** (also known as **basal ganglia**) consist of several masses of gray matter located deep within the cerebral white matter (see ▌Table 5-1 and ▌Figure 5-14). In the CNS, a **nucleus** (plural, **nuclei**) is a functioning group of neuron cell bodies.

The basal nuclei play an important inhibitory role in motor control.

The basal nuclei play a complex role in controlling movement. In particular, they are important in (1) inhibiting muscle tone throughout the body (proper muscle tone is normally maintained by a balance of excitatory and inhibitory inputs to the neurons that innervate skeletal muscles); (2) selecting and maintaining purposeful motor activity while suppressing useless or unwanted patterns of movement; and (3) helping monitor and coordinate slow, sustained contractions, especially those related to posture and support. The basal nuclei do not directly influence the efferent motor neurons that bring about muscle contraction but act instead by modifying ongoing activity in motor pathways.

To accomplish these complex integrative roles, the basal nuclei receive and send out a large volume of information, as is indicated by the tremendous number of fibers linking them to other regions of the brain. One important pathway consists of strategic interconnections that form a complex feedback loop linking the motor regions of the cerebral cortex, the basal nuclei, and the thalamus. The thalamus positively reinforces voluntary motor behavior initiated by the cortex, whereas the basal nuclei modulate this activity
▌Figure 5-14 Frontal section of the brain. The cerebral cortex, an outer shell of gray matter, surrounds an inner core of white matter. Deep within the cerebral white matter are several masses of gray matter, the basal nuclei. The ventricles are cavities in the brain through which the cerebrospinal fluid flows. The thalamus forms the walls of the third ventricle. For comparison, the colors used for the thalamus and basal nuclei are the same as those used in the lateral view depicted in ▌Table 5-1, p. 144.

by exerting an inhibitory effect on the thalamus to eliminate antagonistic or unnecessary movements. The basal nuclei also inhibit motor activity by acting through neurons in the brain stem.

Clinical Note The importance of the basal nuclei in motor control is evident in **Parkinson's disease (PD)**. This condition is associated with a gradual destruction of neurons that release the neurotransmitter dopamine in the basal nuclei. Because the basal nuclei lack enough dopamine to exert their normal roles, three types of motor disturbances characterize PD: (1) increased muscle tone, or rigidity; (2) involuntary, useless, or unwanted movements, such as *resting tremors* (for example, hands rhythmically shaking, making it difficult or impossible to hold a cup of coffee); and (3) slowness in initiating and carrying out different motor behaviors. People with PD find it difficult to stop ongoing activities. If sitting down, they tend to remain seated, and if they get up, they do so slowly. The standard treatment for PD is the administration of *levodopa (L-dopa),* a precursor of dopamine. Dopamine itself cannot be given because it is unable to cross the BBB, but L-dopa can enter the brain from the blood. Once inside the brain, L-dopa is converted into dopamine, thus substituting for the deficient neurotransmitter.

The thalamus is a sensory relay station and is important in motor control.

Deep within the brain near the basal nuclei is the **diencephalon**, a midline structure that forms the walls of the third ventricular cavity, one of the spaces through which CSF flows (see **I** Figure 5-5, p. 138). The diencephalon consists of two main parts, the *thalamus* and the *hypothalamus* (see **I** Table 5-1 and **I** Figures 5-7b, 5-14, and 5-15).

The **thalamus** serves as a "relay station" for preliminary processing of sensory input. All sensory input synapses in the thalamus on its way to the cortex. The thalamus screens out insignificant signals and routes the important sensory impulses to appropriate areas of the somatosensory cortex, and to other regions of the brain. Along with the brain stem and cortical association areas, the thalamus helps direct attention to stimuli

of interest. For example, parents can sleep soundly through the noise of outdoor traffic but become instantly aware of their baby's slightest whimper. The thalamus is also capable of crude awareness of various sensations but cannot distinguish their location or intensity. Some degree of consciousness resides here as well. Finally, the thalamus plays an important role in motor control by positively reinforcing voluntary motor behavior initiated by the cortex.

The hypothalamus regulates many homeostatic functions.

The **hypothalamus** is a collection of specific nuclei and associated fibers that lie beneath the thalamus. It is an integrating center for many important homeostatic functions and is an important link between the autonomic nervous system and the endocrine system. Specifically, the hypothalamus (1) controls body temperature; (2) controls thirst and urine output; (3) controls food intake; (4) controls anterior pituitary hormone secretion; (5) produces posterior pituitary hormones; (6) controls uterine contractions and milk ejection; (7) serves as a major autonomic nervous system coordinating center, which in turn affects all smooth muscle, cardiac muscle, and exocrine glands; (8) plays a role in emotional and behavioral patterns; and (9) participates in the sleep–wake cycle.

The hypothalamus is the brain area most involved in directly regulating the internal environment. For example, when the body is cold, the hypothalamus initiates internal responses to increase heat production (such as shivering) and to decrease heat loss (such as constricting the skin blood vessels to reduce

Unless otherwise noted, all content on this page is © Cengage Learning.

the f ow of warm blood to the body surface, where heat could be lost to the external environment). Other areas of the brain, such as the cerebral cortex, act more indirectly to regulate the internal environment. For example, a person who feels cold is motivated to voluntarily put on warmer clothing, close the window, turn up the thermostat, and so on. Even these voluntary behavioral activities are strongly inf uenced by the hypothalamus, which, as a part of the limbic system, functions with the cortex in controlling emotions and motivated behavior. We now turn to the limbic system and its functional relations with the higher cortex.

5.6 Emotion, Behavior, and Motivation

The **limbic system** is not a separate structure but a functional system consisting of a ring of forebrain structures that surround the brain stem and are interconnected by intricate neuron pathways (❙Figure 5-16). It includes portions of each of the following: the lobes of the cerebral cortex (especially the limbic association cortex), the basal nuclei, the thalamus, and the hypothalamus. This complex interacting network is associated with emotions, basic behavioral patterns, motivation, learning, and memory. Let us examine each of these brain functions further.

The limbic system plays a key role in emotion.

The concept of **emotion** encompasses subjective emotional feelings and moods (such as anger, fear, sadness, and joy) plus the overt physical responses associated with these feelings. These responses include specific behavioral patterns (for example, preparing for attack or defense when angered by an adversary) and observable emotional expressions (for example, laughing, crying, or blushing). Emotions are highly subjective and can vary among individuals in response to an identical circumstance. The limbic system plays a central role in all aspects of emotion. Stimulating specific regions of the limbic system during brain surgery produces vague subjective sensations
that the patient may describe as joy, satisfaction, or pleasure in one region and discouragement, fear, or anxiety in another. For example, the **amygdala** is especially important in processing inputs that give rise to the sensation of fear and anxiety. In humans and to an undetermined extent in other species, higher levels of the cortex are also crucial for conscious awareness of emotional feelings.

The limbic system and higher cortex participate in controlling basic behavioral patterns.

Basic behavioral patterns controlled at least in part by the limbic system include those aimed at individual survival (attack, searching for food) and those directed toward perpetuating the species (sociosexual behaviors conducive to mating). These behaviors are inborn and shared among members of a species. In experimental animals, stimulating the limbic system brings about complex and even bizarre behaviors. For example, stimulation in one area can elicit responses of anger and rage in a normally docile animal, whereas stimulation in another area results in placidity and tameness, even in an otherwise vicious animal. Stimulation in yet another limbic area can induce sexual behaviors such as copulatory movements.

The extensive involvement of the hypothalamus in the limbic system governs the involuntary internal responses of various body systems in preparation for appropriate action to accompany a particular emotional state. For example, the hypothalamus controls the increase of heart rate and respiratory rate, elevation of blood pressure, and diversion of blood to skeletal muscles that occur in anticipation of attack or when angered. These preparatory changes in the internal state require no conscious control.

In executing complex behavioral activities such as attacking, f eeing, or mating, the individual (humans and other animals) must interact with the external environment. Higher cortical mechanisms are called into play to connect the limbic system and hypothalamus with the outer world so that appropriate overt behaviors are manifested. At the simplest level, the cortex provides the neural mechanisms necessary for implementing the appropriate skeletal muscle activity required to approach or avoid an adversary, participate in sexual activity, or display emotional expression. For example, the stereotypical sequence of movement for the universal human emotional expression of smiling is preprogrammed in the cortex and can be called forth by the limbic system. One can also voluntarily call

❙Figure 5-16 **Limbic system.** The structures located in the interior of the brain that constitute the limbic system (in *pink*) are revealed in this partially transparent view of the brain.

forth the smile program, as when posing for a picture. Even individuals blind from birth have normal facial expressions—that is, they do not learn to smile by observation. Smiling means the same thing in every culture, despite widely differing environmental experiences.

Higher cortical levels also can reinforce, modify, or suppress basic behavioral responses so that actions can be guided by planning, strategy, and judgment based on an understanding of the situation. Even if you are angry at someone and your body is internally preparing for attack, you can usually judge whether an attack is appropriate and can consciously suppress the external manifestation of this basic emotional behavior. Thus, the higher levels of the cortex, particularly the prefrontal and limbic association areas, are important in conscious, learned control of innate behavioral patterns. Using fear as an example, exposure to an aversive experience calls two parallel tracks into play for processing this emotional stimulus: a fast track in which the lower-level amygdala plays a key role and a slower track mediated primarily by the higher-level prefrontal cortex. The fast track permits a rapid, rather crude, instinctive response ("gut reaction") and is essential for the "feeling" of being afraid. The slower track involving the prefrontal cortex permits a more refined response to the aversive stimulus based on a rational analysis of the current situation compared to stored past experiences. The prefrontal cortex formulates plans and guides behavior, suppressing impulsive amygdala-induced responses that may be inappropriate for the situation at hand.

Motivated behaviors are goal directed.

An individual tends to reinforce behaviors that have proved gratifying and to suppress behaviors that have been associated with unpleasant experiences. Certain regions of the limbic system have been designated as **"reward"** and **"punishment" centers** because stimulation in these respective areas gives rise to pleasant or unpleasant sensations. When a self-stimulating device is implanted in a reward center, an experimental animal will self-deliver up to 5000 stimulations per hour and continue self-stimulation in preference to food, even when starving. When the device is implanted in a punishment center, animals avoid stimulation at all costs. Reward centers are found most abundantly in regions involved in mediating the highly motivated behavioral activities of eating, drinking, and sexual activity.

Motivation is the ability to direct behavior toward specific goals. Some goal-directed behaviors are aimed at satisfying specific identifiable physical needs related to homeostasis. **Homeostatic drives** represent the subjective urges associated with specific bodily needs that motivate appropriate behavior to satisfy those needs. As an example, the sensation of thirst accompanying a water deficit in the body drives an individual to drink to satisfy the homeostatic need for water. However, whether water, a soft drink, or another beverage is chosen as the thirst quencher is unrelated to homeostasis. Much human behavior does not depend on purely homeostatic drives related to simple tissue deficits such as thirst. Human behavior is influenced by experience, learning, and habit, shaped in a complex framework of unique personal gratifications blended with cultural expectations. To what extent, if any, motivational drives

unrelated to homeostasis, such as the drive to pursue a particular career or win a certain race, are involved with the reinforcing effects of the reward and punishment centers is unknown. Indeed, some individuals motivated toward a particular goal may even deliberately "punish" themselves in the short term to achieve their long-range gratification (for example, the temporary pain of training in preparation for winning a competitive athletic event).

Norepinephrine, dopamine, and serotonin are neurotransmitters in pathways for emotions and behavior.

The underlying neurophysiological mechanisms responsible for the psychological observations of emotions and motivated behavior largely remain a mystery, although the neurotransmitters *norepinephrine, dopamine,* and *serotonin* all have been implicated. Norepinephrine and dopamine, both chemically classified as *catecholamines* (see p. 121), are known transmitters in the regions that elicit the highest rates of self-stimulation in animals equipped with do-it-yourself devices. Numerous **psychoactive drugs** affect moods in humans, and some of these drugs have been shown to influence self-stimulation in experimental animals. For example, increased self-stimulation is observed after the administration of drugs that increase catecholamine synaptic activity, such as *amphetamine,* an "upper" drug. Amphetamine stimulates the release of dopamine from dopamine-secreting neurons.

Although most psychoactive drugs are used therapeutically to treat various mental disorders, others, unfortunately, are abused. Many abused drugs act by enhancing the effectiveness of dopamine in the "pleasure" pathways, thus initially giving rise to an intense sensation of pleasure. As you have already learned, an example is cocaine, which blocks the reuptake of dopamine at synapses (see p. 112).

Clinical Note **Depression** is among the psychiatric disorders associated with defects in limbic system neurotransmitters. (As a distinction, *psychiatric disorders* involve abnormal activity in specific neurotransmitter pathways in the absence of detectable brain lesions, whereas *neurological disorders* are associated with specific lesions of the brain and may or may not involve abnormalities in neurotransmission. Examples of neurological disorders include Parkinson's disease and Alzheimer's disease.) Depression is a psychiatric mood disorder. In psychiatry, **mood** is an abstract term referring to a person's prolonged subjective emotional state that influences his or her behavior and perception of external events. Depression is characterized by a pervasive negative mood accompanied by a generalized loss of interests, an inability to experience pleasure, and suicidal tendencies. A functional deficiency of serotonin, norepinephrine, or both is implicated in depression. These neurotransmitters are synaptic messengers in regions of the brain involved in pleasure and motivation, suggesting that the pervasive sadness and lack of interest (no motivation) in patients who are depressed are related at least partly to deficiencies of these neurotransmitters. Areas of the brain that play a significant role in depression are the limbic system, especially the amygdala and hip-

pocampus, both of which are located in the medial temporal lobe (see ▌Figure 5-16), and the medial prefrontal cortex. All of these brain regions are central to emotion and behavior. For example, research shows that the hippocampus is 9% to 13% smaller in depressed women compared with women who are not depressed. Events perceived as being stressful can trigger depression, but the underlying link has not been determined. Recall that stress suppresses production of new neurons in the hippocampus.

All effective antidepressant drugs increase the available concentration of these two neurotransmitters in the CNS. There are four main classes of antidepressants:

Selective serotonin reuptake inhibitors (SSRIs). As implied by the name, these drugs selectively block the reuptake of released serotonin into the presynaptic terminal, thus prolonging serotonin activity at synapses (see p. 108). *Prozac (fluoxetine),* the most widely prescribed drug in American psychiatry, is illustrative.

Serotonin norepinephrine reuptake inhibitors (SNRIs). By blocking the reuptake of both released serotonin and norepinephrine, SNRIs cause these neurotransmitters to linger longer at synapses. An example of an SNRI is *Cymbalta (duloxetine).* SSRIs and SNRIs are newer classes of antidepressants.

Tricyclic antidepressants (TCAs). TCAs are an older class of drug that also blocks reuptake of norepinephrine and serotonin, especially norepinephrine, thus prolonging action of these neurotransmitters at synapses, but unlike SNRIs, TCAs also affect activity of the autonomic nervous system and thus have more undesirable side effects. *Pamelor (nortriptyline)* belongs to this class of antidepressants.

Monoamine oxidase inhibitors (MAOIs). The oldest class of antidepressants, MAOIs elevate levels of norepinephrine, serotonin, and dopamine by inhibiting monoamine oxidase, an enzyme that breaks down these three neurotransmitters. MAOIs tend to exert more side effects than more selective antidepressants, especially when combined with certain foods and other medicines. *Emsam (selegiline)* is an MAOI administered as a patch worn on the skin.

Antidepressants immediately boost the concentration of affected neurotransmitters at synapses, yet a reduction in symptoms of depression typically does not take place until several weeks after medication begins. Some experts believe that people do not start to feel better as soon as the neurotransmitter levels increase because improvement of mood further depends on growth of new neurons and formation of new connections in the hippocampus, a process that takes several weeks and is stimulated by antidepressants. Furthermore, antidepressants trigger formation of new astrocytes, which are also reduced in numbers in areas of the brain affected by depression.

Researchers are optimistic that as understanding of the molecular mechanisms of mental disorders is expanded in the future, many psychiatric problems can be corrected or better managed through drug or other therapeutic intervention, a hope of great medical significance.

Check Your Understanding 5.6

1. State the brain functions associated with the limbic system.
2. Name the brain area most important in processing the sensation of fear.
3. List the three neurotransmitters involved in pathways that process emotions and motivated behavior.

5.7 Learning and Memory

In addition to their involvement in emotion and basic behavioral patterns, the limbic system and higher cortex are involved in learning and memory. The cerebellum also plays a key role in some types of learning and memory.

Learning is the acquisition of knowledge as a result of experiences.

Learning is the acquisition of knowledge or skills as a consequence of experience, instruction, or both. Rewards and punishments are integral parts of many types of learning. If an animal is rewarded on responding in a particular way to a stimulus, the likelihood increases that the animal will respond in the same way again to the same stimulus as a consequence of this experience. Conversely, if a particular response is accompanied by punishment, the animal is less likely to repeat the same response to the same stimulus. When behavioral responses that give rise to pleasure are reinforced or those accompanied by punishment are avoided, learning has taken place. Housebreaking a puppy is an example. If the puppy is praised when it urinates outdoors but scolded when it wets the carpet, it will soon learn the acceptable place to empty its bladder. Thus, learning is a change in behavior that occurs as a result of experiences. It highly depends on the organism's interaction with its environment. The only limits to the effects that environmental influences can have on learning are the biological constraints imposed by species-specific and individual genetic endowments.

Memory is laid down in stages.

Memory is the storage of acquired knowledge for later recall. Learning and memory form the basis by which individuals adapt their behavior to their particular external circumstances. Without these mechanisms, it would be impossible for individuals to plan for successful interactions and to intentionally avoid predictably disagreeable circumstances.

The neural change responsible for retention or storage of knowledge is known as the **memory trace**, or **engram**. Generally, concepts, not verbatim information, are stored. As you read this page, you are storing the concept discussed, not the specific words. Later, when you retrieve the concept from memory, you will convert it into your own words. It is possible, however, to memorize bits of information word by word.

Storage of acquired information is accomplished in at least two stages: short-term memory and long-term memory (▌Table 5-2). **Short-term memory** lasts for seconds to hours, whereas **long-term memory** is retained for days to years. The process of

Comparison of Short-Term and Long-Term Memory

Characteristic	Short-Term Memory	Long-Term Memory
Time of storage after acquisition of new information	Immediate	Later; must be transferred from short-term to long-term memory through consolidation; enhanced by practice or recycling of information through short-term mode
Duration	Lasts for seconds to hours	Retained for days to years
Capacity of storage	Limited	Very large
Retrieval time (remembering)	Rapid retrieval	Slower retrieval, except for thoroughly ingrained memories, which are rapidly retrieved
Inability to retrieve (forgetting)	Permanently forgotten; memory fades quickly unless consolidated into long-term memory	Usually only transiently unable to access; relatively stable memory trace
Mechanism of storage	Involves transient modifications in functions of preexisting synapses, such as altering amount of neurotransmitter released	Involves relatively permanent functional or structural changes between existing neurons, such as formation of new synapses; synthesis of new proteins plays a key role

transferring and fixing short-term memory traces into long-term memory stores is known as **consolidation**.

Working memory, or what has been called "the erasable blackboard of the mind," is a complex type of short-term memory you use on an ongoing basis to carry out daily activities. Working memory temporarily holds and interrelates various pieces of information relevant to a current mental task. Through your working memory, you brief y hold and process data for immediate use—both newly acquired information and related, previously stored knowledge that is transiently brought forth into working memory—so that you can evaluate the incoming data in context. This integrative function is crucial to your ability to reason, plan, and make judgments. By comparing and manipulating new and old information within your working memory, you can comprehend what you are reading, carry on a conversation, calculate a restaurant tip in your head, find your way home, and know that you should put on warm clothing if you see snow outside. In short, working memory enables people to string thoughts together in a logical sequence and plan for future action.

Recent findings suggest that once an established memory is actively recalled, it becomes labile (unstable or subject to change) and must be **reconsolidated** into a restabilized, inactive state. New information may be incorporated into the old memory trace during reconsolidation. Thus, an old memory may actually be changed each time it is recalled.

Comparison of Short-Term and Long-Term Memory
Newly acquired information is initially deposited in short-term memory, which has a limited capacity for storage. Information in short-term memory has one of two eventual fates. Either it is soon forgotten (for example, forgetting a telephone number after you have looked it up and finished dialing), or it is trans-

ferred into the more permanent long-term memory mode through active practice or rehearsal. The recycling of newly acquired information through short-term memory increases the likelihood that the information is consolidated into long-term memory. (Therefore, when you cram for an exam, your long-term retention of the information is poor!) The original short-term memory rapidly fades unless it is consolidated to provide a more enduring long-term memory. Sometimes only parts of memories are fixed, while other parts fade away. Information of interest or importance to the individual is more likely to be recycled and fixed in long-term stores, whereas less important information is quickly erased.

The storage capacity of the long-term memory bank is much larger than the capacity of short-term memory. Different informational aspects of long-term memory traces seem to be processed, codified, and then stored with other memories of the same type; for example, visual memories are stored separately from auditory memories. This organization facilitates future searching of memory stores to retrieve desired information. For example, in remembering a woman you once met, you may use various recall cues from different storage pools, such as her name, her appearance, the fragrance she wore, an incisive comment she made, or the song playing in the background.

Stored knowledge is of no use unless it can be retrieved and used to inf uence current or future behavior. Because long-term memory stores are larger, it often takes longer to retrieve information from long-term memory than from short-term memory. *Remembering* is the process of retrieving specific information from memory stores; *forgetting* is the inability to retrieve stored information. Information lost from short-term memory is permanently forgotten, but information in long-term storage is often forgotten only temporarily. For example, you may be transiently unable to remember an acquaintance's name and

then have it suddenly "come to you" later. Some forms of long-term memory involving information or skills used daily are essentially never forgotten and are rapidly accessible, such as knowing your name or being able to write.

Amnesia Occasionally, individuals suffer from a lack of memory that involves whole portions of time rather than isolated bits of information. This condition, known as **amnesia**, occurs in two forms. The most common form, *retrograde* (meaning "going backward") *amnesia,* is the inability to recall recent past events. It usually follows a traumatic event that interferes with electrical activity of the brain, such as a concussion or stroke. If a person is knocked unconscious, the content of short-term memory is essentially erased, resulting in loss of memory about activities that occurred within about the last half hour before the event. Severe trauma may interfere with access to recently acquired information in long-term stores also.

Anterograde (meaning "going forward") *amnesia,* conversely, is the inability to consolidate memory in long-term storage for later retrieval. It is usually associated with lesions of the medial portions of the temporal lobes, which are generally considered critical regions for memory consolidation. People suffering from this condition may be able to recall things they learned before the onset of their problem, but they cannot establish new permanent memories. New information is lost as quickly as it fades from short-term memory. In one case study, the person could not remember where the bathroom was in his new home but still had total recall of his old home.

Interestingly, the processes of human memory are adapting to new communication technology. Through widespread use of computers and smartphones, the Internet has become a ubiquitous presence in most of our lives and serves as a readily accessible external memory source. Having immediate access to vast stores of information online thanks to databases and search engines has reduced the need to commit as much information to memory. Studies show that people who expect to be able to easily access needed information are less apt to consolidate short-term memory into the long-term mode. On a simple level, have you memorized the phone numbers of your friends and family, a common practice in the past, or do you rely on pushing their numbers on speed dial?

Short-term memory and long-term memory involve different molecular mechanisms.

Obviously, some change must take place within the neural circuitry of the brain to account for the altered behavior that follows learning. Different mechanisms are responsible for short-term and long-term memory. Short-term memory involves transient modifications in the function of preexisting synapses, such as a temporary change in the amount of neurotransmitter released in response to stimulation or temporary increased responsiveness of the postsynaptic cell to the neurotransmitter within affected nerve pathways. Long-term memory, in contrast, involves relatively permanent functional or structural changes between existing neurons in the brain. Let us look at each of these types of memory in more detail.

Short-term memory involves transient changes in synaptic activity.

Ingenious experiments in the sea snail *Aplysia* have shown that two forms of short-term memory—habituation and sensitization—result from modification of different channel proteins in presynaptic terminals of specific afferent neurons involved in the pathway that mediates the behavior being modified. This modification, in turn, brings about changes in neurotransmitter release. **Habituation** is a decreased responsiveness to repetitive presentations of an indifferent stimulus—that is, one that is neither rewarding nor punishing. **Sensitization** is increased responsiveness to mild stimuli following a strong or noxious stimulus. *Aplysia* reflexly withdraws its gill when its siphon, a breathing organ at the top of its gill, is touched. Afferent (presynaptic) neurons responding to touch of the siphon directly synapse on efferent (postsynaptic) motor neurons controlling gill withdrawal. The snail becomes habituated when its siphon is repeatedly touched—that is, it learns to ignore the stimulus and no longer withdraws its gill in response. Sensitization, a more complex form of learning, takes place in *Aplysia* when it is given a hard bang on the siphon. Subsequently, the snail withdraws its gill more vigorously in response to even mild touch. These different forms of learning affect the same site—the synapse between a siphon afferent and a gill efferent—in opposite ways. Habituation depresses this synaptic activity, whereas sensitization enhances it. These transient modifications persist for as long as the memory.

Mechanism of Habituation As a result of habituation, the voltage-gated Ca^{2+} channels in a siphon afferent axon terminal do not open as readily when an action potential arrives, reducing entry of exocytosis-inducing Ca^{2+}, which leads to a decrease in neurotransmitter release. As a consequence of less neurotransmitter binding at the membrane of the motor neuron to the gill, the postsynaptic potential is reduced compared to normal, resulting in a diminished behavioral response controlled by the gill efferent (decreased gill withdrawal). Thus, the memory for habituation in *Aplysia* is stored in the form of modification of specific Ca^{2+} channels. With no further training, this reduced responsiveness lasts for several hours. A similar process is responsible for short-term habituation in other species studied, although in higher species the involvement of intervening interneurons makes the process somewhat more complicated. Habituation is probably the most common form of learning and is believed to be the first learning process to take place in human infants. By learning to ignore indifferent stimuli, the animal or person is free to attend to other more important stimuli.

Mechanism of Sensitization Sensitization in *Aplysia,* which results from increased Ca^{2+} influx into the siphon afferent terminal, does not have a direct effect on presynaptic Ca^{2+} channels. Instead, it indirectly enhances Ca^{2+} entry via presynaptic facilitation (see p. 111). The neurotransmitter serotonin is released from a facilitating interneuron that synapses on the presynaptic terminal to bring about increased release of presynaptic neurotransmitter in response to an action potential. Sero-

tonin does so by triggering activation of a cAMP second-messenger pathway (see p. 123) that causes blockage of K^+ channels, thereby prolonging the action potential in the presynaptic terminal. (Remember that K^+ efflux is responsible for returning the potential to resting during an action potential.) Because the Ca^{2+} channels are kept open longer as a result of the prolonged action potential, more Ca^{2+} enters the terminal. The subsequent increase in neurotransmitter release produces a larger postsynaptic potential, resulting in a more vigorous gill-withdrawal response.

Thus, existing synaptic pathways may be functionally interrupted (habituated) or enhanced (sensitized) during simple learning. Scientists speculate that much of short-term memory is similarly a temporary modification of already existing processes. Several lines of research suggest that the cAMP cascade, especially activation of protein kinase, plays an important role, at least in elementary forms of learning and memory.

Memories more complex than habituation and sensitization that involve conscious awareness are initially stored by means of long-term potentiation, a mechanism that involves more persistent changes in activity of existing synapses.

Mechanism of Long-Term Potentiation With **long-term potentiation (LTP)**, modifications take place as a result of increased use at a given preexisting synapse that enhance the future ability of the presynaptic neuron to excite the postsynaptic neuron—that is, this connection gets stronger the more often it is used. Such strengthening of synaptic activity results in the formation of more EPSPs in the postsynaptic neuron in response to chemical signals from this particular excitatory presynaptic input. The increased excitatory responsiveness is ultimately translated into more action potentials being sent along this postsynaptic cell to other neurons. LTP lasts for days or even weeks—long enough for this short-term memory to be consolidated into more permanent long-term memory. LTP is especially prevalent in the hippocampus, a site critical for converting short-term memories into long-term memories. Less commonly, poorly understood **long-term depression (LTD)**, or weakening of synaptic transmission, has been demonstrated.

Enhanced synaptic transmission with LTP could theoretically result from either changes in the postsynaptic neuron (such as increased responsiveness to the neurotransmitter via insertion of more receptors for this messenger in the postsynaptic membrane) or in the presynaptic neuron (such as increased release of neurotransmitter). The underlying mechanisms for LTP are still the subject of much research and debate. Most likely, multiple mechanisms are involved in this complex phenomenon. It appears that there are several forms of LTP, some arising from changes only in the postsynaptic neuron and others also having a presynaptic component. Based on current scientific evidence, the following is a plausible mechanism for LTP involving both a postsynaptic change and a presynaptic modification (❙ Figure 5-17).

LTP begins when a presynaptic neuron releases the common excitatory neurotransmitter glutamate in response to an action potential. Glutamate binds to two types of receptors on the postsynaptic neuron: *AMPA receptors* and *NMDA receptors*. An **AMPA receptor** is a chemically mediated receptor-channel that opens on binding of glutamate and permits net entry of Na^+ ions, leading to formation of an EPSP at the postsynaptic neuron (see pp. 116 and 106). This is the ordinary receptor at excitatory synapses about which you already learned. An **NMDA receptor** is a receptor-channel that permits Ca^{2+} entry when it is open. This receptor-channel is unusual because it is both chemically gated and voltage dependent. It is closed by both a gate and by a magnesium ion (Mg^{2+}) that physically blocks the channel opening at resting potential. Two events must happen almost simultaneously to open an NMDA receptor-channel: presynaptic glutamate release and postsynaptic depolarization by other inputs. The gate opens on binding of glutamate, but this action alone does not permit Ca^{2+} entry. Additional depolarization of the postsynaptic neuron beyond that produced by the EPSP resulting from glutamate binding to the AMPA receptor is needed to depolarize the postsynaptic neuron enough to force Mg^{2+} out of the channel. Thus, even though glutamate binds with the NMDA receptor, the channel does not open unless the postsynaptic cell is sufficiently depolarized as a result of other excitatory activity. The postsynaptic cell can be sufficiently depolarized to expel Mg^{2+} in two ways: by repeated input from this single excitatory presynaptic neuron, resulting in temporal summation of EPSPs from this source, or by additional excitatory input from another presynaptic neuron at about the same time, resulting in spatial summation of EPSPs (see p. 108). When the NMDA receptor-channel opens as a result of simultaneous gate opening and Mg^{2+} expulsion, Ca^{2+} enters the postsynaptic cell. The entering Ca^{2+} activates a Ca^{2+} second-messenger pathway in this neuron. This second-messenger pathway leads to the physical insertion of additional AMPA receptors in the postsynaptic membrane. Because of the increased availability of AMPA receptors, the postsynaptic cell exhibits a greater EPSP response to subsequent release of glutamate from the presynaptic cell. This heightened sensitivity of the postsynaptic neuron to glutamate from the presynaptic cell helps maintain LTP.

Furthermore, at some synapses, activation of the Ca^{2+} second-messenger pathway in the postsynaptic neuron causes this cell to release a retrograde ("going backward") paracrine that diffuses to the presynaptic neuron (see p. 114). Here, the retrograde paracrine activates a second-messenger pathway in the presynaptic neuron, ultimately enhancing the release of glutamate from the presynaptic neuron. This positive feedback strengthens the signaling process at this synapse, also helping sustain LTP. Note that in this mechanism, a chemical factor from the postsynaptic neuron influences the presynaptic neuron, just the opposite direction of neurotransmitter activity at a synapse. Most investigators believe that the retrograde messenger is **nitric oxide**, a chemical that performs a bewildering array of other functions in the body. These other functions range from dilation of blood vessels in the penis during erection to destruction of foreign invaders by the immune system (see pp. 346, 411 and 733).

The modifications that take place during the development of LTP are sustained long after the activity that led to these changes has ceased. Therefore, information can be transmitted along this same synaptic pathway more efficiently when activated in the future—that is, the synapse "remembers." LTP is

specific for the activated pathway. Pathways between other inactive presynaptic inputs and the same postsynaptic cell are not affected. Note that LTP develops in response to frequent activity across a synapse as a result of repetitive, intense firing of a given input (as with repeatedly going over a particular fact during studying) or to the linking of one input with another input firing at the same time. For example, when you smell a pie baking in the oven, your mouth waters in anticipation of the imminent arrival of a tasty treat you have come to associate with this aroma. The taste and feel of food in the mouth is the

built-in trigger for salivation. However, through experience, neurons in the pathway that control salivation link input arising from the smell of pie with input from its delicious taste. After the smell-input pathway is strengthened through development of LTP and ultimate consolidation into long-term storage, the smell of pie alone can cause salivation.

Ethanol in alcoholic beverages blocks NMDA receptors while facilitating GABA function. Ethanol's blockage of NMDA receptors is likely the reason people have difﬁculty remembering what happened during a time of heavy drinking. Furthermore, by enhancing the actions of GABA, the brain's major inhibitory neurotransmitter, ethanol depresses overall CNS activity.

Studies suggest a regulatory role for the cAMP second-messenger pathway in the development and maintenance of LTP in addition to the Ca^{2+} second-messenger pathway. Participation of cAMP may hold a key to linking short-term memory to long-term memory consolidation.

Long-term memory involves formation of new, permanent synaptic connections.

Whereas short-term memory involves transient strengthening of preexisting synapses, long-term memory storage requires activation of specific genes that control synthesis of proteins, needed for lasting structural or functional changes at specific synapses. Examples of such changes include formation of new synaptic connections or permanent changes in presynaptic or postsyn-

1 Glutamate is released from activated presynaptic neuron.

2 Glutamate binds with both AMPA and NMDA receptors.

3 Binding opens AMPA receptor-channel.

4 Na^+ entry through open AMPA channel depolarizes postsynaptic neuron, producing EPSP.

5 Binding opens gate of NMDA receptor-channel but Mg^{2+} still blocks channel. Sufficient depolarization from this AMPA opening plus other EPSPs drives Mg^{2+} out.

6 Ca^{2+} entry through open NMDA channel activates Ca^{2+} second-messenger pathway.

7 Second-messenger pathway promotes insertion of additional AMPA receptors in postsynaptic membrane, increasing its sensitivity to glutamate.

8 Second-messenger pathway also triggers release of retrograde paracrine (likely nitric oxide).

9 Nitric oxide stimulates long-lasting increase in glutamate release by presynaptic neuron.

ⅠFigure 5-17 **Possible pathways for long-term potentiation**.
FIGURE FOCUS: *Would simultaneous binding of glutamate from a presynaptic neuron to both AMPA and NMDA receptors at a postsynaptic neuron automatically trigger a chain of events leading to long-term potentiation? Explain why or why not.*

aptic membranes. Thus, long-term memory storage involves permanent physical changes in the brain. Long-term memory holds the sum total of all you can remember about what you have done, who you have known, where you have been, when something took place, and what you have learned.

Studies comparing the brains of experimental animals reared in a sensory-deprived environment with those raised in a sensory-rich environment demonstrate readily observable microscopic differences. The animals afforded more environmental interactions—and therefore, more opportunity to learn—displayed greater branching, elongation of dendrites, and more dendritic spines in nerve cells in regions of the brain suspected to be involved with memory storage. Greater dendritic surface area presumably provides more sites for synapses. Thus, long-term memory may be stored at least in part by a particular pattern of dendritic branching and synaptic contacts.

No one knows for sure how the transient short-term memory is converted to the permanent long-term mode, but many researchers believe that cAMP and *immediate early genes* play critical roles in memory consolidation. cAMP can switch on **cAMP responsive element binding protein (CREB)**, which acts on DNA to ultimately infuence synthesis of new proteins important for maintaining long-term memory. (Recall that this second messenger also plays a regulatory role in LTP and in sensitization.) The **immediate early genes (IEGs)** govern synthesis of proteins that encode long-term memory. The exact role that these critical newly synthesized long-term memory proteins might play remains speculative. They may be needed for structural changes in dendrites or used for synthesis of more neurotransmitters or additional receptor sites. Alternatively, they may accomplish long-term modification of neurotransmitter release by sustaining biochemical events initially activated by short-term memory processes.

Most investigation of learning and memory has focused on changes in synaptic connections within the brain's gray matter. To complicate the issue further, scientists now have evidence that white matter also changes during learning and memory formation as more myelin surrounds axons, especially during adolescence, speeding up transmission between connected neurons. Neurons produce chemical signals such as **neuregulin** that regulate the extent to which myelin-forming cells wrap themselves around the axon. The amount of neuregulin produced is correlated with the extent of action potential propagation within the axon. Accordingly, researchers propose that conduction velocity can be increased by means of further myelination in more active pathways, and that these changes support learning and memory. In addition to a probable role of white matter, numerous hormones and neuropeptides have also been shown to affect learning and memory processes.

Memory traces are present in multiple regions of the brain.

Another question besides the "how" of memory is the "where" of memory. What parts of the brain are responsible for memory? There is no single "memory center" in the brain. Instead, the neurons involved in memory traces are widely distributed throughout the subcortical and cortical regions of the brain.

The regions of the brain most extensively implicated in memory include the hippocampus, the cerebellum, the prefrontal cortex, and other areas of the cerebral cortex. Despite widespread circuitry for all memories, recent evidence indicates that a particular memory concept may be stored in a sparse number of neurons in a specific location. For example, a small set of neurons might store the concept of "grandmother" and fire in response to all inputs relevant to her, such as seeing her or her picture from various angles and distances, reading her written name, hearing her voice, and so on. According to this controversial proposal, other small sets of neurons would each store other specific concepts.

The Hippocampus and Declarative Memories The hippocampus is a prominent site where LTP takes place and is also crucial for consolidation into long-term memory. The hippocampus is believed to store new long-term memories only temporarily and then transfer them to other cortical sites for more permanent storage. The sites for long-term storage of various types of memories are only beginning to be identified by neuroscientists.

The hippocampus plays an especially important role in **declarative memories**—the "what" memories of specific people, places, objects, facts, and events that often result after only one experience and that can be declared in a statement such as "I saw the Statue of Liberty last summer" or conjured up in a mental image. Declarative memories involve conscious recall. This memory type is sometimes subdivided into **semantic memories** (memories of facts) and **episodic memories** (memories of events in our lives)**.**

Clinical Note People with hippocampal damage are profoundly forgetful of facts critical to daily functioning. Declarative memories typically are the first to be lost. Extensive damage in the hippocampus is evident during autopsy in patients with **Alzheimer's disease**. (For an expanded discussion of Alzheimer's disease, see the boxed feature on pp. 164–165, Concepts, Challenges, and Controversies.)

The Cerebellum and Procedural Memories The cerebellum and relevant cortical regions play an essential role in the "how to" **procedural memories** involving motor skills gained through repetitive training, such as memorizing a particular dance routine. The cortical areas important for a given procedural memory are the specific motor or sensory systems engaged in performing the routine. For example, different groups of muscles are called into play to tap dance than those needed to execute a dive. In contrast to declarative memories, which are consciously recollected from previous experiences, procedural memories can be brought forth without conscious effort. To exemplify, an ice skater during a competition typically performs best by "letting the body take over" the routine instead of thinking about exactly what needs to be done next.

Clinical Note The distinct localization in different parts of the brain of declarative and procedural memory is apparent in people who have hippocampal lesions. They can perform a skill, such as playing a piano, but the next day they have no recollection of having done so.

The Prefrontal Cortex and Working Memory The major orchestrator of the complex reasoning skills associated with *working memory* is the prefrontal association cortex. The prefrontal cortex serves as a temporary storage site for holding relevant data "online" and is largely responsible for the so-called **executive functions** involving manipulation and integration of this information for planning, juggling competing priorities, problem solving, making choices, organizing activities, and inhibiting impulses. Executive functions allow a person to decide what to do instead of just reacting to the situation at hand. The prefrontal cortex carries out these complex reasoning functions in cooperation with all the brain's sensory regions, which are linked to the prefrontal cortex through neural connections.

Researchers have identified different storage bins in the prefrontal cortex, depending on the nature of the current relevant data. For example, working memory involving spatial cues is in a prefrontal location distinct from working memory involving verbal cues or cues about an object's appearance. One recent fascinating proposal suggests that a person's intelligence may be determined by the capacity of working memory to temporarily hold and relate a variety of relevant data.

Check Your Understanding 5.7

1. Define *consolidation.*
2. Compare the molecular mechanisms for short-term and long-term memories.
3. Define long-term potentiation.
4. Distinguish among *declarative memories, procedural memories,* and *working memory* and indicate the brain area primarily associated with each.

5.8 Cerebellum

The **cerebellum** is a highly folded, baseball-sized part of the brain that lies underneath the occipital lobe of the cortex and is attached to the back of the upper portion of the brain stem (see ❙Table 5-1, p. 144 and ❙Figures 5-7b, p. 143, and 5-15, p. 154).

The cerebellum is important in balance and in planning and executing voluntary movement.

About four times as many individual neurons are found in the cerebellum than in the entire rest of the brain, indicative of the importance of this structure. The cerebellum consists of three functionally distinct parts with different roles concerned primarily with subconscious control of motor activity (❙Figure 5-18, p. 166). Specifically, the different parts of the cerebellum perform the following functions:

1. The **vestibulocerebellum** is important for maintaining balance and controls eye movements.
2. The **spinocerebellum** enhances muscle tone and coordinates skilled, voluntary movements. This brain region is especially important in ensuring the accurate timing of various muscle contractions to coordinate movements involving mul-

tiple joints. For example, the movements of your shoulder, elbow, and wrist joints must be synchronized even during the simple act of reaching for a pencil. When cortical motor areas send messages to muscles for executing a particular movement, the spinocerebellum is informed of the intended motor command. This region also receives input from peripheral receptors that inform it about the body movements and positions that are actually taking place. The spinocerebellum essentially acts as "middle management," comparing the "intentions" or "orders" of the higher centers with the "performance" of the muscles and then correcting any "errors" or deviations from the intended movement. The spinocerebellum even seems able to predict the position of a body part in the next fraction of a second during a complex movement and to make adjustments accordingly. If you are reaching for a pencil, for example, this region "puts on the brakes" soon enough to stop the forward movement of your hand at the intended location rather than letting you overshoot your target. These ongoing adjustments, which ensure smooth, precise, directed movement, are especially important for rapidly changing (phasic) activities such as typing, playing the piano, or running.

3. The **cerebrocerebellum** plays a role in planning and initiating voluntary activity by providing input to the cortical motor areas. This is also the region that stores procedural memories.

Recent discoveries suggest that in addition to these well-established functions, the cerebellum has even broader responsibilities, such as perhaps coordinating the brain's acquisition of sensory input. Researchers are currently trying to make sense of new and surprising findings that do not fit with the cerebellum's traditional roles in motor control.

Clinical Note All the following symptoms of cerebellar disease result from a loss of the cerebellum's established motor functions: poor balance; "drunken sailor" gait with wide stance and unsteady walking; nystagmus (rhythmic, oscillating eye movements); reduced muscle tone but no paralysis; inability to perform rapid alternating movements smoothly, such as being unable to swiftly slap the open palm of one hand alternately with the palm or back of the other hand; and inability to stop and start skeletal muscle action quickly. The latter gives rise to an *intention tremor* characterized by oscillating to-and-fro movements of a limb as it approaches its intended destination. A person with cerebellar damage who tries to pick up a pencil may overshoot the pencil and then rebound excessively, repeating this to-and-fro process until success is finally achieved. No tremor is observed except in performing intentional activity, in contrast to the resting tremor associated with disease of the basal nuclei, most notably PD.

The cerebellum and basal nuclei both monitor and adjust motor activity commanded from the motor cortex, and like the basal nuclei, the cerebellum does not directly infuence the efferent motor neurons. Although they perform different roles (for example, the cerebellum enhances muscle tone, whereas the basal nuclei inhibit it), both function indirectly by modifying the output of major motor systems in the brain. The motor command for a particular voluntary activity arises from the motor cortex, but the actual execution of that activity is coordinated subconsciously by these subcortical regions. To illustrate, you voluntarily

Alzheimer's Disease: A Tale of Beta Amyloid Plaques, Tau Tangles, and Dementia

"I CAN'T REMEMBER WHERE I PUT my keys. I must be getting Alzheimer's." The incidence and awareness of **Alzheimer's disease (AD)**, which is characterized in its early stages by loss of recent memories, have become so commonplace that people sometimes jest about having it when they can't remember something. AD is no joking matter, however.

Incidence

AD is the most common and most costly neurological disorder of the CNS. About 5.4 million Americans currently have AD, but because it is an age-related condition and the population is aging, the incidence is expected to climb. The number of affected individuals is expected to swell to 7 million as "baby boomers" age. About 0.1% of those between 60 and 65 years of age are afflicted with the disease, but the incidence rises to 47% among those older than age 85. A small percentage of people with AD are in their 40s and 50s.

Symptoms

AD accounts for about two thirds of the cases of *senile dementia,* which is a generalized age-related diminution of mental abilities. In the earliest stages of AD, only short-term memory is impaired, but as the disease progresses, even firmly entrenched long-term memories, such as recognition of family members, are lost. Confusion, disorientation, and personality changes characterized by irritability and emotional outbursts are common. Higher mental abilities gradually deteriorate as the patient inexorably loses the ability to read, write, and calculate. Language ability and speech are often impaired. In later stages, patients with AD become childlike and are unable to feed, dress, and groom themselves. Patients usually die in a severely debilitated state 4 to 12 years after onset of the disease.

Characteristic Brain Lesions

The characteristic brain lesions of the condition are extracellular *neuritic (senile) plaques* and intracellular *neurofibrillary tangles,* which are dispersed throughout the cerebral cortex and are especially abundant in the hippocampus. A **neuritic plaque** consists of a central core of extracellular, waxy, fibrous protein known as **beta amyloid (Aβ)** surrounded by degenerating dendritic and axonal nerve endings. **Neurofibrillary tangles** are dense bundles of abnormal, paired helical filaments that accumulate in the cell bodies of affected neurons. AD is characterized by degeneration of the cell bodies of certain neurons in the basal forebrain. The acetylcholine-releasing axons of these neurons normally terminate in the cerebral cortex and hippocampus, so the loss of these neurons results in a deficiency of acetylcholine in these areas. Neuron death and loss of synaptic communication are responsible for the ensuing dementia.

Underlying Pathology

Much progress has been made in understanding the pathology underlying the condition in recent years. **Amyloid precursor protein (APP)**, a structural component of all neuronal plasma membranes, is especially abundant in presynaptic terminal endings. APP can be cleaved at different locations to produce different products. Cleavage of APP at one site yields a product believed to play a role in learning and memory. Cleavage of APP at an alternative site yields Aβ. Depending on the exact site of cleavage, two different variants of Aβ are produced and released from the neuron. Normally about 90% of the Aβ is a soluble and harmless form of this product. The other 10% is the dangerous, plaque-forming version, which forms thin, insoluble filaments that readily aggregate into Aβ plaques and also appears to be neurotoxic. Furthermore, some researchers propose a controversial new theory that free-floating, short-chain, potentially toxic soluble molecules (known as *oligomers*) derived from Aβ that diffuse through the brain instead of aggregating into plaques are the real culprits responsible for the symptoms of AD. The balance between these APP products can be shifted by mutations in APP, other genetic defects, age-related or pathological changes in the brain, or perhaps environmental factors. The end result is increased production of toxic Aβ. Some evidence suggests that increased levels of Aβ may arise not from overproduction of this product but from failure to adequately clear from the brain the amount of Aβ normally produced.

Aβ formation is seen early in the course of the disease, with neurofibrillary tangles developing somewhat later. AD does not "just happen" in old age. Instead, it results from a host of gradual, insidious processes that occur over the course of years or decades. Although some pieces of the puzzle have not been identified, the following is a possible scenario based on the findings to date. The deposited Aβ is directly toxic to neurons. Furthermore, the gradual buildup of Aβ plaques attracts microglia to the plaque sites. These immune cells of the brain launch an inflammatory attack on the plaque, releasing toxic chemicals that can damage surrounding "innocent bystander" neurons in the process.

These inflammatory assaults, along with the direct toxicity of the deposited Aβ, also cause changes in the neuronal cytoskeleton that lead to formation of nerve-cell clogging neurofibrillary tangles. The protein **tau** normally associates with tubulin molecules in the formation of microtubules, which serve as axonal "highways" for transport of materials back and forth between the cell body and the axon terminal (see p. 46). Tau molecules act like "railroad ties" anchoring the "rails" of tubulin molecules within the microtubule. If tau molecules become hyperphosphorylated (have too many phosphate groups attached), they cannot interact with tubulin. Research suggests that Aβ binds to receptors on the surface of nerve cells, triggering a chain of intracellular events that leads to tau hyperphosphorylation. When not bound to tubulin, the incapacitated tau molecules intertwine, forming paired helical filaments that aggregate to form neurofibrillary tangles. More important, just as train tracks start to fall apart if too many ties are missing, the microtubules start to break down as increasing numbers of tau molecules can no longer do their job. The resultant loss of the neuron's transport system can lead to death of the cell.

Other factors also play a role in the complex story of AD, but exactly where they fit in is unclear. According to a leading proposal, Aβ causes excessive influx of Ca^{2+}, which triggers a chain of biochemical events that kills the cells. Brain cells that have an abundance of glutamate NMDA receptors, most notably the hippocampal cells involved in long-term potentiation (see p. 160), are especially vulnerable to glutamate toxicity. Loss of hippocampal memory-forming capacity is a hallmark feature of AD. Other studies suggest that cell-damaging free radicals (see p. 142) are produced during the course of the disease. One of the most startling recent discoveries is that Aβ proteins might act much like *prions,* the infectious proteins that lead to brain damage in mad cow disease. Prions are misfolded proteins that wreak havoc by causing other normal similar proteins to also misfold, leading to further misfolding in a toxic chain reaction. These misshapen proteins clump together and ultimately kill nerve cells. The Aβ proteins clumped in plaques are misfolded proteins. This prionlike behavior of aberrant brain proteins may play a role in the neurodegeneration seen not only in AD but also in Parkinson's disease (see p. 154) and amyotrophic lateral sclerosis (see p. 51). Unlike with infectious prions associated with mad cow disease, the normal brain proteins turned prionlike are not transmitted from person to person.

Possible Causes

The underlying trigger for abnormal Aβ formation in AD is unknown in most cases. Many investigators believe the condition has many underlying causes. Both genetic and environmental factors have been implicated in an increased risk of acquiring AD. About 15% of cases are linked to specific, known genetic defects that run in families and cause *early onset,* or *familial Alzheimer's disease.* Individuals with this form of the condition typically develop clinical symptoms in their 40s or 50s.

The other 85% of patients with AD do not begin to manifest symptoms until later in life, somewhere between 65 and 85 years of age. Specific gene traits have also been identified that increase an individual's vulnerability of acquiring *late-onset Alzheimer's disease.* However, not everyone with genetic tendencies for AD develops the disease. Furthermore, many develop the illness with no apparent genetic predisposition. Obviously, other factors must also be at play in producing the condition. Hormonal imbalances may play a role. In particular, research findings suggest that *cortisol,* the stress hormone, increases the propensity to develop the condition. In addition, investigators have been searching for possible environmental triggers, but none have been found to date.

Diagnosis

AD can only be confirmed at autopsy on finding the characteristic brain lesions associated with the disease—Aβ plaques and neurofibrillary tangles. Currently, AD is clinically diagnosed before death by a process of elimination—that is, all other disorders that could produce dementia, such as a stroke or brain tumor, must be ruled out. In 2011, diagnostic criteria for AD were changed for the first time in 25 years, although these new guidelines are being used now primarily in research settings. Researchers hope to confirm that earlier diagnosis of AD via the revised guidelines will lead to interventions early in the disease before dementia occurs. Neurological damage can begin up to 20 years before symptoms appear.

The new diagnostic criteria depend on the presence of *biomarkers* (short for biological marker, anything that can be objectively measured as an indicator of a particular physiological or disease state). The two newly accepted biomarkers for AD are (1) imaging of Aβ plaques in the living brain using a PET scan (see p. 145) following injection of a radioactive compound that binds to Aβ (a recently discovered technique) and (2) measuring Aβ and tau in a cerebrospinal fluid (CSF) sample obtained via a spinal tap.

Treatment

The *National Alzheimer's Project Act* was established in the United States in 2011 with the goal of providing a comprehensive approach for ensuring quality care of patients with AD, family and caregiver support, much needed new treatments, and most ambitiously prevention of the condition by 2025.

Currently available drugs can transiently reduce symptoms in some patients but do nothing to slow down or halt progression of the disease. Two classes of drugs are specifically approved for treatment of AD. One class raises the levels of acetylcholine (the deficient neurotransmitter) in the brain. For example, *Aricept (donepezil),* the most commonly prescribed drug for AD, inhibits the enzyme that normally clears released acetylcholine from the synapse. The second, newer class of approved drugs, an example being *Nemenda (memantine),* interferes with the NMDA receptors, blocking the toxic effects of excess glutamate release. Several over-the-counter agents are also used to treat AD. Antioxidants hold some promise of thwarting free-radical damage. Aspirin and other anti-inflammatory drugs may slow the course of AD by blocking the inflammatory components of the condition.

As researchers continue to unravel the underlying factors, the likelihood of finding various means to block the gradual, relentless progression of AD increases. For example, the search is on for new drugs that might block the cleavage of plaque-forming Aβ from APP or might inhibit the aggregation of Aβ into dangerous plaques, thus halting AD in its tracks in the earliest stages. Another thrust is to clear from the brain toxic Aβ fragments. Right now more than 800 therapeutic approaches targeted at different steps of the AD pathway are under development.

The financial payoff for the drug companies that come up with successful products will be huge, and the broader effect will be even more significant. Prevention or treatment of AD cannot come too soon in view of the tragic toll the condition takes on its victims, their families, and society. The cost of custodial care for patients with AD is currently estimated at $183 billion annually and will continue to rise as a greater percentage of our population ages and becomes afflicted with the condition.

decide to walk, but you do not have to consciously think about the specific sequence of movements you have to perform to accomplish this intentional act. Accordingly, much voluntary activity is actually involuntarily regulated.

You will learn more about motor control when we discuss skeletal muscle physiology in Chapter 8. For now, we move on to the remaining part of the brain, the brain stem.

Check Your Understanding 5.8

1. State the functions of the three parts of the cerebellum.
2. Compare resting tremors and intention tremors.

5.9 Brain Stem

The **brain stem** consists of the **medulla**, **pons**, and **midbrain** (see ▌Table 5-1 and Figure 5-7b).

The brain stem is a vital link between the spinal cord and higher brain regions.

All incoming and outgoing fibers traversing between the periphery and the higher brain centers must pass through the brain stem, with incoming fibers relaying sensory information to the brain and outgoing fibers carrying command signals from the brain for

efferent output. Most of these fibers synapse within the brain stem for important processing. Thus, the brain stem is a critical connecting link between the rest of the brain and the spinal cord.

The functions of the brain stem include the following:

1. Most of the 12 pairs of **cranial nerves** arise from the brain stem. With one major exception, these nerves supply structures in the head and neck with both sensory and motor fibers (▌Table 5-3). They are important in sight, hearing, equilibrium, taste, smell, sensation of the face and scalp, eye movement, chewing, swallowing, facial expressions, and salivation. The major exception is cranial nerve X, the **vagus nerve**. Instead of innervating regions in the head, most branches of the vagus nerve supply organs in the thoracic (chest) and abdominal (belly) cavities. The vagus is the major nerve of the parasympathetic nervous system.

2. Collected within the brain stem are neuronal clusters or **centers** that control heart and blood vessel function, respiration, and many digestive activities. A functional collection of neuronal cell bodies within the CNS is alternately known as a *center,* such as the respiratory control center in the brain stem, or as a *nucleus* (plural *nuclei*), such as the basal nuclei. You will learn about these centers when we discuss the body systems controlled by their activity.

Number	Name	Fiber Types	Functions
I	Olfactory	Sensory	Smell
II	Optic	Sensory	Vision
III	Oculomotor	Mixed (mainly motor)	Eyeball and eyelid movement, pupil constriction, change of lens shape for near vision.
			Proprioception (awareness of position of body parts)
IV	Trochlear	Mixed (mainly motor)	Eyeball movement
			Proprioception
V	Trigeminal	Mixed	Chewing
			Somatic sensations (touch, pressure, pain, and temperature) of face and mouth
VI	Abducens	Mixed (mainly motor)	Eyeball movement
			Proprioception
VII	Facial	Mixed	Facial expression, secretion of saliva and tears
			Taste from front of tongue
VIII	Vestibulocochlear	Sensory	Hearing, sense of equilibrium
IX	Glossopharyngeal	Mixed	Swallowing, secretion of saliva
			Taste from back of tongue, somatic sensation of oral cavity, blood-pressure monitoring
X	Vagus	Mixed	Efferent output for skeletal muscles of pharynx (throat) and larynx (voice box) and for smooth muscle and glands of thoracic and abdominal organs and for cardiac muscle of heart
			Afferent input from thoracic and abdominal organs, blood-pressure monitoring
XI	Accessory	Motor	Efferent output for skeletal muscles of pharynx, larynx, neck, and shoulder
XII	Hypoglossal	Motor	Tongue movement

Carried by afferent fibers   Carried by efferent fibers

3. The brain stem helps regulate muscle ref exes involved in equilibrium and posture.

4. A widespread network of interconnected neurons called the **reticular formation** runs throughout the entire brain stem and into the thalamus. This network receives and integrates all incoming sensory synaptic input. Ascending fibers originating in the reticular formation carry signals upward to arouse and activate the cerebral cortex (IFigure 5-19). These fibers compose the **reticular activating system (RAS)**, which controls
IFigure 5-19 **The reticular activating system.** The reticular formation, a widespread network of neurons within the brain stem (in *red*), receives and integrates all synaptic input. The reticular activating system, which promotes cortical alertness and helps direct attention toward specific events, consists of ascending fibers (in *blue*) that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex.

FIGURE FOCUS*: Describe the pathway by which your alarm going off wakes you up.*

the overall degree of cortical alertness and is important in the ability to direct attention. In turn, fibers descending from the cortex, especially its motor areas, can activate the RAS.

5. The centers that govern sleep are housed within the brain stem and the hypothalamus.

We now examine sleep and the other states of consciousness.

Consciousness refers to awareness of one's existence, thoughts, and surroundings.

The term **consciousness** refers to subjective awareness of the external world and self, including awareness of the private inner world of one's mind—that is, awareness of thoughts, perceptions, dreams, and so on. Even though the final level of awareness resides in the cerebral cortex and a crude sense of awareness is detected by the thalamus, conscious experience depends on the integrated functioning of many parts of the nervous system.

The cellular and molecular basis underlying consciousness is one of the greatest unanswered questions in neuroscience. One proposal that is gaining increasing support is the **global workspace theory**, which suggests that conscious experience depends on the brain functioning as a "brainweb" in which some of the separate bits of subconscious information that are being processed locally at the same time are momentarily broadcast throughout the brain (that is, to a global workspace). This highly coordinated, widespread information exchange among much of the cortex gives rise to subjective experience of the information. That is, we become conscious of what we are experiencing only when information received through specialized channels (such as sensory information) is distributed to much of the cortex, creating a unity of mind.

Normal states of consciousness are wakefulness and sleep. The **sleep–wake cycle** is a normal cyclic variation in awareness of surroundings. In the **waking state** people are alert and aware of their surroundings and consciously engage in coherent thoughts and actions. Wakefulness depends on attention-getting sensory input that "energizes" the RAS and subsequently the activity level of the CNS as a whole. Wakefulness is not a constant level of arousal but varies from maximum alertness to drowsiness, depending on the extent of interaction between peripheral stimuli and the brain. Different arousal and activity states are characterized by different brain wave activity as recorded on an electroencephalogram.

An electroencephalogram is a record of postsynaptic activity in cortical neurons.

Extracellular current f ow arising from electrical activity within the cerebral cortex can be detected by placing recording electrodes on the scalp to produce a graphic record known as an **electroencephalogram**, or **EEG.** These "brain waves" for the most part are not the result of action potentials but instead represent the momentary collective postsynaptic potential activity (that is, excitatory postsynaptic potentials, or EPSPs, and inhibitory postsynaptic potentials, or IPSPs; see pp. 106–107) in the cell bodies and dendrites located in the cortical layers under the recording electrode.

Electrical activity can always be recorded from the living brain, even during sleep and unconscious states, but the waveforms vary,

depending on the degree of activity in the cerebral cortex. Often the waveforms appear irregular, but sometimes distinct patterns in wave frequency (number of waves per second) and amplitude (height of each wave) can be observed. There are five categories of brain waves, depending on the mental state. The higher the frequency of the brain waves, the faster the brain activity. Ranging from the most to the least activity, these waveforms are:

gamma waves, which are the fastest brain waves with the smallest amplitude and are the most recently identified brain waves. (Gamma waves in the brain are distinctly different from gamma rays released from radioactive material, as used in PET scans; see p. 145.) Gamma waves are associated with peak concentration; the highest levels of cognition; and simultaneous processing of information from different brain areas, as when the brain is actively tying together the sights and sounds of a current experience.

beta waves, which have a high frequency and low amplitude and are prominent when you are fully awake, focused, and alert. This is the dominant waveform during much of the day, such as when you are focused on your surroundings, actively thinking, or engaged in conversation.

alpha waves, which have a lower frequency and greater amplitude than beta waves and are present when you are awake,
(a) Alpha and beta waves when awake
(b) Delta waves when in slow-wave sleep, stage 4
(c) Waves during paradoxical sleep

❙Figure 5-20 Electroencephalogram (EEG) patterns under different circumstances. (a) An alpha rhythm when the eyes are closed is replaced by a beta rhythm when the eyes are opened during the waking state. (b) A delta rhythm is associated with deep stage-4 slow-wave sleep. (c) Note that the EEG pattern during paradoxical sleep is similar to the beta rhythm of an alert, awake person.

but relaxed, calm, and not processing much information. ❙Figure 5-20 illustrates how the EEG waveform recorded over the occipital (visual) cortex dramatically shifts between alpha and beta waves in response to simply closing and opening the eyes.

theta waves, which have an even slower frequency and greater amplitude than alpha waves and dominate when you are extremely relaxed, drowsy, or are in light sleep.

delta waves, which have the greatest amplitude and slowest frequency and occur when you are in deep, dreamless sleep (❙Figure 5-20).

Clinical Note The EEG has three major uses:

1. The EEG is often used as a *clinical tool in the diagnosis of cerebral dysfunction*. Diseased or damaged cortical tissue often gives rise to altered EEG patterns. One of the most common neurological diseases accompanied by a distinctively abnormal EEG is **epilepsy**. Epileptic seizures occur when a large collection of neurons undergo abnormal, synchronous action potentials that produce stereotypical, involuntary spasms and alterations in behavior. Different underlying problems, including genetic defects and traumatic brain injuries, can lead to the neuronal hyperexcitability that characterizes epilepsy. Typically there is too little inhibitory compared to excitatory activity, as with compromised functioning of the inhibitory neurotransmitter GABA or prolonged action of the excitatory neurotransmitter glutamate. The seizures may be partial or generalized, depending on the location and extent of the abnormal neuronal discharge. Each type of seizure displays different EEG features.

2. The EEG is also used in the *legal determination of brain death*. Even though a person may have stopped breathing and the heart may have stopped pumping blood, it is often possible to restore and maintain respiratory and circulatory activity if resuscitative measures are instituted soon enough. Yet because the brain is susceptible to O_2 deprivation, irreversible brain damage may occur before lung and heart function can be reestablished, resulting in the paradoxical situation of a dead brain in a living body. The determination of whether a comatose patient being maintained by artificial respiration and other supportive measures is alive or dead has important medical, legal, and social implications. The need for viable organs for modern transplant surgery has made the timeliness of such life-or-death determinations of utmost importance. Physicians, lawyers, and Americans in general have accepted the notion of brain death—that is, a brain that is not functioning, with no possibility of recovery—as the determinant of death under such circumstances. The most widely accepted indication of brain death is electrocerebral silence—a f at EEG.

3. The EEG is also used to *distinguish various stages of sleep*.

Sleep is an active process consisting of alternating periods of slow-wave and paradoxical sleep.

In contrast to being awake, sleeping people are not consciously aware of the external world, but they do have inward conscious experiences such as dreams. Furthermore, they can be aroused by external stimuli, such as an alarm going off. **Sleep** is an active process, not just the absence of wakefulness. The brain's overall level of activity is not reduced during sleep. During certain stages of sleep, O_2 uptake by the brain is even increased above normal waking levels. There are two types of sleep, characterized by different EEG patterns and different behaviors: *slow-wave sleep* and *paradoxical,* or REM, *sleep* (❙Table 5-4).

EEG Patterns During Sleep **Slow-wave sleep** occurs in four stages, each displaying progressively slower EEG waves of higher amplitude (hence, "slow-wave" sleep) (❙Figure 5-20). At the onset of sleep, you move from the light sleep of stage 1 to the deep sleep of stage 4 of slow-wave sleep during a period of 30 to 45 minutes; then you reverse through the same stages in the same amount of time. A 10- to 15-minute episode of **paradoxical sleep** punctuates the end of each slow-wave sleep cycle.

❙**TABLE 5-4** Comparison of Slow-Wave and Paradoxical Sleep

Characteristic	TYPE OF SLEEP	
	Slow-Wave Sleep	Paradoxical Sleep
EEG	Displays slow waves	Similar to EEG of alert, awake person
Motor activity	Considerable muscle tone; frequent shifting	Abrupt inhibition of muscle tone; no movement
Heart rate, respiratory rate, blood pressure	Minor reductions	Irregular
Dreaming	Rare (mental activity is extension of waking-time thoughts)	Common
Arousal	Sleeper easily awakened	Sleeper hard to arouse but apt to wake up spontaneously
Percentage of sleeping time	80%	20%
Other important characteristics	Has four stages; sleeper must pass through this type of sleep first	Rapid eye movements

Paradoxically, your EEG pattern during this time abruptly becomes similar to that of a wide-awake, alert individual, even though you are still asleep (hence, "paradoxical" sleep) (❙Figure 5-20). After the paradoxical episode, the stages of slow-wave sleep repeat. You cyclically alternate between the two types of sleep throughout the night. Brief periods of wakefulness occasionally occur. Most stage 4 deep sleep occurs during the first several hours of sleep, with paradoxical sleep occupying an increasingly greater share of sleep time as morning approaches (❙Figure 5-21). Because of the resemblance of this graphic representation of the cyclical sleep pattern to a city skyline, the pattern of sleep is sometimes referred to as *sleep architecture*.

In a normal sleep cycle, you always pass through slow-wave sleep before entering paradoxical sleep. On average, paradoxical sleep occupies 20% of total sleeping time throughout adolescence and most of adulthood. Infants spend considerably more time in paradoxical sleep. In contrast, paradoxical and deep stage 4 slow-wave sleep declines in the elderly.

Behavioral Patterns During Sleep In addition to distinctive EEG patterns, the two types of sleep are distinguished by behavioral differences. It is difficult to pinpoint exactly when an individual drifts from drowsiness into slow-wave sleep. In this type of sleep, the person still has considerable muscle tone and often shifts body position. Respiratory rate, heart rate, and blood pressure remain regular. During this time, the sleeper can be easily awakened and rarely dreams. The mental activity associated with slow-wave sleep is less visual than dreaming. It is more conceptual and plausible—like an extension of waking-time thoughts concerned with everyday events—and it is less likely to be recalled. The major exception is nightmares, which occur during stages 3 and 4.

The behavioral pattern accompanying paradoxical sleep is marked by abrupt inhibition of muscle tone throughout the body. The muscles are completely relaxed, with no movement taking place except in the eye muscles. Paradoxical sleep is characterized by *rapid eye movements,* hence the alternative name, **REM sleep**. Heart rate and respiratory rate become irregular, and blood pressure may fluctuate. Another characteristic of REM sleep is dreaming. Recent evidence indicates that at least part of the rapid eye movements are related to "watching" the dream imagery, although traditionally scientists thought that the eye movements were caused by an automatic, rhythmic pattern of discharge not influenced by dream content.

Brain imaging of volunteers during REM sleep shows heightened activity in the higher-level visual processing areas and limbic system (seat of emotions), coupled with reduced activity in the prefrontal cortex (seat of reasoning). This activity pattern lays the groundwork for the characteristics of dreaming: internally generated visual imagery reflecting activation of the person's "emotional memory bank" with little guidance or interpretation from the complex thinking areas. As a result, dreams are often charged with intense emotions, a distorted sense of time, and bizarre content that is uncritically accepted as real, with little reflection about all the strange happenings.

The sleep–wake cycle is controlled by interactions among three neural systems.

The sleep–wake cycle, and the various stages of sleep, result from the cyclic interplay of three neural systems: (1) an **arousal system** involving the RAS in the brain stem, which is commanded by a specialized group of neurons in the hypothalamus; (2) a **slow-wave sleep center** in the hypothalamus that contains *sleep-on neurons,* which bring on slow-wave sleep; and (3) a **paradoxical sleep center** in the brain stem that houses REM *sleep-on neurons,* which switches to paradoxical sleep. The patterns of interaction among these three neural regions, which bring about the fairly predictable cyclical sequence between being awake and passing alternately between the two types of sleep, are the subject of intense investigation. A growing body of evidence suggests the following relationships:

1. A group of neurons in the hypothalamus is at the top of the chain of command for regulating the arousal system. These neurons secrete the excitatory neurotransmitter **hypocretin** (also known as **orexin**). Surprisingly, hypocretin is better known as an appetite-enhancing signal, but it is now known to play an important role in arousal too. These hypocretin-secreting neurons fire autonomously (on their own) and continuously and keep you awake and alert by stimulating the RAS. They must be inhibited to induce sleep, as perhaps by IPSPs generated by input from the sleep-on neurons.

2. The **sleep-on neurons** in the slow-wave sleep center appear to be responsible for bringing on sleep, likely by inhibiting the arousal-promoting neurons by releasing the inhibitory neurotransmitter GABA. This mechanism would explain why we enter slow-wave sleep first when we fall asleep. The sleep-on neurons are inactive when a person is awake and are maximally active only during slow-wave sleep. Scientists do not know much about the factors that activate the sleep-on neurons to induce sleep.

3. The **REM sleep-on neurons** in the paradoxical sleep center become very active during REM sleep. It appears that they
❙Figure 5-21 **Typical cyclical sleep pattern in a young adult.**
FIGURE FOCUS: *Describe how the cyclical pattern of slow-wave sleep, REM sleep, and awake periods changes as the person moves from beginning to end of the sleep period depicted.*

can turn off the sleep-on neurons and switch the sleep pattern from slow-wave sleep to REM sleep. The underlying molecular mechanisms responsible for the cyclical interplay between the two types of sleep remain poorly understood.

The normal cycle can easily be interrupted, with the arousal system more readily overriding the sleep systems than vice versa—that is, it is easier to stay awake when you are sleepy than to fall asleep when you are wide awake. The arousal system can be activated by afferent sensory input (for example, a person has difficulty falling asleep when it is noisy) or by input descending to the brain stem from higher brain regions. Intense concentration or strong emotional states, such as anxiety or excitement, can keep a person from falling asleep, just as motor activity, such as getting up and walking around, can arouse a drowsy person. However, you can override the urge to sleep for just so long before the pressure to sleep becomes irresistible. Sleep on a regular basis is an absolute necessity of life, even though scientists are not sure what purpose sleep serves.

The function of sleep is unclear.

Even though humans spend about a third of their lives sleeping, why sleep is needed largely remains a mystery. Sleep is by the brain and for the brain, not for other parts of the body. It is not accompanied by a reduction in neural activity (that is, the brain cells are not "resting"), as once was suspected, but rather by a profound *change* in activity.

One widely accepted proposal holds that sleep provides "catch-up" time for the brain to restore biochemical or physiological processes that have progressively degraded during wakefulness.

The most direct evidence supporting this proposal is the potential role of **adenosine** as a neural sleep factor. Adenosine, the backbone of adenosine triphosphate (ATP), the body's energy currency, is generated during the awake state by metabolically active neurons and glial cells. Thus, the brain's extracellular concentration of adenosine continues to rise the longer a person has been awake. Adenosine, which acts as a neuromodulator, has been shown experimentally to inhibit the arousal center. This action can bring on slow-wave sleep, during which restoration and recovery activities are believed to take place. Injections of adenosine induce apparently normal sleep, whereas **caffeine**, which blocks adenosine receptors in the brain, revives drowsy people by removing adenosine's inhibitory influence on the arousal center. Adenosine levels diminish during sleep, presumably because the brain uses this adenosine as a raw ingredient for replenishing its limited energy stores. Thus, the body's need for sleep may stem from the brain's periodic need to replenish diminishing energy stores. Because adenosine reflects the level of brain cell activity, the concentration of this chemical in the brain may serve as a gauge of how much energy has been depleted.

Another "restoration and recovery" proposal suggests that slow-wave sleep provides time for the brain to repair damage caused by toxic free radicals (see p. 142) produced as by-products of the stepped-up metabolism during the waking state. Other organs can sacrifice and replace cells damaged by free radicals, but this is not an option for the nonregenerative brain.

A related, new "restoration and recovery" role for sleep involves the recently identified cleansing of the brain's intersti-

tial fuid by the glymphatic system whose activity increases during sleep (see p. 137).

One more possible "restoration and recovery" function of REM sleep is to let some of the neural pathways regain full sensitivity. When a person is awake, brain neurons that release the neurotransmitters norepinephrine and serotonin are maximally and continuously active. Release of these neurotransmitters ceases during REM sleep. Studies suggest that constant release of norepinephrine and serotonin can desensitize their receptors. Perhaps REM sleep is needed to restore receptor sensitivity for optimal functioning during the next period of wakefulness.

A different leading theory has nothing to do with restoration and recovery. Instead, other researchers believe that sleep is necessary to allow the brain to "shift gears" to accomplish the long-term structural and chemical adjustments necessary for learning and memory. This theory might explain why infants need so much sleep. Their highly plastic brains are rapidly undergoing profound synaptic modifications in response to environmental stimulation. In contrast, mature individuals, in whom neural changes are less dramatic, sleep less. Some evidence suggests that the different types of sleep might be involved in consolidation of different kinds of memories, with declarative memories being consolidated during slow-wave sleep and procedural memories during REM sleep.

A recent memory-related theory is that sleep, especially slow-wave sleep, is a time for replaying the events of the day, not only to help consolidate memories but perhaps to make recent experiences more meaningful by catching information missed on first pass and by "connecting the dots" between new pieces of information. This information-processing proposal could explain why people with an important decision to make sometimes say they will "sleep on it" before arriving at a conclusion.

The latest, highly debated proposal for sleep's role in learning and memory is the **synaptic homeostasis hypothesis**, which is based on preventing brain overload. According to this proposal, sleep provides off-line time needed for synaptic downscaling to offset the increases in synaptic activity that accompany all kinds of stimulation during wakeful periods (that is, to maintain synaptic homeostasis). During wakefulness, LTP strengthens connections between neurons in many circuits throughout the cortex in response to the day's experiences. The resultant increase in synaptic activity is metabolically costly and eventually day after day would constrain the ability to learn further (for example, only so many new receptors can be inserted into the postsynaptic membrane to strengthen synaptic activity). Evidence gathered in support of this hypothesis suggests that the greater the extent of synaptic potentiation during wakefulness, the more slow-wave sleep activity takes place during the following sleep. These slow waves depress synaptic strength across the board in the cortex. As a result of this synaptic downscaling, the more weakly potentiated synaptic connections made during the day are eliminated, keeping the cortex from filling up with useless connections of inadequate strength. Only the strongest of the newly potentiated memory bonds are preserved (in a sort of "survival of the fittest"). This downsizing restores total synaptic activity to a sustainable baseline level that preserves resources needed for the next day's round of synaptic strengthening and learning.

Another highly controversial new proposal is that local neural networks in the brain may go to sleep at different times, depending on how much they have been used recently. When a particular neuronal circuit is exhausted from prolonged or intense use, it can "fall asleep" even though the rest of the brain remains awake. The characteristic behavioral sleep state kicks in only when most of the brain's neurons are in the sleep mode. Furthermore, portions of the brain that have been relatively inactive during the day may remain "awake" even after the person falls asleep. This scattered pattern of sleep is known as **local use-dependent sleep**.

The various sleep theories are not mutually exclusive. Sleep might serve multiple purposes.

Little is known about the brain's need for cycling between the two types of sleep, although a specified amount of paradoxical sleep appears to be required. Individuals experimentally deprived of paradoxical sleep for a night or two by being aroused every time the paradoxical EEG pattern appeared suffered hallucinations and spent proportionally more time in paradoxical sleep during subsequent undisturbed nights, as if to make up for lost time.

Clinical Note An unusual sleep disturbance is **narcolepsy**. It is characterized by brief (5- to 30-minute), irresistible sleep attacks during the day. A person suffering from this condition suddenly falls asleep during any ongoing activity, often without warning. Patients with narcolepsy typically enter into paradoxical sleep directly without the normal prerequisite passage through slow-wave sleep. Investigators recently learned that narcolepsy is linked to a deficiency of hypocretin as a result of selective autoimmune destruction of the hypocretin-secreting neurons in the hypothalamus.

Impaired states of consciousness are associated with minimal or no awareness.

Impaired states of consciousness include the minimally conscious state, the vegetative state, and coma. A person in a **minimally conscious state** inconsistently shows signs of minimal conscious awareness of self or environment and can move purposefully, such as deliberately making a hand response to a simple command. The **vegetative state** is characterized by periodic sleep–wake cycles but without detectable awareness. The person may appear wide awake but is unaware of surroundings or self. **Coma** is the total unresponsiveness of a living person to external stimuli. These altered states of consciousness are caused either by brain stem damage that interferes with the RAS or by widespread depression of the cerebral cortex, such as accompanies O_2 deprivation or traumatic brain injury. When under **anesthesia**, a person's state of consciousness is more like being in a drug-induced coma than in a deep sleep.

A **concussion** is a transient change in mental status caused by a traumatic brain injury. It

is typified by the following range of symptoms, some but not necessarily all of which may be present: temporary loss of consciousness, headache, confusion, dizziness, and amnesia. Recent studies have raised concerns that repeated blows to the head, especially before the brain has healed from a previous concussion, as can occur in boxing or football, can lead to increased risk in later life for dementia, *chronic traumatic encephalopathy* (progressive degeneration of the brain similar to amyotrophic lateral sclerosis, or Lou Gehrig's disease), Parkinson's disease, or depression. One worrisome finding was that players retired from the National Football League had a 19 times higher incidence of severe memory problems than other men of comparable age.

We have finished discussing the brain and now shift attention to the other CNS component, the spinal cord.

1. List the functions of the brain stem.
2. Define *consciousness*.
3. Discuss the location and functions of the three neural systems that play a role in the sleep–wake cycle.

5.10 Spinal Cord

The **spinal cord** is a long, slender cylinder of nerve tissue that extends from the brain stem. It is about 45 cm (18 in.) long and 1 to 1.5 cm wide (about the width of your finger).
❚ Figure 5-22 Location of the spinal cord relative to the vertebral column.

Figure 5-23 Spinal nerves. The 31 pairs of spinal nerves are named according to the region of the vertebral column from which they emerge. Because the spinal cord is shorter than the vertebral column, spinal nerve roots must descend along the cord before emerging from the vertebral column at the corresponding intervertebral space, especially those beyond the level of the first lumbar vertebra (L1). Collectively these rootlets are called the *cauda equina,* literally "horse's tail." (a) Posterior view of the brain, spinal cord, and spinal nerves (on the right side only). (b) Lateral view of the spinal cord and spinal nerves emerging from the vertebral column.

Cauda equina

(a) Posterior view of spinal cord

(b) Lateral view of spinal cord

The spinal cord extends through the vertebral canal and is connected to the spinal nerves.

Exiting through a large hole in the base of the skull, the spinal cord is enclosed by the protective vertebral column as it descends through the vertebral canal (Figure 5-22). Paired **spinal nerves** emerge from the spinal cord through spaces formed between the bony, winglike arches of adjacent vertebrae. The spinal nerves are named according to the region of the vertebral column from which they emerge (Figure 5-23): There are 8 pairs of *cervical (neck) nerves* (namely, C1 to C8), 12 *thoracic (chest) nerves,* 5 *lumbar (abdominal) nerves,* 5 *sacral (pelvic) nerves,* and 1 *coccygeal (tailbone) nerve.*

During development, the vertebral column grows about 25 cm longer than the spinal cord. Because of this differential growth, segments of the spinal cord that give rise to various spinal nerves are not aligned with the corresponding intervertebral spaces. Most spinal nerve roots must descend along the cord

before emerging from the vertebral column at the corresponding space. The spinal cord itself extends only to the level of the first or second lumbar vertebra (about waist level), so the nerve roots of the remaining nerves are greatly elongated to exit the vertebral column at their appropriate space (Figure 5-23b).

Clinical Note **Spinal taps** to obtain a sample of CSF are performed by inserting a needle into the vertebral canal below the level of the second lumbar vertebra. Insertion at this site does not run the risk of penetrating the spinal cord. The needle pushes aside the nerve roots in this region so that a sample of the surrounding fluid can be withdrawn safely.

The white matter of the spinal cord is organized into tracts.

Although there are some slight regional variations, the cross-sectional anatomy of the spinal cord is generally the same throughout its length (Figure 5-24). In contrast to the brain, where the gray matter forms an outer shell capping an inner white core, the gray matter in the spinal cord forms an inner butterfly-shaped region surrounded by the outer white matter. As in the brain, the cord gray matter consists primarily of neuronal cell bodies and their dendrites, and glial cells. The white matter is organized into **tracts,** which are bundles of nerve fibers (axons of long interneurons) with a similar function. The bundles are grouped into columns that extend the length of the cord. Each of these tracts begins or ends within a particular area of the brain, and each transmits a specific type of information. Some are **ascending** (cord to brain) **tracts** that transmit to the brain signals derived from afferent input. Others are **descending** (brain to cord) **tracts** that relay messages from the brain to efferent neurons (Figure 5-25).

The tracts are generally named for their origin and termination. For example, the **ventral spinocerebellar tract** is an ascending pathway that originates in the spinal cord and runs up

The Central Nervous System | **173**

Figure 5-24 Spinal cord in cross section. Afferent fibers enter through the dorsal root, and efferent fibers exit through the ventral root. Afferent and efferent fibers are enclosed together within a spinal nerve.

the ventral (toward the front) margin of the cord with several synapses along the way until it eventually terminates in the cerebellum (Figure 5-26a). This tract carries information derived from muscle stretch receptors that has been delivered to the spinal cord by afferent fibers for use by the spinocerebellum. In contrast, the **ventral corticospinal tract** is a descending pathway that originates in the motor region of the cerebral cortex, then travels down the ventral portion of the spinal cord, and terminates in the spinal cord on the cell bodies of efferent motor neurons supplying skeletal muscles (Figure 5-26b). Because

various types of signals are carried in different tracts within the spinal cord, damage to particular areas of the cord can interfere with some functions, whereas other functions remain intact.

Each horn of the spinal cord gray matter houses a different type of neuronal cell body.

The centrally located gray matter is also functionally organized (Figure 5-27). The central canal, which is filled with CSF, lies in the center of the gray matter. Each half of the gray matter is arbitrarily divided into a *dorsal (posterior) horn*, a *ventral (anterior) horn*, and a *lateral horn*. The **dorsal horn** contains cell bodies of interneurons on which afferent neurons terminate. The **ventral horn** contains cell bodies of the efferent motor neurons supplying skeletal muscles. Autonomic nerve fibers

Figure 5-25 Ascending and descending tracts in the white matter of the spinal cord in cross section.
Figure 5-26 Examples of ascending and descending pathways in the white matter of the spinal cord. (b) Brain-to-cord pathways of several descending tracts (lateral corticospinal and ventral corticospinal tracts).

supplying cardiac and smooth muscle and exocrine glands originate at cell bodies found in the **lateral horn**.

Spinal nerves carry both afferent and efferent fibers.

Spinal nerves connect with each side of the spinal cord by a *dorsal root* and a *ventral root* (see ❙Figure 5-24). Afferent fibers carrying incoming signals from peripheral receptors

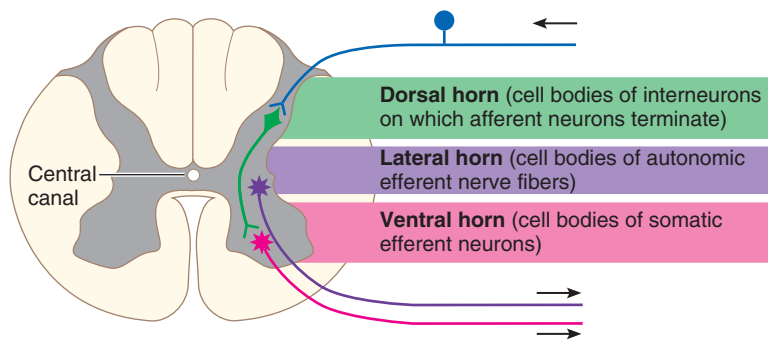
enter the spinal cord through the **dorsal root**. The cell bodies for the afferent neurons at each level are clustered together in a **dorsal root ganglion**. (A collection of neuronal cell bodies located outside the CNS is called a *ganglion,* whereas a functional collection of cell bodies within the CNS is referred to as a *nucleus* or a *center.*) The cell bodies for the efferent neurons originate in the gray matter, and the efferent fibers carrying outgoing signals to muscles and glands exit through the **ventral root**.


Figure 5-27 Regions of the gray matter.

Central canal

Dorsal horn (cell bodies of interneurons on which afferent neurons terminate)

Lateral horn (cell bodies of autonomic efferent nerve fibers)

Ventral horn (cell bodies of somatic efferent neurons)

The dorsal and ventral roots at each level join to form a spinal nerve that emerges from the vertebral column (see ❙Figure 5-24). A spinal nerve contains both afferent and efferent fibers traversing between the spinal cord and a particular body region. Note the relationship between a *nerve* and a *neuron*. A **nerve** is a bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway (❙Figure 5-28). A nerve does not contain a complete nerve cell, only the axonal portions of many neurons. (By this definition, there are no nerves in the CNS! Bundles of axons in the CNS are called tracts.) The individual fibers within a nerve generally do not have any direct influence on one another. They travel together for convenience, just as many individual land telephone lines

are carried within a telephone cable yet any particular landline phone connection can be private without interference from other lines in the cable.

The 31 pairs of spinal nerves and the 12 pairs of cranial nerves that arise from the brain stem constitute the peripheral nervous system. After they emerge, the spinal nerves progressively branch to form a vast network of peripheral nerves that supply the tissues. Because each segment of the spinal cord gives rise to a pair of spinal nerves that ultimately supplies a particular region of the body with both afferent and efferent fibers, the location and extent of sensory and motor deficits associated with spinal-cord injuries can be clinically important in determining the level and extent of the cord injury.

Each spinal nerve carries afferent sensory fibers from a particular region on the body surface called a **dermatome**. The body surface can be mapped with multiple dermatomes, each one associated with a different spinal nerve (❙Figure 5-29a).

Clinical Note **Shingles**, an infection of a sensory nerve fiber and the area of skin supplied by this fiber, is caused by *varicella-zoster virus,* the same virus that causes chicken pox. After a bout of chicken pox, some of the virus may survive and travel in sensory axons to dorsal root ganglia, where it can remain dormant and produce no symptoms for years. When the immune system weakens, as it can with aging, debilitating diseases, or stress, the virus may reactivate and travel back through the sensory axon to the skin. Here the virus causes pain and a blistery rash along a band of skin supplied by the affected nerve; that is, along a dermatome (❙Figure 5-29b). Typically an episode of shingles is limited to a single nerve fiber and dermatome. Shingles occurs in about 30% of those who have had chicken pox and is most common in people older than 50. With development of the chicken pox vaccine in 1995 and development of the shingles vaccine in 2006, the incidence of shingles will continue to decline.

Spinal nerves also carry fibers that branch off to supply internal organs, and sometimes pain originating from one of these organs is "referred" to the corresponding dermatome (surface region) supplied by the same spinal nerve. **Referred pain** originating in the heart, for example, may appear to come from the left shoulder and arm. The mechanism responsible for referred pain is not completely understood. Inputs arising from the heart presumably share a pathway to the brain in common with inputs from the left upper extremity. The higher perception levels, being more accustomed to receiving sensory input from the left arm than from the heart, may interpret the input from the heart as having arisen from the left arm.
The spinal cord is responsible for the integration of many innate reflexes.

The spinal cord is strategically located between the brain and the afferent and efferent fibers of the PNS; this location enables the spinal cord to fulfill

its two primary functions: (1) serving as a link for transmission of information between the brain and rest of the body and (2) integrating reflex activity between afferent input and efferent output without involving the brain.

Reflex Arc A **reflex** is any response that occurs automatically without conscious effort. The neural pathway involved in accomplishing reflex activity is known as a **reflex arc**, which typically includes five basic components:

1. Sensory receptor
2. Afferent pathway
3. Integrating center
4. Efferent pathway
5. Effector organ

The *sensory receptor* (*receptor* for short) responds to a stimulus, which is a detectable change in the environment of the receptor. In response to the stimulus, the receptor produces an action potential that is relayed by the *afferent pathway* to the *integrating center* (usually the CNS) for processing. The integrating center processes all information available to it from this receptor, and from all other inputs, and then "makes a decision" about the appropriate response. The instructions from the integrating center are transmitted via the *efferent pathway* to the *effector organ*—a muscle or gland—that carries out the desired response. Unlike conscious behavior, in which any one of numerous responses is possible, a reflex response is predictable, because the pathway is always the same.

Not all reflex activity involves a clear-cut reflex arc, although the basic principles of a reflex (that is, an automatic response to a detectable change) are present. Pathways for unconscious responsiveness digress from the typical reflex arc in two general ways:

1. *Responses at least partly mediated by hormones.* A particular reflex may be mediated solely by either neurons or hormones or may involve a pathway using both.

2. *Local responses that do not involve either nerves or hormones.* For example, the blood vessels in an exercising muscle dilate because of local metabolic changes, thereby increasing blood flow to match the active muscle's metabolic needs.

Reflex Categories Reflexes can be categorized in the following variable ways:

1. As *spinal* or *cranial reflexes*, depending on the CNS level at which the reflex is integrated. **Spinal reflexes** are integrated by the spinal cord, an example of which is the withdrawal reflex, such as automatically withdrawing your hand from a hot object (see p. 284). To a certain extent, the brain may consciously
(a) **Distribution of dermatomes**

❙Figure 5-29 Dermatomes. (a) Each of the dermatomes is a skin region with sensory innervation provided by a specific spinal nerve and is designated in the figure by the name of the nerve supplying this area. (b) A photograph of shingles, a painful blistery rash caused by infection with varicella-zoster virus of a single spinal nerve and its associated dermatome.

override a spinal reflex, such as when you voluntarily prevent urination if the time is not convenient when the micturition (bladder-emptying) reflex is called forth when your bladder begins to be stretched as it fills with urine (see p. 531). This modulatory influence of the brain is above and beyond the level of the spinal reflex. In the case of a **cranial reflex**, the reflex itself is subconsciously integrated by the brain at levels lower than the cortex, such as by the brain stem or hypothalamus. An example of a cranial reflex is constriction of the pupils of your eyes in response to bright light (see p. 194).

2. As *innate* or *conditioned reflexes,* depending on whether the reflex is inborn or learned. **Innate** (or **simple** or **basic**) **reflexes** are built-in, unlearned responses. The withdrawal reflex, the micturition reflex, and the pupillary constriction reflex are all examples of innate reflexes. **Conditioned** (or **acquired**) **reflexes** are a result of learning, such as increased secretion of saliva on smelling a favorite food being prepared. Increased salivation occurs via the innate salivary reflex (a cranial reflex) on tasting a favorite food, but your mouth waters (increased salivation) via a conditioned salivary reflex once you have learned to associate the smell with the anticipation of getting to eat the tasty food (see p. 575). The spinal cord and brain stem integrate innate reflexes, whereas higher brain levels usually process acquired reflexes. (For a discussion of the role of conditioned reflexes in many sports skills, see the accompanying boxed feature, ❙A Closer Look at Exercise Physiology.)

3. As *somatic* or *autonomic,* depending on which efferent division of the peripheral nervous system and which effector organs are involved. Output in a **somatic reflex** is transmitted by motor neurons to skeletal muscles, an example being the withdrawal reflex. Output in an **autonomic** (or **visceral**) **reflex** is

Swan Dive or Belly Flop: It's a Matter of CNS Control

SPORT SKILLS MUST BE LEARNED. Much of the time, strong innate reflexes must be overridden to perform the skill. Learning to dive into water, for example, is very difficult initially. Strong head-righting reflexes controlled by sensory organs in the neck and ears initiate a straightening of the neck and head before the beginning diver enters the water, causing what is commonly known as a "belly flop." In a backward dive, the head-righting reflex causes the beginner to land on his or her back or even in a sitting position. To perform any motor skill that involves body inversions, somersaults, back flips, or other abnormal postural movements, the person must learn to consciously inhibit basic postural reflexes. This is accomplished by having the person concentrate on specific body positions during the movement. For example, to perform a somersault, the person must concentrate on keeping the chin tucked and grabbing the knees. After the skill is performed repeatedly, new synaptic patterns are formed in the CNS, and the new or conditioned response substitutes for the natural innate reflex responses. Sport skills must be practiced until the movement becomes automatic; then the athlete is free during competition to think about strategy or the next move to be performed in a routine.

carried via the autonomic nervous system to smooth muscle, cardiac muscle, or glands. The micturition, pupillary constriction, and salivary reflexes are all autonomic reflexes. Another example of an autonomic reflex is the baroreceptor (blood-pressure regulating) reflex (see p. 367).

4. As *monosynaptic* or *polysynaptic*, depending on how many synapses are in the reflex arc.

The simplest reflex is the stretch reflex, in which an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle terminates directly on the efferent neuron supplying the same skeletal muscle to cause it to contract and counteract the stretch (see p. 282). In this reflex, the integrating center is the single synapse within the spinal cord between the afferent and the efferent pathways. The output of this system (whether or not the muscle contracts in response to passive stretch) depends on the extent of summation of EPSPs at the cell body of the efferent neuron arising from the frequency of afferent input (determined by the extent of stretch detected by the receptor). Integration in this case simply involves summation of EPSPs from a single source. The stretch reflex is a **monosynaptic** ("one synapse") **reflex** because the only synapse in the reflex arc is the one between the afferent neuron and the efferent neuron. All other reflexes are **polysynaptic** ("many synapses") because interneurons are interposed in the reflex pathway and, therefore, a number of synapses are involved.

You will learn more about specific reflexes in later chapters devoted to the involved effector organs.

2. Distinguish among a *tract, ganglion, nucleus, center,* and *nerve.*

3. List the components of a reflex arc.

4. Describe the ways in which reflexes can be categorized.

Homeostasis: Chapter in Perspective

To interact in appropriate ways with the external environment to stay alive, such as in acquiring food, and to make the internal adjustments necessary to maintain homeostasis, the body must be informed about any changes taking place in the external and the internal environment and must be able to process this information and send messages to various muscles and glands to accomplish the desired results. The nervous system, one of the body's two major regulatory systems, plays a central role in this life-sustaining communication. The central nervous system, which consists of the brain and spinal cord, receives information about the external and the internal environment by means of afferent peripheral nerves. After sorting, processing, and integrating this input, the CNS sends directions, by means of efferent peripheral nerves, to bring about appropriate muscular contractions and glandular secretions.

With its swift electrical signaling system, the nervous system is especially important in controlling the rapid responses of the body. Many neurally controlled muscular and glandular activities are aimed toward maintaining homeostasis. The CNS is the main site of integration between afferent input and efferent output. It links the appropriate response to a particular input so that conditions compatible with life are maintained in the body. For example, when informed by the afferent nervous system that blood pressure has fallen, the CNS sends appro-

priate commands via the efferent nervous system to the heart and blood vessels to increase blood pressure to normal. Likewise, when informed that the body is overheated, the CNS promotes secretion of sweat, among other cooling responses. Evaporation of sweat helps cool the body to normal temperature. Were it not for this processing and integrating ability of the CNS, maintaining homeostasis in an organism as complex as a human would be impossible.

At the simplest level, the spinal cord integrates many basic protective and evacuative reflexes that do not require conscious participation, such as withdrawing from a painful stimulus and emptying of the urinary bladder. In addition to serving as a more complex integrating link between afferent input and efferent output, the brain is responsible for the initiation of all voluntary movement; complex perceptual awareness of the external environment; self-awareness; language; and abstract neural phenomena such as thinking, learning, remembering,

consciousness, emotions, creativity, and personality traits. All neural activity—from the most private thoughts to commands for motor activity, from enjoying a concert to retrieving memories from the distant past—is ultimately attributable to propagation of action potentials along individual nerve cells and chemical transmission between cells.

During evolutionary development, the nervous system has become progressively more complex. Newer, more complicated, and more sophisticated layers of the brain have been piled on top of older, more primitive regions. Mechanisms for governing many basic activities necessary for survival are built into the older parts of the brain. The newer, higher levels progressively modify, enhance, or nullify actions coordinated by lower levels in a hierarchy of command; they also add new capabilities. Many of these higher neural activities are not aimed at maintaining life, but they add immeasurably to the quality of being alive.

Review Exercises Answers begin on p. A-26

Reviewing Terms and Facts

1. The major function of the CSF is to nourish the brain. *(True or false?)*

2. In emergencies when O_2 supplies are low, the brain can perform anaerobic metabolism. *(True or false?)*

3. Stellate cells initially process sensory input to the cortex, whereas pyramidal cells send fibers from the cortex to terminate on efferent motor neurons. *(True or false?)*

4. Damage to the left cerebral hemisphere brings about paralysis and loss of sensation on the left side of the body. *(True or false?)*

5. The hands and structures associated with the mouth have a disproportionately large share of representation in both the sensory and the motor cortexes. *(True or false?)*

6. The left cerebral hemisphere specializes in artistic and musical ability, whereas the right side excels in verbal and analytical skills. *(True or false?)*

7. The specific function a particular cortical region will carry out is permanently determined during embryonic development. *(True or false?)*

8. The amygdala is the brain area where long-term potentiation and memory consolidation take place. *(True or false?)*

9. _____ is a decreased responsiveness to an indifferent stimulus that is repeatedly presented.

10. The process of transferring and fixing short-term memory traces into long-term memory stores is known as _____.

11. Afferent fibers enter through the _____ root of the spinal cord, and efferent fibers leave through the _____ root.

12. Using the answer code on the right, indicate which neurons are being described (a characteristic may apply to more than one class of neurons):

1. have receptor at peripheral endings
2. lie entirely within the CNS
3. lie primarily within the peripheral nervous system
4. innervate muscles and glands
5. cell body is devoid of presynaptic inputs
6. predominant type of neuron
7. responsible for thoughts, emotions, memory, etc.

    (a) afferent neurons
    (b) efferent neurons
    (c) interneurons

13. Match the following:

1. consists of nerves carrying information between the periphery and the CNS
2. consists of the brain and spinal cord
3. division of the peripheral nervous system that transmits signals to the CNS
4. division of the peripheral nervous system that transmits signals from the CNS
5. supplies skeletal muscles
6. supplies smooth muscle, cardiac muscle, and glands

    (a) somatic nervous system
    (b) autonomic nervous system
    (c) central nervous system
    (d) peripheral nervous system
    (e) efferent division
    (f) afferent division

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Discuss the function of each of the following: astrocytes, oligodendrocytes, ependymal cells, microglia, cranium, vertebral column, meninges, cerebrospinal fuid, and blood–brain barrier.

2. Compare the composition of white and gray matter.

3. Draw and label the major functional areas of the cerebral cortex, indicating the functions attributable to each area.

4. Define *cognition*.

5. Describe the circumstances in which the default mode network is active.

6. Discuss the function of each of the following parts of the brain: thalamus, hypothalamus, basal nuclei, limbic system, cerebellum, and brain stem.

7. Define *somesthetic sensations* and *proprioception*.

8. Discuss the roles of Broca's area and Wernicke's area in language.

9. Compare short-term and long-term memory.

10. Discuss the difference between AMPA and NMDA glutamate receptors and their roles in long-term potentiation.

11. What is the reticular activating system?

12. Describe the appearance and consciousness level associated with each waveform on an electroencephalogram.

13. Compare slow-wave and paradoxical (REM) sleep.

14. Discuss what types of neuronal cell bodies are located in the dorsal, ventral, and lateral horns of the spinal cord.

15. Distinguish between a monosynaptic and a polysynaptic refex.

Applying Clinical Reasoning

Julio D., who had recently retired, was enjoying an afternoon of playing golf when suddenly he experienced a severe headache and dizziness. These symptoms were quickly followed by numbness and partial paralysis on the upper right side of his body, accompanied by an inability to speak. After being rushed to the emergency room, Julio was diagnosed as having suffered a stroke. Given the observed neurological impairment, what areas of his brain were affected?

Thinking at a Higher Level

1. Special studies designed to assess the specialized capacities of each cerebral hemisphere have been performed on "split-brain" patients. In these people, the corpus callosum—the bundle of fibers that links the two halves of the brain—has been surgically cut to prevent the spread of epileptic seizures from one hemisphere to the other. Even though no overt changes in behavior, intellect, or personality occur in these patients, because both hemispheres individually receive the same information, deficits are observable with tests designed to restrict information to one brain hemisphere at a time. One such test involves limiting a visual stimulus to only half of the brain. Because of a crossover in the nerve pathways from the eyes to the occipital cortex, the visual information to the right of a midline point is transmitted to only the left half of the brain, whereas visual information to the left of this point is received by only the right half of the brain. A split-brain patient presented with a visual stimulus that reaches only the left hemisphere accurately describes the object seen, but when a visual stimulus is presented to only the right hemisphere, the patient denies having seen anything. The right hemisphere does receive the visual input, however, as demonstrated by nonverbal tests. Even though a split-brain patient denies having seen anything after an object is presented to the right hemisphere, the patient can correctly match the object by picking it out from among several objects, usually to the patient's surprise. What is your explanation of this finding?

2. Which of the following symptoms are most likely to occur as the result of a severe blow to the back of the head?
   a. paralysis
   b. hearing impairment
   c. visual disturbances
   d. burning sensations
   e. personality disorders

3. The hormone insulin enhances the carrier-mediated transport of glucose into most of the body's cells but not into brain cells. The uptake of glucose from the blood by neurons does not depend on insulin. Knowing the brain's need for a continuous supply of blood-borne glucose, predict the effect that insulin excess would have on the brain.

4. Give examples of conditioned refexes you have acquired.

5. Under what circumstances might it be inadvisable to administer a clot-dissolving drug to a stroke victim?

The Peripheral Nervous System: Afferent Division; Special Senses
Science Source

A scanning electron micrograph of rods and cones. Rods and cones are the photoreceptors (light detectors) in the eye. Their outer segments, which are rod shaped in rods (*blue*) and cone shaped in cones (*green*), contain photopigments that absorb light in the initial step of vision.

Homeostasis Highlights

The nervous system, one of the two major regulatory systems of the body, consists of the central nervous system (CNS), composed of the brain and spinal cord, and the **peripheral nervous system (PNS)**, composed of the afferent and efferent fibers that relay signals between the CNS and the periphery (other parts of the body).

The **afferent division** of the PNS detects, encodes, and transmits peripheral signals to the CNS, thus informing the CNS about the internal and the external environment. This afferent input to the controlling centers of the CNS is essential in maintaining homeostasis. To make appropriate adjustments in effector organs via efferent output, the CNS has to "know" what is going on. Afferent input is also used to plan for voluntary actions unrelated to homeostasis.

6.1 Receptor Physiology

The peripheral nervous system consists of nerve fibers that carry information between the CNS and other parts of the body. The afferent division of the PNS sends information about the external and the internal environment to the CNS.

A **stimulus** is a change detectable by the body. Stimuli exist in various energy forms, or **modalities**, such as heat, light, sound, pressure, and chemical changes. Afferent neurons have **sensory receptors** (*receptors* for short) at their peripheral endings that respond to stimuli in both the external world and the internal environment. (Although both are called *receptors,* stimulus sensitive sensory receptors are distinctly different from the plasma-membrane protein receptors that bind with extracellular chemical messengers; see p. 59.) Because the only way afferent neurons can transmit information to the CNS about stimuli is via action potential propagation, receptors must convert these other forms of energy into electrical signals. Stimuli bring about graded potentials known as **receptor potentials** in the receptor. The conversion of stimulus energy into a receptor potential is known as **sensory transduction**. Receptor potentials in turn trigger action potentials in the afferent fiber.

Receptors have differential sensitivities to various stimuli.

Each type of receptor is specialized to respond to one type of stimulus, its **adequate stimulus**. For example, receptors in the eye are sensitive to light, receptors in the ear to sound waves, and heat receptors in the skin to heat energy. Because of this differential sensitivity of receptors, we cannot see with our ears or hear with our eyes. Some receptors can respond weakly to stimuli other than their adequate stimulus, but even when activated by a different stimulus, a receptor still gives rise to the sensation usually detected by that receptor type. As an example, the adequate stimulus for eye receptors (photoreceptors) is light, to which they are exquisitely sensitive, but these receptors can also be activated to a lesser degree by mechanical stimulation. When hit in the eye, a person often "sees stars" because the mechanical pressure stimulates the photoreceptors.

Types of Receptors According to Their Adequate Stimulus Depending on the type of energy to which they ordinarily respond, receptors are categorized as follows:

- **Photoreceptors** are responsive to visible light.

- **Mechanoreceptors** are sensitive to mechanical energy. Examples include skeletal muscle receptors sensitive to stretch, the receptors in the ear containing fine hairs that are bent as a result of sound waves, and blood pressure–monitoring baroreceptors.

- **Thermoreceptors** are sensitive to heat and cold.

- **Osmoreceptors** detect changes in the concentration of solutes in the extracellular fluid (ECF) and the resultant changes in osmotic activity (see p. 67).

- **Chemoreceptors** are sensitive to specific chemicals. Chemoreceptors include the receptors for taste and smell and those located deeper within the body that detect O_2 and CO_2 concentrations in the blood or the chemical content of the digestive tract.

- **Nociceptors**, or **pain receptors**, are sensitive to tissue damage such as cutting or burning. Intense stimulation of any receptor is also perceived as painful.

Although not yet fully accepted as a receptor category, **itch-specific receptors** were recently discovered in the skin. This finding is contrary to the long-held belief that itch is a mild manifestation of pain elicited by stimulation of nociceptors on exposure to itch-inducing substances, for example histamine released in response to a mosquito bite. The urge to scratch can also be a symptom of some systemic conditions as a result of central processing unrelated to input from skin itch receptors, as may occur in kidney or liver failure for example.

Some sensations are compound sensations in that their perception arises from central integration of several simultaneously activated primary sensory inputs. For instance, the perception of wetness comes from touch, pressure, and thermal receptor input; there is no such thing as a "wetness receptor."

Uses for Information Detected by Receptors The information detected by receptors is conveyed via afferent neurons to the CNS, where it is used for various purposes:

- Afferent input is essential for control of efferent output, both for regulating motor behavior in accordance with external circumstances and for coordinating internal activities directed at maintaining homeostasis. At the most basic level, afferent input provides information (of which the person may or may not be consciously aware) for the CNS to use in directing activities necessary for survival. On a broader level, we could not interact successfully with our environment or with one another without sensory input.

- Processing of sensory input by the reticular activating system in the brain stem is critical for cortical arousal and consciousness (see p. 167).

- Central processing of sensory information gives rise to our perceptions of the world around us.

- Selected information delivered to the CNS may be stored for future reference.

- Sensory stimuli can have a profound effect on our emotions. The smell of just-baked apple pie, the sensuous feel of silk, the sight of a loved one, the sound of someone sharing bad news—sensory input can gladden, sadden, arouse, calm, anger, frighten, or evoke a range of other emotions.

We next examine how adequate stimuli initiate action potentials that ultimately are used for these purposes.

A stimulus alters the receptor's permeability, leading to a graded receptor potential.

A receptor may be either (1) a specialized ending of the afferent neuron or (2) a separate receptor cell closely associated with the peripheral ending of the neuron. Stimulation of a receptor alters its membrane permeability, usually by opening channels that permit an inward flux of Na^+, which depolarizes the receptor membrane (see p. 88). (There are exceptions; for example, pho-

toreceptors are hyperpolarized on stimulation.) This local depolarization, the receptor potential, is a graded potential. As is true of all graded potentials, the stronger the stimulus, the greater the permeability change and the larger the receptor potential (see p. 89). Also, receptor potentials have no refractory period, so summation in response to rapidly successive stimuli is possible. Because the receptor region has few to no voltage-gated Na^+ channels and thus has a high threshold, action potentials do not take place at the receptor itself. (The channels in the receptor region that open in response to a stimulus are not voltage-gated Na^+ channels and vary depending on the receptor type.) For long-distance transmission, the receptor potential must be converted into action potentials that can be propagated along the afferent fiber.

Receptor potentials may initiate action potentials in the afferent neuron.

If a receptor potential is large enough, it may trigger an action potential in the afferent neuron membrane next to the receptor by promoting the opening of voltage-gated Na^+ channels in this adjacent region. In myelinated afferent fibers, this trigger zone is the node of Ranvier closest to the receptor. The means by which the Na^+ channels are opened differ depending on whether the receptor is a specialized afferent ending or a separate cell.

■ In the case of a specialized afferent ending, local current flow between the activated receptor ending undergoing a receptor potential and the cell membrane next to the receptor depolarizes this adjacent region (❙Figure 6-1a). If the region is depolarized to threshold, voltage-gated Na^+ channels open here, triggering an action potential that is conducted along the afferent fiber to the CNS.

■ In the case of a separate receptor cell, the receptor cell synapses with the ending of the afferent neuron (❙Figure 6-1b). A receptor potential promotes the opening of voltage-gated Ca^{2+} channels in the receptor cell. The resultant Ca^{2+} entry causes the release by exocytosis of a neurotransmitter that diffuses across the synaptic cleft and binds with specific protein receptors on the afferent neuron membrane. This binding opens chemically gated Na^+ receptor-channels (see p. 116). If the re-
(a) Receptor potential in specialized afferent ending

1. In sensory receptors that are specialized afferent neuron endings, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.

2. Local current flow between depolarized receptor ending and adjacent region opens voltage-gated Na^+ channels.

3. Na^+ entry initiates action potential in afferent fiber that self-propagates to CNS.
(b) Receptor potential in separate receptor cell

1. In sensory receptors that are separate cells, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.

2. This local depolarization opens voltage-gated Ca^{2+} channels.

3. Ca^{2+} entry triggers exocytosis of neurotransmitter.

4. Neurotransmitter binding opens chemically gated receptor-channels at afferent ending, permitting net Na^+ entry.

5. Resultant depolarization opens voltage-gated Na^+ channels in adjacent region.

6. Na^+ entry initiates action potential in afferent fiber that self-propagates to CNS.

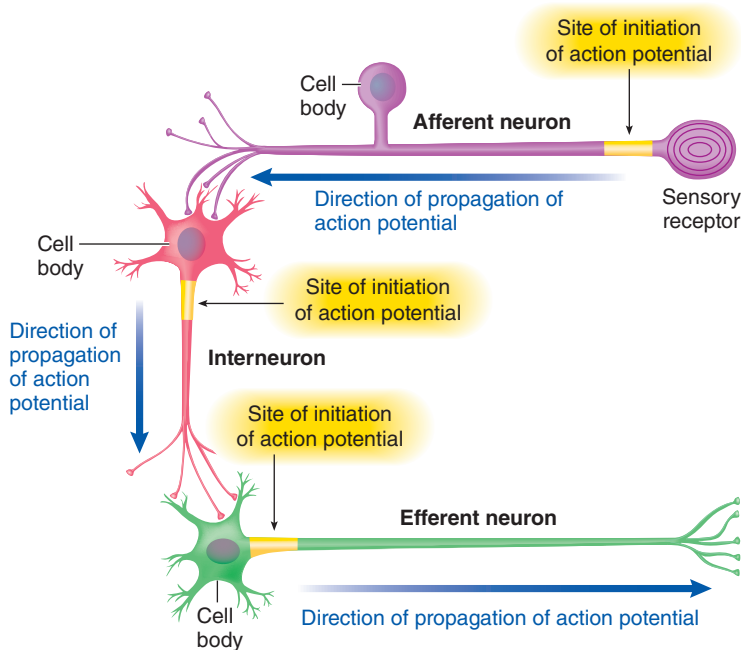
❙Figure 6-1 **Conversion of receptor potential into action potentials.** (a) Specialized afferent ending as sensory receptor. Local current flow between a depolarized receptor ending undergoing a receptor potential and the adjacent region initiates an action potential in the afferent fiber by opening voltage-gated Na^+ channels. (b) Separate receptor cell as sensory receptor. The depolarized receptor cell undergoing a receptor potential releases a neurotransmitter that binds with chemically gated channels in the afferent fiber ending. This binding leads to a depolarization that opens voltage-gated Na^+ channels, initiating an action potential in the afferent fiber.


Figure 6-2 Comparison of the initiation site of an action potential in the three types of neurons.

many pressure receptors in the skin as does a more forceful touch applied to the same area. Stimulus intensity is therefore distinguished both by the frequency of action potentials generated in the afferent neuron and by the number of receptors and thus afferent fibers activated within the area.

Receptors may adapt slowly or rapidly to sustained stimulation.

Stimuli of the same intensity do not always result in receptor potentials of the same magnitude in the same receptor. Some receptors diminish the extent of their depolarization despite sustained stimulus strength, a phenomenon called **adaptation**. Subsequently, the frequency of action potentials generated in the afferent neuron decreases—that is, the receptor "adapts" to the stimulus by no longer responding to it to the same degree.

Types of Receptors According to Their Speed of Adaptation Depending on their speed of adaptation,

sultant Na$^+$ entry depolarizes the afferent neuron ending to threshold, voltage-gated Na$^+$ channels open here, triggering an action potential that self-propagates to the CNS.

Note that the initiation site of action potentials in an afferent neuron differs from the site in an efferent neuron or interneuron. In the latter two types of neurons, action potentials are initiated at the axon hillock located at the start of the axon next to the cell body (see p. 96). By contrast, action potentials are initiated at the peripheral end of an afferent nerve fiber next to the receptor, a long distance from the cell body (**Figure 6-2**).

The intensity of the stimulus is reflected by the magnitude of the receptor potential. The larger the receptor potential, the greater the frequency of action potentials generated in the afferent neuron (**Figure 6-3**). A larger receptor potential cannot bring about a larger action potential (because of the all-or-none law), but it can induce more rapid firing of action potentials (see p. 99). The more rapidly an afferent fiber fires, the more neurotransmitter it releases. This neurotransmitter influences the next cell in the neural pathway, passing on information about stimulus strength. Stimulus strength is also reflected by the size of the area stimulated. Stronger stimuli usually affect larger areas, so correspondingly more receptors respond. For example, a light touch does not activate as

Stimulus strength

Magnitude of receptor potential

Frequency of action potentials in afferent fiber

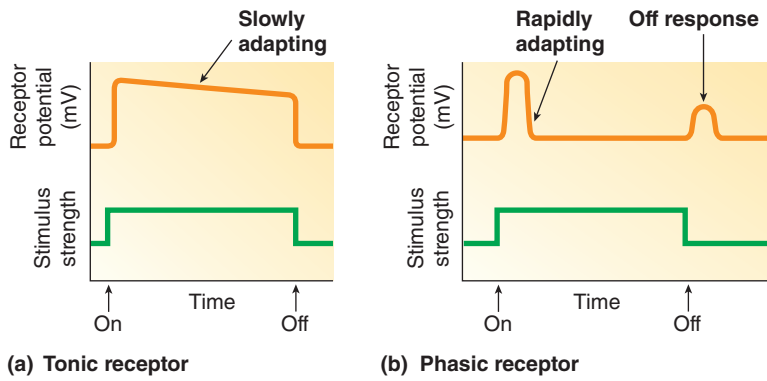
Figure 6-3 Coding of stimulus strength by an afferent neuron.
FIGURE FOCUS: *How would an acid-monitoring neuron's activity change compared to normal if body fluids became too acidic? If they became too alkaline?*


Figure 6-4 Tonic and phasic receptors. (a) A tonic receptor does not adapt at all or adapts slowly to a sustained stimulus and thus provides continuous information about the stimulus. (b) A phasic receptor adapts rapidly to a sustained stimulus and frequently exhibits an off response when the stimulus is removed. Thus, the receptor signals changes in stimulus intensity rather than relaying status quo information.

receptors are classified as *tonic receptors* or *phasic receptors.* **Tonic receptors** do not adapt or adapt slowly (Figure 6-4a). These receptors are useful when it is valuable to maintain information about a stimulus. Examples of tonic receptors are muscle stretch receptors, which monitor muscle length, and joint proprioceptors, which measure the degree of joint flexion. To maintain posture and balance, the CNS must continually get information about the degree of muscle length and joint position. It is important, therefore, that these receptors do *not* adapt to a stimulus but continue to generate action potentials to relay this information to the CNS.

Phasic receptors are rapidly adapting receptors. The receptor quickly adapts by no longer responding to a maintained stimulus. Some phasic receptors, most notably the *Pacinian corpuscle,* respond with a slight depolarization called the **off response** when the stimulus is removed (Figure 6-4b). Phasic receptors are useful when it is important to signal a change in stimulus intensity rather than to relay status quo information. Many *tactile (touch) receptors* that signal changes in pressure on the skin surface are phasic receptors. Because these receptors adapt rapidly, you are not continually conscious of wearing your watch, rings, and clothing. When you put something on, you soon become accustomed to it because of these receptors' rapid adaptation. When you take the item off, you are aware of its removal because of the off response.

Tactile Receptors Tactile (touch) receptors in the skin are mechanoreceptors. The mechanical forces of a stimulus distort nonspecific cation channel proteins in the plasma membrane of these receptors, leading to net Na^+ entry, which causes a receptor potential that triggers an action potential in the afferent fiber. Sensory input from these receptors

informs the CNS of the body's contact with objects in the external environment. Tactile receptors include the following (Figure 6-5):

- A **hair receptor** is rapidly adapting and senses hair movement and very gentle touch, such as stroking the hair on your arm with a wisp of cotton.
- A **Merkel's disc** is slowly adapting and detects light, sustained touch and texture, such as reading Braille.
- A **Pacinian corpuscle** is rapidly adapting and responds to vibrations and deep pressure.
- **Ruffini endings** are slowly adapting and respond to deep, sustained pressure and stretch of the skin, such as during a massage.
- A **Meissner's corpuscle** is rapidly adapting and sensitive to light, fluttering touch, such as tickling with a feather.

Mechanism of Adaptation in the Pacinian Corpuscle The mechanism by which adaptation is accomplished varies for different receptors and is not fully understood for all receptor types. Many receptors adapt as a result of inactivation of channels that opened in response to the stimulus. Adaptation in the well-studied Pacinian corpuscle depends on the physical properties of this receptor. A Pacinian corpuscle is

Hair receptor: hair movement and very gentle touch

Merkel's disc: light, sustained touch

Pacinian corpuscle: vibrations and deep pressure

Ruffini endings: deep pressure

Meissner's corpuscle: light, fluttering touch
Figure 6-5 Tactile receptors in the skin.

a specialized receptor ending that consists of concentric layers of connective tissue resembling layers of an onion wrapped around the peripheral terminal of an afferent neuron. When pressure is first applied to the Pacinian corpuscle, the underlying terminal responds with a receptor potential of a magnitude that reflects the intensity of the stimulus. As the stimulus continues, the pressure energy is dissipated because it causes the receptor layers to slip (just as steady pressure on a peeled onion causes its layers to slip). Because this physical effect filters out the steady component of the applied pressure, the underlying neuronal ending no longer responds with a receptor potential—that is, adaptation has occurred.

Adaptation should not be confused with habituation (see p. 159). Although both these phenomena involve decreased neural responsiveness to repetitive stimuli, they operate at different points in the neural pathway. Adaptation is a receptor adjustment in the PNS, whereas habituation involves a modification in synaptic effectiveness in the CNS.

Visceral afferents carry subconscious input; sensory afferents carry conscious input.

Action potentials generated by receptors in afferent fibers in response to stimuli are propagated to the CNS. Afferent information about the internal environment, such as blood pressure and the concentration of CO_2 in the body fluids, never reaches the level of conscious awareness, but this input is essential for determining the appropriate efferent output to maintain homeostasis. The incoming pathway for information derived from the internal viscera (organs in the body cavities, such as the abdominal cavity) is called a **visceral afferent**. Even though mostly subconscious information is transmitted via visceral afferents, people do become aware of pain signals arising from viscera. Afferent input derived from receptors located at the body surface or in the muscles or joints typically reaches the level of conscious awareness. This input is known as *sensory information,* and the incoming pathway is considered a **sensory afferent**. Sensory information is categorized as (1) **somatic** (body sense) **sensation** arising from the body surface, including *somesthetic sensation* from the skin and *proprioception* from the muscles, joints, skin, and inner ear (see p. 147); or (2) **special senses**, including *vision, hearing, equilibrium, taste,* and *smell.* (See the accompanying boxed feature, ❙A Closer Look at Exercise Physiology, for a description of the usefulness of proprioception in athletic performance.) Final processing of sensory input by the CNS not only is essential for interaction with the environment for basic survival (for example, food procurement and defense from danger), but also adds immeasurably to the richness of life.

Each somatosensory pathway is "labeled" according to modality and location.

On reaching the spinal cord, afferent information has two possible destinies: (1) it may become part of a reflex arc, bringing about an appropriate effector response, or (2) it may be relayed upward to the brain via ascending pathways for further processing and possible conscious awareness. Pathways conveying conscious somatic sensation, the **somatosensory pathways**, consist of discrete chains of neurons, or **labeled lines**, synaptically interconnected in a particular sequence to accomplish progressively more sophisticated processing of the sensory information.

Labeled Lines The afferent neuron with its peripheral receptor that first detects the stimulus is known as a **first-order sensory neuron**. It synapses on a **second-order sensory neuron**, either in the spinal cord or the medulla, depending on which sensory pathway is involved. This neuron then synapses on a **third-order sensory neuron** in the thalamus, and so on. With each step, the input is processed further. A particular sensory modality detected by a specialized receptor type is sent over a specific afferent and ascending pathway (a neural pathway committed to that modality) to excite a defined area in the somatosensory cortex—that is, a particular sensory input is **projected** to a specific region of the cortex (see ❙Figure 5-26a, p. 175, for an example). Thus, different types of incoming information are kept separated within specific labeled lines between the periphery and the cortex. In this way, even though all information is propagated to the CNS via the same type of signal (action potentials), the brain can decode the type and location of the stimulus. ❙Table 6-1 summarizes how the CNS is informed of the type (what), location (where), and intensity (how much) of a stimulus.

Phantom Pain Activation of a sensory pathway at any point gives rise to the same sensation that would be produced by stimulation of the receptors in the body part itself. This phenomenon is the traditional explanation for **phantom pain**—for example, pain perceived as originating in the foot by a person whose leg has been amputated at the knee. Irritation of the severed endings of the afferent

❙**TABLE 6-1** Coding of Sensory Information

Stimulus Property	Mechanism of Coding
Type of stimulus (stimulus modality)	Distinguished by the type of receptor activated and the specific pathway over which this information is transmitted to a particular area of the cerebral cortex
Location of stimulus	Distinguished by the location of the activated receptive field and the pathway that is subsequently activated to transmit this information to the area of the somatosensory cortex representing that particular location
Intensity of stimulus (stimulus strength)	Distinguished by the frequency of action potentials initiated in an activated afferent neuron and the number of receptors (and afferent neurons) activated

Back Swings and Prejump Crouches: What Do They Share in Common?

PROPRIOCEPTION, THE SENSE OF THE body's position in space, is critical to any movement and is especially important in athletic performance, whether it be a figure skater performing triple jumps on ice, a gymnast performing a difficult f oor routine, or a football quarterback throwing perfectly to a spot 60 yards downfield. To control skeletal muscle contraction to achieve the desired movement, the CNS must be continuously apprised of the results of its action through sensory feedback.

A number of receptors provide proprioceptive input. Muscle proprioceptors provide feedback information on muscle tension and length. Joint proprioceptors provide feedback on joint acceleration, angle, and direction of movement. Skin proprioceptors inform the CNS of weight-bearing pressure on the skin.

Proprioceptors in the inner ear, along with those in neck muscles, provide information about head and neck position so that the CNS can orient the head correctly. For example, neck ref exes facilitate essential trunk and limb movements during somersaults, and divers and tumblers use strong movements of the head to maintain spins.

The most complex and probably one of the most important proprioceptors is the muscle spindle (see p. 281). Muscle spindles are found throughout a muscle but tend to be concentrated in its center. Each spindle lies parallel to the muscle fibers within the muscle. The spindle is sensitive to both the muscle's rate of change in length and the final length achieved. If a muscle is stretched, each muscle spindle within the muscle is also stretched, and the afferent neuron whose peripheral axon terminates on the muscle spindle is stimulated. The afferent fiber passes into the spinal cord and synapses directly on the motor neurons that supply the same muscle. Stimulation of the stretched muscle as a result of this stretch ref ex causes the muscle to contract sufficiently to relieve the stretch.

Older persons or those with weak quadriceps (thigh) muscles unknowingly take advantage of the muscle spindle by pushing on the center of the thighs when they get up from a sitting position. Contraction of the quadriceps muscle extends the knee joint, thus straightening the leg. The act of pushing on the center of the thighs when getting up slightly stretches the quadriceps muscle in both limbs, stimulating the muscle spindles. The resultant stretch ref ex aids in contraction of the quadriceps muscles and helps the person assume a standing position.

In sports, people use the muscle spindle to advantage all the time. To jump high, as in basketball jump balls, an athlete starts by crouching down. This action stretches the quadriceps muscles and increases the firing rate of their spindles, thus triggering the stretch ref ex that reinforces the quadriceps muscles' contractile response so that these extensor muscles of the legs gain additional power. The same is true for crouch starts in running events. The backswing in tennis, golf, and baseball similarly provides increased muscular excitation through ref ex activity initiated by stretched muscle spindles.

---

pathways in the stump can trigger action potentials that, on reaching the foot region of the somatosensory cortex, are interpreted as pain in the missing foot. New evidence suggests that in addition, the sensation of phantom pain may arise from extensive remodeling of the brain region that originally handled sensations from the severed limb. This "remapping" of the "vacated" area of the brain is speculated to somehow lead to signals from elsewhere being misinterpreted as pain arising from the missing extremity.

Acuity is influenced by receptive field size and lateral inhibition.

Each somesthetic sensory neuron responds to stimulus information only within a circumscribed region of the skin surface surrounding it; this region is called its **receptive field**. The size of a receptive field varies inversely with the density of receptors in the region; the more closely receptors of a particular type are spaced, the smaller the area of skin each monitors. The smaller the receptive field is in a region, the greater its **acuity** or **discriminative ability**. Compare the tactile discrimination in your fingertips with that in your calf by "feeling" the same object with both. You can sense more precise information about the

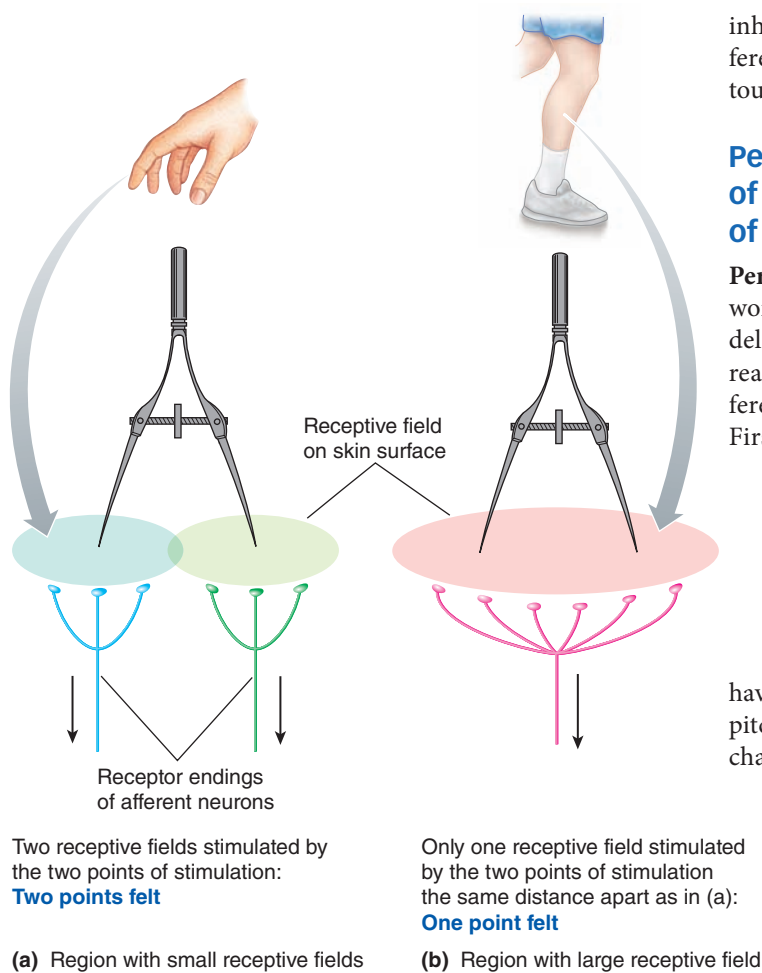
object with your richly innervated fingertips because the receptive fields there are small; as a result, each neuron signals information about small, discrete portions of the object's surface. An estimated 17,000 tactile mechanoreceptors are present in the fingertips and palm of each hand. In contrast, the skin over the calf is served by relatively few sensory endings with larger receptive fields. Subtle differences within each large receptive field cannot be detected (▮Figure 6-6). The distorted cortical representation of various body parts in the sensory homunculus (see p. 149) corresponds precisely with the innervation density; more cortical space is allotted for sensory reception from areas with smaller receptive fields and, accordingly, greater tactile discriminative ability.

Besides receptor density, a second factor influencing acuity is *lateral inhibition*. You can appreciate the importance of this phenomenon by slightly indenting the surface of your skin with the point of a pencil (▮Figure 6-7a). The receptive field is excited immediately under the center of the pencil point where the stimulus is most intense, but the surrounding receptive fields are also stimulated, only to a lesser extent because they are less distorted. If information from these marginally excited afferent fibers in the fringe of the stimulus area were to reach the cortex, localization of the pencil point would

Two receptive fields stimulated by the two points of stimulation:
Two points felt

Only one receptive field stimulated by the two points of stimulation the same distance apart as in (a):
One point felt

(a) Region with small receptive fields

(b) Region with large receptive field


❙Figure 6-6 **Comparison of discriminative ability of regions with small versus large receptive fields.** The relative tactile acuity of a given region can be determined by the *two-point threshold-of-discrimination test.* If the two points of a pair of calipers applied to the surface of the skin stimulate two different receptive fields, two separate points are felt. If the two points touch the same receptive field, they are perceived as only one point. By adjusting the distance between the caliper points, one can determine the minimal distance at which the two points can be recognized as two rather than one, which reflects the size of the receptive fields in the region. With this technique, it is possible to plot the discriminative ability of the body surface. The two-point threshold ranges from 2 mm in the fingertip (enabling a person to read Braille, where the raised dots are spaced 2.5 mm apart) to 48 mm in the poorly discriminative skin of the calf of the leg.

be blurred. To facilitate localization and sharpen contrast, **lateral inhibition** occurs within the CNS (❙Figure 6-7b, p. 189). With lateral inhibition, each activated signal pathway inhibits the pathways next to it by stimulating inhibitory interneurons that pass laterally between ascending fibers serving neighboring receptive fields. The most strongly activated pathway originating from the center of the stimulus area inhibits the less excited pathways from the fringe areas to a greater extent than the weakly activated pathways in the fringe areas inhibit the more excited central pathway. Blockage of further transmission in the weaker inputs increases the contrast between wanted and unwanted information so that the pencil point can be precisely localized. The extent of lateral

inhibitory connections within sensory pathways varies for different modalities. Those with the most lateral inhibition—touch and vision—bring about the most accurate localization.

Perception is the conscious awareness of surroundings derived from interpretation of sensory input.

Perception is our conscious interpretation of the external world as created by the brain from a pattern of nerve impulses delivered to it from receptors. Is the world, as we perceive it, reality? The answer is a resounding no. Our perception is different from what is really "out there" for several reasons. First, humans have receptors that detect only a limited number of existing energy forms. We perceive sounds, colors, shapes, textures, smells, tastes, and temperature but are not informed of magnetic forces, polarized light waves, radio waves, or X-rays because we do not have receptors to respond to the latter energy forms. What is not detected by receptors, the brain will never know. Our response range is limited even for the energy forms for which we do have receptors. For example, dogs can hear a whistle whose pitch is above our level of detection. Second, the information channels to our brains are not high-fidelity recorders. During precortical processing of sensory input, some features of stimuli are accentuated and others are suppressed or ignored, as through lateral inhibition. Third, the cerebral cortex further manipulates the data, comparing the sensory input with other incoming information and with memories of past experiences to extract the significant features—for example, sifting out a friend's words from the hubbub of sound in a school cafeteria. In the process, the cortex often fills in or distorts the information to abstract a logical perception—that is, it "completes the picture." Much of our daily perceptual experience is made by taking what we know and using that information to fill in the blanks to imagine what we do not know. As a simple example, you "see" a white square in ❙Figure 6-8 even though there is not a white square but right-angle wedges taken out of four red circles. Optical illusions illustrate how the brain interprets reality according to its own rules. Thus, our perceptions do not replicate reality. Other species, equipped with different types of receptors, sensitivities, and neural processing, perceive a markedly different world from what we perceive.

Having completed our general discussion of receptor physiology, we now examine one important somatic sensation in greater detail—pain.

(b) The most intensely activated receptor pathway halts transmission of impulses in the less intensely stimulated pathways through lateral inhibition. This process facilitates localization of the site of stimulation.

6.2 Pain

Pain is primarily a protective mechanism triggered on stimulation of danger-sensing nociceptors (pain receptors) that brings to conscious awareness tissue damage that is occurring or about to occur. Because of their value to survival, nociceptors do not adapt to sustained or repetitive stimulation. Storage of painful experiences in memory helps us avoid potentially harmful events in the future.

Stimulation of nociceptors elicits the perception of pain plus motivational and emotional responses.

Pain is more than a direct response to a stimulus. Unlike other somatosensory modalities, the sensation of pain is accompanied by motivated behavioral responses (such as withdrawal or defense) and emotional reactions (such as crying or fear). Also, unlike other sensations, the subjective perception of pain can be influenced by other past or present experiences (for example, heightened pain perception accompanying fear of the dentist or lowered pain perception in an injured athlete during a competitive event). Therefore pain is a personal, multidimensional experience.

Categories of Pain Receptors There are three categories of nociceptors: **Mechanical nociceptors** respond to mechanical damage such as cutting, crushing, or pinching; **thermal nociceptors** respond to temperature extremes, especially heat; and **polymodal nociceptors** respond equally to all kinds of damaging stimuli, including irritating chemicals released from injured tissues.

Clinical Note All nociceptors can be sensitized by *prostaglandins,* which greatly enhance the receptor response to noxious stimuli (that is, it hurts more when prostaglandins are present). Prostaglandins are a type of eicosanoid, a lipid signal molecule derived from a fatty acid in the plasma membrane that acts locally where released (see p. 119). Tissue injury, among other things, can lead to local release of prostaglandins. These paracrines act on nearby nociceptors' peripheral endings to lower their threshold for activation. Aspirin-like drugs inhibit the synthesis of prostaglandins, accounting at least in part for the pain-relieving properties of these drugs.

Fast and Slow Afferent Pain Fibers Pain impulses originating at nociceptors are transmitted to the CNS via one of two types of afferent fibers (❙ Table 6-2). Signals arising from noci-

ITABLE 6-2 Characteristics of Pain

Fast Pain	Slow Pain
Occurs on stimulation of mechanical and thermal nociceptors	Occurs on stimulation of polymodal nociceptors
Carried by small, myelinated A-delta fibers	Carried by small, unmyelinated C fibers
Produces sharp, prickling sensation	Produces dull, aching, burning sensation
Easily localized	Poorly localized
Occurs first	Occurs second; persists for longer time; more unpleasant

ceptors that respond to mechanical damage such as cutting or to thermal damage such as burning are transmitted over small, myelinated **A-delta fibers** at rates of up to 30 m/sec (the **fast pain pathway**). Impulses from polymodal nociceptors that respond to chemicals released into the ECF from damaged tissue are carried by small, unmyelinated **C fibers** at a slower rate of 12 m/sec or less (the **slow pain pathway**). Think about the last time you cut or burned your finger. You undoubtedly felt a sharp twinge of pain at first, with a more diffuse, disagreeable pain commencing shortly thereafter. Pain typically is perceived initially as a brief, sharp, prickling sensation that is easily localized; this is fast pain originating from specific mechanical or heat nociceptors. This feeling is followed by a dull, aching, poorly localized sensation that persists for a longer time and is more unpleasant; this is slow pain triggered by chemicals, especially **bradykinin**, a normally inactive substance that is activated by enzymes released into the ECF from damaged tissue. Bradykinin and related compounds not only provoke pain by stimulating the polymodal nociceptors, but they also contribute to the inflammatory response to tissue injury (see Chapter 12). This slow, aching pain is activated for a prolonged time because of the persistence of released chemicals at the site long after removal of the mechanical or thermal stimulus that caused the tissue damage.

Clinical Note Interestingly, the peripheral receptors of afferent C fibers are activated by **capsaicin**, the ingredient in hot chili peppers that gives them their fiery zing. (In addition to binding with pain receptors, capsaicin binds with heat receptors—hence the burning sensation when eating hot peppers.) Ironically, local application of capsaicin can reduce clinical pain, most likely by overstimulating and damaging the nociceptors with which it binds.

Higher-Level Processing of Pain Input Multiple structures are involved in pain processing—primary afferent pain fibers, ascending pain pathways in the spinal cord, and brain regions involved with pain perception. The primary afferent pain fibers synapse with specific second-order excitatory interneurons in the dorsal horn of the spinal cord. In response

to stimulus-induced action potentials, afferent pain fibers release neurotransmitters that influence these next neurons in line. The two best known pain neurotransmitters are *substance P* and *glutamate.* **Substance P**, which is unique to pain fibers, activates ascending pathways that transmit nociceptive signals to higher levels for further processing (**I** Figure 6-9a). Ascending pain pathways have different destinations in the *cortex,* the *thalamus,* and the *reticular formation.* Cortical somatosensory processing areas localize the pain, whereas other cortical areas participate in other conscious components of the pain experience, such as deliberation about the incident. Pain can still be perceived at the level of the thalamus in the absence of the cortex. The reticular formation increases the level of alertness associated with the noxious encounter. Interconnections from the thalamus and reticular formation to the *hypothalamus* and *limbic system* elicit the behavioral and emotional responses accompanying the painful experience. The limbic system is especially important in perceiving the unpleasant aspects of pain.

Glutamate, the other neurotransmitter released from primary afferent pain terminals, is a major excitatory neurotransmitter (see p. 107). Glutamate acts on two different plasma membrane receptors on the dorsal horn excitatory interneurons, with two different outcomes (see p. 160). First, binding of glutamate with its *AMPA receptors* leads to permeability changes that ultimately result in generation of action potentials in the dorsal horn cells. These action potentials transmit the pain message to higher centers. Second, binding of glutamate with its *NMDA receptors* leads to Ca^{2+} entry into these neurons. This pathway is not involved in the transmission of pain messages. Instead, Ca^{2+} initiates second-messenger systems that make the dorsal horn cells more excitable than usual (see p. 117). This hyperexcitability contributes in part to the exaggerated sensitivity of an injured area to subsequent exposure to painful or even normally nonpainful stimuli, such as a light touch. Think about how exquisitely sensitive your sunburned skin is, even to clothing. Other mechanisms also contribute to supersensitivity of an injured area. For example, responsiveness of the pain-sensing peripheral receptors can be boosted so that they react more vigorously to subsequent stimuli. This exaggerated sensitivity presumably serves a useful purpose by discouraging activities that could cause further damage or interfere with healing of the injured area. Usually this hypersensitivity resolves as the injury heals.

Clinical Note Persistent, **chronic pain**, sometimes excruciating, can occur in the absence of tissue injury. In contrast to the acute pain accompanying peripheral injury, which serves as a normal protective mechanism to warn of impending or actual damage to the body, abnormal chronic pain results from prolonged hypersensitivity within the pain transmission pathways in the peripheral nerves or in the CNS—that is, pain is perceived because of abnormal signaling within the pain pathways in the absence of typical painful stimuli. Recent evidence suggests that the persistent, abnormal excitability among neurons in the pain pathways that leads to chronic pain is the result of a complex interplay among the involved neurons, glial cells (especially microglia and astrocytes; see p. 136), and immune cells. These cells release many types of intercellular chemical messengers, such as inflammatory cytokines (see

Figure 6-9 Substance P pain pathway and analgesic pathway. (a) When activated by a noxious stimulus, some afferent pain pathways release substance P, which activates ascending pain pathways that provide various brain regions with input for processing different aspects of the painful experience. (b) Endogenous opioids released from descending analgesic (pain-relieving) pathways bind with opiate receptors at the synaptic knob of the afferent pain fiber. This binding inhibits the release of substance P, thereby blocking transmission of pain impulses along the ascending pain pathways.

FIGURE FOCUS: *At what point in the depicted analgesic pathway does* Oxycontin (oxycodone) *(derived from a poppy plant) act to suppress pain?*

(a) Substance P pain pathway

(b) Analgesic pathway

p. 118) that are meant to be helpful, such as by promoting healing in response to the original tissue insult. However, many of these molecules increase the excitability of involved neurons via long-term potentiation (LTP) (see p. 160), a state that can last long after the initial damage is healed. By unleashing exagger-ated reactions to stimuli that are ordinarily too mild to trigger a response, the overly sensitive neurons continue to fire and transmit pain signals in the absence of obvious tissue damage. Chronic pain is sometimes categorized as **neuropathic pain**. Worldwide, 15% to 20% of adults suffer from this affliction.

The brain has a built-in analgesic system.

In addition to the chain of neurons connecting peripheral noci-ceptors with higher CNS structures for pain perception, the CNS contains a built-in pain-suppressing or **analgesic system** that suppresses transmission in the pain pathways as they enter the spinal cord. Three brain-stem regions are part of this descending analgesic pathway: the *periaqueductal gray matter* (gray matter surrounding the cerebral aqueduct, a narrow canal that connects the third and fourth ventricular cavities) and specific nuclei in the *medulla* and *reticular formation.* Electrical stimulation of any of these parts of the brain produces profound analgesia.

The periaquaductal gray matter stimulates particular neu-rons whose cell bodies lie in the medulla and reticular forma-tion and that terminate on inhibitory interneurons in the dorsal horn of the spinal cord (❙ Figure 6-9b). These inhibitory inter-neurons release *enkephalin,* an endogenous opioid that binds with **μ opiate receptors** at the afferent pain-fiber terminal. People have long known that **morphine**, a component of the opium poppy, is a powerful analgesic. Researchers considered it unlikely that the body has been endowed with opiate receptors only to interact with chemicals derived from a flower. They therefore began to search for the substances that normally bind with these opiate receptors. The result was the discovery of **endogenous opioids** (morphinelike substances)—the **endor-phins**, **enkephalins**, and **dynorphin**—which are important in the body's natural analgesic system. These endogenous opioids serve as analgesic neurotransmitters. Binding of enkephalin from the dorsal-horn inhibitory interneuron with the afferent pain-fiber terminal suppresses the release of substance P via presynaptic inhibition, thereby blocking further transmission of the pain signal (see p. 111). Morphine binds to these same opiate receptors, which largely accounts for its analgesic prop-erties. Furthermore, injection of morphine into the periaque-ductal gray matter and medulla causes profound analgesia, suggesting that endogenous opioids also are released centrally to block pain.

It is not clear how this natural pain-suppressing mechanism is normally activated. Factors known to modulate pain include exercise, stress, and acupuncture.

■ Endorphins are released during prolonged exercise and are natural painkillers and mood enhancers. Endorphins are be-lieved to be a major player in "runner's high," a feeling of eu-phoria some avid runners (or other vigorous exercisers) get during high-intensity exertion that gets them hooked on exer-cise. Recent evidence suggests that endocannibinoids, body-made marijuanalike chemical messengers, also may contribute to runner's high (see p. 110).

■ Some types of stress also induce analgesia. It is sometimes disadvantageous for a stressed organism to display the normal reaction to pain. For example, when two male lions are fight-ing for dominance of the group, withdrawing, escaping, or resting when injured would mean certain defeat.

■ **Acupuncture analgesia (AA)** is the technique of relieving pain by inserting and manipulating fine needles at key points. The overwhelming body of evidence supports the *acupuncture*

endorphin hypothesis as the primary mechanism of AA's ac-tion. According to this hypothesis, the needle twirling acti-vates specific afferent nerve fibers, which send impulses to the CNS. Here, the incoming impulses cause analgesia by blocking pain transmission at both the spinal-cord and the brain level through use of endorphins and other endogenous opioids. Several other neurotransmitters, such as serotonin and norepi-nephrine, as well as cortisol, the major hormone released dur-ing stress, are implicated as well.

This completes our discussion of somatic sensation. Whereas somatic sensation is detected by widely distributed receptors that provide information about the body's interactions with the environment in general, each of the special senses has highly localized, extensively specialized receptors that respond to unique environmental stimuli. We now turn attention to the special senses, starting with vision.

Check Your Understanding 6.2

1. Explain why pain is considered a multidimensional experience.
2. Compare the type of pain signals transmitted via A-delta fibers and C fibers.
3. Describe the role of endogenous opioids in the body's natural analgesic system.

6.3 Eye: Vision

For vision, the eyes capture the patterns of illumination in the environment as an "optical picture" on a layer of light-sensitive cells, the *retina.* The coded image on the retina is transmitted through the steps of visual processing until it is finally con-sciously perceived as a visual likeness of the original image. Before considering the steps involved in the process of vision, we first examine how the eyes are protected from injury.

Protective mechanisms help prevent eye injuries.

Several mechanisms help protect the eyes from injury. Except for its anterior (front) portion, the eyeball is sheltered by the bony socket in which it is positioned. The **eyelids** act like shutters to protect the exposed part of the eye from environmental insults. They close reflexly to cover the eye under threatening circum-stances, such as rapidly approaching objects, dazzling light, and when the eye or eyelashes are touched. Frequent spontaneous blinking of the eyelids helps disperse the lubricating, cleansing, bactericidal ("germ-killing") **tears**. Tears are produced continu-ously by the **lacrimal gland** in the upper lateral corner under the eyelid. This eye-washing fluid flows across the anterior surface of the eye and drains into tiny canals in the medial corner of each eye (❙ Figure 6-10a), eventually emptying into the back of the nasal passageway. This drainage system cannot handle the pro-fuse tear production during crying, so the tears overflow from the eyes. (The tears associated with crying have a different com-position than the ongoing tear production.) The eyes are also

equipped with protective **eyelashes**, which trap fine, airborne debris such as dust before it can fall into the eye.

The eye is a fluid-filled sphere enclosed by three specialized tissue layers.

Each eye is a spherical, fluid-filled structure enclosed by three layers. From outermost to innermost, these are (1) the *sclera/cornea;* (2) the *choroid/ciliary body/iris;* and (3) the *retina* (❙Figure 6-10b). Most of the eyeball is covered by a tough outer layer of connective tissue, the **sclera**, which forms the visible white part of the eye (❙Figure 6-10a). Anteriorly, the outer layer consists of the transparent **cornea**, through which light rays pass into the interior of the eye. The middle layer underneath the sclera is the highly pigmented **choroid**, which contains many blood vessels that nourish the retina. The choroid layer becomes specialized anteriorly to form the ciliary body and iris, which we describe shortly. The innermost coat under the choroid is the **retina**, which consists of an outer pigmented layer and an inner nervous-tissue layer. The latter contains the *rods* and *cones,* the photoreceptors that convert light energy into nerve impulses. Like the black walls of a photographic studio, the pigment in the choroid and retina absorbs light after it strikes the retina to prevent reflection or scattering of light within the eye.

The interior of the eye consists of two fluid-filled cavities, separated by an elliptical **lens**, all of which are transparent to permit light to pass through the eye from the cornea to the retina. In an adult, the lens is about 10 mm in diameter, the size of a shirt button. The larger posterior cavity between the lens and the retina contains a clear, jellylike substance, the **vitreous humor**. The vitreous humor helps maintain the spherical shape of the eyeball. The anterior cavity between the cornea and the lens contains a clear, watery fluid, the **aqueous humor**. The aqueous humor carries nutrients for the cornea and lens, both of which lack a blood supply. Blood vessels in these structures would impede the passage of light to the photoreceptors.

The aqueous humor is produced at a rate of about 5 mL/day by a capillary network within the **ciliary body**, a specialized anterior derivative of the choroid layer. This fluid drains into a canal at the edge of the cornea and eventually enters the blood. *Clinical Note* If the aqueous humor is not drained as rapidly as it forms (for example, because of a blocked drainage canal), the excess accumulates in the anterior cavity, causing the pressure to rise within the eye. This condition is known as **glaucoma**. The excess aqueous humor pushes the lens backward into the vitreous humor, which in turn pushes against the inner neural layer of the retina. This compression causes retinal and optic nerve damage that can lead to blindness if the condition is not treated.

The amount of light entering the eye is controlled by the iris.

Not all light passing through the cornea reaches the light-sensitive photoreceptors because of the presence of the **iris**, a thin, pigmented smooth muscle that forms a visible ringlike structure within the aqueous humor (❙Figure 6-10a and b). The pigment in the iris is responsible for eye color. The varied flecks, lines, and other nuances of the iris are unique for each individual, making the iris the basis of the latest identification technology. Recognition of iris patterns by a video camera that captures iris images and translates the landmarks into a computerized code is more foolproof than fingerprinting or even DNA testing.

The round opening in the center of the iris through which light enters the interior portions of the eye is the **pupil**. The size

Pupil

Iris

Radial (dilator) muscle runs radially

Pupillary constriction

Pupillary dilation
of this opening can be adjusted by variable contraction of the iris smooth muscles to admit more or less light as needed. The iris contains two sets of smooth muscle networks, one *circular* (the muscle fibers run in a ringlike fashion within the iris) and the other *radial* (the fibers project outward from the pupillary margin like bicycle spokes) (❙Figure 6-11). Because muscle fibers shorten when they contract, the pupil gets smaller when the **circular** (or **constrictor**) **muscle** contracts and forms a smaller ring. This reflex pupillary constriction occurs in bright light to decrease the amount of light entering the eye. When the **radial** (or **dilator**) **muscle** shortens, the size of the pupil increases. Such pupillary dilation occurs in dim light to allow the entrance of more light. Iris muscles are controlled by the autonomic nervous system. Parasympathetic nerve fibers innervate the circular

muscle (causing pupillary constriction), and sympathetic fibers supply the radial muscle (causing pupillary dilation).

The eye refracts entering light to focus the image on the retina.

Light is a form of electromagnetic radiation composed of particlelike individual packets of energy called **photons** that travel in wavelike fashion. The distance between two wave peaks is known as the *wavelength* (❙Figure 6-12). The wavelengths in the electromagnetic spectrum range from 10^{-14} m (quadrillionths of a meter, as in the extremely short cosmic rays) to 10^4 m (10 km, as in long radio waves) (❙Figure 6-13). The photoreceptors in the eye are sensitive only to wavelengths between 400 and 700 nanometers (nm; billionths of a meter). Thus, **visible light** is only a small portion of the total electromagnetic spectrum. Light of different wavelengths in this visible band is perceived as different color sensations. The shorter visible wavelengths are sensed as violet and blue; the longer wavelengths are interpreted as orange and red.

In addition to having variable wavelengths, light energy varies in intensity—that is, the amplitude, or height, of the wave (see ❙Figure 6-12). Dimming a bright red light does not change its color; it just becomes less intense or less bright.

Light waves *diverge* (radiate outward) in all directions from every point of a light source. The forward movement of a light wave in a particular direction is known as a **light ray**. Divergent light rays reaching the eye must be bent inward to be focused back into a point (the **focal point**) on the light-sensitive retina and provide an accurate image of the light source (❙Figure 6-14).
❙Figure 6-12 Properties of an electromagnetic wave. A wavelength is the distance between two wave peaks. The intensity is the amplitude of the wave.
Figure 6-13 Electromagnetic spectrum. The wavelengths in the electromagnetic spectrum range from less than 10^{-14} m to 10^4 m. The visible spectrum includes wavelengths ranging from 400 to 700 nanometers (nm).

Process of Refraction Light travels faster through air than through other transparent media such as water and glass. When a light ray enters a medium of greater density, it is slowed down (the converse is also true). The course of direction of the ray changes if it strikes the surface of the new medium at any angle other than perpendicular (❙Figure 6-15). The bending of a light ray is known as **refraction**. With a curved surface such as a lens, the greater the curvature, the greater is the degree of bending and the stronger the lens. When a light ray strikes the curved surface of any object of greater density, the direction of refraction depends on the angle of the curvature (❙Figure 6-16). A **convex surface** curves outward (like the outer surface of a ball), whereas a **concave surface** curves inward (like a cave). Convex surfaces converge light rays, bringing them closer together. Because convergence is essential for bringing an image to a focal point, refractive surfaces of the eye are convex. Concave surfaces diverge light rays (spread them farther apart). A concave lens

is useful for correcting certain refractive errors of the eye, such as nearsightedness.

The Eye's Refractive Structures The two structures most important in the eye's refractive ability are the *cornea* and the *lens.* The curved corneal surface, the first structure light passes through as it enters the eye, contributes most extensively to the eye's total refractive ability because the difference in density at the air–cornea interface is greater than the differences in density between the lens and the fluids surrounding it. In **astigmatism**, the curvature of the cornea is uneven, so light rays are unequally refracted. The refractive ability of a person's cornea remains constant because the curvature of the cornea never changes. In contrast, the refractive ability of the lens can be adjusted by changing its curvature as needed for near or far vision.

Rays from light sources more than 20 feet away are considered parallel by the time they reach the eye. Light rays originating from near objects are still diverging when they reach the eye. For a given refractive ability of the eye, the diverging rays of a near source come to a focal point a greater distance behind the lens than the parallel rays of a far source come to a focal point (❙Figure 6-17a and b). However, in a particular eye, the distance between the lens and the retina always remains the same. Therefore, a greater distance beyond the lens is not available for bringing near objects into focus. Yet for clear vision, the refractive structures of the eye must bring both near and far light sources into focus on the retina. If an image is focused before it reaches the retina or is not yet focused

Point source of light   Light rays   Eye structures that bend light rays   Light rays focused on retina
Figure 6-14 Focusing of diverging light rays. Diverging light rays must be bent inward to be focused.
Figure 6-15 **Refraction.** A light ray is bent (refracted) when it strikes the surface of a medium of different density from the one in which it had been traveling (for example, moving from air into glass) at any angle other than perpendicular to the new medium's surface. Thus, the pencil in the glass of water appears to bend. What is happening, though, is that the light rays coming to the camera (or your eyes) are bent as they pass through the water, then the glass, and then the air. Consequently, the pencil appears distorted.
(a) Convex lens
(b) Concave lens

Figure 6-16 **Refraction by convex and concave lenses.** (a) A lens with a convex surface converges the rays (brings them closer together). (b) A lens with a concave surface diverges the rays (spreads them farther apart).

when it reaches the retina, it will be blurred. To bring both near and far light sources into focus on the retina (that is, in the same distance), a stronger lens must be used for the near source (**Figure 6-17c**). Let us see how the strength of the lens can be adjusted as needed.

Accommodation increases the strength of the lens for near vision.

The ability to adjust the strength of the lens is known as **accommodation**. The strength of the lens depends on its shape, which in turn is regulated by the ciliary muscle. The **ciliary muscle** is part of the ciliary body, an anterior specialization of the choroid layer. The ciliary body has two major components: the ciliary muscle and the capillary network that produces the aqueous humor. The ciliary muscle is a circular ring of smooth muscle attached to the lens by **suspensory ligaments** (**Figure 6-18a**).

When the ciliary muscle is relaxed, the suspensory ligaments are taut, and they pull the lens into a flattened, weakly refractive shape (**Figure 6-18b**). As the muscle contracts, its circumference decreases, slackening the tension in the suspensory ligaments (**Figure 6-18c**). When the suspensory ligaments are not pulling on the lens, it becomes more spherical because of its inherent elasticity. The greater curvature of the more rounded lens increases its strength, further bending light rays. In the normal eye, the ciliary muscle is relaxed and the lens is flat for far vision but the muscle contracts to let the lens become more convex and stronger for near vision. The ciliary muscle is controlled by the autonomic nervous system, with sympathetic stimulation causing its relaxation and parasympathetic stimulation causing its contraction.

(a) Parallel rays of distant light source

(b) Diverging rays of near light source

(c) Stronger lens needed to focus near light source
❙ Figure 6-17 Focusing of distant and near sources of light. (a) The rays from a distant (far) light source (more than 20 feet from the eye) are parallel by the time the rays reach the eye. (b) The rays from a near light source (less than 20 feet from the eye) are still diverging when they reach the eye. A longer distance is required for a lens of a given strength to bend the diverging rays from a near light source into focus than to bend the parallel rays from a distant light source into focus. (c) To focus both a distant and a near light source in the same distance (the distance between the lens and retina), a stronger lens must be used for the near source.

Clinical Note The lens is made up of about 1000 layers of cells that destroy their nucleus and organelles during development so that the cells are perfectly transparent. Lacking DNA and protein-synthesizing machinery, mature lens cells cannot regenerate or repair themselves. Cells in the center of the lens are in double jeopardy. Not only are they oldest, but they also are farthest from the aqueous humor, the lens's nutrient source. With advancing age, these non-renewable central cells die and become stiff. With loss of elasticity, the lens can no longer assume the spherical shape required to accommodate for near vision. This age-related reduction in accommodative ability, **presbyopia**, affects most people by middle age (45 to 50 years), requiring them to resort to corrective lenses for near vision (reading).
(a) Anterior view of suspensory ligaments extending from ciliary muscles to lens
❙ Figure 6-18 Mechanism of accommodation. (a) Suspensory ligaments extend from the ciliary muscle to the outer edge of the lens. (b) When the ciliary muscle is relaxed, the suspensory ligaments are taut, putting tension on the lens so that it is flat and weak. (c) When the ciliary muscle is contracted, the suspensory ligaments become slack, reducing the tension on the lens, allowing it to assume a stronger, rounder shape because of its elasticity.

The Peripheral Nervous System: Afferent Division; Special Senses | **197**

Figure 6-19 Emmetropia, myopia, and hyperopia. This figure compares far vision and near vision (a) in the normal eye with (b) nearsightedness and (c) farsightedness in both their (1) uncorrected and (2) corrected states. The vertical dashed line represents the normal distance of the retina from the cornea—that is, the site at which an image is brought into focus by the refractive structures in a normal eye.

The normally transparent elastic fibers in the lens may become opaque so that light cannot pass through, a condition known as a **cataract**. The defective lens can be surgically removed and vision restored by an implanted artificial lens.

Other common vision disorders are *nearsightedness (myopia)* and *farsightedness (hyperopia)*. In a normal eye (**emmetropia**) (❚Figure 6-19a), a far light source is focused on the retina without accommodation, whereas the strength of the lens is increased by accommodation to bring a near source into focus.

In **myopia** (❙Figure 6-19b1) because the eyeball is too long or the lens is too strong, a near light source is brought into focus on the retina without accommodation (even though accommodation is normally used for near vision), whereas a far light source is focused in front of the retina and is blurry. Thus, a myopic individual has better near vision than far vision, a condition that can be corrected by a concave lens (❙Figure 6-19b2). With **hyperopia** (❙Figure 6-19c1), either the eyeball is too short or the lens is too weak. Far objects are focused on the retina only with accommodation, whereas near objects are focused behind the retina even with accommodation and, accordingly, are blurry. Thus, a hyperopic individual has better far vision than near vision, a condition that can be corrected by a convex lens (❙Figure 6-19c2). Instead of using corrective eyeglasses or contact lenses, many people are now opting to compensate for refractive errors with laser eye surgery (such as LASIK) to permanently change the shape of the cornea.

Light must pass through several retinal layers before reaching the photoreceptors.

The major function of the eye is to focus light rays from the environment on the rods and cones, the photoreceptor cells of the retina. The photoreceptors then transform the light energy into electrical signals for transmission to the CNS.

The receptor-containing portion of the retina is actually an anatomic extension of the CNS, not a separate peripheral organ. During embryonic development, the retinal cells "back out" of the nervous system, so the retinal layers, surprisingly, are facing backward. The neural portion of the retina consists of three layers of excitable cells (❙Figure 6-20): (1) the outermost layer (closest to the choroid) containing the **rods** and **cones**, whose light-sensitive ends face the choroid (away from the incoming light); (2) a middle layer of **bipolar cells** and associated interneurons; and (3) an inner layer of **ganglion cells**. Axons of the ganglion cells join to form the **optic nerve**, which leaves the retina slightly off center. The point on the retina at which the optic nerve leaves and through which blood vessels pass is the **optic disc** (see ❙Figure 6-10b, p. 193). This region is often called the **blind spot**; no image can be detected in this area because it has no rods and cones (❙Figure 6-21). We are normally not aware of the blind spot because central processing somehow "fills in" the missing spot. You can discover the existence of your own blind spot by a simple demonstration (❙Figure 6-22).

Light must pass through the ganglion and bipolar layers before reaching the photoreceptors in all areas of the retina except the fovea. In the **fovea**, which is a pinhead-sized depression located in the exact center of the retina (see ❙Figure 6-10b), the bipolar and ganglion cell layers are pulled aside so that light strikes the photoreceptors directly. Because of this feature, and because only cones
❙Figure 6-20 Retinal layers. The retinal visual pathway extends from the photoreceptor cells (rods and cones, whose light-sensitive ends face the choroid away from the incoming light) to the bipolar cells to the ganglion cells. The horizontal and amacrine cells are interneurons that act locally for retinal processing of visual input.

FIGURE FOCUS: *Does convergence exist in the pathway from rods to bipolar cells to ganglion cells? How about in the pathway from cones to bipolar cells to ganglion cells? Remember these wiring patterns. They will be important in a later discussion.*
Blind spot   Macula lutea

Figure 6-21 View of the retina seen through an ophthalmoscope. With an ophthalmoscope, a lighted viewing instrument, it is possible to view the optic disc (blind spot) and macula lutea within the retina at the rear of the eye.

Figure 6-23 View with macular degeneration.

(which have greater acuity or discriminative ability than the rods) are found here, the fovea is the point of most distinct vision. In fact, the fovea has the greatest concentration of cones in the retina. Thus, we turn our eyes so that the image of the object at which we are looking is focused on the fovea. The pea-sized area immediately surrounding the fovea, the **macula lutea**, also has a high concentration of cones and fairly high acuity (see **Figure 6-21**). Macular acuity, however, is less than that of the fovea because of the overlying ganglion and bipolar cells in the macula.

Clinical Note **Age-related macular degeneration (AMD)** is the leading cause of blindness in the Western Hemisphere. This condition is characterized by loss of photoreceptors in the macula lutea in association with advancing age. Its victims have "doughnut" vision. They suffer a loss in the middle of their visual field, which normally has the highest acuity, and are left with only the less distinct peripheral vision (**Figure 6-23**).

Phototransduction by retinal cells converts light stimuli into neural signals.

Photoreceptors (rod and cone cells) consist of three parts (**Figure 6-24a**):

1. An *outer segment,* which lies closest to the eye's exterior, facing the choroid. It detects the light stimulus.
Figure 6-22 Demonstration of the blind spot. Find the blind spot in your left eye by closing your right eye and holding the book about 4 inches from your face. While focusing on the cross, gradually move the book away from you until the circle vanishes from view. At this time, the image of the circle is striking the blind spot of your left eye. You can similarly locate the blind spot in your right eye by closing your left eye and focusing on the circle. The cross disappears when its image strikes the blind spot of your right eye.

2. An *inner segment,* which lies in the middle of the photoreceptor's length. It contains the metabolic machinery of the cell.

3. A *synaptic terminal,* which lies closest to the eye's interior, facing the bipolar cells. It varies its rate of neurotransmitter release, depending on the extent of dark or light exposure detected by the outer segment.

The outer segment, which is rod shaped in rods and cone shaped in cones (**Figure 6-24a** and chapter opener photo, p. 181), consists of stacked, flattened, membranous discs containing an abundance of light-sensitive **photopigments**. Each retina contains more than 125 million photoreceptors, and more than 1 billion photopigments may be packed into the outer segment of each photoreceptor.

Photopigments undergo chemical alterations when activated by light. Through a series of steps, this light-induced change and subsequent activation of the photopigment bring about a receptor potential in the photoreceptor that ultimately leads to the generation of action potentials in ganglion cells, which transmit this information to the brain for visual processing. A photopigment consists of two components: **opsin**, an integral protein in the disc plasma membrane; and **retinal**, a derivative of vitamin A. Retinal is the light-absorbing part of the photopigment.

Phototransduction, the process of converting light stimuli into electrical signals, is basically the same for all photoreceptors, but the mechanism is contrary to the usual means by which receptors respond to their adequate stimulus. Receptors typically *depolarize* when stimulated, but photoreceptors *hyperpolarize* on light absorption. Let us first examine the status of the photoreceptors in the dark, and then consider what happens when they are exposed to light. We use rods as an example, but the same events take place in cones, except that they preferentially absorb light in different parts of the visible spectrum.

Photoreceptor Activity in the Dark The photopigment in rods is **rhodopsin**. Retinal exists in different conformations in the dark and light. In the dark, it exists as 11-*cis* retinal,

Figure 6-24 Photoreceptors. (a) The three parts of the rods and cones, the eye's photoreceptors. Note in the outer segment of the rod and cone the stacked, flattened, membranous discs, which contain an abundance of photopigment molecules. (b) A photopigment, such as rhodopsin, depicted here and found in rods, consists of opsin, a plasma-membrane protein, and retinal, a vitamin-A derivative. In the dark, 11-*cis*-retinal is bound within the interior of opsin and the photopigment is inactive. In the light, retinal changes to all-*trans*-retinal, activating the photopigment.

(a) Structure of rods and cones

(b) Photopigment rhodopsin in the dark and light

which fits into a binding site within the interior of the opsin portion of rhodopsin (Figure 6-24b). The plasma membrane of a photoreceptor's outer segment contains chemically gated Na$^+$ channels. Unlike other chemically gated channels that respond to extracellular chemical messengers, these channels respond to an internal second messenger, **cyclic GMP**, or **cGMP** (cyclic guanosine monophosphate). Binding of cGMP to these Na$^+$ channels keeps them open. In the absence of light, the concentration of cGMP is high (Figure 6-25a). (Light absorption leads to the breakdown of cGMP.) Therefore, the Na$^+$ channels of a photoreceptor, unlike most receptors, are open in the absence of stimulation, that is, in the dark. The resultant passive inward Na$^+$ leak, the so-called *dark current,* depolarizes the photoreceptor. The passive spread of this depolarization from the outer segment (where the Na$^+$ channels are located) to the synaptic terminal (where the photoreceptor's neurotransmitter is stored) keeps the synaptic terminal's voltage-gated Ca^{2+} channels open. Ca^{2+} entry triggers the

release by exocytosis of the neurotransmitter glutamate from the synaptic terminal while in the dark.

Photoreceptor Activity in the Light On exposure to light, the concentration of cGMP is decreased through a series of biochemical steps triggered by photopigment activation (Figure 6-25b). When 11-*cis* retinal absorbs light, it changes to the all-*trans* retinal conformation (see Figure 6-24b). This is the only light-dependent step in the entire process of phototransduction. As a result of this change in shape, retinal no longer fits snugly in its binding site in opsin, causing opsin to also change its conformation, which activates the photopigment. Membrane-bound opsin is similar in shape and behavior to G-protein-coupled receptors (GPCRs; see p. 117), except that instead of being activated by binding with an extracellular chemical messenger, photopigments are activated in response to light absorption by retinal. Rod and cone cells contain a G protein called **transducin**. The activated photopigment

Further retinal processing in bipolar and ganglion cells

❙Figure 6-25 **Phototransduction, further retinal processing, and initiation of action potentials in the visual pathway.** (a) Events occurring in the retina and visual pathway in response to the dark. (b) Events occurring in the retina and visual pathway in response to a light stimulus.

FIGURE FOCUS: *How are photoreceptors depolarized in the absence of a stimulus and hyperpolarized in response to their adequate stimulus? How does a hyperpolarizing receptor potential lead to propagation of action potentials in on-center ganglion cells?*

activates transducin, which in turn activates the intracellular enzyme *phosphodiesterase*. This enzyme degrades cGMP, thus decreasing the concentration of this second messenger in the photoreceptor. During the light excitation process, the reduction in cGMP permits the chemically gated Na^+ channels to close. This channel closure stops the depolarizing Na^+ leak, thereby causing hyperpolarization. The hyperpolarization, which is the receptor potential, passively spreads from the outer segment to the synaptic terminal of the photoreceptor. Here the potential change leads to closure of the voltage-gated Ca^{2+} channels and a subsequent reduction in glutamate release from the synaptic terminal. Thus, photoreceptors are *inhibited by their adequate stimulus* (hyperpolarized by light) and *excited in the absence of stimulation* (depolarized by darkness). The hyperpolarizing potential and subsequent decrease in neurotransmitter release are graded according to the light intensity. The brighter the light is, the greater the hyperpolarizing response and the greater the reduction in glutamate release.

The short-lived active form of the photopigment quickly dissociates into opsin and retinal. The retinal is converted back into its 11-*cis* form. In the dark, enzyme-mediated mechanisms rejoin opsin and this recycled retinal to restore the photopigment to its original inactive conformation (see ❙Figure 6-24b).
Further Retinal Processing of Light Input How does the retina signal the brain about light stimulation through such an inhibitory response? Further retinal processing involves different influences of glutamate on two parallel pathways. Each photoreceptor synapses with two side-by-side bipolar cells, one an *on-center bipolar cell* and the other an *off-center bipolar cell*. These cells, in turn, terminate respectively on *on-center ganglion cells* and *off-center ganglion* cells, whose axons collectively form the optic nerve for transmission of signals to the brain.

The receptive field of a bipolar or ganglion cell is determined by the field of light detection by the photoreceptor with which it is linked. (Of course light is not directly detected by the bipolar or ganglion cells; light stimulates the photoreceptors, which signal the bipolar cells that in turn send the message to the ganglion cells.) **On-center** and **off-center cells** respond in opposite ways, depending on the relative comparison of illumination between the center and periphery (surround) of their receptive fields. Think of the receptive field as a doughnut. An on-center cell increases its rate of firing when light is most intense at the center of its receptive field (that is, when the doughnut hole is lit up) and stops firing when its surround is most intensely illuminated. In contrast, an off-center cell increases its firing rate when light is the brightest in the periphery of its receptive field (that is, when the doughnut itself is lit up) and stops firing when light is most intense in its center (❙Figure 6-26a). Thus, on-center cells are "turned on" and off-center cells are "turned off" when light shines most intensely on their centers. Both cells respond only weakly when light shines evenly on both their centers and surrounds. This response pattern is useful for enhancing the difference in light level between one small area at the center of a receptive field and the illumination immediately around it. By emphasizing differences in relative brightness, this mechanism helps define contours of images,

but in so doing, information about absolute brightness is sacrificed (❙Figure 6-26b).

Glutamate released from the photoreceptor terminal in the dark has opposite effects on the two types of bipolar cells because they have different types of receptors that lead to different channel responses on binding with this neurotransmitter. Glutamate hyperpolarizes (inhibits) on-center bipolar cells and depolarizes (excites) off-center bipolar cells. When glutamate secretion decreases on light exposure, this reduction depolarizes (stimulates) the hyperpolarized on-center bipolar cells and hyperpolarizes (inhibits) the depolarized off-center bipolar cells. The bipolar cells pass on the information about patterns of illumination to the next neurons in the processing chain, the ganglion cells, by changing their rate of neurotransmitter release in accordance with their state of polarization—increased neurotransmitter release on depolarization and decreased neurotransmitter release on hyperpolarization.

Bipolar cells, similar to the photoreceptors, display graded potentials. Action potentials do not originate until the ganglion cells (the first neurons in the chain that must propagate the visual message over long distances to the brain) are stimulated. As the firing rates of the on-center and off-center ganglion cells change in response to the changing pattern of illumination, the brain is informed about the rapidity and extent of change in contrast within the visual image.

Receptive field of on-center cell   **Receptive field of off-center cell**

Off — Inhibited by light   Excited by light — On

On — Excited by light   Inhibited by light — Off

Both types of cells are weakly stimulated by uniform light on both center and surround.

(a) Receptive fields of on-center and off-center cells
(b) Outcome of retinal processing by on-center and off-center cells

❙**Figure 6-26 On-center and off-center cells in retina.** (a) On-center cells are excited and off-center cells are inhibited by bright light in the centers of their receptive fields. (b) Retinal processing by on-center and off-center ganglion cells is largely responsible for enhancing differences in relative (rather than absolute) brightness, which helps define contours. Note that the gray circle surrounded by black appears brighter than the one surrounded by white, even though the two circles are identical (same shade and size).

Rods provide indistinct gray vision at night; cones provide sharp color vision during the day.

The retina contains 20 times more rods than cones (120 million rods compared to 6 million cones per eye). Cones are most abundant in the macula lutea in the center of the retina. From this point outward, the concentration of cones decreases and the concentration of rods increases. Rods are most abundant in the periphery. We have examined the similar way in which phototransduction takes place in rods and cones. Now we focus on the differences between these photoreceptors (❙ Table 6-3).

Rods Have High Sensitivity; Cones Have Lower Sensitivity The outer segments are longer in rods than in cones, so they contain more photopigments and thus can absorb light more readily. Also, as you will see shortly, the way in which rods connect with other neurons in their processing pathway further increases the sensitivity of rod vision. Rods have high sensitivity, so they can respond to the dim light of night. Cones, by contrast, have lower sensitivity to light, being activated only by bright daylight. Thus, rods are specialized for night vision and cones for day vision.

Cone Vision Has High Acuity; Rod Vision Has Low Acuity The pathways by which cones are "wired" to the other retinal neuronal layers confer high acuity (sharpness, or the ability to distinguish between two nearby points). Thus, cones provide sharp vision with high resolution for fine detail during the day. By contrast, the wiring pathways of rods provide low acuity, so you can see at night but at the expense of distinctness. Let us see how wiring patterns influence sensitivity and acuity.

Little convergence of neurons takes place in the retinal pathways for cone output (see p. 112). Each cone generally has a private line connecting it to a particular ganglion cell. In contrast, much convergence occurs in rod pathways. Output from more than 100 rods may converge via bipolar cells on a single ganglion cell. Before a ganglion cell can have an action potential, the cell must be brought to threshold through influence of the graded potentials in the photoreceptors to which it is wired.

❙ TABLE 6-3 Properties of Rod Vision and Cone Vision

Rods	Cones
120 million per retina	6 million per retina
More numerous in periphery	Concentrated in fovea
High sensitivity	Low sensitivity
Night vision	Day vision
Low acuity	High acuity
Much convergence in retinal pathways	Little convergence in retinal pathways
Vision in shades of gray	Color vision

Because a single-cone ganglion cell is influenced by only one cone, only bright daylight is intense enough to induce a sufficient receptor potential in the cone to ultimately bring the ganglion cell to threshold. The abundant convergence in the rod visual pathways, in contrast, offers good opportunities for summation of subthreshold events in a rod ganglion cell (see p. 108). Whereas a small receptor potential induced by dim light in a single cone would not be sufficient to bring its ganglion cell to threshold, similar small receptor potentials induced by the same dim light in multiple rods converging on a single ganglion cell would have an additive effect to bring the rod ganglion cell to threshold. Because rods can bring about action potentials in response to small amounts of light, they are much more sensitive than cones. (Rods are also more sensitive than cones because they have more photopigment.) However, because cones have dedicated lines into the optic nerve, each cone transmits information about an extremely small receptive field on the retinal surface. Cones are thus able to provide highly detailed vision at the expense of sensitivity. With rod vision, acuity is sacrificed for sensitivity. Because many rods share a single ganglion cell, once an action potential is initiated, it is impossible to discern which of the multiple rod inputs were activated to bring the ganglion cell to threshold. Objects appear fuzzy when rod vision is used because of this poor ability to distinguish between two nearby points.

Cones Provide Color Vision; Rods Provide Vision in Shades of Gray There are four different photopigments, one in the rods and one in each of three types of cones—**red**, **green**, and **blue cones**. Each photopigment has the same retinal but a different opsin. Because each opsin binds retinal in a unique way, each of the four photopigments absorbs different wavelengths of light in the visible spectrum to varying degrees. Each photopigment maximally absorbs a particular wavelength but also absorbs a range of wavelengths shorter and longer than this peak absorption. The farther a wavelength is from the peak wavelength absorbed, the less strongly the photopigment responds. Rods absorb the greatest range of wavelengths. The absorption curves for the three cone types overlap so that two or three cones may respond to a given wavelength but to a different extent (❙ Figure 6-27). Because the photopigments in the three types of cones each respond selectively to a different part of the visible light spectrum, the brain can compare the responses of the three cone types, making color vision in daylight possible. In contrast, the brain cannot discriminate among various wavelengths when using visual input from the rods. The rhodopsin in every rod responds in the same way to a given wavelength, so no comparison among rod inputs is possible. Therefore, rods provide vision at night only in shades of gray by detecting different intensities, not different colors. We now examine color vision in further detail.

Color vision depends on the ratios of stimulation of the three cone types.

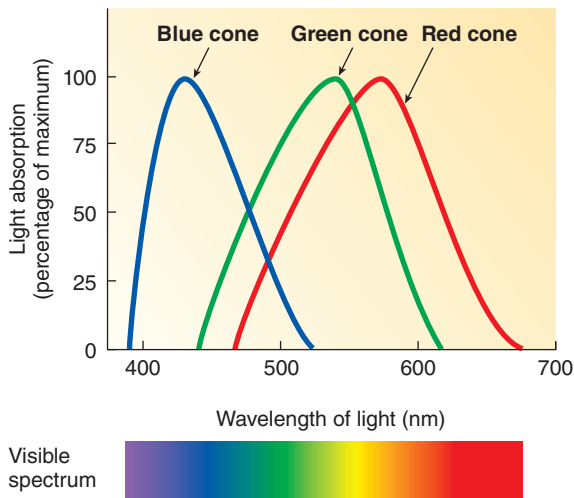
Vision depends on stimulation of photoreceptors by light. Certain objects in the environment, such as the sun, fire, and light bulbs, emit light. But how do you see objects such as chairs,


Figure 6-27 Sensitivity of the three types of cones to different wavelengths.

trees, and people, which do not emit light? The pigments in various objects selectively absorb particular wavelengths of light transmitted to them from light-emitting sources, and the unabsorbed wavelengths are reflected from the objects' surfaces. These reflected light rays enable you to see the objects. An object perceived as blue absorbs the longer red and green wavelengths of light and reflects the shorter blue wavelengths, which can be absorbed by the photopigment in your blue cones, thereby activating them.

Each cone type is most effectively activated by a particular wavelength of light in the range of color indicated by its name. The *S-type photopigment* in blue cones absorbs light maximally in the *s*hort-wavelength (blue) part of the visible spectrum, whereas the *M-type photopigment* in green cones is most sensitive to the *m*edium wavelengths (green) of visible light, and the *L-type photopigment* in red cones responds best to the *l*ong (red) wavelengths. However, cones also respond in varying degrees to other wavelengths (Figure 6-27). According to the **trichromatic theory** of color vision, the perception of the many colors of the world depends on the three cone types' various *ratios of stimulation* in response to different wavelengths (*tri* means "three;" *chroma* refers to "color"). A wavelength perceived as blue does not stimulate red or green cones but excites blue cones maximally. (The percentage of maximal stimulation for red, green, and blue cones, respectively, is 0:0:100.) The sensation of yellow, in comparison, arises from a stimulation ratio of 83:83:0—that is, red and green cones are each stimulated 83% of maximum, while blue cones are not excited. The ratio for green is 31:67:36, and so on, with various combinations giving rise to the sensation of all the different colors. White is a mixture of all wavelengths of light, whereas black is the absence of light.

The extent to which each of the cone types is excited is coded and transmitted in separate parallel pathways to the brain. Distinct color processing pathways in the primary visual cortex in the occipital lobe of the brain (see Figure 5-11, p. 148) combine and process these inputs to generate the perception of color. The concept of color is in the mind of the beholder, but most of us agree on what color we see because we have the same types of

cones and use similar neural pathways for comparing their output. Occasionally, however, individuals lack a particular cone type, so their color vision is a product of the differential sensitivity of only two types of cones, a condition known as **color blindness**. Not only do color-defective individuals perceive certain colors differently, but they are also unable to distinguish as many varieties of colors (Figure 6-28). For example, people with certain color defects cannot distinguish between red and green. At a traffic light, they can tell which light is "on" by its intensity, but they must rely on the position of the bright light to know whether to stop or go. Because the defective gene associated with red–green color blindness is on the X sex chromosome, the incidence of this condition is greater in males than in females (affecting 8% of men and less than 1% of women). Females have XX and males have XY sex chromosomes; see p. 718. A female who has a defective copy of the gene on one X chromosome usually has a good copy of the gene on her other X chromosome and so has normal color vision, but a male who has a defective copy of the gene on his X chromosome has no comparable gene on his Y chromosome as a backup and so is color blind.

In addition to the trichromatic theory, which applies to the way the retina detects colors with the three cone types, the complementary opponent-process theory applies to further visual processing of information from the cones at a point where inputs from these photoreceptors are interconnected neurally. The **opponent-process theory** of color vision states that subsequent neural handling of trichromatic signals from the cones involves antagonist responses to opponent color pairs within three separate processing channels, namely red versus green, blue versus yellow, and black versus white. Specialized ganglion cells known as **opponent color cells**, which display baseline action potential activity, have opposite responses to the members of a color pair. For example, the firing rate of a red–green opponent cell, which receives both red-cone and green-cone input from the same vicinity of the retina, increases above baseline when it processes a signal from a red

Figure 6-28 **Color blindness chart.** People with red–green color blindness cannot detect the number 29 in this chart.

light and decreases below baseline when it processes a signal from a green light. Opponent colors in a pair are in competition; that is, stimulation of this opponent color cell by red input inhibits green input, and vice versa, because the firing rate of this cell cannot be increased and decreased at the same time. Thus red and green are mutually antagonistic. This explains why we never see both members of an opponent color pair at the same place and at the same time. That is, we don't see reddish green or bluish yellow. However, we do see combinations of colors that are in different pairs, for example reddish blue (purple) or yellowish red (orange). There is no yellow cone, but blue–yellow opponent cells respond to input from blue cones compared to combined information from red and green cones. (Remember that the sensation of yellow comes from near maximum stimulation of both red and green cones, with no excitation of blue cones.) The black–white opponent processing channel distinguishes darkness and lightness, not specific colors. According to the opponent-process theory, color vision depends on the differential response of these various opponent color cells, which enhances our perception of color contrast, similar to the way in which the differential response of on-center and off-center ganglion cells enhances differences in relative brightness. Further processing of opponent colors takes place in the thalamus and visual cortex.

The opponent-process theory can account for the visual phenomena of opponent color afterimages. When you intently stare at one color of an opponent pair for 30 seconds, then look away at a white space, you briefly perceive a ghostly image of the opposite color (❚Figure 6-29). This optical illusion is an opponent color **afterimage**. When you stare at the blue square, the blue cones fatigue from overstimulation and lose their sensitivity. When you shift your gaze to the white space, the cones that detect the opponent color (yellow, detected by combined activation of red and green cones) are not fatigued and have just been removed from prolonged inhibition by blue cone input. Thus these "fresh" cones can respond to the medium and long wavelengths of light in the white light, whereas the fatigued blue cones briefly are unable to respond to the short wavelengths in the white light. (Recall that white light contains all wavelengths of color.) Because the light reflected off the white paper is able to excite only the yellow-detecting cones, you briefly see a yellow afterimage until the blue cones recover and you once again see all wavelengths, that is, white.

The sensitivity of the eyes can vary markedly through dark and light adaptation.

The eyes' sensitivity to light depends on the amount of light-responsive photopigment present in the rods and cones. When you go from bright sunlight into darkened surroundings, you cannot see anything at first, but gradually you begin to distinguish objects as a result of the process of **dark adaptation**. Breakdown of photopigments during exposure to sunlight tremendously decreases photoreceptor sensitivity. In the dark, the photopigments broken down during light exposure are gradually regenerated. As a result, the sensitivity of your eyes gradually increases so that you begin to see in the darkened surroundings. However, only the highly sensitive, rejuvenated rods are "turned on" by the dim light.

Conversely, when you move from the dark to the light (for example, leaving a movie theater and entering bright sunlight), at first your eyes are very sensitive to the dazzling light. With little contrast between lighter and darker parts, the entire image appears bleached. As some of the photopigments are rapidly broken down by the intense light, the sensitivity of the eyes decreases and normal contrasts can again be detected, a process known as **light adaptation**. The rods are so sensitive to light that enough rhodopsin is broken down in bright light to essentially "burn out" the rods—that is, after the rod photopigments have already been broken down by the bright light, they no longer respond to the light. Therefore, only the less sensitive cones are used for day vision.

Our eyes' sensitivity can change as much as 1 million times as they adjust to various levels of illumination through dark and light adaptation. These adaptive measures are also enhanced by pupillary reflexes that adjust the amount of available light permitted to enter the eye.

Clinical Note Because retinal is a derivative of vitamin A, adequate amounts of this nutrient must be available for synthesis of photopigments. **Night blindness** occurs as a result of dietary deficiencies of vitamin A. Although photopigment concentrations in both rods and cones are reduced in this condition, there is still enough cone photopigment to respond to the intense stimulation of bright light, except in the most severe cases. However, even modest reductions in rhodopsin content can decrease the sensitivity of rods so much that they cannot respond to dim light. The person can see in the day using cones but cannot see at night because the rods are no longer functional. Thus, carrots are "good for your eyes" because they are rich in vitamin A.

Visual information is modified and separated before reaching the visual cortex.

The field of view that can be seen without moving the head is known as the **visual field**. The information that reaches the **primary visual cortex** in the occipital lobe is not a replica of the visual field for several reasons:

1. The image detected on the retina at the onset of visual processing is upside down and backward because of bending of

❚**Figure 6-29 Demonstration of opponent color afterimage.** Focus on the small black circle in the middle of the blue square while you slowly count to 30. Then quickly shift your gaze to the small black triangle in the middle of the white space to the right of the blue square and watch for an afterimage in the white space. What color is the afterimage?

the light rays. Once it is projected to the brain, the inverted image is interpreted as being in its correct orientation.

2. The information transmitted from the retina to the brain is not merely a point-to-point record of photoreceptor activation. Before the information reaches the brain, the retinal neuronal layers beyond the rods and cones reinforce selected information and suppress other information to enhance contrast. The differential activity of on-center and off-center cells along with the contributions of specialized retinal interneurons, the *horizontal cells* and *amacrine cells* (see ❚Figure 6-20), are responsible for much of this retinal processing. For example, horizontal cells participate in lateral inhibition, by which strongly excited cone pathways suppress activity in surrounding pathways of weakly stimulated cones. This increases the dark–bright contrast to enhance the sharpness of boundaries.

3. Various aspects of visual information, such as shape, color, and motion, are separated and projected in parallel pathways to different regions of the cortex. Only when these separate bits of processed information are integrated by higher visual regions is a reassembled picture of the visual scene perceived.

Clinical Note Patients with lesions in specific visual-processing regions of the brain may be unable to completely combine components of a visual impression. For example, a person may be unable to discern movement of an object but have reasonably good vision for shape, pattern, and color. Sometimes the defect can be remarkably specific, like being unable to recognize familiar faces while retaining the ability to recognize inanimate objects.

4. Because of the pattern of wiring between the eyes and the visual cortex, the left half of the cortex receives information only from the right half of the visual field as detected by both eyes, and the right half receives input only from the left half of the visual field of both eyes.

As light enters the eyes, light rays from the left half of the visual field fall on the right half of the retina of both eyes (the medial or inner half of the left retina and the lateral or outer half of the right retina) (❚Figure 6-30a). Similarly, rays from the right half of the visual field reach the left half of each retina (the lateral half of the left retina and the medial half of the right retina). Each optic nerve exiting the retina carries information from both halves of the retina it serves. This information is separated as the optic nerves meet at the **optic chiasm** located underneath the hypothalamus (*chiasm* means "cross") (see ❚Figure 5-7b, p. 143). Within the optic chiasm, the fibers from the medial half of each retina cross to the opposite side, but those from the lateral half remain on the original side. The reorganized bundles of fibers leaving the optic chiasm are known as **optic tracts**. Each optic tract carries information from the lateral half of one retina and the medial half of the other retina. Therefore, this partial crossover brings together, from the two eyes, fibers that carry information from the same half of the visual field. Each optic tract, in turn, delivers to the half of the brain on its same side information about the opposite half of the visual field.

Clinical Note Knowledge of these pathways can facilitate diagnosis of visual defects arising from interruption of the visual pathway at various points (❚Figure 6-30b).

Before we move on to how the brain processes visual information, take a look at ❚Table 6-4, which summarizes the functions of the various components of the eyes.
❚Figure 6-30 The visual pathway and visual deficits associated with lesions in the pathway. (a) Note that the left half of the visual cortex in the occipital lobe receives information from the right half of the visual field of both eyes (in *green*), and the right half of the cortex receives information from the left half of the visual field of both eyes (in *red*). (b) Each visual deficit illustrated is associated with a lesion at the corresponding numbered point of the visual pathway in part (a).

| TABLE 6-4 Functions of the Major Components of the Eye

Structures	Location	Function
Aqueous humor	Anterior cavity between the cornea and lens	Clear, watery fluid that is continually formed and carries nutrients to the cornea and lens
Bipolar cells	Middle layer of nerve cells in the retina	Important in retinal processing of light stimulus
Blind spot	Point slightly off center on the retina where the optic nerve exits; is devoid of photoreceptors (also known as *optic disc*)	Route for passage of the optic nerve and blood vessels
Choroid	Middle layer of the eye	Pigmented to prevent scattering of light rays in the eye; contains blood vessels that nourish the retina; anteriorly specialized to form the ciliary body and iris
Ciliary body	Specialized anterior derivative of the choroid layer; forms a ring around the outer edge of the lens	Produces aqueous humor and contains the ciliary muscle
Ciliary muscle	Circular muscular component of the ciliary body; attached to the lens by means of suspensory ligaments	Important in accommodation
Cones	Photoreceptors in the outermost layer of the retina	Responsible for high acuity, color, and day vision
Cornea	Anterior, clear, outermost layer of the eye	Contributes most extensively to the eye's refractive ability
Fovea	Exact center of the retina	Region with greatest acuity
Ganglion cells	Inner layer of nerve cells in the retina	Important in retinal processing of light stimulus; form the optic nerve
Iris	Visible pigmented ring of muscle within the aqueous humor	Varies size of the pupil by variable contraction; responsible for eye color
Lens	Between the aqueous humor and vitreous humor; attaches to the ciliary muscle by suspensory ligaments	Provides variable refractive ability during accommodation
Macula lutea	Area immediately surrounding the fovea	Has high acuity because of abundance of cones
Optic disc	*(See entry for blind spot)*	
Optic nerve	Leaves each eye at the optic disc (blind spot)	First part of the visual pathway to the brain
Pupil	Anterior round opening in the middle of the iris	Permits variable amounts of light to enter the eye
Retina	Innermost layer of the eye	Contains the photoreceptors (rods and cones)
Rods	Photoreceptors in the outermost layer of the retina	Responsible for high-sensitivity, black-and-white, and night vision
Sclera	Tough outer layer of the eye	Protective connective tissue coat; forms the visible white part of the eye; anteriorly specialized to form the cornea
Suspensory ligaments	Suspended between ciliary muscle and lens	Important in accommodation
Vitreous humor	Between the lens and retina	Semiliquid, jellylike substance that helps maintain spherical shape of the eye

The thalamus and visual cortex elaborate the visual message.

The first stop in the brain for information in the visual pathway is the *lateral geniculate nucleus* of the thalamus (❙ Figure 6-30a). It separates information received from the eyes and relays it via fiber bundles known as **optic radiations** to different zones in the primary visual cortex located in the occipital lobes. Each zone processes different aspects of the visual stimulus (for example, form, movement, color, and depth). This sorting process is no small task because each optic nerve contains more than a million fibers carrying information from the photoreceptors in one retina. This is more than all the afferent fibers

carrying somatosensory input from all other regions of the body! Researchers estimate that hundreds of millions of neurons occupying about 40% of the cortex participate in visual processing, compared to 8% devoted to touch perception and 3% to hearing. Yet the connections in the visual pathways are precise. The lateral geniculate nucleus and each of the zones in the cortex that processes visual information have a topographical map representing the retina point for point. As with the somatosensory cortex, the neural maps of the retina are distorted. The fovea, the retinal region capable of greatest acuity, has much greater representation in the neural map than the more peripheral regions of the retina do.

Depth Perception Although each half of the visual cortex receives information simultaneously from the same part of the visual field as received by both eyes, the messages from the two eyes are not identical. Each eye views an object from a slightly different vantage point, even though the overlap is tremendous. The overlapping area seen by both eyes at the same time is known as the **binocular** ("two-eyed") field of vision, which is important for **depth perception**. Like other areas of the cortex, the primary visual cortex is organized into functional columns, each processing information from a small region of the retina. Independent alternating columns are devoted to information about the same point in the visual field from the right and left eyes. The brain uses the slight disparity in the information received from the two eyes to estimate distance, allowing you to perceive three-dimensional objects in spatial depth. Some depth perception is possible using only one eye, based on experience and comparison with other cues. For example, if your one-eyed view includes a car and a building and the car is larger, you correctly interpret that the car must be closer to you than the building is.

Clinical Note Sometimes the two views are not successfully merged. This condition may occur for two reasons: (1) The eyes are not both focused on the same object simultaneously because of defects of the external eye muscles that make fusion of the two eyes' visual fields impossible (for example, being cross-eyed); or (2) the binocular information is improperly integrated during visual processing. The result is double vision, or **diplopia**, a condition in which the disparate views from both eyes are seen simultaneously.

Hierarchy of Visual Cortical Processing Within the cortex, visual information is first processed in the primary visual cortex and then is sent to surrounding higher-level visual areas for even more complex processing and abstraction. The visual cortex is precisely organized both vertically and horizontally. Vertical columns extend through the thickness of the cortex from its outer surface to the white matter. Each column is made up of cells that process the same bit of visual input. There are three types of columns, based on the type of visual input they process: (1) as discussed in the preceding section, an alternating system of *ocular dominance columns* devoted to input from the left or the right eye is important for binocular interaction and depth perception; (2) *orientation columns* related to axis of orientation of visual stimuli play a key role in perceiving form and movement; and (3) shortened columns known as *blobs* process color.

The orientation columns contain a hierarchy of visual cells that respond to increasingly complex stimuli. Three types of visual cortical neurons have been identified based on the complexity of stimulus requirements needed for the cell to respond; these are called **simple**, **complex**, and **hypercomplex cells**. All of the cells within a given orientation column process input arising from visual stimuli in the same axis of orientation, such as a slit of light oriented vertically, horizontally, or at some oblique angle. The primary visual cortex has orientation columns for every possible axis of orientation. Dissection of visual input into these various orientations is important for discerning form and movement. The visual cortex is also organized into six layers, with each layer consisting of specific cell types. For example, simple cells are found in layer IV. Simple and complex cells are stacked on top of one another in a specific way within each orientation column. Hypercomplex cells are found only in higher visual-processing areas. Horizontal connections within the layers link vertical columns that carry out similar functions. Each layer has different inputs and outputs and is specialized to perform a particular task.

Unlike a retinal cell that responds to the amount of light, a cortical cell fires only when it receives a particular pattern of illumination for which it is programmed. These patterns are built up by converging connections that originate from closely aligned photoreceptor cells in the retina. For example, in the orientation columns some simple cells fire only when a bar is viewed vertically in a specific location, others when a bar is horizontal, and others at various oblique orientations. Movement of a critical axis of orientation becomes important for response by some of the complex cells. Hypercomplex cells add a new dimension to visual processing by responding only to particular edges, corners, and curves. Each level of cortical visual neurons has increasingly greater capacity for abstraction of information built up from the increasing convergence of input from lower-level neurons. In this way, the cortex transforms the dotlike pattern of photoreceptors stimulated to varying degrees by varying light intensities in the retinal image into information about position, orientation, movement, contour, and length. Other aspects of visual information, such as depth perception and color perception, are processed simultaneously by the other vertical and horizontal organizational systems. How and where the entire image is finally put together is still unresolved. This is similar to the blobs of paint on an artist's palette versus the finished portrait; the separate pigments do not represent a portrait of a face until they are appropriately integrated on a canvas.

Visual input goes to other areas of the brain not involved in vision perception.

Not all fibers in the visual pathway terminate in the visual cortex. Some are projected to other regions of the brain for purposes other than direct vision perception. Examples of nonsight activities dependent on input from the rods and cones include (1) contribution to cortical alertness and attention (for example, you get drowsy in a dimly lit room), (2) control of pupil size (for example, your pupils constrict in bright light), and (3) control of eye movements (for example, input from your

"Seeing" with the Tongue or the Ear

ALTHOUGH EACH TYPE OF SENSORY input is received primarily by a distinct brain region responsible for perception of that modality, the regions of the brain involved with perceptual processing receive sensory signals from a variety of sources. Thus, the visual cortex receives sensory input not only from the eyes, but also from the body surface and ears. One group of scientists exploited, in an unusual but exciting way, this sharing of sensory input by multiple regions of the brain. They developed *BrainPort,* a noninvasive device that enables the blind to crudely perceive shapes and motion in space by means of a *tongue display unit (TDU)*, a f at, 9-cm², lollipop-like unit consisting of a grid of electrodes that is positioned against the tongue (see the accompanying figure). A miniature camera mounted on glasses sends visual data to a handheld base unit that converts light input into a pattern of electrical signals that are sent to the TDU, where they activate touch receptors on the tongue. The pattern of "tingling" on the tongue (similar to the feeling of effervescent champagne) as a result of the light-induced electrical signals corresponds with the image recorded by the camera. With practice, the visual cortex interprets this alternate sensory input as a visual image. As one of the investigators who developed this technique claims, a person

BrainPort in use. A miniature camera built into the glasses sends visual data to the handheld device, which converts the light input into electrical signals that it transmits to the tongue display unit. The brain interprets the resultant pattern of tongue tingling as a crude visual image.

WICAB

photoreceptors is used to guide contraction of your external eye muscles to enable you to read this page). Each eye is equipped with a set of six **external eye muscles** that position and move the eye so that it can better locate, see, and track objects. Eye movements are among the fastest, most discretely controlled movements of the body.

About 3% of the eyes' ganglion cells are not wired to rods and cones and are not involved in visual processing. Instead, they make **melanopsin**, a light-sensitive pigment that plays a key role in setting the body's "biological clock" to march in step with the light–dark cycles (see p. 661).

Some sensory input may be detected by multiple sensory-processing areas in the brain.

Before shifting gears to another sense—hearing—we should mention a new theory regarding the senses that challenges the prevailing view that the separate senses feed into distinct brain regions that handle only one sense. A growing body of evidence suggests that the brain regions devoted almost exclusively to a certain sense, such as the visual cortex for visual input and the somatosensory cortex for touch input, actually receive a variety of sensory signals. No sense works alone. For example, tactile and auditory signals also arrive in the visual cortex. One study using new brain-imaging techniques showed that people blind from birth use the visual cortex

when they read Braille, even though they are not "seeing" anything. The tactile input from their fingers reaches the visual area of the brain as well as the somatosensory cortex. This input helps them "visualize" the patterns of the Braille bumps. More and more evidence supports this multisensory revolution, the notion that our senses "eavesdrop" on one another and that the brain makes sense of the world by deriving information from as many avenues as possible and blending the diverse forms of sensory perception.

Also reinforcing the notion that central processing of different types of sensory input overlaps to some extent, scientists recently discovered *multisensory neurons*—brain cells that react to multiple sensory inputs instead of just to one. No one knows whether these cells are rare or commonplace in the brain. (See the accompanying boxed feature, ▍Concepts, Challenges, and Controversies, for one way in which researchers exploited this sharing of sensory input by multiple regions of the brain.)

Such cross-sensory experiences may also be the basis of **synaesthesia** (meaning "joining of senses"), a poorly understood condition in which two or more senses are connected. For example, those with synaesthesia may "see" letters, words, and numbers as colors, "taste" shapes, or "hear" colors. Synaesthetic abilities are very specific for the individual. One person with synaesthesia may always see "M" as indigo blue; another may always see this letter as red. The blending of senses occurs in one direction only; even though "M" is always red, red can be seen without conjuring up the letter "M."

sees with the visual cortex, not with the eyes. Any means of sending signals to the visual cortex can be perceived as a visual image. For example, with this device, the blind can see the shapes of furniture, track the movement of people, identify doorways and elevator buttons, read letters and numbers, pick up a cup without groping, or enjoy the f ickering of a candle f ame. Although using the tongue as a surrogate eye can never provide anywhere near the same vision as a normal eye, even this limited visual input can enable a sightless person to get around more easily and enjoy a better quality of life.

The tongue is a better choice than the skin for receiving this light-turned-tactile input because the saliva is an electrically conducive f uid that readily conducts the current generated in the device by the visual input. Furthermore, the tongue is densely populated with tactile receptors, opening up the possibility that the tongue can provide higher acuity of visual input than the skin could. In fact, researchers plan to improve the resolution of the device by increasing the number of in-the-mouth electrodes.

In a related approach, other researchers have created an iPhone app, *EyeMusic*, that can scan and convert images into sequences of sound that allow the blind to "see" with sound. With this technology,

sound frequencies correspond to particular aspects of the scene. For example, higher frequencies of sound denote higher locations in the image. With training, the user can learn to "hear" everyday visual scenes, such as identifying individuals by their general facial characteristics (for instance by hair color, whether or not they have a beard or are wearing glasses, and so on).

Still other research groups have alternately developed microelectronic chips for implant in the eye to bypass defective photoreceptors or, much farther out, in the visual cortex (to circumvent deficits in the visual pathway) to enable the blind to "see the light" at least to some extent. Several different versions of retinal implants in early stages of development have enabled blind people to make out the basic outlines of people and objects, detect movement in front of them, and even to string together words by reading high-contrast letters. Several other promising avenues under investigation for halting or even reversing the loss of sight in degenerative eye diseases are injecting functional genes into eyes blinded by genetic mutations in retinal cells (already here), regenerating the retina through fetal retinal transplants, growing replacement retinas in the laboratory, and stem cell therapy (see p. 10).

For the remainder of the chapter, we will concentrate on the mainstream function of the other special senses. We next shift attention from the eyes to the ears.

6.4 Ear: Hearing and Equilibrium

Each **ear** consists of three parts: the *external,* the *middle,* and the *inner ear* (❙Figure 6-31). The external and middle portions of the ear transmit airborne sound waves to the fluid-filled inner ear, amplifying sound energy in the process. The inner ear houses two sensory systems: the *cochlea,* which contains the receptors for conversion of sound waves into nerve impulses,

making hearing possible, and the *vestibular apparatus,* which is necessary for the sense of equilibrium.

Sound waves consist of alternate regions of compression and rarefaction of air molecules.

Hearing is the neural perception of sound energy. It helps a person interact with both the external environment and with human society. Hearing involves two aspects: the identification of the sounds (what) and their localization (where). We first examine the characteristics of sound waves and then explore how the ears and brain process sound input to accomplish hearing.

Sound waves are traveling vibrations of air. They consist of regions of high pressure, caused by compression of air molecules, alternating with regions of low pressure, caused by rarefaction of the molecules (❙Figure 6-32a). Any device capable of producing such a disturbance pattern in air molecules is a source of sound. A simple example is a tuning fork. When a tuning fork is struck, its prongs vibrate. As a prong of the fork moves in one direction (❙Figure 6-32b), air molecules ahead of it are pushed closer together, or compressed, increasing the pressure in this area. Simultaneously, as the prong moves forward, the air molecules behind the prong spread out, or are rarefied, lowering the pressure in that region. As the prong moves in the opposite direction, an opposite wave of compression and rarefaction is created. Even though individual molecules are moved only short distances as the tuning fork vibrates, alternating waves of com-
I Figure 6-31 **Anatomy of the ear.**

pression and rarefaction spread out considerable distances in a rippling fashion. Disturbed air molecules disturb other molecules in adjacent regions, setting up new regions of compression and rarefaction, and so on (I Figure 6-32c). Sound energy gradually dissipates as sound waves travel farther from the original sound source; it finally dies out when the last sound wave is too weak to disturb the air molecules around it.

Sound waves can also travel through media other than air, such as water. They do so less efficiently, however; greater pressures are required to cause movements of fluid than movements of air because of the fluid's greater inertia (resistance to change).

Sound is characterized by its pitch (tone), intensity (loudness), and timbre (quality) (I Figure 6-33):

■ The **pitch**, or **tone**, of a sound (for example, whether it is a C or a G note) is determined by the *frequency* of vibrations. The greater the frequency of vibration, the higher the pitch. Human ears can detect sound waves with frequencies from 20 to 20,000 cycles per second, or **hertz (Hz)**, but are most sensitive to frequencies between 1000 and 4000 Hz.

■ The **intensity**, or **loudness**, of a sound depends on the *amplitude* of the sound waves, or the pressure differences between a high-pressure region of compression and a low-pressure region of rarefaction. Within the hearing range, the greater the amplitude, the louder the sound. Human ears can detect a wide range of sound intensities, from the slightest whisper to the painfully loud takeoff of a jet. Loudness is measured in **decibels (dB)**, which are a logarithmic measure of intensity compared with the faintest sound that can be heard—the **hearing threshold**. Because of the logarithmic relationship, every 10 dB indicates a 10-fold increase in loudness. A few ex-

amples of common sounds illustrate the magnitude of these increases (I Table 6-5). Note that the rustle of leaves at 10 dB is 10 times louder than hearing threshold but the sound of a jet taking off at 150 dB is 1 quadrillion (1 million billion) times, not 150 times, louder than the faintest audible sound. Sounds greater than 100 dB can permanently damage the sensitive sensory apparatus in the cochlea.

■ The **timbre**, or **quality**, of a sound depends on its *overtones,* which are additional frequencies superimposed on the fundamental pitch or tone. A tuning fork has a pure tone, but most sounds lack purity. For example, complex mixtures of overtones impart different sounds to different instruments playing the same note (a C note on a trumpet sounds different from C on a piano). Overtones are likewise responsible for characteristic differences in voices. Timbre enables the listener to distinguish the source of sound waves because each source produces a different pattern of overtones. Thanks to timbre, you can tell whether it is your mother or girlfriend calling on the phone before you say the wrong thing.

Next we describe how sound waves are detected by our ears, and then converted into neural signals that are sent to the brain for interpretation.

The external ear plays a role in sound localization.

The specialized receptor cells for sound are located in the fluid-filled inner ear. Airborne sound waves must therefore be channeled toward and transferred into the inner ear, compensating for the loss in sound energy that naturally occurs as sound

▌Figure 6-32 **Formation of sound waves.** (a) Sound waves are alternating regions of compression and rarefaction of air molecules. (b) A vibrating tuning fork sets up sound waves as the air molecules ahead of the advancing arm of the tuning fork are compressed while the molecules behind the arm are rarefied. (c) Disturbed air molecules bump into molecules beyond them, setting up new regions of air disturbance more distant from the original source of sound. In this way, sound waves travel progressively farther from the source, even though each individual air molecule travels only a short distance when it is disturbed. The sound wave dies out when the last region of air disturbance is too weak to disturb the region beyond it.

waves pass from air into water. This function is performed by the external ear and the middle ear.

The **external ear** (see ▌Figure 6-31) consists of the *pinna* (ear), *external auditory meatus* (ear canal), and *tympanic membrane* (eardrum). The **pinna**, a prominent skin-covered flap of cartilage, collects sound waves and channels them down the ear canal. The **ear canal** tunnels through the temporal bone from the exterior to the **tympanic membrane**, a thin membrane that separates the external ear and the middle ear.

Many species (dogs, for example) can cock their ears in the direction of sound to collect more sound waves, but human ears are relatively immobile. Because of its shape, the pinna partially shields sound waves that approach the ear from the rear and thus helps a person distinguish whether a sound is coming from directly in front or behind. Sound localization for sounds approaching from the right or left depends on the sound wave reaching the ear closer to the sound source slightly before it arrives at the farther ear. The auditory cortex integrates all these cues to determine the location of the sound source. It is difficult to localize sound with only one functional ear.

The tympanic membrane vibrates in unison with sound waves in the external ear.

The tympanic membrane, which is stretched across the entrance to the middle ear, vibrates when struck by sound waves. The alternating

higher- and lower-pressure regions of a sound wave cause the exquisitely sensitive eardrum to bow inward and outward in unison with the wave's frequency.

For the membrane to be free to move as sound waves strike it, the resting air pressure on both sides of the tympanic membrane must be equal. The outside of the eardrum is exposed to atmospheric pressure that reaches it through the ear canal. The inside of the eardrum facing the middle ear cavity is also exposed to atmospheric pressure via the **eustachian (auditory) tube**, which connects the middle ear to the **pharynx** (back of the throat) (see ▌Figure 6-31). The eustachian tube is normally closed, but it can be pulled open by yawning, chewing, and swallowing. Such opening permits air pressure within the

▌Figure 6-33 **Properties of sound waves.**

ITABLE 6-5 Relative Magnitude of Common Sounds

Sound	Loudness in Decibels (dB)	Comparison to Faintest Audible Sound (Hearing Threshold)
Rustle of leaves	10 dB	10 times louder
Ticking of watch	20 dB	100 times louder
Whispering	30 dB	1 thousand times louder
Normal conversation	60 dB	1 million times louder
Food blender, lawn mower, hair dryer	90 dB	1 billion times louder
Loud rock concert, ambulance siren	120 dB	1 trillion times louder
Takeoff of jet plane	150 dB	1 quadrillion times louder

middle ear to equilibrate with atmospheric pressure so that pressures on both sides of the tympanic membrane are equal. During rapid external pressure changes (for example, during air flight), the eardrum bulges painfully as the pressure outside the ear changes while the pressure in the middle ear remains unchanged. Opening the eustachian tube by yawning allows the pressure on both sides of the tympanic membrane to equalize, relieving the pressure distortion as the eardrum "pops" back into place.

Clinical Note Infections originating in the throat sometimes spread through the eustachian tube to the middle ear. The resulting fluid accumulation in the middle ear not only is painful but also interferes with sound conduction across the middle ear.

The middle ear bones convert tympanic membrane vibrations into fluid movements in the inner ear.

The **middle ear** transfers the vibrating movements of the tympanic membrane to the fluid of the inner ear. This transfer is facilitated by a movable chain of three small bones, or **ossicles** (the **malleus**, **incus**, and **stapes**), that extend across the middle ear (IFigure 6-34a). The first bone, the malleus, is attached to the tympanic membrane, and the last bone, the stapes, is attached to the **oval window**, the entrance into the fluid-filled cochlea. As the tympanic membrane vibrates in response to sound waves, the chain of bones is set into motion at the same frequency, transmitting this frequency of movement from the tympanic membrane to the oval window. The resulting pressure on the oval window with each vibration produces wavelike movements in the inner ear fluid at the same frequency as the original sound waves. Recall that it takes greater pressure to set fluid in motion than needed to move air, but the ossicular system amplifies the pressure of the airborne sound waves sufficiently by two mechanisms to produce fluid movements in the cochlea. First, because the surface area of the tympanic membrane is much larger than that of the oval window, pressure is increased as force exerted on the tympanic membrane is con-

veyed by the ossicles to the oval window (pressure = force/unit area). Second, the lever action of the ossicles provides an additional mechanical advantage. Together, these mechanisms increase the force exerted on the oval window by 20 times what it would be if the airborne sound wave struck the oval window directly. This additional pressure is sufficient to set the cochlear fluid in motion.

Several tiny muscles in the middle ear contract reflexly in response to loud sounds (greater than 70 dB), causing the tympanic membrane to tighten and limiting movement of the ossicular chain. This reduced movement of middle ear structures diminishes the transmission of loud sound waves to the inner ear to protect the delicate sensory apparatus from damage. This reflex response is relatively slow, however, happening at least 40 msec after exposure to a loud sound. It thus provides protection only from prolonged loud sounds, not from sudden sounds like an explosion. Taking advantage of this reflex, World War II antiaircraft guns were designed to make a loud prefiring sound to protect the gunner's ears from the much louder boom of the actual firing.

The cochlea contains the organ of Corti, the sense organ for hearing.

The pea-sized, snail-shaped **cochlea**, the "hearing" portion of the inner ear, is a coiled tubular system lying deep within the temporal bone (see IFigure 6-31) (*cochlea* means "snail"). It is easier to understand the functional components of the cochlea by "uncoiling" it, as shown in IFigure 6-34a. The cochlea is divided throughout most of its length into three fluid-filled longitudinal compartments. A blind-ended **cochlear duct**, which is also known as the **scala media**, constitutes the middle compartment. It tunnels lengthwise through the center of the cochlea, not quite reaching its end. The upper compartment, the **scala vestibuli**, follows the inner contours of the spiral, and the **scala tympani**, the lower compartment, follows the outer contours (IFigure 6-34a and b). The fluid within the scala vestibuli and scala tympani is called **perilymph**. The cochlear duct contains a slightly different fluid, the **endolymph** (IFigure

6-35a). The region beyond the tip of the cochlear duct where the fluid in the upper and lower compartments is continuous is called the **helicotrema**. The scala vestibuli is sealed from the middle ear cavity by the oval window, to which the stapes is attached. Another small membrane-covered opening, the **round window**, seals the scala tympani from the middle ear. The thin **vestibular membrane** forms the ceiling of the cochlear duct and separates it from the scala vestibuli. The **basilar membrane** forms the floor of the cochlear duct, separating it from the scala tympani. The basilar membrane is especially
Fluid movement within the perilymph set up by vibration of the oval window follows two pathways:

Pathway 1: Through the scala vestibuli, around the heliocotrema, and through the scala tympani, causing the round window to vibrate. This pathway just dissipates sound energy.

Pathway 2: A "shortcut" from the scala vestibuli through the basilar membrane to the scala tympani. This pathway triggers activation of the receptors for sound by bending the hairs of hair cells as the organ of Corti on top of the vibrating basilar membrane is displaced in relation to the overlying tectorial membrane.

important because it bears the **organ of Corti**, the sense organ for hearing.

Hair cells in the organ of Corti transduce fluid movements into neural signals.

The organ of Corti, which rests on top of the basilar membrane throughout its full length, contains **auditory hair cells** that are the receptors for sound. The 15,000 hair cells within each cochlea are arranged in four parallel rows along the length of the basilar membrane: one row of **inner hair cells** and three rows of **outer hair cells** (see ❙Figure 6-34c and d). Protruding from the surface of each hair cell are about 100 hairs known as **stereocilia**, which are actin-stiffened microvilli, not true cilia (see p. 50). Hair cells are mechanoreceptors; they generate neural signals when their surface hairs are mechanically deformed by fluid movements in the inner ear. These stereocilia contact the **tectorial membrane**, an awninglike projection overhanging the organ of Corti throughout its length (see ❙Figure 6-34b and c).

The pistonlike action of the stapes against the oval window sets up pressure waves in the upper compartment. Because fluid is incompressible, pressure is dissipated in two ways as the stapes causes the oval window to bulge inward: (1) displacement of the round window and (2) deflection of the basilar membrane (❙Figure 6-35a). In the first of these pathways, the pressure wave pushes the perilymph forward in the upper compartment, around the helicotrema, and into the lower compartment, where it causes the round window to bulge outward into the middle ear cavity to compensate for the pressure increase. As the stapes rocks backward and pulls the oval window outward toward the middle ear, the perilymph shifts in the opposite direction, displacing the round window inward. This pathway does not result in sound reception; it just dissipates pressure.

Pressure waves of frequencies associated with sound reception take a "shortcut" (❙Figure 6-35a). Pressure waves in the upper compartment are transferred through the thin vestibular membrane, into the cochlear duct and then through the basilar membrane into the lower compartment. Transmission of pressure waves through the basilar membrane causes this membrane to move up and down, or vibrate, in synchrony with the pressure wave. Because the organ of Corti rides on the basilar membrane, the hair cells also move up and down.

Role of the Inner Hair Cells The inner and outer hair cells differ in function. The inner hair cells are the ones that "hear": They transform the mechanical forces of sound (cochlear fluid vibration) into the electrical impulses of hearing (action potentials propagating auditory messages to the cerebral cortex). Because the stereocilia of these receptor cells are connected to the stiff, stationary tectorial membrane, they are bent back and forth when the oscillating basilar membrane shifts their position in relationship to the tectorial membrane (❙Figure 6-36). This back-and-forth mechanical deformation of the hairs alternately opens and closes mechanically gated cation channels (see p. 89) in the hair cell, resulting in alternating depolarizing and hyperpolarizing potential changes—the receptor potential—at the same frequency as the original sound stimulus.

The stereocilia (hairs) from the hair cells of the basilar membrane contact the overlying tectorial membrane. These hairs are bent when the basilar membrane is deflected in relation to the stationary tectorial membrane. This bending of the inner hair cells' hairs opens mechanically gated channels, leading to ion movements that result in a receptor potential.

❙Figure 6-36 Bending of hairs on deflection of the basilar membrane.

The stereocilia of each hair cell are organized into three rows of increasing heights in a precise staircaselike pattern resembling organ pipes (❙Figure 6-37a). **Tip links**, which are CAMs (cell adhesion molecules; see p. 60), link the tip of one stereocilium to the side of the next taller stereocilium in the next row up (❙Figure 6-37b). The tallest stereocilia in the top row is directly linked with the overlying tectorial membrane. When the basilar membrane moves upward, the bundle of stereocilia bends toward its tallest membrane that is connected to the stationary tectorial membrane, stretching the tip links. Stretched tip links tug open the mechanically gated cation channels to which they are attached (❙Figure 6-37c). The resultant ion movement is unusual because of the unique composition of the endolymph that bathes the stereocilia. In sharp contrast to ECF elsewhere, endolymph has a higher concentration of K^+ than found inside the hair cell. Some cation channels are open in a resting hair cell, allowing low-level K^+ entry down its concentration gradient. When more cation channels are pulled open, more K^+ enters the hair cell. This additional entering K^+ depolarizes (excites) the hair cell. When the basilar membrane moves in the opposite direction, the hair bundle bends away from the tallest stereocilium, slackening the tip links and closing all the channels. As a result, K^+ entry ceases, hyperpolarizing the hair cell.

Like photoreceptors, hair cells do not undergo action potentials. The inner hair cells communicate via a chemical synapse with the terminals of afferent nerve fibers making up the **auditory (cochlear) nerve**. Because of low-level K^+ entry, the inner hair cells spontaneously release some neurotransmitter (glutamate) via Ca^{2+}-induced exocytosis in the absence of stimulation. Depolarization of these hair cells opens more voltage-gated Ca^{2+} channels. The resultant additional Ca^{2+} entry increases their rate of neurotransmitter secretion, which steps up the rate of firing in the afferent fibers with which the inner

hair cells synapse. Conversely, the firing rate decreases below resting level as these hair cells release less neurotransmitter when they are hyperpolarized on displacement in the opposite direction.

To summarize, the ear converts sound waves in the air into oscillating movements of the basilar membrane that bends the hairs of the receptor cells back and forth. This shifting mechanical deformation of the hairs alternately opens and closes the

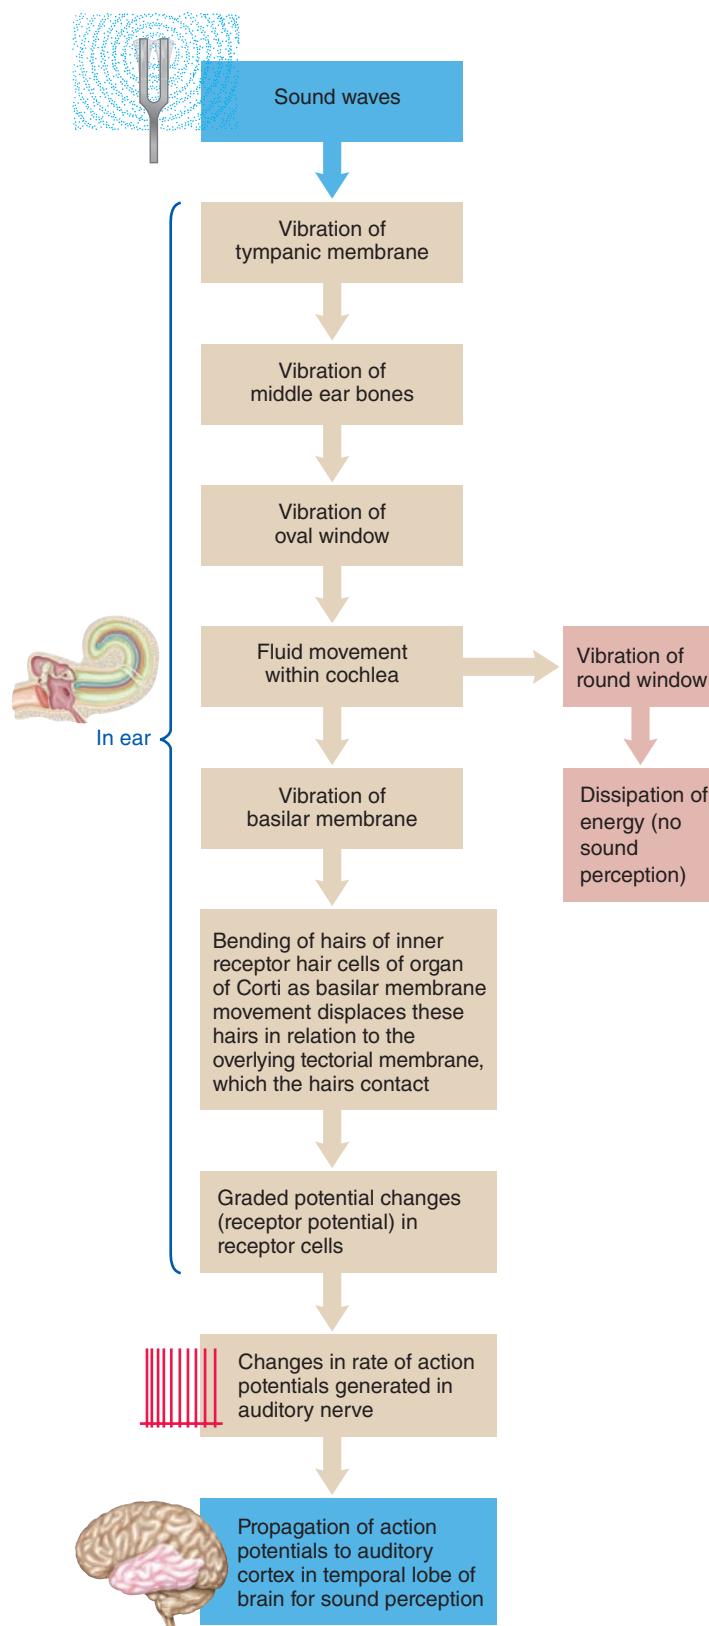
receptor cells' channels, bringing about graded potential changes in the receptor that lead to changes in the rate of action potentials propagated to the brain. These neural signals are perceived by the brain as sound sensations (❙Figure 6-38).

Role of the Outer Hair Cells Whereas the inner hair cells send auditory signals to the brain over afferent fibers, the outer hair cells do not signal the brain about incoming sounds. Instead, the outer hair cells actively and rapidly change length in response to changes in membrane potential, a behavior known as **electromotility**. The outer hair cells shorten on depolarization and lengthen on hyperpolarization. These changes in length mechanically amplify or accentuate the motion of the basilar membrane. An analogy would be a person deliberately pushing the pendulum of a grandfather clock in time with its swing to accentuate its motion. Such modification of basilar membrane movement improves and tunes stimulation of the inner hair cells. Thus, the outer hair cells enhance the response of the inner hair cells, the real auditory sensory receptors, making them exquisitely sensitive to sound intensity and highly discriminatory between various pitches of sound.

Pitch discrimination depends on the region of the basilar membrane that vibrates.

Pitch discrimination (that is, the ability to distinguish among various frequencies of incoming sound waves) depends on the shape and properties of the basilar membrane, which is narrow and stiff at its oval window end and wide and flexible at its helicotrema end (see ❙Figure 6-35b). Different regions of the basilar membrane naturally vibrate maximally at different frequencies—that is, each frequency displays peak vibration at a different position along the membrane. The narrow end nearest the oval window vibrates best with high-frequency pitches, whereas the wide end nearest the helicotrema vibrates maximally with low-frequency tones (see ❙Figure 6-35c). The pitches in between are sorted out precisely along the length of the membrane from higher to lower frequency. As a sound wave of a particular frequency is set up in the cochlea by oscillation of the stapes, the wave travels to the region of the basilar membrane that naturally responds maximally to that frequency. The energy of the pressure wave is dissipated with this vigorous membrane oscillation, so the wave dies out at the region of maximal displacement.

The hair cells in the region of peak vibration of the basilar membrane undergo the most mechanical deformation and accordingly are the most excited. You can think of the organ of Corti as a piano with 15,000 keys (represented by the 15,000 hair cells) rather than the usual 88 keys. Each hair cell is "tuned" to an optimal sound frequency, determined by its location on the organ of Corti. Different sound waves promote maximal movement of different regions of the basilar membrane and thus activate differently tuned hair cells (that is, different sound waves "strike" different "piano keys"). This information is propagated to the CNS, which interprets the pattern of hair cell stimulation as a sound of a particular frequency. The basilar membrane is so fine-tuned that the peak membrane response to a single pitch probably extends no more than the width of a few hair cells.



❙Figure 6-38 **Pathway for sound transduction**.

Overtones of varying frequencies cause many points along the basilar membrane to vibrate simultaneously but less intensely than the fundamental tone, enabling the CNS to distinguish the timbre of the sound (**timbre discrimination**).

Loudness discrimination depends on the amplitude of vibration.

Intensity (loudness) discrimination depends on the amplitude of vibration. As sound waves originating from louder sound sources strike the eardrum, they cause it to vibrate more vigorously (that is, bulge in and out to a greater extent) but at the same frequency as a softer sound of the same pitch. The greater tympanic membrane deflection translates into greater basilar membrane movement in the region of peak responsiveness, causing greater bending of the hairs in this region. The CNS interprets this greater hair bending as a louder sound. Thus, pitch discrimination depends on "where" the basilar membrane maximally vibrates and loudness discrimination depends on "how much" this place vibrates.

The auditory system is so sensitive and can detect sounds so faint that the distance of basilar membrane deflection is comparable to only a fraction of the diameter of a hydrogen atom, the smallest of atoms. No wonder very loud sounds, which cannot be sufficiently attenuated by protective middle ear reflexes (for example, the sounds of a typical rock concert), can set up such violent vibrations of the basilar membrane that irreplaceable hair cells are actually sheared off or permanently distorted, leading to partial hearing loss (❚Figure 6-39). Damage can occur not only from brief exposure to high-intensity sounds but also from frequent exposure to moderately loud noises (those greater than 75 dB), something common in today's environment.

The auditory cortex is mapped according to tone.

Just as various regions of the basilar membrane are associated with particular tones, the **primary auditory cortex** in the temporal lobe is also *tonotopically* organized. Each region of the basilar membrane is linked to a specific region of the primary auditory cortex. Accordingly, specific cortical neurons are activated only by particular tones—that is, each region of the auditory cortex becomes excited only in response to a specific tone detected by a selected portion of the basilar membrane.

The afferent neurons that pick up the auditory signals from the inner hair cells exit the cochlea via the auditory nerve. The neural pathway between the organ of Corti and the auditory cortex involves several synapses en route, the most notable of which are in the brain stem and *medial geniculate nucleus* of the thalamus. The brain stem uses the auditory input for alertness and arousal. The thalamus sorts and relays the signals upward. Unlike signals in the visual pathways, auditory signals from each ear are transmitted to both temporal lobes because the fibers partially cross over in the brain stem. For this reason, a disruption of the auditory pathways on one side beyond the brain stem does not affect hearing in either ear to any extent.

The primary auditory cortex perceives discrete sounds, whereas the surrounding higher-order auditory cortex integrates the separate sounds into a coherent, meaningful pattern. Think about the complexity of the task accomplished by your auditory system. When you are at a concert, your organ of Corti responds to the simultaneous mixture of the instruments, the applause and hushed talking of the audience, and the background noises in the theater. You can distinguish these separate parts of the many sound waves reaching your ears and can pay attention to those of importance to you.

Deafness is caused by defects in either conduction or neural processing of sound waves.

Clinical Note Loss of hearing, or **deafness**, may be temporary or permanent, partial or complete. Deafness is classified into two types—*conductive deafness* and *sensorineural deafness*—depending on the part of the hearing mechanism that fails to function adequately. **Conductive deafness** occurs when sound waves are not adequately conducted through the external and middle portions of the ear to set the fluids in the inner ear in motion. Possible causes include physical blockage of the ear canal with earwax, rupture of the eardrum, middle ear infections with accompanying fluid accumulation, or restriction of ossicular movement because of bony adhesions. In **sensorineural deafness**, sound waves are transmitted to the inner ear, but they are not translated into nerve signals that are interpreted by the brain as sound sensations. The defect can lie in the organ of Corti, in the auditory nerves or, rarely, in the ascending auditory pathways or auditory cortex.

One of the most common causes of partial hearing loss, **neural presbycusis**, is a degenerative, age-related process that occurs as hair cells "wear out" with use. Over time, exposure to even ordinary modern-day sounds eventually damages hair cells so that, on average, adults have lost more than 40% of their cochlear hair cells by age 65. Hearing loss is the second most common physical disability in the United
(a) Normal hair cells

(b) Damaged hair cells

❚Figure 6-39 **Loss of hair cells caused by loud noises.** The scanning electron micrographs show portions of the organ of Corti, with its three rows of outer hair cells and one row of inner hair cells, from the inner ear of (a) a normal guinea pig and (b) a guinea pig after a 24-hour exposure to noise at 120 decibels SPL (sound pressure level), a level approached by loud rock music.

States. Currently, more than 48 million Americans have some degree of hearing loss, and this number is expected to climb to 78 million by 2030. Unfortunately, partial hearing loss caused by excessive exposure to loud noises is affecting people at younger ages than in the past because we live in an increasingly noisy environment. An estimated 6.5 million children between 6 and 19 years of age in the United States already have some hearing damage resulting from amplified music and other noise pollution. Hair cells that process high-frequency sounds are the most vulnerable to destruction.

Hearing aids are helpful in conductive deafness but are less beneficial for sensorineural deafness. These devices increase the intensity of airborne sounds and may modify the sound spectrum and tailor it to the person's particular pattern of hearing loss at higher or lower frequencies. For the sound to be perceived, however, the receptor cell–neural pathway system must still be intact.

The first **cochlear implant** went on the market in 1972. These electronic devices, which are surgically implanted, transduce sound signals into electrical signals that can directly stimulate the auditory nerve, thus bypassing a defective cochlear system. Cochlear implants cannot restore normal hearing, but they do permit recipients to recognize sounds. Success ranges from an ability to "hear" a phone ringing to being able to carry on a conversation over the phone.

Recent findings suggest that in the future it may be possible to restore hearing by stimulating an injured inner ear to repair itself. Scientists have long considered the hair cells of the inner ear irreplaceable. Thus, hearing loss resulting from hair cell damage caused by the aging process or exposure to loud noises is considered permanent. Encouraging new studies suggest, to the contrary, that hair cells in the inner ear have the latent ability to regenerate in response to an appropriate chemical signal. Researchers are currently trying to develop a drug that spurs regrowth of hair cells, thus repairing inner ear damage and hopefully restoring hearing. Other investigators are employing a gene therapy approach to prompt growth of replacement hair cells. Still others are using neural growth factors to coax auditory nerve cell endings to resprout in the hopes of reestablishing lost neural pathways.

The vestibular apparatus is important for equilibrium by detecting head position and motion.

In addition to its cochlear-dependent role in hearing, the inner ear has another specialized component, the **vestibular apparatus**, which provides information essential for the sense of equilibrium and for coordinating head movements with eye and postural movements (❙Figure 6-40). **Equilibrium** is the sense of body orientation and motion. The vestibular apparatus consists of two sets of structures lying within a tunneled-out region of the temporal bone near the cochlea—the *semicircular canals* and the *otolith organs*.

The vestibular apparatus detects changes in position and motion of the head. As in the cochlea, all components of the vestibular apparatus contain endolymph and are surrounded by perilymph. Also, similar to the organ of Corti, the vestibular components each contain hair cells that respond to mechanical deformation triggered by specific movements of the endolymph. And like the auditory hair cells, the vestibular receptors may be either depolarized or hyperpolarized, depending on the direction of the fluid movement. Unlike information from the auditory system, much of the information provided by the vestibular apparatus does not reach the level of conscious awareness.

Role of the Semicircular Canals The **semicircular canals** detect rotational or angular acceleration or deceleration of the head, such as when turning the head, starting or stopping spinning, or somersaulting. Each ear contains three Hula-Hoop-shaped semicircular canals arranged three-dimensionally in planes that lie at right angles to each other. The receptor hair cells of each semicircular canal are situated on top of a saddle-shaped ridge located in the **ampulla**, a swelling at the base of the canal (❙Figure 6-40a and b). The hairs are embedded in an overlying, caplike, gelatinous layer, the **cupula**, which protrudes into the endolymph and stretches to the roof of the ampulla. The force of moving endolymph pushes against the cupula, causing it to bow so that the embedded hairs are bent.

Acceleration or deceleration during rotation of the head in any direction causes endolymph movement in at least one of the semicircular canals because of their three-dimensional arrangement. As you start to move your head, the bony canal and the ridge of hair cells embedded in the cupula move with your head. Initially, however, the fluid within the canal, not being attached to your skull, does not move in the direction of the rotation but lags behind because of its inertia. (Because of inertia, a resting object remains at rest and a moving object continues to move in the same direction unless the object is acted on by some external force that induces change.) When the endolymph is left behind as you start to rotate your head, the fluid that is in the same plane as the head movement is in effect shifted in the opposite direction from the movement (similar to your body tilting to the right as the car in which you are riding suddenly turns to the left) (❙Figure 6-40c). This fluid movement causes the cupula to lean in the opposite direction from the head movement, bending the sensory hairs embedded in it. If your head movement continues at the same rate in the same direction, the endolymph catches up and moves in unison with your head so that the hairs return to their unbent position. When your head slows down and stops, the reverse situation occurs. The endolymph briefly continues to move in the direction of the rotation while your head decelerates to a stop. As a result, the cupula and its hairs are transiently bent in the direction of the preceding spin, which is opposite to the way they were bent during acceleration.

The hairs of a **vestibular hair cell** consist of one cilium, the **kinocilium**, along with a tuft of 20 to 50 microvilli—the **stereocilia**—arranged in rows of decreasing height from the taller kinocilium (❙Figure 6-40d) (see p. 48). As in the auditory hair cell, the stereocilia are linked by tip links. When the stereocilia are deflected by endolymph movement, the resultant tension on the tip links pulls on mechanically gated ion channels in the hair cell. Depending on whether the ion channels are mechanically opened or closed by hair bundle displacement, the hair cell either depolarizes or hyperpolarizes. Each hair cell is oriented so

IFigure 6-40 **Structure and activation of vestibular apparatus.** The scanning electron micrograph shows the kinocilium and stereocilia on the hair cells within the vestibular apparatus.

FIGURE FOCUS: *What direction will the endolymph in your semicircular canals move as you do a forward somersault?*

that it depolarizes when its stereocilia are bent toward the kinocilium and hyperpolarizes when the stereocilia are bent away from the kinocilium. The hair cells form a chemically mediated synapse with terminal endings of afferent neurons whose axons join with those of the other vestibular structures to form the **vestibular nerve**. This nerve unites with the auditory nerve from the cochlea to form the **vestibulocochlear nerve**. Depolarization increases the release of neurotransmitter from the hair cells, thereby bringing about an increased rate of firing in the afferent fibers; conversely, hyperpolarization reduces neurotransmitter release from the hair cells, in turn decreasing the frequency of action potentials in the afferent fibers. When the fluid gradually comes to a halt, the hairs straighten again. Thus, the semicircular canals detect changes in the rate of rotational movement (rotational acceleration or deceleration) of your head. They do not respond when your head is motionless or when it is moving in a circle at a constant speed.

Role of the Otolith Organs The **otolith organs** provide information about the position of the head relative to gravity (that is, static head tilt) and detect changes in the rate of linear motion (moving in a straight line regardless of direction). The otolith organs, the **utricle** and the **saccule**, are saclike structures housed within a bony chamber situated between the semicircular canals and the cochlea (❚Figure 6-40a). The hairs (kinocilium and stereocilia) of the receptor hair cells in these sense organs also protrude into an overlying gelatinous sheet, whose movement displaces the hairs and results in changes in hair cell potential. Many tiny crystals of calcium carbonate—the **otoliths** ("ear stones")—are suspended within the gelatinous layer, making it heavier and giving it more inertia than the surrounding fluid (❚Figure 6-41a). When a person is in an upright position, the hairs within the utricle are oriented vertically and the saccule hairs are lined up horizontally.

Let us look at the *utricle* as an example. Its otolith-embedded, gelatinous mass shifts positions and bends the hairs in two ways:

1. When you tilt your head in any direction so that it is no longer vertical (that is, when your head is not straight up and down), the hairs are bent in the direction of the tilt because of the gravitational force exerted on the top-heavy gelatinous

❚Figure 6-41 **Structure and activation of a receptor cell unit in the utricle.**

layer (❙Figure 6-41b). This bending produces depolarizing or hyperpolarizing receptor potentials depending on the tilt of your head. The CNS thus receives different patterns of neural activity depending on head position with respect to gravity.

2. The utricle hairs are also displaced by any change in horizontal linear motion (such as moving straight forward, backward, or to the side). As you start to walk forward (❙Figure 6-41c), the top-heavy otolith membrane at first lags behind the endolymph and hair cells because of its greater inertia. The hairs are thus bent to the rear, in the opposite direction of the forward movement of your head. If you maintain your walking pace, the gelatinous layer soon catches up and moves at the same rate as your head so that the hairs are no longer bent. When you stop walking, the otolith sheet continues to move forward briefly as your head slows and stops, bending the hairs toward the front. Thus, the hair cells of the utricle detect horizontally directed linear acceleration and deceleration, but they do not provide information about movement in a straight line at constant speed.

The saccule functions similarly to the utricle, except that it responds selectively to tilting of the head away from a horizontal position (such as getting up from bed) and to vertically directed linear acceleration and deceleration (such as jumping up and down or riding in an elevator). Together the otolith organs let you know which way is up and what direction you are heading.

Signals arising from the various components of the vestibular apparatus are carried through the vestibulocochlear nerve to the **vestibular nuclei**, a cluster of neuronal cell bodies in the brain stem, and to the cerebellum. Here, the vestibular information is integrated with input from the eyes, skin surface, joints, and muscles for (1) maintaining balance and desired posture; (2) controlling the external eye muscles so that the eyes remain fixed on the same point, despite movement of the head; and (3) perceiving motion and orientation.

Clinical Note Some people, for poorly understood reasons, are especially sensitive to particular motions that activate the vestibular apparatus and cause symptoms of dizziness and nausea; this sensitivity is called **motion sickness**. Occasionally, fluid imbalances within the inner ear lead to **Ménière's disease**. Not surprisingly because both the vestibular apparatus and cochlea contain the same inner ear fluids, both vestibular and auditory symptoms occur with this condition. An afflicted individual suffers transient attacks of severe vertigo (dizziness) accompanied by pronounced ringing in the ears and some loss of hearing. During these episodes, the person cannot stand upright and reports feeling as though self or surrounding objects in the room are spinning around.

Permanent damage to the semicircular canals causes poor balance and shaky, blurred vision when the head is moving (because the person cannot keep the eyes on target during the motion). Now researchers are working on a bionic ear implant that incorporates a miniature gyroscope for sensing head rotation in all three dimensions, which ultimately sends electrical signals to electrodes that stimulate the vestibular nerve, thus bypassing a defective semicircular canal system and restoring balance.

❙Table 6-6 summarizes the functions of the major components of the ear.

6.5 Chemical Senses: Taste and Smell

Unlike the eyes' photoreceptors and the ears' mechanoreceptors, the receptors for taste and smell are chemoreceptors, which generate neural signals on binding with particular chemicals in their environment. The sensations of taste and smell in association with food intake influence the flow of digestive juices and affect appetite. Furthermore, stimulation of taste or smell receptors induces pleasurable or objectionable sensations and signals the presence of something to seek (a nutritionally useful, good-tasting food) or to avoid (a potentially toxic, bad-tasting substance). Thus, the chemical senses provide a "quality-control" checkpoint for substances available for ingestion. In lower animals, smell also plays a major role in finding direction, in seeking prey or avoiding predators, and in sexual attraction to a mate. The sense of smell is less sensitive in humans and less important in influencing our behavior (although millions of dollars are spent annually on perfumes and deodorants to make us smell better and appear more socially attractive). We first examine the mechanism of taste (**gustation**) and then turn attention to smell (**olfaction**).

Taste receptor cells are located primarily within tongue taste buds.

The chemoreceptors for **taste** sensation are packaged in taste buds, about 10,000 of which are present in the oral cavity and throat, with the greatest percentage on the upper surface of the tongue. A **taste bud** consists of about 50 long, spindle-shaped *taste receptor cells* packaged with *supporting cells* in an arrangement like slices of an orange (❙Figure 6-42). Each taste bud has a small opening, the **taste pore**, through which fluids in the mouth come into contact with the surface of its receptor cells. **Taste receptor cells** are modified epithelial cells with many surface folds, or microvilli, that protrude slightly through the taste pore, greatly increasing the surface area exposed to the oral contents. The plasma membrane of the microvilli contains receptor sites that bind selectively with chemical molecules in the environment. Only chemicals in solution—either ingested liquids or solids that have been dissolved in saliva—can attach to receptor cells and evoke the

TABLE 6-6 Functions of the Major Components of the Ear

Structure	Location	Function
External ear		Collects and transfers sound waves to the middle ear
Pinna (ear)	Skin-covered flap of cartilage located on each side of the head	Collects sound waves and channels them down the ear canal; contributes to sound localization
External auditory meatus (ear canal)	Tunnel from the exterior through the temporal bone to the tympanic membrane	Directs sound waves to the tympanic membrane
Tympanic membrane (eardrum)	Thin membrane that separates the external ear and the middle ear	Vibrates in synchrony with sound waves that strike it, setting middle ear bones in motion
Middle ear		Transfers vibrations of the tympanic membrane to the fluid in the cochlea
Malleus, incus, stapes	Movable chain of bones that extends across the middle ear cavity; malleus attaches to the tympanic membrane, and stapes attaches to the oval window	Oscillate in synchrony with tympanic membrane vibrations and set up wavelike movements in the cochlear perilymph at the same frequency
Inner ear: cochlea		Houses sensory system for hearing
Oval window	Thin membrane at the entrance to the cochlea; separates the middle ear from the scala vestibuli	Vibrates in unison with movement of the stapes, to which it is attached; oval window movement sets cochlear perilymph in motion
Scala vestibuli	Upper compartment of the cochlea, a snail-shaped tubular system that lies deep within the temporal bone	Contains perilymph that is set in motion by oval window movement driven by oscillation of middle ear bones
Scala tympani	Lower compartment of the cochlea	Contains perilymph that is continuous with the scala vestibuli
Cochlear duct (scala media)	Middle compartment of the cochlea; a blind-ended tubular compartment that tunnels through the center of the cochlea	Contains endolymph; houses the basilar membrane
Basilar membrane	Forms the floor of the cochlear duct	Vibrates in unison with perilymph movements; bears the organ of Corti, the sense organ for hearing
Organ of Corti	Rests on top of the basilar membrane throughout its length	Contains hair cells, the receptors for sound; inner hair cells undergo receptor potentials when their hairs are bent as a result of fluid movement in the cochlea
Tectorial membrane	Stationary membrane that overhangs the organ of Corti and contacts the surface hairs of the receptor hair cells	Serves as the stationary site against which the hairs of the receptor cells are bent and undergo receptor potentials as the vibrating basilar membrane moves in relation to this overhanging membrane
Round window	Thin membrane that separates the scala tympani from the middle ear	Vibrates in unison with fluid movements in perilymph to dissipate pressure in the cochlea; does not contribute to sound reception
Inner ear: vestibular apparatus		Houses sensory systems for equilibrium and provides input essential for maintaining posture and balance
Semicircular canals	Three semicircular canals arranged three-dimensionally in planes at right angles to each other near the cochlea	Detect rotational or angular acceleration or deceleration
Utricle	Saclike structure in a bony chamber between the cochlea and semicircular canals	Detects changes in head position away from vertical and horizontally directed linear acceleration and deceleration
Saccule	Lies next to the utricle	Detects changes in head position away from horizontal and vertically directed linear acceleration and deceleration

sensation of taste. Binding of a taste-provoking chemical, a **tastant**, with a receptor cell alters the cell's ionic channels to produce a depolarizing receptor potential. Like the other special sense receptors, a depolarizing receptor potential opens voltage-gated Ca^{2+} channels, leading to the entry of Ca^{2+}, which promotes release of neurotransmitter. This neurotransmitter (serotonin or ATP [adenosine triphosphate], depending on the taste sensation), in turn, initiates action potentials within terminal endings of afferent nerve fibers with which the receptor cell synapses. Each taste receptor cell responds to only one tastant.

Most receptors are carefully sheltered from direct exposure to the environment, but the taste receptor cells, by virtue of their task, frequently come into contact with potent chemicals. Unlike the eye or ear receptors, which are irreplaceable, taste receptors have a life span of about 10 days. Epithelial cells surrounding the taste bud differentiate first into supporting cells and then into receptor cells to constantly renew the taste bud components.

Terminal afferent endings of several cranial nerves terminate on taste buds in various regions of the mouth. Signals in these sensory inputs are conveyed via synaptic stops in the brain stem and thalamus to the **primary gustatory** (or **taste) cortex**, where the taste is perceived. The primary gustatory cortex is found in the *insula,* a cortical region that lays hidden from the surface in an especially deep fold, the lateral sulcus, that separates the temporal lobes from the overlying parietal and frontal lobes (see ꓲFigure 5-10, p. 147). Contrary to the long-held belief that each primary taste is encoded by a unique ensemble of neurons dispersed throughout the gustatory cortex without any spatial clustering, recent evidence suggests that each taste modality is represented in its own separate territory in the gustatory cortex. This taste map is similar to the way in which brain regions that process tactile, visual, and auditory input are organized into spatial maps. Unlike most sensory input, the gustatory pathways are primarily uncrossed. Taste signals are also sent to the hypothalamus and limbic system to add affective dimensions, such as whether the taste is pleasant or unpleasant, and to process behavioral aspects associated with taste and smell.

Taste discrimination is coded by patterns of activity in various taste bud receptors.

We can discriminate among thousands of taste sensations, yet all tastes are varying combinations of five **primary tastes**: *salty, sour, sweet, bitter,* and *umami.* Umami, a meaty or savory taste, has recently been added to the list of primary tastes.

The five established primary taste sensations are elicited by the following stimuli:

■ **Salty taste** is stimulated by chemical salts, especially NaCl (table salt). Direct entry of positively charged Na^+ ions through specialized Na^+ channels in the receptor cell membrane, a movement that reduces the cell's internal negativity, is responsible for receptor depolarization in response to salt. Saltiness signals the presence of electrolytes, necessary components of a healthy diet.

■ **Sour taste** is caused by acids, which contain a free hydrogen ion, H^+. The citric acid content of lemons, for example, accounts for their distinctly sour taste. Depolarization of the receptor cell by sour tastants occurs because H^+ blocks K^+ channels in the receptor cell membrane. The resultant decrease in the passive movement of positively charged K^+ ions out of the cell reduces the internal negativity, producing a depolarizing receptor potential. For animals and early humans using taste as a guide to evaluate the nutritional value of a potential food source, a sour taste could indicate spoiled food.

■ **Sweet taste** is a pleasurable sensation evoked by the particular configuration of glucose. From an evolutionary perspective, we crave sweet foods because they supply necessary calories in a readily usable form. However, other organic molecules with similar structures but no calories, such as saccharin, aspartame, sucralose, and other artificial sweeteners, can also interact with "sweet" receptor binding sites. Binding of glucose or another chemical with a sweet taste receptor activates a G protein, which acts through a cAMP second-messenger pathway (see p. 123) in the taste cell to ultimately cause phosphorylation and blockage of K^+ channels in the receptor cell membrane, leading to a depolarizing receptor potential.

■ **Bitter taste** is elicited by a more chemically diverse group of tastants than the other taste sensations. For example, alkaloids (such as caffeine, nicotine, strychnine, morphine, and other toxic plant derivatives) and poisonous substances, all taste bitter, presumably as a protective mechanism to discourage ingestion of these potentially dangerous compounds (the tendency is to spit out something bitter). Taste cells that detect bitter flavors possess about 30 bitter receptor types, all of which are G-protein-coupled receptors, each of which responds to a different bitter flavor. (By comparison, there appears to be only one receptor type each for the other primary tastes.) Because each bitter taste receptor cell has a diverse family of bitter receptors, a wide variety of unrelated chemi-

cals all taste bitter despite their diverse structures. This mechanism expands the ability of a bitter taste receptor cell to detect a wide range of potentially harmful chemicals. The first G protein in taste—**gustducin**—was identified in one of the bitter signaling pathways. This G protein, which sets off a second-messenger pathway in the taste cell, is very similar to the visual G protein, transducin. (Gustducin is also the G protein in the sweet and umami signaling pathways.)

■ **Umami taste**, a pleasant savory taste that was first identified and named by a Japanese researcher, is triggered by amino acids, especially glutamate (*umami* means "pleasant savory taste"). The presence of amino acids, as found in meat, for example, is a marker for a desirable, nutritionally protein-rich food. Glutamate binds to a GPCR and acts via a second-messenger pathway. In addition to giving us our sense of meaty flavors, this pathway is responsible for the distinctive taste of the flavor additive monosodium glutamate (MSG), which is especially popular in Asian dishes.

Note that transduction of salt and sour taste is mediated by ion channels, whereas transduction of the other three primary tastes depends on GPCRs. The different GPCRs for detection of sweet, umami, and bitter have been identified. Bitter is detected by T2R receptors (of which there are about 30 different variants), whereas sweet and umami are detected by specific combinations of two of the three different T1R receptors. Sweet taste results from binding of a tastant to the receptor combination of T1R2 + T1R3; umami taste is triggered by tastant binding to the receptor combination of T1R1 + T1R3.

Another new taste sensation has also been proposed—**fat taste**. Scientists have identified a sensor in the mouth for long-chain fatty acids, which could explain our fondness for fat-rich foods (think full-fat ice cream compared to the less satisfactory fat-free version). Early evidence suggests that people who have a higher sensitivity to the taste of fat (that is, they can detect fat at lower concentrations) tend to consume less fat and are not as likely to be overweight as people whose sensitivity to fat taste is lower (that is, they detect fat only at higher concentrations). This finding could be relevant in the fight against obesity.

Each receptor cell is preferentially responsive to one of the taste modalities. The richness of fine taste discrimination beyond the primary tastes depends on subtle differences in the stimulation patterns of all taste buds in response to various substances, similar to the variable stimulation of the three cone types that gives rise to the range of color sensations. For example, eating seasoned lemon chicken simultaneously stimulates salt, sour, and umami taste receptors.

Taste perception is also influenced by information derived from other receptors, especially odor. Complex flavors beyond the five primary tastes depend on smell. When you temporarily lose your sense of smell during a cold because of swollen nasal passageways, your sense of taste is also markedly reduced, even though your taste receptors are unaffected by the cold. Other factors affecting taste include temperature and texture of the food and psychological factors associated with past experiences with the food. How the gustatory cortex accomplishes the complex perceptual processing of taste sensation is not yet known.

The gut and airways "taste" too.

Interestingly, scientists have discovered cells in the stomach and intestine that have the same GPCRs and gustducin-activated pathways for "tasting" sweet, umami, and bitter as those in the tongue taste buds. The gut taste cells sense the chemical composition of the contents in the lumen of the digestive tract and are believed to trigger physiological responses important in dealing with the food. For example, when the gut taste cells detect something sweet (indicative of a nutritive substance), they initiate a cascade of events leading to production of molecules that stimulate gut motility, enhance absorption of glucose by the digestive tract, stimulate secretion of insulin (a hormone that promotes cell uptake and storage of glucose) in anticipation of the blood-borne arrival of absorbed sweet food, and contribute to the sensation of being full. By contrast, detection by the gut taste cells of something bitter (suggestive of being potentially toxic) slows absorption or spurs vomiting.

More recently the same GPCRs used by the taste buds for detecting tastants, especially the T2R bitter-detecting receptors, have also been identified in epithelial cells lining the respiratory airways. Here the T2R receptors respond to inhaled toxic dusts and aerosols and produce the sensation of irritation, which may trigger protective reflexes such as sneezing or coughing to help expel the potentially dangerous irritant.

The olfactory receptors in the nose are specialized endings of renewable afferent neurons.

The **olfactory** ("smell") **mucosa**, a 3-cm^2 patch of mucosa in the ceiling of the nasal cavity, contains three cell types: *olfactory receptor cells, supporting cells,* and *basal cells* (❙Figure 6-43). The supporting cells secrete mucus, which coats the nasal passages. The basal cells are precursors for new olfactory receptor cells, which are replaced about every 2 months. The sense of **smell** depends on the **olfactory receptor cells** detecting odors, or scents. An olfactory receptor cell is an afferent neuron whose receptor portion lies in the olfactory mucosa in the nose and whose afferent axon traverses into the brain. The axons of the olfactory receptor cells collectively form the **olfactory nerve**.

The receptor portion of an olfactory receptor cell consists of an enlarged knob bearing several long cilia that extend like a tassel to the surface of the mucosa (❙Figure 6-43). These cilia contain the receptors for binding of **odorants**, molecules that can be smelled. During quiet breathing, odorants typically reach the sensitive receptors only by diffusion because the olfactory mucosa is above the normal path of airflow. The act of sniffing enhances this process by drawing the air currents upward within the nasal cavity so that a greater percentage of the odoriferous molecules in the air come into contact with the olfactory mucosa. Odorants also reach the olfactory mucosa during eating by wafting up to the nose from the mouth through the pharynx (back of the throat).

To be smelled, a substance must be (1) sufficiently volatile (easily vaporized) so that some of its molecules can enter the nose in the inspired air and (2) sufficiently water soluble so that it can dissolve in the mucus coating the olfactory mucosa. As
Figure 6-43 Location and structure of the olfactory receptor cells. The photo is an electron micrograph of the tassel of cilia at the sensory ending of an olfactory receptor.

with taste receptors, molecules must be dissolved to be detected by olfactory receptors.

Various parts of an odor are detected by different olfactory receptors and sorted into "smell files."

The human nose contains 5 million olfactory receptors, of which there are 1000 types. During smell detection, an odor is "dissected" into various components. Each receptor responds to only one discrete component of an odor rather than to the whole odorant molecule. Accordingly, each of the various parts of an odor is detected by one of the thousand different receptors, and a given receptor can respond to a particular odor component that may be shared by different scents. Compare this to the three cone types for coding color vision and the taste buds that respond differentially to only five (maybe six) primary tastes to accomplish coding for taste discrimination.

Binding of an appropriate scent signal to an olfactory receptor activates a specific G protein, G_{olf}, triggering a cascade of cAMP-dependent intracellular reactions that leads to opening of an olfactory-specific cAMP-gated channel. This channel opening leads to net Na^+ and Ca^{2+} entry, which causes a depolarizing receptor potential that generates action potentials in the afferent fiber. The frequency of the action potentials depends on the concentration of the stimulating chemical molecules.

The afferent fibers arising from the receptor endings in the nose pass through tiny holes in the flat bone plate separating the olfactory mucosa from the overlying brain tissue (**Figure**

6-43). They immediately synapse in the **olfactory bulb**, a complex neural structure containing several layers of cells that are functionally similar to the retinal layers of the eye. The twin olfactory bulbs, one on each side, are about the size of small grapes (see **Figure 5-16, p. 155). Each olfactory bulb is lined by small, ball-like neural junctions known as **glomeruli** (meaning "little balls") (**Figure 6-44). Within each glomerulus, the terminals of receptor cells carrying information about a particular scent component synapse with the next cells in the olfactory pathway, the **mitral cells**. Because each glomerulus receives signals only from receptors that detect a particular odor component, the glomeruli serve as "smell files." The separate components of an odor are sorted into different glomeruli, one component per file. Thus, the glomeruli, which are the first relay station in the brain for processing olfactory information, play a key role in organizing scent perception.

The mitral cells on which the olfactory receptors terminate in the glomeruli refine the smell signals and relay them to the brain for further processing. Fibers leaving the olfactory bulb travel in two routes:

1. A route going primarily to the lower medial sides of the temporal lobes, especially to regions of the limbic system. A group of structures in this area are collectively considered the **primary olfactory cortex**, the largest component of which is the *piriform* (or *pyriform*) *cortex*. This route, which includes hypothalamic involvement, permits close coordination between smell and behavioral reactions associated with feeding, mating, and direction orienting.
❚Figure 6-44 Processing of scents in the olfactory bulb. Each of the glomeruli lining the olfactory bulb receives synaptic input from only one type of olfactory receptor, which, in turn, responds to only one discrete component of an odorant. Thus, the glomeruli sort and file the various components of an odoriferous molecule before relaying the smell signal to the mitral cells and higher brain levels for further processing.
FIGURE FOCUS: *When you smell your favorite cologne, how are the different components of that odor processed by your olfactory receptors and olfactory bulb?*

2. A route through the thalamus to higher centers, especially the *orbitofrontal cortex*, located on the medial ventral surface of the frontal lobe above the boney orbits that house the eyes. As with other senses, this cortical route is important for conscious perception and fine discrimination of smell.

Odor discrimination is coded by patterns of activity in the olfactory bulb glomeruli.

Because each odorant activates multiple receptors and glomeruli in response to its various odor components, odor discrimination is based on different patterns of glomeruli activated by various scents. In this way, the cortex can distinguish more than 10,000 scents. Studies indicate that a particular scent may be variably perceived by different people. What is a pleasant odor for one person may be unpleasant for another.

This mechanism for sorting out and distinguishing odors is very effective. A noteworthy example is our ability to detect methyl mercaptan (garlic odor) at a concentration of 1 molecule per 50 billion molecules in the air. This substance is added to odorless natural gas to enable us to detect potentially lethal gas leaks. Despite this impressive sensitivity, humans have a poor sense of smell compared to other species. By comparison, dogs' sense of smell is hundreds of times more sensitive than

that of humans. Bloodhounds, for example, have about 4 billion olfactory receptor cells compared to our 5 million such cells, accounting for bloodhounds' superior scent-sniffing ability.

The olfactory system adapts quickly, and odorants are rapidly cleared.

Although the olfactory system is sensitive and highly discriminating, it is also quickly adaptive. Sensitivity to a new odor diminishes rapidly after a short period of exposure to it, even though the odor source continues to be present. This reduced sensitivity does not involve receptor adaptation, as researchers thought for years; actually, the olfactory receptors themselves adapt slowly. It apparently involves some sort of adaptation process in the CNS. Adaptation is specific for a particular odor, and responsiveness to other odors remains unchanged.

What clears the odorants away from their binding sites on the olfactory receptors so that the sensation of smell doesn't "linger" after the source of the odor is removed? Several "odor-eating" enzymes in the olfactory mucosa serve as molecular janitors, clearing away the odoriferous molecules so that they do not continue to stimulate the olfactory receptors. Interestingly, these odorant-clearing enzymes are very similar chemically to detoxification enzymes found in the liver. (These liver enzymes inactivate potential toxins absorbed from the digestive tract; see p. 27.) This resemblance may not be coincidental. Researchers speculate that the nasal enzymes may serve the dual purpose of clearing the olfactory mucosa of old odorants and transforming potentially harmful chemicals into harmless molecules. Such detoxification would serve a very useful purpose, considering the open passageway between the olfactory mucosa and the brain.

The vomeronasal organ detects pheromones.

In addition to the olfactory mucosa, the nose contains another sense organ, the **vomeronasal organ (VNO)**, which is common in mammals but until recently was thought nonexistent in humans. The VNO is located about half an inch inside the human nose next to the vomer bone, hence its name. It detects **pheromones**, nonvolatile chemical signals passed subconsciously between individuals of the same species. In animals, binding of a pheromone to its receptor on the surface of a neuron in the VNO triggers an action potential that travels through nonolfactory pathways to the limbic system, the brain region that governs emotional responses and sociosexual behaviors. These signals never reach the higher levels of conscious awareness. In animals, the VNO is known as the "sexual nose" for its

role in governing reproductive and social behaviors, such as identifying and attracting a mate and communicating social status.

Some scientists now claim the existence of pheromones in humans, although many skeptics doubt these findings. The major goal of investigators in the field is to identify the key chemicals that serve as pheromones in humans (one candidate, for instance, is the nonsmelly steroid compound *androstadienone* found in male sweat) and to learn how the body processes these surreptitious signals. Although the role of the VNO in human behavior has not been validated, some researchers suspect that it is responsible for spontaneous "feelings" between people, either "good chemistry," such as "love at first sight," or "bad chemistry," such as "getting bad vibes" from someone you just met. They speculate that pheromones in humans subtly influence sexual activity, compatibility with others, or group behavior, similar to the role they play in other mammals, although this messenger system is nowhere as powerful or important in humans as in animals. For example, a recent study suggests that a chemical signal (that is, a pheromone) in women's emotional tears reduces sexual arousal in males. Not only did men who sniffed these tear drops suddenly feel less sexually interested than those who sniffed saline drops did, but the tear sniffers experienced a small but measurable decrease in testosterone (male sex hormone) levels. Because messages conveyed by the VNO seem to bypass cortical consciousness, the response to the largely odorless pheromones is not a distinct, discrete perception, such as smelling a favorite fragrance, but more like an inexplicable impression.

Check Your Understanding 6.5

1. List the five established primary tastes and the stimuli that evoke each of these taste sensations.
2. Discuss the role of gustducin in taste signaling.
3. Describe how odor discrimination is accomplished.

Homeostasis: Chapter in Perspective

To maintain a life-sustaining stable internal environment, the body must constantly make adjustments to compensate for myriad internal and external factors that continuously threaten to disrupt homeostasis, such as internal acid production or external exposure to cold. Many of these adjustments are directed by the nervous system, one of the body's two major regulatory systems. The central nervous system (CNS), the integrating and decision-making component of the nervous system, must continuously be informed of "what's happening" in both the internal and the external environment so that it can command appropriate responses in the organ systems to maintain the body's viability. In other words, the CNS must know what changes are taking place before it can respond to these changes.

The afferent division of the peripheral nervous system (PNS) is the communication link by which the CNS is informed about the internal and the external environment. The afferent division detects, encodes, and transmits peripheral signals to the CNS for processing. Afferent input is necessary for arousal, perception, and determination of efferent output.

Afferent information about the internal environment, such as the CO_2 level in the blood, never reaches the level of conscious awareness, but this input to the controlling centers of the CNS is essential for maintaining homeostasis. Afferent input that reaches the level of conscious awareness, called sensory information, includes somesthetic and proprioceptive sensation (body sense) and special senses (vision, hearing, equilibrium, taste, and smell).

The body sense receptors are distributed over the entire body surface and throughout the joints and muscles. Afferent signals from these receptors provide information about what's happening directly to each specific body part in relation to the external environment (that is, the "what," "where," and "how much" of stimulatory inputs to the body's surface and the momentary position of the body in space). In contrast, each special sense organ is restricted to a single site in the body. Rather than provide information about a specific body part, a special sense organ provides a specific type of information about the external environment that is useful to the body as a whole. For example, through their ability to detect, extensively analyze, and integrate patterns of illumination in the external environment, the eyes and visual processing system enable you to see your surroundings. The same integrative effect could not be achieved if photoreceptors were scattered over your entire body surface, as are touch receptors.

Sensory input (both body sense and special senses) enables a complex multicellular organism such as a human to interact in meaningful ways with the external environment in procuring food, defending against danger, and engaging in other behavioral actions geared toward maintaining homeostasis. In addition to providing information essential for interactions with the external environment for basic survival, the perceptual processing of sensory input adds immeasurably to the richness of life, such as enjoyment of a good book, concert, or meal.

Review Exercises Answers begin on p. A-28

Reviewing Terms and Facts

1. Conversion of the energy forms of stimuli into electrical energy by the receptors is known as _____.

2. The type of stimulus to which a particular receptor is most responsive is called its _____.

3. All afferent information is sensory information. *(True or false?)*

4. Off-center ganglion cells increase their rate of firing when a beam of light strikes the periphery of their receptive field. *(True or false?)*

5. During dark adaptation, rhodopsin is gradually regenerated to increase the sensitivity of the eyes. *(True or false?)*

6. An optic nerve carries information from the lateral and medial halves of the same eye, whereas an optic tract carries information from the lateral half of one eye and the medial half of the other. *(True or false?)*

7. Displacement of the round window generates neural impulses perceived as sound sensations. *(True or false?)*

8. Stereocilia of the inner hair cells hyperpolarize when they bend toward and depolarize when they bend away from their tallest member. *(True or false?)*

9. Hair cells in different regions of the organ of Corti and neurons in different regions of the auditory cortex are activated by different tones. *(True or false?)*

10. The receptor potential in a sour taste receptor cell occurs when H^+ in an acid blocks K^+ channels in the receptor cell membrane. *(True or false?)*

11. Rapid adaptation to odors results from adaptation of the olfactory receptors. *(True or false?)*

12. Match the following:

1. layer that contains photoreceptors	(a) choroid
2. point from which optic nerve leaves retina	(b) aqueous humor
3. forms white part of eye	(c) fovea
4. thalamic structure that processes visual input	(d) lateral geniculate nucleus
5. colored diaphragm of muscle that controls amount of light entering eye	(e) cornea
	(f) retina
	(g) lens
6. contributes most to refractive ability	(h) optic disc; blind spot
7. supplies nutrients to lens and cornea	(i) iris
8. produces aqueous humor	(j) ciliary body
9. contains vascular supply for retina and a pigment that minimizes scattering of light within eye	(k) optic chiasm
	(l) sclera
10. has adjustable refractive ability	

11. portion of retina with greatest acuity

12. point at which fibers from medial half of each retina cross to opposite side

13. Using the answer code on the right, indicate which properties apply to taste and/or smell:

1. Receptors are separate cells that synapse with terminal endings of afferent neurons.	(a) applies to taste
2. Receptors are specialized endings of afferent neurons.	(b) applies to smell
3. Receptors are regularly replaced.	(c) applies to both taste and smell
4. Specific chemicals in the environment attach to special binding sites on the receptor surface, leading to a depolarizing receptor potential.	
5. There are two processing pathways: a limbic system route and a thalamic–cortical route.	
6. Discriminative ability is based on patterns of receptor stimulation by five (maybe six) different modalities.	
7. A thousand different receptor types are used.	
8. Information from receptor cells is filed and sorted by neural junctions called glomeruli.	

Understanding Concepts

(Answers at www.cengagebrain.com)

1. List and describe the receptor types according to their adequate stimulus.

2. Compare tonic and phasic receptors.

3. Explain how acuity is influenced by receptive field size and by lateral inhibition.

4. Compare the fast and slow pain pathways.

5. Describe the built-in analgesic system of the brain.

6. Describe the process of phototransduction by photoreceptors and further retinal processing by bipolar and ganglion cells.

7. Compare the functional characteristics of rods and cones.

8. Discuss the trichromatic theory and the opponent-process theory of color vision.

9. What are sound waves? What is responsible for the pitch, intensity, and timbre of a sound?

10. Describe the function of each of the following parts of the ear: pinna, ear canal, tympanic membrane, ossicles, oval window, and various parts of the cochlea. Include a discussion of how sound waves are transduced into action potentials.

11. Discuss the functions of the semicircular canals, the utricle, and the saccule.

12. Describe the location, structure, and general means of activation of the receptors for taste and smell.

13. Compare the processes of color vision, hearing, taste, and smell discrimination.

Solving Quantitative Exercises

1. Calculate the difference in the time it takes for an action potential to travel 1.3 m between the slow (12 m/sec) and fast (30 m/sec) pain pathways.

2. Have you ever noticed that humans have circular pupils, whereas cats' pupils are more elongated from top to bottom? For simplicity in calculation, assume the cat's pupil is rectangular. The following calculations will help you understand the implication of this difference. For simplicity, assume a constant intensity of light.

   a. If the diameter of a human's circular pupil were decreased by half on contraction of the constrictor muscle of the iris, by what percentage would the amount of light allowed into the eye be decreased?

   b. If a cat's rectangular pupil were decreased by half along one axis only, by what percentage would the amount of light allowed into the eye be decreased?

   c. Comparing these calculations, do humans or cats have more precise control over the amount of light falling on the retina?

3. A decibel is the unit of sound level, β, defined as follows:

$$\beta = (10 \text{ dB}) \log_{10}(I/I_0)$$

where I is *sound intensity,* or the rate at which sound waves transmit energy per unit area. The units of I are watts per square meter (W/m^2). I_0 is a constant intensity close to the human hearing threshold, namely, 10^{-12} W/m^2.

   a. For the following sound levels, calculate the corresponding sound intensities:

   (1) 20 dB (a ticking watch)

   (2) 70 dB (a car horn)

   (3) 120 dB (a loud rock concert)

   (4) 170 dB (a space shuttle launch)

   b. Explain why the sound levels of these sounds increase by the same increment (that is, each sound is 50 dB higher than the one preceding it), yet the incremental increases in sound intensities you calculated are so different. What implications does this have for performance of the human ear?

Applying Clinical Reasoning

Suzanne J. complained to her physician of bouts of dizziness. The physician asked her whether by "dizziness" she meant a feeling of lightheadedness, as if she were going to faint (a condition known as **syncope**), or a feeling that she or surrounding objects in the room were spinning around (a condition known as **vertigo**). Why is this distinction important in the differential diagnosis of her condition? What are some possible causes of each of these symptoms?
Thinking at a Higher Level

1. Patients with certain nerve disorders are unable to feel pain. Why is this disadvantageous?

2. Ophthalmologists often instill eye drops in their patients' eyes to bring about pupillary dilation, which makes it easier for the physician to view the eye's interior. In what way would the drug in the eye drops affect autonomic nervous system activity in the eye to cause the pupils to dilate?

3. A patient complains of not being able to see the right half of the visual field with either eye. At what point in the patient's visual pathway does the defect lie?

4. *Retinitis pigmentosa* is a hereditary eye disease characterized by gradual accumulation of excess pigment in the retina, which leads to slow degeneration of photoreceptors, especially rods. What symptoms would occur as a result of rod deterioration?

5. Explain how middle ear infections interfere with hearing. Of what value are the "tubes" that are sometimes surgically placed in the eardrums of patients with a history of repeated middle ear infections accompanied by chronic fluid accumulation?

The Peripheral Nervous System: Efferent Division

A light micrograph of a motor neuron innervating skeletal muscle cells. When a motor neuron (*black*) reaches a skeletal muscle, it divides into many terminal branches, each of which forms a neuromuscular junction (*enlarged ending*) with a single long, cylindrical muscle cell (*red*). Release of neurotransmitter from knoblike terminal buttons (*small black dots*) in the neuromuscular junction excites the muscle cell to trigger contraction.

CHAPTER AT A GLANCE

7.1 Autonomic Nervous System

7.2 Somatic Nervous System

7.3 Neuromuscular Junction

Homeostasis Highlights

The nervous system, one of the two major regulatory systems of the body, consists of the central nervous system (CNS), composed of the brain and spinal cord, and the **peripheral nervous system (PNS)**, composed of the afferent and efferent fibers that relay signals between the CNS and the periphery (other parts of the body).

Once informed by the afferent division of the PNS that a change in the internal or the external environment is threatening homeostasis, the CNS makes appropriate adjustments to maintain homeostasis. The CNS makes these adjustments by controlling the activities of effector organs (muscles and glands), transmitting signals from the CNS to these organs through the **efferent division** of the PNS.

7.1 Autonomic Nervous System

The efferent division of the PNS is the communication link by which the CNS controls muscles and glands, the effector organs that carry out the intended effects or actions (typically contraction or secretion, respectively). The CNS regulates these effectors by initiating action potentials in the cell bodies of efferent neurons whose axons terminate on these organs. Cardiac muscle, smooth muscle, most exocrine glands, some endocrine glands, and adipose tissue (fat) are innervated by the **autonomic nervous system**, the involuntary branch of the peripheral efferent division. Skeletal muscle is innervated by the **somatic nervous system**, the branch of the efferent division subject to voluntary control. The following are examples of the effects of neural control on various effectors composed of different types of muscle and gland tissue:

- *Heart (cardiac muscle)*: increased pumping of blood by the heart when blood pressure falls too low

- *Stomach (smooth muscle)*: delayed emptying of the stomach until the intestine is ready to process the food

- *Respiratory muscles (skeletal muscle)*: augmented breathing in response to exercise

- *Sweat glands (exocrine glands)*: initiation of sweating on exposure to a hot environment

- *Endocrine pancreas (endocrine gland)*: increased secretion of insulin, a hormone that puts excess nutrients in storage following a meal

As these examples illustrate, much of efferent output is directed toward maintaining homeostasis. The efferent output to skeletal muscles is also directed toward voluntarily controlled nonhomeostatic activities, such as riding a bicycle or texting a message. (Many effector organs are also subject to hormonal control or to intrinsic control; see p. 16.)

Almost all neurally controlled effector organ responses are directly mediated by one of two neurotransmitters: acetylcholine or norepinephrine. Acting independently, these neurotransmitters bring about such diverse effects as salivary secretion, bladder contraction, and voluntary motor movements. These effects are a prime example of how the same chemical messenger may cause different responses in various tissues, depending on specialization of the effector organs.

An autonomic nerve pathway consists of a two-neuron chain.

Each autonomic nerve pathway extending from the CNS to an innervated organ is a two-neuron chain (❚Figure 7-1). The cell body of the first neuron in the series is located in the CNS. Its axon, the **preganglionic fiber**, synapses with the cell body of the second neuron, which lies within a ganglion. (Recall that a ganglion is a cluster of neuronal cell bodies outside the CNS.) The axon of the second neuron, the **postganglionic fiber**, innervates the effector organ.

The autonomic nervous system has two subdivisions—the **sympathetic** and the **parasympathetic nervous systems**[1] (❚Figure 7-2). Sympathetic nerve fibers originate in the lateral horn of the thoracic (chest) and lumbar (abdominal) regions of the spinal cord (see pp. 173 and 175). Most sympathetic preganglionic fibers are very short, synapsing with cell bodies of postganglionic neurons within ganglia that lie in a **sympathetic ganglion chain** (also called the **sympathetic trunk**) located along either side of the spinal cord (see ❚Figure 5-22, p. 172). Long postganglionic fibers originate in the ganglion chain and end on the effector organs. Some preganglionic fibers pass through the ganglion chain without synapsing. Instead, they end later in sympathetic **collateral ganglia** about halfway between the CNS and the innervated organs, with postganglionic fibers traveling the rest of the distance.

Parasympathetic preganglionic fibers arise from the cranial (brain) and sacral (lower spinal cord) areas of the CNS. These fibers are longer than sympathetic preganglionic fibers because they do not end until they reach **terminal ganglia** that lie in or near the effector organs. Very short postganglionic fibers end on the cells of an organ itself.

---

[1]Some physiologists include the enteric nervous system in the autonomic nervous system, but we consider it as a separate entity (see pp. 135 and 572).

Sympathetic postganglionic fiber		

❙Figure 7-2 Autonomic nervous system. The sympathetic nervous system originates in the thoracolumbar regions of the spinal cord and has short cholinergic preganglionic fibers and long adrenergic postganglionic fibers. The parasympathetic nervous system originates in the brain and sacral region of the spinal cord and has long cholinergic preganglionic fibers and short cholinergic postganglionic fibers. Sympathetic and parasympathetic postganglionic fibers typically both innervate the same effector organs. The adrenal medulla is a modified sympathetic ganglion, which releases E and NE into the blood. Nicotinic cholinergic receptors respond to ACh released by all autonomic preganglionic fibers. Muscarinic cholinergic receptors respond to ACh released by parasympathetic postganglionic fibers. α_1, α_2, β_1, and β_2 adrenergic receptors are variably located at the autonomic effectors and differentially respond to NE released by sympathetic postganglionic fibers and to E released by the adrenal medulla.

FIGURE FOCUS*: (1) Which of the types of autonomic fibers release acetylcholine (ACh)? (2) Would a drug that interferes with ACh action at nicotinic receptors block the influence of the parasympathetic nervous system, the sympathetic nervous system, or both, at effector organs? (3) How about for a drug that interferes with ACh action at muscarinic receptors?*

Parasympathetic postganglionic fibers release acetylcholine; sympathetic ones release norepinephrine.

Sympathetic and parasympathetic preganglionic fibers release the same neurotransmitter, **acetylcholine (ACh)**, but the postganglionic endings of these two systems release different neurotransmitters (the neurotransmitters that influence the autonomic effectors). Parasympathetic postganglionic fibers release ACh. Accordingly, they, along with all autonomic preganglionic fibers, are called **cholinergic fibers**. Most sympathetic postganglionic fibers, in contrast, are called **adrenergic fibers** because they release **noradrena-**

line, commonly known as **norepinephrine (NE)**.[2] Both ACh and NE also serve as chemical messengers elsewhere in the body. Acetylcholine is released from the terminals of all motor neurons supplying skeletal muscle and serves as a neurotransmitter in the CNS. Norepinephrine also serves as a neurotransmitter in the CNS and is released from the adrenal medulla as a hormone as well.

The following are exceptions to this general pattern of autonomic neurotransmitter release:

■ The sympathetic postganglionic fibers that supply most sweat glands secrete ACh rather than NE.

■ Some autonomic fibers are **nonadrenergic**, **noncholinergic**: they do not release either NE or ACh. Instead they use other chemical mediators as neurotransmitters. For example, *adenosine triphosphate (ATP)* is secreted by some sympathetic fibers supplying blood-vessel smooth muscle to cause vasoconstriction (vessel narrowing). (However, most sympathetically induced vasoconstriction is brought about by NE, which is released from most sympathetic postganglionic fibers.) By contrast, *nitric oxide (NO)* released by parasympathetic fibers supplying the blood vessels of the penis contributes to the vasodilation (vessel widening) that leads to erection (hardening of the penis). Nonadrenergic, noncholinergic fibers are scattered among traditional autonomic fibers that supply not only blood vessels but also digestive, respiratory, urinary, and reproductive organs.

■ Many autonomic fibers release **cotransmitters** along with the classical neurotransmitters. For example, certain sympathetic postganglionic fibers cosecrete *neuropeptide Y (NPY)* along with NE. NPY functions as a neuromodulator; that is, it modulates the release and actions of NE instead of exerting a direct action on the effector organ (see p. 110). Autonomic cotransmitters include ATP, dopamine, and various peptides such as NPY, vasoactive intestinal peptide (VIP), endogenous opioids (see p. 192), and others.

Postganglionic autonomic fibers do not end in a single terminal swelling like a synaptic knob. Instead, the terminal branches of autonomic fibers have numerous swellings, or **varicosities**, that simultaneously release neurotransmitter over a large area of the innervated organ rather than on single cells (see ❙Figures 7-1 and 8-33, p. 292). Because of this diffuse release of neurotransmitter, and because any resulting change in electrical activity is spread throughout a smooth or cardiac muscle mass via gap junctions (see p. 62), autonomic activity typically influences whole organs instead of discrete cells.

---

[2]*Noradrenaline (norepinephrine)* is chemically similar to *adrenaline (epinephrine)*, the primary hormone product secreted by the adrenal medulla (an endocrine gland). Because a United States pharmaceutical company marketed this product for use as a drug under the trade name Adrenalin, the scientific community in this country prefers the alternative name "epinephrine" as a generic term for this chemical messenger, and accordingly, "noradrenaline" is known as "norepinephrine." In most other English-speaking countries, however, "adrenaline" and "noradrenaline" are the terms of choice.

The sympathetic and parasympathetic nervous systems dually innervate most visceral organs.

Afferent information coming from the viscera (internal organs) usually does not reach the conscious level (see p. 186). Examples of visceral afferent information include input from the baroreceptors that monitor blood pressure and input from the chemoreceptors that monitor the protein or fat content of ingested food. This input is used to direct the activity of the autonomic efferent neurons. Autonomic efferent output regulates visceral activities such as circulation and digestion. Like visceral afferent input, autonomic efferent output operates outside the realm of consciousness and voluntary control.

Most visceral organs are innervated by both sympathetic and parasympathetic nerve fibers (❙Figure 7-3). Innervation of a single organ by both branches of the autonomic nervous system is known as **dual innervation** (*dual* means "pertaining to two"). ❙Table 7-1 summarizes the major effects of these autonomic branches. Although the details of this array of autonomic responses are described more fully later when the individual effector organs are discussed, you can infer one general concept by looking over the table now. As you can see, the sympathetic and parasympathetic nervous systems generally exert opposite effects in a particular organ. Sympathetic stimulation increases the heart rate, whereas parasympathetic stimulation decreases it; sympathetic stimulation slows movement within the digestive tract, whereas parasympathetic stimulation enhances digestive motility. Note that both systems increase the activity of some organs and reduce the activity of others.

Rather than memorize a list such as in ❙Table 7-1, it is better to logically deduce the actions of the two systems by first understanding the circumstances under which each system dominates. Usually, both systems are partially active—that is, normally some level of action potential activity exists in both the sympathetic and the parasympathetic fibers supplying a particular organ. This ongoing activity is called **sympathetic** or **parasympathetic tone**. Under given circumstances, activity of one division can dominate the other. *Sympathetic dominance* to a particular organ exists when the sympathetic fibers' rate of firing to that organ increases above tone level, coupled with a simultaneous decrease below tone level in the parasympathetic fibers' frequency of action potentials to the same organ. The reverse situation is true for *parasympathetic dominance.* The balance between sympathetic and parasympathetic activity can be shifted separately for individual organs to meet specific demands (for example, sympathetically induced dilation of the pupil in dim light; see p. 194), or a more generalized, widespread discharge of one autonomic system in favor of the other can be elicited to control bodywide functions. Massive widespread discharges take place more often in the sympathetic system. The value of massive sympathetic discharge is clear, considering the circumstances during which this system usually dominates.

Times of Sympathetic Dominance The sympathetic system promotes responses that prepare the body for strenuous
Figure 7-3 Structures innervated by the sympathetic and the parasympathetic nervous systems.

KEY

- Sympathetic preganglionic fiber
- Sympathetic postganglionic fiber
- Parasympathetic preganglionic fiber
- Parasympathetic postganglionic fiber

Organ	Effect of Sympathetic Stimulation (and Types of Adrenergic Receptors)	Effect of Parasympathetic Stimulation
Heart	Increases heart rate and increases force of contraction of the whole heart) (β_1)	Decreases heart rate and decreases force of contraction of the atria only
Most innervated blood vessels	Constricts (α_1)	Dilates vessels supplying the penis and clitoris only
Lungs	Dilates the bronchioles (airways) (β_2)	Constricts the bronchioles
	Inhibits mucus secretion (α)	Stimulates mucus secretion
Digestive tract	Decreases motility (movement) (α_2, β_2)	Increases motility
	Contracts sphincters (to prevent forward movement of contents) (α_1)	Relaxes sphincters (to permit forward movement of contents)
	Inhibits digestive secretions (α_2)	Stimulates digestive secretions
Urinary bladder	Relaxes (β_2)	Contracts (emptying)
Eye	Dilates the pupil (contracts radial muscle) (α_1)	Constricts the pupil (contracts circular muscle)
	Adjusts the eye for far vision (β_2)	Adjusts the eye for near vision
Liver (glycogen stores)	Glycogenolysis (glucose is released) (β_2)	None
Adipose cells (fat stores)	Lipolysis (fatty acids are released) (β_2)	None
Exocrine glands		
Exocrine pancreas	Inhibits pancreatic exocrine secretion (α_2)	Stimulates pancreatic exocrine secretion (important for digestion)
Sweat glands	Stimulates secretion by sweat glands; important in cooling the body (α_1; most are cholinergic)	None
Salivary glands	Stimulates a small volume of thick saliva rich in mucus (α_1)	Stimulates a large volume of watery saliva rich in enzymes
Endocrine glands		
Adrenal medulla	Stimulates epinephrine and norepinephrine secretion (cholinergic)	None
Endocrine pancreas	Inhibits insulin secretion; stimulates glucagon secretion (α_2)	Stimulates insulin and glucagon secretion
Genitals	Controls ejaculation (males) and orgasmic contractions (both sexes) (α_1)	Controls erection (penis in males and clitoris in females)
Brain activity	Increases alertness (receptors unknown)	None

physical activity in emergency or stressful situations, such as a physical threat from the outside. This response is typically referred to as a **"fight-or-flight"** response (some physiologists even throw in **fright**, too), because the sympathetic system readies the body to fight against or flee from (and be frightened by) the threat. Think about the body resources needed in such circumstances. The heart beats more rapidly and more forcefully, blood pressure is elevated by generalized constriction of the blood vessels, respiratory airways dilate to permit maximal airflow, glycogen (stored sugar) and fat stores are broken down to release extra fuel into the blood, and blood vessels supplying skeletal muscles dilate. All these responses are aimed at providing increased flow of oxygenated, nutrient-rich blood to the

skeletal muscles in anticipation of strenuous physical activity. Furthermore, the pupils dilate and the eyes adjust for far vision, letting the person visually assess the entire threatening scene. Sweating is promoted in anticipation of excess heat production by the physical exertion. Because digestive and urinary activities are not essential in meeting the threat, the sympathetic system inhibits these activities.

Times of Parasympathetic Dominance The parasympathetic system dominates in quiet, relaxed situations. Under such nonthreatening circumstances, the body can be concerned with its "general housekeeping" activities, such as digestion. The parasympathetic system promotes such **"rest-and-digest"**

bodily functions while slowing down those activities that are enhanced by the sympathetic system. For example, the heart does not need to beat rapidly and forcefully when the person is in a tranquil setting.

Advantage of Dual Autonomic Innervation Dual innervation of organs with nerve fibers whose actions oppose each other enables precise control over an organ's activity, like having both an accelerator and a brake to control the speed of a car. If an animal suddenly darts across the road as you are driving, you could eventually stop if you just took your foot off the accelerator, but you might stop too slowly to avoid hitting the animal. If you simultaneously apply the brake as you lift up on the accelerator, however, you can come to a more rapid, controlled stop. In a similar manner, a sympathetically accelerated heart rate could gradually be reduced to normal following a stressful situation by decreasing the firing rate in the cardiac sympathetic nerve (letting up on the accelerator). However, the heart rate can be reduced more rapidly by simultaneously increasing activity in the parasympathetic supply to the heart (applying the brake). Indeed, the two divisions of the autonomic nervous system are usually reciprocally controlled; increased activity in one division is accompanied by a corresponding decrease in the other.

There are several exceptions to the general rule of dual reciprocal innervation by the two branches of the autonomic nervous system; the most notable are the following:

■ *Innervated blood vessels* receive only sympathetic nerve fibers. (Of the blood vessel types, most arterioles and veins are innervated; arteries and capillaries are not [see pp. 343 and 361].) Regulation of vessel caliber in innervated blood vessels (that is, promoting vasoconstriction or vasodilation) is accomplished by increasing or decreasing the firing rate above or below tone level, respectively, in these sympathetic fibers. The only blood vessels to receive both sympathetic and parasympathetic fibers are those supplying the penis and clitoris. The precise vascular control this dual innervation affords these organs is important in accomplishing erection.

■ *Sweat glands* are innervated only by sympathetic nerves. Remember that the postganglionic fibers of most of these nerves are unusual because they secrete ACh rather than NE.

■ *Salivary glands* are innervated by both autonomic divisions, but unlike elsewhere, sympathetic and parasympathetic activities are not antagonistic. Both stimulate salivary secretion, but the saliva's volume and composition differ, depending on which autonomic branch is dominant.

You will learn more about these exceptions in later chapters. We now turn to the adrenal medulla, a unique endocrine component of the sympathetic nervous system.

The adrenal medulla is a modified part of the sympathetic nervous system.

The two *adrenal glands* lie above the kidneys, one on each side (*ad* means "next to"; *renal* means "kidney"). The adrenal glands are endocrine glands, each with an outer portion, the *adrenal cortex,* and an inner portion, the *adrenal medulla* (see pp. 672 and 681–682). The **adrenal medulla** is a modified sympathetic

ganglion that does not give rise to postganglionic fibers. Instead, on stimulation by the preganglionic fiber that originates in the CNS, it secretes catecholamine hormones (see p. 121) into the blood (see ❙Figure 7-2). Not surprisingly, the hormones are identical or similar to postganglionic sympathetic neurotransmitters. About 20% of the adrenal medullary hormone output is norepinephrine, and the remaining 80% is the closely related **epinephrine (E) (adrenaline)** (see footnote 2, p. 236). These hormones, in general, reinforce activity of the sympathetic nervous system.

Several receptor types are available for each autonomic neurotransmitter.

Because each autonomic neurotransmitter and medullary hormone stimulates activity in some tissues but inhibits activity in others, the particular responses must depend on specialization of the tissue cells rather than on properties of the chemicals themselves. Responsive tissue cells have one or more of several types of plasma membrane receptor proteins for these chemical messengers. Binding of a neurotransmitter to a receptor induces the tissue-specific response.

Cholinergic Receptors Researchers have identified two types of ACh (cholinergic) receptors—*nicotinic* and *muscarinic*—on the basis of their response to particular drugs. **Nicotinic receptors** are activated by the tobacco plant derivative nicotine, whereas **muscarinic receptors** are activated by the mushroom poison muscarine (❙Table 7-2).

Nicotinic receptors are found on the postganglionic cell bodies in all autonomic ganglia. These receptors respond to ACh released from both sympathetic and parasympathetic preganglionic fibers. These receptors are nonspecific cation receptor-channels that permit passage of both Na^+ and K^+ when ACh binds to them (see p. 116). Because the permeability of the postganglionic membrane to Na^+ and K^+ on opening of these channels is essentially equal, the relative movement of these ions through the channels depends on their electrochemical driving forces. Recall that at resting potential the net driving force for Na^+ is much greater than that for K^+ because the resting potential is much closer to the K^+ equilibrium potential than to the Na^+ equilibrium potential. Both the concentration and the electrical gradients for Na^+ are inward, whereas the outward concentration gradient for K^+ is almost, but not quite, balanced by the opposing inward electrical gradient (see p. 82). As a result, when ACh triggers the opening of these receptor-channels, considerably more Na^+ moves inward than K^+ moves outward, bringing about a depolarization that leads to initiation of an action potential in the postganglionic cell.

Muscarinic receptors are found on effector cell membranes (cardiac muscle, smooth muscle, and glands). They bind with ACh released from parasympathetic postganglionic fibers. The five subtypes of muscarinic receptors are all linked to G proteins that activate second-messenger pathways leading to the target cell response (see p. 117).

Adrenergic Receptors The two major classes of adrenergic receptors for norepinephrine and epinephrine are **alpha (α)**

TABLE 7-2 Properties of Autonomic Receptor Types

Receptor Type	Neurotransmitter Affinity	Effector(s) with Receptor Type	Mechanism of Action at Effector	Effect on Effector
Nicotinic	ACh from autonomic preganglionic fibers	All autonomic postganglionic cell bodies; adrenal medulla	Opens nonspecific cation receptor-channels	Excitatory
	ACh from motor neurons	Motor end plates of skeletal muscle fibers	Opens nonspecific cation receptor-channels	Excitatory
Muscarinic	ACh from parasympathetic postganglionic fibers	Cardiac muscle, smooth muscle, glands	Activates various G-protein-coupled receptor pathways, depending on effector	Excitatory or inhibitory, depending on effector
α_1	Greater affinity for NE (from sympathetic postganglionic fibers) than for E (from the adrenal medulla)	Most sympathetic target tissues	Activates IP_3–Ca^{2+} second-messenger pathway	Excitatory
α_2	Greater affinity for NE than for E	Digestive organs	Inhibits cAMP	Inhibitory
β_1	Equal affinity for NE and for E	Heart	Activates cAMP	Excitatory
β_2	Affinity for E only	Smooth muscles of arterioles and bronchioles	Activates cAMP	Inhibitory

and **beta (β) receptors**, which are further subclassified into α_1 and α_2 and into β_1 and β_2 **receptors,** respectively (Table 7-2). These various receptor types are distinctly distributed among sympathetically controlled effector organs as follows:

- α_1 receptors are present on most sympathetic target tissues.
- α_2 receptors are located mainly on digestive organs.
- β_1 receptors are restricted to the heart.
- β_2 receptors are found on smooth muscles of arterioles and bronchioles (small blood vessels and airways).

Different receptor types also have different affinities (attraction) for norepinephrine and epinephrine:

- α receptors of both subtypes have a greater affinity for NE than for E.
- β_1 receptors have about equal affinities for NE and E.
- β_2 receptors bind only with E.

All adrenergic receptors are coupled to G proteins, but the ensuing pathway activated on binding of a catecholamine differs for the various receptor types:

- Activation of both β_1 and β_2 receptors brings about the target cell response by activating the cyclic adenosine monophosphate (cAMP) second-messenger pathway (see p. 123).
- Stimulation of α_1 receptors elicits the desired response via the IP_3–Ca^{2+} second-messenger pathway (see p. 124).
- By contrast, binding of a neurotransmitter to an α_2 receptor inhibits cAMP production in the target cell.

The effector organ response also varies depending on the adrenergic receptor type:

- Activation of α_1 receptors usually brings about an excitatory response in the effector organ—for example, arteriolar constriction caused by increased contraction of smooth muscle in the walls of these blood vessels.
- Activation of α_2 receptors, in contrast, brings about an inhibitory response in the effector, such as decreased smooth muscle contraction in the digestive tract.
- Stimulation of β_1 receptors, which are found only in the heart, causes an excitatory response—namely, increased rate and force of cardiac contraction.
- The response to β_2 receptor activation is generally inhibitory, such as arteriolar or bronchiolar dilation caused by relaxation of the smooth muscle in the walls of these tubular structures.

As a quick rule, activation of the subscript "1" versions of adrenergic receptors leads to excitatory responses, and activation of the subscript "2" versions leads to inhibitory responses.

Autonomic Agonists and Antagonists Drugs are available that selectively alter autonomic responses at each of the receptor types. An **agonist** binds to the neurotransmitter's receptor and causes the same response as the neurotransmitter would. An **antagonist**, by contrast, binds with the receptor, preventing the neurotransmitter from binding and causing a response, yet the antagonist itself produces no response. Thus, an agonist mimics the neurotransmitter's response, and an

antagonist blocks the neurotransmitter's response. Some of these drugs are only of experimental interest, but others are important therapeutically. For example, *atropine* blocks the effect of ACh at muscarinic receptors but does not affect nicotinic receptors. Because ACh released at both parasympathetic and sympathetic preganglionic fibers combines with nicotinic receptors, blockage at nicotinic synapses would knock out both these autonomic branches. By acting selectively to interfere with ACh action only at muscarinic junctions, which are the sites of parasympathetic postganglionic action, atropine blocks parasympathetic effects but does not influence sympathetic activity. Doctors use this principle to suppress salivary and bronchial secretions before surgery and thus reduce the risk of a patient inhaling these secretions into the lungs.

Likewise, drugs that act selectively at α- and β-adrenergic receptor sites to either activate or block specific sympathetic effects are widely used. Following are several examples. *Salbutamol* selectively activates β_2-adrenergic receptors at low doses, making it possible to dilate the bronchioles in the treatment of asthma without undesirably stimulating the heart (which has mostly β_1 receptors). By contrast, *metoprolol* selectively blocks β_1-adrenergic receptors and is prescribed to treat high blood pressure because it decreases the amount of blood the heart pumps into the blood vessels. Metoprolol does not affect β_2 receptors and so has no effect on the bronchioles.

Many regions of the CNS are involved in the control of autonomic activities.

Messages from the CNS are delivered to cardiac muscle, smooth muscle, and glands via autonomic nerves, but what CNS regions regulate autonomic output? Autonomic control of these effectors is mediated by reflexes and through centrally located control centers. Going back one step further, ultimately information carried to the CNS via visceral afferents is used to determine the appropriate output via autonomic efferents to the effectors to maintain homeostasis. (Some physiologists regard visceral affer-

ents as part of the autonomic nervous system, whereas others consider the sympathetic and parasympathetic efferents as being the only components of the autonomic nervous system.)

■ Some autonomic reflexes, such as urination, defecation, and erection, are integrated at the spinal-cord level, but all these spinal reflexes are subject to control by higher levels of consciousness.

■ The medulla within the brain stem is the region most directly responsible for autonomic output. Centers for controlling cardiovascular, respiratory, and digestive activity via the autonomic system are located there.

■ The hypothalamus plays an important role in integrating the autonomic, somatic, and endocrine responses that automatically accompany various emotional and behavioral states. For example, the increased heart rate, blood pressure, and respiratory activity associated with anger or fear are brought about by the hypothalamus acting through the medulla.

■ Autonomic activity can also be influenced by the prefrontal association cortex through its involvement with emotional expression. An example is blushing when embarrassed, which is caused by dilation of blood vessels supplying the skin of the cheeks. Such responses are mediated through hypothalamic–medullary pathways.

▮Table 7-3 summarizes the main distinguishing features of the sympathetic and parasympathetic nervous systems.

Check Your Understanding 7.1

1. Illustrate the origin, termination, fiber length, and neurotransmitter released for parasympathetic and sympathetic preganglionic fibers and postganglionic fibers.

2. Compare the times of sympathetic and of parasympathetic dominance.

3. Discuss the relationship of the adrenal medulla to the autonomic nervous system.

▮**TABLE 7-3** Comparison of the Sympathetic and the Parasympathetic Nervous System

Feature	Sympathetic System	Parasympathetic System
Origin of preganglionic fiber	Thoracic and lumbar regions of the spinal cord	Brain and sacral region of the spinal cord
Origin of postganglionic fiber	Sympathetic ganglion chain (near the spinal cord) or collateral ganglia (about halfway between spinal cord and effector organs)	Terminal ganglia (in or near effector organs)
Fiber length	Short preganglionic fibers, long postganglionic fibers	Long preganglionic fibers, short postganglionic fibers
Neurotransmitter released	Preganglionic: ACh Postganglionic: NE	Preganglionic: ACh Postganglionic: ACh
Types of receptors for neurotransmitters	For preganglionic neurotransmitter: nicotinic For postganglionic neurotransmitter: α_1, α_2, β_1, β_2	For preganglionic neurotransmitter: nicotinic For postganglionic neurotransmitter: muscarinic
Dominance	Dominates in "fight-or-flight" situations	Dominates in "rest-and-digest" situations

7.2 Somatic Nervous System

Motor neurons supply skeletal muscle.

Motor neurons, whose axons constitute the somatic nervous system, supply skeletal muscles and bring about movement (*motor* means "movement"). (Sometimes all efferent neurons are referred to as *motor neurons,* but we reserve this term for the efferent somatic fibers that supply skeletal muscles.) The cell bodies of almost all motor neurons are within the ventral horn of the spinal cord (see p. 175). The only exception is that the cell bodies of motor neurons supplying muscles in the head are in the brain stem. Unlike the two-neuron chain of autonomic nerve fibers, the axon of a motor neuron is continuous from its origin in the CNS to its ending on skeletal muscle. Motor-neuron axon terminals release ACh, which brings about excitation and contraction of the innervated muscle cells. Motor neurons can only stimulate skeletal muscles, in contrast to autonomic fibers, which can either stimulate or inhibit their effector organs. Inhibition of skeletal muscle activity can be accomplished only within the CNS through inhibitory synaptic input to the dendrites and cell bodies of the motor neurons supplying that particular muscle.

Motor neurons are the final common pathway.

Motor-neuron dendrites and cell bodies are influenced by many converging presynaptic inputs, both excitatory and inhibitory. Some of these inputs are part of spinal reflex pathways originating with peripheral sensory receptors. Others are part of descending pathways originating within the brain. Areas of the brain that exert control over skeletal muscle movements include the motor regions of the cortex, the basal nuclei, the cerebellum, and the brain stem (see pp. 148–150, 153, 163, and 166–167; also see ❙Table 8-3, p. 280, for a summary of motor control and Figure 5-26b, p. 175, for specific examples of these descending motor pathways).

Motor neurons are considered the **final common pathway** because the only way any other parts of the nervous system can influence skeletal muscle activity is by acting on these motor neurons. The level of activity in a motor neuron and its subsequent output to the skeletal muscle fibers it innervates depend on the relative balance of excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs) (see pp. 106–107) brought about by its presynaptic inputs originating from these diverse sites in the brain.

The somatic system is under voluntary control, but much of skeletal muscle activity involving posture, balance, and stereotypical movements is subconsciously controlled. You may decide you want to start walking, but you do not have to consciously bring about the alternate contraction and relaxation of the involved muscles because these movements are involuntarily coordinated by lower brain centers.

The cell bodies of motor neurons may be selectively destroyed by **poliovirus**. The result is paralysis of the muscles innervated by the affected neurons. **Amyotrophic lateral sclerosis (ALS)**, also known as **Lou Gehrig's disease**, is the most common motor-neuron disease. This

❙**TABLE 7-4** Comparison of the Autonomic and the Somatic Nervous System

Feature	Autonomic Nervous System	Somatic Nervous System
Site of origin	Sympathetic: lateral horn of thoracic and lumbar spinal cord Parasympathetic: brain and sacral spinal cord	Ventral horn of spinal cord for most; those supplying muscles in head originate in brain
Number of neurons from CNS to effector organ	Two-neuron chain (preganglionic and postganglionic)	Single neuron (motor neuron)
Organs innervated	Cardiac muscle, smooth muscle, most exocrine and some endocrine glands	Skeletal muscle
Type of innervation	Most effector organs dually innervated by the two antagonistic branches of this system (sympathetic and parasympathetic)	Effector organs innervated only by motor neurons
Neurotransmitter at effector organs	May be ACh (parasympathetic terminals) or NE (sympathetic terminals)	Only ACh
Effects on effector organs	Either stimulation or inhibition (antagonistic actions of two branches)	Stimulation only (inhibition possible only centrally through IPSPs on dendrites and cell body of motor neuron)
Type of control	Under involuntary control	Subject to voluntary control; much activity subconsciously coordinated
Higher centers involved in control	Spinal cord, medulla, hypothalamus, prefrontal association cortex	Spinal cord, motor cortex, basal nuclei, cerebellum, brain stem

incurable condition is characterized by degeneration and eventual death of motor neurons. The result is gradual loss of motor control, progressive paralysis, and finally death within 3 to 5 years of onset. The exact cause is uncertain, although researchers are investigating a variety of potential underlying problems. Among these are pathological changes in neurofilaments that block axonal transport of crucial materials (see p. 51), extracellular accumulation of toxic levels of the excitatory neurotransmitter glutamate, aggregation of misfolded intracellular proteins, mitochondrial dysfunction leading to reduced energy production, and activation of

protein-cutting enzymes (caspases, the ones involved in apoptosis; see p. 43) that selectively cut up the neuronal cell body and nucleus.

Before turning to the junction between a motor neuron and the muscle cells it innervates, we pull together in table form two groups of information we have been examining in this and preceding nervous system chapters. ❙Table 7-4 summarizes the features of the two branches of the efferent division of the PNS: the autonomic nervous system and the somatic nervous system. ❙Table 7-5 compares the three functional types of neurons: afferent neurons, efferent neurons, and interneurons.

❙**TABLE 7-5** Comparison of Types of Neurons

Feature	Afferent Neuron	Efferent Neuron in Autonomic Nervous System	Efferent Neuron in Somatic Nervous System	Interneuron
Origin, structure, location	Receptor at peripheral ending; elongated peripheral axon travels in the peripheral nerve; cell body located in the dorsal root ganglion; short central axon enters the spinal cord	Two-neuron chain; first neuron (preganglionic fiber) originates in the CNS and terminates on a ganglion; second neuron (postganglionic fiber) originates in the ganglion and terminates on the effector organ	Cell body of motor neuron in the spinal cord; long axon travels in the peripheral nerve and terminates on the effector organ	Lies entirely within the CNS; some cell bodies originate in the brain, with long axons traveling down the spinal cord in descending pathways; some originate in the spinal cord, with long axons traveling up the cord to the brain in ascending pathways; others form short local connections
Termination	Interneurons*	Effector organs (cardiac muscle, smooth muscle, glands)	Effector organs (skeletal muscle)	Other interneurons and efferent neurons
Function	Carries information about the external and the internal environment to the CNS	Carries instructions from the CNS to the effector organs	Carries instructions from the CNS to the effector organs	Processes and integrates afferent input; initiates and coordinates efferent output; is responsible for thought and other higher mental functions
Convergence of input on cell body	No (only input is through the receptor)	Yes	Yes	Yes
Effect of input to neuron	Can only be excited (through a receptor potential induced by a stimulus; must reach threshold for an action potential)	Can be excited or inhibited (through EPSPs and IPSPs at the first neuron; must reach threshold for an action potential)	Can be excited or inhibited (through EPSPs and IPSPs; must reach threshold for an action potential)	Can be excited or inhibited (through EPSPs and IPSPs; must reach threshold for an action potential)
Site of action potential initiation	First excitable portion of the membrane adjacent to the receptor	Axon hillock	Axon hillock	Axon hillock
Divergence of output	Yes	Yes	Yes	Yes
Effect of output on effector organ	Only excites	Postganglionic fiber either excites or inhibits	Only excites	Either excites or inhibits

*Except in stretch reflex where afferent neuron terminates directly on efferent neuron; see p. 178.

1. Compare the effector organs innervated by the autonomic nervous system and by the somatic nervous system.

2. Explain why motor neurons are the final common pathway.

7.3 Neuromuscular Junction

Motor neurons and skeletal muscle fibers are chemically linked at neuromuscular junctions.

An action potential in a motor neuron is rapidly propagated from the cell body within the CNS to the skeletal muscle along the large myelinated axon (efferent fiber) of the neuron. As the axon approaches a muscle, it divides and loses its myelin sheath. Each of these axon terminals forms a special junction, a **neuromuscular junction**,[3] with one of the many muscle cells that compose the whole muscle (❙Figure 7-4 and chapter opener photo, p. 233). Each branch innervates only one muscle cell; therefore, each muscle cell has only one neuromuscular junc-

---

[3]Many scientists refer to a **synapse** as any junction between two cells that handle information electrically. According to this broad point of view, *chemical synapses* include junctions between two neurons and those between a neuron and an effector cell (such as muscle cells of any type or gland cells), and *electrical synapses* include gap junctions between smooth muscle cells, between cardiac muscle cells, or between some neurons. We narrowly reserve the term *synapse* specifically for neuron-to-neuron junctions and use different terms for other types of junctions, such as the term *neuromuscular junction* for a junction between a motor neuron and a skeletal muscle cell.

tion. Both the neural and muscular components make up the neuromuscular junction, just as a synapse includes both presynaptic and postsynaptic components. A single muscle cell, called a **muscle fiber**, is long and cylindrical. Within a neuromuscular junction, the axon terminal splits into multiple fine branches, each of which ends in an enlarged knoblike structure called the **terminal button**, or **bouton**. The entire axon terminal ending (all the fine branches with terminal buttons) fits into a shallow depression, or groove, in the underlying muscle fiber. This specialized underlying portion of the muscle cell membrane is called the **motor end plate** (❙Figure 7-5).

ACh is the neuromuscular junction neurotransmitter.

Nerve and muscle cells do not come into direct contact at a neuromuscular junction. The space, or cleft, between these two structures is too large for electrical transmission of an impulse between them (that is, an action potential cannot "jump" that far). Just as at a neuronal chemical synapse (see p. 103), a chemical messenger carries the signal between a terminal button and the muscle fiber. This neurotransmitter is ACh.

Release of ACh at the Neuromuscular Junction Each terminal button contains thousands of vesicles that store ACh. Propagation of an action potential to the axon terminal (❙Figure 7-5, step **1**) triggers the opening of voltage-gated calcium (Ca^{2+}) channels in all of its terminal buttons (see p. 89). We focus on one terminal button, but the same events take place concurrently at all terminal buttons of a given neuromuscular junction. When Ca^{2+} channels open, Ca^{2+} diffuses into the terminal button from its higher extracellular concentration
❙Figure 7-4 **Motor neuron innervating skeletal muscle cells.** The cell body of a motor neuron originates in the ventral horn of the spinal cord. The axon (somatic efferent fiber) exits through the ventral root and travels through a spinal nerve to the skeletal muscle it innervates. When the axon reaches a skeletal muscle, it divides into many axon terminals, each of which forms a neuromuscular junction with a single muscle cell (muscle fiber). The axon terminal within a neuromuscular junction further divides into fine branches, each of which ends in an enlarged terminal button. Note that the muscle fibers innervated by a single axon terminal are dispersed throughout the muscle, but for simplicity they are grouped together in this figure.

FIGURE FOCUS: *What is the relationship among* axon terminal, neuromuscular junction, *and* terminal button?

(step **2**), which in turn causes release of ACh by exocytosis from several hundred vesicles into the cleft (step **3**).

Formation of an End-Plate Potential The released ACh diffuses across the cleft and binds with chemically gated receptor-channels of the cholinergic nicotinic type on the motor end-plate portion of the muscle fiber membrane (step **4**). Binding with ACh causes these receptor-channels to open. They are nonspecific cation channels that permit both Na^+ and K^+ traffic through them (step **5**). Because of the greater electrochemical gradient for Na^+ than for K^+, considerably more Na^+ moves inward than K^+ moves outward, depolarizing the motor end plate. The collective potential change resulting from these ion movements across all of

the terminal buttons within a neuromuscular junction is called the **end-plate potential (EPP)**. It is a graded potential similar to an EPSP, except that an EPP is much larger for the following reasons: (1) A neuromuscular junction consists of multiple terminal buttons, each of which simultaneously releases ACh on activation of the axon terminal; (2) more neurotransmitter is released from a terminal button than from a presynaptic knob in response to an action potential; (3) the motor end plate has a larger surface area and a higher density of neurotransmitter receptor-channels and thus has more sites for binding with neurotransmitter than a subsynaptic membrane has; and (4) accordingly, many more receptor-channels are opened in response to neurotransmitter release at a neuromuscular junction than at a synapse. This permits a greater net influx of positive ions and a larger depolarization

1 An action potential in a motor neuron is propagated to the terminal button.

2 This local action potential triggers the opening of voltage-gated Ca^{2+} channels and the subsequent entry of Ca^{2+} into the terminal button.

3 Ca^{2+} triggers the release of acetylcholine (ACh) by exocytosis from a portion of the vesicles.

4 ACh diffuses across the space separating the nerve and muscle cells and binds with receptor-channels specific for it on the motor end plate of the muscle cell membrane.

5 This binding brings about the opening of these nonspecific cation channels, leading to a relatively large movement of Na^+ into the muscle cell compared to a smaller movement of K^+ outward.

6 The result is an end-plate potential. Local current flow occurs between the depolarized end plate and the adjacent membrane.

7 This local current flow opens voltage-gated Na^+ channels in the adjacent membrane.

8 The resultant Na^+ entry reduces the potential to threshold, initiating an action potential, which is propagated throughout the muscle fiber.

9 ACh is subsequently destroyed by acetylcholinesterase, an enzyme located on the motor end-plate membrane, terminating the muscle cell's response.

❙Figure 7-5 **Events at a neuromuscular junction**.
FIGURE FOCUS: *By studying this figure, what are three ways that detrimental chemical agents could interfere with the normal action of ACh at the neuromuscular junction?*

(an EPP) at a neuromuscular junction. As with an EPSP, an EPP is a graded potential, whose magnitude depends on the amount and duration of ACh at the end plate.

Initiation of an Action Potential The motor end-plate region itself does not have a threshold potential, so an action potential cannot be initiated at this site. However, an EPP brings about an action potential in the rest of the muscle fiber as follows: The neuromuscular junction is usually in the middle of the long, cylindrical muscle fiber. When an EPP takes place, local current flow occurs between the depolarized end plate and the adjacent, resting cell membrane in both directions step **6**), opening voltage-gated Na^+ channels and thus reducing the potential to threshold in the adjacent areas (step **7**). The subsequent action potential initiated at these sites propagates throughout the muscle fiber membrane by contiguous conduction (step **8**) (see p. 96). The spread runs in both directions, away from the motor end plate toward both ends of the fiber. This electrical activity triggers contraction of the muscle fiber. Thus, by means of ACh, an action potential in a motor neuron brings about an action potential and subsequent contraction in the muscle fiber.

Unlike synaptic transmission, an EPP is normally large enough to cause an action potential in the muscle cell. Therefore, one-to-one transmission of an action potential typically occurs at a neuromuscular junction; one action potential in a nerve cell triggers one action potential in a muscle cell that it innervates. At a synapse, one action potential in a presynaptic neuron cannot by itself bring about an action potential in a postsynaptic neuron. An action potential in a postsynaptic neuron occurs only when summation of EPSPs brings the membrane to threshold. As another comparison between these two junctions, a neuromuscular junction is always excitatory (an EPP), whereas a synapse may be either excitatory (an EPSP) or inhibitory (an IPSP).

Acetylcholinesterase ends ACh activity at the neuromuscular junction.

To ensure purposeful movement, a muscle cell's response to stimulation by its motor neuron must be switched off promptly when there is no longer a signal from the motor neuron. The muscle cell's electrical response is turned off by an enzyme in the motor end-plate membrane, **acetylcholinesterase (AChE)**, which inactivates ACh.

As a result of diffusion, many of the released ACh molecules come into contact with and bind to receptor-channels on the surface of the motor end-plate membrane. However, some of the ACh molecules bind with AChE, which is also at the end-plate surface. Being quickly inactivated, this ACh never contributes to the EPP. The ACh that does bind with receptor-channels does so briefly (for about 1 millionth of a second) and then detaches. Some of the detached ACh molecules quickly rebind with receptor-channels, keeping these end-plate channels open, but some randomly contact AChE instead and are inactivated (step **9**). As this process repeats, more ACh is inactivated until all of it has been removed from the cleft within a few milliseconds after its release. ACh removal ends the EPP, so

the remainder of the muscle cell membrane returns to resting potential. Now the muscle cell can relax. Or, if sustained contraction is essential for the desired movement, another motor-neuron action potential leads to the release of more ACh, which keeps the contractile process going. By removing contraction-inducing ACh from the motor end plate, AChE permits the choice of allowing relaxation to take place (no more ACh released) or keeping the contraction going (more ACh released), depending on the body's momentary needs.

The neuromuscular junction is vulnerable to several chemical agents and diseases.

Clinical Note Several chemical agents and diseases affect the neuromuscular junction by acting at different sites in the transmission process, as the following examples illustrate.

Black Widow Spider Venom Causes Explosive Release of ACh The venom of black widow spiders exerts its deadly effect by triggering explosive release of ACh from the storage vesicles, not only at neuromuscular junctions but at all cholinergic sites. All cholinergic sites undergo prolonged depolarization, the most harmful result of which is respiratory failure. Breathing is accomplished by alternate contraction and relaxation of respiratory muscles, particularly the diaphragm, a dome-shaped sheet of skeletal muscle that forms the floor of the thoracic (chest) cavity. Respiratory paralysis occurs as a result of prolonged depolarization of the diaphragm. During this so-called *depolarization block,* the voltage-gated Na^+ channels are trapped in their inactivated state (that is, they remain in their closed and not capable of opening conformation; see p. 92). This depolarization block prohibits the initiation of new action potentials and resultant contraction of the diaphragm. As a consequence, the victim cannot breathe.

Botulinum Toxin Blocks Release of ACh Botulinum toxin, in contrast, exerts its lethal blow by blocking the release of ACh from the terminal button in response to a motor-neuron action potential. *Clostridium botulinum* toxin causes **botulism**, a form of food poisoning. When this toxin is consumed, it prevents muscles from responding to nerve impulses. Death results from respiratory failure caused by inability to contract the diaphragm. Botulinum toxin is one of the most lethal poisons known; ingesting less than 0.0001 mg can kill an adult human. (See the accompanying boxed feature, ▌Concepts, Challenges, and Controversies, to learn about a wrinkle in the botulinum toxin story.)

Curare Blocks Action of ACh at Receptor-Channels Other chemicals interfere with neuromuscular junction activity by blocking the effect of released ACh. The best-known example is the antagonist **curare**, which reversibly binds to the ACh receptor-channels on the motor end plate. Unlike ACh, however, curare does not alter membrane permeability, nor is it inactivated by AChE. When curare occupies ACh receptor-channels, ACh cannot combine with and open these channels to permit the ionic movement responsible for an EPP. Conse-

Botulinum Toxin's Reputation Gets a Facelift

THE POWERFUL TOXIN PRODUCED BY *Clostridium botulinum* causes the deadly food poisoning botulism. Yet this dreaded, highly lethal poison has been put to use as a treatment for alleviating specific movement disorders and, more recently, has been added to the list of tools that cosmetic surgeons use to fight wrinkles.

During the past several decades, botulinum toxin, marketed in therapeutic doses as *Botox,* has offered welcome relief to people with painful, disruptive neuromuscular diseases known categorically as **dystonias**. These conditions are characterized by spasms (excessive, sustained, involuntarily produced muscle contractions) that result in involuntary twisting or abnormal postures, depending on the body part affected. For example, painful neck spasms that twist the head to one side result from *spasmodic torticollis* (*tortus* means "twisted"; *collum* means "neck"), the most common dystonia. The problem is believed to arise from too little inhibitory input compared to excitatory input to the motor neurons that supply the affected muscle. The reasons for this imbalance in motor-neuron input are unknown. The end result of excessive motor-neuron activation is sustained, disabling contraction of the muscle supplied by the overactive motor neurons. Fortunately, injecting minuscule amounts of botulinum toxin into the affected muscle causes a reversible, partial paralysis of the muscle. Botulinum toxin interferes with the release of muscle-contraction-causing ACh from the overactive motor neurons at the neuromuscular junctions in the treated muscle. The goal is to inject just enough botulinum toxin to alleviate the troublesome spasmodic contractions but not enough to eliminate the normal contractions needed for ordinary movements. The therapeutic dose is considerably less than the amount of toxin needed to induce even mild symptoms of botulinum

poisoning. Botulinum toxin is eventually cleared away, so its muscle-relaxing effects wear off after 3 to 6 months, at which time the treatment must be repeated.

The first dystonia for which Botox was approved as a treatment by the U.S. Food and Drug Administration (FDA) was *blepharospasm* (*blepharo* means "eyelid"). In this condition, sustained and involuntary contractions of the muscles around the eye nearly permanently close the eyelids.

Botulinum toxin's potential as a treatment option for cosmetic surgeons was accidentally discovered when physicians noted that injections used to counter abnormal eye muscle contractions also smoothed the appearance of wrinkles in the treated areas. It turns out that frown lines, crow's feet, and furrowed brows are caused by facial muscles that have become overactivated, or permanently contracted, as a result of years of performing certain repetitive facial expressions. By relaxing these muscles, botulinum toxin temporarily smoothes out these age-related wrinkles. Botox now has FDA approval as an antiwrinkle treatment. The agent is considered an excellent alternative to facelift surgery for combating lines and creases. This treatment is among the most rapidly growing cosmetic procedures in the United States, especially in the entertainment industry and in high-fashion circles. However, as with its therapeutic use to treat dystonias, the costly injections of botulinum toxin must be repeated every 3 to 6 months to maintain the desired effect in appearance. Furthermore, Botox does not work against the fine, crinkly wrinkles associated with years of excessive sun exposure because these wrinkles are caused by skin damage, not by contracted muscles.

---

quently, because muscle action potentials cannot occur in response to nerve impulses to these muscles, paralysis ensues. When enough curare is present to block a significant number of ACh receptor-channels, the person dies from respiratory paralysis caused by inability to contract the diaphragm. In the past, some peoples used curare as a deadly arrowhead poison.

Organophosphates Prevent Inactivation of ACh **Organophosphates** are a group of chemicals that modify neuromuscular junction activity in yet another way—namely, by irreversibly inhibiting AChE. Inhibition of AChE prevents the inactivation of released ACh. Death from organophosphates also results from respiratory failure because the diaphragm remains in a depolarization block and cannot repolarize and return to resting conditions then be stimulated to contract again to bring in a fresh breath of air. In addition to organophosphates' lethal action at nicotinic receptors of respiratory muscles, other symptoms occur related to the effect of ACh buildup at muscarinic

receptors, such as drooling, pupillary constriction, vomiting, and diarrhea, as well as from ACh overstimulation in the brain, which can lead to seizures. These toxic agents are used in some pesticides (for example, *malathion* used as a mosquito control product) and as military nerve gases (such as the chemical weapon *sarin gas*).

Myasthenia Gravis Inactivates ACh Receptor-Channels **Myasthenia gravis**, a disease involving the neuromuscular junction, is characterized by extreme muscular weakness (*myasthenia* means "muscular weakness"; *gravis* means "severe"). It is an autoimmune (meaning "immunity against self") condition in which the body erroneously produces antibodies against its motor end-plate ACh receptor-channels. Thus, not all released ACh molecules can find a functioning receptor-channel with which to bind. As a result, AChE destroys much of the ACh before it ever has a chance to interact with a receptor-channel and contribute to the EPP. Treatment consists

of administering a drug such as *neostigmine* that inhibits AChE temporarily (in contrast to the toxic organophosphates, which irreversibly block this enzyme). This drug prolongs the action of ACh at the neuromuscular junction by permitting it to build up for the short term. The resultant EPP is of sufficient magnitude to initiate an action potential and subsequent contraction in the muscle fiber, as it normally would.

Check Your Understanding 7.3

1. Discuss the role of ACh and of AChE at a neuromuscular junction.
2. Compare the magnitude of an EPP and an EPSP and explain the functional significance of this difference.
3. Describe the cause, symptoms, and treatment of myasthenia gravis.

Homeostasis: Chapter in Perspective

The nervous system, along with the other major regulatory system, the endocrine system, controls most muscle contractions and gland secretions. Whereas the afferent division of the PNS detects and carries information to the CNS for processing and decision making, the efferent division of the PNS carries directives from the CNS to the effector organs (muscles and glands), which carry out the intended response. Much of this efferent output is directed toward maintaining homeostasis.

The autonomic nervous system, which is the efferent branch that innervates smooth muscle, cardiac muscle, and glands, plays a major role in the following homeostatic activities, among others:

- Regulating blood pressure
- Controlling digestive juice secretion and digestive tract contractions that mix ingested food with the digestive juices
- Controlling sweating to help maintain body temperature

The somatic nervous system, the efferent branch that innervates skeletal muscle, contributes to homeostasis by stimulating the following activities:

- Skeletal muscle contractions that enable the body to move in relation to the external environment, contributing to homeostasis by moving the body toward food or away from harm
- Contractions that accomplish breathing to maintain appropriate levels of O_2 and CO_2 in the body
- Shivering, which is important in maintaining body temperature

In addition, efferent output to skeletal muscles accomplishes many movements that are not aimed at maintaining a stable internal environment but nevertheless enrich our lives and enable us to engage in activities that contribute to society, such as dancing, building bridges, or performing surgery.

Review Exercises Answers begin on p. A-29

Reviewing Terms and Facts

1. Sympathetic preganglionic fibers begin in the thoracic and lumbar segments of the spinal cord. *(True or false?)*

2. Action potentials are transmitted on a one-to-one basis at both a neuromuscular junction and a synapse. *(True or false?)*

3. The sympathetic nervous system
   a. is always excitatory.
   b. innervates only tissues concerned with protecting the body against challenges from the outside environment.
   c. has short preganglionic and long postganglionic fibers.
   d. is part of the afferent division of the PNS.
   e. is part of the somatic nervous system.

4. Acetylcholinesterase
   a. is stored in vesicles in the terminal button.
   b. combines with receptor-channels on the motor end plate to bring about an end-plate potential.
   c. is inhibited by organophosphates.
   d. is the chemical transmitter at the neuromuscular junction.
   e. paralyzes skeletal muscle by strongly binding with acetylcholine (ACh) receptor-channels.

5. The two divisions of the autonomic nervous system are the _____ nervous system, which dominates in "fight-or-flight" situations, and the _____ nervous system, which dominates in "rest-and-digest" situations.

6. The _____ is a modified sympathetic ganglion that does not give rise to postganglionic fibers but instead secretes hormones similar or identical to sympathetic postganglionic neurotransmitters into the blood.

7. The _____ is the specialized portion of muscle cell membrane that underlies the terminal button at a neuromuscular junction.

8. Using the answer code on the right, identify the autonomic neurotransmitter being described:

1. is secreted by all preganglionic fibers	(a) acetylcholine
	(b) norepinephrine
2. is secreted by sympathetic postganglionic fibers	
3. is secreted by parasympathetic postganglionic fibers	
4. is secreted by the adrenal medulla	
5. is secreted by motor neurons	
6. binds to muscarinic or nicotinic receptors	
7. binds to α or β receptors	

9. Using the answer code on the right, indicate which type of efferent output is being described:

1. is composed of two-neuron chains	(a) characteristic of the somatic nervous system
2. innervates cardiac muscle, smooth muscle, and glands	(b) characteristic of the autonomic nervous system
3. innervates skeletal muscle	
4. consists of the axons of motor neurons	
5. exerts either an excitatory or an inhibitory effect on its effector organs	
6. dually innervates its effector organs	
7. exerts only an excitatory effect on its effector organs	

10. Using the answer code on the right, indicate what types of receptors are present for each of the organs listed (more than one answer may apply).

1. heart	(a) α_1
2. arteriolar smooth muscle	(b) α_2
3. bronchiolar smooth muscle	(c) β_1
4. skeletal muscle fibers	(d) β_2
5. adrenal medulla	(e) nicotinic
6. digestive glands	(f) muscarinic

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Distinguish between preganglionic and postganglionic fibers.

2. What is the advantage of dual innervation of many organs by both branches of the autonomic nervous system?

3. Distinguish among the following types of receptors in terms of mechanism of action and effect at the effector organ: nicotinic receptors, muscarinic receptors, α_1 receptors, α_2 receptors, β_1 receptors, and β_2 receptors.

4. Compare *agonists* and *antagonists.*

5. What regions of the CNS regulate autonomic output?

6. Describe the sequence of events that occurs at a neuromuscular junction.

7. Explain why an end-plate potential (EPP) has a larger magnitude than an excitatory postsynaptic potential (EPSP).

8. Discuss the effect each of the following has at the neuromuscular junction: black widow spider venom, botulinum toxin, curare, myasthenia gravis, and organophosphates.

Solving Quantitative Exercises

1. When a muscle fiber is activated at the neuromuscular junction, tension does not begin to rise until about 1 msec after initiation of the action potential in the muscle fiber. Many things occur during this delay, one time-consuming event being diffusion of ACh across the neuromuscular junction. The following equation can be used to calculate how long this diffusion takes:

$$t = x^2/2D$$

In this equation, x is the distance covered, D is the diffusion coefficient, and t is the time it takes for the substance to diffuse across the distance x. In this example, x is the width of the cleft between the neuronal terminal button and the muscle fiber at the neuromuscular junction (assume 200 nm), and D is the diffusion coefficient of ACh (assume 1×10^{-5} cm^2/sec). How long does it take ACh to diffuse across the neuromuscular junction?

Applying Clinical Reasoning

Christopher K. experienced chest pains when he climbed the stairs to his fourth-floor office or played tennis, but he had no symptoms when not physically exerting himself. His condition was diagnosed as *angina pectoris* (*angina* means "pain"; *pectoris* means "chest"), heart pain that occurs whenever the blood supply to the heart muscle cannot meet the muscle's need for oxygen delivery. This condition usually is caused by narrowing of the blood vessels supplying the heart by cholesterol-containing deposits. Most people with this condition do not have any pain at rest but experience bouts of pain whenever

the heart's need for oxygen increases, such as during exercise or emotionally stressful situations that increase sympathetic nervous activity. Christopher obtains immediate relief of angina attacks by promptly taking a vasodilator drug such as *nitroglycerin,* which relaxes the smooth muscle in the walls of his narrowed heart vessels. Consequently, the vessels open more widely and more blood can flow through them. For prolonged treatment, his doctor has indicated that Christopher will experience fewer and less severe angina attacks if he takes a β_1-blocker drug, such as *metoprolol,* regularly. Explain why.

Thinking at a Higher Level

1. Explain why epinephrine, which causes arteriolar constriction (narrowing) in most tissues, is often administered in conjunction with local anesthetics.

2. Would skeletal muscle activity be affected by atropine (see)? Why or why not?

3. Considering that you can voluntarily control the emptying of your urinary bladder by contracting (preventing emptying) or relaxing (permitting emptying) your external urethral sphincter, a ring of muscle that guards the exit from the bladder, of what type of muscle is this sphincter composed and what branch of the nervous system supplies it?

4. The venom of certain poisonous snakes contains α-bungarotoxin, which binds tenaciously to ACh receptor sites on the motor end-plate membrane. What would the resultant symptoms be?

5. Explain how destruction of motor neurons by poliovirus or amyotrophic lateral sclerosis can be fatal.

Muscle Physiology
CNRI/Science Source

A scanning electron micrograph of a skeletal muscle fiber. Skeletal muscle cells, or muscle fibers, are long, cylindrical, and striated (striped). A muscle fiber is packed with myofibrils, which are cylinder-shaped contractile structures that run the length of the fiber and have alternating dark and light bands responsible for the muscle fiber's striations.

Homeostasis Highlights

Muscles are contraction specialists. The three types of muscle are skeletal, smooth, and cardiac. **Skeletal muscle** attaches to the skeleton. Contraction of skeletal muscles moves bones to which they are attached, allowing the body to perform a variety of motor activities. Skeletal muscles that support homeostasis include those important in acquiring, chewing, and swallowing food and those essential for breathing. Also, heat-generating muscle contractions help regulate body temperature. Skeletal muscles are further used to move the body away from harm. Skeletal muscle contractions are also important for nonhomeostatic activities, such as dancing or operating a computer. **Smooth muscle** is found in the walls of hollow organs and tubes. Controlled contraction of smooth muscle regulates movement of blood through blood vessels, food through the digestive tract, air through respiratory airways, and urine to the exterior. **Cardiac muscle** is found only in the walls of the heart, whose contraction pumps life-sustaining blood throughout the body.

8.1 Structure of Skeletal Muscle

By moving specialized intracellular components, muscle cells can develop tension and shorten (contract). Through their highly developed ability to contract, groups of muscle cells working together within a muscle can produce movement and do work. Controlled contraction of muscles allows (1) purposeful movement of the whole body or parts of the body (such as walking or waving your hand), (2) manipulation of external objects (such as driving a car or moving a piece of furniture), (3) propulsion of contents through hollow internal organs (such as circulation of blood or movement of a meal through the digestive tract), and (4) emptying the contents of certain organs to the external environment (such as urination or giving birth).

Muscle comprises the largest group of tissues in the body, accounting for approximately half of body weight. Skeletal muscle alone makes up about 40% of body weight in men and 32% in women, with smooth and cardiac muscle making up another 10% of total weight. Although these three muscle types are structurally and functionally distinct, they can be classified in two ways according to common characteristics (Figure 8-1). First, muscles are categorized as *striated* (skeletal and cardiac muscle) or *unstriated* (smooth muscle), depending on whether alternating dark and light bands, or striations (stripes), can be seen when the muscle is viewed under a light microscope. Second, muscles are categorized as *voluntary* (skeletal muscle) or *involuntary* (cardiac and smooth muscle), depending on whether they are innervated by the somatic nervous system and subject to voluntary control or are innervated by the autonomic nervous system and not subject to voluntary control, respectively (see p. 234). Although skeletal muscle is categorized as voluntary, because it can be consciously controlled, much skeletal muscle activity is also subject to subconscious, involuntary regulation, such as that related to posture, balance, and rhythmic movements like walking.

Most of this chapter is a detailed examination of the most abundant and best understood muscle: skeletal muscle. Skeletal muscles make up the muscular system. The chapter concludes with a discussion of the unique properties of smooth and cardiac muscle in comparison to skeletal muscle.

Skeletal muscle fibers are striated by a highly organized internal arrangement.

A single skeletal muscle cell, known as a **muscle fiber**, is relatively large, elongated, and cylinder shaped, measuring from 10 to 100 micrometers (μm) in diameter and up to 750,000 μm, or 2.5 feet, in length (1 μm = 1 millionth of a meter). A skeletal muscle consists of a number of muscle fibers lying parallel to one another and bundled together by connective tissue (Figure 8-2a). The fibers usually extend the entire length of the muscle. During embryonic development, the huge skeletal muscle fibers are formed by the fusion of many smaller cells called **myoblasts** (*myo* means "muscle"; *blast* refers to a primitive cell that forms more specialized cells); thus, one striking feature is the presence of multiple nuclei dispersed just beneath the plasma membrane in a single muscle cell (see Figure 8-1a). Another feature is the abundance of mitochondria, the energy-generating organelles, as would be expected with the high energy demands of a tissue as active as skeletal muscle.

A skeletal muscle fiber contains numerous **myofibrils**, which are cylindrical intracellular structures 1 μm in diameter that extend the entire length of the muscle fiber (Figure 8-2b

and chapter opener photo). Myofibrils are specialized contractile elements that constitute 80% of the volume of the muscle fiber. Each myofibril consists of a regular arrangement of highly organized cytoskeletal microfilaments (see p. 44)—the thick and the thin filaments (■Figure 8-2c). The **thick filaments**, which are 12 to 18 nm in diameter and 1.6 μm in length, are special assemblies of the protein *myosin,* whereas the thin filaments, which are 5 to 8 nm in diameter and 1.0 μm long, are made up primarily of the protein *actin* (■Figure 8-2d). The levels of organization in a skeletal muscle can be summarized as follows:

Whole muscle	→	muscle fiber	→	myofibril	→	thick and thin filament	→	myosin and actin
(an organ)		(a cell)		(a specialized intracellular structure)		(cytoskeletal elements)		(protein molecules)
A and I Bands Viewed with an electron microscope, a myofibril displays alternating dark bands (the A bands) and light bands (the I bands) (■Figure 8-3). The bands of all the myofibrils lined up parallel to one another collectively produce the striated appearance of a skeletal muscle fiber visible under a light microscope. Alternate stacked sets of thick and thin filaments that slightly overlap one another are responsible for the A and I bands (see ■Figure 8-2c). Several cytoskeletal proteins maintain this precise filament geometry.

An **A band** is made up of a stacked set of thick filaments along with the portions of the thin filaments that overlap on both ends of the thick filaments. The thick filaments lie only within the A band and extend its entire width. The lighter area within the middle of the A band, where the thin filaments do not reach, is the **H zone**. Only the central portions of the thick filaments are found in this region. Supporting proteins that hold the thick filaments together vertically within each stack can be seen as the **M line**, which extends vertically down the middle of the A band within the center of the H zone.

An **I band** consists of the remaining portion of the thin filaments that do not project into the A band. Visible in the middle

of each I band is a dense, vertical **Z line**. The area between two Z lines is called a **sarcomere**, which is the functional unit of skeletal muscle. A **functional unit** of any organ is the smallest component that can perform all functions of that organ. Accordingly, a sarcomere is the smallest component of a muscle fiber that can contract. The Z line is a flat, cytoskeletal disc that connects the thin filaments of two adjoining sarcomeres. Each relaxed sarcomere is about 2 μm in width and consists of one whole A band and half of each of the two I bands located on either side. An I band contains only thin filaments from two adjacent sarcomeres but not the entire length of these filaments. During growth, a muscle increases in length by adding new sarcomeres on the ends of the myofibrils, not by increasing the size of each sarcomere.

Single strands of a giant, highly elastic protein known as **titin** extend in both directions from the M line along the length of the thick filament to the Z lines at opposite ends of the sarcomere (see ■Figure 8-2e). Titin is the largest protein in the body, being made up of nearly 30,000 amino acids. It serves three important roles:

1. *Serving as scaffolding.* Along with the M-line proteins, titin helps stabilize the position of the thick filaments in relation to the thin filaments, thus contributing to sarcomere stability.

2. *Acting as an elastic spring.* By acting like a spring, titin greatly augments a muscle's elasticity. That is, titin helps a muscle stretched by an external force passively recoil to its resting length when the stretching force is removed, much like a stretched spring. Because it behaves like an elastic spring and lies parallel to the thick and thin filaments, titin (along with the elastic connective tissue surrounding the muscle fibers) constitutes the **parallel-elastic component** of muscle.

3. *Participating in signal transduction.* Titin is also involved in diverse signaling pathways, such as the complex pathway involved in muscle enlargement in response to weight lifting.

Cross Bridges With an electron microscope, fine **cross bridges** can be seen extending from each thick filament toward the surrounding thin filaments in the areas where the thick and thin filaments overlap (see the longitudinal view in ■Figure 8-2c). Three-dimensionally, the thin filaments are arranged hexagonally around the thick filaments. Cross bridges project from each thick filament in all six directions toward the six surrounding thin filaments. Each thin filament, in turn, is surrounded by three thick filaments (see the cross-section view through an A band in ■Figure 8-2c). A single muscle fiber may contain an estimated 16 billion thick and 32 billion thin filaments, all arranged in this precise pattern within the myofibrils.

Myosin forms the thick filaments.

Each thick filament has several hundred myosin molecules packed together in a specific arrangement. A **myosin** molecule is a protein consisting of two identical subunits, each shaped somewhat like a golf club (■Figure 8-4a). The tail ends of the two subunits are intertwined around each other like golf-club shafts twisted together, with the two globular heads projecting

out at one end. Myosin can bend at hinge points in two locations: one along the tail and the other at the "neck" or junction of the tail with each head. The two halves of each thick filament are mirror images made up of myosin molecules lying lengthwise in a regular, staggered array, with their tails oriented toward the center of the filament and their globular heads protruding outward at regular intervals (IFigure 8-4b). The heads form the cross bridges between the thick and thin filaments. Each cross bridge has two sites crucial to the contractile process: (1) an actin-binding site and (2) a myosin ATPase (ATP-splitting) site.

Actin is the main structural component of the thin filaments.

Thin filaments consist of three proteins: *actin, tropomyosin,* and *troponin* (IFigure 8-5). **Actin** molecules, the primary structural proteins of the thin filament, are spherical. The thin filament's backbone is formed by actin molecules joined into two strands and twisted together, like two intertwined strings of pearls. Each actin molecule has a binding site for attaching with a myosin cross bridge. Binding of myosin and actin at the cross bridges leads to contraction of the muscle fiber, by a mechanism to be described shortly. Myosin and actin are not unique to muscle cells (see p. 49), but these proteins are more abundant and more highly organized in muscle cells.

In a relaxed muscle fiber, contraction does not take place; actin cannot bind with cross bridges because of the way the two other types of protein—tropomyosin and troponin—are positioned within the thin filament. **Tropomyosin** molecules are threadlike proteins that lie end to end alongside the groove of the actin spiral. In this position, tropomyosin covers the actin sites that bind with the cross bridges, blocking the interaction that leads to muscle contraction. The other thin filament component, **troponin**, is a protein complex made of three polypeptide units: one binds to tropomyosin, one binds to actin, and a third can bind with Ca^{2+}.

When troponin is not bound to Ca^{2+}, this protein stabilizes tropomyosin in its blocking

IFigure 8-5 Composition of a thin filament. The main structural component of a thin filament is two chains of spherical actin molecules that are twisted together. Troponin molecules (which consist of three small, spherical subunits) and threadlike tropomyosin molecules are arranged to form a ribbon that lies alongside the groove of the actin helix and physically covers the binding sites on actin molecules for attachment with myosin cross bridges. (The thin filaments shown here are not drawn in proportion to the thick filaments in Figure 8-4. Thick filaments are several times larger in diameter than thin filaments.)

position over actin's cross-bridge binding sites (❙ Figure 8-6a). When Ca^{2+} binds to troponin, the shape of this protein is changed in such a way that tropomyosin slips away from its blocking position (❙ Figure 8-6b). With tropomyosin out of the way, actin and myosin can bind and interact at the cross bridges, resulting in muscle contraction. Tropomyosin and troponin are often called **regulatory proteins** because of their role in covering (preventing contraction) or exposing (permitting contraction) the binding sites for cross-bridge interaction between actin and myosin.

Check Your Understanding 8.1

1. Compare the relationship among myofibrils, muscle fibers, and a whole muscle.

2. Illustrate the relative positions of the cytoskeletal structures that make up a sarcomere.

3. Describe how actin, tropomyosin, and troponin are organized in a relaxed muscle fiber.

8.2 Molecular Basis of Skeletal Muscle Contraction

Several important links in the contractile process remain to be discussed. How does cross-bridge interaction between actin and myosin bring about muscle contraction? How does a muscle action potential trigger this contractile process? What is the source of the Ca^{2+} that physically repositions troponin and tropomyosin to permit cross-bridge binding? We now turn attention to these topics.

During contraction, cycles of cross-bridge binding and bending pull the thin filaments inward.

Cross-bridge interaction between actin and myosin brings about muscle contraction by means of the sliding filament mechanism.

Sliding Filament Mechanism The thin filaments on each side of a sarcomere slide inward over the stationary thick filaments toward the A band's center during contraction (❙ Figure 8-7). As they slide inward, the thin filaments pull the Z lines to which they are attached closer together, so the sarcomere shortens. As all sarcomeres throughout the muscle fiber's length shorten simultaneously, the entire fiber shortens. This is the **sliding filament mechanism** of muscle contraction. The H zone, in the center of the A band where the thin filaments do not reach, becomes smaller as the thin filaments approach each other when they slide more deeply inward. The I band, which consists of the portions of the thin filaments that do not overlap with the thick filaments, narrows as the thin filaments further overlap the thick filaments during their inward slide. The thin filaments themselves do not change length during muscle fiber shortening. The width of the A band remains unchanged during contraction because its width is determined by the length of the thick filaments, and the thick filaments do not change length during the shortening process. Note that neither the thick nor the thin filaments decrease in length to shorten the sarcomere. Instead, contraction is accomplished by the thin filaments from the opposite sides of each sarcomere sliding closer together between the thick filaments.

Power Stroke During contraction, with the tropomyosin and troponin "chaperones" pulled out of the way by Ca^{2+}, the myosin heads or cross bridges from a thick filament can bind with the

I Figure 8-7 Changes in banding pattern during shortening. During muscle contraction, each sarcomere shortens as the thin filaments slide closer together between the thick filaments so that the Z lines are pulled closer together. The width of the A bands does not change as a muscle fiber shortens, but the I bands and H zones become shorter.

FIGURE FOCUS: *Predict what happens to the H zone when the thin filaments from opposite sides of an A band touch each other as they slide inward toward the center of the sarcomere.*

actin molecules in the surrounding thin filaments. Myosin is a motor protein, similar to kinesin and dynein. Recall that kinesin and dynein have little feet that "walk" along microtubules to transport specific products (as within a neuronal axon; see

p. 47) or to move microtubules in relation to one another (as to accomplish beating of cilia or flagella; see p. 49). In the same way, myosin cross bridges "walk" along an actin filament to pull it inward relative to the stationary thick filament. Let us concentrate on a single cross-bridge interaction (I Figure 8-8a). The two myosin heads of each myosin molecule act independently, with only one head attaching to actin at a given time. When the binding site on an actin molecule is exposed, the myosin molecule tilts at the hinge point on the tail, elevating the myosin head to facilitate the binding of this cross bridge to the nearest actin molecule. On binding, the myosin head tilts 45 degrees inward. Bending at this neck hinge point creates a "stroking" motion that pulls the thin filament toward the center of the sarcomere, like the stroking of a boat oar. This action is known as the **power stroke** of a cross bridge. A single power stroke pulls the thin filament inward only a small percentage of the total shortening distance. Repeated cycles of cross-bridge binding and bending complete the shortening.

At the end of one cross-bridge cycle, the link between the myosin cross bridge and actin molecule breaks. The cross bridge returns to its original angle and binds to an actin molecule behind its previous actin partner. The cross bridge tilts inward again to pull the thin filament in farther, then detaches and repeats the cycle. Repeated cycles of cross-bridge power

Figure 8-9 The T tubules and sarcoplasmic reticulum in relationship to the myofibrils. The transverse (T) tubules are membranous, perpendicular extensions of the surface membrane that dip deep into the muscle fiber at the junctions between the A and I bands of the myofibrils. The sarcoplasmic reticulum (SR) is a fine, membranous network that runs longitudinally and surrounds each myofibril, with separate segments encircling each A band and I band. The ends of each segment are expanded to form lateral sacs that lie next to the adjacent T tubules.

strokes successively pull in the thin filaments, much like pulling in a rope hand over hand.

Because of the way myosin molecules are oriented within a thick filament (▌Figure 8-8b), all cross bridges stroke toward the center of the sarcomere so that all six of the surrounding thin filaments on each end of the sarcomere are pulled inward simultaneously (▌Figure 8-8c). The cross bridges aligned with given thin filaments do not all stroke in unison, however. At any time during contraction, part of the cross bridges are attached to the thin filaments and are stroking, while others are returning to their original conformation in preparation for binding with another actin molecule. Thus, some cross bridges are "holding on" to the thin filaments, whereas others "let go" to bind with new actin. Were it not for this asynchronous cycling of the cross bridges, the thin filaments would slip back toward their resting position between strokes.

How does muscle excitation switch on this cross-bridge cycling? The term **excitation–contraction coupling** refers to the series of events linking muscle excitation (the presence of an action potential in a muscle fiber) to muscle contraction (cross-bridge activity that causes the thin filaments to slide closer together to produce sarcomere shortening). We now turn to this topic.

Calcium is the link between excitation and contraction.

Skeletal muscles are stimulated to contract by release of acetylcholine (ACh) at neuromuscular junctions between motor-neuron terminal buttons and muscle fibers. Recall that binding of ACh with the motor end plate of a muscle fiber brings about

permeability changes in the muscle fiber, resulting in an action potential that is conducted over the entire surface of the muscle cell membrane (see p. 245). The plasma membrane in muscle is sometimes called the **sarcolemma**. Two other membranous structures within the muscle fiber play important roles in linking this excitation to contraction—*transverse tubules* and *sarcoplasmic reticulum*. We examine them next.

Spread of the Action Potential Down the Transverse Tubules At each junction of an A band and I band, the surface membrane dips into the muscle fiber to form a **transverse tubule (T tubule)**, which runs perpendicularly from the surface of the muscle cell membrane into the central portions of the muscle fiber (▌Figure 8-9). Because the T tubule membrane is continuous with the sarcolemma, an action potential on the surface membrane spreads down into the T tubule, rapidly transmitting the surface electrical activity into the interior of the fiber. The presence of a local action potential in the T tubules leads to permeability changes in a separate membranous network within the muscle fiber, the sarcoplasmic reticulum.

Release of Calcium from the Sarcoplasmic Reticulum

The **sarcoplasmic reticulum (SR)** is a modified endoplasmic reticulum (see p. 27) that consists of a fine network of interconnected membrane-enclosed compartments surrounding each myofibril like a mesh sleeve (▌Figure 8-9). This membranous network encircles the myofibril throughout its length but is not continuous. Separate segments of SR are wrapped around each A band and each I band. The ends of each segment expand to form saclike regions, the **lateral sacs** (alternatively known as **terminal cisternae**), which are separated from the adjacent T tubules by a slight gap. The lateral sacs store Ca^{2+}. Spread of an action potential down a T tubule triggers release of Ca^{2+} from the SR into the cytosol.

How is a change in T tubule potential linked with the release of Ca^{2+} from the lateral sacs? T tubule membrane proteins known as **dihydropyridine receptors** (because they are blocked by the drug dihydropyridine) serve as voltage sensors (▌Figure 8-10a). Local depolarization of the T tubules activates the dihydropyridine receptors, which in turn trigger the opening of directly abutting foot proteins (alias Ca^{2+}-release channels or ryanodine receptors) in the adjacent lateral sacs. An orderly arrangement of **foot proteins** spans the gap between the T tubule and the lateral sac (▌Figure 8-10b). These foot proteins not only bridge the gap, but also serve as Ca^{2+}-**release channels** and are also known as **ryanodine receptors** because they are locked in the open position by the plant chemical ryanodine.

When these Ca^{2+}-release channels are opened in the presence of a local action potential in the adjacent T tubule, Ca^{2+} is released into the cytosol from the lateral sacs (▌Figure 8-10c).

By slightly repositioning the troponin and tropomyosin molecules, this released Ca^{2+} exposes the binding sites on the actin molecules so that they can link with the myosin cross bridges at their complementary binding sites. Excitation–contraction coupling is summarized in ❙Figure 8-11.

ATP-Powered Cross-Bridge Cycling A myosin cross bridge has two special sites: an actin-binding site and an ATPase site (see ❙Figure 8-4a). The latter is an enzymatic site that can bind the energy carrier *adenosine triphosphate (ATP)* and split it into *adenosine diphosphate (ADP)* and *inorganic phosphate (Pi)*, yielding energy in the process. The breakdown of ATP occurs on the myosin cross bridge before the bridge ever links with an actin molecule (❙Figure 8-12 step **1**). The ADP and P_i remain tightly bound to the myosin, and the generated energy is stored within the cross bridge to produce a high-energy form of myosin. To use an analogy, the cross bridge is "cocked" like a gun, ready to be fired when the trigger is pulled. When the muscle fiber is excited, Ca^{2+} pulls the troponin–tropomyosin complex out of its blocking position so that the energized (cocked) myosin cross bridge can bind with an actin molecule (step **2a**). This contact between myosin and actin "pulls the trigger," causing the cross-bridge bending that produces the power stroke (step **3**). P_i is released from the cross bridge during the power stroke. After the power stroke is complete, ADP is released.

When the muscle is not excited and Ca^{2+} is not released, troponin and tropomyosin remain in their blocking position so that actin and the myosin cross bridges do not bind and no power stroking takes place (step **2b**).

When P_i and ADP are released from myosin following contact with actin and the subsequent

power stroke, the myosin ATPase site is free for attachment of another ATP molecule. The actin and myosin remain linked at the cross bridge until a fresh molecule of ATP attaches to myosin at the end of the power stroke. Attachment of the new ATP molecule reduces the binding affinity between the myosin head and actin, thus allowing the cross bridge to detach (step **4a**) and return to its unbent form. The newly attached ATP is then split by myosin ATPase, recocking and energizing the myosin cross bridge once again so that it is ready to start another cycle (step **1**). On binding with another actin molecule, the energized cross bridge again bends, and so on, successively pulling the thin filament inward to accomplish contraction.

Rigor Mortis Note that fresh ATP must attach to myosin to permit the cross-bridge link between myosin and actin to break at the end of a cycle, even though the ATP is not split during this dissociation process. The need for ATP in separating myosin and actin is amply shown in **rigor mortis**. This "stiffness of death" is a generalized locking in place of the skeletal muscles that begins 3 to 4 hours after death and completes in about 12 hours. Following death, the cytosolic concentration of Ca^{2+} begins to rise, most likely because the inactive muscle cell membrane cannot keep out extracellular Ca^{2+} and perhaps because Ca^{2+} leaks out of the lateral sacs. This Ca^{2+} moves troponin and tropomyosin aside, letting actin bind with the myosin cross bridges, which were already charged with ATP before death. Dead cells cannot produce any more ATP, so actin and myosin, once bound, cannot detach because they lack fresh ATP. The thick and thin filaments

8 When action potentials stop, Ca^{2+} is taken up by the sarcoplasmic reticulum. With no Ca^{2+} on troponin, tropomyosin moves back to its original position, blocking myosin cross-bridge binding sites on actin. Contraction stops and the thin filaments passively slide back to their original relaxed positions.

3 Ca^{2+} binds to troponin on thin filaments.

Myosin cross-bridge binding site

Actin-binding site

Cycle repeats

7 After the power stroke, the cross bridge detaches from actin. If Ca^{2+} is still present, the cycle returns to step 5.

4 Ca^{2+} binding to troponin causes tropomyosin to change shape, physically moving it away from its blocking position; this uncovers the binding sites on actin for the myosin cross bridges.

6 The binding triggers the cross bridge to bend, pulling the thin filament over the thick filament toward the center of the sarcomere. This power stroke is powered by energy provided by ATP.

5 Myosin cross bridges attach to actin at the exposed binding sites.

❙Figure 8-11 Excitation–contraction coupling and muscle relaxation. Steps 1 through 7 show the events that couple neurotransmitter release and subsequent electrical excitation of the muscle cell with muscle contraction. At step 7, if Ca^{2+} is still present, the cross-bridge cycle returns to step 5 for another power stroke. If Ca^{2+} is no longer present as a consequence of step 8, relaxation occurs.

thus stay linked by the immobilized cross bridges, leaving dead muscles stiff (step **4b**). During the next several days, rigor mortis gradually subsides as the proteins involved in the rigor complex begin to degrade.

Relaxation How is relaxation normally accomplished in a living muscle? Just as an action potential in a muscle fiber turns on the contractile process by triggering release of Ca^{2+} from the lateral sacs into the cytosol, the contractile process is turned off and **relaxation** occurs when Ca^{2+} is returned to the lateral sacs when local electrical activity stops. The SR has an energy-consuming carrier, the **sarcoplasmic/endoplasmic reticulum Ca^{2+}–ATPase (SERCA) pump,** which actively transports Ca^{2+} from the cytosol and concentrates it in the lateral sacs (see **Figure 8-11**). Recall that the end-plate potential and resultant muscle-fiber action potential stop when the membrane-bound enzyme acetylcholinesterase removes ACh from the neuromuscular junction (see p. 246). When a local action potential is no longer in the T tubules to trigger release of Ca^{2+}, the ongoing activity of the SERCA pump returns released Ca^{2+} back into the lateral sacs. Removing cytosolic Ca^{2+} lets the troponin–tropomyosin complex slip back into its blocking position, so actin and myosin can no longer bind at the cross bridges. The thin filaments, freed from cycles of cross-bridge attachment and pulling, return passively to their resting position. The muscle fiber has relaxed. Next we see how long the contractile activity initiated by a single action potential lasts before relaxation occurs.

Contractile Activity Far Outlasts the Electrical Activity that Initiated It. A single action potential in a skeletal muscle fiber lasts only 1 to 2 msec. The onset of the resulting contractile response lags behind the action potential because the entire excitation–contraction coupling must occur before cross-bridge activity begins. In fact, the action potential is over before the contractile apparatus even becomes operational. This time delay of a few milliseconds between stimulation and onset of contraction is called the **latent period** (**Figure 8-13**). Time is also needed for generating tension within the muscle fiber by means of the sliding interactions between the thin and the thick filaments through cross-bridge activity. The time from contraction onset until peak tension develops—**contraction time**—varies from 15 to 50 msec, depending on muscle fiber type. The contractile response does not end until the lateral sacs have taken up all Ca^{2+} released in response to the action potential. This reuptake of Ca^{2+} is also time-consuming. As Ca^{2+} is pumped back into the lateral sacs, cytosolic Ca^{2+} is reduced
Figure 8-13 **Relationship of an action potential to the resultant muscle twitch in a slow contracting fiber.** The duration of the action potential is not drawn to scale but is exaggerated. Note that the resting potential of a skeletal muscle fiber is –90 mV, compared to a resting potential of −70 mV in a neuron.

and, as a result, cross-bridge activity declines and overall contractile force decreases. The time from peak tension until relaxation is complete—**relaxation time**—varies from 15 to 50 msec, again depending on muscle fiber type. Consequently, the entire contractile response to a single action potential may last from 30 msec in fast contracting fibers to 100 msec or more in slow contracting fibers. This is much longer than the duration of the action potential that initiates contraction (30 to 100 msec as compared to 1 to 2 msec). This fact is important in the body's ability to produce muscle contractions of variable strength, as you will discover in the next section.

Check Your Understanding 8.2

1. Illustrate the relationship between the thick and the thin filaments in a relaxed sarcomere and in a contracted sarcomere.

2. Explain the role of the dihydropyridine and the ryanodine receptors in the process of excitation–contraction coupling.

3. Describe the cross-bridge cycle and indicate whether ATP, ADP, or ADP and P_i are bound to the myosin head during the various stages of the cycle.

4. Explain why muscles are stiff during rigor mortis.

8.3 Skeletal Muscle Mechanics

Thus far we have focused on contraction in a single muscle fiber. In the body, groups of muscle fibers are organized into whole muscles. We now turn to contraction of whole muscles.

Whole muscles are groups of muscle fibers bundled together and attached to bones.

The about 600 skeletal muscles in the body range in size from delicate external eye muscles that control eye movements and contain only a few hundred fibers to large, powerful leg muscles that contain several hundred thousand fibers.

Each muscle is sheathed by connective tissue that penetrates from the surface into the muscle to envelop each individual fiber and divide the muscle into bundles. The connective tissue extends beyond the ends of the muscle to form tough, collagenous **tendons** that attach the muscle to bones. A tendon may be quite long, attaching to a bone some distance from the fleshy part of the muscle. For example, many muscles involved in finger movement are in the forearm, with long tendons extending down to attach to the bones of the fingers. (You can readily see these tendons move on the top of your hand when you wiggle your fingers.) This arrangement permits greater dexterity; the fingers would be thicker and more awkward if all the muscles used in finger movement were actually in the fingers.

Muscle tension is transmitted to bone as the contractile component tightens the series-elastic component.

Tension is produced internally within the sarcomeres, considered the **contractile component** of the muscle, as a result of cross-bridge activity and the resulting sliding of filaments. However, the sarcomeres are not attached directly to the bones. Instead, the tension generated by these contractile elements must be transmitted to the bone via a tendon before the bone can be moved. Tendons have a certain degree of passive elasticity. This noncontractile elastic tissue is in series with the contractile component (being *in series* means that one component is positioned after another in a row) and thus is called the **series-elastic component** of the muscle (unlike titin, which is a major part of the parallel-elastic component and contributes to the muscle's passive elastic recoil). The series-elastic component behaves like a stiff spring placed between the internal tension-generating elements and the bone that is to be moved against an external **load**, or opposing force (**I**Figure 8-14). Shortening of the sarcomeres stretches the series-elastic component (tendon). Muscle tension is transmitted to the bone by this tightening of the series-elastic component. This force applied to the bone moves the bone against a load.

A muscle is typically attached to at least two bones across a joint by means of tendons that extend from each end of the muscle. When the muscle shortens during contraction, the position of the joint changes as one bone is moved in relation to the other—for example, *flexion* (bending) of the elbow joint by

IFigure 8-14 **Relationship between the contractile component and the series-elastic component in transmitting muscle tension to bone.** Muscle tension is transmitted to the bone by means of the stretching and tightening of the muscle's elastic tendon as a result of sarcomere shortening brought about by cross-bridge cycling.

Labels in figure: Thick and thin filaments (contractile component) and titin (parallel-elastic component); Tendon (series-elastic component); Load; Load

flex your elbow without lifting any external object, there is still a load, albeit a minimal one—the weight of your forearm being moved against the force of gravity.

There are three primary types of contraction. In an **isotonic contraction**, the load remains constant as the muscle changes length. In an **isokinetic contraction**, the velocity of shortening remains constant as the muscle changes length. In an **isometric contraction**, the muscle is prevented from shortening, so tension develops at constant muscle length. The same internal events occur in isotonic, isokinetic, and isometric contractions: Muscle excitation turns on the tension-generating contractile process; the cross bridges start cycling; and filament sliding shortens the sarcomeres, which stretches the series-elastic components to exert forces on the bones at the sites of the muscle's origin and insertion.

Considering your biceps as an example, assume you are going to lift an object. When the tension developing in your biceps becomes great enough to overcome the weight of the object in your hand, you can lift the object, with the whole muscle shortening in the process. Because the weight of the object does not change as it is lifted, this type of contraction is an *isotonic* (literally, "constant tension") *contraction*. Owing to the mechanical arrangement of the joint, as the angle of the joint changes while the object is lifted, muscle tension must also change to counterbalance the load. Thus, muscle tension does not remain constant throughout the period of shortening during an isotonic contraction (despite its name) even though the load remains constant.

Isokinetic (literally, "constant motion") *contractions* occur when muscle fibers shorten at a constant velocity, or speed. Isokinetic contractions do not take place normally but can be achieved using special exercise machines set up to require muscle contraction at a constant velocity throughout the entire range in motion. One of the proposed advantages of isokinetic exercise is more rapid development of muscle strength.

What happens if you try to lift an object too heavy for you (that is, if the tension you can develop in your arm muscles is less than required to lift the load)? In this case, the muscle cannot shorten and lift the object but remains at constant length despite the development of tension, so an *isometric* ("constant length") *contraction* occurs. In addition to occurring when the load is too great, isometric contractions take place when the tension developed in the muscle is deliberately less than needed to move the load, with the goal of keeping the muscle at a fixed

contraction of the biceps and *extension* (straightening) of the elbow by contraction of the triceps (IFigure 8-15). The end of the muscle attached to the more stationary part of the skeleton is called the **origin**, and the end attached to the skeletal part that moves is the **insertion**. Note that because muscle contraction can only pull and not push bone, two different antagonistic muscles or muscle groups are situated to pull on opposite sides of the joint. For example, the biceps can pull the joint in one direction (flexion) and the triceps can pull the joint in the other direction (extension).

The three primary types of contraction are isotonic, isokinetic, and isometric.

Not all muscle contractions shorten muscles and move bones. For a muscle to shorten during contraction, the tension developed in the muscle must exceed the forces that oppose movement of the bone to which the muscle's insertion is attached. In the case of elbow flexion, the opposing force or load is the weight of an object being lifted. When you

IFigure 8-15 **Flexion and extension of the elbow joint.**

Labels: Flexion — Origin of biceps; Biceps contracts; Insertion of biceps. Extension — Origin of triceps; Triceps contracts; Insertion of triceps.

length. These submaximal isometric contractions are important for maintaining posture (such as keeping the legs stiff while standing) and for supporting objects in a fixed position (such as holding a beverage between sips).

Muscle contractions often are not of one pure primary type. Muscle tension, length, and velocity of shortening may vary throughout a range of motion. Think about pulling back a bow and arrow. The tension of your biceps muscle continuously increases to overcome the progressively increasing resistance as you stretch the bow further. At the same time, the joint angle changes and the muscle progressively shortens as your elbow bends to draw the bow farther back. Such a contraction does not occur at constant tension, length, or velocity.

Concentric and Eccentric Contractions There are also two other descriptors of muscle contraction—*concentric* and *eccentric*. In **concentric contractions** the muscle shortens, whereas with **eccentric contractions** the muscle lengthens. An example of an eccentric contraction is lowering a book to place it on a desk. During this action, the muscle fibers in the biceps are lengthening but are still actively contracting in opposition to being passively stretched by the load. The contraction itself does not lengthen the muscle; the contraction is resisting the stretch of the muscle imposed externally by the weight of the book.

Other Contractions Some skeletal muscles do not attach to bones at both ends but still produce movement. For example, tongue muscles are not attached at the free end. Contractions of tongue muscles maneuver the free, unattached portion of the tongue to facilitate speech and eating. External eye muscles attach to the skull at their origin and to the eye, not another bone, at their insertion. Contractions of these muscles produce eye movements that enable us to track moving objects or read. A few skeletal muscles known as **sphincters** are not attached to bone at all and actually prevent movement. Sphincters are voluntarily controlled rings of skeletal muscles that, when contracted, close an opening, thereby guarding movement of material through the opening, such as the exit of urine and feces from the body.

The velocity of shortening is related to the load.

The load is also an important determinant of the velocity with which a muscle changes length (❚ Figure 8-16). During a concentric contraction, the greater the load, the lower the velocity at which a single muscle fiber (or a constant number of contracting fibers within a muscle) shortens. The speed of shortening is maximal when there is no external load, progressively decreases with an increasing load, and falls to zero (no shortening—isometric contraction) when the load cannot be overcome by maximal tension. You have frequently experienced this **load–velocity relationship**. You can lift light objects requiring little muscle tension quickly, whereas you can lift very heavy objects only slowly, if at all. This relationship between load and shortening velocity is a fundamental property of muscle, presumably because the power stroke slows when the myosin head tilts against a greater load.
❚ Figure 8-16 **Load–velocity relationship in concentric contractions.** The velocity of shortening decreases as the load increases.

Whereas load and velocity for shortening are *inversely* related for *concentric* contractions, load and velocity for lengthening are *directly* related for *eccentric* contractions. An external force (load) greater than a muscle's maximal contraction force causes the muscle to lengthen, with the velocity of lengthening being directly dependent on the load.

Although muscles can accomplish work, much of the energy is converted to heat.

Muscle accomplishes work in a physical sense only when an object is moved. **Work** is defined as force multiplied by distance. **Force** can be equated to the muscle tension required to overcome the load (the weight of the object). The amount of work accomplished by a contracting muscle therefore depends on how much an object weighs and how far it is moved. In an isometric contraction when no object is moved, the muscle contraction's efficiency as a producer of external work is zero. All energy consumed by the muscle during the contraction is converted to heat. In an isotonic or isokinetic contraction, the muscle's efficiency is about 25%. Of the energy consumed by the muscle during the contraction, 25% is realized as external work, whereas the remaining 75% is converted to heat.

Much of this heat is not wasted energy because it is used in maintaining body temperature. In fact, shivering—a form of involuntarily induced skeletal muscle contraction—is a well-known means of increasing heat production on a cold day. Heavy exercise on a hot day, in contrast, may overheat the body because the normal heat-loss mechanisms may not be able to compensate for this increase in heat production.

Interactive units of skeletal muscles, bones, and joints form lever systems.

Most skeletal muscles are attached to bones across joints, forming lever systems. A **lever** is a rigid structure capable of moving around a pivot point known as a **fulcrum**. In the body, the bones function as levers, the joints serve as fulcrums, and the skeletal muscles provide the force to move the bones. The portion of a lever between the fulcrum and the point where a force

is applied by the muscle is called the **power arm**; the portion between the fulcrum and the force exerted by a load is known as the **load arm** (❚Figure 8-17a).

The most common type of lever system in the body is exemplified by flexion of the elbow joint on contraction of the biceps. Skeletal muscles, such as the biceps, consist of many parallel (side-by-side) tension-generating fibers that can exert a large force at their insertion but shorten only a small distance and at relatively slow velocity. The lever system of the elbow joint amplifies the slow, short movements of the biceps to produce more rapid movements of the hand that cover a greater distance. Consider how an object weighing 5 kg is lifted by the hand (❚Figure 8-17b). When the biceps contracts, it exerts an upward force at the point where it inserts on the forearm bone about 5 cm away from the elbow joint, the fulcrum. Thus, the power arm of this lever system is 5 cm long. The length of the load arm, the distance from the elbow joint to the hand, averages 35 cm. In this case, the load arm is seven times longer than the power arm, which enables the load to be moved a distance seven times greater than the shortening distance of the muscle (while the biceps shortens a distance of 1 cm, the hand moves the load a distance of 7 cm) and at a velocity seven times greater (the hand moves 7 cm during the time that the biceps shortens 1 cm).

The disadvantage of this lever system is that at the point of insertion the biceps muscle must exert a force seven times greater than the load. To keep from dropping the 5-kg load, the product of the length of the power arm times the force in the biceps must equal the product of the length of the load arm times the force exerted by the load. These products are referred to as **moments** (force times power arm or force times load arm). The moment for the load is 5 kg (force) times 35 cm (load arm). This must be matched by the moment for the muscle;

35 kg (force) times 5 cm (power arm). To lift the 5-kg load, the biceps muscle must generate a force greater than 35 kg. As shown by this example, skeletal muscles typically work at a mechanical disadvantage in that they must exert a considerably greater force than the actual load to be moved. Nevertheless, the amplification of velocity and distance afforded by the lever arrangement enables muscles to move loads faster over greater distances than would otherwise be possible. This amplification provides valuable maneuverability and speed.

Next we examine the means by which muscle tension can be graded or varied.

Contractions of a whole muscle can be of varying strength.

A single action potential in a muscle fiber produces a brief, weak contraction called a **twitch**, which is too short and not strong enough to be useful and thus rarely occurs. Muscle fibers are arranged into whole muscles, where they function cooperatively to produce contractions of variable grades of strength stronger than a twitch. You can vary the force you exert by the same muscle, depending on whether you are picking up a piece of paper, a book, or a 50-pound weight. Two primary factors can be adjusted to accomplish gradation of whole-muscle tension: (1) *the number of muscle fibers contracting within a muscle* and (2) *the tension developed by each contracting fiber*. We discuss each of these factors in turn.

(a) Most common type of lever system in body

(b) Flexion of elbow joint as example of body lever action
❚**Figure 8-17 Lever systems of muscles, bones, and joints.** Note that the lever ratio (length of the power arm to length of the load arm) is 1:7 (5 cm:35 cm), which amplifies the distance and velocity of movement seven times (distance moved by the muscle [extent of shortening] =1 cm, distance moved by the hand = 7 cm, velocity of muscle shortening = 1 cm/unit of time, hand velocity = 7 cm/unit of time), but at the expense of the muscle having to exert seven times the force of the load (muscle force = 35 kg, load = 5 kg).

FIGURE FOCUS: *If the biceps of a child inserts 4 cm from the elbow and the length of the arm from the elbow to the hand is 28 cm, how much force must the biceps generate for the child to lift a 6-kg backpack with one hand?*

The number of fibers contracting within a muscle depends on the extent of motor unit recruitment.

The greater the number of fibers contracting, the greater the total muscle tension. Therefore, larger muscles consisting of more muscle fibers can generate more tension than smaller muscles with fewer fibers can.

Each whole muscle is innervated by a number of different motor neurons. When a motor neuron enters a muscle, it branches, with each axon terminal supplying a single muscle fiber (❙Figure 8-18). One motor neuron innervates a number of muscle fibers, but each muscle fiber is supplied by only one motor neuron. When a motor neuron is activated, all the muscle fibers it supplies are stimulated to contract simultaneously. This team of concurrently activated components—one motor neuron plus all the muscle fibers it innervates—is called a **motor unit**. The muscle fibers that compose a motor unit are dispersed throughout the whole muscle; thus, their simultaneous contraction results in an evenly distributed, although weak, contraction of the whole muscle. Each muscle consists of numerous intermingled motor units. For a weak contraction of the whole muscle, only one or a few of its motor units are activated. For stronger and stronger contractions, more and more motor units are recruited, or stimulated to contract simultaneously, a phenomenon known as **motor unit recruitment**.

How much stronger the contraction is with the recruitment of each additional motor unit depends on motor unit size (that is, the number of muscle fibers controlled by a single motor neuron). The number of muscle fibers per motor unit and the number of motor units per muscle vary widely, depending on the specific function of the muscle. For muscles that produce precise, delicate movements, such as external eye muscles and hand muscles, a single motor unit may contain as few as a dozen muscle fibers. Because so few muscle fibers are involved with each motor unit, recruitment of each additional motor unit adds only a small increment to the whole muscle's strength of contraction. These small motor units allow fine control over muscle tension. In contrast, in muscles designed for powerful, coarsely controlled movement, such as those of the legs, a single motor unit may contain 1500 to 2000 muscle fibers. Recruitment of motor units in these muscles results in large incremental increases in whole-muscle tension. More powerful contractions occur at the expense of less precisely controlled gradations. Thus, the number of muscle fibers participating in the whole muscle's total contractile effort depends on the number of motor units recruited and the number of muscle fibers per motor unit in that muscle.

To delay or prevent **fatigue** (inability to maintain muscle tension at a given level) during a sustained contraction involving only a portion of a muscle's motor units, as is necessary in muscles supporting the weight of the body against the force of gravity, **asynchronous recruitment** of motor units takes place. The body alternates motor unit activity, like shifts at a factory, to give motor units that have been active an opportunity to rest while others take over. Changing of the shifts is carefully coordinated, so the sustained contraction is smooth rather than jerky. Asynchronous recruitment is possible only for submaxi-
❙Figure 8-18 **Motor units in a skeletal muscle.**

mal contractions, during which only some of the motor units must maintain the desired level of tension. During maximal contractions, when all muscle fibers must participate, it is impossible to alternate motor unit activity to prevent fatigue. This is one reason you cannot support a heavy object as long as you can support a light one.

Furthermore, the type of muscle fiber activated varies with the extent of gradation. Most muscles consist of a mixture of fiber types that differ metabolically, some being more resistant to fatigue than others. During weak or moderate endurance-type activities (aerobic exercise), the motor units most resistant to fatigue are recruited first. The last fibers to be called into play in the face of demands for further increases in tension are those that fatigue rapidly. An individual can therefore engage in endurance activities for prolonged periods but can only briefly maintain bursts of all-out, powerful effort. Of course, even the muscle fibers most resistant to fatigue eventually tire if required to maintain a certain level of sustained tension.

The frequency of stimulation can influence the tension developed by each muscle fiber.

Whole-muscle tension depends not only on the number of muscle fibers contracting, but also on the tension developed by each contracting fiber. Various factors influence the extent to which tension can be developed, including the following:

1. Frequency of stimulation
2. Length of the fiber at the onset of contraction
3. Extent of fatigue
4. Thickness of the fiber

We now examine the effect of frequency of stimulation; we discuss the other factors in later sections.

Twitch Summation and Tetanus Even though a single action potential in a muscle fiber produces only a twitch, contractions with longer duration and greater tension can be achieved by repeated stimulation of the fiber. Let us see what

happens when a second action potential occurs in a muscle fiber. If the muscle fiber has completely relaxed before the next action potential takes place, a second twitch of the same magnitude as the first occurs (▌Figure 8-19a). The same excitation–contraction events take place each time, resulting in identical twitch responses. If, however, the muscle fiber is stimulated a second time before it has completely relaxed from the first twitch, a second action potential causes a second contractile response, which is added "piggyback" on top of the first twitch (▌Figure 8-19b). The two twitches from the two action potentials add together, or sum, to produce greater tension in the fiber than that produced by a single action potential, a process known as **twitch summation**.

Twitch summation is possible only because the duration of the action potential (1 to 2 msec) is much shorter than the duration of the resulting twitch (30 msec to 100 msec). Once an action potential has been initiated, a brief refractory period occurs during which another action potential cannot be initiated (see p. 98). It is therefore impossible to achieve summation of action potentials. The membrane must return to resting potential and recover from its refractory period before another action potential can occur. However, because the action potential and refractory period are over long before the resulting muscle twitch is completed, the muscle fiber may be restimulated while some contractile activity still exists to produce summation of the mechanical response.

If the muscle fiber is stimulated so rapidly that it does not have a chance to relax at all between stimuli, a smooth, sustained contraction of maximal strength known as **tetanus**

occurs (▌Figure 8-19c). A tetanic contraction is usually three to four times stronger than a single twitch. (Don't confuse this normal muscle tetanus with the disease tetanus; see p. 112.)

Twitch summation results primarily from a sustained elevation in cytosolic Ca²⁺.

What is the mechanism of twitch summation and tetanus at the cell level? The tension produced by a contracting muscle fiber increases as a result of greater cross-bridge cycling. The series-elastic component (tendon) must be stretched to transmit the tension generated in the muscle fibers to the bone, and it takes time to stretch this elastic element. Accordingly, two factors contribute to twitch summation: (1) sustained elevation in cytosolic Ca^{2+} permitting greater cross-bridge cycling, and (2) more time to stretch the series-elastic component.

The most important factor in the development of twitch summation is sustained elevation in cytosolic Ca^{2+} as the frequency of action potentials increases. Enough Ca^{2+} is released in response to a single action potential to interact with all the troponin within the cell. As a result, all cross bridges are free to participate in the contractile response. How, then, can repetitive action potentials bring about a greater contractile response? The difference depends on how long enough Ca^{2+} is available. The cross bridges remain active and continue to cycle as long as enough Ca^{2+} is present to keep the troponin–tropomyosin complexes away from the cross-bridge binding sites on actin. Each troponin–tropomyosin complex spans a distance of seven actin molecules. Thus, binding of Ca^{2+} to one troponin mole-
▌Figure 8-19 **Twitch summation and tetanus.**

FIGURE FOCUS: *Compare the relative tension developed in a single twitch and during tetanus. What accounts for this difference in tension?*

cule leads to the uncovering of only seven cross-bridge binding sites on the thin filament.

As soon as Ca^{2+} is released in response to an action potential, the SERCA pump starts pumping Ca^{2+} back into the lateral sacs. As the cytosolic Ca^{2+} concentration subsequently declines, less Ca^{2+} is present to bind with troponin, so some of the troponin–tropomyosin complexes slip back into their blocking positions. Consequently, not all cross-bridge binding sites remain available to participate in the cycling process during a single twitch induced by a single action potential. Because not all cross bridges find a binding site, the resulting contraction during a single twitch is not of maximal strength.

If action potentials and twitches occur far enough apart in time for all released Ca^{2+} from the first contractile response to be pumped back into the lateral sacs between the action potentials, an identical twitch response occurs as a result of the second action potential. If, however, a second action potential occurs and more Ca^{2+} is released while the Ca^{2+} that was released in response to the first action potential is being taken back up, the cytosolic Ca^{2+} concentration remains high and might even be elevated further. This prolonged availability of Ca^{2+} in the cytosol permits more of the cross bridges to continue participating in the cycling process for a longer time. As a result, tension development increases correspondingly. As the frequency of action potentials increases, the duration of elevated cytosolic Ca^{2+} concentration increases, and contractile activity likewise increases until a maximum tetanic contraction is reached. With tetanus, the maximum number of cross-bridge binding sites remains uncovered so that cross-bridge cycling, and consequently tension development, is at its peak.

The second factor contributing to twitch summation is related to the elastic structures of the muscle fiber. During a single twitch, the contraction does not last long enough to completely stretch the series-elastic component and allow the full sarcomere-generated tension to be transmitted to the bone. At the end of the twitch, the elastic elements slowly relax, or recoil, to their initial nonstretched state. If another twitch occurs before the elastic elements have completely relaxed, the tension from the second twitch adds to the residual tension in the series-elastic component remaining from the first twitch. With greater frequencies of action potentials and more frequent twitches, less time is available for the elastic elements to recoil between twitches. Consequently, as the frequency of action potentials increases, the tension in the series-elastic component transmitted to the bone progressively increases until it reaches its maximum during tetanus.

Because skeletal muscle must be stimulated by motor neurons to contract, the nervous system plays a key role in regulating contraction strength. The two main factors subject to control to accomplish gradation of contraction are the *number of motor units stimulated* and the *frequency of their stimulation*. The areas of the brain that direct motor activity combine tetanic contractions and precisely timed shifts of asynchronous motor unit recruitment to execute smooth rather than jerky contractions.

Additional factors not directly under nervous control also influence the tension developed during contraction. Among these is the length of the fiber at the onset of contraction, to which we now turn attention.

At the optimal muscle length, maximal tension can be developed.

A relationship exists between the length of the muscle before the onset of contraction and the tetanic tension that each contracting fiber can subsequently develop at that length. Every muscle has an **optimal length (l_o)** at which maximal force can be achieved during a tetanic contraction beginning at that length—that is, more tension can be achieved during tetanus when beginning at l_o than can be achieved when the contraction begins with the muscle longer or shorter than l_o. This **length–tension relationship** can be explained by the sliding filament mechanism of muscle contraction.

Contractile Activity at l_o At l_o, when maximum tension can be developed (point A in ❙Figure 8-20), the thin filaments optimally overlap the regions of the thick filaments where the cross bridges are located. At this length, a maximal number of cross bridges and actin molecules are accessible to each other for cycles of binding and bending. The central region of thick filaments, where the thin filaments do not overlap at l_o, lacks cross bridges; only myosin tails are found here.

Contractile Activity at Lengths Greater Than l_o At greater lengths, as when a muscle is passively stretched (point B), the thin filaments are pulled out from between the thick filaments, decreasing the number of actin sites available for cross-bridge binding—that is, some of the actin sites and cross bridges no longer "match up," so they "go unused." When less cross-bridge activity can occur, less tension can develop. In fact, when the muscle is stretched to about 70% longer than its l_o (point C) the thin filaments are completely pulled out from between the thick filaments, preventing cross-bridge activity; consequently, no contraction can occur.

Contractile Activity at Lengths Less Than l_o If a muscle is shorter than l_o before contraction (point D), less tension can be developed for three reasons:

1. The thin filaments from the opposite sides of the sarcomere overlap, which limits the opportunity for the cross bridges to interact with actin.
2. The ends of the thick filaments become forced against the Z lines, so further shortening is impeded.
3. Besides these two mechanical factors, at muscle lengths less than 80% of l_o, not as much Ca^{2+} is released during excitation–contraction coupling for reasons unknown. Furthermore, by an unknown mechanism, the ability of Ca^{2+} to bind to troponin and pull the troponin–tropomyosin complex aside is reduced at shorter muscle lengths. Consequently, fewer actin sites are uncovered for participation in cross-bridge activity.

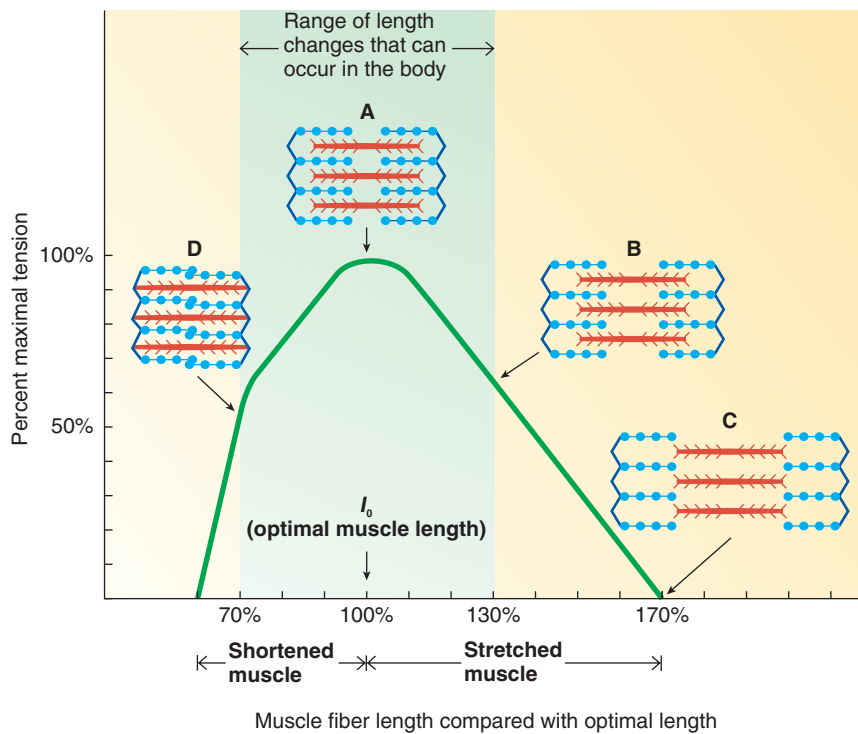
Limitations on Muscle Length The extremes in muscle length that prevent development of tension occur only under experimental conditions, when a muscle is removed and stimulated at various lengths. Attachment of muscles to the skeleton imposes limits on muscle shortening and lengthening. Muscles


Figure 8-20 Length–tension relationship. Maximal contraction strength can be achieved when a muscle fiber is at its optimal length (l_o) before the onset of contraction because this is the point of optimal overlap of thick-filament cross bridges and thin-filament cross-bridge binding sites (point A). The percentage of maximal contraction strength that can be achieved decreases when the muscle fiber is longer or shorter than l_o before contraction. When it is longer, fewer thin-filament binding sites are accessible for binding with thick-filament cross bridges because the thin filaments are pulled out from between the thick filaments (points B and C). When the fiber is shorter, fewer thin-filament binding sites are exposed to thick-filament cross bridges because the thin filaments overlap (point D). Also, further shortening and tension development are impeded as the thick filaments become forced against the Z lines (point D). In the body, the resting muscle length (that is, when the muscle is not actively contracting or passively positioned) is near l_o. Furthermore, because of restrictions imposed by skeletal attachments, muscles cannot vary beyond 30% of their l_o in either direction (the range screened in light green). At the outer limits of this range, muscles still can achieve about 50% of their maximal contraction strength.

FIGURE FOCUS: *What percentage of maximal tension can a muscle generate if it is positioned at 80% of its optimal length at the onset of contraction?*

are positioned so that their relaxed length (the length when the muscle is not actively contracting or passively positioned) is approximately at l_o; thus, they can achieve near maximal tetanic contraction most of the time. (The sarcomeres are between 2.0 and 2.2 μm wide at l_o, and the relaxed width of a sarcomere averages about 2.0 μm.) Furthermore, because of skeletal constraints, muscles cannot be stretched or shortened more than 30% of their optimal length. Even at the outer limits (130% and 70% of l_o), the muscles still can generate half their maximum tension.

The factors covered thus far that influence how much tension a contracting muscle fiber can develop—the frequency of stimulation and the muscle length at onset of contraction—can vary from contraction to contraction. Other determinants of muscle fiber tension—how resistant the muscle fiber is to fatigue and how thick the fiber is—do not vary from contraction to contraction but depend on the fiber type and can be modified over time. We consider these other factors next.

1. Explain how muscle tension is transmitted to bone.
2. Compare how the contraction force needed to support a 5-kg load and the velocity of moving the hand would be affected if the tendon of insertion of the biceps muscle were 10 cm instead of 5 cm from the elbow (fulcrum) in Figure 8-17.
3. Describe the means by which the strength of contraction of a skeletal muscle can be changed to generate greater force.
4. Describe the role of Ca^{2+} in twitch summation.

8.4 Skeletal Muscle Metabolism and Fiber Types

Four steps in the excitation, contraction, and relaxation processes require ATP:

1. Splitting of ATP by myosin ATPase provides the energy for the power stroke of the cross bridge.
2. Binding (but not splitting) of a fresh molecule of ATP to myosin lets the cross bridge detach from the actin filament at the end of a power stroke so that the cycle can be repeated. This ATP is later split to provide energy for the next stroke of the cross bridge.
3. Active transport of Ca^{2+} back into the lateral sacs of the SR during relaxation depends on energy derived from the breakdown of ATP.
4. The ATP-dependent Na^+–K^+ pump actively returns the ions (Na^+ back out of the cell and K^+ back into the cell) that moved during the generation of a contraction-inducing action potential in the muscle cell.

Muscle fibers have alternate pathways for forming ATP.

Because ATP is the only energy source that can be directly used for these activities, for contractile activity to continue, ATP must constantly be supplied. Only limited stores of ATP are immediately available in muscle tissue, enough to power the first few seconds of exercise. However, three pathways supply additional ATP as needed during muscle contraction: (1) transfer of a high-energy phosphate from creatine phosphate to ADP, (2) oxidative phosphorylation (the electron transport system and chemiosmosis), and (3) glycolysis.

Creatine Phosphate **Creatine phosphate** is the first energy storehouse tapped at the onset of contractile activity (Figure 8-21, step **3a**). Like ATP, creatine phosphate contains a high-

1 During **muscle contraction,** ATP is split by myosin ATPase to power cross-bridge stroking. Also, a fresh ATP must bind to myosin to let the cross bridge detach from actin at the end of a power stroke before another cycle can begin.

2 During **relaxation,** ATP is needed to run the Ca^{2+} pump that transports Ca^{2+} back into the lateral sacs of the sarcoplasmic reticulum. ATP is also used by the Na^+–K^+ pump to return Na^+ and K^+ moved during contraction-inducing action potentials.

3 The **metabolic pathways that supply the ATP** needed to accomplish contraction and relaxation are

3a transfer of a high-energy phosphate from **creatine phosphate** to ADP (immediate source);

3b **oxidative phosphorylation** (the main source when O_2 is present), fueled by glucose derived from muscle glycogen stores or by glucose and fatty acids delivered by the blood; and

3c **glycolysis** (the main source when O_2 is not present). Pyruvate, the end product of glycolysis, is converted to lactate when lack of O_2 prevents the pyruvate from being further processed by the oxidative phosphorylation pathway.

❙Figure 8-21 **Metabolic pathways producing ATP used during muscle contraction and relaxation.**

energy phosphate group, which can be donated directly to ADP to form ATP. Just as energy is released when the terminal phosphate bond in ATP is split, energy is released when the bond between phosphate and creatine is broken. The energy released from the hydrolysis of creatine phosphate, along with the phosphate, can be donated directly to ADP to form ATP. This reaction, which is catalyzed by the muscle cell enzyme **creatine kinase**, is reversible; energy and phosphate from ATP can be transferred to creatine to form creatine phosphate:

$$\text{Creatine phosphate} + \text{ADP} \overset{\text{creatine kinase}}{\rightleftharpoons} \text{creatine} + \text{ATP}$$

As energy reserves are built up in a resting muscle, the increased concentration of ATP favors transfer of the high-energy phosphate group from ATP to form creatine phosphate. By contrast, at the onset of contraction when myosin ATPase splits the meager reserves of ATP, the resultant fall in ATP favors transfer of the high-energy phosphate group from stored creatine phosphate to form more ATP. A rested muscle contains about five times as much creatine phosphate as ATP. Thus, most energy is stored in muscle in creatine phosphate pools. Because only one enzymatic reaction is involved in this energy transfer, ATP can be formed rapidly (within a fraction of a second) by using creatine phosphate.

Thus, creatine phosphate is the first source for supplying additional ATP when exercise begins. Muscle ATP levels actually remain fairly constant early in contraction, but creatine phosphate stores become depleted. In fact, short bursts of high-intensity contractile effort, such as high jumps, sprints, or weight lifting, are supported primarily by ATP derived at the expense of creatine phosphate. Creatine phosphate stores typically power 5 to 10 seconds of exercise before the stores run out.

Some athletes hoping to gain a competitive edge take oral creatine supplements to boost their performance in short-term, high-intensity activities. (We naturally get creatine in our diets, especially in meat.) Loading the muscles with extra creatine means larger creatine phosphate stores—that is, larger energy stores that can translate into a small edge in performance of activities requiring short, explosive bursts of energy. Yet creatine supplements should be used with caution because the long-term health effects are unknown. Also, extra creatine stores are of no use in activities of longer duration that rely on more long-term energy-supplying mechanisms.

Oxidative Phosphorylation The multistep oxidative phosphorylation pathway produces ATP at a relatively slow rate when compared to the transfer of a high-energy phosphate from creatine phosphate to ADP or the process of glycolysis. Oxidative phosphorylation takes place within the muscle mitochondria if sufficient O_2 is present (see p. 37). Oxygen is required to support the mitochondrial electron transport system, which, together with chemiosmosis by ATP synthase, efficiently harnesses energy captured from the breakdown of nutrient molecules and uses it to generate ATP. This pathway is fueled by glucose or fatty acids, depending on the intensity and duration of the activity (❚ Figure 8-21, step 3b). Although it provides a rich yield of 32 ATP molecules for each glucose molecule processed, oxidative phosphorylation is relatively slow because of the number of enzymatic steps involved.

During light exercise (such as walking) to moderate exercise (such as jogging or swimming), muscle cells can form enough ATP through oxidative phosphorylation to keep pace with the modest energy demands of the contractile machinery for prolonged periods. To sustain ongoing oxidative phosphorylation, exercising muscles depend on delivery of adequate O_2 and nutrients to maintain their activity. Activity supported in this way is **aerobic** ("with O_2") or **endurance-type exercise**.

Most O_2 required for oxidative phosphorylation is delivered by the blood. Increased O_2 is made available to muscles during exercise by several means: Deeper, more rapid breathing brings more O_2 into the blood; the heart contracts more rapidly and forcefully to pump more oxygenated blood to the tissues; more blood is diverted to exercising muscles by dilation of the blood vessels supplying them; and hemoglobin molecules that carry O_2 in the blood release more O_2 in exercising muscles. (These mechanisms are discussed further in later chapters.) Furthermore, some types of muscle fibers have an abundance of **myoglobin**, which is similar to hemoglobin. Myoglobin can store small amounts of O_2, but more important, it increases the rate of O_2 transfer from the blood into muscle fibers.

Glucose and fatty acids, ultimately derived from food eaten, are also delivered to muscle cells by the blood. In addition, muscle cells are able to store limited quantities of glucose in the form of glycogen (chains of glucose). Furthermore, up to a point the liver can store excess ingested carbohydrates as glycogen, which can be broken down to release glucose into the blood for use between meals. *Carbohydrate loading*—increasing carbohydrate intake before a competition—is a tactic used by some athletes in hopes of boosting performance in endurance events such as marathons. However, once muscle and liver glycogen stores are filled, excess ingested carbohydrates (or any other energy-rich nutrient) are converted to body fat.

Glycolysis There are limits as to how much O_2 the lungs can pick up and the circulatory system can deliver to exercising muscles. Furthermore, in near-maximal contractions, the powerful contraction almost squeezes closed the blood vessels that course through the muscle, severely limiting O_2 availability to the muscle fibers. Even when O_2 is available, the relatively slow oxidative phosphorylation system may not be able to produce ATP rapidly enough to meet the muscle's needs during intense activity. A skeletal muscle's energy consumption may increase up to 100-fold when going from rest to high-intensity exercise. When O_2 delivery or oxidative phosphorylation cannot keep pace with the demand for ATP formation as the intensity of exercise increases, the muscle fibers rely increasingly on glycolysis to generate ATP (❚ Figure 8-21, step 3c) (see p. 35). The chemical reactions of glycolysis yield products for ultimate entry into the oxidative phosphorylation pathway, but glycolysis can also proceed alone in the absence of further processing of its products by oxidative phosphorylation. During glycolysis, a glucose molecule is broken down into two pyruvate molecules, yielding two ATP molecules in the process. Pyruvate can be further degraded by oxidative phosphorylation to extract more energy. However, glycolysis alone has two advantages over the oxidative phosphorylation pathway: (1) glycolysis can form ATP in the absence of O_2 (operating *anaerobically*—that is,

"without O_2"), and (2) it can proceed more rapidly than oxidative phosphorylation. Although glycolysis extracts considerably fewer ATP molecules from each nutrient molecule processed, because of its speed its rate of ATP production can exceed the rate of generation of ATP by oxidative phosphorylation as long as glucose is present. Activity that can be supported in this way is anaerobic or **high-intensity exercise**.

Lactate Production Even though anaerobic glycolysis provides a means of performing intense exercise when O_2 delivery or the oxidative phosphorylation capacity is exceeded, using this pathway has two consequences. First, large amounts of nutrient fuel must be processed because glycolysis is less efficient than oxidative phosphorylation in converting nutrient energy into the energy of ATP. (Glycolysis yields a net of 2 ATPs for each glucose molecule degraded, whereas the oxidative phosphorylation pathway can extract 32 ATPs from each glucose molecule.) Muscle cells can store limited quantities of glucose as glycogen, but anaerobic glycolysis rapidly depletes these glycogen supplies. Therefore, anaerobic high-intensity exercise can be sustained for only a short duration, in contrast to the body's prolonged ability to sustain aerobic, endurance-type activities. Anaerobic glycolysis can support muscle contractile activity for less than 2 minutes.

Second, when the end product of anaerobic glycolysis, pyruvate, cannot be further processed by oxidative phosphorylation, it is converted to **lactate**. Lactate accumulation has been implicated in the acute muscle soreness (burning sensation) that occurs when intense exercise is actually taking place. (The delayed-onset muscle pain and stiffness that begin the day after unaccustomed muscular exertion, however, are caused by reversible structural damage.) Furthermore, lactate (lactic acid) picked up by the blood produces the metabolic acidosis accompanying intense exercise.

Fatigue may be of muscle or central origin.

Contractile activity in a particular skeletal muscle cannot be maintained at a high level indefinitely. Eventually, the tension in the muscle declines as fatigue sets in. There are two types of fatigue: muscle fatigue and central fatigue.

Muscle fatigue occurs when an exercising muscle can no longer respond to stimulation with the same degree of contractile activity. Muscle fatigue is a defense mechanism that protects a muscle from reaching a point at which it can no longer produce ATP. An inability to produce ATP would result in rigor mortis (obviously not an acceptable outcome of exercise). The underlying causes of muscle fatigue are unclear. The primary implicated factors include the following:

■ The *local increase in inorganic phosphate* from ATP breakdown is considered the primary cause of muscle fatigue. Increased levels of P_i reduce the strength of contraction by interfering with the power stroke of the myosin heads. In addition, increased P_i appears to decrease the sensitivity of the regulatory proteins to Ca^{2+} and to decrease the amount of Ca^{2+} released from the lateral sacs.

■ *Inappropriate leakage of Ca^{2+}* through the SR's Ca^{2+}-release channels is the latest factor implicated in muscle fatigue after long and intense exercise. Some of the leaked Ca^{2+} exits the cell and cannot be returned to the SR by the SERCA pump. This Ca^{2+} loss from the cell depletes the SR Ca^{2+} supply needed to sustain contractile activity, leading to weaker contractions. Furthermore, exposure to leaked Ca^{2+} during fatiguing exercise activates proteases, protein-snipping enzymes that cause transient muscle damage, which likely contributes to weakening of contractions.

■ *Depletion of glycogen energy reserves* may also lead to muscle fatigue in exhausting exercise.

The time of onset of muscle fatigue varies with the type of muscle fiber (some fibers being more resistant to fatigue than others) and with the intensity of the exercise (more rapid onset of fatigue being associated with high-intensity activities).

Central fatigue occurs when the central nervous system (CNS) no longer adequately activates the motor neurons supplying the working muscles. The person slows down or stops exercising even though the muscles are still able to perform. Central fatigue often is psychologically based. During strenuous exercise, central fatigue may stem from discomfort associated with the activity; it takes strong motivation (a will to win) to deliberately persevere when in pain. In less strenuous activities, central fatigue may reduce physical performance in association with boredom and monotony (such as assembly-line work) or tiredness (lack of sleep). The mechanisms involved in central fatigue are poorly understood. In some cases, central fatigue may stem from increased levels of serotonin (a neurotransmitter) and tryptophan (an amino acid from which serotonin is made) within the brain.

Increased O_2 consumption is necessary to recover from exercise.

A person continues to breathe deeply and rapidly for some time after exercising. The need for elevated O_2 uptake during recovery from exercise (**excess postexercise oxygen consumption,** or **EPOC**) results from various factors. The best known is repayment of an **oxygen deficit** incurred during exercise, when contractile activity was being supported by ATP derived from nonoxidative sources such as creatine phosphate and anaerobic glycolysis. During exercise, the creatine phosphate stores of active muscles are reduced, lactate may accumulate, and glycogen stores may be tapped; the extent of these effects depends on the intensity and duration of the activity. Oxygen is needed for recovery of the energy systems. During the recovery period, fresh supplies of ATP are formed by oxidative phosphorylation using the newly acquired O_2, which is provided by the sustained increase in breathing after exercise has stopped. Most of this ATP is used to resynthesize creatine phosphate to restore its reserves, which can be accomplished in a few minutes. Any accumulated lactate is converted back into pyruvate, part of which is used by the oxidative phosphorylation system for ATP production. The remainder of the pyruvate is converted back into glucose by the liver. Most of this glucose is used to replenish the glycogen stores drained from the muscles and liver during exercise. These biochemical reactions involving

pyruvate require O_2 and take several hours for completion. Thus, EPOC provides the O_2 needed to restore the creatine phosphate system, remove lactate, and at least partially replenish glycogen stores.

Unrelated to increased O_2 uptake is the need to restore nutrients after grueling exercise, such as marathon races, in which glycogen stores are severely depleted. In such cases, long-term recovery can take a day or more, because the exhausted energy stores require nutrient intake for full replenishment. Therefore, depending on the type and duration of activity, recovery can be complete within a few minutes or can require more than a day.

Part of EPOC is not directly related to repayment of energy stores but instead results from a general metabolic disturbance following exercise. For example, the local increase in muscle temperature arising from heat-generating contractile activity speeds up the rate of all chemical reactions in the muscle tissue, including those dependent on O_2. Likewise, body temperature rises several degrees Fahrenheit during exercise. A rise in temperature speeds up O_2-consuming chemical reactions. Until body temperature returns to preexercise levels, the increased speed of these chemical reactions partly accounts for EPOC. Furthermore, the secretion of epinephrine, a hormone that increases O_2 consumption by the body, is elevated during exercise. Until the circulating level of epinephrine returns to its preexercise state, O_2 uptake is increased above normal.

We have been looking at the contractile and metabolic activities of skeletal muscle fibers in general. However, not all skeletal muscle fibers use these mechanisms to the same extent. We next examine the types of muscle fibers based on their speed of contraction and how they are metabolically equipped to generate ATP.

The three types of skeletal muscle fibers differ in ATP hydrolysis and synthesis.

Classified by their biochemical capacities, there are three major types of muscle fibers (▮Table 8-1):

1. Slow-oxidative (type I) fibers
2. Fast-oxidative (type IIa) fibers
3. Fast-glycolytic (type IIx) fibers

As their names imply, the two main differences among these fiber types are their speed of contraction (slow or fast) and the type of enzymatic machinery they primarily use for ATP formation (oxidative or glycolytic).

Fast Versus Slow Fibers Fast fibers have higher myosin ATPase (ATP-splitting) activity than slow fibers do. The higher the ATPase activity, the more rapidly ATP is split and the faster the rate at which energy is made available for cross-bridge cycling. The result is a fast twitch,

compared to the slower twitches of those fibers that split ATP more slowly. The time to peak twitch tension for fast fibers is 15 to 40 msec compared to 50 to 100 msec for slow fibers (▮Figure 8-22a). Thus, two factors determine the speed with which a muscle contracts: the load (load–velocity relationship) and the myosin ATPase activity of the contracting fibers (fast or slow twitch).

Oxidative Versus Glycolytic Fibers Fiber types also differ in ATP-synthesizing ability. Those with a greater capacity to form ATP are more resistant to fatigue. Some fibers are better equipped for oxidative phosphorylation, whereas others rely primarily on anaerobic glycolysis for synthesizing ATP. Because oxidative phosphorylation yields considerably more ATP from each nutrient molecule processed, it does not readily deplete energy stores. Furthermore, it does not result in lactate accumulation. Oxidative types of muscle fibers are therefore more resistant to fatigue than glycolytic fibers are.

Other related characteristics distinguishing these three fiber types are summarized in ▮Table 8-1. As you would expect, the oxidative fibers, both slow and fast, contain an abundance of mitochondria, the organelles that house the enzymes involved in oxidative phosphorylation. Because adequate oxygenation is essential to support this pathway, these fibers are richly supplied with capillaries. Oxidative fibers also have high myoglobin content. Myoglobin not only helps support oxidative fibers' O_2 dependency, but also gives them a red color, just as oxygenated hemoglobin produces the red color of arterial blood. Accordingly, these muscle fibers are called **red fibers**.

In contrast, the fast fibers specialized for glycolysis contain few mitochondria but have a high content of glycolytic enzymes instead. Also, to supply the large amounts of glucose needed for glycolysis, they contain a lot of stored glycogen. Because the glycolytic fibers need relatively less O_2 to function, they have

▮TABLE 8-1 Characteristics of Skeletal Muscle Fibers

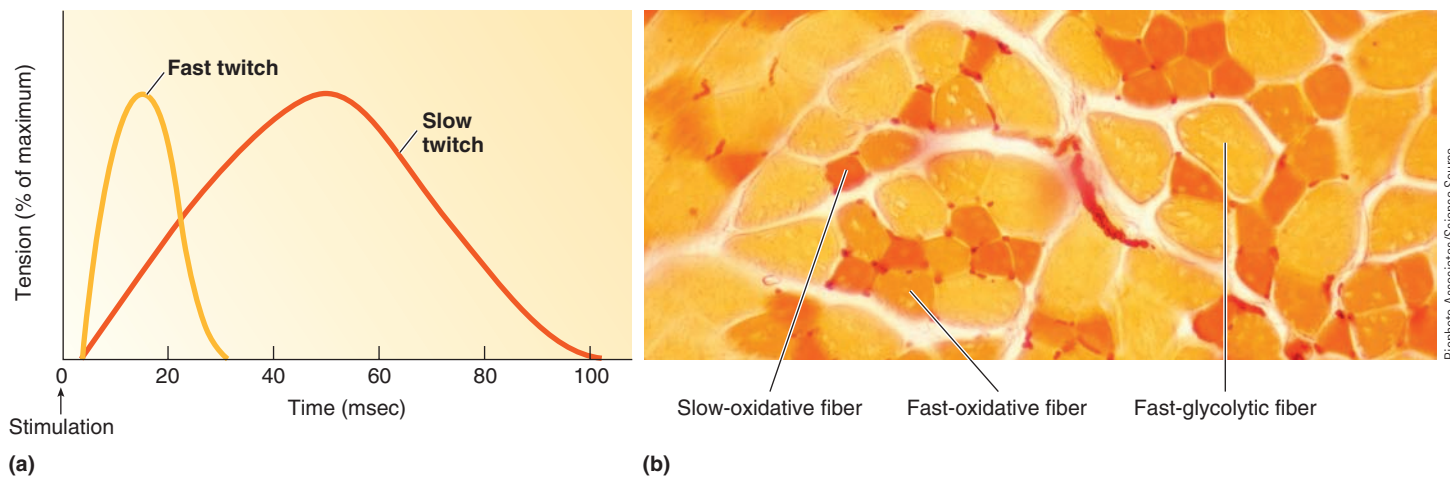
Characteristic	Slow-Oxidative (Type I) Fiber	Fast-Oxidative (Type IIa) Fiber	Fast-Glycolytic (Type IIx) Fiber
Myosin–ATPase activity	Low	High	High
Speed of contraction	Slow	Fast	Fast
Resistance to fatigue	High	Intermediate	Low
Oxidative phosphorylation capacity	High	High	Low
Enzymes for anaerobic glycolysis	Low	Intermediate	High
Mitochondria	Many	Many	Few
Capillaries	Many	Many	Few
Myoglobin content	High	High	Low
Color of fiber	Red	Red	White
Glycogen content	Low	Intermediate	High


Figure 8-22 Muscle fiber types. (a) Comparison of the speed of contraction of fast and slow muscle fiber types. (b) Cross section of a human muscle showing the distribution of slow-oxidative, fast-oxidative, and fast-glycolytic muscle fiber types.

only a meager capillary supply compared with the oxidative fibers. The glycolytic fibers contain little myoglobin and therefore are pale in color, so they are sometimes called **white fibers**. (The most readily observable comparison between red and white fibers is the dark and white meat in poultry; muscles of the legs consist primarily of red fibers and the breast muscles consist primarily of white fibers.)

Genetic Endowment of Muscle Fiber Types In humans, most muscles contain a mixture of all three fiber types (**I** Figure 8-22b); the percentage of each type is largely determined by the type of activity for which the muscle is specialized. Accordingly, a high proportion of slow-oxidative fibers are found in muscles specialized for maintaining low-intensity contractions for long periods without fatigue, such as the muscles of the back and legs that support the body's weight against the force of gravity. A preponderance of fast-glycolytic fibers are found in the arm muscles, which are adapted for performing rapid, forceful movements such as lifting heavy objects.

The percentage of these various fibers not only differs among muscles within an individual but also varies considerably among individuals. Athletes genetically endowed with a higher percentage of the fast-glycolytic fibers are good candidates for power and sprint events, whereas those with a greater proportion of slow-oxidative fibers are more likely to succeed in endurance activities such as marathon races.

Of course, success in any event depends on many factors other than genetic endowment, such as the extent and type of training and the level of dedication. Indeed, the mechanical and metabolic capabilities of muscle fibers can change a lot in response to the patterns of demands placed on them. Let us see how.

Muscle fibers adapt considerably in response to the demands placed on them.

Different types of exercise produce different patterns of neuronal discharge to the muscle involved. Depending on the pattern of neural activity, long-term adaptive changes occur in the muscle fibers, enabling them to respond most efficiently to the types of demands placed on the muscle. Two types of changes can be induced in muscle fibers: changes in their oxidative capacity and changes in their diameter.

Improvement in Oxidative Capacity Regular aerobic endurance exercise, such as long-distance jogging or swimming, promotes metabolic changes within the oxidative fibers, which are the ones primarily recruited during aerobic exercise. For example, the number of mitochondria and the number of capillaries supplying blood to these fibers both increase. Muscles so adapted can use O_2 more efficiently and therefore can better endure prolonged activity without fatiguing. However, they do not change in size.

Muscle Hypertrophy The actual size of the muscles can be increased by regular bouts of anaerobic, short-duration, high-intensity resistance training, such as weight lifting. The resulting muscle enlargement comes primarily from an increase in diameter (**hypertrophy**) of the fast-glycolytic fibers called into play during such powerful contractions. Most fiber thickening results from increased synthesis of myosin and actin filaments, which permits a greater opportunity for cross-bridge interaction and consequently increases the muscle's contractile strength. The mechanical stress that resistance training exerts on a muscle fiber triggers signaling proteins, which turn on genes that direct the synthesis of more myosin and actin. Vigorous weight training can double or triple a muscle's size. The resultant bulging muscles are better adapted to activities that require intense strength for brief periods, but endurance has not been improved.

Influence of Testosterone Men's muscle fibers are thicker, and accordingly, their muscles are larger and stronger than those of women, even without weight training, because of the actions of testosterone, a steroid hormone secreted primarily in males. Testosterone promotes the synthesis and assembly of myosin and actin. This fact has led some athletes, both males

and females, to the dangerous practice of taking this or closely related steroids to increase their athletic performance. (To explore this topic further, see the boxed feature (on pp. 276–277, |A Closer Look at Exercise Physiology.)

Interconversion Between Fast Muscle Types All the muscle fibers within a single motor unit are of the same fiber type. This pattern usually is established early in life, but the two types of fast-twitch fibers are interconvertible, depending on training efforts—that is, fast-glycolytic fibers can be converted to fast-oxidative fibers, and vice versa, depending on the types of demands repetitively placed on them. Adaptive changes in skeletal muscle gradually reverse to their original state over a period of months if the regular exercise program that induced these changes is discontinued.

Slow and fast fibers are not interconvertible, however. Although training can induce changes in muscle fibers' metabolic support systems, whether a fiber is fast or slow twitch depends on the fiber's nerve supply. Slow-twitch fibers are supplied by motor neurons that exhibit a low-frequency pattern of electrical activity, whereas fast-twitch fibers are innervated by motor neurons that display intermittent rapid bursts of electrical activity. Experimental switching of motor neurons supplying slow muscle fibers with those supplying fast fibers gradually reverses the speed at which these fibers contract.

Muscle Atrophy At the other extreme, if a muscle is not used, its actin and myosin content decreases, its fibers become smaller, and the muscle accordingly **atrophies** (decreases in mass) and becomes weaker. Muscle atrophy can take place in three ways. (1) **Disuse atrophy** occurs when a muscle is not used for a long period even though the nerve supply is intact, as when a cast or brace must be worn or during prolonged bed confinement. (2) **Denervation atrophy** occurs after the nerve supply to a muscle is lost. If the muscle is stimulated electrically until innervation can be reestablished, such as during regeneration of a severed peripheral nerve, atrophy can be diminished but not entirely prevented. Contractile activity itself obviously plays an important role in preventing atrophy; however, poorly understood factors released from active nerve endings, perhaps packaged with the ACh vesicles, apparently contribute to the integrity and growth of muscle tissue. (3) **Age-related atrophy**, or **sarcopenia**, occurs naturally with aging. Beginning at approximately 40 years of age, people progressively lose motor neurons, particularly those that innervate the fast-glycolytic fiber types. As a result, a gradual loss of muscle mass, strength, and speed of muscle contraction occurs in aging individuals. Reduced rates of protein synthesis and lowered hormone levels (growth hormone, testosterone, and insulin-like growth factor-I) contribute to this loss of muscle mass. On average, most people lose about a quarter of a pound of muscle per year starting in their 40s. Although age-related muscle atrophy is inevitable, resistance training exercise and proper diet can slow the rate of development of sarcopenia.

Limited Repair of Muscle When a muscle is damaged, limited repair is possible, even though muscle cells cannot divide mitotically to replace lost cells. A small population of inactive muscle-specific stem cells called **satellite cells** are located close to the muscle surface (see p. 10). When a muscle fiber is damaged, locally released factors activate the satellite cells, which divide to give rise to myoblasts, the same undifferentiated cells that formed the muscle during embryonic development. A group of myoblasts fuse to form a large, multinucleated cell, which immediately begins to synthesize and assemble the intracellular machinery characteristic of the muscle, ultimately differentiating completely into a mature muscle fiber. With extensive injury, this limited mechanism is not adequate to completely replace all the lost fibers. In that case, the remaining fibers often hypertrophy to compensate.

Transplantation of satellite cells or myoblasts provides one of several glimmers of hope for victims of **muscular dystrophy**, a hereditary pathological condition characterized by progressive degeneration of contractile elements, which are ultimately replaced by fibrous tissue. (See the boxed feature on pp. 278–279, |Concepts, Challenges, and Controversies, for further information on this devastating condition.)

We have now completed our discussion of all the determinants of whole-muscle tension in a skeletal muscle, which are summarized in |Table 8-2. Next, we examine the central and local mechanisms involved in regulating the motor activity performed by these muscles.

Check Your Understanding 8.4

1. State four functions related to muscle excitation, contraction, and relaxation that require ATP.

2. Describe the differences between muscle fibers in a turkey drumstick (slow-oxidative) and muscles fibers in turkey breast meat (fast-glycolytic).

3. Discuss the relative contributions of creatine phosphate, glycolysis, and oxidative phosphorylation to the production of ATP during running of a marathon.

|TABLE 8-2 Determinants of Whole-Muscle Tension in Skeletal Muscle

Number of Fibers Contracting

Number of motor units recruited*

Number of muscle fibers per motor unit

Number of muscle fibers available to contract (size of muscle)

Tension Developed by Each Contracting Fiber

Frequency of stimulation (twitch summation and tetanus)*

Length of fiber at onset of contraction (length–tension relationship)

Extent of fatigue

Type of fiber (fatigue-resistant oxidative or fatigue-prone glycolytic)

Thickness of fiber (strength training and testosterone)

*Factors controlled to accomplish gradation of contraction.

Are Athletes Who Use Steroids to Gain Competitive Advantage Really Winners or Losers?

ATHLETES INVOLVED IN ELITE SPORTS or competitions such as the Olympics are tested for use of performance-enhancing drugs and those found to be using substances outlawed by sports federations are banned from participating or lose awards earned in the event. One such group of drugs is **anabolic androgenic steroids** (*anabolic* means "buildup of tissues," *androgenic* means "male producing," and *steroids* are a class of hormone). These agents are closely related to testosterone, the natural male sex hormone, which is responsible for promoting the increased muscle mass characteristic of males.

Although their use is outlawed (possessing anabolic steroids without a prescription became a federal offense in 1991), these agents are taken by many athletes who specialize in power events such as weight lifting and sprinting in the hopes of increasing muscle mass and, accordingly, muscle strength. Both male and female athletes have resorted to using these substances in an attempt to gain a competitive edge. Bodybuilders also take anabolic steroids. Furthermore, these performance enhancers are widely used in professional sports. There are an estimated 1 million anabolic steroid abusers in the United States. Compounding the problem, underground chemists have created new synthetic performance-enhancing steroids undetectable by standard drug tests.

Studies have confirmed that steroids can increase muscle mass when used in large amounts and coupled with heavy exercise. The adverse effects of these drugs, however, outweigh any benefits derived.

Adverse Effects on the Reproductive System

In males, testosterone secretion and sperm production by the testes are normally controlled by hormones from the anterior pituitary gland. In negative-feedback fashion, testosterone inhibits secretion of these controlling hormones so that a constant level of testosterone is maintained. The anterior pituitary is similarly inhibited by androgenic steroids taken as a drug. Because the testes do not receive their normal stimulatory input from the anterior pituitary, testosterone secretion and sperm production decrease and the testes shrink. This hormone abuse also may set the stage for testicular and prostate cancer.

In females, who normally lack potent androgenic hormones, anabolic steroid drugs not only promote "male-type" muscle mass and strength but also "masculinize" the users in other ways, such as by inducing growth of facial hair and by deepening the voice. Furthermore, inhibition of the anterior pituitary by androgenic drugs suppresses the hormonal output that controls ovarian function. The result is failure to ovulate, menstrual irregularities, and decreased secretion of "feminizing" female sex hormones. Their decline diminishes breast size and other female characteristics.

Adverse Effects on the Cardiovascular System

Use of anabolic steroids induces cardiovascular changes that increase the risk of developing atherosclerosis, which in turn is associated with an increased incidence of heart attacks and strokes (see p. 327).

8.5 Control of Motor Movement

The nervous system controls motor movement by activating motor neurons, the final common pathway for motor processing (see p. 242). Each activated motor neuron triggers contraction of all of the skeletal muscle fibers within its motor unit.

Motor activity can be classified as reflex, voluntary, or rhythmic.

Particular patterns of motor unit output govern motor activity, which can be divided into three broad, overlapping classes: somatic reflex responses, voluntary movements, and rhythmic activities. These movements differ in their complexity and in the nervous system level at which they are integrated.

■ **Somatic reflex responses** are automatic responses brought about by skeletal muscle contraction that take place without

conscious effort (see p. 177). Somatic reflexes are the least complex type of purposeful motor movement. They include protective reflexes and postural reflexes. Examples of *protective reflexes* are withdrawing from a painful stimulus and coughing. *Postural reflexes* maintain the desired position of the head, trunk, and limbs and stabilize our balance against gravity and other external forces as we stand and move about. Examples of postural reflexes include the stretch reflex, which is the simplest reflex and involves involuntary contraction to counteract passive stretching of a muscle; and the more complicated vestibular reflexes, which bring the body and head in proper alignment when a person gets off balance. Postural reflexes are elicited in response to input from the following sources: (1) proprioceptors in the muscles and joints that provide information regarding the relative position and movement of the body and its different parts (see p. 187), (2) the vestibular apparatus in the inner ear, which detects changes in position and motion of the head (see p. 221), (3) touch receptors that monitor pressure on the skin from interaction with the environment (such as standing on

Adverse Effects on the Liver

Liver dysfunction is common with high steroid intake because the liver, which normally inactivates steroid hormones and prepares them for urinary excretion, is overloaded by the excess steroid intake. The incidence of liver cancer is also increased.

Adverse Effects on Behavior

Anabolic steroid use promotes aggressive, even hostile behavior—the so-called 'roid rages.

Addictive Effects

Another concern is addiction to anabolic steroids of some who abuse these drugs. This apparent tendency to become chemically dependent on steroids is alarming because the potential for adverse effects on health increases with long-term, heavy use—the kind of use that would be expected from someone hooked on the drug.

Thus, for health reasons, without even taking into account the legal and ethical issues, people should not use anabolic steroids. However, the problem appears to be worsening. Currently, the international black market for anabolic steroids is estimated at $1 billion per year.

Other Cheating Ways to Build Muscle Mass

Athletes seeking an artificial competitive edge have resorted to other illicit measures besides taking anabolic steroids, such as us-ing the hormone *erythropoietin,* see p. 385) to promote production of extra O_2-carrying red blood cells or using *human growth hormone* to spur muscle buildup. More worrisome, scientists predict the next illicit frontier will be gene doping. **Gene doping** refers to gene therapy aimed at improving athletic performance, such as by promoting production of naturally occurring muscle-building chemicals (for example, *insulin-like growth factor-I*); by blocking production of *myostatin,* a natural body chemical that puts the brakes on muscle growth; or by boosting endurance by tinkering with the nuclear receptor *PPAR-*δ, which regulates genes involved in energy use, insulin action, and muscle metabolism. Because these chemicals occur naturally in the body, detection of gene doping will be a challenge.

More than 100 drugs are currently banned by the World Anti-Doping Agency (WADA). Furthermore, to keep pace in the race between regulators and athlete dopers, WADA introduced guidelines in 2009 for the **athlete biological passport (ABP)**, which is based on blood tests administered multiple times per year that look for physiological consequences of doping rather than for abused substances themselves. Any suspicious change from the athlete's baseline pattern raises the alarm for further testing. The ABP is used in addition to traditional testing for specific drugs. WADA continues to expand the ABP by striving to identify new biological markers to indirectly detect more types of doping.

---

the ground), and (4) the eyes, which provide visual input about body position with relation to surroundings. Somatic reflexes may be integrated in the spinal cord (spinal reflexes, for example the withdrawal reflex) or at the brain stem level (cranial reflexes, for example vestibular reflexes). Most somatic reflexes can be modulated by conscious input from the cerebral cortex. To exemplify, a diver can learn to override neck-righting reflexes to execute a complicated dive involving abnormal postural movements (see p. 277).

■ **Voluntary movements** are the most complex type of motor activity. They are goal-directed movements initiated and terminated at will and are integrated by the cerebral cortex. Examples range from simple acts such as picking up a cup of coffee to highly skilled movements such as gymnastics or playing a musical instrument. Unconscious postural adjustments are integrated as necessary with all voluntary motor tasks. With repetitive practice, learned voluntary movements like gymnastic or dance routines become almost reflexlike: The learned actions get stored as procedural memory in the cerebellum and their execution can be brought forth by un-conscious brain levels without deliberate thought of each maneuver (see p. 162). "Muscle memory" is the term applied to having the body unconsciously reproduce a memorized voluntary motor routine.

■ **Rhythmic activities** are stereotypical movements repeated in a general pattern, like walking or chewing. The cerebral cortex consciously starts and stops rhythmic activities but the details of their execution are accomplished in reflexlike fashion by lower CNS levels without conscious effort. For example, networks of specific interconnected excitatory and inhibitory interneurons and their associated motor neurons in the spinal cord function as **central pattern generators**. Once activated, central pattern generators autonomously bring about rhythmic patterned outputs such as walking by commanding precisely timed alternate contraction and relaxation of multiple muscles of the legs in a cyclical, coordinated fashion to accomplish repetitive stepping movements. Output from these intrinsic oscillatory networks can be modulated by higher motor areas in the cortex, such as if you decide to pick up your walking speed or turn a corner.

Muscular Dystrophy: When One Small Step Is a Big Deal

HOPE OF TREATMENT IS ON the horizon for **muscular dystrophy (MD)**, a fatal muscle-wasting disease that primarily strikes boys and relentlessly leads to their death before age 30.

Symptoms

Muscular dystrophy encompasses more than 30 distinct hereditary pathological conditions, which have in common a progressive degeneration of contractile elements and their replacement by fibrous tissue. The gradual muscle wasting is characterized by progressive weakness over a period of years. Typically, a patient with MD begins to show symptoms of muscle weakness at about 2 to 3 years of age, becomes wheelchair bound when he is 10 to 12 years old, and dies within the next 15 or so years, either from respiratory failure when his respiratory muscles become too weak or from heart failure when his heart becomes too weak.

Cause

The disease is caused by a recessive genetic defect on the X sex chromosome, of which males have only one copy. (Males have XY sex chromosomes; females have XX sex chromosomes.) If a male inherits from his mother an X chromosome bearing the defective dystrophic gene, he is destined to develop the disease, which affects 1 out of every 3500 boys worldwide. To acquire the condition, females must inherit a dystrophic-carrying X gene from both parents, a much rarer occurrence.

The defective gene responsible for *Duchenne muscular dystrophy (DMD),* the most common and most devastating form of the disease, was pinpointed in 1986. The gene normally produces **dystrophin**, a large protein that provides structural stability to the muscle cell's plasma membrane. Dystrophin is part of a complex of membrane-associated proteins that form a mechanical link between actin, a major component of the muscle cell's internal cytoskeleton, and the extracellular matrix, an external support network. This mechanical reinforcement of the plasma membrane enables the muscle cell to withstand the stresses and strains encountered during repeated cycles of contraction and stretching.

Dystrophic muscles are characterized by a lack of dystrophin. Although this protein represents only 0.002% of the total amount of skeletal muscle protein, its presence is crucial in maintaining the integrity of the muscle cell membrane. The absence of dystrophin permits a constant leakage of Ca^{2+} into the muscle cells. This Ca^{2+} activates proteases that harm the muscle fibers. The resultant ongoing damage leads to the muscle wasting and ultimate fibrosis that characterize the disorder.

With the discovery of the dystrophin gene and its deficiency in DMD came the hope that scientists could somehow replenish this missing protein in the muscles of the disease's young victims. Although the disease is still considered untreatable and fatal, several lines of research are being pursued vigorously to intervene in the relentless muscle loss.

Gene-Therapy Approach

One approach is a possible "gene fix." With gene therapy, healthy genes are usually delivered to the defective cells by means of viruses. Viruses operate by invading a body cell and micromanaging the cell's genetic machinery. In this way, the virus directs the host cell to synthesize the proteins needed for viral replication. With gene therapy, the desired gene is inserted into an incapacitated virus that cannot cause disease but can still enter the target cell and take over genetic commands.

One of the big challenges for gene therapy for DMD is the enormous size of the dystrophin gene. This gene, being more than 3 million base pairs long, is the largest gene ever found. It does not fit inside the viruses usually used to deliver genes to cells—they only have enough space for a gene one thousandth the size of the dystrophin gene. Therefore, researchers have created a minigene that is one thousandth of the size of the dystrophin gene but still contains the essential components for directing the synthesis of dystrophin. This

Multiple neural inputs influence motor unit output.

Control of any motor movement, regardless of its level of complexity, depends on converging input to the motor neurons of specific motor units. Three levels of input to the motor neurons control their output to the muscle fibers they innervate:

1. *Input from afferent neurons.* This input, usually through intervening interneurons, occurs at the level of the spinal cord. Afferent neuronal input to motor neurons, which is typically proprioceptive or painful in nature, elicits somatic spinal reflexes. Spinal reflexes initiated by input from afferent neurons are important in maintaining posture and in executing basic protective movements, such as the withdrawal reflex. Afferent information may also be transmitted via ascending pathways to higher cortical levels for perception, planning voluntary movements, and so on, but this pathway is above and beyond input to motor neurons in the spinal cord for reflex responses.

2. *Input from the primary motor cortex.* Fibers originating from neuronal cell bodies known as **pyramidal cells** within the primary motor cortex (see p. 148) descend directly without synaptic interruption to terminate on motor neurons (or

stripped-down minigene can fit inside the viral carrier. Injection of these agents has stopped and even reversed the progression of MD in experimental animals. Gene therapy clinical trials in humans have not been completed.

Cell-Transplant Approach

Another approach involves injecting cells that can functionally rescue the dystrophic muscle tissue. *Myoblasts* are undifferentiated cells that fuse to form the large, multinucleated skeletal muscle cells during embryonic development. After development, a small group of stem cells known as *satellite cells* remain close to the muscle surface. Satellite cells can be activated to form myoblasts, which can fuse together to form a new skeletal muscle cell to replace a damaged cell. When the loss of muscle cells is extensive, however, as in MD, this limited mechanism is not adequate to replace all the lost fibers.

One therapeutic approach for MD under study involves the transplantation of dystrophin-producing myoblasts harvested from muscle biopsies of healthy donors into the patient's dwindling muscles. Other researchers are pinning their hopes on delivery of satellite cells or partially differentiated adult stem cells that can be converted into healthy muscle cells (see p. 10).

Utrophin Approach

An alternative strategy that holds considerable promise for treating MD is upregulation of **utrophin**, a naturally occurring protein in muscle that is closely related to dystrophin. Eighty percent of the amino acid sequence for dystrophin and utrophin is identical, but these two proteins normally have different functions. Whereas dystrophin is dispersed throughout the muscle cell's surface membrane, where it contributes to the membrane's structural stability, utrophin is concentrated at the motor end plate. Here, utrophin plays a role in anchoring the acetylcholine receptors.

When researchers genetically engineered dystrophin-deficient mice that produced extra amounts of utrophin, this utrophin upregulation compensated in large part for the absent dystrophin—that is, the additional utrophin dispersed throughout the muscle cell membrane, where it assumed dystrophin's responsibilities. The result was improved intracellular Ca^{2+} homeostasis, enhanced muscle strength, and a marked reduction in the microscopic signs of muscle degeneration. Researchers are now scrambling to find a drug that will entice muscle cells to overproduce utrophin in humans, in the hopes of preventing or even repairing the muscle wasting that characterizes this devastating condition.

RNA "Bandage" Approach

The most recent promising approach is circumventing the portions of messenger RNA that carry the faulty message from mutated DNA that leads to failure to synthesize dystrophin. When specially prepared nucleotide snippets that bind to the parts of messenger RNA transcribed from the defective parts of DNA are injected intramuscularly, the snippets cover up the faulty parts of the message. These "bandaged" parts of the modified messenger RNA are skipped over during translation when the protein is being synthesized. The result is a modified version of the dystrophin protein that is shortened but often still functional. The investigators are encouraged by animal studies and early studies in humans that suggest dystrophin is being produced in muscles following injection with these RNA bandages.

Anti-Myostatin Approach

Still other groups are exploring different tactics, such as interventions with newly designed drugs that increase the size of dwindling muscle fibers to counter the functional decline of dystrophic muscles. As an example, scientists have learned that **myostatin**, a protein produced in muscle cells, normally inhibits skeletal muscle growth in a check-and-balance fashion. They are working on ways to inhibit this inhibitor in patients with MD, thereby stimulating muscle growth.

These steps toward an eventual treatment mean that hopefully one day the boys affected by MD will be able to take steps on their own instead of being destined to wheelchairs and early death.

---

on local interneurons that terminate on motor neurons) in the spinal cord. These fibers make up the **corticospinal** (or **pyramidal**) **motor system**.

3. *Input from the brain stem as part of the multineuronal motor system.* The pathways composing the **multineuronal** (or **extrapyramidal** or **brain stem**) **motor system** include synapses that involve many regions of the brain (*extra* means "outside of"; *pyramidal* refers to the pyramidal system). The final link in multineuronal pathways is the brain stem (see p. 166), which in turn is influenced by motor regions of the cortex, the cerebellum, and the basal nuclei. In addition, the primary motor cortex itself is interconnected with the thalamus, as well as with premotor and supplementary motor areas; these are all part of the multineuronal system.

The corticospinal system plays a key role in mediating performance of fine, discrete, voluntary movements of the hands and fingers, such as those required to send a text message. Premotor and supplementary motor areas, with input from the cerebrocerebellum, plan the voluntary motor command that is issued to the appropriate motor neurons by the primary motor cortex through this descending system. The multineuronal system, in contrast, primarily regulates overall body posture involving involuntary movements of large muscle

CNS Region	Involvement in Motor Control
Motor neurons* in the spinal cord	Receive direct input from afferent neurons, brain stem, and primary motor cortex
	Send output to skeletal muscle fibers
	Serve as final common pathway; are efferent component for somatic spinal reflexes, voluntary motor activities, and rhythmic activities
Brain stem	Receives input from motor cortex, cerebellum, basal nuclei, and afferent neurons
	Serves as final link in multineuronal motor system
	Directly influences motor neurons in spinal cord
	Origin of cranial nerves that supply motor fibers to head; mediates cranial somatic reflexes and rhythmic activities
	Shares information with cerebellum; routes sensory information to thalamus
	Regulates postural reflexes and coordinates eye and head movements
Primary motor cortex	Receives input from higher motor areas (premotor cortex and supplementary motor area) and from thalamus
	Fibers from pyramidal cells make up corticospinal motor system
	Directly influences motor neurons
	Triggers voluntary movement
	Provides output to brain stem, cerebellum, basal nuclei, and thalamus for motor control
Higher motor areas (premotor cortex and supplementary motor area)	Receive input from cerebellum and sensory areas of cortex
	Are part of multineuronal motor system; do not directly influence motor neurons; act through primary motor cortex
	Important for planning and coordination of complex movement sequences
	Send voluntary motor command to primary motor cortex for execution
Cerebellum	Shares information with brain stem; monitors motor commands from motor cortex and sensory feedback from muscle
	Does not directly influence motor neurons; modulates corticospinal and multineuronal motor systems by acting on higher cortical motor areas and brain stem
	Improves accuracy of rapidly changing movements by comparing cortical command with muscle execution and makes adjustments as needed; important in balance; enhances muscle tone
	Plans skilled muscle activity
	Serves as site for procedural ("muscle sense") memory
Basal nuclei	Receive input from cortical motor and sensory areas
	Do not act directly on motor neurons; modulate multineuronal and corticospinal motor systems by acting through the cortex, brain stem, and thalamus
	Inhibit muscle tone and useless patterns of movement; coordinate slow, sustained movement; contribute to motor planning
Thalamus	Receives motor-related input from primary motor cortex and basal nuclei; receives sensory input from brain stem
	Part of multineuronal motor system; does not act directly on motor neurons; is part of a complex feedback loop linking motor cortex, basal nuclei, and thalamus
	Positively reinforces voluntary motor activity initiated by cortex; basal nuclei modulate this activity by inhibiting thalamus to eliminate unnecessary movements

groups of the trunk and limbs. The corticospinal and multi-neuronal systems show considerable complex interaction and overlapping of function. To voluntarily manipulate your thumbs to text message, for example, you subconsciously assume a particular posture of your arms that lets you hold your phone in the proper position.

The only brain regions that directly influence motor neurons are the primary motor cortex and brain stem; the other involved brain regions indirectly regulate motor activity by adjusting motor output from the motor cortex and brain stem. Numerous complex interactions take place among these various brain regions; the most important are presented in ▌Table 8-3, which summarizes the major involvement of different regions of the CNS in motor control. (See Chapter 5 for further discussion of the specific roles of these regions.)

Muscle tone refers to an ongoing, involuntary, low-level state of tension in a muscle even at rest. Skeletal muscle tone is important in maintaining postural stability. Without it, you would be floppy, like a rag doll. The skeleton itself cannot hold your body in position. Tension in muscles that are attached to the bones holds the bones in place. Skeletal muscle tone is due to both elastic properties of the muscle that resist passive stretching and continuous, minimal stimulation by motor neurons that produces a constant state of partial muscle contraction. Muscle tone is regulated by postural reflexes and output from the multineuronal motor system, namely the spinocerebellum, basal nuclei, and brain stem. Of course more forceful purposeful contractions above tonic level can be commanded at any time.

Clinical Note Some inputs converging on motor neurons are excitatory, whereas others are inhibitory. Coordinated movement depends on an appropriate balance of activity in these inputs. The following types of motor abnormalities result from defective motor control:

■ Loss of descending inhibitory inputs on motor neurons may result in **spastic paralysis**, a condition characterized by increased muscle tone (rigidity) and augmented limb reflexes.

■ In contrast, loss of excitatory input from higher centers brings about **flaccid paralysis**. In this condition, the muscles are limp with reduced or no muscle tone and the person cannot voluntarily contract them, although spinal reflex activity is still present. Damage to the primary motor cortex on one side of the brain, as with a stroke, leads to flaccid paralysis on the opposite half of the body (**hemiplegia**, or paralysis of one side of the body). Disruption of all descending pathways, as in traumatic severance of the spinal cord, produces flaccid paralysis below the level of the damaged region—**quadriplegia** (paralysis of all four limbs) in upper spinal cord damage and **paraplegia** (paralysis of the legs) in lower spinal cord injury.

■ Destruction of motor neurons—either their cell bodies or efferent fibers (as with amyotrophic lateral sclerosis [Lou Gehrig's disease]; see p. 242)—causes flaccid paralysis and lack of reflex responsiveness in the affected muscles.

■ Disorders of the cerebellum (such as cerebellar ataxia; *ataxia* means "without coordination") or basal nuclei (for example, Parkinson's disease; see p. 154) results not in paralysis

but in uncoordinated, clumsy activity and inappropriate patterns of movement. These regions normally smooth out activity initiated voluntarily. Furthermore, cerebellar damage results in decreased muscle tone, whereas impairment of the basal nuclei leads to increased muscle tone.

■ Damage to higher cortical regions (premotor cortex or supplementary motor area) involved in planning motor activity (for instance brought about by traumatic brain injury or by surgical removal of a tumor in the vicinity) results in the inability to establish appropriate motor commands to accomplish desired goals.

Muscle receptors provide afferent information needed to control skeletal muscle activity.

To plan coordinated, purposeful skeletal muscle activity, the brain regions that direct motor output depend on afferent input from various sources. For example, if you are going to catch a ball, the motor systems must program sequential motor commands that move and position your body correctly for the catch, using predictions of the ball's direction and rate of movement provided by visual input. Many muscles acting simultaneously or alternately at different joints are called into play to shift your body's location and position rapidly while maintaining your balance. To appropriately program muscle activity, your CNS must know the starting position of your body. Furthermore, it must be constantly informed by proprioceptive input about the progression of movement it has initiated so that it can make adjustments as needed.

Proprioceptors are found in the joints and the muscles themselves. They provide information about the location of body parts relative to one another and about body movement. You can demonstrate your joint and muscle proprioceptors in action by closing your eyes and bringing the tips of your right and left index fingers together at any point in space. You can do so without seeing where your hands are because your brain is informed of the position of your hands and other body parts at all times by afferent input from the joint and muscle receptors.

For effective control of motor output, the CNS needs continual information regarding ongoing changes in muscle length and tension. Two types of muscle proprioceptors—*muscle spindles* and *Golgi tendon organs*—provide this input. Muscle length is monitored by muscle spindles; changes in muscle tension are detected by Golgi tendon organs. Both these receptor types are activated by muscle stretch, but they convey different types of information. Let us see how.

Muscle Spindle Structure **Muscle spindles**, which are distributed throughout the fleshy part of a skeletal muscle, consist of collections of specialized muscle fibers known as **intrafusal fibers**, which lie within spindle-shaped connective tissue capsules parallel to the "ordinary" **extrafusal fibers** (*fusus* means "spindle") (▌Figure 8-23a). Unlike an ordinary extrafusal skeletal muscle fiber, which contains contractile elements (myofibrils) throughout its entire length, an intrafusal fiber has a noncontractile central portion, with the contractile elements being limited to both ends.

I**Figure 8-23 Muscle receptors.** (a) A muscle spindle consists of a collection of specialized intrafusal fibers that lie within a connective tissue capsule parallel to the ordinary extrafusal skeletal muscle fibers. The muscle spindle is innervated by its own gamma motor neuron and is supplied by two types of afferent sensory terminals, the primary (annulospiral) endings and the secondary (flower-spray) endings, both of which are activated by stretch. (b) The Golgi tendon organ is entwined with the collagen fibers in a tendon and monitors changes in muscle tension transmitted to the tendon.

Each muscle spindle has its own private efferent and afferent nerve supply. The efferent neuron that innervates a muscle spindle's intrafusal fibers is known as a **gamma motor neuron**, whereas the motor neurons that supply the extrafusal fibers are called **alpha motor neurons**. Two types of afferent sensory endings terminate on the intrafusal fibers and serve as muscle spindle receptors, both of which are activated by stretch. The **primary (annulospiral) endings** are wrapped around the cen-

tral portion of the intrafusal fibers; they detect changes in the length of the fibers during stretching as well as the speed with which it occurs. The **secondary (flower-spray) endings**, which are clustered at the end segments of many of the intrafusal fibers, are sensitive only to changes in length. Muscle spindles play a key role in the stretch reflex.

Stretch Reflex Whenever a whole muscle is passively stretched, its muscle spindle intrafusal fibers are likewise stretched, increasing the firing rate in the afferent nerve fibers whose sensory endings terminate on the stretched spindle fibers. The afferent neuron directly synapses on the alpha motor neuron that innervates the extrafusal fibers of the same muscle, resulting in contraction of that muscle (I Figure 8-24a, ❶ and ❷). This monosynaptic (one-synapse) **stretch reflex** (see p. 178) serves as a local negative-feedback mechanism to sense and resist changes in muscle length when an additional load is applied.

The classic example of the stretch reflex is the **patellar tendon**, or **knee-jerk**, **reflex** (I Figure 8-25). The extensor muscle of the knee is the *quadriceps femoris,* which forms the anterior (front) portion of the thigh and is attached just below the knee to the tibia (shinbone) by the *patellar tendon*. Tapping this tendon with a rubber mallet passively stretches the quadriceps muscle, activating its spindle receptors. The resulting stretch reflex brings about contraction of this extensor muscle, causing the knee to extend and raise the foreleg in the well-known knee-jerk fashion.

Clinical Note This test is routinely done as a preliminary assessment of nervous system function. A normal knee jerk indicates that a number of neural and muscular components—muscle spindle, afferent input, motor neurons, efferent output, neuromuscular junctions, and the muscles themselves— are functioning normally. It also indicates an appropriate balance of excitatory and inhibitory input to the motor neurons

from higher brain levels. Muscle jerks may be absent or depressed with loss of higher-level excitatory inputs, or may be greatly exaggerated with loss of inhibitory input to the motor neurons from higher brain levels.

The stretch reflex is a postural reflex. The primary purpose of the patellar tendon reflex is to react to loads that tend to stretch the extensor muscles of the legs. Whenever your knee joint tends to buckle while standing, walking, running or jumping, your quadriceps muscle is stretched. The resulting enhanced contraction of this extensor muscle brought about by the stretch reflex quickly straightens out the knee, keeping your leg extended so that you remain upright. A similar stretch reflex involving the biceps muscle comes into play when you catch an object with your hand or fill a water glass that you are holding. The resultant stretch of the muscle spindle in your biceps initi-

ates a stretch reflex in this muscle that helps you catch the object or continue to hold the water glass as it gets heavier during filling.

Coactivation of Gamma and Alpha Motor Neurons Gamma motor neurons initiate contraction of the muscular end regions of intrafusal fibers (see ❙Figure 8-24a, **3**). This contractile response is too weak to have any influence on whole-muscle tension, but it does have an important localized effect on the muscle spindle itself. If there were no compensating mechanisms, shortening of the whole muscle by alpha motor-neuron stimulation of extrafusal fibers would slacken the spindle fibers so that they would be less sensitive to stretch and therefore not as effective as muscle length detectors (❙Figure 8-24b and c). **Alpha-gamma coactivation** (simultaneous stimulation of the gamma motor-neuron system and the alpha motor-neuron system) during reflex and voluntary contractions (❙Figure 8-24a, **4**) takes the slack out of the spindle fibers as the whole muscle shortens, letting these receptor structures maintain their high sensitivity to stretch over a wide range of muscle lengths. Gamma motor-neuron stimulation triggers simultaneous contraction of both contractile ends of the intrafusal fibers, causing tightening of their central (noncontractile) portions to remove slack in the muscle spindle (❙Figure 8-24d). Whereas the extent of alpha motor-neuron activation depends on the intended strength of the motor response, the extent of simultaneous gamma motor-neuron

activity to the same muscle depends on the anticipated distance of shortening. When shortening of the overall muscle is less than expected (for example, the load is greater than anticipated), the muscle spindle receptors signal the alpha motor neurons to increase their rate of firing and, thereby, compensate for the additional load.

Golgi Tendon Organs In contrast to muscle spindles, which lie within the belly of the muscle, Golgi tendon organs are in the tendons of the muscle, where they can respond to changes in the muscle's tension rather than to changes in its length. Because a number of factors determine the tension developed in the whole muscle during contraction (for example, frequency of stimulation or length of the muscle at the onset of contraction), it is essential that motor control systems be apprised of
Figure 8-25 Patellar tendon reflex (a stretch reflex). Tapping the patellar tendon with a rubber mallet stretches the muscle spindles in the quadriceps femoris muscle. The resultant monosynaptic stretch reflex results in contraction of this extensor muscle, causing the characteristic knee-jerk response.

the tension actually achieved so that adjustments can be made if necessary.

A Golgi tendon organ consists of endings of an afferent fiber entwined within bundles of connective tissue (collagen) fibers that make up the tendon (see ❙ Figure 8-23b). When the extrafusal muscle fibers contract, the resulting pull on the tendon tightens the collagen bundles, which in turn increase the tension exerted on the bone to which the tendon is attached. In the process, the entwined Golgi organ afferent receptor endings are stretched, causing the afferent fibers to fire; the frequency of firing is directly related to the tension developed. This afferent information is sent to the brain for processing. Much of this information is used subconsciously for smoothly executing motor activity, but unlike afferent information from the muscle spindles, afferent information from the Golgi tendon organ reaches the level of conscious awareness. You are aware of the tension within a muscle but not of its length.

Scientists once thought the Golgi tendon organ triggered a protective spinal reflex that halted further contraction and brought about sudden reflex relaxation when the muscle tension became great enough, thus helping prevent damage to the muscle or tendon from excessive, tension-developing muscle contractions. Scientists now believe, however, that this receptor is a pure sensor and does not initiate any reflexes. Other unknown mechanisms are apparently involved in inhibiting further contraction to prevent tension-induced damage.

We now turn attention to two other somatic spinal reflexes, the withdrawal reflex and the crossed extensor reflex.

Skeletal muscle reflexes can be triggered by painful stimulation of the skin.

All other reflexes besides the monosynaptic stretch reflex are polysynaptic. Two common polysynaptic spinal reflexes can be elicited in response to painful cutaneous stimulation of an extremity: the withdrawal reflex (a protective reflex) and the crossed extensor reflex (a postural reflex).

Withdrawal Reflex When a person touches a hot stove (or receives another painful stimulus), a withdrawal reflex is initiated to withdraw from the painful stimulus (❙ Figure 8-26). When a pain receptor in the skin is stimulated enough to reach threshold, an action potential is generated in the afferent neuron. Once the afferent neuron enters the spinal cord, it diverges to synapse with the following interneurons (the letters correspond to those in step ❸ of Figure 8-26).

1. An excited afferent neuron stimulates excitatory interneurons that in turn stimulate the efferent motor neurons supplying the biceps (❸a). The resultant contraction of the biceps causes flexion of the elbow joint, which leads to withdrawal of the hand from the injurious stimulus.

2. The afferent neuron also stimulates inhibitory interneurons that inhibit the efferent neurons supplying the triceps (❸b) to prevent it from contracting. When the biceps contracts to flex the elbow, it would be counterproductive for the triceps, which extends the elbow joint, to contract. Therefore, built into the withdrawal reflex is inhibition of the muscle that antagonizes (opposes) the desired response. This type of connection involving stimulation of the nerve supply to one muscle and simultaneous inhibition of the nerves to its antagonistic muscle is known as **reciprocal innervation**.

3. The afferent neuron stimulates still other interneurons that carry the signal up the spinal cord to the brain via an ascending pathway (❸c). Only when the impulse reaches the sensory area of the cortex is the person aware of the pain, its location, and the type of stimulus. Also, when the impulse reaches the brain, the information can be stored as memory, and the person can start thinking about the situation—how it happened,

1 Painful heat stimulus activates thermal pain receptor in finger.

2 Action potentials are generated in afferent pathway, which propagates impulses to the spinal cord.

3 Spinal cord serves as the integrating center. Here afferent neuron stimulates:
3a excitatory interneurons, which stimulate motor neurons to biceps.
3b inhibitory interneurons, which inhibit motor neurons to triceps.
3c interneurons that are part of ascending pathway to brain.

4 One efferent pathway stimulates biceps to contract. Other efferent pathway leads to relaxation of triceps by preventing counterproductive excitation and contraction of this antagonistic muscle.

5 The biceps and triceps are effectors. Resultant flexion of elbow joint pulls hand away from painful stimulus. This response completes the withdrawal reflex.

6 Events that occur in brain on arrival of signal via ascending pathway, such as awareness of pain, memory storage, and so on, are above and beyond reflex arc.

Figure 8-26 The withdrawal reflex.

what to do about it, and so on. All this activity at the conscious level is beyond the basic reflex.

As with all spinal reflexes, the brain can modify the withdrawal reflex. Impulses may be sent down descending pathways to the efferent motor neurons supplying the involved muscles to override the input from the receptors, actually preventing the biceps from contracting despite the painful stimulus. When your finger is being pricked to obtain a blood sample, pain receptors are stimulated, initiating the withdrawal reflex. Knowing that you must be brave and not pull your hand away, you can consciously override the reflex by sending IPSPs via descending pathways to the motor neurons supplying the biceps and EPSPs to those supplying the triceps. The activity in these efferent neurons depends on the sum of activity of all their synaptic inputs. Because the neurons supplying your biceps are now receiving more IPSPs from your brain (voluntary) than EPSPs from the afferent pain pathway (reflex), these neurons are inhibited and do not reach threshold. Therefore, the biceps is not stimulated to contract and withdraw your hand. Simultaneously, the neu-

rons to your triceps are receiving more EPSPs from your brain than IPSPs via the reflex arc, so they reach threshold, fire, and consequently stimulate the triceps to contract. In this way, you voluntarily override the withdrawal reflex and keep your arm extended despite the painful stimulus.

Crossed Extensor Reflex Spinal reflex action is not necessarily limited to motor responses on the side of the body to which the stimulus is applied. Assume that a person steps on a tack instead of burning a finger. A reflex arc is initiated to withdraw the injured foot from the painful stimulus, while the opposite leg simultaneously prepares to suddenly bear all the weight so that the person does not lose balance or fall (**Figure 8-27**). Unimpeded bending of the injured extremity's knee is accomplished by concurrent reflex stimulation of the muscles that flex the knee and inhibition of the muscles that extend the knee. This response is a typical withdrawal reflex. At the same time, unimpeded extension of the opposite limb's knee is accomplished by activation of pathways that cross over to the

Having completed our discussion of skeletal muscle, we now examine smooth and cardiac muscle.

Check Your Understanding 8.5

1. Distinguish among the three classes of motor activity.
2. Describe the three levels of direct input to motor neurons.
3. Diagram the patellar tendon reflex.

8.6 Smooth and Cardiac Muscle

The two other types of muscle—smooth muscle and cardiac muscle—share some basic properties with skeletal muscle, but each also displays unique contractile characteristics (|Table 8-4). The three muscle types all have a specialized contractile apparatus made up of thin actin filaments that slide relative to stationary thick myosin filaments in response to a rise in cytosolic Ca^{2+} to accomplish contraction. Also, they all directly use ATP as the energy source for cross-bridge cycling. However, the

Characteristic	Skeletal Muscle	Multiunit Smooth Muscle	Single-Unit Smooth Muscle	Cardiac Muscle
Mechanism of contraction	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism
Innervation	Somatic nervous system	Autonomic nervous system	Autonomic nervous system	Autonomic nervous system
Level of control	Under voluntary control; also subject to subconscious regulation	Under involuntary control	Under involuntary control	Under involuntary control

Presence of gap junctions	No	Yes (very few)	Yes	Yes
Speed of contraction	Fast or slow, depending on type of fiber	Very slow	Very slow	Slow
Means by which gradation is accomplished	Varying number of motor units contracting (motor unit recruitment) and frequency at which they are stimulated (twitch summation)	Varying number of muscle fibers contracting and varying cytosolic Ca^{2+} concentration in each fiber by autonomic and hormonal influences	Varying cytosolic Ca^{2+} concentration through myogenic activity and influences of the autonomic nervous system, mechanical stretch, hormones, and local metabolites	Varying length of fibers (extent of filling of heart chambers) and varying cytosolic Ca^{2+} concentration through autonomic, hormonal, and local metabolite influences
Clear-cut length–tension relationship	Yes	No	No	Yes

structure and organization of fibers within these muscle types vary, as do their mechanisms of excitation and the means by which excitation and contraction are coupled. Furthermore, important distinctions occur in the contractile response itself. We spend the rest of this chapter highlighting unique features of smooth and cardiac muscle as compared with skeletal muscle, saving more detailed discussion of their function for chapters on organs containing these muscle types.

Smooth muscle cells are small and unstriated.

Most smooth muscle cells are found in the walls of hollow organs and tubes. Their contraction exerts pressure on and regulates forward movement of the contents of these structures.

Both smooth and skeletal muscle cells are elongated, but in contrast to their large, cylindrical skeletal muscle counterparts, smooth muscle cells are spindle shaped (tapered at both ends), have a single nucleus, and are considerably smaller (2 to 10 μm in diameter and 50 to 400 μm long). Also unlike skeletal muscle cells, a single smooth muscle cell does not extend the full length of a muscle. Instead, groups of smooth muscle cells are typically arranged in sheets (see ❙Figure 8-1c).

A smooth muscle cell has three types of filaments: (1) thick myosin filaments, which are longer than those in skeletal muscle; (2) thin actin filaments, which contain tropomyosin but lack troponin; and (3) filaments of intermediate size, which do not directly participate in contraction but are part of the cytoskeletal framework that supports the cell shape. Smooth muscle filaments do not form myofibrils and are not arranged in the sarcomere pattern found in skeletal muscle. Thus, smooth muscle cells do not show the banding or striation of skeletal muscle, hence the term *smooth* for this muscle type.

Lacking sarcomeres, smooth muscle does not have Z lines, but it does have **dense bodies** containing the same protein constituent found in Z lines (❙Figure 8-28). Dense bodies are positioned throughout the smooth muscle cell, as well as attached to the internal surface of the plasma membrane. Dense bodies are held in place by a scaffold of intermediate filaments. The actin filaments are anchored to the dense bodies. Considerably more actin is present in smooth muscle cells than in skeletal muscle cells, with 10 to 15 thin filaments for each thick myosin filament in smooth muscle compared to 2 thin filaments for each thick filament in skeletal muscle.

The thick- and thin-filament contractile units are oriented slightly diagonally from side to side within the smooth muscle cell in an elongated, diamond-shaped lattice, rather than running parallel with the long axis as myofibrils do in skeletal muscle (❙Figure 8-29a). Relative sliding of the thin filaments past the thick filaments during contraction causes the filament lattice to shorten and expand from side to side. As a result, the whole cell shortens and bulges out between the points where the thin filaments are attached to the inner surface of the plasma membrane (❙Figure 8-29b).

Unlike in skeletal muscle, myosin molecules are arranged in a smooth-muscle thick filament so that cross bridges are present along the entire filament length (that is, there is no bare portion in the center of a smooth-muscle thick filament). As a result, the surrounding thin filaments can be pulled along the

Smooth muscle cells   Dense bodies
❙Figure 8-28 **Electron micrograph of smooth muscle cells.** Note the presence of dense bodies and lack of banding.

thick filaments for longer distances than in skeletal muscle. Also dissimilar to skeletal muscle (in which all thin filaments surrounding a thick filament are pulled toward the center of the stationary thick filament), the myosin proteins in smooth-muscle thick filaments are organized so that half of the surrounding thin filaments are pulled toward one end of the stationary thick filament and the other half are pulled toward the opposite end (❙Figure 8-29b).

Smooth muscle cells are turned on by Ca^{2+}-dependent phosphorylation of myosin.

The thin filaments of smooth muscle cells do not contain troponin, and tropomyosin does not block actin's cross-bridge binding sites. What, then, prevents actin and myosin from binding at the cross bridges in the resting state, and how is cross-bridge activity switched on in the excited state? Lightweight chains of proteins are attached like "necklaces" to the heads of myosin molecules, near the "neck" region. These so-called **light chains** are only of secondary importance in skeletal muscle, but they have a crucial regulatory function in smooth muscle. Smooth muscle myosin can interact with actin only when the light chain is *phosphorylated* (that is, has an inorganic phosphate from ATP attached to it). During excitation, the increased cytosolic Ca^{2+} acts as an intracellular messenger, initiating a chain of biochemical events that results in phosphorylation of the myosin light chain (❙Figure 8-30). Smooth muscle Ca^{2+} binds with **calmodulin**, an intracellular protein found in most cells that is structurally similar to troponin (see p. 124). This Ca^{2+}–calmodulin complex binds to and activates another protein, **myosin light chain kinase (MLC kinase)**, which in turn phosphorylates the myosin light chain. This phosphate on the myosin light chain is in addition to the phosphate accompanying ADP on the myosin cross-bridge ATPase site during the energy-supplying cycle that powers cross-bridge bending. The P_i on the light chain per-

(b) Contracted smooth muscle cell
❚Figure 8-29 **Arrangement of thick and thin filaments in a smooth muscle cell in relaxed and contracted states.**

mits the myosin cross bridge to bind with actin so that cross-bridge cycling can begin. Therefore, smooth muscle is triggered to contract by a rise in cytosolic Ca^{2+}, similar to what happens in skeletal muscle, but in smooth muscle, Ca^{2+} ultimately turns on the cross bridges by inducing a *chemical* change in myosin in the *thick* filaments (phosphorylation), whereas in skeletal muscle it exerts its effects by causing a *physical* change at the *thin* filaments (moving troponin and tropomyosin from their blocking positions) (❚Figure 8-31).

Phasic smooth muscle contracts in bursts; tonic smooth muscle maintains tone.

Smooth muscle can be grouped into two categories depending on its pattern of contractile activity and how its cytosolic Ca^{2+} concentration increases: *phasic smooth muscle* and *tonic smooth muscle*. **Phasic smooth muscle** contracts in bursts, triggered by action potentials that lead to increased cytosolic Ca^{2+}. These bursts in contraction are characterized by pronounced increases in contractile activity. Phasic smooth muscle is most abundant in the walls of hollow organs that push contents through them, such as digestive organs. Phasic digestive contractions mix food with digestive juices and propel the mass forward for further processing. **Tonic smooth muscle** is usually partially contracted at all times; that is, it exhibits smooth muscle tone. Tone exists because this type of smooth muscle has a relatively low resting potential of -55 to -40 mV. Some surface-membrane voltage-gated Ca^{2+} channels are open at these potentials. The resultant Ca^{2+} entry maintains a state of

Contraction	Contraction

❙Figure 8-31 Comparison of the role of Ca2⁺ in bringing about contraction in smooth muscle and skeletal muscle.

partial contraction, or tone, in the absence of action potentials. Tonic smooth muscle does not display bursts of contractile activity but instead incrementally varies its extent of contraction above or below this tonic level in response to regulatory factors, which alter the cytosolic Ca^{2+} concentration. The smooth muscle in walls of arterioles is an example of tonic smooth muscle. The ongoing tonic contraction in these small blood vessels squeezes down on the blood flowing through them and is one of the major contributing factors to maintenance of blood pressure.

A smooth muscle cell has no T tubules and a poorly developed SR. In phasic smooth muscle, the increased cytosolic Ca^{2+} that triggers contraction comes from two sources: Most Ca^{2+} enters from the extracellular fluid (ECF), but some is released intracellularly from the sparse SR stores. Unlike their role in skeletal muscle cells, voltage-sensitive dihydropyridine receptors in the plasma membrane of smooth muscle cells function as Ca^{2+} channels. When these surface-membrane channels are opened in response to an action potential, Ca^{2+} enters down its concentration gradient from the ECF. The entering Ca^{2+} triggers the opening of Ca^{2+} channels in the SR so that small additional amounts of Ca^{2+} are released intracellularly from this meager source. Because smooth muscle cells are so much smaller in diameter than skeletal muscle fibers, most Ca^{2+} entering from the ECF can influence cross-bridge activity, even in the central portions of the cell, without requiring an elaborate T tubule–SR mechanism.

One of the major means of increasing cytosolic Ca^{2+} concentration and thus increasing contractile activity in tonic smooth muscle is binding of an extracellular chemical messenger, such as norepinephrine or various hormones, to a G-protein-coupled receptor, which activates the IP_3–Ca^{2+} second-messenger pathway (see p. 124). The membrane of the SR in tonic smooth muscle has IP_3 receptors, which like ryanodine receptors, are Ca^{2+}-release channels. IP_3 binding leads to release of contractile-inducing Ca^{2+} from this intracellular store into the cytosol. This is how norepinephrine released from the sympathetic nerve endings acts on arterioles to increase blood pressure.

Relaxation in smooth muscle is accomplished by removal of Ca^{2+} as it is actively transported out across the plasma membrane or back into the SR, depending on its source. When Ca^{2+} is removed, myosin is dephosphorylated (the phosphate is removed) and can no longer interact with actin, so the muscle relaxes.

We still have not addressed the question of how action potentials are initiated in smooth muscle. Smooth muscle is grouped in another way into two categories—*multiunit* and *single-unit smooth muscle*—based on differences in how the muscle fibers become excited. Let us compare them.

Multiunit smooth muscle is neurogenic.

Multiunit smooth muscle exhibits properties partway between those of skeletal muscle and those of single-unit smooth muscle. As the name implies, a multiunit smooth muscle consists of multiple discrete units that function independently of one another and must be separately stimulated by nerves to undergo action potentials and contract, similar to skeletal muscle motor units. Thus, contractile activity in both skeletal muscle and multiunit smooth muscle is **neurogenic** ("nerve produced"). That is, contraction in these muscle types is initiated only in response to stimulation by the nerves supplying the muscle. All multiunit smooth muscle is phasic, contracting only when neurally stimulated. Whereas skeletal muscle is innervated by the voluntary somatic nervous system (motor neurons), multiunit (as well as single-unit) smooth muscle is supplied by the involuntary autonomic nervous system.

Multiunit smooth muscle is found (1) in the walls of large blood vessels; (2) in small airways to the lungs; (3) in the muscle of the eye that adjusts the lens for near or far vision; (4) in the iris of the eye, which alters the pupil size to adjust the amount of light entering the eye; and (5) at the base of hair follicles, contraction of which causes "goose bumps."

Single-unit smooth muscle cells form functional syncytia.

Most smooth muscle is **single-unit smooth muscle**, alternatively called **visceral smooth muscle**, because it is found in the walls of the hollow organs or viscera (for example, the digestive, reproductive, and urinary tracts and small blood vessels). The term *single-unit smooth muscle* derives from the muscle fibers that make up this type of muscle becoming excited and contracting as a single unit. The muscle fibers in single-unit smooth muscle are electrically linked by gap junctions (see p. 62). When an action potential occurs anywhere within a sheet of single-unit smooth muscle, it is quickly propagated via these special points of electrical contact throughout the entire group of interconnected cells, which then contract as a single, coordinated unit. Such a group of interconnected muscle cells that function electrically and mechanically as a unit is known as a **functional syncytium** (plural, *syncytia; syn* means "together"; *cyt* means "cell").

Thinking about the role of the uterus during labor can help you appreciate the significance of this arrangement. Muscle cells composing the uterine wall act as a functional syncytium. They repetitively become excited and contract as a unit during labor, exerting a series of coordinated "pushes" that eventually deliver the baby. Independent, uncoordinated contractions of individual muscle cells in the uterine wall could not exert the uniformly applied pressure needed to expel the baby.

Single-unit smooth muscle is myogenic.

Single-unit smooth muscle is **self-excitable**, so it does not require nervous stimulation for contraction. Single-unit smooth muscle may be of the phasic or tonic type. In phasic single-unit smooth muscle, clusters of specialized cells within a functional syncytium display spontaneous electrical activity; that is, they can undergo action potentials without any external stimulation. In contrast to the other excitable cells we have been discussing (such as neurons, skeletal muscle fibers, and multiunit smooth muscle), the self-excitable cells of phasic single-unit smooth muscle do not maintain a constant resting potential. Instead, their membrane potential inherently fluctuates without any influence by factors external to the cell. Two major types of spontaneous depolarizations displayed by self-excitable cells are *pacemaker potentials* and *slow-wave potentials.*

Pacemaker Potentials With **pacemaker potentials**, the membrane potential gradually depolarizes on its own because of shifts in passive ionic fluxes accompanying automatic changes in ion channel permeability (❙ Figure 8-32a). When the membrane has depolarized to threshold, an action potential is initiated. After repolarizing, the membrane potential again depolarizes to threshold, cyclically continuing in this manner to repetitively self-generate action potentials.

Self-excitable smooth muscle pacemaker cells are specialized to initiate action potentials, but they are not equipped to contract. Only a few of all the cells in a functional syncytium are noncontractile, pacemaker cells. Most smooth muscle cells are specialized to contract but cannot self-initiate action potentials. However, once an action potential is initiated by a self-
(a) Pacemaker potential
(b) Slow-wave potential

❙ Figure 8-32 **Self-generated electrical activity in smooth muscle.** (a) With pacemaker potentials, the membrane gradually depolarizes to threshold on a regular periodic basis without any nervous stimulation. These regular depolarizations cyclically trigger self-induced action potentials. (b) In slow-wave potentials, the membrane gradually undergoes self-induced hyperpolarizing and depolarizing swings in potential. A burst of action potentials occurs if a depolarizing swing brings the membrane to threshold.

FIGURE FOCUS: *(1) A depolarizing pacemaker potential always initiates an action potential.* (True or false?) *(2) A depolarizing slow-wave potential always initiates an action potential.* (True or false?)

excitable pacemaker cell, it is conducted to the remaining contractile, nonpacemaker cells of the functional syncytium via gap junctions, so the entire group of connected cells contracts as a unit without any nervous input. Such nerve-independent contractile activity initiated by the muscle itself is called **myogenic activity** ("muscle-produced" activity), in contrast to the neurogenic activity of skeletal muscle and multiunit smooth muscle.

Slow-Wave Potentials **Slow-wave potentials** are spontaneous, gradually alternating depolarizing and hyperpolarizing swings in potential (❙ Figure 8-32b) brought about by unknown means. They occur only in smooth muscle of the digestive tract. Slow-wave potentials are initiated by specialized clusters of nonmuscle pacemaker cells within the digestive tract wall and spread to the adjacent smooth muscle cells via gap junctions. If threshold is reached at the peak of a depolarizing swing, a burst of action potentials occurs. These action potentials bring about myogenically induced contraction. Threshold is not always

reached, however, so the oscillating slow-wave potentials can continue without generating action potentials and contractile activity. Whether threshold is reached depends on the starting point of the membrane potential at the onset of its depolarizing swing. The starting point, in turn, is influenced by neural and local factors typically associated with meals (see Chapter 16 for further detail).

Recall that tonic single-unit smooth muscle cells have sufficient cytosolic Ca^{2+} to maintain low level tension even without action potentials, so they too are myogenic. (Thus, multiunit smooth muscles are all neurogenic and phasic; single-unit smooth muscles are all myogenic and may be phasic or tonic.)

Gradation of single-unit smooth muscle contraction differs from that of skeletal muscle.

Single-unit smooth muscle differs from skeletal muscle in the way contraction is graded. Gradation of skeletal muscle contraction is entirely under neural control by means of motor unit recruitment and twitch summation. In single-unit smooth muscle, gap junctions ensure that an entire smooth muscle sheet contracts as a single unit, making it impossible to vary the number of muscle fibers contracting. Only the tension of the fibers can be modified to achieve varying strengths of contraction of the whole organ. The portion of cross bridges activated and the tension subsequently developed in single-unit smooth muscle can be graded by varying the cytosolic Ca^{2+} concentration. A single excitation in smooth muscle does not cause all cross bridges to switch on, in contrast to skeletal muscles, where a single action potential triggers release of enough Ca^{2+} to permit all cross bridges to cycle. As Ca^{2+} concentration increases in smooth muscle, more cross bridges are brought into play and greater tension develops.

Modification of Smooth Muscle Activity by the Autonomic Nervous System Smooth muscle is typically innervated by both branches of the autonomic nervous system. In single-unit smooth muscle (both phasic and tonic), this nerve supply does not *initiate* contraction, but it can *modify* the rate and strength of contraction, either enhancing or retarding the inherent contractile activity of a given organ. Recall that the isolated motor end-plate region of a skeletal muscle fiber interacts with ACh released from a single axon terminal of a motor neuron. In contrast, the receptors that bind with autonomic neurotransmitters are dispersed throughout the entire surface membrane of a smooth muscle cell. Smooth muscle cells are sensitive to

varying degrees and in varying ways to autonomic neurotransmitters, depending on the cells' distribution of cholinergic and adrenergic receptors (see pp. 239–240).

Each terminal branch of a postganglionic autonomic fiber travels across the surface of one or more smooth muscle cells, releasing neurotransmitter from the vesicles within its multiple varicosities (bulges) as an action potential passes along the terminal (❚ Figure 8-33). The neurotransmitter diffuses to the many receptors specific for it on the cells underlying the terminal. Thus, in contrast to the discrete one-to-one relationship at motor end plates, a given smooth muscle cell can be influenced by more than one type of neurotransmitter, and each autonomic terminal can influence more than one smooth muscle cell.

Other Factors Influencing Smooth Muscle Activity Other factors (besides autonomic neurotransmitters) can influence the rate and strength of both multiunit and single-unit smooth muscle contraction, including mechanical stretch, certain hormones, local metabolites, and specific drugs. The smooth muscle of digestive organs is also influenced by the enteric nervous system, which is a specialized network of nerve fibers built into the wall of the digestive tract (see pp. 135 and 572). Some smooth muscle is poorly innervated, an example being the uterus, in which case the rate and strength of contraction is regulated entirely by circulating and locally released chemical messengers, which vary with the stage of the menstrual cycle and with the stage of pregnancy. All these factors ultimately act by modifying the permeability of Ca^{2+} channels in the plasma membrane, the SR, or both, through a variety of mechanisms. Thus, smooth muscle is subject to more external influences than skeletal muscle is, even though smooth muscle can contract on its own and skeletal muscle cannot.

Next, as we look at the length–tension relationship in smooth muscle, we consider the effect of mechanical stretch (as occurs during filling of a hollow organ) on smooth muscle contractility. We examine the extracellular chemical influences (certain hormones and local metabolites) on smooth muscle

contractility in later chapters when we discuss regulation of the various organs that contain smooth muscle.

Smooth muscle can still develop tension yet inherently relaxes when stretched.

The relationship between muscle fiber length before contraction and the tension that can be developed on a subsequent contraction is less closely linked in smooth muscle than in skeletal muscle. The range of lengths over which a smooth muscle fiber can develop near-maximal tension is greater than the range for skeletal muscle. Smooth muscle can still develop considerable tension even when stretched up to 2.5 times its resting length, for two reasons. First, in contrast to skeletal muscle, in which the resting length is near its l_o, in smooth muscle the resting (nonstretched) length is much shorter than its l_o. Therefore, smooth muscle can be stretched considerably before reaching its optimal length. Second, the thin filaments still overlap the longer thick filaments even in the stretched-out position, so cross-bridge interaction and tension development can still take place. In contrast, when skeletal muscle is stretched only three-fourths longer than its resting length, the thick and thin filaments are completely pulled apart and can no longer interact (see ▌Figure 8-20, p. 269).

The ability of a considerably stretched smooth muscle fiber to still develop tension is important, because the smooth muscle fibers within the wall of a hollow organ are progressively stretched as the volume of the organ's contents expands. Consider the urinary bladder as an example. Even though the muscle fibers in the urinary bladder are stretched as the bladder gradually fills with urine, they still maintain their tone and can even develop further tension in response to inputs that regulate bladder emptying. If considerable stretching prevented tension development, as in skeletal muscle, a filled bladder would not be capable of emptying.

Stress Relaxation Response When a smooth muscle is suddenly stretched, it initially increases its tension, much like the tension created in a stretched rubber band. The muscle quickly adjusts to this new length, however, and inherently relaxes to the tension level before the stretch, probably as a consequence of rearrangement of cross-bridge attachments. Smooth muscle cross bridges detach comparatively slowly. On sudden stretching, it is speculated that any attached cross bridges would strain against the stretch, contributing to a passive (not actively generated) increase in tension. As these cross bridges detach, the filaments would be permitted to slide into an unstrained stretched position, restoring the tension to its original level. This inherent property of smooth muscle is called the **stress relaxation response**.

Advantages of the Smooth Muscle Length–Tension Relationship These two responses of smooth muscle to being stretched—being able to develop tension even when considerably stretched and inherently relaxing when stretched—are highly advantageous. They enable smooth muscle to exist at a variety of lengths with little change in tension. As a result, a hollow organ enclosed by smooth muscle can accommodate variable volumes

of contents with little change in the pressure exerted on the contents except when the contents are to be pushed out of the organ. At that time, the tension is deliberately increased by fiber shortening. Smooth muscle fibers can contract to half their normal length, enabling hollow organs to dramatically empty their contents on increased contractile activity; thus, smooth-muscled viscera can easily accommodate large volumes but can empty to practically zero volume. This length range in which smooth muscle normally functions (anywhere from 0.5 to 2.5 times the normal length) is greater than the limited length range within which skeletal muscle remains functional.

Smooth muscle contains a lot of connective tissue, which helps prevent a hollow organ from being overstretched. Unlike skeletal muscle, in which the skeletal attachments restrict how far the muscle can be stretched, this connective tissue puts an upper limit on how much a smooth-muscled hollow organ can hold.

Smooth muscle is slow and economical.

A smooth muscle contractile response proceeds more slowly than a skeletal muscle twitch. ATP splitting by myosin ATPase is much slower in smooth muscle, so cross-bridge activity and filament sliding occur about 10 times more slowly in smooth muscle than in skeletal muscle. A single smooth muscle contraction may last as long as 3 seconds (3000 msec), compared to the maximum of 100 msec for a single contractile response in skeletal muscle. Smooth muscle also relaxes more slowly because of slower Ca^{2+} removal. Slowness should not be equated with weakness, however. Smooth muscle can generate the same contractile tension per unit of cross-sectional area as skeletal muscle, but it does so more slowly and at considerably less energy expense. Because of slow cross-bridge cycling during smooth muscle contraction, cross bridges stay attached for more time during each cycle, compared with skeletal muscle; that is, the cross bridges "latch onto" the thin filaments for a longer time each cycle. This **latch phenomenon** enables smooth muscle to maintain tension with comparatively less ATP consumption because each cross-bridge cycle uses up one molecule of ATP. The duration of force maintained by a single cross-bridge interaction lasts about eight times longer in smooth muscle than in skeletal muscle. Smooth muscle is therefore an economical contractile tissue, making it well suited for long-term sustained contractions with little energy consumption and without fatigue. In contrast to the rapidly changing demands placed on your skeletal muscles as you maneuver through and manipulate your external environment, your smooth muscle activities are geared for long-term duration and slower adjustments to change. Because of its slowness and the less ordered arrangement of its filaments, smooth muscle has often been mistakenly viewed as a poorly developed version of skeletal muscle. Actually, smooth muscle is just as highly specialized for the demands placed on it. It is an extremely adaptive, efficient tissue.

Nutrient and O_2 delivery are generally adequate to support the smooth muscle contractile process. Smooth muscle can use a wide variety of nutrient molecules for ATP production. There are no energy storage pools comparable to creatine phosphate in smooth muscle; they are not necessary. Oxygen delivery is

usually adequate to keep pace with the low rate of oxidative phosphorylation needed to provide ATP for the energy-efficient smooth muscle. If necessary, anaerobic glycolysis can sustain adequate ATP production if O_2 supplies are diminished.

Cardiac muscle blends features of both skeletal and smooth muscle.

Cardiac muscle, found only in the heart, shares structural and functional features with both skeletal and single-unit smooth muscle. Like skeletal muscle, cardiac muscle is striated, with its thick and thin filaments highly organized into a banding pattern. Cardiac thin filaments contain troponin and tropomyosin, which constitute the site of Ca^{2+} action in switching on cross-bridge activity, as in skeletal muscle. Also like skeletal muscle, cardiac muscle has a clear length–tension relationship. Like the oxidative skeletal muscle fibers, cardiac muscle cells have lots of mitochondria and myoglobin. They also have T tubules and a moderately well-developed SR.

Like smooth muscle, cardiac muscle fibers are slender and short (10 to 20 μm in diameter and 50 to 100 μm long). Like single-unit smooth muscle, the heart displays pacemaker (but not slow-wave) activity, initiating its action potentials without any external influence. Cardiac cells are interconnected by gap junctions found in *intercalated discs* that join cells together (see ▮ Figure 8-1b). Gap junctions enhance the spread of action potentials throughout the heart, just as in single-unit smooth muscle. As in smooth muscle, Ca^{2+} enters the cytosol from both the ECF and the SR during cardiac excitation. Ca^{2+} entry from the ECF occurs through voltage-gated dihydropyridine receptors, which also act as Ca^{2+} channels in the T tubule membrane. This Ca^{2+} entry from the ECF triggers release of Ca^{2+} intracellularly from the SR. Also similarly, the heart is innervated by the autonomic nervous system, which, along with certain hormones and local factors, can modify the rate and strength of contraction.

Unique to cardiac muscle, cardiac fibers are joined in a branching network, and cardiac muscle action potentials last much longer before repolarizing. Further details of cardiac muscle's features are addressed in the next chapter.

Check Your Understanding 8.6

1. Compare the thick and thin filaments of skeletal muscle and smooth muscle.
2. Describe the differences between multiunit and single-unit smooth muscle.
3. Contrast the sources and roles of Ca^{2+} in skeletal, smooth, and cardiac muscle.

Homeostasis: Chapter in Perspective

Skeletal muscles comprise the muscular system itself. Cardiac muscle and smooth muscle are part of organs that make up other body systems. Cardiac muscle is found only in the heart, which is part of the circulatory system. Smooth muscle is found in the walls of hollow organs and tubes, including blood vessels in the circulatory system, airways in the respiratory system, bladder in the urinary system, stomach and intestines in the digestive system, and tubular components of the reproductive system (an example being the uterus in females).

Contraction of skeletal muscles accomplishes movement of body parts in relation to one another and movement of the whole body in relation to the external environment. Thus, these muscles permit you to move through and manipulate your external environment. At a general level, some of these movements are aimed at maintaining homeostasis, such as moving the body toward food or away from harm. Examples of more specific homeostatic functions accomplished by skeletal muscles include chewing and swallowing food for further breakdown in the digestive system into usable energy-producing nutrient molecules (the mouth and throat muscles are all skeletal muscles), and breathing to obtain O_2 and get rid of CO_2 (the respiratory muscles are all skeletal muscles). Contracting skeletal muscles also are the major source of heat production in maintaining body temperature. Skeletal muscles further accomplish many nonhomeostatic activities that enable us to work and play—for example, operating a piece of equipment or riding a bicycle—so that we can contribute to society and enjoy ourselves.

All other systems of the body, except the immune (defense) system, depend on their nonskeletal muscle components to enable them to accomplish their homeostatic functions. For example, contraction of cardiac muscle in the heart pushes life-sustaining blood forward into the blood vessels, and contraction of smooth muscle in the stomach and intestines pushes ingested food through the digestive tract at a rate appropriate for the digestive juices secreted along the route to break down the food into usable units.

Review Exercises Answers begin on p. A-31

Reviewing Terms and Facts

1. When an action potential in a muscle fiber is completed, the contractile activity initiated by the action potential stops. *(True or false?)*

2. The velocity at which a muscle shortens depends entirely on the ATPase activity of its fibers. *(True or false?)*

3. When a skeletal muscle is maximally stretched, it can develop maximal tension on contraction because the actin filaments can slide in a maximal distance. *(True or false?)*

4. Smooth muscle can develop tension even when considerably stretched because the thin filaments still overlap with the long, thick filaments. *(True or false?)*

5. The muscle shortens in a(n) _____ contraction, whereas the muscle lengthens in a(n) _____ contraction.

6. _____ motor neurons supply extrafusal muscle fibers, whereas intrafusal fibers are innervated by _____ motor neurons.

7. The three types of atrophy are _____, _____, and _____.

8. An ongoing, involuntary, low-level state of muscle tension is known as _____.

9. A group of interconnected muscle cells that function electrically and mechanically as a unit because of the presence of gap junctions is called a _____.

10. Prolonged attachment of the cross bridge to actin during each cross-bridge cycle in smooth muscle is known as the _____.

11. Which of the following is *not* involved in bringing about muscle relaxation?
   a. reuptake of Ca^{2+} by the sarcoplasmic reticulum
   b. no more ATP
   c. no more action potential
   d. removal of ACh at the end plate by acetylcholinesterase
   e. filaments sliding back to their resting position

12. Match the following (with reference to skeletal muscle):

1. Ca^{2+}	(a) cyclically binds with the myosin cross bridges during contraction
2. T tubule	
3. ATP	
4. lateral sac of the sarcoplasmic reticulum	(b) has ATPase activity
	(c) supplies energy for the power stroke of a cross bridge
5. myosin	(d) rapidly transmits the action potential to the central portion of the muscle fiber
6. troponin– tropomyosin complex	
	(e) stores Ca^2
7. actin	(f) pulls the troponin–tropomyosin complex out of its blocking position
	(g) prevents actin from interacting with myosin when the muscle fiber is not excited

13. Indicate which of the following shorten during muscle contraction. *(Indicate all correct answers.)*
   a. thick filament
   b. thin filament
   c. A band
   d. I band
   e. H zone
   f. sarcomere

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Describe the levels of organization in a skeletal muscle.

2. What produces the striated appearance of skeletal muscles? Describe or draw the arrangement of thick and thin filaments that gives rise to the banding pattern.

3. Explain what a functional unit is and name the functional unit of skeletal muscle.

4. Describe the composition of thick and thin filaments.

5. Describe the sliding filament mechanism of muscle contraction. How do cross-bridge power strokes bring about shortening of the muscle fiber?

6. Compare the excitation–contraction coupling process in skeletal muscle with that in smooth muscle.

7. How can gradation of skeletal muscle contraction be accomplished?

8. What is a motor unit? Compare the size of motor units in finely controlled muscles with those specialized for coarse, powerful contractions. Describe motor unit recruitment.

9. Explain twitch summation and tetanus.

10. How does a skeletal muscle fiber's length at the onset of contraction affect the strength of the subsequent contraction?

11. Compare isotonic, isokinetic, and isometric contractions.

12. Describe the role of each of the following in powering skeletal muscle contraction: ATP, creatine phosphate, oxidative phosphorylation, and glycolysis. Distinguish between aerobically and anaerobically supported exercises.

13. Compare the three types of skeletal muscle fibers.

14. What are the roles of the corticospinal system and multineuronal system in controlling motor movement?

15. Describe the structure and function of muscle spindles and Golgi tendon organs.

16. Contrast the arrangement and stroking pattern of cross bridges in smooth muscle with that in skeletal muscle.

17. What activates myosin light chain kinase in smooth muscle? What does activated myosin light chain kinase do?

18. Distinguish between phasic and tonic smooth muscle.

19. Distinguish between multiunit and single-unit smooth muscle.

20. Differentiate between neurogenic and myogenic muscle activity.

21. How can smooth muscle contraction be graded?

22. Compare the contractile speed and relative energy expenditure of skeletal muscle with that of smooth muscle.

23. In what ways is cardiac muscle functionally similar to skeletal muscle and to single-unit smooth muscle?

Solving Quantitative Exercises

1. Consider two individuals each throwing a baseball, one a weekend athlete and the other a professional pitcher.

   a. Given the following information, calculate the velocity of the ball as it leaves the amateur's hand:

- The distance from his shoulder socket (humeral head) to the ball is 70 cm.
- The distance from his humeral head to the points of insertion of the muscles moving his arm forward (we must simplify here because the shoulder is such a complex joint) is 9 cm.
- The velocity of muscle shortening is 2.6 msec.

   b. The professional pitcher throws the ball 85 miles per hour. If his points of insertion are also 9 cm from the humeral head and the distance from his humeral head to the ball is 90 cm, how much faster did the professional pitcher's muscles shorten compared to the amateur's?

2. The velocity at which a muscle shortens is related to the force that it can generate in the following way:[1]

$$v = b(F_0 - F) / (F + a)$$

where v is the velocity of shortening, and F_0 can be thought of as an "upper load limit," or the maximum force a muscle can generate against a resistance. The parameter a is inversely proportional to the cross-bridge cycling rate, and b is proportional to the number of sarcomeres in line in a muscle. Draw the resistance (load)–velocity curve predicted by this equation by plotting the points $F = 0$ and $F = F_0$. Values of v are on the vertical axis; values of F are on the horizontal axis; a, b, and F_0 are constants.

   a. Notice that the curve generated from this equation is the same as that in Figure 8-16, p. 264. Why does the curve have this shape? That is, what does the shape of the curve tell you about muscle performance in general?

   b. What happens to the resistance (load)–velocity curve when F_0 is increased? When the cross-bridge cycling rate is increased? When the size of the muscle is increased? How will each of these changes affect the performance of the muscle?

Applying Clinical Reasoning

Jason W. is waiting impatiently for the doctor to finish removing the cast from his leg, which Jason broke the last day of school 6 weeks ago. Summer vacation is half over, and he hasn't been able to swim, play baseball, or ride his bike. When the cast is finally off, Jason's excitement gives way to concern when he sees that the injured limb is noticeably smaller in diameter than his normal leg. What explains this reduction in size? How can the leg be restored to its normal size and functional ability?

Thinking at a Higher Level

1. Why does regular aerobic exercise provide more cardiovascular benefit than weight training does? (*Hint:* The heart responds to the demands placed on it in a way similar to that of skeletal muscle.)

2. Put yourself in the position of the scientists who discovered the sliding filament mechanism of muscle contraction by considering what molecular changes must be involved to account for the observed alterations in the banding pattern during contraction. If you were comparing a relaxed and contracted muscle fiber under an electron microscope (see Figure 8-3, p. 254), how could you determine that the thin filaments do not change in length during muscle contraction? You cannot see or measure a single thin filament at this magnification. (*Hint:* What landmark in the banding pattern represents each end of the thin filament? If these landmarks are the same distance apart in a relaxed and contracted fiber, then the thin filaments must not change in length.) How could you determine that thick filaments remain the same length?

3. What type of off-the-snow training would you recommend for a competitive downhill skier versus a competitive cross-country skier? What adaptive skeletal muscle changes would you hope to accomplish in each case?

4. Explain how the rate of firing of the muscle spindle receptors (primary and secondary endings) would change if (a) the gamma motor neurons are activated, but the alpha motor neurons are not activated and (b) the gamma motor neurons are not activated, but the alpha motor neurons are activated.

5. When the bladder is filled and the micturition (urination) reflex is initiated, the nervous supply to the bladder promotes contraction of the bladder and relaxation of the external urethral sphincter, a ring of muscle that guards the exit from the bladder. If the time is inopportune for bladder emptying when the micturition reflex is initiated, the external urethral sphincter can be voluntarily tightened to prevent urination even though the bladder is contracting. Using your knowledge of the muscle types and their innervation, of what types of muscle are the bladder and the external urethral sphincter composed, and what branch of the efferent division of the peripheral nervous system supplies each of these muscles?

Cardiac Physiology

Homeostasis Highlights

To maintain homeostasis, essential materials such as O_2 and nutrients must continually be picked up from the external environment and delivered to the cells, and waste products must continually be removed. Furthermore, excess heat generated by muscles must be transported to the skin where it can be lost from the body surface to help maintain body temperature. Homeostasis also depends on the transfer of hormones, which are important regulatory chemical messengers, from their site of production to their site of action. The **circulatory system**, which contributes to homeostasis by serving as the body's transport system, consists of the heart, blood vessels, and blood.

All body tissues constantly depend on the life-supporting blood flow the **heart** provides them by contracting, or beating. The heart drives blood through the blood vessels for delivery to the tissues in sufficient amounts, whether the body is at rest or engaging in vigorous exercise.

9.1 Anatomy of the Heart

From just days following conception until death, the beat goes on. Throughout an average human life span, the heart contracts about 3 billion times, never stopping except for a fraction of a second to fill between beats. Within about 3 weeks after conception, the heart of the developing embryo starts to function. It is the first organ to become functional. At this time, the human embryo is only a few millimeters long, about the size of a capital letter on this page.

The heart develops so early and is so crucial throughout life because the circulatory system is the body's transport system. A human embryo, having little yolk available as food, depends on promptly establishing a circulatory system that can interact with the mother's circulation to pick up and distribute to the developing tissues the supplies needed for survival and growth. Thus begins the story of the circulatory system, which serves throughout life as a vital pipeline for transporting materials on which the cells of the body absolutely depend.

The **circulatory system** has three components:

1. The **heart** is the pump that imparts pressure to the blood to establish the pressure gradient needed for blood to flow to the tissues. Like all liquids, blood flows down a pressure gradient from an area of higher pressure to an area of lower pressure. This chapter focuses on cardiac physiology (*cardia* means "heart").

2. The **blood vessel**s are the passageways through which blood is directed and distributed from the heart to all parts of the body and subsequently returned to the heart. The smallest of the blood vessels are designed for rapid exchange of materials between the surrounding tissues and the blood within the vessels (see Chapter 10).

3. **Blood** is the transport medium within which materials being transported long distances in the body, such as O_2, CO_2, nutrients, wastes, electrolytes, and hormones, are dissolved or suspended (see Chapter 11).

Blood travels continuously through the circulatory system to and from the heart through two separate vascular (blood vessel) loops, both originating and terminating at the heart (❚Figure 9-1). The **pulmonary circulation** consists of a closed loop of vessels carrying blood between the heart and the lungs (*pulmo* means "lung"). The **systemic circulation** is a circuit of vessels carrying blood between the heart and all body systems (except for the air sacs of the lungs, which are supplied by the pulmonary circulation). Each of these vascular loops forms a figure "8." The pulmonary circulation simultaneously loops through the right lung and the left lung; the systemic circulation simultaneously loops through the upper half and the lower half of the body.

The heart is positioned in the middle of the thoracic cavity.

The heart is a hollow, muscular organ about the size of a clenched fist. It lies in the **thoracic** (chest) **cavity** about midline between the **sternum** (breastbone) anteriorly and the **vertebrae**

KEY
- ▪ O_2-rich blood
- ▪ O_2-poor blood
❚Figure 9-1 **Pulmonary and systemic circulations in relation to the heart.** The circulatory system consists of two separate vascular loops: the pulmonary circulation, which carries blood between the heart and lungs, and the systemic circulation, which carries blood between the heart and organ systems. Each of these loops forms a figure "8," with the pulmonary circulation simultaneously supplying the right and left lungs and the systemic circulation simultaneously supplying the upper body and lower body.

FIGURE FOCUS: *Examine this figure to correctly complete the following description of blood flow through the heart. The (right/left) side of the heart receives O_2-poor blood from the (systemic/pulmonary) circulation and pumps it into the (systemic/pulmonary) circulation. The (right/left) side of the heart receives O_2-rich blood from the (systemic/pulmonary) circulation and pumps it into the (systemic/pulmonary) circulation.*

(backbone) posteriorly. Place your hand over your heart. People usually put their hand on the left side of the chest, even though the heart is actually in the middle. The heart has a broad **base** at the top and tapers to a pointed tip, the **apex**, at the bottom. It is situated at an angle under the sternum so that its base lies predominantly to the right and the apex lies to the left of the sternum. When the heart beats forcefully, the apex thumps against the inside of the chest wall on the left. Because we are aware of the beating heart through the apex beat on the left, we tend to think—erroneously—that the entire heart is on the left. The heart's position between bony structures anteriorly and posteriorly makes it possible to manually drive blood out of the heart when it is not pumping effectively. Rhythmically depressing the sternum compresses the heart between the sternum and the vertebrae so that blood is squeezed out into the blood vessels, maintaining blood flow to the tissues. This *external cardiac compression,* which is part of **cardiopulmonary resuscitation (CPR)**, may be lifesaving until appropriate therapy can restore the heart to normal function.

The heart is a dual pump.

Although anatomically the heart is a single organ, the right and left sides of the heart function as two separate pumps. The heart is divided into right and left halves and has four chambers, an upper and a lower chamber within each half (▮Figure 9-2a). The upper chambers, the **atria** (singular, *atrium*), receive blood returning to the heart and transfer it to the lower chambers, the **ven-tricles**, which pump blood from the heart. The vessels that return blood from the tissues to the atria are **veins**, and those that carry blood away from the ventricles to the tissues are **arteries**. The two halves of the heart are separated by the **sep-tum**, a continuous muscular partition that prevents blood mixing from the two sides of the heart. This separation is extremely important because the right side of the heart receives and pumps O_2-poor blood, whereas the left side of the heart receives and pumps O_2-rich blood.
The Complete Circuit of Blood Flow Let us look at how the heart functions as a dual pump by tracing a drop of blood through one complete circuit (▮Figure 9-2a). Blood returning from the systemic circulation enters the right atrium via two large veins, the **venae cavae**, one returning blood from above and the other returning blood from below heart level. The drop of blood entering the right atrium has returned from the body tissues, where O_2 has been taken from it and CO_2 has been added to it. This partially deoxygenated blood flows from the right atrium into the right ventricle, which pumps it out through the **pulmonary artery**. This artery immediately forms two branches, one going to each of the two lungs. Thus, *the right side of the heart receives deoxygenated blood from the systemic circulation and pumps it into the pulmonary circulation.*

▮**Figure 9-2 Blood flow through and pump action of the heart.** (a) The arrows indicate the direction of blood flow. To illustrate the direction of blood flow through the heart, all of the heart valves are shown open, which is never the case. (b) Note that the left ventricular wall is much thicker than the right wall.

Within the lungs, the drop of blood loses its extra CO_2 and picks up a fresh supply of O_2 by means of gas exchange with the air sacs before being returned to the left atrium via the **pulmonary veins** coming from both lungs. This O_2-rich blood returning to the left atrium subsequently flows into the left ventricle, the pumping chamber that propels the blood to the body systems—that is, *the left side of the heart receives oxygenated blood from the pulmonary circulation and pumps it into the systemic circulation.* The single large artery carrying blood away from the left ventricle is the **aorta**. Major arteries branch from the aorta to bring blood to the various organs.

In contrast to the pulmonary circulation, in which all the blood flows through the lungs, the systemic circulation may be viewed as a series of parallel pathways. Part of the blood pumped out by the left ventricle goes to the digestive system, part to the kidneys, part to the brain, part to the muscles, and so on (see ▐Figure 10-1, p. 336). Even the heart muscle itself and the lung tissue other than the air sacs, namely the airways and lung connective tissue, receive blood from the left ventricle. Thus, the output of the left ventricle is distributed so that each part of the body receives a fresh blood supply. Accordingly, the drop of blood we are tracing goes to only one of the systemic organs. Tissue cells within the organ take O_2 from the blood and use it to oxidize nutrients for energy production; in the process, the tissue cells form CO_2 as a waste product that is added to the blood (see pp. 5 and 39). The drop of blood, now partially depleted of O_2 content and increased in CO_2 content, returns to the right side of the heart, which again pumps it to the lungs for gas exchange with the air sacs. One circuit is complete.

Comparison of the Right and Left Pumps Both sides of the heart simultaneously pump equal amounts of blood. The volume of O_2-poor blood being pumped to the lungs by the right side of the heart soon becomes the same volume of O_2-rich blood being delivered to the tissues by the left side of the heart. The pulmonary circulation is a low-pressure, low-resistance system, whereas the systemic circulation is a high-pressure, high-resistance system. Pressure is the force exerted on the vessel walls by the blood pumped into them by the heart. Resistance is the opposition to blood flow, largely caused by friction between the flowing blood and the vessel wall. Even though the right and left sides of the heart pump the same amount of blood, the left side works harder because it pumps an equal volume of blood at a higher pressure into a higher-resistance and longer system. Accordingly, the heart muscle on the left side is thicker than the muscle on the right side, making the left side a stronger pump (▐Figure 9-2a and b).

Pressure-operated heart valves ensure that blood flows in the right direction through the heart.

Blood flows through the heart in one fixed direction—from veins, to atria, to ventricles, to arteries. The presence of four one-way **heart valves** ensures this unidirectional flow of blood. The valves are positioned so that they open and close passively because of pressure differences, similar to a one-way door

When pressure is greater behind the valve, it opens.

Valve opened

When pressure is greater in front of the valve, it closes. Note that when pressure is greater in front of the valve, it does not open in the opposite direction; that is, it is a one-way valve.

Valve closed; does not open in opposite direction
▐Figure 9-3 **Mechanism of valve action**.

(▐Figure 9-3). A forward pressure gradient (that is, a greater pressure behind the valve) forces the valve open, much as you open a door by pushing on one side of it, whereas a backward pressure gradient (that is, a greater pressure in front of the valve) forces the valve closed, just as you apply pressure to the opposite side of the door to close it. Note that a backward gradient can force the valve closed but cannot force it to swing open in the opposite direction—that is, heart valves are not like swinging, saloon-type doors.

Atrioventricular Valves Between the Atria and Ventricles Two of the heart valves, the **right** and **left atrioventricular (AV) valves**, are positioned between the atrium and the ventricle on the right and the left sides, respectively (▐Figure 9-4a). These valves let blood flow from the atria into the ventricles during ventricular filling (when atrial pressure exceeds ventricular pressure) but prevent the backflow of blood from the ventricles into the atria during ventricular emptying (when ventricular pressure greatly exceeds atrial pressure). If the rising ventricular pressure did not force the AV valves to close as the ventricles contracted to empty, much of the blood would inefficiently be forced back into the atria and veins instead of being pumped into the arteries. The right AV valve is also called the **tricuspid valve** (*tri* means "three") because it consists of three cusps or leaflets (▐Figure 9-4b). Likewise, the left AV valve, which has two cusps, is often called the **bicuspid valve** (*bi* means "two") or the **mitral valve** (because of its physical resemblance to a mitre, or a bishop's traditional hat).

The edges of the AV valve leaflets are fastened by tough, thin cords of tendinous-type tissue, the **chordae tendineae**, which prevent the valve from *everting* (that is, from being forced by the high ventricular pressure to open in the opposite direction into the atria). These cords extend from the edges of each cusp and attach to small, nipple-shaped **papillary muscles**, which protrude from the inner surface of the ventricular walls (*papilla* means "nipple"). When the ventricles contract, the papillary muscles also contract, pulling downward on the chordae tendineae. This pulling exerts tension on the closed AV valve cusps to hold them in position, much like tethering ropes hold down a hot-air balloon. This action helps keep the valve tightly sealed in the face of a strong backward pressure gradient (▐Figure 9-4c).

(d) Prevention of eversion of semilunar valves

❚Figure 9-4 Heart valves. Eversion of the AV valves is prevented by tension on the valve leaflets exerted by the chordae tendineae when the papillary muscles contract. When the semilunar valves are swept closed, their up-turned edges fit together in a deep, leakproof seam that prevents valve eversion.

Semilunar Valves Between the Ventricles and Major Arteries The two remaining heart valves, the **aortic** and **pulmonary valves**, lie at the juncture where the major arteries leave the ventricles (❚Figure 9-4a). They are known as **semilunar valves** because they have three cusps, each resembling a shallow half-moon-shaped pocket (*semi* means "half"; *lunar* means "moon") (❚Figure 9-4b). These valves are forced open when the left and right ventricular pressures exceed the pres-

sure in the aorta and pulmonary artery, respectively, during ventricular contraction and emptying. Closure results when the ventricles relax and ventricular pressures fall below the aortic and pulmonary artery pressures. The closed valves prevent blood from flowing from the arteries back into the ventricles from which it has just been pumped.

The semilunar valves are prevented from everting by the anatomic structure and positioning of the cusps. When on ventricular relaxation a backward pressure gradient is created, the back surge of blood fills the pocketlike cusps and sweeps them into a closed position, with their unattached upturned edges fitting together in a deep, leak-proof seam (❚Figure 9-4d).

No Valves Between the Atria and Veins Even though there are no valves between the atria and veins, backflow of blood from the atria into the veins usually is not a significant problem for two reasons: (1) Atrial pressures usually are not much higher than venous pressures, and (2) the sites where the venae cavae enter the atria are partially compressed during atrial contraction.

Fibrous Skeleton Surrounding the Valves Four interconnecting rings of dense connective tissue known as the **fibrous skeleton** of the heart surround and support the four heart valves, similar to the way the interconnected plastic rings hold together a six pack of beverage cans (❚Figure 9-5). The fibrous skeleton also separates the atria from the ventricles and provides a fairly rigid structure for attachment of the cardiac muscle. The atrial muscle mass is anchored above the rings, and the ventricular muscle mass is attached to the bottom of the rings.

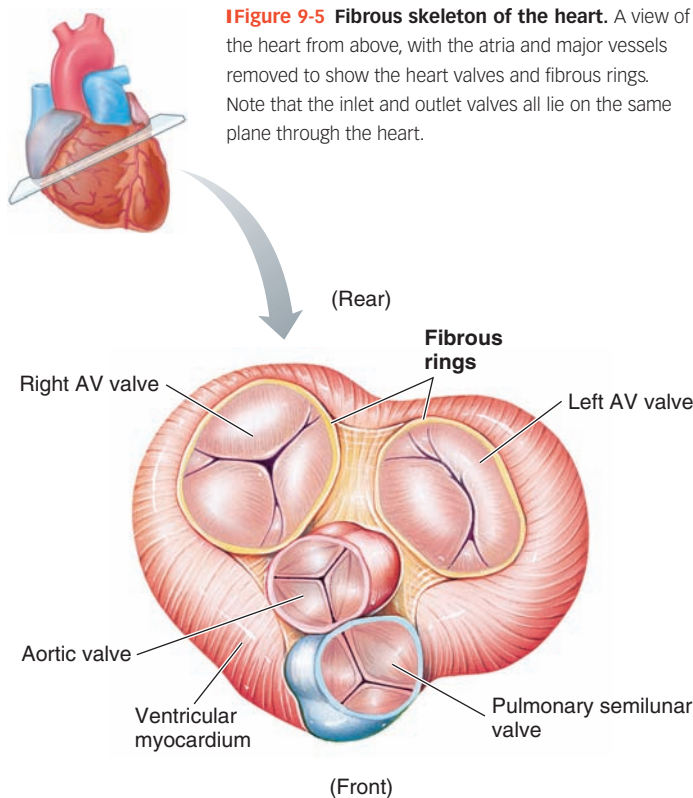
It might seem surprising that the inlet valves to the ventricles (the AV valves) and the outlet valves from the ventricles (the semilunar valves) all lie on the same plane through the heart, as delineated by the fibrous skeleton. This relationship comes about because the heart forms from a single tube that


Figure 9-5 Fibrous skeleton of the heart. A view of the heart from above, with the atria and major vessels removed to show the heart valves and fibrous rings. Note that the inlet and outlet valves all lie on the same plane through the heart.

(a) Bundles of cardiac muscle are arranged spirally around the ventricle. When they contract, they "wring" blood from the apex to the base where the major arteries exit.

Intercalated discs

Manfred Kage/Science Source

(b) Cardiac muscle fibers branch and are interconnected by intercalated discs.

bends on itself and twists on its axis during embryonic development. Another outcome of developmental twisting is that the cardiac muscle fibers run spirally around the blood-filled chambers, an arrangement that helps the heart pump blood more efficiently. Let us see how.

The heart walls are composed primarily of spirally arranged cardiac muscle fibers.

The heart wall has three distinct layers:

■ A thin, inner layer, the **endothelium**, a unique type of epithelial tissue that lines the entire circulatory system

■ A middle layer, the **myocardium**, which is composed of cardiac muscle and constitutes the bulk of the heart wall (*myo* means "muscle")

■ A thin, external layer, the **epicardium**, that covers the heart (*epi* means "on")

The myocardium consists of interlacing bundles of cardiac muscle fibers arranged spirally around the circumference of the heart (❚Figure 9-6a). As a result of this arrangement, when the ventricular muscle contracts and shortens, the diameter of the ventricular chambers is reduced while the apex is simultaneously pulled upward toward the top of the heart in a rotating manner. This exerts a "wringing" effect, efficiently exerting pressure on the blood within the enclosed chambers and directing it upward toward the openings of the major arteries that exit at the base of the ventricles.

Desmosome

Plasma membranes of adjacent cardiac muscle fibers

Gap junction

Action potential

Intercalated disc

(c) Intercalated discs contain two types of membrane junctions: mechanically important desmosomes that hold the cardiac cells together and electrically important gap junctions that link the cells of each chamber into a functional syncytium.

❚Figure 9-6 **Organization of cardiac muscle fibers.**

To support their ongoing, rhythmic, contractile activity, cardiac muscle cells have an abundance of energy-generating mitochondria, and they receive a rich blood supply, which is delivered by about one capillary for each myocardial fiber.

Cardiac muscle fibers are interconnected by intercalated discs and form functional syncytia.

The individual cardiac muscle cells are interconnected to form branching fibers, with adjacent cells joined end to end at specialized structures called **intercalated discs**[1] (❙Figure 9-6b). Two types of membrane junctions are present within an intercalated disc: desmosomes and gap junctions (❙Figure 9-6c). A *desmosome,* a type of adhering junction that mechanically holds cells together, is particularly abundant in tissues such as the heart that are subject to considerable mechanical stress (see p. 61). At intervals along the intercalated disc, the opposing membranes approach each other closely to form *gap junctions,* which are areas of low electrical resistance that allow action potentials to spread from one cardiac cell to adjacent cells (see p. 62). Some specialized cardiac muscle cells can generate action potentials without any nervous stimulation. When one of the cardiac cells spontaneously undergoes an action potential, the electrical impulse spreads to all the other cells that are joined by gap junctions in the surrounding muscle mass so that they become excited and contract as a single, *functional syncytium* (see p. 291). The atria and the ventricles each form a functional syncytium and contract as separate units. The synchronous contraction of the muscle cells that make up the walls of each of these chambers produces the force needed to eject the enclosed blood.

No gap junctions join the atrial and ventricular contractile cells; furthermore, the atria and the ventricles are separated by the electrically nonconductive fibrous skeleton that surrounds and supports the valves. However, an important, specialized conduction system facilitates and coordinates transmission of electrical excitation from the atria to the ventricles to ensure synchronization between atrial and ventricular pumping.

Heart muscle performs an endocrine function in addition to pumping blood. The atria and ventricles each secrete a hormone involved in regulation of blood pressure. These related hormones both act on the kidneys to promote elimination of water-retaining salt into the urine. The resultant loss of water in the urine reduces blood volume and blood pressure accordingly. This hormonal action of cardiac muscle cells will be discussed further in a later chapter.

The heart is enclosed by the pericardial sac.

The heart is enclosed in the double-walled, membranous **pericardial sac** (*peri* means "around"). The sac consists of two layers—a tough, fibrous covering and a secretory lining. The outer fibrous covering of the sac attaches to the connective tis-

sue partition that separates the lungs. This attachment anchors the heart so that it remains properly positioned within the chest. The sac's secretory lining secretes a thin **pericardial fluid**, which provides lubrication to prevent friction between the pericardial layers as they glide over each other with every beat of the heart.

Clinical Note **Pericarditis**, an inflammation of the pericardial sac that results in painful friction between the two pericardial layers, occurs occasionally because of viral or bacterial infection.

We next explain how action potentials are initiated and spread throughout the heart, followed by a discussion of how this electrical activity brings about coordinated pumping.

Check Your Understanding 9.1

1. Schematically draw the relationship of the pulmonary circulation and the systemic circulation to the chambers of the heart.

2. Name and discuss the functions of the four heart valves.

3. Describe an intercalated disc.

9.2 Electrical Activity of the Heart

Contraction of cardiac muscle cells to eject blood is triggered by action potentials sweeping across the muscle cell membranes. The heart contracts, or beats, rhythmically as a result of action potentials that it generates by itself, a property called **autorhythmicity**, or **automaticity** (*auto* means "self"). There are two specialized types of cardiac muscle cells:

1. **Contractile cells**, which are 99% of the cardiac muscle cells, do the mechanical work of pumping. These working cells normally do not initiate their action potentials.

2. **Autorhythmic cells**, the small but extremely important remainder of the cardiac cells, do not contract but instead are specialized for initiating and conducting the action potentials responsible for contraction of the working cells.

Cardiac autorhythmic cells display pacemaker activity.

In contrast to nerve and skeletal muscle cells, in which the membrane remains at constant resting potential unless the cell is stimulated, the cardiac autorhythmic cells do not have a resting potential. Instead, they display *pacemaker activity*—that is, their membrane potential slowly depolarizes, or drifts, between action potentials until threshold is reached, at which time the membrane fires or has an action potential. An autorhythmic cell membrane's slow drift to threshold is called the **pacemaker potential** (❙Figure 9-7; see also p. 291). Through repeated cycles of drift and fire, these autorhythmic cells cyclically initiate action potentials, which then spread throughout the heart to trigger rhythmic beating without any nervous stimulation.

---

[1]Many sources use the spelling *disk* in *intercalated disc*. However, the Federative International Committee on Anatomical Terminology indicates that *disc* is the preferred spelling for anatomical references.
Figure 9-7 **Pacemaker activity of cardiac autorhythmic cells.** The first half of the pacemaker potential is the result of simultaneous opening of unique funny channels, which permits inward Na^+ current, and closure of K^+ channels, which reduces outward K^+ current. The second half of the pacemaker potential is the result of opening of T-type Ca^{2+} channels. Once threshold is reached, the rising phase of the action potential is the result of opening of L-type Ca^{2+} channels, whereas the falling phase is the result of opening of K^+ channels.

FIGURE FOCUS: *How would a low ECF K^+ concentration affect the rate of slow depolarization to threshold in an autorhythmic cell?*

Pacemaker Potential in Autorhythmic Cells Complex interactions of several different ionic mechanisms are responsible for the pacemaker potential. The most important changes in ion movement that give rise to the pacemaker potential are (1) an increased inward Na^+ current, (2) a decreased outward K^+ current, and (3) an increased inward Ca^{2+} current.

The initial phase of the slow depolarization to threshold is caused by net Na^+ entry through a type of voltage-gated channel found only in cardiac pacemaker cells. Typically, voltage-gated channels open when the membrane becomes less negative (depolarizes), but these unique channels open when the potential becomes more negative (hyperpolarizes) at the end of repolarization from the previous action potential. Because of their unusual behavior, they are called **funny,** or **I_f, channels.** When one action potential ends and the I_f channels open, the resultant depolarizing net inward Na^+ current through these open channels starts immediately moving the pacemaker cell's membrane potential toward threshold once again.

The second mechanism contributing to this pacemaker potential is a progressive reduction in the passive outward flux of K^+. In cardiac autorhythmic cells, permeability to K^+ does not remain constant between action potentials as it does in nerve and skeletal muscle cells. The K^+ channels that opened during the falling phase of the preceding action potential slowly close at negative potentials. This slow closure gradually diminishes the outflow of K^+ down its concentration gradient. The resultant slow decline in the rate of K^+ efflux occurring simul-

taneous with the slow inward leak of Na^+ through the open I_f channels further contributes to the early drift toward threshold.

The third ionic contribution to pacemaker potential is increased Ca^{2+} entry. In the second half of the pacemaker potential, the I_f channels close and transient Ca^{2+} channels **(T-type Ca^{2+} channels)**, one of two types of voltage-gated Ca^{2+} channels, open before the membrane reaches threshold. ("T" stands for *transient*.) The resultant brief influx of Ca^{2+} further depolarizes the membrane, bringing it to threshold, at which time the transient Ca^{2+} channels close.

These permeability changes in surface membrane ion channels that cyclically bring the membrane of autorhythmic cells to threshold are collectively termed the **membrane clock mechanism**, which was long thought to be solely responsible for the pacemaker potential. Recent evidence, however, suggests that another clock, the **Ca^{2+} clock mechanism**, acts concurrently and independently of the membrane clock as a redundant means of self-depolarizing the membrane of autorhythmic cells to threshold. The Ca^{2+} clock depends on local Ca^{2+} recycling within a pacemaker cell. Spontaneous, rhythmic local releases of Ca^{2+} from the sarcoplasmic reticulum (SR) (see p. 258) increase the cytosolic Ca^{2+} concentration. Each time the cytosolic Ca^{2+} concentration rises, the *Na^+–Ca^{2+} exchanger (NCX)*, which is a plasma membrane antiport carrier (see p. 74), repetitively transports one intracellular Ca^{2+} ion out for every three extracellular Na^+ ions it moves in. This exchange leads to net inward movement of positive ions, a process that gradually depolarizes the autorhythmic cell to threshold. These two clocks act cooperatively to ensure periodic generation of the pacemaker potential that drives cardiac rhythmicity. This cooperative relationship between the membrane clock and Ca^{2+} clock is known as the **coupled-clock system**. The same regulatory mechanisms influence the "ticking speed" of both clocks so that they are synchronized to bring the membrane of pacemaker cells to threshold at a frequency befitting the body's momentary needs, such as speeding up the heart rate during exercise.

Next we see what happens when the pacemaker potential brings the membrane to threshold.

Action Potential in Autorhythmic Cells Once threshold is reached, the rising phase of the action potential occurs in response to activation of a long-lasting, voltage-gated Ca^{2+} channel (**L-type Ca^{2+} channel**; "L" standing for *long-lasting*) and a subsequently large influx of Ca^{2+}. The Ca^{2+}-induced rising phase of a cardiac pacemaker cell differs from that in nerve and skeletal muscle cells, where Na^+ influx rather than Ca^{2+} influx swings the potential in the positive direction.

The falling phase is the result, as usual, of the K^+ efflux that occurs when K^+ permeability increases on activation of voltage-gated K^+ channels, coupled with closure of the L-type Ca^{2+} channels. After the action potential is over, slow closure of these K^+ channels contributes to the next slow depolarization to threshold.

Ca^{2+} influx during the rising phase, combined with active reuptake of Ca^{2+} by the sarcoplasmic/endoplasmic reticulum Ca^{2+} ATPase pump (SERCA pump; see p. 261), refills the intracellular Ca^{2+} stores. The Na^+–K^+ pump returns to the extracel-

lular fluid (ECF) the Na^+ that moved into the pacemaker cell during the early phase of slow depolarization as well as the Na^+ that enters via NCX. Simultaneously the pump moves back into the cell the K^+ that exited during the falling phase. These actions reset the Ca^{2+} clock and membrane clock for another cycle of slow depolarization to threshold and initiation of another self-induced action potential.

The sinoatrial node is the normal pacemaker of the heart.

The specialized noncontractile cardiac cells capable of auto-rhythmicity lie in the following specific sites (❙Figure 9-8):

1. The **sinoatrial node (SA node)**, a small, specialized region in the right atrial wall near the opening of the superior (upper) vena cava.

2. The **atrioventricular node (AV node)**, a small bundle of specialized cardiac muscle cells located at the base of the right atrium near the septum, just above the junction of the atria and ventricles.

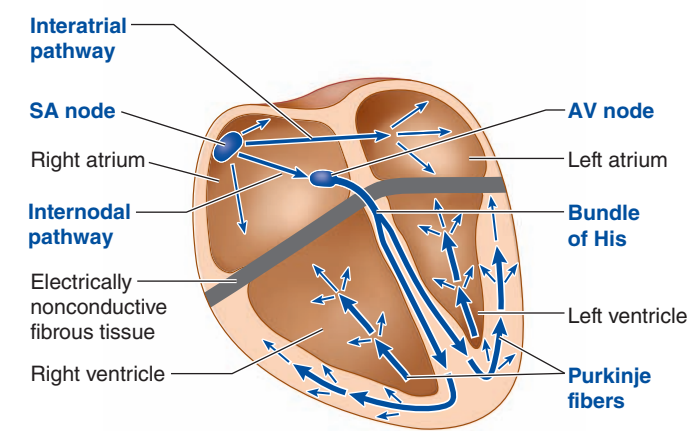
3. The **bundle of His** (pronounced *Hiss*) or **atrioventricular bundle**, a tract of specialized cells that originates at the AV node and enters the septum between the ventricles. Here, it divides to form the right and left bundle branches that travel down the septum, curve around the tip of the ventricular chambers, and travel back toward the atria along the outer walls.

4. **Purkinje fibers**, small terminal fibers that extend from the bundle of His and spread throughout the ventricular myocardium, much like small twigs of a tree branch.

Normal Pacemaker Activity Because these various auto-rhythmic cells have different rates of slow depolarization to threshold, the rates at which they can generate action potentials also differ. The number of action potentials per minute each type of autorhythmic cell can generate under resting conditions is as follows:

- The rate for the SA node is 70–80
- The rate for the AV node is 40–60
- The rate for the Bundle of His and Purkinje fibers is 20–40

The heart cells with the fastest rate of action potential initiation are localized in the SA node. Once an action potential occurs in any cardiac muscle cell, it is propagated throughout the rest of the myocardium via gap junctions and the specialized conduction system. Therefore, the SA node, which normally has the fastest rate of autorhythmicity, at 70 to 80 action potentials per minute, drives the rest of the heart at this rate and thus is known as the **pacemaker** of the heart—that is, the entire heart becomes excited, triggering the contractile cells to contract and the heart to beat at the pace set by SA node autorhythmicity, normally at 70 to 80 beats per minute. The other autorhythmic tissues cannot assume their own naturally slower rates because they are activated by action potentials originating in the SA node before they can reach threshold at their slower rhythm.

The following analogy shows how the SA node drives the rest of the heart at its own pace. Suppose a train has 100 cars, 3 of which are engines capable of moving on their own; the other 97 cars must be pulled (❙Figure 9-9a). One engine (the SA node) can travel at 70 miles per hour (mph) on its own, another engine (the AV node) at 50 mph, and the last engine (the Purkinje fibers) at 30 mph. If all these cars are joined, the engine that travels at 70 mph pulls the rest of the cars at that speed. The engines that can travel at lower speeds on their own are pulled at a faster speed by the fastest engine and therefore cannot assume their slower rate as long as a faster engine drives them.
(a) Specialized conduction system of the heart


(b) Spread of cardiac excitation

❙Figure 9-8 **Specialized conduction system of the heart and spread of cardiac excitation.** An action potential initiated at the SA node first spreads throughout both atria. Two specialized atrial conduction pathways facilitate its spread: the interatrial and internodal pathways. The AV node is the only point where an action potential can spread from the atria to the ventricles. From the AV node, the action potential spreads rapidly throughout the ventricles, hastened by a specialized ventricular conduction system consisting of the bundle of His and Purkinje fibers.

The other 97 cars (nonautorhythmic, contractile cells), being unable to move on their own, likewise travel at the speed the fastest engine pulls them.

Abnormal Pacemaker Activity If for some reason the fastest engine breaks down (SA node damage), the next-fastest engine (AV node) takes over and the entire train travels at 50 mph—that is, if the SA node becomes nonfunctional such as from a heart attack, the AV node assumes pacemaker activity (IFigure 9-9b). If impulse conduction becomes blocked between the atria and the ventricles, the atria continue at the typical rate of 70 beats per minute, and the ventricular tissue, not being driven by the faster SA nodal rate, assumes its own, slower autorhythmic rate of about 30 beats per minute, initiated by the Purkinje fibers. This situation is like a breakdown of the second engine (AV node) so that the lead

engine (SA node) becomes disconnected from the slow third engine (Purkinje fibers) and the rest of the cars (IFigure 9-9c). The lead engine (and cars connected directly to it—that is, the atrial cells) continues at 70 mph while the rest of the train proceeds at 30 mph. This **complete heart block** occurs when the conducting tissue between the atria and the ventricles is damaged and becomes nonfunctional. A ventricular rate of 30 beats per minute supports only a very sedentary existence; in fact, the patient usually becomes comatose.

When a person has an abnormally low heart rate, as in SA node failure or heart block, an **artificial pacemaker** can be used. Such an implanted device rhythmically generates impulses that spread throughout the heart to drive both the atria and the ventricles at the typical rate of 70 beats per minute.

Occasionally, an area of the heart, such as a Purkinje fiber, becomes overly excitable and depolarizes more rapidly than the
(a) Normal pacemaker activity: Whole train goes **70 mph** (heart rate set by SA node, the fastest autorhythmic tissue).
(b) Takeover of pacemaker activity by AV node when the SA node is nonfunctional: Train goes **50 mph** (the next fastest autorhythmic tissue, the AV node, sets the heart rate).
(c) Takeover of ventricular rate by the slower ventricular autorhythmic tissue in complete heart block: First part of train goes **70 mph**; last part goes **30 mph** (atria are driven by SA node; ventricles assume own, much slower rhythm).
(d) Takeover of pacemaker activity by an ectopic focus: Train is driven by ectopic focus, which is now going faster than the SA node (the whole heart is driven more rapidly by an abnormal pacemaker).

IFigure 9-9 Analogy of pacemaker activity. In complete heart block (c), when ventricular rate is taken over by the slower ventricular autorhythmic tissue the atrial rate (not shown) is still driven by the SA node.

SA node. (The slow engine suddenly goes faster than the lead engine; ▮Figure 9-9d). This abnormally excitable area, an **ectopic focus**, initiates a premature action potential that spreads throughout the rest of the heart before the SA node can initiate a normal action potential (*ectopic* means "out of place"). The resultant contraction is called a **premature ventricular contraction (PVC)**. If the ectopic focus continues to discharge at its more rapid rate, pacemaker activity shifts from the SA node to the ectopic focus. The heart rate abruptly becomes greatly accelerated and continues this rapid rate for a variable period until the ectopic focus returns to normal. Such overly irritable areas may be associated with heart disease, but more frequently they occur in response to anxiety; lack of sleep; or excess caffeine, nicotine, or alcohol consumption.

We now turn to how an action potential, once initiated, is conducted throughout the heart.

The spread of cardiac excitation is coordinated to ensure efficient pumping.

Once initiated in the SA node, an action potential spreads throughout the rest of the heart. For efficient cardiac function, the spread of excitation should satisfy three criteria:

1. *Atrial excitation and contraction should be complete before the onset of ventricular contraction.* Complete ventricular filling requires that atrial contraction precede ventricular contraction. During cardiac relaxation, the AV valves are open, so venous blood entering the atria continues to flow directly into the ventricles. Almost 80% of ventricular filling occurs by this means before atrial contraction. When the atria do contract, more blood is squeezed into the ventricles to complete ventricular filling. Ventricular contraction then occurs to eject blood from the heart into the arteries.

If the atria and ventricles were to contract simultaneously, the AV valves would close immediately because ventricular pressures would greatly exceed atrial pressures. The ventricles have thicker walls and, accordingly, can generate more pressure. Atrial contraction would be unproductive because the atria could not squeeze blood into the ventricles through closed valves. Therefore, to ensure complete filling of the ventricles—to obtain the remaining 20% of ventricular filling that occurs during atrial contraction—the atria must become excited and contract before ventricular excitation and contraction. During a normal heartbeat, atrial contraction occurs about 160 msec before ventricular contraction.

2. *Excitation of cardiac muscle fibers should be coordinated to ensure that each heart chamber contracts as a unit to pump efficiently.* If the muscle fibers in a heart chamber became excited and contracted randomly rather than contracting simultaneously in a coordinated fashion, they would be unable to eject blood. A smooth, uniform ventricular contraction is essential to squeeze out the blood. As an analogy, assume you have a basting syringe full of turkey pan juice. If you merely poke a finger here or there into the rubber bulb of the syringe, you will not eject much juice. However, if you compress the bulb in a smooth, coordinated fashion, you can squeeze out the juice to baste the turkey.

Clinical Note In a similar manner, contraction of isolated cardiac muscle fibers cannot successfully pump blood. Such random, uncoordinated excitation and contraction of cardiac cells is known as **fibrillation**. Ventricular fibrillation is more serious than atrial fibrillation. Ventricular fibrillation rapidly causes death because of the heart's inability to pump blood. This condition can often be corrected by *electrical defibrillation,* in which a strong electrical current is applied on the chest wall. When this current reaches the heart, it depolarizes all parts of the heart simultaneously and serves as a "reset button." Usually the first part of the heart to recover is the SA node, which takes over pacemaker activity, again initiating impulses that trigger the synchronized contraction of the rest of the heart.

3. *The pair of atria and pair of ventricles should be functionally coordinated so that both members of the pair contract simultaneously.* This coordination permits synchronized pumping of blood into the pulmonary and systemic circulations.

The normal spread of cardiac excitation is carefully orchestrated to ensure that these criteria are met and the heart functions efficiently, as follows (see ▮Figure 9-8b).

Atrial Excitation An action potential originating in the SA node first spreads throughout both atria, primarily from cell to cell via gap junctions. In addition, several specialized conduction pathways speed up conduction of the impulse through the atria.

■ The *interatrial pathway* extends from the SA node within the right atrium to the left atrium. Because this pathway rapidly transmits the action potential from the SA node to the pathway's termination in the left atrium, a wave of excitation can spread across the gap junctions throughout the left atrium at the same time as excitation is similarly spreading throughout the right atrium. This ensures that both atria become depolarized to contract simultaneously.

■ The *internodal pathway* extends from the SA node to the AV node. The AV node is the only point of electrical contact between the atria and the ventricles; in other words, because the atria and the ventricles are structurally connected by electrically nonconductive fibrous tissue, the only way an action potential in the atria can spread to the ventricles is by passing through the AV node. The internodal conduction pathway directs the spread of an action potential originating at the SA node to the AV node to ensure sequential contraction of the ventricles following atrial contraction. Hastened by this pathway, the action potential arrives at the AV node within 30 msec of SA node firing.

Conduction Between the Atria and the Ventricles The action potential is conducted relatively slowly through the AV node. This slowness is advantageous because it allows time for complete ventricular filling. The impulse is delayed about 100 msec (the **AV nodal delay**), which enables the atria to become completely depolarized and to contract, emptying their contents into the ventricles, before ventricular depolarization and contraction occur.

Ventricular Excitation After the AV nodal delay, the impulse travels rapidly down the septum via the right and left branches of the bundle of His and throughout the ventricular myocardium via the Purkinje fibers. The network of fibers in this ventricular conduction system is specialized for rapid propagation of action potentials. Its presence hastens and coordinates the spread of ventricular excitation to ensure that the ventricles contract as a unit. The action potential is transmitted through the entire Purkinje fiber system within 30 msec.

Although this system carries the action potential rapidly to a large number of cardiac muscle cells, it does not terminate on every cell. The impulse quickly spreads from the excited cells to the rest of the ventricular muscle cells by means of gap junctions.

The ventricular conduction system is more highly organized and more important than the atrial conduction pathways. Because the ventricular mass is so much larger than the atrial mass, the ventricular conduction system is crucial for hastening the spread of excitation in the ventricles. Purkinje fibers can transmit an action potential six times faster than the ventricular syncytium of contractile cells could. If the entire ventricular depolarization process depended on cell-to-cell spread of the impulse via gap junctions, the ventricular tissue immediately next to the AV node would become excited and contract before the impulse had even passed to the heart apex. This, of course, would not allow efficient pumping. Rapid conduction of the action potential down the bundle of His and its swift, diffuse distribution throughout the Purkinje network lead to almost simultaneous activation of the ventricular myocardial cells in both ventricular chambers, which ensures a single, smooth, coordinated contraction that can efficiently eject blood into the systemic and pulmonary circulations at the same time.

The action potential of cardiac contractile cells shows a characteristic plateau.

The action potential in cardiac contractile cells, although initiated by the nodal pacemaker cells, varies considerably in ionic mechanisms and shape from the SA node potential (compare ❙Figures 9-7 and 9-10). Unlike the membrane of autorhythmic cells, the membrane of contractile cells remains essentially at rest, about −90 millivolts (mV), until excited by electrical activity propagated from the pacemaker. Myocardial contractile cells have several subclasses of K^+ channels. At resting potential, the type of K^+ channel that is open is especially leaky.[2] The resultant outward movement of K^+ through these channels keeps the resting potential close to the K^+ equilibrium potential at −90 mV. Once the membrane of a ventricular myocardial contractile cell is depolarized to threshold via current flow through gap junctions, an action potential is generated by a complicated interplay of changes in membrane permeability and potential as follows (❙Figure 9-10):

1. During the rising phase of the action potential, the membrane potential rapidly reverses to a positive value of about
❙Figure 9-10 **Action potential in cardiac contractile cells.** The action potential in cardiac contractile cells differs considerably from the action potential in cardiac autorhythmic cells (compare with Figure 9-7, p. 304). The rapid rising phase of the action potential in contractile cells is the result of Na^+ entry on opening of fast Na^+ channels at threshold. The early, brief repolarization after the potential reaches its peak is because of limited K^+ efflux on opening of transient K^+ channels, coupled with inactivation of the Na^+ channels. The prolonged plateau phase is the result of slow Ca^{2+} entry on opening of L-type Ca^{2+} channels, coupled with reduced K^+ efflux on closure of several types of K^+ channels. The rapid falling phase is the result of K^+ efflux on opening of ordinary voltage-gated K^+ channels, as in other excitable cells. Resting potential is maintained by opening of leaky K^+ channels.

FIGURE FOCUS: *Compare the role of L-type Ca^{2+} channels in development of an action potential in cardiac contractile cells and in autorhythmic cells.*

+20 to +30 mV (depending on the myocardial cell) as a result of activation of voltage-gated Na^+ channels and Na^+ subsequently rapidly entering the cell, as it does in other excitable cells undergoing an action potential (see p. 93). These are the same type of double-gated Na^+ channels found in nerve and skeletal muscle cells. At peak potential, the Na^+ permeability then rapidly plummets to its low resting value.

2. At peak potential, another subclass of K^+ channels transiently opens. The resultant fast, limited efflux of K^+ through these transient channels brings about a brief, small repolarization as the membrane becomes slightly less positive.

3. Unique to the cardiac contractile cells, however, the membrane potential is maintained close to this peak positive level for several hundred milliseconds, producing a **plateau phase** of the action potential. In contrast, the short action potential of neurons and skeletal muscle cells lasts 1 to 2 msec. This plateau is maintained by two voltage-dependent permeability changes: activation of "slow" L-type Ca^{2+} channels and a marked decrease in K^+ permeability in the cardiac contractile cell membrane. These permeability changes occur in response to the sudden change in voltage during the rising phase of the action

---

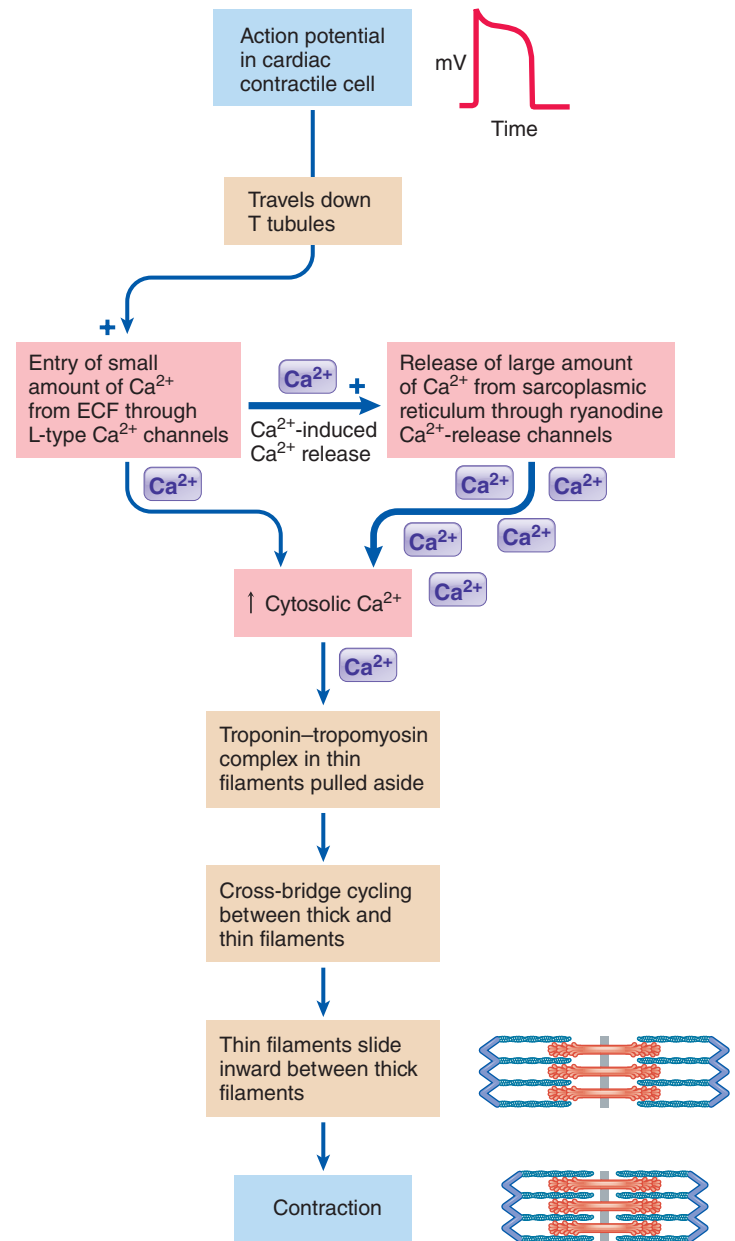
[2]For reasons beyond the scope of this book, this channel type is officially known as an *inward rectifier K^+ channel*, and the "ordinary" K^+ channel discussed shortly is called a *delayed rectifier K^+ channel.*

potential. Opening of the L-type Ca^{2+} channels results in a slow, inward diffusion of Ca^{2+} because Ca^{2+} is in greater concentration in the ECF. This continued influx of positively charged Ca^{2+} prolongs the positivity inside the cell and is primarily responsible for the plateau part of the action potential. This effect is enhanced by the concomitant decrease in K^+ permeability on closure of both the briefly opened transient K^+ channels and the leaky K^+ channels open at resting potential. The resultant reduction in outward movement of positively charged K^+ prevents rapid repolarization of the membrane and thus contributes to prolongation of the plateau phase.

4. The rapid falling phase of the action potential results from inactivation of the Ca^{2+} channels and delayed activation of "ordinary" voltage-gated K^+ channels, yet another subclass of K^+ channels identical to the ones responsible for repolarization in neurons and skeletal muscle cells. The decrease in Ca^{2+} permeability diminishes the slow, inward movement of positive Ca^{2+}, whereas the sudden increase in K^+ permeability simultaneously promotes rapid outward diffusion of positive K^+. Thus, as in other excitable cells, the cell returns to resting potential as K^+ leaves the cell. At resting potential, the ordinary voltage-gated K^+ channels close and the leaky K^+ channels open once again.

Next we see how this action potential initiates contraction.

Calcium Entry From the ECF Induces a Much Larger Ca^{2+} Release From the Sarcoplasmic Reticulum. In cardiac contractile cells, the L-type Ca^{2+} channels lie mostly in the transverse (T) tubules. (In fact, these channels are modified dihydropyridine receptors found in skeletal muscle T tubules; see p. 258.) As you just learned, these voltage-gated channels open during a local action potential. Thus, unlike in skeletal muscle, Ca^{2+} diffuses into the cytosol from the ECF across the T tubule membrane during a cardiac action potential. This entering Ca^{2+} triggers the opening of nearby ryanodine Ca^{2+}-release channels in the adjacent lateral sacs of the SR (see p. 258). By means of this action, termed **Ca^{2+}-induced Ca^{2+} release**, Ca^{2+} entering the cytosol from the ECF induces a much larger release of Ca^{2+} into the cytosol from the intracellular stores (❙Figure 9-11). The resultant local bursts of Ca^{2+} release, known as **Ca^{2+} sparks**, from the SR collectively increase the cytosolic Ca^{2+} pool sufficiently to turn on the contractile machinery. Ninety percent of the Ca^{2+} needed for muscle contraction comes from the SR. This extra supply of Ca^{2+}, coupled with the slow Ca^{2+} removal processes, is responsible for the long period of cardiac contraction, which lasts about three times longer than the contraction of a single skeletal muscle fiber (300 msec compared to 100 msec). This increased contractile time ensures adequate time to eject the blood.

As in skeletal muscle, the role of cytosolic Ca^{2+} is to bind with the troponin–tropomyosin complex and physically pull it aside to allow cross-bridge cycling and contraction (❙Figure 9-11 and see p. 256). However, unlike in skeletal muscle, in which sufficient Ca^{2+} is always released to turn on all the cross bridges, in cardiac muscle the extent of cross-bridge activity varies with the amount of cytosolic Ca^{2+}. As we will show, various regulatory factors can alter the amount of cytosolic Ca^{2+}.


❙Figure 9-11 **Excitation–contraction coupling in cardiac contractile cells.**

Removal of Ca^{2+} from the cytosol by energy-dependent mechanisms in both the plasma membrane (primarily by means of the Na^+–Ca^{2+} exchanger, or NCX) and the SR (via the SERCA pump) restores the blocking action of troponin and tropomyosin, so contraction ceases and the heart muscle relaxes.

A long refractory period prevents tetanus of cardiac muscle.

Like other excitable tissues, cardiac muscle has a refractory period. During the refractory period, a second action potential cannot be triggered until the membrane has recovered from the preceding action potential. In skeletal muscle, the refractory period is very short compared with the duration of the resulting contraction, so the fiber can be restimulated before the first contraction is complete to produce summation of contractions.

Rapidly repetitive stimulation that does not let the muscle fiber relax between stimulations results in a sustained, maximal contraction known as *tetanus* (see ❚ Figure 8-19, p. 267).

In contrast, cardiac muscle has a long refractory period that lasts about 250 msec because of the prolonged plateau phase of the action potential. This is almost as long as the period of contraction initiated by the action potential; a cardiac muscle fiber contraction averages about 300 msec (❚ Figure 9-12). Consequently, cardiac muscle cannot be restimulated until contraction is almost over, precluding summation of contractions and tetanus of cardiac muscle. This is a valuable protective mechanism because pumping of blood requires alternate periods of contraction (emptying) and relaxation (filling). A prolonged tetanic contraction would prove fatal: The heart chambers could not be filled and emptied again.

The chief factor responsible for the long refractory period is inactivation, during the prolonged plateau phase, of the Na^+ channels that were activated during the initial Na^+ influx of the rising phase—that is, the double-gated Na^+ channels are in their closed and not capable of opening conformation (see p. 92). Not until the membrane recovers from this inactivation process (when the membrane has already repolarized to resting), can the Na^+ channels be activated once again to begin another action potential.

The ECG is a record of the overall spread of electrical activity through the heart.

The electrical currents generated by cardiac muscle during depolarization and repolarization spread into the tissues around the heart and are conducted through the body fluids. A small part of this electrical activity reaches the body surface, where it can be detected using recording electrodes. The record produced is an **electrocardiogram,** or **ECG**. (Alternatively, the abbreviation EKG is often used, from the ancient Greek word *kardia,* instead of the Latin *cardia,* for "heart.")

When considering what an ECG represents, remember these three important points:

1. An ECG is a recording of that part of the electrical activity present in body fluids from the cardiac impulse that reaches the body surface, not a direct recording of the actual electrical activity of the heart.

2. The ECG is a complex recording representing the *overall* spread of activity throughout the heart during depolarization and repolarization. It is not a recording of a *single* action potential in a single cell at a single point in time. The record at any given time represents the sum of electrical activity in all the cardiac muscle cells, some of which may be undergoing action potentials while others may not yet be activated. For example, immediately after the SA node fires, the atrial cells are undergoing action potentials while the ventricular cells are still at resting potential. At a later point, the electrical activity spreads to the ventricular cells while the atrial cells are repolarizing. Therefore, the overall pattern of cardiac electrical activity varies with time as the impulse passes throughout the heart.

3. The recording represents comparisons in voltage detected by electrodes at two points on the body surface, not the actual potential. For example, the ECG does not record a potential when the ventricular muscle is either completely depolarized or completely repolarized; both electrodes are "viewing" the same potential, so no difference in potential between the two electrodes is recorded.

The exact pattern of electrical activity recorded from the body surface depends on the orientation of the recording electrodes. Electrodes may be loosely thought of as "eyes" that "see" electrical activity and translate it into a visible recording, the ECG record. Whether an upward or downward deflection is recorded is determined by the way the electrodes are oriented with respect to the current flow in the heart. For example, the spread of excitation across the heart is "seen" differently from the right arm, from the left leg, or from a recording directly over the heart. Even though the same electrical events are occurring in the heart, different waveforms representing the same electrical activity result when electrodes at different points on the body record this activity.

To provide a common basis for comparison and for recognizing deviations from normal, the same 12 conventional electrode arrangements, or leads, are routinely used for all ECG recordings (❚ Figure 9-13). When an electrocardiograph machine is connected between recording electrodes at two points on the body, the specific arrangement of each pair of connections is called a **lead**. The 12 leads each record electrical activity in the heart from different locations—six different electrode arrangements from the limbs and six chest leads at various sites around the heart.

❚Figure 9-12 **Relationship of an action potential and the refractory period to the duration of the contractile response in cardiac muscle.**

Different parts of the ECG record can be correlated to specific cardiac events.

Interpretation of the wave configurations recorded from each lead depends on a thorough knowledge of the sequence of cardiac excitation spread and the position of the heart relative to electrode placement. A normal ECG has three distinct waveforms: the P wave, the QRS complex, and the T wave (❙Figure 9-14). (The letters only indicate the orderly sequence of the waves. The inventor of the technique started in mid-alphabet when naming the waves.)

- The **P wave** represents atrial depolarization.
- The **QRS complex** represents ventricular depolarization.
- The **T wave** represents ventricular repolarization.

These waves of depolarization and repolarization bring about alternating contraction and relaxation of the heart, respectively.

Note the following points about the ECG record:

1. Firing of the SA node does not generate enough electrical activity to reach the body surface, so no wave is recorded for SA nodal depolarization. Therefore, the first recorded wave, the P wave, occurs when the wave of depolarization spreads across the atria.

2. In a normal ECG, no separate wave for atrial repolarization is visible. The electrical activity associated with atrial repolarization normally takes place simultaneously with ventricular depolarization and is masked by the QRS complex.

3. The P wave is smaller than the QRS complex because the atria have a smaller muscle mass than the ventricles and consequently generate less electrical activity.

4. At the following three points in time, no net current flow is occurring in the heart muscle, so the ECG remains at baseline:

   a. *During the AV nodal delay.* This delay is represented by the interval of time between the end of P and the onset of QRS; this segment of the ECG is known as the **PR segment**. (It is called the "PR segment" rather than the "PQ segment" because the Q deflection is small and sometimes absent, whereas the R deflection is the dominant wave of the complex.) Current is flowing through the AV node, but the magnitude is too small for the ECG electrodes to detect.

(a) Limb leads

(b) Chest leads

❙**Figure 9-13 Electrocardiogram leads.** (a) The six limb leads include leads I, II, III, aVR, aVL, and aVF. Leads I, II, and III are bipolar leads because two recording electrodes are used. The tracing records the *difference* in potential between the two electrodes. For example, lead I records the difference in potential detected at the right arm and left arm. The electrode placed on the right leg serves as a ground and does not record. The aVR, aVL, and aVF leads are unipolar leads. Even though two electrodes are used, only the actual potential under one "exploring" electrode is recorded. The other electrode is set at zero potential and serves as a neutral reference point. For example, the aVR lead records the potential reaching the right arm in comparison to the rest of the body. (b) The six chest leads, V₁ through V₆, are also unipolar leads. The exploring electrode records the potential of the cardiac muscle immediately beneath the electrode in six different locations surrounding the heart.

b. *When the ventricles are completely depolarized and the cardiac contractile cells are undergoing the plateau phase of their action potential before they repolarize,* represented by the **ST segment**. This segment lies between QRS and T; it coincides with the time during which ventricular activation is complete and the ventricles are contracting and emptying. Note that the ST segment is not a record of cardiac contractile activity. The ECG is a measure of the electrical activity that triggers the subsequent mechanical activity.

c. *When the heart muscle is completely repolarized,* after the T wave and before the next P wave. This period is called the **TP segment**, which coincides with the time when the ventricles are at rest and ventricular filling is taking place.

The ECG can detect abnormal heart rates and rhythms and heart muscle damage.

Clinical Note Because electrical activity triggers mechanical activity, abnormal electrical patterns are usually accompanied by abnormal contractile activity of the heart. Thus, evaluation of ECG patterns can provide useful information about the heart's status. The main deviations from normal that can be found through an ECG are (1) abnormalities in rate, (2) abnormalities in rhythm, and (3) cardiac myopathies (❙Figure 9-15). (For use of the ECG in stress tests, see the boxed feature on p. 314, ❙A Closer Look at Exercise Physiology.)

❙Figure 9-15 **Representative heart conditions detectable through electrocardiography.**

QRS complexes on the calibrated paper used to record an ECG. A rapid heart rate of more than 100 beats per minute is called **tachycardia** (*tachy* means "fast"), whereas a slow heart rate of fewer than 60 beats per minute is called **bradycardia** (*brady* means "slow").

Abnormalities in Rhythm *Rhythm* refers to the regularity or spacing of the ECG waves. Any variation from the normal rhythm and sequence of excitation of the heart is termed an **arrhythmia**. It may result from ectopic foci, alterations in SA node pacemaker activity, or interference with conduction. Heart rate is also often altered. *Premature ventricular contractions* originating from an ectopic focus are common deviations from normal rhythm. Other abnormalities in rhythm easily

detected on an ECG include atrial flutter, atrial fibrillation, ventricular fibrillation, and heart block.

Atrial flutter is characterized by a rapid but regular sequence of atrial depolarizations at rates between 200 and 380 beats per minute. The ventricles rarely keep pace with the racing atria. Because the conducting tissue's refractory period is longer than that of the atrial muscle, the AV node is unable to respond to every impulse that converges on it from the atria. Maybe only one out of every two or three atrial impulses successfully passes through the AV node to the ventricles. Such a situation is referred to as a *2:1 or 3:1 rhythm.* The fact that not every atrial impulse reaches the ventricle in atrial flutter is important because it precludes a rapid ventricular rate of more than 200 beats per minute. Such a high rate would not allow adequate time for ventricular filling between beats. In such a case, the output of the heart would be reduced to the extent that loss of consciousness or even death could result because of decreased blood flow to the brain.

Atrial fibrillation is characterized by rapid, irregular, uncoordinated depolarizations of the atria with no definite P waves. Accordingly, atrial contractions are chaotic and asynchronized. Because impulses reach the AV node erratically, the ventricular rhythm is also very irregular. The QRS complexes are normal in shape but occur sporadically. Variable lengths of time between ventricular beats are available for ventricular filling. Some ventricular beats come so close together that little filling can occur between beats. When less filling occurs, the subsequent contraction is weaker. In fact, some of the ventricular contractions may be too weak to eject enough blood to produce a palpable wrist pulse. In this situation, if the heart rate is determined directly, either by the apex beat or via the ECG, and the pulse rate is taken concurrently at the wrist, the heart rate exceeds the pulse rate. Such a difference in heart rate and pulse rate is known as a **pulse deficit**. Normally, the heart rate coincides with the pulse rate because each cardiac contraction initiates a pulse wave as it ejects blood into the arteries.

Ventricular fibrillation is a very serious rhythmic abnormality in which multiple impulses travel erratically in all directions around the ventricles. The ECG tracing is very irregular with no detectable pattern or rhythm. The resultant chaotic contractions are so disorganized that the ventricles are ineffectual as pumps. If circulation is not restored in less than four minutes through external cardiac compression or electrical defibrillation, irreversible brain damage occurs, and death is imminent.

Another type of arrhythmia, **heart block**, arises from defects in the cardiac conducting system. The atria still beat regularly, but the ventricles occasionally fail to be stimulated and thus do not contract following atrial contraction. Impulses between the atria and ventricles can be blocked to varying degrees. In some forms of heart block, only every second or third atrial impulse is passed to the ventricles. This is known as *2:1 or 3:1 block,* which can be distinguished from the 2:1 or 3:1 rhythm associated with atrial flutter by the rates involved. In heart block, the atrial rate is normal but the ventricular rate is considerably below normal, whereas in atrial flutter the atrial rate is very high, in accompaniment with a normal or above-normal ventricular rate. *Complete heart block* is characterized by complete dissociation between atrial and ventricular activity,

The What, Who, and When of Stress Testing

STRESS TESTS, OR GRADED EXERCISE TESTS, are conducted primarily to aid in diagnosing or quantifying heart or lung disease and to evaluate the functional capacity of asymptomatic individuals. The tests are usually given on motorized treadmills or bicycle ergometers (stationary, variable-resistance bicycles). Workload intensity (how hard the subject is working) is adjusted by progressively increasing the speed and incline of the treadmill or by progressively increasing the pedaling frequency and resistance on the bicycle. The test starts at a low intensity and continues until a prespecified workload is achieved, physiological symptoms occur, or the subject is too fatigued to continue.

During diagnostic testing, the patient is monitored with an ECG and blood pressure is taken each minute. A test is considered positive if ECG abnormalities occur (such as ST segment depression, inverted T waves, or dangerous arrhythmias) or if physical symptoms such as chest pain develop. A test that is interpreted as positive in a person who does not have heart disease is called a *false-positive test.* In men, false positives occur only about 10% to 20% of the time, so the diagnostic stress test for men has a *specificity* of 80% to 90%. Women have a greater frequency of false-positive test results, with a corresponding lower specificity of about 70%.

The *sensitivity* of a test means that people with disease are correctly identified and there are few false negatives. The sensitivity of the stress test is 60% to 80%—that is, if 100 people with heart disease were tested, 60 to 80 would be correctly identified, but 20 to 40 would have a *false-negative test*. Although stress testing is now an important diagnostic tool, it is just one of several tests used to determine the presence of coronary artery disease.

Stress tests are also conducted on people not suspected of having heart or lung disease to determine their present functional capacity. These functional tests are administered in the same way as diagnostic tests, but exercise physiologists conduct them and a physician need not be present. These tests are used to establish safe exercise prescriptions, to aid athletes in establishing optimal training programs, and to serve as research tools to evaluate the effectiveness of a particular training regimen. Functional stress testing is becoming more prevalent as more people are joining hospital- or community-based wellness programs for disease prevention.

---

with impulses from the atria not being conducted to the ventricles at all. The SA node continues to govern atrial depolarization, but the ventricles generate their own impulses at a rate slower than that of the atria. On the ECG, the P waves exhibit a normal rhythm. The QRS and T waves also occur regularly but more slowly than the P waves and independently of P wave rhythm. Because atrial activity and ventricular activity are not synchronized, waves for atrial repolarization may appear, no longer masked by the QRS complex.

Cardiac Myopathies Abnormal ECG waves are also important in recognizing **cardiac myopathies** (damage of the heart muscle). **Myocardial ischemia** is inadequate delivery of oxygenated blood to the heart tissue. Actual death, or **necrosis**, of heart muscle cells occurs when a blood vessel supplying that area of the heart becomes blocked or ruptured. This condition is **acute myocardial infarction**, commonly called a **heart attack**. Abnormal QRS waveforms appear when part of the heart muscle becomes necrotic. Furthermore, damaged heart muscle cells release characteristic enzymes into the blood that can be measured to provide a further index of the extent of myocardial damage.

Check Your Understanding 9.2

1. Draw two graphs comparing the electrical activity in a cardiac autorhythmic cell and in a cardiac contractile cell. Label the ion movement responsible for each change in potential.
2. List the autorhythmic tissues of the heart and indicate the normal rate of action potential discharge of each.

3. Define *Ca^{2+}-induced Ca^{2+} release*.
4. Draw and label a normal ECG and state the electrical event associated with each waveform. Explain why no separate wave for atrial repolarization is visible on a normal ECG.

9.3 Mechanical Events of the Cardiac Cycle

The mechanical events of the cardiac cycle—contraction, relaxation, and the resultant changes in blood flow through the heart—are brought about by the rhythmic changes in cardiac electrical activity.

The heart alternately contracts to empty and relaxes to fill.

The **cardiac cycle** consists of alternate periods of **systole** (contraction and emptying) and **diastole** (relaxation and filling). Contraction results from the spread of excitation across the heart, whereas relaxation follows the subsequent repolarization of the cardiac muscle. The atria and ventricles go through separate cycles of systole and diastole. Unless qualified, the terms *systole* and *diastole* refer to what is happening with the ventricles.

The following discussion and corresponding ❚ Figure 9-16 correlate various events that occur concurrently during the cardiac cycle, including ECG features, pressure changes, volume changes, valve activity, and heart sounds. This integrated diagram is known as **Wigger's diagram**. Only the events on the

left side of the heart are described, but keep in mind that identical events are occurring on the right side of the heart, except that the pressures are lower. To complete one full cardiac cycle, our discussion begins and ends with ventricular diastole.

Mid-Ventricular Diastole During most of ventricular diastole, the atrium is still also in diastole. This stage corresponds to the TP segment on the ECG—the interval after ventricular repolarization and before another atrial depolarization. Because of the continuous inflow of blood from the venous system into the atrium, atrial pressure slightly exceeds ventricular pressure even though both chambers are relaxed (❙Figure 9-16, point **1**). Because of this pressure differential, the AV valve is open and blood flows directly from the atrium into the ventricle throughout the filling phase of ventricular diastole (❙Figure 9-16, heart a). As a result of this passive filling, the ventricular volume slowly continues to rise even before atrial contraction takes place (point **2**).

Late Ventricular Diastole Late in ventricular diastole, the SA node reaches threshold and fires. The impulse spreads throughout the atria, which appears on the ECG as the P wave (point **3**). Atrial depolarization brings about atrial contraction, raising the atrial pressure curve (point **4**) and squeezing more blood into the ventricle. The excitation–contraction coupling process takes place during the short delay between the P wave and the rise in atrial pressure. The corresponding rise in ventricular pressure (point **5**) that occurs simultaneously with the rise in atrial pressure results from the additional volume of blood added to the ventricle by atrial contraction (point **6** and heart b). Throughout atrial contraction, atrial pressure still slightly exceeds ventricular pressure, so the AV valve remains open.

End of Ventricular Diastole Ventricular diastole ends at the onset of ventricular contraction. By this time, atrial contraction and ventricular filling are completed. The volume of blood in the ventricle at the end of diastole (point **7**) is known as the **end-diastolic volume (EDV)**, which averages about 135 mL. No more blood is added to the ventricle during this cycle. Therefore, the end-diastolic volume is the maximum amount of blood that the ventricle contains during this cycle.

Onset of Ventricular Systole After atrial excitation, the impulse travels through the AV node and specialized conduction system to excite the ventricle. Simultaneously, the atria are contracting. By the time ventricular activation is complete, atrial contraction is already over. The QRS complex represents this ventricular excitation (point **8**), which induces ventricular contraction. The ventricular pressure curve sharply increases shortly after the QRS complex (that is, after excitation–contraction coupling has occurred), signaling the onset of ventricular systole (point **9**). As ventricular contraction begins, ventricular pressure immediately exceeds atrial pressure. This backward pressure differential forces the AV valve closed (point **9**).

Isovolumetric Ventricular Contraction After ventricular pressure exceeds atrial pressure and the AV valve has closed, to open the aortic valve, the ventricular pressure must continue to increase until it exceeds aortic pressure. Therefore, after the AV valve closes and before the aortic valve opens, the ventricle briefly remains a closed chamber (point **10**). Because all valves are closed, no blood can enter or leave the ventricle during this time, which is termed the period of **isovolumetric ventricular contraction** (*isovolumetric* means "constant volume and length") (heart c). Because no blood enters or leaves the ventricle, the ventricular chamber stays at constant volume, and the muscle fibers stay at constant length (point **11**) while ventricular pressure continues to rise.

Ventricular Ejection When ventricular pressure exceeds aortic pressure (point **12**), the aortic valve is forced open and ejection of blood begins (heart d). The amount of blood pumped out of each ventricle with each contraction is called the **stroke volume (SV)**. The aortic pressure curve rises as blood is forced into the aorta from the ventricle faster than blood is draining off into the smaller vessels at the other end (point **13**). The ventricular volume decreases substantially as blood is rapidly pumped out (point **14**). Ventricular systole includes both isovolumetric ventricular contraction and ventricular ejection.

End of Ventricular Systole The ventricle does not empty completely during ejection. Normally, only about half the blood within the ventricle at the end of diastole is pumped out during the subsequent systole. The amount of blood left in the ventricle at the end of systole when ejection is complete is the **end-systolic volume (ESV)** (point **15**), which averages about 65 mL. This is the least amount of blood that the ventricle contains during this cycle.

The difference between the volume of blood in the ventricle before contraction and the volume after contraction is the amount of blood ejected during the contraction, that is, EDV − ESV = SV. In our example, EDV is 135 mL, ESV is 65 mL, and SV is 70 mL.

Onset of Ventricular Diastole The T wave signifies ventricular repolarization at the end of ventricular systole (point **16**). When the ventricle repolarizes and starts to relax, ventricular pressure falls below aortic pressure and the aortic valve closes (point **17**). Closure of the aortic valve produces a disturbance or notch on the aortic pressure curve, the **dicrotic notch** (point **18**). No more blood leaves the ventricle during this cycle because the aortic valve has closed.

Isovolumetric Ventricular Relaxation When the aortic valve closes, the AV valve is not yet open because ventricular pressure still exceeds atrial pressure, so no blood can enter the ventricle from the atrium. Therefore, all valves are again closed for a brief period known as **isovolumetric ventricular relaxation** (point **19** and heart e). The muscle fiber length and chamber volume (point **20**) remain constant. No blood leaves or enters as the ventricle continues to relax and the pressure steadily falls.

Ventricular Filling When ventricular pressure falls below atrial pressure, the AV valve opens (point **21**), and ventricular filling occurs again. Ventricular diastole includes both isovolumetric ventricular relaxation and ventricular filling.

Figure 9-16 Cardiac cycle. This diagram depicts various events that occur concurrently during the cardiac cycle. Follow each horizontal strip across to see the changes that take place in the electrocardiogram; aortic, ventricular, and atrial pressures; ventricular volume; and heart sounds throughout the cycle. The last half of diastole, one full systole and diastole (one full cardiac cycle), and another systole are shown for the left side of the heart. Follow each vertical strip downward to see what happens simultaneously with each of these factors during each phase of the cardiac cycle. See the text (pp. 315 and 317) for a detailed explanation of the numbered points. The sketches of the heart illustrate the flow of O_2-poor (*dark blue*) and O_2-rich (*dark pink*) blood in and out of the ventricles during the cardiac cycle.

FIGURE FOCUS: *If the length of the diastolic filling phase is reduced by one half because the heart rate increases, would only half as much blood enter the ventricles? Use this figure to defend your answer.*

(a) Passive filling during ventricular and atrial diastole

(b) Atrial contraction

(c) Isovolumetric ventricular contraction

(d) Ventricular ejection

(e) Isovolumetric ventricular relaxation

Ventricular filling (AV valves open; semilunar valves closed)

(All valves closed)

Ventricular emptying (Semilunar valves open; AV valves closed)

(All valves closed)
Atrial repolarization and ventricular depolarization occur simultaneously, so the atria are in diastole throughout ventricular systole. Blood continues to flow from the pulmonary veins into the left atrium. As this incoming blood pools in the atrium, atrial pressure rises continuously (point **22**). When the AV valve opens at the end of ventricular systole, blood that accumulated in the atrium during ventricular systole pours rapidly into the ventricle (heart a again). Ventricular filling thus occurs rapidly at first (point **23**) because of the increased atrial pressure resulting from the accumulation of blood in the atria. Then ventricular filling slows down (point **24**) as the accumulated blood has already been delivered to the ventricle. During this period of reduced filling, blood continues to flow from the pulmonary veins into the left atrium and through the open AV valve into the left ventricle. During late ventricular diastole, when the ventricle is filling slowly, the SA node fires again, and the cardiac cycle starts over (point **25**).

Another way besides Wigger's diagram of viewing the relationship between pressure and volume throughout the cardiac cycle is a **pressure–volume loop**, which does not consider the element of time but is an excellent tool for visualizing pressure and volume changes as valves open and close and blood flows in and out of the ventricle (❚Figure 9-17).

When the body is at rest, one complete cardiac cycle lasts 800 msec, with 300 msec devoted to ventricular systole and 500 msec taken up by ventricular diastole. Significantly, much of ventricular filling occurs early in diastole during the rapid-filling phase. During times of rapid heart rate, diastole length is shortened more than systole length is. For example, if the heart rate increases from 75 to 180 beats per minute, the duration of diastole decreases about 75%, from 500 msec to 125 msec. This greatly reduces the time available for ventricular relaxation and filling. However, because much ventricular filling is accomplished during early diastole, filling is not seriously impaired during periods of increased heart rate, such as during exercise. There is a limit, however, to how rapidly the heart can beat without decreasing the period of diastole to the point that ventricular filling is severely impaired. At heart rates greater than 200 beats per minute, diastolic time is too short to allow adequate ventricular filling. With inadequate filling, the resultant cardiac output is deficient. Normally, ventricular rates do not exceed 200 beats per minute because the relatively long refractory period of the AV node will not allow impulses to be conducted to the ventricles more frequently than this.

Two normal heart sounds are associated with valve closures.

Two major heart sounds normally can be heard with a stethoscope during the cardiac cycle. The **first heart sound** is low-pitched, soft, and relatively long; it, sounds like "lub." The **second heart sound** has a higher pitch and is shorter and sharper; it sounds like "dup." Thus, one normally hears "lub-dup-lub-dup-lub-dup . . . ." The first heart sound is associated with closure of the AV valves, whereas the second sound is associated with closure of the semilunar valves (see the "Heart sounds" line at the bottom of the graphs in ❚Figure 9-16). Opening of valves does not produce any sound.
1 The AV valve opens.

2 Passive ventricular filling occurs. Volume increases considerably and pressure increases slightly as blood enters.

3 Atrial contraction completes ventricular filling. End-diastolic volume is reached at the end of this phase.

4 The AV valve closes.

5 Isovolumetric ventricular contraction occurs. Volume remains constant; pressure increases markedly.

6 The aortic valve opens.

7 A stroke volume of blood is ejected. As blood leaves, volume decreases considerably as pressure peaks, then falls more slowly until end-systolic volume is reached at the end of this phase.

8 The aortic valve closes.

9 Isovolumetric ventricular relaxation occurs. Volume remains constant; pressure falls sharply.

Back to step **1**.

❚Figure 9-17 **Left-ventricular pressure–volume loop for a single cardiac cycle.**
FIGURE FOCUS: *How would the difference in pressure between point 4 (AV valve closure) and point 6 (semilunar valve opening) in a right-ventricular pressure–volume loop compare with the difference in pressure between these same two points in this left-ventricular pressure–volume loop (taking into account that the pulmonary valve instead of the aortic valve is opening at 6 and closing at 8 in the right-sided loop)? How would the change in volume between points 6 and 8 compare in these two pressure–volume loops?*

The sounds are caused by vibrations set up within the walls of the ventricles and major arteries during valve closure, not by the valves snapping shut. Because the AV valves close at the onset of ventricular contraction, when ventricular pressure first exceeds atrial pressure, the first heart sound signals the onset of ventricular systole (❚Figure 9-16, point **9**). The semilunar valves close at the onset of ventricular relaxation, as the left and

right ventricular pressures fall below the aortic and pulmonary artery pressures, respectively. The second heart sound, therefore, signals the onset of ventricular diastole (point **17**).

Turbulent blood flow produces heart murmurs.

Clinical Note Abnormal heart sounds, or **murmurs**, are usually (but not always) associated with cardiac disease. Blood normally flows in a *laminar* fashion—that is, layers of the fluid slide smoothly over one another (*lamina* means "layer"). Laminar flow does not produce an audible sound. When blood flow becomes turbulent, however, a sound can be heard (❙Figure 9-18).

(a) Laminar flow (does not create any sound)

(b) Turbulent flow (can be heard)

❙Figure 9-18 **Comparison of laminar and turbulent flow**.

Stenotic and Insufficient Valves The most common cause of turbulence is valve malfunction, either a stenotic or an insufficient valve. A **stenotic valve** is a stiff, narrowed valve that does not open completely. Blood must be forced through the constricted opening at tremendous velocity, resulting in turbulence that produces an abnormal whistling sound similar to the sound produced when you force air rapidly through narrowed lips to whistle. An **insufficient**, or **incompetent**, **valve** is one that cannot close completely because the valve edges do not fit together properly. Turbulence is produced when blood flows backward through the insufficient valve and collides with blood moving in the opposite direction, creating a swishing or gurgling murmur. Such backflow of blood is known as **regurgitation**. An insufficient heart valve is often called a **leaky valve** because it lets blood leak back through when the valve should be closed.

Most often, both valvular stenosis and insufficiency are caused by **rheumatic fever**, an autoimmune ("immunity against self") disease triggered by a streptococcus bacterial infection. Antibodies formed against toxins produced by these bacteria interact with many of the body's tissues, resulting in immunological damage. The heart valves are among the most susceptible tissues in this regard. Large, hemorrhagic, fibrous lesions form along the inflamed edges of an affected heart valve, causing the valve to become thickened, stiff, and scarred. Sometimes the leaflet edges permanently adhere to each other. Depending on the extent and specific nature of the lesions, the valve may become either stenotic or insufficient or some degree of both. Rheumatic fever is much less common since antibiotics that can treat "strep throat" became available. On occasion children are born with malfunctioning valves.

Timing of Murmurs The valve involved and the type of defect can usually be detected by the timing and location of the murmur. The *timing* of the murmur refers to the part of the cardiac cycle during which the murmur is heard. Recall that the first heart sound signals the onset of ventricular systole and the second heart sound signals the onset of ventricular diastole. Thus, a murmur between the first and the second heart sounds ("lub-murmur-dup—lub-murmur-dup") is a **systolic murmur**. A **diastolic murmur**, in contrast, occurs between the second and the first heart sounds ("lub-dup-murmur—lub-dup-murmur"). The sound of the murmur characterizes it as either a stenotic (whistling) murmur or an insufficient (swishy) mur-

mur. Armed with these facts, one can determine the cause of a valvular murmur. For example, a whistling murmur (denoting a stenotic valve) occurring between the first and the second heart sounds (denoting a systolic murmur)—that is, *lub-whistle-dup*—indicates stenosis in a valve that should be open during systole. It could be either the aortic or the pulmonary semilunar valve through which blood is being ejected. Identifying which of these valves is stenotic is accomplished by finding where the murmur is best heard. Each heart valve can be heard best at a specific location on the chest. Noting where a murmur is loudest helps the diagnostician tell which valve is involved. Let's analyze another example for practice. A swishy diastolic murmur—*lub-dup-swish*—signifies that a valve that should be closed during diastole (a semilunar valve) does not close completely, that is, is insufficient. Using the same line of reasoning, you can figure out that a *lub-dup-whistle* murmur denotes a stenotic AV valve, whereas a *lub-swish-dup* murmur is a sign of an insufficient AV valve.
The main concern with a heart murmur is not the murmur itself but the harmful circulatory results of the defect. An *echocardiogram* can be used to further evaluate a valve defect. With this noninvasive technique, ultrasound waves transmitted to the heart bounce off the valves and heart chambers. Returning echoes of the waves are processed by a computer and assembled into moving pictures of the beating heart that can be viewed on a monitor. The resultant images are used to identify various abnormalities in valves and heart muscle.

Check Your Understanding 9.3

1. Define *systole* and *diastole*.
2. State the pressure relationships among the aortic, atrial, and ventricular pressures (for example, ventricular pressure > aortic pressure > atrial pressure) during each of these phases of the cardiac cycle: (1) ventricular filling, (2) isovolumetric ventricular contraction, (3) ventricular ejection, and (4) isovolumetric ventricular relaxation (think what pressure relationships must exist for the valves to be opened or closed as appropriate in each phase).
3. Distinguish among end-diastolic volume, end-systolic volume, and stroke volume.

9.4 Cardiac Output and Its Control

Cardiac output (CO) is the volume of blood pumped by *each ventricle* per minute (not the total amount of blood pumped by the heart). During any period, the volume of blood flowing through the pulmonary circulation is the same as the volume flowing through the systemic circulation. Therefore, the cardiac output from each ventricle normally is the same, although minor variations may occur on a beat-to-beat basis.

Cardiac output depends on heart rate and stroke volume.

The two determinants of cardiac output are **heart rate (HR)** (beats per minute) and **stroke volume (SV)** (volume of blood pumped per beat or stroke). The average resting HR is 70 beats per minute, established by SA node rhythmicity; the average resting SV is 70 mL per beat, producing an average CO of 4900 mL per minute, or close to 5 L per minute:

$$CO = HR \times SV$$
$$= 70 \text{ beats/min} \times 70 \text{ mL/beat}$$
$$= 4900 \text{ mL/min} \approx 5 \text{ L/min}$$

Because the body's total blood volume averages 5 to 5.5 liters, each half of the heart pumps the equivalent of the entire blood volume each minute. In other words, each minute the right ventricle normally pumps 5 liters of blood through the lungs and the left ventricle pumps 5 liters through the systemic circulation. At this rate, each half of the heart would pump about 2.5 million liters of blood in just 1 year. Yet this is only the resting CO; during exercise, CO can increase to 20 to 25 liters per minute (and even more in trained athletes during heavy endurance-type exercise). The difference between the cardiac output at rest and the maximum volume of blood the heart can pump per minute is called the **cardiac reserve**.

How can CO vary so tremendously, depending on the demands of the body? You can readily answer this question by thinking about how your heart pounds rapidly (increased heart rate) and forcefully (increased stroke volume) when you engage in strenuous physical activities (when you need increased cardiac output). Thus, regulation of CO depends on control of both HR and SV.

Heart rate is determined primarily by autonomic influences on the SA node.

The heart is innervated by both divisions of the autonomic nervous system, which can modify the rate (and the strength) of contraction, even though nervous stimulation is not required to initiate contraction. The parasympathetic nerve to the heart, the *vagus nerve,* primarily supplies the atrium, especially the SA and AV nodes. Parasympathetic innervation of the ventricles is sparse. The cardiac sympathetic nerves also supply the atria, including the SA and AV nodes, and richly innervate the ventricles as well.

Both the parasympathetic and sympathetic nervous system bring about their effects on the heart primarily by altering the activity of the cyclic adenosine monophosphate (cAMP) second-messenger pathway in the innervated cardiac cells. Acetylcholine (ACh) released from the vagus nerve binds to a muscarinic cholinergic receptor and is coupled to an inhibitory G protein that reduces activity of the cAMP pathway (see pp. 117, 123, and 239). By contrast, the sympathetic neurotransmitter norepinephrine binds with a β_1-adrenergic receptor and is coupled to a stimulatory G protein that accelerates the cAMP pathway in the target cells (see p. 240). The cAMP pathway leads to phosphorylation and altered activity of various proteins within cardiac muscle, for example, keeping channels open longer. Let us examine the specific effects that parasympathetic and sympathetic stimulation have on the heart (Table 9-1).

❙TABLE 9-1 Effects of the Autonomic Nervous System on Heart Activity

Area Affected	Effect of Parasympathetic Stimulation	Effect of Sympathetic Stimulation
SA node	Decreases the rate of depolarization to threshold; decreases the heart rate	Increases the rate of depolarization to threshold; increases the heart rate
AV node	Decreases excitability; increases the AV nodal delay	Increases excitability; decreases the AV nodal delay
Ventricular conduction pathway	No effect	Increases excitability; hastens conduction through the bundle of His and Purkinje cells
Atrial muscle	Decreases contractility; weakens contraction	Increases contractility; strengthens contraction
Ventricular muscle	No effect	Increases contractility; strengthens contraction
Adrenal medulla (an endocrine gland)	No effect	Promotes secretion of epinephrine, a hormone that augments sympathetic nervous system actions
Veins	No effect	Increases venous return, which increases the strength of cardiac contraction via intrinsic control
(a) Autonomic influence on SA node potential
(b) Control of heart rate by autonomic nervous system

❙Figure 9-19 Autonomic control of SA node activity and heart rate.
(a) Parasympathetic stimulation decreases the rate of SA nodal depolarization so that the membrane reaches threshold more slowly and has fewer action potentials, whereas sympathetic stimulation increases the rate of depolarization of the SA node so that the membrane reaches threshold more rapidly and has more frequent action potentials. (b) Because each SA node action potential ultimately leads to a heartbeat, increased parasympathetic activity decreases the heart rate, whereas increased sympathetic activity increases the heart rate.

Effect of Parasympathetic Stimulation on the Heart

The parasympathetic nervous system's influence on the SA node is to decrease HR (❙Figure 9-19). In a different mechanism than its usual reduction in cAMP activity, ACh slows heart rate primarily by increasing K^+ permeability of the pacemaker cells in the SA node by binding with muscarinic cholinergic receptors that are coupled directly to ACh-regulated K^+ channels by a G protein. This action augments opening of these K^+ channels. As a result, the rate at which spontaneous action potentials are initiated is reduced through a twofold effect:

1. Enhanced K^+ permeability hyperpolarizes the SA node membrane because more positive K^+ ions leave than normal, making the inside even more negative. Because the "resting" potential starts even farther away from threshold, it takes longer to reach threshold.

2. The enhanced K^+ permeability induced by vagal stimulation also opposes the automatic reduction in K^+ permeability that contributes to development of the pacemaker potential. This countering effect decreases the SA node's rate of spontaneous depolarization, prolonging the time required to drift to threshold. ACh, by inhibiting the cAMP pathway, also depresses both the inward movement of Na^+ and Ca^{2+} through the I_f and T-type channels, respectively, further slowing the depolarization to threshold. Therefore, the SA node reaches threshold and fires less frequently, decreasing the heart rate.

■ Parasympathetic stimulation decreases the AV node's excitability, prolonging transmission of impulses to the ventricles even longer than the usual AV nodal delay. This effect is brought about by increasing K^+ permeability, which hyperpolarizes the membrane, thereby retarding the initiation of excitation in the AV node.

■ Parasympathetic stimulation of the atrial contractile cells shortens the plateau phase of the action potential by reducing the slow inward current carried by Ca^{2+}. As a result, atrial contraction is weakened.

■ The parasympathetic system has little effect on ventricular contraction because of the sparseness of parasympathetic innervation to the ventricles.

Thus, the heart is more "leisurely" under parasympathetic influence—it beats less rapidly, the time between atrial and ventricular contraction is stretched out, and atrial contraction is weaker. These actions are appropriate, considering that the parasympathetic system controls heart action in quiet, relaxed situations when the body is not demanding enhanced cardiac output.

Effect of Sympathetic Stimulation on the Heart
In contrast, the sympathetic nervous system, which controls heart action in emergency or exercise situations that require greater blood flow, "revs up" the heart.

■ The main effect of sympathetic stimulation on the SA node is to speed up depolarization so that threshold is reached more rapidly. In pacemaker cells, the rate of depolarization increases as a result of greater inward movement of Na^+ and Ca^{2+} through augmented I_f and T-type Ca^{2+} channels. This swifter drift to threshold under sympathetic influence permits more frequent action potentials and a correspondingly faster heart rate (❙Figure 9-19 and ❙Table 9-1).

■ Sympathetic stimulation of the AV node reduces the AV nodal delay by increasing conduction velocity, as a result enhancing the slow, inward Ca^{2+} current.

■ Similarly, sympathetic stimulation speeds up spread of the action potential throughout the specialized conduction pathway.

■ In the atrial and ventricular contractile cells, both of which have many sympathetic nerve endings, sympathetic stimula-

tion increases contractile strength so that the heart beats more forcefully and squeezes out more blood. This effect is produced by increasing Ca^{2+} permeability through prolonged opening of L-type Ca^{2+} channels. The resultant enhanced Ca^{2+} influx strengthens contraction by intensifying Ca^{2+} participation in excitation–contraction coupling.

■ Sympathetic stimulation not only increases the speed of contraction by allowing greater influx of Ca^{2+} into the cell through L-type Ca^{2+} channels, but it also speeds up relaxation by enhancing the SERCA pump that removes Ca^{2+} from the cytosol (see p. 261).

The overall effect of sympathetic stimulation on the heart, therefore, is to improve its effectiveness as a pump by increasing HR, decreasing the delay between atrial and ventricular contraction, decreasing conduction time throughout the heart, increasing the force of contraction, and speeding up the relaxation process so that more time is available for filling.

Control of Heart Rate Thus, as is typical of the autonomic nervous system, parasympathetic and sympathetic effects on heart rate are antagonistic (oppose each other). At any given moment, HR is determined largely by the balance between inhibition of the SA node by the vagus nerve and stimulation by the cardiac sympathetic nerves. Under resting conditions, parasympathetic discharge dominates because ACh (the parasympathetic neurotransmitter) suppresses sympathetic activity by inhibiting the release of norepinephrine (the sympathetic neurotransmitter) from neighboring sympathetic nerve endings. If all autonomic nerves to the heart were blocked, the resting HR would increase from its average value of 70 beats per minute to about 100 beats per minute, which is the inherent rate of the SA node's spontaneous discharge when not subjected to any nervous influence. (We use 70 beats per minute as the normal rate of SA node discharge because this is the average rate under normal resting conditions when parasympathetic activity dominates.) HR can be altered beyond this resting level in either direction by shifting the balance of autonomic nervous stimulation. HR is speeded up by simultaneously increasing sympathetic and decreasing parasympathetic activity; HR is slowed by a concurrent rise in parasympathetic activity and decline in sympathetic activity. The relative level of activity in these two autonomic branches to the heart in turn is primarily coordinated by the *cardiovascular control center* in the brain stem.

Although autonomic innervation is the primary means by which HR is regulated, other factors affect it as well. The most important is epinephrine, a hormone secreted into the blood from the adrenal medulla on sympathetic stimulation. Epinephrine acts in a manner similar to norepinephrine to increase HR, thus reinforcing the direct effect that the sympathetic nervous system has on the heart.

Stroke volume is determined by the extent of venous return and by sympathetic activity.

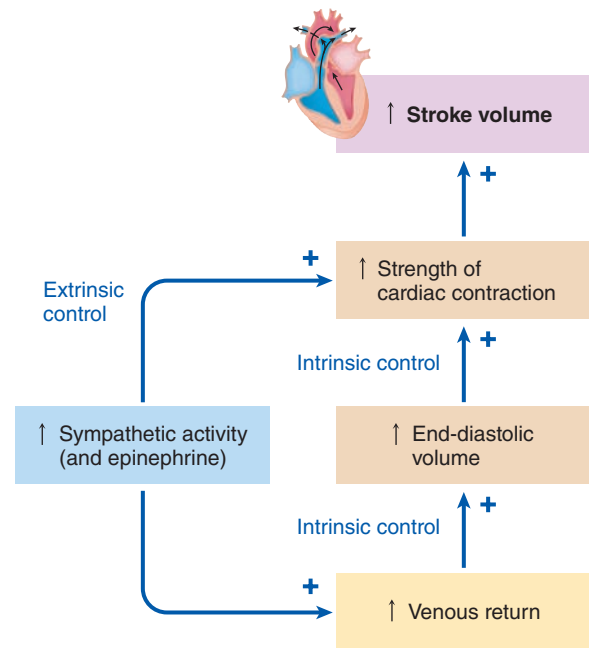
The other component besides heart rate that determines cardiac output is stroke volume, the amount of blood pumped out by each ventricle during each beat. Two types of control influence


Figure 9-20 Intrinsic and extrinsic control of stroke volume.

stroke volume: (1) *intrinsic control* related to the extent of venous return and (2) *extrinsic control* related to the extent of sympathetic stimulation of the heart. Both factors increase SV by increasing the strength of heart contraction (Figure 9-20). Let us examine each of these mechanisms in detail.

Increased end-diastolic volume results in increased stroke volume.

Intrinsic control of stroke volume, which refers to the heart's inherent ability to vary SV, depends on the direct correlation between end-diastolic volume (EDV) and SV. As more blood returns to the heart, the heart pumps out more blood, but the relationship is not as simple as it might seem because the heart does not eject all the blood it contains. This intrinsic control depends on the length–tension relationship of cardiac muscle, which is similar to that of skeletal muscle. For skeletal muscle, the resting muscle length is approximately the optimal length (l_o) at which maximal tension can be developed during a subsequent contraction. When the skeletal muscle is longer or shorter than l_o, the subsequent contraction is weaker (see Figure 8-20, p. 269). For cardiac muscle, the resting cardiac muscle fiber length is less than l_o. Therefore, the length of cardiac muscle fibers normally varies along the ascending limb of the length–tension curve. An increase in cardiac muscle fiber length, by moving closer to l_o, increases the contractile tension of the heart on the following systole (Figure 9-21).

Unlike in skeletal muscle, the length–tension curve of cardiac muscle normally does not operate at lengths that fall within the region of the descending limb. That is, within physiologic limits, cardiac muscle does not get stretched beyond its l_o to the point that contractile strength diminishes with further stretching.
Figure 9-21 Intrinsic control of stroke volume (Frank–Starling curve). The cardiac muscle fiber's length, which is determined by the extent of venous filling, is normally less than the optimal length (l_o) for developing maximal tension. Therefore, an increase in end-diastolic volume (EDV) (that is, an increase in venous return), by moving the cardiac muscle fiber length closer to l_o, increases the contractile tension of the fibers on the next systole. A stronger contraction squeezes out more blood. Thus, as more blood is returned to the heart and EDV increases, the heart automatically pumps out a corresponding larger stroke volume (SV).

Frank–Starling Law of the Heart What causes cardiac muscle fibers to vary in length before contraction? Skeletal muscle length can vary before contraction because of the positioning of the skeletal parts to which the muscle is attached, but cardiac muscle is not attached to any bones. The main determinant of cardiac muscle fiber length is the degree of diastolic filling. An analogy is a balloon filled with water—the more water you put in, the larger the balloon becomes, and the more it is stretched. Likewise, the greater the diastolic filling, the larger the EDV, and the more the heart is stretched. The more the heart is stretched, the longer the cardiac fibers before contraction. The increased length results in a greater force on the subsequent cardiac contraction and thus in a greater SV. This intrinsic relationship between EDV and SV is known as the **Frank–Starling law of the heart**. Stated simply, the law says that the heart normally pumps out during systole the volume of blood returned to it during diastole; increased venous return results in increased SV. In ❙ Figure 9-21, assume that EDV increases from point A to point B. You can see that this increase in EDV is accompanied by a corresponding increase in SV from point A¹ to point B¹. The extent of filling is referred to as the **preload** because it is the workload imposed on the heart before contraction begins.

Advantages of the Cardiac Length–Tension Relationship The built-in relationship matching SV with venous return has two important advantages. First, this intrinsic mechanism equalizes output between the right and the left sides of the heart so that blood pumped out by the heart is equally distributed between the pulmonary and systemic circulations. If, for example, the right side of the heart ejects a larger SV, more blood enters the pulmonary circulation, so venous return to the left side of the heart increases accordingly. The increased EDV of the left side of the heart causes it to contract more forcefully, so it too pumps out a larger SV. In this way, output of the two ventricular chambers is kept equal. If such equalization did not happen, too much blood would be dammed up in the venous system before the ventricle with the lower output.

Second, when a larger CO is needed, as during exercise, venous return is increased by the sympathetic nervous system constricting the veins to drive blood forward and by the contracting muscles compressing the veins, which squeezes more blood toward the heart. The resulting increase in EDV automatically increases SV correspondingly. Because exercise also increases HR, these two factors act together to increase CO so that more blood can be delivered to the exercising muscles.

Mechanism of the Cardiac Length–Tension Relationship

Although the length–tension relationship in cardiac muscle fibers depends to a degree on the extent of overlap of thick and thin filaments, similar to the length–tension relationship in skeletal muscle, the key factor relating cardiac muscle fiber length to tension development is the dependence of myofilament Ca^{2+} sensitivity on the fiber's length. Specifically, as a cardiac muscle fiber is stretched as a result of greater ventricular filling, its myofilaments are pulled closer together side by side. As a result of this reduction in distance between the thick and thin filaments, more cross-bridge interactions between myosin and actin can take place when Ca^{2+} pulls the troponin–tropomyosin complex away from actin's cross-bridge binding sites—that is, myofilament Ca^{2+} sensitivity increases. Thus, the length–tension relationship in cardiac muscle depends not on muscle fiber length per se but on the resultant variations in lateral spacing between the myosin and actin filaments.

We now shift from intrinsic to extrinsic control of SV.

Sympathetic stimulation increases the contractility of the heart.

In addition to intrinsic control, SV is subject to **extrinsic control** by factors originating outside the heart, the most important of which are actions of the cardiac sympathetic nerves and epinephrine (see ❙ Table 9-1). Sympathetic stimulation and epinephrine enhance the heart's **contractility**, which is the strength of contraction at any given EDV. In other words, on sympathetic stimulation the heart contracts more forcefully and squeezes out a greater percentage of the blood it contains, leading to more complete ejection. This increased contractility results from the increased Ca^{2+} influx triggered by norepinephrine and epinephrine. The extra cytosolic Ca^{2+} lets the myocardial fibers generate more force through greater cross-bridge

cycling than they would without sympathetic influence. Normally, the EDV is 135 mL and the end-systolic volume (ESV) is 65 mL for a SV of 70 mL (❙Figure 9-22a). Under sympathetic influence, for the same EDV of 135 mL, the ESV might be 35 mL and the SV 100 mL (❙Figure 9-22b). In effect, sympathetic stimulation shifts the Frank–Starling curve to the left (❙Figure 9-23). Depending on the extent of sympathetic stimulation, the curve can be shifted to varying degrees, up to a maximal increase in contractile strength of about 100% greater than normal.

The **ejection fraction** is the ratio of stroke volume to end-diastolic volume (ejection fraction = SV/EDV); that is, it is the proportion of the blood in the ventricle that is pumped out. The ejection fraction is often used clinically as an indication of contractility. A healthy heart normally has an ejection fraction of 50% to 75% under resting conditions and may go as high as 90% during strenuous exercise, but a failing heart may pump out 30% or less.

Sympathetic stimulation increases SV not only by strengthening cardiac contractility but also by enhancing venous return (see ❙Figure 9-22c). Sympathetic stimulation constricts the veins, which squeezes more blood forward from the veins to the heart, increasing the EDV and subsequently increasing SV even further.

Summary of Factors Affecting Stroke Volume and Cardiac Output The strength of cardiac muscle contraction and, accordingly, stroke volume can thus be graded by (1) varying the initial length of the muscle fibers, which in turn depends on the degree of ventricular filling before contraction (intrinsic control), and (2) varying the extent of sympathetic stimulation (extrinsic control) (see ❙Figure 9-20). This is in contrast to gradation of skeletal muscle, in which twitch summation and recruitment of motor units play key roles in producing variable strength of muscle contraction. These mechanisms do not apply to cardiac muscle. In cardiac muscle, twitch summation is impossible because of the long refractory period. Recruitment of motor units is not possible because heart muscle cells are arranged into functional syncytia where all contractile cells become excited and contract with every beat, instead of into distinct motor units that can be discretely activated. Therefore, unlike skeletal muscle, where graded contractions can be produced by varying the number of muscle cells contracting within the muscle, either all cardiac muscle fibers contract or none do. A "halfhearted" contraction is not possible. Cardiac contraction is thus graded by varying the strength of contraction of all the cardiac muscle cells by intrinsic and extrinsic control mechanisms.

All the factors that determine CO by influencing HR or SV are summarized in ❙Figure 9-24. Note that sympathetic stimulation increases CO by increasing both HR and SV. Sympathetic activity to the heart increases, for example, during exercise when the

(a) Normal stroke volume

End-diastolic volume 135 mL
Stroke volume 70 mL

❙Figure 9-22 **Effect of sympathetic stimulation on stroke volume.**

working skeletal muscles need increased delivery of O_2-laden blood to support their high rate of ATP consumption.

We next examine how the afterload influences the ability of the heart to pump out blood.

High blood pressure increases the workload of the heart.

When the ventricles contract, to force open the semilunar valves they must generate sufficient pressure to exceed the blood pressure in the major arteries. The arterial blood pressure is called the **afterload** because it is the workload imposed
❙Figure 9-23 **Shift of the Frank–Starling curve to the left by sympathetic stimulation.** For the same end-diastolic volume (point A), a larger stroke volume (from point B to point C) is ejected on sympathetic stimulation as a result of increased contractility of the heart. The Frank–Starling curve is shifted to the left by variable degrees, depending on the extent of sympathetic stimulation.
Figure 9-24 Control of cardiac output. Because cardiac output equals heart rate times stroke volume, this figure is a composite of Figure 9-19b (control of heart rate) and Figure 9-20 (control of stroke volume).

FIGURE FOCUS: *Through what regulatory mechanisms can a transplanted heart, which does not have any innervation, adjust cardiac output to meet the body's changing needs?*

on the heart after contraction has begun. If arterial blood pressure is chronically elevated (high blood pressure) or if the exit valve is stenotic, the ventricle must generate more pressure to eject blood. For example, instead of generating the normal pressure of 120 mm Hg, the ventricular pressure may need to rise as high as 400 mm Hg to force blood through a narrowed aortic valve.

The heart may be able to compensate for a sustained increase in afterload by hypertrophying, that is, by increasing the thickness of the cardiac muscle fibers (see p. 274). This enables it to contract more forcefully and maintain a normal SV despite an abnormal impediment to ejection. However, a diseased heart or a heart weakened with age may not be able to compensate completely; in that case, heart failure ensues. Even if the heart is initially able to compensate for a chronic increase in afterload, the sustained extra workload placed on the heart can eventually cause pathological changes in the heart that lead to heart failure, a topic to which we now turn.

A failing heart cannot pump out enough blood.

Clinical Note **Heart failure (HF)** is the inability of CO to keep pace with the body's demands for supplies and removal of wastes. Heart failure can be of two types: *systolic HF*, in which the heart has difficulty pumping blood out, or *diastolic HF*, in which the heart has trouble filling. Traditionally all HF was considered systolic, but improvements in cardiac imaging technology, such as use of echocardiograms, have revealed that nearly half of all cases are diastolic HF. Heart failure presently affects 5 million Americans, with this number expected to rise as the population ages.

Defect in Systolic Heart Failure The prime defect in **systolic HF** is decreased cardiac contractility—that is, weakened cardiac muscle cells contract less effectively, resulting in a greatly reduced ejection fraction. Either one or both ventricles may progressively weaken and fail. Systolic HF may occur for a variety of reasons, but the two most common are (1) damage to the heart muscle as a result of a heart attack or impaired circulation to the cardiac muscle and (2) prolonged pumping against a chronically increased afterload, as with a sustained elevated blood pressure or a stenotic semilunar valve.

With systolic HF, the intrinsic ability of the heart to develop pressure and eject a SV is reduced so that the heart operates on a lower length–tension curve (❙Figure 9-25a). The Frank–Starling curve shifts downward and to the right such that, for a given EDV, a failing heart pumps out a smaller SV than a normal healthy heart does.

Compensatory Measures for Systolic Heart Failure In the early stages of systolic HF, two major compensatory measures help restore SV to normal. First, sympathetic activity to the heart is reflexly increased, which increases heart contractility toward normal (❙Figure 9-25b). Sympathetic stimulation can help compensate only for a limited time, however, because the heart becomes less responsive to norepinephrine after prolonged exposure, and furthermore, norepinephrine stores in the heart's sympathetic nerve terminals become depleted. Second, when CO is reduced, the kidneys, in a compensatory attempt to improve their reduced blood flow, retain extra salt and water in the body during urine formation to expand the blood volume. The increase in circulating blood volume increases the EDV. The resultant stretching of the cardiac muscle fibers enables the weakened heart to pump out a normal SV (❙Figure 9-25b). The heart is now pumping out the blood returned to it but is operating at a greater cardiac muscle fiber length.

Decompensated Systolic Heart Failure As the disease progresses and heart contractility deteriorates further, the heart reaches a point at which it can no longer pump out a normal SV despite compensatory measures. At this point, the heart slips from compensated HF into a state of decompensated HF. Now the cardiac muscle fibers are stretched to the point that they are operating in the descending limb of the length–tension curve. *Forward failure* occurs as the heart fails to pump an adequate amount of blood forward to the tissues because the SV becomes progressively smaller. *Backward failure* occurs simultaneously as the failing heart cannot pump out all of the blood returned to it (SV cannot keep pace with
(a) Reduced contractility in a failing heart
(b) Compensation for heart failure

❙Figure 9-25 Compensated heart failure. (a) The Frank–Starling curve shifts downward and to the right in a failing heart. Because its contractility is decreased, the failing heart pumps out a smaller stroke volume at the same end-diastolic volume than a normal heart does. (b) During compensation for heart failure, reflex sympathetic stimulation shifts the Frank–Starling curve of a failing heart to the left, increasing the contractility of the heart toward normal. A compensatory increase in end-diastolic volume as a result of blood volume expansion further increases the strength of contraction of the failing heart. Operating at a longer cardiac muscle fiber length, a compensated failing heart is able to eject a normal stroke volume.

venous return) so that the "backlogged" returning blood continues to dam up in the venous system. Congestion of blood in the venous system behind a failing ventricle is the reason this condition is sometimes termed **congestive heart failure**.

Left-sided failure has more serious consequences than right-sided failure. Backward failure of the left side leads to pulmonary edema (excess tissue fluid in the lungs) because blood dams up in the lungs. This fluid accumulation in the lungs reduces exchange of O_2 and CO_2 between air and blood in the lungs, reducing arterial oxygenation and elevating levels of acid-forming CO_2 in the blood. In addition, one of the more serious consequences of left-sided forward failure is inadequate blood flow to the kidneys, which causes a twofold problem. First, vital kidney function is depressed; second, the kidneys retain even more salt and water in the body during

urine formation as they try to expand the blood volume even further to improve their reduced blood flow. Excessive fluid retention worsens the already existing problems of venous congestion.

Treatment of congestive heart failure therefore includes measures that reduce salt and water retention and increase urinary output and drugs that enhance the contractile ability of the weakened heart—digitalis, for example. *Digitalis* increases cardiac contractility by causing accumulation of cytosolic Ca^{2+}.

Diastolic Heart Failure With the more recently recognized **diastolic HF**, the ventricles do not fill normally either because the heart muscle does not adequately relax between beats or because it stiffens and cannot expand as much as usual. The heart can pump properly and the ejection fraction is normal. For this reason, diastolic HF is alternatively called **heart failure with preserved ejection fraction**. However, even though the ejection fraction is normal (that is, the ventricles pump out a normal percentage of the blood present in their chambers), less blood than normal is pumped out by a diastolic failing heart because the ventricles are inadequately filled with blood. Both forward and backward failure, including congestive heart failure, can result, so symptoms are similar to systolic HF.

The abnormal ventricular relaxation and stiffness associated with diastolic HF are attributed to (1) excess collagen deposition in the ventricular muscle's extracellular matrix (see p. 60); (2) increased passive tension of titin, the giant elastic protein found in striated muscle (see p. 254); and (3) elevated resting cardiac muscle tension caused by slow or incomplete removal of cytosolic Ca^{2+} following an action potential.

No drugs are available yet that reliably help the heart relax, so treatment of diastolic HF is aimed at relieving symptoms, halting underlying causes, or lessening aggravating factors, such as by controlling high blood pressure.

Check Your Understanding 9.4

1. Indicate the effect (increase or decrease) of parasympathetic stimulation and sympathetic stimulation on heart rate and stroke volume.

2. Draw a graph showing the relationship between end-diastolic volume and stroke volume, according to the Frank–Starling law of the heart.

3. Define *preload* and *afterload*.

9.5 Nourishing the Heart Muscle

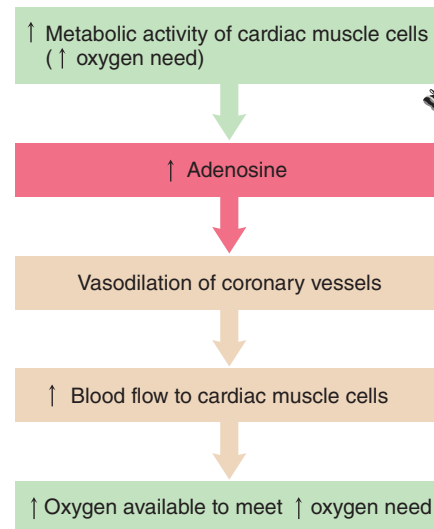
Cardiac muscle cells contain an abundance of mitochondria, the O_2-dependent energy organelles. Up to 40% of the cell volume of cardiac muscle cells is occupied by mitochondria, indicative of how much the heart depends on O_2 delivery and aerobic metabolism to generate the energy necessary for contraction (see pp. 34 and 39). Cardiac muscle also has an abundance of myoglobin, which stores limited amounts of O_2 within the heart for immediate use (see p. 271).

The heart receives most of its blood supply through the coronary circulation during diastole.

Although all the blood passes through the heart, the heart muscle cannot extract O_2 or nutrients from the blood within its chambers for two reasons. First, the watertight endothelial lining does not permit blood to pass from the chamber into the myocardium. Second, the heart walls are too thick to permit diffusion of O_2 and other supplies from the blood in the chamber to the individual cardiac cells. Therefore, like other tissues of the body, heart muscle must receive blood through blood vessels, specifically via the **coronary circulation** (see the chapter opener photo, p. 297 and ❚Figure 9-29, p. 331). The coronary arteries branch from the aorta just beyond the aortic valve, and the coronary veins empty into the right atrium.

The heart muscle receives most of its blood supply during diastole. Blood flow to the heart muscle cells is substantially reduced during systole for two reasons: (1) The contracting myocardium compresses the major branches of the coronary arteries and (2) the open aortic valve partially blocks the entrance to the coronary vessels. Thus, about 70% of coronary arterial flow occurs during diastole, driven by the aortic blood pressure, with only 30% occurring during systole, driven by ventricular contraction.

This limited time for coronary blood flow becomes especially important during rapid heart rates, when diastolic time is much reduced. Just when increased demands are placed on the heart to pump more rapidly, it has less time to provide O_2 and nourishment to its own musculature to accomplish the increased workload.

Matching of Coronary Blood Flow to Heart Muscle's O_2 Needs Nevertheless, under normal circumstances, the heart muscle receives adequate blood flow to support its activities—even during exercise, when the rate of coronary blood flow increases up to five times its resting rate. Extra blood is delivered to the cardiac cells primarily by vasodilation, or enlargement, of the coronary vessels, which lets more blood flow through them, especially during diastole. The increased coronary blood flow is necessary to meet the heart's increased O_2 requirements because the heart, unlike most other tissues, is unable to remove much additional O_2 from the blood passing through its vessels to support increased metabolic activities. Most other tissues under resting conditions extract only about


❚Figure 9-26 **Matching of coronary blood flow to the O_2 need of cardiac muscle cells.**

25% of the O_2 available from the blood flowing through them, leaving a considerable O_2 reserve that can be drawn on when a tissue has increased O_2 needs—that is, the tissue can immediately increase the O_2 available to it by removing a greater percentage of O_2 from the blood passing through it. In contrast, the heart, even under resting conditions, removes up to 65% of the O_2 available in the coronary vessels, far more than is withdrawn by other tissues. This leaves little O_2 in reserve in the coronary blood should cardiac O_2 demands increase. Therefore, the primary means by which more O_2 can be made available to the heart muscle is by increasing coronary blood flow.

Coronary blood flow is adjusted primarily in response to changes in the heart's O_2 requirements. Among the proposed links between blood flow and O_2 needs is *adenosine,* which is formed from adenosine triphosphate (ATP) during cardiac metabolic activity. Cardiac cells form and release more adenosine when cardiac activity increases, and the heart accordingly needs more O_2 and uses more ATP as an energy source. The released adenosine, acting as a paracrine (see p. 114), induces dilation of the coronary blood vessels, allowing more O_2-rich blood to flow to the more active cardiac cells to meet their increased O_2 demand (❚Figure 9-26). This matching of O_2 delivery to O_2 needs is crucial because heart muscle depends on oxidative processes to generate energy. The heart cannot get enough ATP through anaerobic metabolism (see p. 39).

Nutrient Supply to the Heart Although the heart must rely heavily on its O_2 supply to generate ATP, it can tolerate wide variations in its nutrient supply. As fuel sources, the heart primarily uses fatty acids and, to a lesser extent, glucose and lactate, depending on their availability. Because cardiac muscle is adaptable and can shift metabolic pathways to use whatever nutrient is available, the primary danger of

Unless otherwise noted, all content on this page is © Cengage Learning.

insufficient coronary blood flow is not fuel shortage but O_2 deficiency.

Atherosclerotic coronary artery disease can deprive the heart of essential O_2.

Clinical Note Adequacy of coronary blood flow is relative to the heart's O_2 demands at any moment. In the normal heart, coronary blood flow increases correspondingly as O_2 demands rise. With coronary artery disease, coronary blood flow may not be able to keep pace with rising O_2 needs. The term **coronary artery disease (CAD)** refers to pathological changes within the coronary artery walls that diminish blood flow through these vessels. A given rate of coronary blood flow may be adequate at rest but insufficient in physical exertion or other stressful situations.

CAD is the underlying cause of about 50% of all deaths in the United States and worldwide. More people die of complications of CAD than from all cancers combined. CAD can cause myocardial ischemia and possibly lead to a heart attack by three mechanisms: (1) profound vascular spasm of the coronary arteries, (2) formation of atherosclerotic plaques, and (3) thromboembolism. We discuss each in turn.

Vascular Spasm **Vascular spasm** is an abnormal spastic constriction that transiently narrows the coronary vessels. Vascular spasms are associated with the early stages of CAD and are most often triggered by exposure to cold, physical exertion, or anxiety. The condition is reversible and usually does not last long enough to damage the cardiac muscle.

When too little O_2 is available in the coronary vessels, the endothelium (blood vessel lining) releases *platelet-activating factor (PAF)*. PAF, which exerts a variety of actions, was named for its first discovered effect, activating platelets. Among its other effects, PAF, once released from the endothelium, diffuses to the underlying vascular smooth muscle and causes it to contract, bringing about vascular spasm.

Development of Atherosclerosis **Atherosclerosis** is a progressive, degenerative arterial disease that leads to occlusion (gradual blockage) of affected vessels, reducing blood flow through them. Atherosclerosis is characterized by plaques forming beneath the vessel lining within arterial walls. An **atherosclerotic plaque** consists of a lipid-rich core covered by an abnormal overgrowth of smooth muscle cells, topped off by a collagen-rich connective tissue cap. As the plaque forms, it bulges into the vessel lumen (❙Figure 9-27).

Although all the contributing factors have not yet been identified, in recent years investigators have sorted out the following complex sequence of events in the gradual development of atherosclerosis:

1. Atherosclerosis starts with injury to the blood vessel wall, which triggers an *inflammatory response* that sets the stage for plaque buildup. Normally, inflammation is a protective response that fights infection and promotes repair of damaged tissue (see p. 408). However, when the cause of the injury persists within the vessel wall, the sustained, low-grade inflammatory response over a course of decades can insidiously lead to
❙**Figure 9-27** **Atherosclerotic plaque in a coronary vessel**.

arterial plaque formation and heart disease. Plaque formation likely has many causes. Suspected artery-abusing agents that may set off the vascular inflammatory response include oxidized cholesterol, free radicals, high blood pressure, homocysteine, chemicals released from fat cells, or even bacteria and viruses that damage blood vessel walls. The most common triggering agent appears to be oxidized cholesterol. (For further discussion of the role of cholesterol and other factors in the development of atherosclerosis, see the boxed feature on pp. 328–329, ❙Concepts, Challenges, and Controversies.)

2. Typically, the initial stage of atherosclerosis is characterized by accumulation beneath the endothelium of excessive amounts of *low-density lipoprotein (LDL)*, the so-called bad cholesterol in combination with a protein carrier. As LDL accumulates within the vessel wall, this cholesterol product becomes oxidized, primarily by oxidative wastes produced by the blood vessel cells. These wastes are *free radicals,* very unstable electron-deficient particles that are highly reactive and cause cell damage by snatching electrons from other molecules. Antioxidant vitamins that prevent LDL oxidation, such as *vitamin E, vitamin C,* and *beta-carotene,* slow plaque deposition.

Atherosclerosis: Cholesterol and Beyond

THE CAUSE OF ATHEROSCLEROSIS IS still not entirely clear. Certain high-risk factors have been associated with an increased incidence of atherosclerosis and coronary artery disease. Included among them are genetic predisposition, obesity, advanced age, smoking, hypertension, lack of exercise, high blood concentrations of C-reactive protein, elevated levels of homocysteine, infectious agents, and (most notoriously) elevated cholesterol levels in the blood.

Sources of Cholesterol

The body has two sources of cholesterol: (1) dietary intake of cholesterol, with animal products such as egg yolk, red meats, and butter being especially rich in this lipid (animal fats contain cholesterol, whereas plant fats typically do not), and (2) manufacture of cholesterol by cells, especially liver cells.

"Good" versus "Bad" Cholesterol

Actually, the amount of cholesterol bound to various plasma protein carriers, not the total blood cholesterol, is most important to the risk of developing atherosclerotic heart disease. Because cholesterol is a lipid, it is not very soluble in blood. Most cholesterol in the blood is attached to specific plasma protein carriers in the form of lipoprotein complexes, which are soluble in blood. The three major lipoproteins are named for their density of protein as compared to lipid: (1) **high-density lipoproteins (HDL)**, which contain the most protein and least cholesterol; (2) **low-density lipoproteins (LDL)**, which have less protein and more cholesterol; and (3) **very-low-density lipoproteins (VLDL)**, which have the least protein and most lipid, but the lipid they carry is neutral fat, not cholesterol.

Cholesterol carried in LDL complexes has been termed "bad" cholesterol because cholesterol is transported *to* the cells, including those lining the blood vessel walls, by LDL. The propensity toward developing atherosclerosis substantially increases with elevated levels of LDL. The presence of oxidized LDL within an arterial wall is a major trigger for the inflammatory process that leads to development of atherosclerotic plaques (see p. 327).

In contrast, cholesterol carried in HDL complexes has been dubbed "good" cholesterol because HDL removes cholesterol *from* the cells and transports it to the liver for partial elimination from the body. HDL also helps protect against formation of atherosclerotic plaques by inhibiting oxidation of LDL. Furthermore, HDL has anti-inflammatory action, helps stabilize atherosclerotic plaques so that they are less prone to rupture, and reduces clot formation, all actions that counter progressive development of atherosclerosis. The risk of atherosclerosis is inversely related to HDL concentration in the blood—that is, higher HDL levels are associated with a lower incidence of atherosclerotic heart disease.

Some other factors known to influence atherosclerotic risk can be related to HDL levels; for example, cigarette smoking lowers HDL, whereas regular exercise raises HDL.

Cholesterol Uptake by Cells

Unlike most lipids, cholesterol is not used as metabolic fuel by cells. Instead, it is an essential component of plasma membranes. In addition, a few special cell types use cholesterol as a precursor for synthesis of secretory products, such as steroid hormones and bile salts. Although most cells can synthesize some of the cholesterol needed for their plasma membranes, they cannot manufacture sufficient amounts and therefore must rely on supplemental cholesterol being delivered by the blood. Cells accomplish cholesterol uptake from the blood by synthesizing receptor proteins specifically capable of binding LDL and inserting these receptors into the plasma membrane. When an LDL particle binds to one of the membrane receptors, the cell engulfs the particle by receptor-mediated endocytosis, receptor and all (see p. 31). Within the cell, lysosomal enzymes break down the LDL to free the cholesterol, making it available to the cell for synthesis of new cellular membrane. The LDL receptor, which is also freed within the cell, is recycled back to the surface membrane.

If too much free cholesterol accumulates in the cell, the cell shuts down synthesis of LDL receptor proteins so that it takes up less cholesterol from the blood. Faced with a cholesterol shortage, in contrast, the cell makes more LDL receptors so that it can engulf more cholesterol from the blood.

Maintenance of Blood Cholesterol Level and Cholesterol Metabolism

Maintaining a constant blood-borne cholesterol supply to the cells involves an interaction between dietary cholesterol and synthesis of

3. In response to the presence of oxidized LDL or other irritants, the endothelial cells produce chemicals that attract *monocytes,* a type of white blood cell, to the site. These immune cells trigger a local inflammatory response.

4. Once they leave the blood and enter the vessel wall, monocytes settle down permanently, enlarge, and become large phagocytic cells called *macrophages.* Macrophages voraciously phagocytize (see p. 31) the oxidized LDL until these cells become so packed with fatty droplets that they appear foamy under a microscope. Now called *foam cells,* these engorged macrophages accumulate beneath the vessel lining and form a visible *fatty streak,* the beginning of an atherosclerotic plaque.

5. Thus, the earliest stage of a plaque is accumulation beneath the endothelium of a cholesterol-rich deposit. The disease progresses as smooth muscle cells within the blood vessel wall migrate from the muscular layer of the blood vessel to a position on top of the lipid accumulation, just beneath the endothelium. This migration is triggered by chemicals released at

cholesterol by the liver. When the amount of dietary cholesterol is increased, hepatic (liver) synthesis of cholesterol is turned off because cholesterol in the blood directly inhibits a hepatic enzyme essential for cholesterol synthesis. Thus, as more cholesterol is ingested, the liver produces less. Conversely, when cholesterol intake from food is reduced, the liver synthesizes more of this lipid because the inhibitory effect of cholesterol on the crucial hepatic enzyme is removed. In this way, the blood concentration of cholesterol is maintained at a fairly constant level despite changes in cholesterol intake; thus, it is difficult to significantly reduce cholesterol levels in the blood by decreasing cholesterol intake.

HDL transports cholesterol to the liver. The liver secretes cholesterol, and cholesterol-derived bile salts, into the bile. Bile enters the intestinal tract, where bile salts participate in the digestive process. Most of the secreted cholesterol and bile salts are subsequently reabsorbed from the intestine into the blood to be recycled to the liver. However, the cholesterol and bile salts not reclaimed by absorption are eliminated in the feces and lost from the body. Thus, the liver has a primary role in determining total blood cholesterol levels, and the interplay between LDL and HDL determines the traffic flow of cholesterol between the liver and other cells.

Varying the intake of dietary fatty acids may alter total blood cholesterol levels by influencing one or more of the mechanisms involving cholesterol balance. The blood cholesterol level tends to be raised by ingesting saturated fatty acids found predominantly in animal fats because these fatty acids stimulate cholesterol synthesis and inhibit its conversion to bile salts. In contrast, ingesting polyunsaturated fatty acids, the predominant fatty acids of most plants, tends to reduce blood cholesterol levels by enhancing elimination of both cholesterol and cholesterol-derived bile salts in the feces.

Risk Factors Besides Cholesterol

Despite the strong links between cholesterol and heart disease, more than half of all patients with heart attacks have a normal cholesterol profile and no other well-established risk factors. Clearly, other factors are involved in the development of coronary artery disease in these people. These same factors may also contribute to development of atherosclerosis in people with unfavorable cholesterol levels. The following are among the leading other possible risk factors:

■ Elevated blood levels of **homocysteine** have been implicated as a strong predictor for heart disease, independent of the person's cholesterol or lipid profile. Homocysteine is formed as an intermediate product during metabolism of the essential dietary amino acid *methionine*. Investigators believe homocysteine contributes to atherosclerosis by promoting proliferation of vascular smooth muscle cells, an early step in development of this condition. Furthermore, homocysteine appears to damage endothelial cells and cause oxidation of LDL, both of which contribute to plaque formation. Three B vitamins—*folic acid, vitamin B_{12}* and *vitamin B_6*—all are important in pathways that clear homocysteine from the blood.

■ People with elevated levels of **C-reactive protein (CRP)**, a blood-borne marker of inflammation, have a higher risk for developing coronary artery disease. About half of all people who have a heart attack have high CRP, whereas high CRP is much less common in those without heart disease. Because inflammation plays a crucial role in the development of atherosclerosis, anti-inflammatory drugs such as aspirin help prevent heart attacks. Furthermore, aspirin protects against heart attacks through its role in inhibiting clot formation. Also, *statin* drugs not only lower LDL, but also have anti-inflammatory effects.

■ Accumulating data implicate an infectious agent as the underlying culprit in some cases of atherosclerotic disease. Among the leading suspects are respiratory infection–causing *Chlamydia pneumoniae,* cold sore–causing herpes virus, and gum disease–causing bacteria. If a link between infections and coronary artery disease can be confirmed, antibiotics may be added as a heart-disease prevention strategy.

As you can see, the relationships among atherosclerosis, cholesterol, and other factors are far from clear. Much research on this complex disease is currently in progress because the incidence of atherosclerosis is so high and its consequences are potentially fatal.

the inflammatory site. At their new location, the smooth muscle cells continue to divide and enlarge. Together the lipid-rich core and overlying smooth muscle form a maturing plaque.

6. As it continues to develop, the plaque progressively bulges into the lumen of the vessel, narrowing the opening through which blood can flow.

7. Further contributing to vessel narrowing, oxidized LDL inhibits release of *nitric oxide* from the endothelial cells. Nitric oxide is a local chemical messenger that relaxes the underlying layer of normal smooth muscle cells within the vessel wall. Relaxation of these smooth muscle cells dilates the vessel. Because of reduced nitric oxide release, vessels damaged by developing plaques cannot dilate as readily as normal.

8. A thickening plaque also interferes with nutrient exchange for cells located within the involved arterial wall, leading to degeneration of the wall in the vicinity of the plaque. The damaged area is invaded by *fibroblasts* (scar-forming cells), which form a collagen-rich connective tissue cap over the plaque.

9. Late in the disease, Ca^{2+} often precipitates in the plaque. A vessel so afflicted becomes hard and cannot distend easily.

Thromboembolism and Other Complications of Atherosclerosis Atherosclerosis attacks arteries throughout the body, but the most serious consequences involve damage to the vessels of the brain and heart. Atherosclerosis in regions other than the brain and heart is known as **peripheral artery disease (PAD)**, which most commonly reduces blood flow to the legs. The resultant intermittent leg pain when circulation in the legs becomes inadequate during muscular exertion may be a warning that atherosclerosis is present in the brain and heart, too. In the brain, atherosclerosis is the prime cause of strokes, whereas in the heart it brings about myocardial ischemia and its complications. The following are potential complications of coronary atherosclerosis:

■ *Angina pectoris.* Gradual enlargement of a protruding plaque continues to narrow the vessel lumen and progressively diminishes coronary blood flow, triggering increasingly frequent bouts of transient myocardial ischemia as the ability to match blood flow with cardiac O_2 needs becomes more limited. Although the heart cannot normally be "felt," pain is associated with myocardial ischemia. Such cardiac pain, known as **angina pectoris** (meaning "pain of the chest"), can be felt beneath the sternum and is often referred to (or appears to come from) the left shoulder and down the left arm (see p. 176). The symptoms of angina pectoris recur whenever cardiac O_2 demands become too great in relation to the coronary blood flow—for example, during exertion or emotional stress. The pain is thought to result from stimulation of cardiac nerve endings by the accumulation of lactate when the heart shifts to its limited ability to perform anaerobic metabolism. The ischemia associated with the characteristically brief angina attacks is usually temporary and reversible and can be relieved by rest, taking vasodilator drugs such as *nitroglycerin,* or both. Nitroglycerin brings about coronary vasodilation by being metabolically converted to nitric oxide, which in turn relaxes the vascular smooth muscle.

■ *Thromboembolism.* The enlarging atherosclerotic plaque can rupture, or break through the weakened endothelial lining that covers it, a process that can trigger clot formation. Foam cells release chemicals that weaken the fibrous cap of a plaque by breaking down the connective tissue fibers. Plaques with thick fibrous caps are considered stable because they are not likely to rupture. However, plaques with thinner fibrous caps are unstable because they are likely to rupture and trigger clot formation.

When a plaque ruptures through the endothelium, blood is exposed to collagen in the plaque's collagen-rich connective tissue cap. Blood platelets (formed elements of the blood involved in plugging vessel defects and in clot formation) normally do not adhere to smooth, healthy vessel linings. However, when platelets contact collagen at the site of vessel damage, they stick to the site and help promote the formation of a blood clot. Furthermore, foam cells produce a potent clot promoter. Such an abnormal clot attached to a vessel wall is called a **thrombus**. The thrombus may enlarge gradually until it completely blocks the vessel at that site, or the continued flow of blood past the thrombus may break it loose. As it heads downstream, such a freely floating clot, or **embolus**, may completely plug a smaller vessel (❙ Figure 9-28). Thus, through **thromboembolism**, atherosclerosis can result in a gradual or sudden occlusion of a coronary vessel (or any other vessel).

■ *Heart attack.* When a coronary vessel is completely plugged, the cardiac tissue served by the vessel soon dies from O_2 deprivation and a heart attack occurs, unless the area can be supplied with blood from nearby vessels.

Sometimes a deprived area of cardiac tissue is lucky enough to receive blood from more than one pathway. **Collateral circulation** exists when small terminal branches from adjacent blood vessels nourish the same area. These accessory vessels cannot develop suddenly after an abrupt blockage but may be lifesaving if already developed. Such alternate vascular pathways often develop over a period of time when an atherosclerotic constriction progresses slowly, or they may be induced by sustained demands on the heart through regular aerobic exercise.

In the absence of collateral circulation, the extent of the damaged area during a heart attack depends on the size of the blocked vessel: The larger the vessel occluded, the greater the area deprived of blood supply. As ❙ Figure 9-29 illustrates, a blockage at point A in the coronary circulation would cause more extensive damage than a blockage at point B would. Because there are only two major coronary arteries, complete blockage of either one of these main branches results in extensive myocardial damage. Left coronary artery blockage is most devastating because this vessel supplies blood to 85% of the cardiac tissue.

I Figure 9-29 **Extent of myocardial damage as a function of the size of the occluded vessel.**

The four possible outcomes of a heart attack are:

1. *Immediate death* resulting from (a) acute systolic heart failure occurring because the heart is too weakened to pump effectively to support the body tissues, or (b) fatal ventricular fibrillation brought about by damage to the specialized conducting tissue or induced by O_2 deprivation

2. *Delayed death from complications* because of (a) fatal rupture of the dead, degenerating area of the heart wall affected by the acute infarction, or (b) slowly progressing congestive heart failure because the pumping ability of the weakened heart is unable to keep up with venous return

3. *Full functional recovery* owing to replacement of the damaged area with a strong scar, accompanied by hypertrophy (enlargement) of the remaining normal contractile tissue to compensate for the lost cardiac musculature

4. *Recovery with impaired function* on account of persistence of permanent functional defects, such as bradycardia or conduction blocks, caused by destruction of irreplaceable autorhythmic or conductive tissues

The discovery in 2006 of cardiac stem cells, coupled with earlier studies demonstrating that injecting damaged hearts with stem cells derived from other sources improves cardiac function, has generated hopes of future regenerative therapies. Even though the heart has the potential to produce new myocardial cells on its own through activity of its stem cells, this regenerative ability is minimally functional. Only 1% of heart muscle cells are replaced each year in young adults, and the yearly turnover rate drops to less than half of that in the elderly. For this reason, damaged heart muscle cells are replaced with scar tissue, not new muscle cells. Scientists hope to find a way to spur the latent stem cells into action so that myocardial cells can be replaced if they are lost. Another approach under investigation is to genetically reprogram scar tissue cells (fibroblasts) to transform them into heart muscle cells after a heart attack.

Check Your Understanding 9.5

1. Explain why heart muscle receives most of its blood supply during diastole.

2. Discuss how coronary blood flow varies to match the heart muscle's O_2 needs.

3. Describe an atherosclerotic plaque.

Homeostasis: Chapter in Perspective

Survival depends on continual delivery of needed supplies to all body cells and on ongoing removal of wastes generated by the cells. Furthermore, regulatory chemical messengers, such as hormones, must be transported from their production site to their action site, where they control a variety of activities, most of which are directed toward maintaining a stable internal environment. Finally, to maintain normal body temperature, excess heat produced during muscle contraction must be carried to the skin, where the heat can be lost from the body surface.

The circulatory system contributes to homeostasis by serving as the body's transport system. It provides a way to rapidly move materials from one part of the body to another. Without the circulatory system, materials would not get quickly enough to where they need to be to support life-sustaining activities. For example, O_2 would take months to years to diffuse from the body surface to internal organs, yet through the heart's swift pumping action the blood can pick up and deliver O_2 and other substances to all the cells in a few seconds.

The heart is a dual pump that continuously circulates blood between the lungs, where O_2 is picked up, and the other body tissues, which use O_2 to support their energy-generating chemical reactions. As blood is pumped through the various tissues, other substances besides O_2 are exchanged between the blood and the tissues. For example, blood picks up nutrients as it flows through the digestive organs, and other tissues remove nutrients from blood as it flows through them. Even excess heat is transported by blood from exercising muscles to the skin surface, where it is lost to the external environment.

Although all body tissues constantly depend on the life-supporting blood flow provided to them by the heart, the heart itself is quite an independent organ. It can take care of many of its needs without any outside influence. Contraction of this magnificent muscle is self-generated through a carefully orchestrated interplay of changing ionic permeabilities. Local mechanisms within the heart ensure that blood flow to the cardiac muscle normally meets the heart's need for O_2. In

addition, the heart has built-in capabilities to vary its strength of contraction, depending on the amount of blood returned to it. The heart does not act entirely autonomously, however. It is innervated by the autonomic nervous system and is influenced by the hormone epinephrine, both of which can vary heart rate and contractility, depending on the body's needs for blood delivery. Furthermore, as with all tissues, the cells that make up the heart depend on the other body systems to maintain a stable internal environment in which they can survive and function.

Review Exercises Answers begin on p. A-32

Reviewing Terms and Facts

1. The heart lies in the left half of the thoracic cavity. *(True or false?)*

2. The left ventricle is a stronger pump than the right ventricle because more blood is needed to supply the body tissues than to supply the lungs. *(True or false?)*

3. The only point of electrical contact between the atria and the ventricles is the fibrous skeletal rings that surround and support the heart valves. *(True or false?)*

4. Entrance of Ca^{2+} through funny channels is responsible for the unique plateau phase of the action potential in cardiac contractile cells. *(True or false?)*

5. The atria and the ventricles each act as a functional syncytium. *(True or false?)*

6. Contraction of the papillary muscles tugs on the chordae tendinae to pull open the AV valves during diastole. *(True or false?)*

7. The three components of the circulatory system are _____, _____, and _____.

8. The three layers of the heart wall are _____, _____, and _____.

9. Adjacent cardiac muscle cells are joined end to end at specialized structures known as _____, which contain two types of membrane junctions: _____ and _____.

10. _____% of ventricular filling is normally accomplished before atrial contraction begins.

11. The link that coordinates coronary blood flow with myocardial oxygen needs is _____.

12. Which of the following is the proper sequence of cardiac excitation?

   a. SA node → AV node → atrial myocardium → bundle of His → Purkinje fibers → ventricular myocardium

   b. SA node → atrial myocardium → AV node → bundle of His → ventricular myocardium → Purkinje fibers

   c. SA node → atrial myocardium → ventricular myocardium → AV node → bundle of His → Purkinje fibers

   d. SA node → atrial myocardium → AV node → bundle of His → Purkinje fibers → ventricular myocardium

13. Sympathetic stimulation of the heart

   a. increases the heart rate

   b. increases the contractility of the heart muscle

   c. shifts the Frank–Starling curve to the left

   d. both (a) and (b)

   e. all of the above

14. Match the following:

1. receives O_2-poor blood from the venae cavae	(a) AV valves
2. prevents backflow of blood from the ventricles to the atria	(b) semilunar valves
	(c) left atrium
3. pumps O_2-rich blood into the aorta	(d) left ventricle
4. prevents backflow of blood from the arteries into the ventricles	(e) right atrium
	(f) right ventricle
5. pumps O_2-poor blood into the pulmonary artery	
6. receives O_2-rich blood from the pulmonary veins	

15. Circle the correct choice in each instance to complete the statement: The first heart sound is associated with closing of the *(AV/semilunar)* valves and signals the onset of *(systole/diastole)*, whereas the second heart sound is associated with closing of the *(AV/semilunar)* valves and signals the onset of *(systole/diastole)*.

16. Use the following answer code to compare the relative magnitudes of the pair of items in question:

(a) = Item A is greater than item B

(b) = Item B is greater than item A

(c) = Item A and item B are approximately equal

   1. A. Resistance and pressure in pulmonary circulation
      B. Resistance and pressure in systemic circulation

   2. A. Volume of blood pumped out by left side of heart
      B. Volume of blood pumped out by right side of heart

3. A. Spontaneous rate of depolarization to threshold in SA node

   B. Spontaneous rate of depolarization to threshold in ventricular Purkinje fibers

4. A. Velocity of impulse conduction through AV node

   B. Velocity of impulse conduction through bundle of His and Purkinje fibers

5. A. Rate of ventricular filling in early diastole

   B. Rate of ventricular filling in late diastole

6. A. Stroke volume when EDV equals 130 mL

   B. Stroke volume when EDV equals 160 mL

7. A. Normal stroke volume

   B. Stroke volume on sympathetic stimulation

8. A. Normal stroke volume

   B. Stroke volume on parasympathetic stimulation

9. A. Volume of blood in ventricles at onset of isovolumetric ventricular contraction

   B. Volume of blood in ventricles at end of isovolumetric ventricular contraction

10. A. Volume of blood in left ventricle at the time aortic valve opens

    B. Volume of blood in left ventricle at the time aortic valve closes

11. A. Volume of blood in left ventricle at the time left AV valve opens

    B. Volume of blood in left ventricle at the time left AV valve closes

12. A. Duration of refractory period in cardiac muscle

    B. Duration of contraction in cardiac muscle

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Trace a drop of blood through one complete circuit of the circulatory system.

2. Describe the location and function of each of the four heart valves. What keeps each of these valves from everting?

3. Describe the structure and arrangement of cardiac muscle cells. What are the two specialized types of cardiac muscle cells?

4. Discuss the ionic movements involved in the membrane clock mechanism and Ca^{2+} clock mechanism that are collectively responsible for the pacemaker potential.

5. Why is the SA node the pacemaker of the heart?

6. Describe the normal spread of cardiac excitation. What is the significance of the AV nodal delay? Why is the ventricular conduction system important?

7. Compare the changes in permeability, ionic movements, and membrane potential associated with an action potential in a nodal pacemaker cell with those in a myocardial contractile cell.

8. Why is tetanus of cardiac muscle impossible? Why is this inability advantageous?

9. What electrical event does each component of the ECG represent?

10. Describe the mechanical events (that is, pressure changes, volume changes, valve activity, and heart sounds) of the cardiac cycle. Correlate the mechanical events of the cardiac cycle with the changes in electrical activity.

11. Compare the defect, murmur associated with, and circulatory consequences of a stenotic and an insufficient valve.

12. Distinguish among cardiac output, ejection fraction, and cardiac reserve.

13. Discuss autonomic nervous system control of heart rate.

14. Describe intrinsic and extrinsic control of stroke volume.

15. What are the pathological changes and consequences of coronary artery disease?

16. Discuss the sources, transport, and elimination of cholesterol in the body. Distinguish between "good" cholesterol and "bad" cholesterol.

Solving Quantitative Exercises

1. During heavy exercise, the CO of a trained athlete may increase to 40 liters per minute. If SV could not increase above the normal value of 70 mL, what HR would be necessary to achieve this CO? Is such a HR physiologically possible?

2. How much blood remains in the heart after systole if the SV is 85 mL and the EDV is 125 mL?

3. Calculate the ejection fraction in each of the three circumstances illustrated in Figure 9-22, p. 323.

Applying Clinical Reasoning

In a physical exam Rachel B.'s heart rate was rapid and very irregular. Furthermore, her heart rate, determined directly by listening to her heart with a stethoscope, exceeded the pulse rate taken concurrently at her wrist. No definite P waves could be detected on Rachel's ECG. The QRS complexes were normal in shape but occurred sporadically. Given these findings, what is the most likely diagnosis of Rachel's condition? Explain why the condition is characterized by a rapid, irregular heartbeat. Would CO be seriously impaired by this condition? Why or why not? What accounts for the pulse deficit?

Thinking at a Higher Level

1. The stroke volume ejected on the next heartbeat after a premature ventricular contraction (PVC) is usually larger than normal. Can you explain why? (*Hint:* At a given heart rate, the interval between a PVC and the next normal beat is longer than the interval between two normal beats.)

2. Trained athletes usually have lower resting heart rates than normal (for example, 50 beats per minute in an athlete compared to 70 beats per minute in a sedentary individual). Considering that the resting CO is 5000 mL per minute in both trained athletes and sedentary people, what is responsible for the bradycardia of trained athletes?

3. During fetal life, because of the tremendous resistance offered by the collapsed, nonfunctioning lungs, the pressures in the right half of the heart and pulmonary circulation are higher than those in the left half of the heart and systemic circulation, a situation that reverses after birth. Also in the fetus, a vessel called the **ductus arteriosus** connects the pulmonary artery and aorta as these major vessels both leave the heart. The blood pumped out by the heart into the pulmonary circulation is shunted from the pulmonary artery into the aorta through the ductus arteriosus, bypassing the nonfunctional lungs. What force is driving blood to flow in this direction through the ductus arteriosus?

At birth, the ductus arteriosus normally collapses and eventually degenerates into a thin, ligamentous strand. On occasion, this fetal bypass fails to close properly at birth, leading to a patent (open) ductus arteriosus. In what direction would blood flow through a patent ductus arteriosus? What possible outcomes would you predict might occur as a result of this blood flow?

4. There are two branches of the bundle of His, the right and left bundle branches, each of which travels down its respective side of the ventricular septum (see ❙Figure 9-8, p. 305). Occasionally, conduction through one of these branches becomes blocked (so-called *bundle-branch block*). In this case, the wave of excitation spreads out from the terminals of the intact branch and eventually depolarizes the whole ventricle, but the normally stimulated ventricle completely depolarizes a considerable time before the ventricle on the side of the defective bundle branch. For example, if the left bundle branch is blocked, the right ventricle will be completely depolarized two to three times more rapidly than the left ventricle. How would this defect affect the heart sounds?

5. Occasionally a child is born with a defective aortic valve that is both stenotic and insufficient. The abnormally shaped valve leaflets neither open nor close properly. List the sequence of sounds that would be heard when listening to the heart with a stethoscope, taking into account the timing and type of murmur(s).

The Blood Vessels and Blood Pressure

<div style="text-align:right">**10**</div>

Susumu Nishinaga/Science Source

A scanning electron micrograph of a resin cast of blood vessels supplying the small intestine. After liquid resin injected into the vessels hardens, the tissues are chemically digested leaving a cast of the highly branched vessels. The myriad smallest blood vessels are capillaries across which materials are exchanged between the blood and surrounding cells.

Homeostasis Highlights

The circulatory system contributes to homeostasis by serving as the body's transport system. The **blood vessels** transport and distribute blood pumped through them by the heart to meet the body's needs for O_2 and nutrient delivery, waste removal, and hormonal signaling. The highly elastic **arteries** transport blood from the heart to the organs and serve as a pressure reservoir to continue driving blood forward when the heart is relaxing and filling. The **mean arterial blood pressure** is closely regulated to ensure adequate blood delivery to the organs. The amount of blood that flows through a given organ depends on the caliber (internal diameter) of the highly muscular **arterioles** that supply the organ. Arteriolar caliber is subject to control so that flow to particular organs can be variably adjusted to best serve the body's needs at the moment. The thin-walled **capillaries** are the actual site of exchange between blood and surrounding tissue cells. The highly distensible **veins** return blood from the organs to the heart and serve as a blood reservoir.

335

10.1 Patterns and Physics of Blood Flow

Most body cells are not in direct contact with the external environment, yet these cells must make exchanges with this environment, such as picking up O_2 and nutrients and eliminating wastes. Furthermore, chemical messengers must be transported between cells to accomplish integrated activity. To achieve these long-distance exchanges, cells are linked with one another and with the external environment by vascular (blood vessel) highways. Blood is transported to all parts of the body through a system of vessels that brings fresh supplies to the vicinity of all cells while removing their wastes.

To review, all blood pumped by the right side of the heart passes through the pulmonary circulation to the lungs for O_2 pickup and CO_2 removal. The blood pumped by the left side of the heart into the systemic circulation is distributed in various proportions to the systemic organs through a parallel arrangement of vessels that branch from the aorta (▮Figure 10-1). This arrangement ensures that all organs receive blood of the same composition—that is, one organ does not receive "leftover" blood that has passed through another organ. Because of this parallel arrangement, blood flow through each systemic organ can be independently adjusted as needed.

We first examine some general principles regarding blood flow patterns and the physics of blood flow. Then we turn attention to the various types of blood vessels through which blood flows. We end by discussing how blood pressure is regulated to ensure adequate delivery of blood to the tissues.

To maintain homeostasis, reconditioning organs receive blood flow in excess of their needs.

Blood is constantly "reconditioned" so that its composition remains relatively constant despite an ongoing drain of supplies to support metabolic activities and despite continual addition of wastes from the tissues. Organs that **recondition** the blood normally receive much more blood flow than is necessary to meet their basic metabolic needs, so they can adjust the extra blood to achieve homeostasis. For example, large percentages of the cardiac output (CO) are distributed to the digestive tract (to pick up nutrients), to the kidneys (to eliminate metabolic wastes and adjust water and electrolyte composition), and to the skin (to eliminate heat). Blood flow to the other organs—heart, skeletal muscles, and so on—is solely for filling these organs' metabolic needs and can be adjusted according to their level of activity. For example, during exercise, additional blood is delivered to the active muscles to meet their increased metabolic needs.

Because reconditioning organs—digestive organs, kidneys, and skin—receive blood flow in excess of their needs, they can withstand temporary reductions in blood flow much better than other organs can that do not have this extra margin of blood supply. The brain in particular suffers irreparable damage when transiently deprived of blood supply. After only 4 minutes without O_2, permanent brain damage occurs. Therefore, con-
▮Figure 10-1 **Distribution of cardiac output (CO) at rest.** The lungs receive all the blood pumped out by the right side of the heart, whereas the systemic organs each receive some of the blood pumped out by the left side of the heart. The percentage of pumped blood received by the various organs under resting conditions is indicated. This distribution of CO can be adjusted as needed.

stant delivery of adequate blood to the brain, which can least tolerate disrupted blood supply, is a high priority in the overall operation of the circulatory system.

In contrast, the reconditioning organs can tolerate significant reductions in blood flow for quite a long time, and often do. For example, during exercise some of the blood that normally flows through the digestive organs and kidneys is diverted to the skeletal muscles. Likewise, to conserve body heat, blood flow through the skin is markedly restricted during exposure to cold.

Later in the chapter, you will see how distribution of CO is adjusted according to the body's current needs. For now, we concentrate on the factors that influence blood flow through a given blood vessel.

Blood flow through a vessel depends on the pressure gradient and vascular resistance.

The **flow rate** of blood through a vessel (that is, the volume of blood passing through per unit of time) is directly proportional to the pressure gradient (as the pressure gradient increases, flow rate increases) and inversely proportional to vascular resistance (as resistance increases, flow rate decreases):

$$F = \Delta P/R$$

where

F = flow rate of blood through a vessel
ΔP = pressure gradient
R = resistance of blood vessel

Pressure Gradient The **pressure gradient** is the difference in pressure between the beginning and the end of a vessel. Blood flows from an area of higher pressure to an area of lower pressure down a pressure gradient. Contraction of the heart imparts pressure to the blood, which is the main driving force for flow through a vessel. Because of frictional losses (resistance), the pressure drops as blood flows throughout the vessel's length. Accordingly, pressure is higher at the beginning than at the end of the vessel, establishing a pressure gradient for forward flow of blood through the vessel. The greater the pressure gradient forcing blood through a vessel, the greater the flow rate through that vessel (❚Figure 10-2a). Think of a garden hose attached to a faucet. If you turn on the faucet slightly, a small stream of water flows out of the end of the hose because the pressure is slightly greater at the beginning than at the end of the hose. If you open the faucet all the way, the pressure gradient increases tremendously so that water flows through the hose faster and spurts from the end of the hose. Note that the *difference* in pressure between the two ends of a vessel, not the absolute pressures within the vessel, determines flow rate (❚Figure 10-2b).

Resistance The other factor influencing flow rate through a vessel is **resistance**, which is a measure of the hindrance or opposition to blood flow through the vessel, caused by friction between the moving fluid and the stationary vascular walls. As resistance to flow increases, it is more difficult for blood to pass through the vessel, so flow rate decreases (as long as the pressure gradient remains unchanged). When resistance

50 mm Hg pressure — 10 mm Hg pressure

ΔP = 40 mm Hg
Vessel 1

90 mm Hg pressure — 10 mm Hg pressure

ΔP = 80 mm Hg
Vessel 2

ΔP in vessel 2 = 2 times that of vessel 1

Flow in vessel 2 = 2 times that of vessel 1
Flow ∝ ΔP

(a) Comparison of flow rate in vessels with a different ΔP

90 mm Hg pressure — 10 mm Hg pressure

ΔP = 80 mm Hg
Vessel 2

180 mm Hg pressure — 100 mm Hg pressure

ΔP = 80 mm Hg
Vessel 3

ΔP in vessel 3 = the same as that of vessel 2, despite the larger absolute values

Flow in vessel 3 = the same as that of vessel 2
Flow ∝ ΔP

(b) Comparison of flow rate in vessels with the same ΔP

❚Figure 10-2 **Relationship of flow to the pressure gradient in a vessel.** (a) As the difference in pressure (ΔP) between the two ends of a vessel increases, the flow rate increases proportionately. (b) Flow rate is determined by the *difference* in pressure between the two ends of a vessel, not the magnitude of the pressures at each end.

---

increases, the pressure gradient must increase correspondingly to maintain the same flow rate. Accordingly, when the vessels offer more resistance to flow, the heart must work harder to maintain adequate circulation.

Resistance to blood flow is (1) directly proportional to viscosity of the blood, (2) directly proportional to vessel length, and (3) inversely proportional to vessel radius, which is by far the most important:

$$R \propto \eta \, L/r^4$$

where

η = viscosity
L = vessel length
r = vessel radius

Viscosity refers to the friction developed between the molecules of a fluid as they slide over each other during flow of the fluid. The thicker a liquid is, the greater its viscosity, the greater the resistance to flow. For example, molasses flows more slowly than water because molasses has greater viscosity. Blood viscosity is determined primarily by the number of circulating red blood cells. Normally, this factor is relatively constant and not important in controlling resistance. Occasionally, however, blood viscosity and resistance to flow are increased because an excessive number of red blood cells are present, in which case blood flow is more sluggish than normal.

Because blood "rubs" against the lining of the vessels as it flows past, the greater the vessel surface area in contact with the blood, the greater the resistance to flow. Surface area is determined by both the length and the radius of the vessel. At a constant radius, the longer the vessel is, the greater the surface area and the greater the resistance to flow. Because vessel length remains constant in the body, it is not a variable factor in the control of vascular resistance.

Therefore, the major determinant of resistance to flow is the vessel's radius. Fluid passes more readily through a large vessel than through a smaller vessel. The reason is that a given volume of blood comes into contact with more of the surface area of a small-radius vessel than of a larger-radius vessel, resulting in greater resistance (❚Figure 10-3a).

Furthermore, a slight change in the radius of a vessel brings about a substantial change in flow because, as can be noted in the preceding equation for R, resistance is inversely proportional to the fourth power of the radius (multiplying the radius by itself four times; $R \propto 1/r^4$). Thus, doubling the radius reduces
(a) Comparison of contact of a given volume of blood with the surface area of a small-radius vessel and a large-radius vessel

Radius in vessel 2 = 2 times that of vessel 1

Resistance in vessel 2 = 1/16 that of vessel 1

Flow in vessel 2 = 16 times that of vessel 1

Resistance $\propto 1/r^4$
Flow $\propto r^4$
(b) Influence of vessel radius on resistance and flow

❚Figure 10-3 **Relationship of resistance and flow to the vessel radius.** (a) The smaller-radius vessel offers more resistance to blood flow because the blood "rubs" against a larger surface area. (b) Doubling the radius decreases the resistance to 1/16 and increases the flow 16 times because the resistance is inversely proportional to the fourth power of the radius.

FIGURE FOCUS: *How would the flow rate in vessel 3, which has the same radius as vessel 2 but double the pressure gradient, compare with the flow rate in vessel 1 and in vessel 2? How would the flow rate in vessel 4, which has double the radius of vessel 2 but the same pressure gradient as vessels 1 and 2, compare with the flow rate in vessel 1 and in vessel 2?*

For simplicity, only two capillary beds within two organs are illustrated.

❚Figure 10-4 **Basic organization of the cardiovascular system.** Arteries progressively branch as they carry blood from the heart to the organs. A separate small arterial branch delivers blood to each of the various organs. As a small artery enters the organ it is supplying, it branches into arterioles, which further branch into an extensive network of capillaries. The capillaries rejoin to form venules, which further unite to form small veins that leave the organ. The small veins progressively merge as they carry blood back to the heart.

the resistance to 1/16th its original value ($r^4 = 2 \times 2 \times 2 \times 2 = 16$; $R = 1/16$) and therefore increases flow through the vessel 16-fold (at the same pressure gradient) (❚Figure 10-3b). The converse is also true: Only 1/16th as much blood flows through a vessel at the same driving pressure when its radius is halved. Importantly, the radius of arterioles can be regulated and is the key factor in controlling resistance to blood flow throughout the vascular circuit.

Poiseuille's Law The factors that affect flow rate through a vessel are integrated in **Poiseuille's law** as follows:

$$\text{Flow rate} = \frac{\pi \Delta P r^4}{8 \eta L}$$

The significance of the relationships among flow, pressure, and resistance will become even more apparent as we embark on a voyage through the vessels.

The vascular tree consists of arteries, arterioles, capillaries, venules, and veins.

The systemic and pulmonary circulations each consist of a closed system of vessels (❚Figure 10-4). These vascular loops each are made up of a continuum of different blood vessel types that begins and ends with the heart.

Looking specifically at the systemic circulation, **arteries**, which carry blood from the heart to the organs, branch into a "tree" of progressively smaller vessels, with the various branches delivering blood to different regions of the body. When a small artery reaches the organ it is supplying, it branches into numerous **arterioles**. The volume of blood flowing through an organ can be adjusted by regulating the caliber (internal diameter) of the organ's arterioles. Arterioles branch further within the organs into **capillaries**, the smallest of vessels, across which all exchanges are made with surrounding cells. Capillary exchange is the entire purpose of the circulatory system; all other activi-

ties of the system are directed toward ensuring an adequate distribution of replenished blood to capillaries for exchange with all cells. Capillaries rejoin to form small **venules**, which further merge to form small **veins** that leave the organs. The small veins progressively unite to form larger veins that eventually empty into the heart. The arterioles, capillaries, and venules are collectively referred to as the **microcirculation** because they are only visible through a microscope. The microcirculatory vessels are all located within the organs.

The pulmonary circulation consists of the same vessel types, but all the blood in this loop goes between the heart and the lungs. If all of the vessels in the body were strung end to end, they could circle the circumference of Earth twice. In discussing the vessel types in this chapter, we refer to their roles in the systemic circulation, starting with systemic arteries.

Check Your Understanding 10.1

1. Name the reconditioning organs.
2. Give the equation showing the relationship among flow rate of blood through a vessel, the pressure gradient, and the resistance to flow and give the equation for the relationship between resistance and vessel radius.
3. List the blood vessel types, state their functions, and indicate which comprise the microcirculation.

10.2 Arteries

The consecutive segments of the vascular tree are specialized to perform specific tasks (❙Table 10-1).

❙TABLE 10-1 Features of Blood Vessels

Feature	Arteries	Arterioles	Capillaries	Veins
Number	Several hundred*	Half a million	10 billion	Several hundred*
Special features	Thick, highly elastic, walls; large radii*	Highly muscular, well-innervated walls; small radii	Very thin walled; large total cross-sectional area	Thin walled compared to arteries; highly distensible; large radii*
Functions	Passageway from the heart to organs; pressure reservoir	Primary resistance vessels; determine distribution of cardiac output	Site of exchange; determine distribution of extracellular fluid between plasma and interstitial fluid	Passageway to the heart from organs; blood reservoir

Arteries serve as rapid-transit passageways to the organs and as a pressure reservoir.

Arteries are specialized (1) to serve as rapid-transit passageways for blood from the heart to the organs (because of their large radius, arteries offer little resistance to blood flow) and (2) to act as a **pressure reservoir** to provide the driving force for blood when the heart is relaxing.

How do the arteries act as a pressure reservoir? The heart alternately contracts to pump blood into the arteries and then relaxes to refill with blood from the veins. When the heart is relaxing and refilling, no blood is pumped out. However, capillary flow does not fluctuate between cardiac systole and diastole—that is, blood flow is continuous through the capillaries supplying the organs. The driving force for the continued flow of blood to the organs during cardiac relaxation is provided by elastic recoil of the walls of large arteries. Let us see how.

All vessels are lined with an *endothelium,* a single layer of smooth, flat endothelial cells, which is continuous with the endothelial lining of the heart (see p. 302). A thick wall made up of smooth muscle and connective tissue surrounds the arteries' endothelial lining (**Table 10-1**). Arterial connective tissue contains an abundance of two types of connective tissue fibers: *collagen fibers,* which provide tensile strength against the high, driving pressure of blood ejected from the heart, and *elastin fibers,* which give the arterial walls elasticity (**Figure 10-5**). The large arteries nearest the heart contain relatively more elastin and are called **elastic arteries**. As the major vessels branch into medium-size vessels approaching the organs, the vessel wall becomes relatively less elastic and more muscular, giving rise to the term **muscular arteries** for these vessels.

As the heart pumps blood into the arteries during ventricular systole, a greater volume of blood enters the arteries from the heart than leaves them to flow into the smaller arterioles downstream because these smaller vessels have a greater resistance to flow than the arteries do. However, because of the abundance of elastin in the arterial walls, they behave much like a balloon does when you blow it up. The highly elastic large arteries expand to temporarily hold the excess volume of ejected blood, storing some of the pressure energy imparted by cardiac contraction in their stretched walls—just as a balloon expands to accommodate the extra volume of air you blow into it (**Figure 10-6a**). When the heart relaxes and temporarily stops pumping blood into the arteries, the stretched arterial walls passively recoil, like an inflated balloon that is released. This **elastic recoil** exerts pressure on the blood in the large arteries during diastole. The pressure pushes the excess blood contained in the arteries into the vessels downstream, ensuring continued blood flow to the organs when the heart is relaxing and not pumping blood into the system (**Figure 10-6b**).

Arterial pressure fluctuates in relation to ventricular systole and diastole.

Blood pressure, the force exerted by the blood against a vessel wall, depends on the volume of blood contained within the vessel and the **compliance**, or **distensibility**, of the vessel walls (how easily they can be stretched). If the volume of blood entering the arteries were equal to the volume of blood leaving the arteries during the same period, arterial blood pressure would remain constant. This is not the case, however. During ventricular systole, a stroke volume of blood enters the arteries from the ventricle, while only about one third as much

(a) Heart contracting and emptying

(b) Heart relaxing and filling
Figure 10-6 Arteries as a pressure reservoir. Because of their elasticity, arteries act as a pressure reservoir. (a) The elastic arteries distend during cardiac systole as more blood is ejected into them than drains off into the narrow, high-resistance arterioles downstream. (b) Elastic recoil of arteries during cardiac diastole continues driving blood forward when the heart is not pumping.

blood leaves the arteries to enter the arterioles. During diastole, no blood enters the arteries, while blood continues to leave, driven by elastic recoil. The maximum pressure exerted in the arteries when blood is ejected into them during systole, the **systolic pressure**, averages 120 mm Hg. The minimum pressure within the arteries when blood is draining off into the rest of the vessels during diastole, the **diastolic pressure**, averages 80 mm Hg. Although ventricular pressure falls to 0 mm Hg during diastole, arterial pressure does not fall to 0 mm Hg because the next cardiac contraction refills the arteries before all the blood drains off (❙Figure 10-7a; also see ❙Figure 9-16, p. 316).

Clinically, arterial blood pressure is expressed as systolic pressure over diastolic pressure, with desirable blood pressure being 120/80 (read "120 over 80") mm Hg or slightly less.

When you palpate (feel with your fingers) an artery lying close to the surface of the skin (such as at your wrist or neck), you can feel the artery expand as the pressure rises during systole when blood is ejected into the arterial system by the left ventricle. What you feel when you "take a pulse" is the difference between systolic and diastolic pressures; you don't feel anything during diastole, but you feel the surge in pressure during systole. This pressure difference is known as the **pulse pressure**. When blood pressure is 120/80, pulse pressure is 40 mm Hg (120 minus 80 mm Hg). Because the pulse can be felt each time the ventricles pump blood into the arteries, the pulse rate is a measure of the heart rate.

Blood pressure can be measured indirectly by using a sphygmomanometer.

The changes in arterial pressure throughout the cardiac cycle can be measured directly by connecting a pressure-measuring device to a needle inserted in an artery. However, it is more convenient and reasonably accurate to measure the pressure indirectly with a **sphygmomanometer**, an externally applied inflatable cuff attached to a pressure gauge. When the cuff is wrapped around the upper arm and then inflated with air, the pressure of the cuff is transmitted through the tissues to the underlying brachial artery, the main vessel carrying blood to the forearm (❙Figure 10-7b). The technique involves balancing the pressure in the cuff against the pressure in the artery. When cuff pressure is greater than the pressure in the vessel, the vessel is pinched closed so that no blood flows through it. When blood pressure is greater than cuff pressure, the vessel is open and blood flows through.

During the determination of blood pressure, a stethoscope is placed over the brachial artery at the inside bend of the elbow just below the cuff. No sound can be detected either when blood is not flowing through the vessel or when blood is flowing in the normal, smooth laminar flow (see p. 318). Turbulent blood flow, in contrast, creates vibrations that can be heard. The sounds heard when determining blood pressure, known as **Korotkoff sounds**, are distinct from the heart sounds associated with valve closure heard when listening to the heart with a stethoscope.

At the onset of a blood pressure determination, the cuff is inflated to a pressure greater than systolic blood pressure so

that the brachial artery collapses. Because the externally applied pressure is greater than the peak internal pressure, the artery remains completely pinched closed throughout the entire cardiac cycle; no sound can be heard because no blood is passing through (point ❶ in ❙Figure 10-7c). As air in the cuff is slowly released, the pressure in the cuff is gradually reduced. When the cuff pressure falls to just below the peak systolic pressure, the artery transiently opens a bit when the blood pressure reaches this peak. Blood escapes through the partially occluded artery for a brief interval before the arterial pressure falls below the cuff pressure and the artery collapses again. This spurt of blood is turbulent, so it can be heard. Thus, the highest cuff pressure at which the *first sound* can be heard indicates the *systolic pressure* (point ❷). As the cuff pressure continues to fall, blood intermittently spurts through the artery and produces a sound with each subsequent cardiac cycle whenever the arterial pressure exceeds the cuff pressure (point ❸).

When the cuff pressure finally falls below diastolic pressure, the brachial artery is no longer pinched closed during any part of the cardiac cycle, and blood can flow uninterrupted through the vessel (point ❺). With the return of nonturbulent blood flow, no further sounds can be heard. Therefore, the lowest cuff pressure at which the *last sound* can be detected indicates the *diastolic pressure* (point ❹).

Mean arterial pressure is the main driving force for blood flow.

The **mean arterial pressure (MAP)** is the *average pressure* driving blood forward into the tissues throughout the cardiac cycle. MAP, not the systolic or diastolic pressure, is the pressure that is monitored and regulated. Contrary to what you might expect, MAP is not the halfway value between systolic and diastolic pressure (for example, with a blood pressure of 120/80, MAP is not 100 mm Hg). The reason is that arterial pressure remains closer to diastolic than to systolic pressure for a longer portion of each cardiac cycle. At resting heart rate, about two thirds of the cardiac cycle is spent in diastole and only one third in systole. As an analogy, if a race car traveled 80 miles per hour (mph) for 40 minutes and 120 mph for 20 minutes, its average speed would be 93 mph, not the halfway value of 100 mph. Similarly, a good approximation of MAP can be determined using the following equation:

$$MAP = diastolic\ pressure + 1/3\ pulse\ pressure$$

At 120/80,

$$MAP = 80 + (1/3)\ 40 = 93\ mm\ Hg$$

Because arteries offer little resistance to flow, only a negligible amount of pressure energy is lost in them because of friction. Therefore, arterial pressure—systolic, diastolic, pulse, or mean—is essentially the same in all arteries (❙Figure 10-8).

Blood pressure exists throughout the entire vascular tree, but when discussing a person's "blood pressure" without qualifying which blood vessel type is being referred to, the term is tacitly understood to mean the pressure in the arteries.
(a) Arterial blood pressure
(b) Use of a sphygmomanometer in determining blood pressure
When blood pressure is 120/80:
When cuff pressure is greater than 120 mm Hg and exceeds blood pressure throughout the cardiac cycle:

No blood flows through the vessel.

1 No sound is heard because no blood is flowing.
When cuff pressure is between 120 and 80 mm Hg:

Blood flow through the vessel is turbulent whenever blood pressure exceeds cuff pressure.

2 The first sound is heard at peak systolic pressure.

3 Intermittent sounds are produced by turbulent spurts of flow as blood pressure cyclically exceeds cuff pressure.
When cuff pressure is less than 80 mm Hg and is below blood pressure throughout the cardiac cycle:

Blood flows through the vessel in smooth, laminar fashion.

4 The last sound is heard at minimum diastolic pressure.

5 No sound is heard thereafter because of uninterrupted, smooth, laminar flow.

(c) Blood flow through the brachial artery in relation to cuff pressure and sounds

❙Figure 10-7 Arterial blood pressure and its measurement. (a) The systolic pressure is the peak pressure exerted in the arteries when blood is pumped into them during ventricular systole. The diastolic pressure is the lowest pressure exerted in the arteries when blood is draining off into the vessels downstream during ventricular diastole. The pulse pressure is the difference between systolic and diastolic pressure. The mean pressure is the average pressure throughout the cardiac cycle. (b) During measurement of blood pressure, the pressure in the sphygmomanometer (inflatable cuff) can be varied to prevent or permit blood flow in the underlying brachial artery. Turbulent blood flow can be detected with a stethoscope, whereas smooth laminar flow and no flow are inaudible. (c) The *red shaded areas* in the graph are the times during which blood is flowing in the brachial artery.

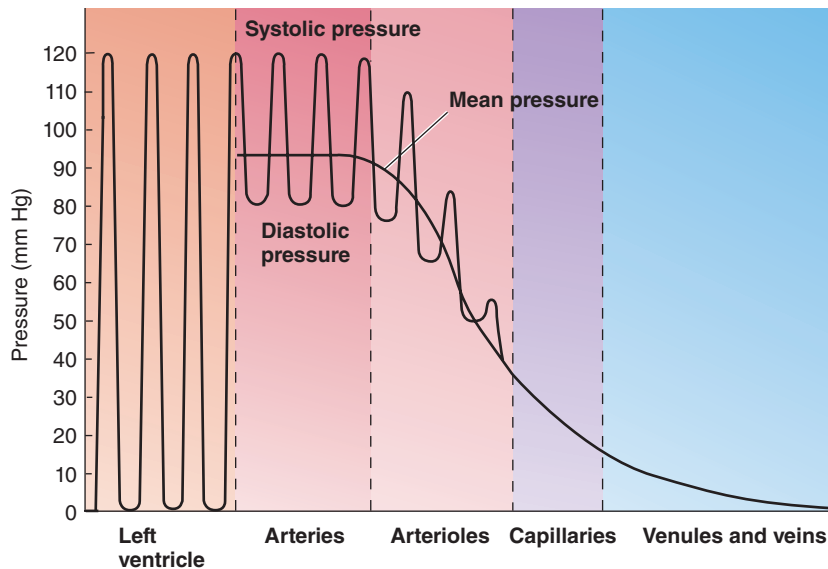
FIGURE FOCUS: *Assume a person has a blood pressure recording of 125/77. (1) What is the systolic pressure? (2) What is the diastolic pressure? (3) What is the pulse pressure? (4) What is the mean arterial pressure? (5) Would any sound be heard when the pressure in an external cuff around the arm was 130 mm Hg?* (Yes or no?) *(6) Would any sound be heard when cuff pressure was 118 mm Hg? (7) Would any sound be heard when cuff pressure was 75 mm Hg?*


Figure 10-8 Pressures throughout the systemic circulation. Left ventricular pressure swings between a low pressure of 0 mm Hg during diastole to a high pressure of 120 mm Hg during systole. Arterial blood pressure, which fluctuates between a peak systolic pressure of 120 mm Hg and a low diastolic pressure of 80 mm Hg each cardiac cycle, is of the same magnitude throughout the arteries. Because of the arterioles' high resistance, the pressure drops precipitously and the systolic-to-diastolic swings in pressure are converted to a nonpulsatile pressure when blood flows through the arterioles. The pressure continues to decline but at a slower rate as blood flows through the capillaries and venous system.

Check Your Understanding 10.2

1. Indicate what structural feature enables arteries to serve as a pressure reservoir.

2. Draw a graph of average arterial blood pressure throughout the cardiac cycle, labeling the systolic pressure, diastolic pressure, and pulse pressure.

3. Calculate MAP if blood pressure is 135/90.

10.3 Arterioles

When an artery reaches the organ it is supplying, it branches into numerous arterioles within the organ.

Arterioles are the major resistance vessels.

Arterioles are the main resistance vessels in the vascular tree because their radius is small enough to offer considerable resistance to flow. (Even though capillaries have a smaller radius than arterioles, you will see later how collectively the capillaries do not offer as much resistance to flow as the arterioles do.) In contrast to the low resistance of the arteries, the high degree of arteriolar resistance causes a marked drop in mean pressure as blood flows through these small vessels. On average, the pressure falls from the MAP of 93 mm Hg (the pressure of the blood entering the arterioles from the arteries), to 37 mm Hg, the pressure of the blood leaving the arterioles and entering the capillaries (Figure 10-8). This decline in pressure helps estab-

lish the pressure differential that encourages the flow of blood from the heart to the various organs downstream. Arteriolar resistance also converts the pulsatile systolic-to-diastolic pressure swings in the arteries into the nonfluctuating pressure present in the capillaries.

The radius (and, accordingly, the resistances) of arterioles supplying individual organs can be adjusted independently to accomplish two functions: (1) to variably distribute the cardiac output among the systemic organs, depending on the body's momentary needs, and (2) to help regulate arterial blood pressure. Before considering how such adjustments are important in accomplishing these two functions, we discuss the mechanisms involved in adjusting arteriolar resistance.

Vasoconstriction and Vasodilation Unlike arteries, arteriolar walls contain little elastic connective tissue. However, they do have a thick layer of smooth muscle that is richly innervated by sympathetic nerve fibers (see Table 10-1). The smooth muscle is also sensitive to many local chemical changes, to a few circulating hormones, and to mechanical factors such as stretch. The smooth muscle layer runs circularly around the arteriole (Figure 10-9a); so when the smooth muscle layer contracts, the vessel's circumference (and its radius) becomes smaller, increasing resistance and decreasing flow through that vessel.

Vasoconstriction is the term applied to such narrowing of a vessel (Figure 10-9c). In contrast, the term **vasodilation** refers to enlargement in the circumference and radius of a vessel as a result of its smooth muscle layer relaxing (Figure 10-9d). Vasodilation leads to decreased resistance and increased flow through that vessel.

Vascular Tone The extent of contraction of arteriolar smooth muscle depends on the cytosolic Ca^{2+} concentration. Arteriolar smooth muscle normally displays a state of partial constriction known as **vascular tone**, which establishes a baseline of arteriolar resistance (Figure 10-9b). Two factors are responsible for vascular tone. First, arteriolar smooth muscle is tonic smooth muscle that has sufficient surface-membrane voltage-gated Ca^{2+} channels open even at resting potential to trigger partial contraction (see p. 289). This myogenic activity is independent of any neural or hormonal influences, leading to self-induced contractile activity (see p. 291). Second, the sympathetic fibers supplying most arterioles continually release norepinephrine, which further enhances vascular tone.

This ongoing tone makes it possible to either increase or decrease contractile activity to accomplish vasoconstriction or vasodilation, respectively. Were it not for tone, it would be impossible to reduce tension in an arteriolar wall to accomplish vasodilation; only varying degrees of vasoconstriction would be possible.

A variety of factors can influence the level of contractile activity in arteriolar smooth muscle, thereby substantially

❙Figure 10-9 **Arteriolar vasoconstriction and vasodilation.**

changing resistance to flow in these vessels. Unlike skeletal and cardiac muscle in which action potentials trigger muscle contraction, vascular smooth muscle can undergo graded changes in force in response to chemical, physical, and neural factors without undergoing action potentials. These agents largely act via second-messenger pathways (see p. 117). The factors that cause arteriolar vasoconstriction or vasodilation fall into two categories: *local (intrinsic) controls,* which are important in determining distribution of cardiac output, and *extrinsic controls,* which are important in blood pressure regulation. We look at each of these controls in turn.

Local control of arteriolar radius is important in determining the distribution of cardiac output.

The fraction of the total CO delivered to each organ is not always constant; it varies, depending on the demands for blood at the time. The share of CO received by each organ is determined by the number and caliber of the arterioles supplying that area. Recall that $F = \Delta P/R$. Because blood is delivered to all organs at the same mean arterial pressure, the driving pressure gradient for flow is identical for each organ. Therefore, differences in flow to various organs are determined by differences in the extent of vascularization and by differences in the resistance offered by the arterioles supplying each organ. From moment to moment, the distribution of CO can be varied by differentially adjusting arteriolar resistance in the various vascular beds.

As an analogy, consider a pipe carrying water, with several adjustable valves located throughout its length (❙Figure 10-10). Assuming that water pressure in the pipe is constant, differences in the amount of water flowing into a beaker under each valve depend entirely on which valves are open and to what extent. No water enters beakers under closed valves (high resistance), and more water flows into beakers under valves that are opened completely (low resistance) than into beakers under valves that are only partially opened (moderate resistance).

Similarly, more blood flows to areas whose arterioles offer the least resistance to its passage. During exercise, for example, not only is CO increased, but also because of vasodilation in skeletal muscle and in the heart, a greater percentage of the pumped blood is diverted to these organs to support their increased metabolic activity. Simultaneously, blood flow to the digestive tract and kidneys is reduced as a result of arteriolar vasoconstriction in these organs, leaving more blood available for diversion to the active muscles (see pp. 370–371 for details). Only the blood supply to the brain remains remarkably constant no matter what the person is doing, be it vigorous physical activity, intense mental concentration, or sleep. Although total blood flow to the brain remains constant, new imaging techniques demonstrate that regional blood flow varies within the brain in close correlation with local neural activity patterns (see ❙Figure 5-8, p. 146).

Local (intrinsic) controls are changes within an organ that adjust blood flow through the organ by affecting the smooth muscle of the organ's arterioles to alter their caliber and resistance. Local influences may be either chemical or physical.

Figure 10-10 Flow rate as a function of resistance.

Local chemical influences on arteriolar radius include (1) local metabolic changes and (2) histamine release. Local physical influences include (1) how much the vessel is stretched, (2) the extent of shear stress, and (3) local application of heat or cold. Let us examine the role and mechanism of each of these local influences.

Local metabolic influences on arteriolar radius help match blood flow with the organs' needs.

The most important local chemical influences on arteriolar smooth muscle are related to metabolic changes within a given organ. The influence of these local changes on arteriolar radius is important in matching blood flow through an organ with the organ's metabolic needs. Local metabolic controls are especially important in skeletal muscle and in the heart, the organs whose metabolic activity and need for blood supply normally vary most extensively, and in the brain, whose overall metabolic activity and need for blood supply remain constant. Local controls help maintain the constancy of blood flow to the brain.

Active Hyperemia Arterioles lie within the organ they are supplying and can be acted on by local factors within the organ. During increased metabolic activity, such as when a skeletal muscle is contracting during exercise, local concentrations of several of the organ's chemicals change. For example, the local O_2 concentration decreases as the actively metabolizing cells use up more O_2 to support oxidative phosphorylation for ATP production (see p. 37). This and other local chemical changes produce local arteriolar dilation by triggering relaxation of the arteriolar smooth muscle in the vicinity. Local arteriolar vaso-

dilation then increases blood flow to that particular area. This increased blood flow in response to enhanced tissue activity is called **active hyperemia** (*hyper* means "above normal"; *emia* means "blood"). When cells are more active metabolically, they need more blood to bring in O_2 and nutrients and to remove metabolic wastes.

Conversely, when an organ, such as a relaxed muscle, is less active metabolically and thus has reduced needs for blood delivery, the resultant local chemical changes (for example, increased local O_2 concentration) bring about local arteriolar vasoconstriction and a subsequent reduction in blood flow to the area. Local metabolic changes can thus adjust blood flow as needed without involving nerves or hormones.

Local Metabolic Changes that Influence Arteriolar Radius A variety of local chemical changes act together in a cooperative, redundant manner to bring about these "selfish" local adjustments in arteriolar caliber that match a tissue's blood flow with its needs. Specifically, the following local chemical factors produce relaxation of arteriolar smooth muscle:

- *Decreased O_2.*
- *Increased CO_2.* More CO_2 is generated as a by-product during the stepped-up pace of oxidative phosphorylation that accompanies increased activity.
- *Increased acid.* More carbonic acid is generated from the increased CO_2 produced as the metabolic activity of a cell increases. Also, lactate (lactic acid) accumulates if the glycolytic pathway is used for ATP production (see pp. 39 and 272).
- *Increased K^+.* Repeated action potentials that outpace the ability of the Na^+–K^+ pump to restore the resting concentration gradients (see p. 94) result in an increase in K^+ in the interstitial fluid of a more active tissue.
- *Increased osmolarity.* Osmolarity (the concentration of osmotically active solutes) increases during elevated cellular metabolism.
- *Adenosine release.* Especially in cardiac muscle, adenosine is released in response to increased metabolic activity or O_2 deprivation (see p. 326).

Endothelial Derived Vasoactive Paracrines These local chemical changes do not act directly on vascular smooth muscle to change its contractile state. Instead, they act on arteriolar endothelial cells. **Endothelial cells** are the single layer of spe-

TABLE 10-2 Functions of Endothelial Cells

- Line the blood vessels and heart chambers; serve as a physical barrier between the blood and the remainder of the vessel wall.

- Influence formation of platelet plugs, clotting, and clot dissolution.

- Secrete substances that stimulate new vessel growth and proliferation of smooth muscle cells in vessel walls.

- Secrete cytokines during immune responses.

- Secrete paracrines that promote blood vessel remodeling in response to long-term changes in shear stress (longitudinal force on vessel lining caused by forward blood flow).

- In arterioles, secrete vasoactive paracrines in response to local chemical and physical changes; these substances cause relaxation (vasodilation) or contraction (vasoconstriction) of the underlying smooth muscle.

- In capillaries, help determine capillary permeability by contracting to vary the size of the pores between adjacent endothelial cells.

- Also in capillaries, participate in exchange of materials between the blood and surrounding tissue cells through vesicular transport.

TABLE 10-3 Functions of Nitric Oxide (NO)

- Causes relaxation of arteriolar smooth muscle. By this means, NO plays an important role in controlling blood flow through the tissues and in maintaining mean arterial blood pressure.

- Dilates the arterioles of the penis and clitoris, thus serving as the direct mediator of erection of these reproductive organs. Erection is accomplished by rapid engorgement of these organs with blood.

- Directs blood flow to O_2-starved tissues.

- Used as chemical warfare against bacteria and cancer cells by macrophages, large phagocytic cells of the immune system.

- Interferes with platelet function and blood clotting at sites of vessel damage.

- Serves as a novel type of neurotransmitter in the brain and elsewhere.

- Plays a role in the changes underlying memory.

- By promoting relaxation of digestive-tract smooth muscle, helps regulate peristalsis, a type of contraction that pushes digestive tract contents forward.

- Relaxes the smooth muscle cells in the airways of the lungs, helping keep these passages open to facilitate movement of air in and out of the lungs.

- Modulates the filtering process involved in urine formation.

- May play a role in relaxation of skeletal muscle.

cialized epithelial cells which form the endothelium that lines the lumen of all vessels. Arteriolar endothelial cells release paracrines (locally acting chemical messengers; see p. 114) in response to chemical changes in the cells' environment (such as a reduction in O_2) or physical changes (such as an increase in the frictional force of blood as it flows over the surface of the vessel lining). These vasoactive ("acting on vessels") paracrines act on the underlying smooth muscle to alter its state of contraction, thus locally regulating arteriolar caliber.

Scientists used to regard endothelial cells as little more than a passive barrier between the blood and the rest of the vessel wall. However they have discovered that endothelial cells are active participants in a variety of vessel-related activities in addition to secreting vasoactive paracrines (Table 10-2).

Among the best studied of vasoactive paracrines is **nitric oxide (NO)**, which brings about local arteriolar vasodilation by causing relaxation of arteriolar smooth muscle in the vicinity. It does so by increasing the concentration of the intracellular second messenger cyclic GMP, which leads to activation of an enzyme that reduces phosphorylation of myosin. Remember that smooth-muscle myosin can bind with actin and promote filament sliding through cycles of power strokes only when myosin is phosphorylated (see p. 288). NO plays a role in regulating mean arterial pressure by exerting an ongoing vasodilatory effect. Release of additional NO in response to local metabolic changes promotes further vasodilation in the area. NO is a small, highly reactive, short-lived gas molecule that once was known primarily as a toxic air pollutant. Yet studies have revealed an astonishing number of biological roles for NO, which is produced in many tissues besides endothelial cells. NO is one of the body's most important messenger molecules, as shown by its range of functions listed in Table 10-3. As you can

see, most areas of the body are influenced by this versatile intercellular messenger molecule.

Endothelial cells release other important paracrines besides NO. As an example, **endothelin** causes arteriolar smooth muscle contraction and is one of the most potent vasoconstrictors yet identified. Still other chemicals, released from the endothelium in response to chronic changes in blood flow to an organ, trigger long-term vascular changes that permanently influence blood flow to a region. For instance, **vascular endothelial growth factor (VEGF)** stimulates new vessel growth, a process known as **angiogenesis**.

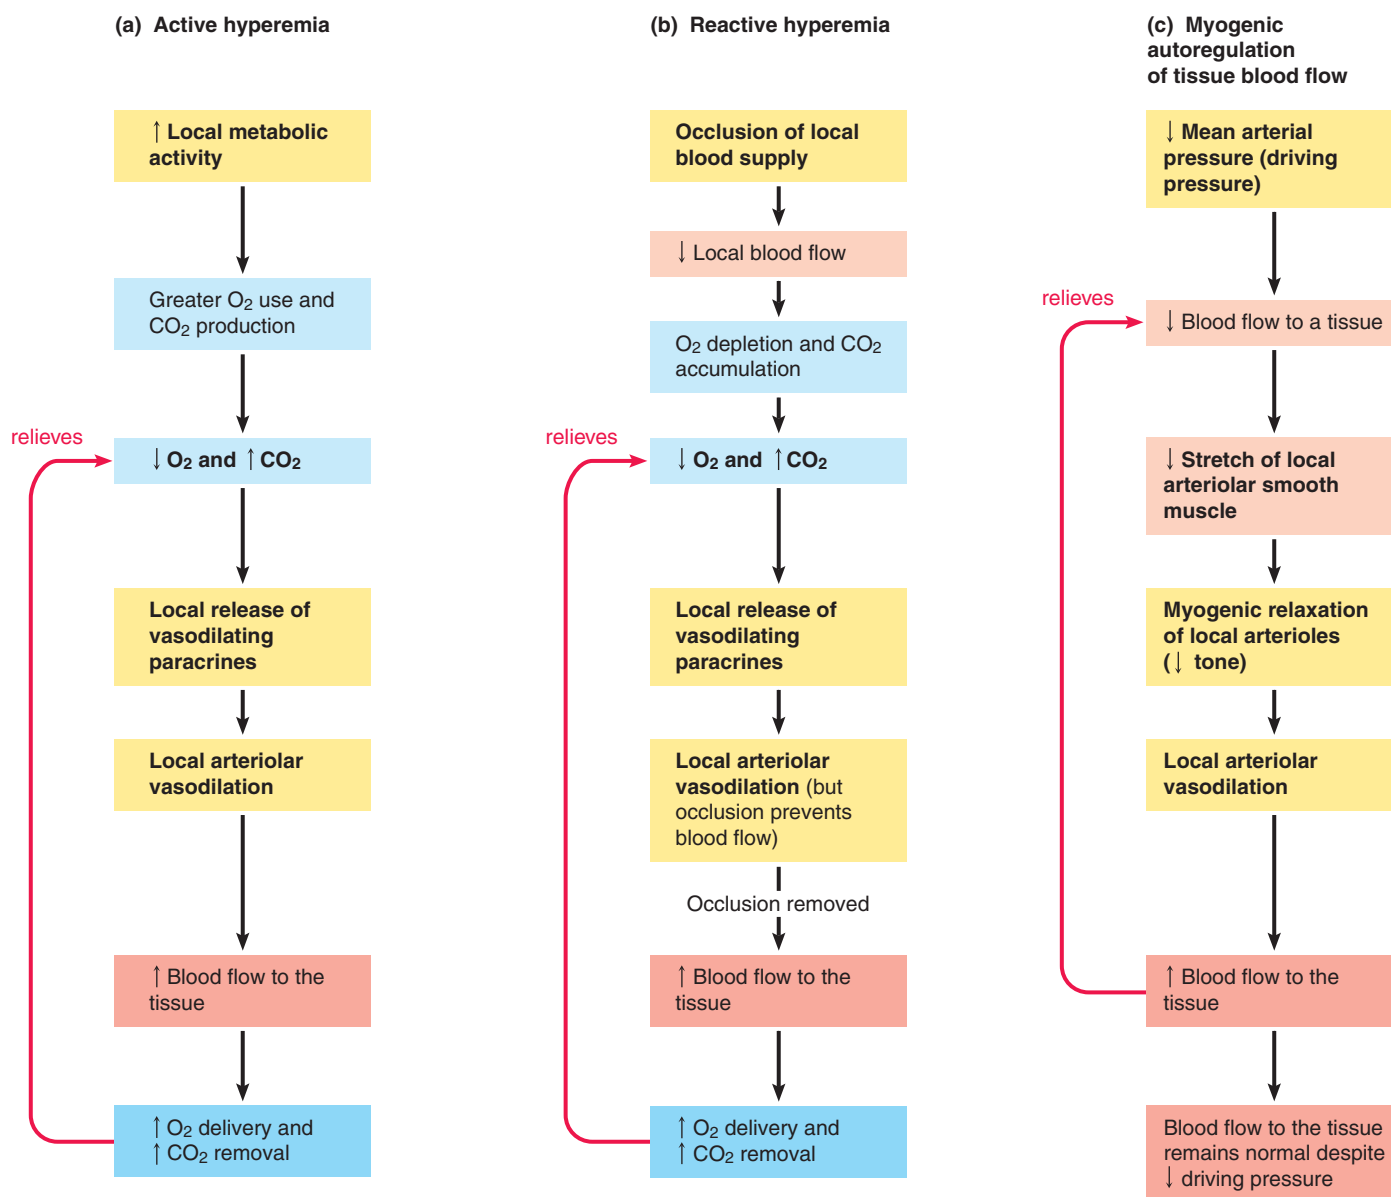
Reactive Hyperemia Active hyperemia takes place in response to changes in local chemical composition resulting from changes in local metabolic activity. When the blood supply to a region is completely occluded (for example, by means of a tourniquet applied to the upper arm when a blood sample is being drawn), many of the same chemical changes occur in the blood-deprived tissue that occur during metabolically induced active hyperemia. In the case of reactive hyperemia, the imbalance between blood supply and metabolic activity occurs because the blood supply is cut off while metabolic activity remains constant. When a tissue's blood supply is blocked, O_2 levels decrease in the deprived tissue; the tissue continues to consume O_2, but no fresh supplies are being delivered. Meanwhile, the concentrations of CO_2, acid, and other metabolites rise. Even though their production does not increase as it does when a tissue is more active metabolically,

these substances accumulate in the tissue when the normal amounts produced are not "washed away" by blood. As a result of these local chemical changes, the arterioles in the blood-deprived area dilate. Despite this arteriolar vasodilation, the occlusion prevents blood flow through these dilated vessels.

However, after the occlusion is removed, blood flow to the previously deprived tissue is transiently much higher than normal because the arterioles are widely dilated. This post-occlusion increase in blood flow is called **reactive hyperemia**. Such a response is beneficial for rapidly restoring the local chemical composition to normal. Of course, prolonged blockage of blood flow (such as by a blood clot that completely blocks a coronary artery during a heart attack; see p. 314) leads to irreversible damage in the deprived tissue.

The same mechanisms are responsible for both active hyperemia and reactive hyperemia—release from the endothelial cells of vasodilating paracrines in response to decreased O_2 and other associated local chemicals that relax the underlying smooth muscle (❙Figure 10-11a and b). The difference lies in the cause responsible for these local chemical changes: increased local metabolic activity in the case of active hyperemia and local blockage of the blood supply to the area in the case of reactive hyperemia.

Local histamine release pathologically dilates arterioles.

Histamine is another local chemical mediator that influences arteriolar smooth muscle, but it is not released in response to local metabolic changes and is not derived from endothelial


❙Figure 10-11 **Major local chemical and physical means of controlling arteriolar caliber.**
FIGURE FOCUS: *Using this figure, identify the triggering cause, the local mediators that produce arteriolar vasodilation, and the compensatory result for (a) active hyperemia, (b) reactive hyperemia, and (c) autoregulation of tissue blood flow.*

cells. Although histamine normally does not participate in controlling blood flow, it is important in certain pathological conditions.

Clinical Note Histamine is synthesized and stored within special connective tissue cells in many organs and in certain types of circulating white blood cells. When organs are injured or during allergic reactions, histamine is released and acts as a paracrine in the damaged region. By promoting relaxation of arteriolar smooth muscle, histamine is the major cause of vasodilation in an injured area. The resultant increase in blood flow into the area produces the redness and contributes to the swelling seen with inflammatory responses (see Chapter 12 for further details).

We now shift from local chemical influences to local physical influences on arteriolar radius, the most important of which is the myogenic response to stretch.

The myogenic response of arterioles to stretch helps tissues autoregulate their blood flow.

Arteriolar smooth muscle responds to being passively stretched by myogenically increasing its tone via vasoconstriction, thereby acting to resist the initial passive stretch.[1] Increased vessel stretching brings about opening of mechanically gated cation channels, which leads to a small depolarization that triggers opening of more surface-membrane voltage-gated Ca^{2+} channels. The resultant Ca^{2+} entry promotes increased smooth muscle contraction, boosting myogenic vessel tone and causing vasoconstriction. Conversely, a reduction in arteriolar stretching decreases myogenic vessel tone and promotes vasodilation. The extent of passive stretch varies with the volume of blood delivered to the arterioles from the arteries, which depends on the mean arterial pressure (the pressure that drives blood into the arterioles). Mean arterial pressure is normally maintained within narrow limits, but if this driving pressure for some reason becomes abnormal, the myogenic response to stretch enables a tissue to resist changes in its own blood flow secondary to changes in MAP by making appropriate adjustments in arteriolar radius. For example, in the presence of sustained elevations in MAP (hypertension), the myogenic response triggered by the initial increased flow of blood to tissues brings about vasoconstriction, which increases arteriolar tone and resistance. This greater degree of vasoconstriction subsequently reduces tissue blood flow toward normal despite this elevated blood pressure (❙Figure 10-12).

Conversely, when MAP falls (such as because of hemorrhage or a weakened heart), the driving force is reduced, so blood flow to organs decreases. Because less blood is flowing through the arterioles, they are not stretched as much as normal. The arterioles respond to this reduced stretch by myogenically relaxing. The increased flow through the vasodilated arterioles helps restore tissue blood flow toward normal despite the reduced driving pressure (see ❙Figure 10-11c).

---

[1]Because of the continuum of vessels, the small muscular arteries behave similarly to arterioles by responding myogenically to varying degrees of stretch.
❙Figure 10-12 **Autoregulation of tissue blood flow.** Even though blood flow through a tissue immediately increases in response to a rise in arterial pressure, the tissue blood flow is reduced gradually as a result of autoregulation within the tissue, despite a sustained increase in arterial pressure.

Simultaneous with these myogenic mechanisms, changes in local blood flow driven by changes in MAP also alter local chemical factors, kind of like a mild reactive hyperemia. When local blood flow initially decreases in response to a fall in MAP, O_2 levels decline and metabolites accumulate, leading to local arteriolar vasodilation and a compensatory increase in blood flow to the tissue. On the other hand, when local blood flow initially increases in response to a rise in MAP, O_2 levels increase and metabolites are washed away more quickly as the blood supply outpaces the level of metabolic activity. These local chemical changes cause local arteriolar vasoconstriction and a compensatory decrease in blood flow.

These local arteriolar myogenic and chemical mechanisms that keep tissue blood flow fairly constant despite rather wide deviations in mean arterial driving pressure is termed **autoregulation** ("self-regulation"). Autoregulatory responses bring local tissue flow back toward normal within a few minutes after the initial change in the driving pressure. Not all organs autoregulate equally. As examples, the brain autoregulates best, the kidneys are good at autoregulation, and skeletal muscle has poor autoregulatory abilities.

Arterioles release vasodilating NO in response to an increase in shear stress.

Another local physical influence on arteriolar caliber is the vessel's response to changes in shear stress. Due to friction, blood flowing over the surface of the vessel lining creates a longitudinal force applied on the endothelial cells in the direction of the flow known as **shear stress**. When shear stress increases, endothelial cells release NO, which diffuses to the underlying smooth muscle and promotes vasodilation. The resultant increase in arteriolar caliber reduces shear stress in the vessel. In response to shear stress on a long-term basis, endothelial cells orient themselves parallel to the direction of blood flow (that is, they line up their long axis to "go with the flow.")

Local heat application dilates arterioles and cold application constricts them.

The effect of temperature changes, another local physical influence, on arterioles can be exploited clinically. Heat application, by causing localized arteriolar vasodilation, is a useful therapeutic agent for promoting increased blood flow to an area. Conversely, applying an ice pack to an inflamed area produces vasoconstriction, which reduces swelling by counteracting histamine-induced vasodilation.

This completes our discussion of local control of arteriolar radius. We now shift to extrinsic control of arteriolar radius.

Extrinsic control of arteriolar radius is important in regulating blood pressure.

Extrinsic control of arteriolar radius includes both neural and hormonal influences, the effects of the sympathetic nervous system being the most important. Sympathetic nerve fibers supply arteriolar smooth muscle everywhere in the systemic circulation except in the brain. Recall that a certain level of ongoing sympathetic activity contributes to vascular tone. Increased sympathetic activity produces generalized arteriolar vasoconstriction, whereas decreased sympathetic activity leads to generalized arteriolar vasodilation. These widespread changes in arteriolar resistance bring about changes in mean arterial pressure because of their influence on total peripheral resistance.

Influence of Total Peripheral Resistance on Mean Arterial Pressure To find the effect of changes in arteriolar resistance on MAP, the equation $F = \Delta P/R$ applies to the entire circulation as well as to a single vessel:

- *F*. Looking at the circulatory system as a whole, flow *(F)* through all the vessels in either the systemic or the pulmonary circulation is equal to the cardiac output (CO).
- ΔP. The pressure gradient (ΔP) for the entire systemic circulation is the mean arterial pressure. (ΔP equals the difference in pressure between the beginning and the end of the systemic circulatory system. The beginning pressure is the MAP as the blood leaves the left ventricle at an average of 93 mm Hg. The end pressure in the right atrium is 0 mm Hg. Therefore, $\Delta P =$ 93 minus 0 = 93 mm Hg, which is equivalent to the MAP.)
- *R*. The total resistance *(R)* offered by all the systemic peripheral vessels together is the **total peripheral resistance (TPR)**. By far, the greatest percentage of the TPR is caused by arteriolar resistance because arterioles are the primary resistance vessels.

Therefore, for the entire systemic circulation, rearranging

$$F = \Delta P/R$$

to

$$\Delta P = F \times R$$

gives us the equation

$$MAP = CO \times TPR$$

(Do not confuse this equation, which indicates the factors that *determine* MAP, with the equation used to *calculate* mean arte-

rial pressure, namely, MAP = diastolic pressure + 1/3 pulse pressure.)

Thus, the extent of TPR offered collectively by all the systemic arterioles influences MAP immensely. A dam provides an analogy to this relationship. At the same time a dam restricts the flow of water downstream, it increases the pressure upstream by elevating the water level in the reservoir behind the dam. Similarly, generalized, sympathetically induced vasoconstriction reflexly reduces blood flow downstream to the organs while elevating the upstream mean arterial pressure, thereby increasing the main driving force for blood flow to all the organs.

These effects seem counterproductive. Why increase the driving force for flow to the organs by increasing MAP while reducing flow to the organs by narrowing the vessels supplying them? In effect, the sympathetically induced arteriolar responses help maintain the appropriate driving pressure head (that is, the MAP) to all organs. The extent to which each organ actually receives blood flow is determined by local arteriolar adjustments that override the sympathetic constrictor effect. If all arterioles were dilated, blood pressure would fall substantially, so there would not be an adequate driving force for blood flow. An analogy is the pressure head for water in the pipes in your home. If the water pressure is adequate, you can selectively obtain satisfactory water flow at any of the faucets by turning the appropriate handle to the open position. If the water pressure in the pipes is too low, however, you cannot obtain satisfactory flow at any faucet, even if you turn the handle to the maximally open position. Tonic sympathetic activity thus constricts most vessels (with the exception of those in the brain) to help maintain a pressure head on which organs can draw as needed through local mechanisms that control arteriolar radius.

Norepinephrine's Influence on Arteriolar Smooth Muscle The norepinephrine released from sympathetic nerve endings combines with α_1-adrenergic receptors on arteriolar smooth muscle to bring about vasoconstriction (see p. 240). Cerebral (brain) arterioles are the only ones that do not have α_1 receptors, so no vasoconstriction occurs in the brain. It is important that cerebral arterioles are not reflexly constricted by neural influences because brain blood flow must remain constant to meet the brain's continuous need for O_2, no matter what is going on elsewhere in the body. Cerebral vessels are almost entirely controlled by local mechanisms that maintain a constant blood flow to support a constant level of brain metabolic activity. In fact, reflex vasoconstrictor activity in the remainder of the cardiovascular system is aimed at maintaining an adequate pressure head for blood flow to the vital brain.

Thus, sympathetic activity contributes in an important way to maintaining MAP, ensuring an adequate driving force for blood flow to the brain at the expense of organs that can better withstand reduced blood flow. Other organs that really need additional blood, such as active muscles (including active heart muscle), obtain it through local controls that override the sympathetic effect.

Local Controls Overriding Sympathetic Vasoconstriction Skeletal and cardiac muscles have the most powerful local control mechanisms with which to override generalized sympa-

thetic vasoconstriction. For example, if you are pedaling a bicycle, the increased activity in the skeletal muscles of your legs brings about an overriding local, metabolically induced vasodilation in those particular muscles, despite the generalized sympathetic vasoconstriction that accompanies exercise. As a result, more blood flows through your leg muscles but not through your inactive arm muscles.

No Parasympathetic Innervation to Arterioles

Arterioles have no significant parasympathetic innervation, with the exception of the abundant parasympathetic vasodilator supply to the arterioles of the penis and clitoris. The rapid, profuse vasodilation induced by parasympathetic stimulation in these organs (by means of promoting release of NO) is largely responsible for accomplishing erection. Vasodilation elsewhere is produced primarily by decreasing sympathetic vasoconstrictor activity below its normal tone level. When MAP rises above normal, reflex reduction in sympathetic vasoconstrictor activity accomplishes generalized arteriolar vasodilation to help bring the driving pressure down toward normal. (Also, the hormone epinephrine causes vasodilation in arteriolar smooth muscle specifically in the skeletal muscles and heart by a mechanism described shortly.)

The cardiovascular control center and several hormones regulate blood pressure.

The main region of the brain that adjusts sympathetic output to the arterioles is the *cardiovascular control center* in the medulla of the brain stem. This is the integrating center for blood pressure regulation. Several other brain regions also influence blood distribution, the most notable being the hypothalamus, which, as part of its temperature-regulating function, controls blood flow to the skin to adjust heat loss to the environment.

In addition to neural reflex activity, several hormones extrinsically influence arteriolar radius. These hormones include the adrenal medullary hormones *epinephrine* and *norepinephrine,* which generally reinforce the sympathetic nervous system in most organs, and *vasopressin* and *angiotensin II,* which are important in controlling fluid balance and blood volume.

Influence of Epinephrine and Norepinephrine

Sympathetic stimulation of the adrenal medulla causes this endocrine gland to release epinephrine and norepinephrine. Adrenal medullary norepinephrine combines with the same α_1 receptors as sympathetically released norepinephrine to produce generalized vasoconstriction. However, epinephrine, the more abundant of the adrenal medullary hormones, combines with both β_2 and α_1 receptors but has a much greater affinity for the β_2 receptors. Activation of β_2 receptors produces vasodilation, but not all tissues have β_2 receptors; they are most abundant in the arterioles of the skeletal muscles and heart. During sympathetic discharge, the released epinephrine combines with the β_2 receptors in the skeletal muscles and heart to reinforce local vasodilatory mechanisms in these tissues. Arterioles in digestive organs and kidneys, in contrast, are equipped only with α_1 receptors. Therefore, the

arterioles of these organs undergo more profound vasoconstriction during generalized sympathetic discharge than those in the skeletal muscles and heart do. Lacking β_2 receptors, the digestive organs and kidneys do not experience an overriding vasodilatory response on top of the α_1 receptor–induced vasoconstriction.

Influence of Vasopressin and Angiotensin II

The two other hormones that extrinsically influence arteriolar tone are vasopressin and angiotensin II. Vasopressin is primarily involved in maintaining water balance by regulating the amount of water the kidneys retain for the body during urine formation (see pp. 524 and 544). Angiotensin II is part of a hormonal pathway, the *renin–angiotensin–aldosterone system,* which is important in regulating the body's salt balance. This pathway promotes salt conservation during urine formation and leads to water retention because salt exerts a water-holding osmotic effect in the ECF (see p. 508). Thus, both these hormones play important roles in maintaining the body's fluid balance, which in turn is an important determinant of blood volume and blood pressure.

In addition, both vasopressin and angiotensin II are potent vasoconstrictors. Their role in this regard is especially crucial during hemorrhage. A sudden loss of blood reduces the blood volume, which triggers increased secretion of both these hormones to help restore blood volume. Their vasoconstrictor effect also helps maintain blood pressure despite abrupt loss of blood volume. (The functions and control of these hormones are discussed more thoroughly in later chapters.)

This completes our discussion of the factors that affect TPR, the most important of which are controlled adjustments in arteriolar radius. These factors are summarized in ❙Figure 10-13. We now turn to the next vessels in the vascular tree, the capillaries.

10.4 Capillaries

Capillaries, the sites for exchange of materials between blood and tissue cells,[2] branch extensively to bring blood within the reach of essentially every cell (see chapter opener photo, p. 335).

---

[2]Actually, some exchange takes place across the other microcirculatory vessels, especially the postcapillary venules. The entire vasculature is a continuum and does not abruptly change from one vascular type to another. When the term *capillary exchange* is used, it tacitly refers to all exchange at the microcirculatory level, the majority of which occurs across the capillaries.

Capillaries are ideally suited to serve as sites of exchange.

There are no carrier-mediated transport systems across capillaries, with the exception of those in the brain that play a role in the blood–brain barrier (see p. 141). Materials are exchanged across capillary walls mainly by diffusion.

Factors that Enhance Diffusion Across Capillaries

Capillaries are ideally suited to enhance diffusion, in accordance with Fick's law of diffusion (see p. 65). They minimize diffusion distances while maximizing surface area and time available for exchange, as follows:

1. Diffusing molecules have only a short distance to travel between blood and surrounding cells because of the thin capillary wall and small capillary diameter, coupled with the proximity of every cell to a capillary. This short dis-

tance is important because the rate of diffusion slows down as the diffusion distance increases.

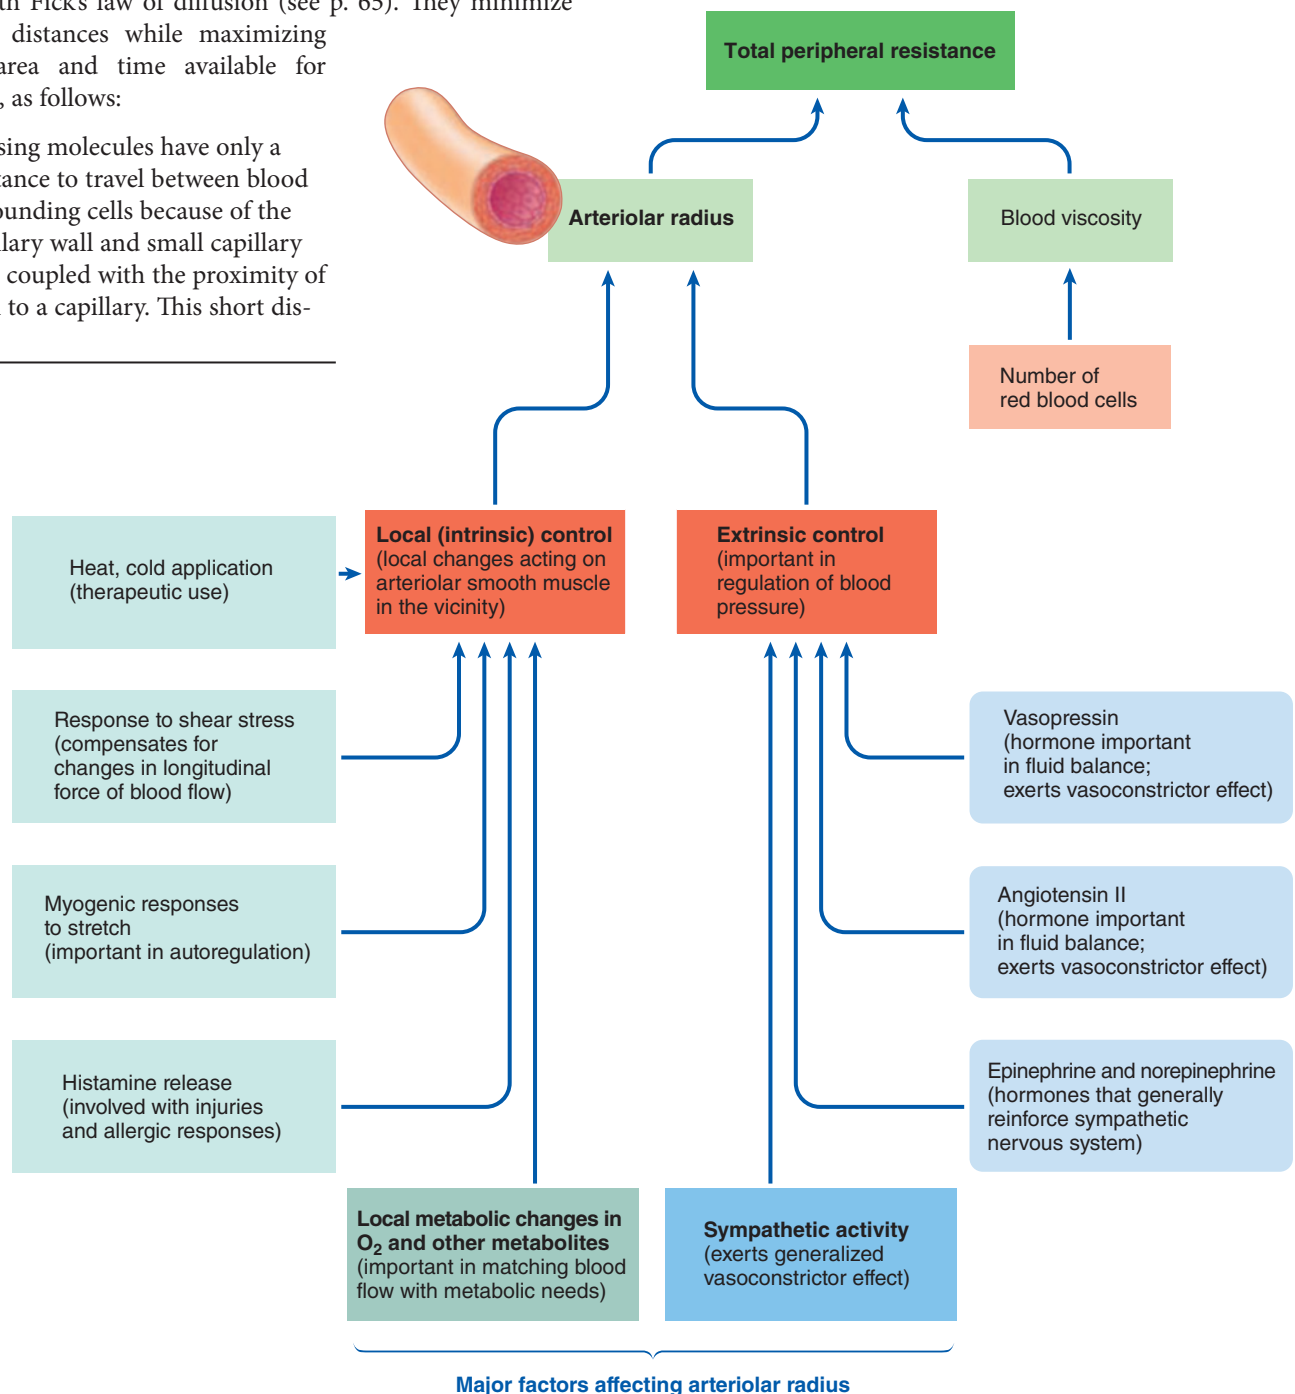
a. Capillary walls are very thin (1 μm in thickness; in contrast, the diameter of a human hair is 100 μm). Capillaries consist of only a single layer of flat endothelial cells—essentially the lining of the other vessel types. No smooth muscle or connective tissue is present (▮Figure 10-14a; also see ▮Table 10-1, p. 339). The endothelial


Figure 10-13 Factors affecting total peripheral resistance (TPR). The primary determinant of TPR is the adjustable arteriolar radius. Two major categories of factors influence arteriolar radius: (1) local (intrinsic) control, which is primarily important in matching blood flow through a tissue with the tissue's metabolic needs and is mediated by local factors acting on the arteriolar smooth muscle; and (2) extrinsic control, which is important in regulating blood pressure and is mediated primarily by sympathetic influence on arteriolar smooth muscle.

Endothelial cell nucleus   Capillary lumen

(b) Capillary bed

▌Figure 10-14 **Capillary anatomy.** (a) Electron micrograph showing that the capillary wall consists of a single layer of endothelial cells. The nucleus of one of these cells is shown. (b) The capillaries are so narrow that red blood cells must pass through the capillary bed in single file.

cells are supported by a thin *basement membrane,* a surrounding acellular (lacking cells) layer of extracellular matrix consisting of glycoproteins and collagen. Materials entering or leaving the capillaries pass freely through the basement membrane. Capillaries also have pores through which water-soluble materials can pass. The size and number of capillary pores vary, depending on the tissue.

b. Each capillary is so narrow (7 μm average diameter) that red blood cells (8 μm diameter) have to squeeze through in single file (▌Figure 10-14b). Plasma contents either are in direct contact with the inside of the capillary wall or are only a short diffusing distance from it.

c. Because of extensive capillary branching, scarcely any cell is farther than 0.1 mm (4/1000 in.) from a capillary.

2. Because capillaries are distributed in such incredible numbers (estimates range from 10 to 40 billion capillaries), a tre-

mendous total surface area is available for exchange (an estimated 600 m^2). Despite this large number of capillaries, at any point in time these microscopic vessels contain only 5% of the total blood volume (250 mL out of a total of 5000 mL). As a result, a small volume of blood is exposed to an extensive surface area. If all capillary surfaces were stretched out in a flat sheet and the volume of blood contained within the capillaries was spread over the top, this would be roughly equivalent to spreading a half pint of paint over the floor of a high school gymnasium. Imagine how thin the paint layer would be!

3. Blood flows more slowly in the capillaries than elsewhere in the circulatory system. The extensive capillary branching is responsible for this slow velocity of blood flow through the capillaries. Let us see why blood slows down in the capillaries.

Slow Velocity of Flow Through Capillaries First, we need to clarify a potentially confusing point. The term *flow* can be used in two contexts—flow rate and velocity of flow. The *flow rate* refers to the *volume* of blood per unit of time flowing through a given segment of the circulatory system (this is the flow we have been talking about in relation to the pressure gradient and resistance). The *velocity of flow* is the *speed,* or distance per unit of time, with which blood flows forward through a given segment of the circulatory system. Because the circulatory system is a closed system, the volume of blood flowing through any level of the system must equal the CO. If the heart pumps out 5 L of blood per minute, and 5 L per minute return to the heart, then 5 L per minute must flow through the arteries, arterioles, capillaries, and veins. Therefore, the flow rate is the same at all levels of the circulatory system.

However, the velocity with which blood flows through the different segments of the vascular tree varies because velocity of flow is inversely proportional to the total cross-sectional area of all vessels at any given level. Even though the cross-sectional area of each capillary is extremely small compared to that of the large aorta, the total cross-sectional area of all capillaries added together is about 750 times greater than the cross-sectional area of the aorta because there are so many capillaries. Accordingly, blood slows considerably as it passes through the capillaries (▌Figure 10-15). This slow velocity allows adequate time for exchange of nutrients and metabolic end products between blood and tissue cells—the sole purpose of the circulatory system. As capillaries rejoin to form veins, the total cross-sectional area is again reduced, and the velocity of blood flow increases as blood returns to the heart.

As an analogy, consider a river (the arterial system) that widens into a lake (the capillaries) and then narrows into a river again (the venous system) (▌Figure 10-16). The flow rate is the same throughout the length of this body of water—that is, identical volumes of water are flowing past all points along the bank of the river and lake. However, the velocity of flow is slower in the wide lake than in the narrow river because the identical volume of water, now spread out over a larger cross-sectional area, moves forward a shorter distance in the wide lake than in the narrow river during a given period. You could readily observe the forward movement of water in the swift-flowing river, but the forward motion of water in the lake would be unnoticeable.
Figure 10-15 Comparison of blood flow rate and velocity of flow in relation to total cross-sectional area. The blood flow rate (*red curve*) is identical through all levels of the circulatory system and is equal to the cardiac output (5 L/min at rest). The velocity of flow (*purple curve*) varies throughout the vascular tree and is inversely proportional to the total cross-sectional area (*green curve*) of all the vessels at a given level. Note that the velocity of flow is slowest in the capillaries, which have the largest total cross-sectional area.

Also, because of the capillaries' tremendous total cross-sectional area, the resistance offered by all capillaries is lower than that offered by all arterioles, even though each capillary has a smaller radius than each arteriole. For this reason, the arterioles contribute more to TPR. Furthermore, arteriolar caliber (and, accordingly resistance) is subject to control, whereas capillary caliber cannot be adjusted.

Water-filled capillary pores permit passage of small, water-soluble substances.

Diffusion across capillary walls also depends on the walls' permeability to the materials being exchanged. Endothelial cells forming the capillary walls fit together like a jigsaw puzzle, but the closeness of the fit varies considerably among organs. In
Figure 10-16 Relationship between total cross-sectional area and velocity of flow. The three dark blue areas represent equal volumes of water. During 1 minute, this volume of water moves forward from points A to points C. Therefore, an identical volume of water flows past points B1, B2, and B3 during this minute—that is, the flow rate is the same at all points along the length of this body of water. However, during that minute the identical volume of water moves forward a much shorter distance in the wide lake (A2 to C2) than in the much narrower river (A1 to C1 and A3 to C3). Thus, velocity of flow is much slower in the lake than in the river. Similarly, velocity of flow is much slower in the capillaries than in the arterial and venous systems.

most capillaries, endothelial cells are *continuous,* or closely joined, with only narrow, water-filled clefts, or **pores**, at the junctions between the cells (Figure 10-17). The size of capillary pores varies from organ to organ. Following is an examination of capillaries of different porosity, from the tightest to the leakiest:

■ At one extreme, the endothelial cells in brain capillaries are joined by tight junctions so that pores are nonexistent (see p. 51). These junctions prevent transcapillary ("across capillary") passage of materials between these cells and thus constitute part of the protective blood–brain barrier.

■ In most capillaries (for example, in skeletal muscle and in lung tissue), small, water-soluble substances such as ions, glucose, and amino acids can readily pass through the water-filled pores, which are about 4 nm wide, but large, water-soluble materials such as plasma proteins are kept from passing through. Lipid-soluble substances, such as O_2 and CO_2, can readily pass through the endothelial cells themselves by dissolving in the lipid bilayer barrier of the plasma membrane surrounding the cells.

■ In addition to having the narrow clefts between endothelial cells, the leakier capillaries of the kidneys and intestines have larger 20- to 100-nm holes known as **fenestrations** (*fenestra* means "window") that extend through the thickness of the endothelial cells. These through-the-cell passageways are important in the rapid movement of fluid across the capillaries in these organs during the formation of urine and during the absorption of a digested meal, respectively.

■ At the other extreme, the endothelial cells of liver cells are *discontinuous*—that is, they are not in such close contact as in continuous capillaries. The gaps between adjacent cells in discontinuous capillaries range from 10 nm to 1000 nm, creating very large pores compared to the 4 nm clefts found in continuous capillaries. Discontinuous capillaries form large channels

The Blood Vessels and Blood Pressure | **353**
(a) Continuous capillary

(b) Transport across a continuous capillary wall

I Figure 10-17 Exchanges across a continuous capillary wall, the most common type of capillary. (a) Slitlike gaps between adjacent endothelial cells form pores within the capillary wall. (b) As depicted in this cross section of a capillary wall, small water-soluble substances are exchanged between the plasma and the interstitial fluid by passing through the water-filled pores, whereas lipid-soluble substances are exchanged across the capillary wall by passing through the endothelial cells. Proteins to be moved across are exchanged by vesicular transport. Plasma proteins generally cannot escape from the plasma across the capillary wall.

known as *sinusoids* that are five times wider than traditional capillaries. Liver sinusoids have fenestrations and such large intercellular pores that even proteins pass through readily. This is adaptive because the liver's functions include synthesis of plasma proteins and the metabolism of protein-bound substances such as cholesterol. These proteins must all pass through the liver's capillary (sinusoid) walls.

The leakiness of various capillary beds is therefore a function of how tightly the endothelial cells are joined (how wide the intercellular spaces are) and whether fenestrations are present, which varies according to the different organs' needs. For convenience, in the future we lump the between-cell pores and the through-the-cell fenestrations into the single category of *capillary pores.*

Scientists traditionally considered the capillary wall a passive sieve, like a brick wall with permanent gaps in the mortar acting as pores. However, they now know that endothelial cells can actively change to regulate capillary permeability—that is, in response to appropriate signals, the "bricks" can readjust themselves to vary the size of the holes between them. Thus, the degree of leakiness does not necessarily remain constant for a given capillary bed. For example, histamine increases capillary permeability by triggering contractile responses in endothelial cells to widen the intercellular gaps. This is not a muscular contraction because no smooth muscle cells are present in capillaries; it is the result of an actin–myosin contractile apparatus in the nonmuscular capillary endothelial cells. Because of these enlarged pores, the affected

capillary wall is leakier. As a result, normally retained plasma proteins escape into the surrounding tissue, where they exert an osmotic effect. Along with histamine-induced vasodilation, the resulting additional local fluid retention contributes to inflammatory swelling (see p. 409).

Vesicular transport also plays a limited role in passage of materials across the capillary wall. Large molecules that are not lipid-soluble, such as protein hormones that must be exchanged between blood and surrounding tissues, are transported from one side of the capillary wall to the other in endocytic–exocytic vesicles, a process called *transcytosis* (see p. 77).

Many capillaries are not open under resting conditions.

The branching and reconverging arrangement within capillary beds varies somewhat, depending on the tissue. Capillaries typically branch either directly from an arteriole or from a thoroughfare channel known as a **metarteriole**, which runs between an arteriole and a venule. Likewise, capillaries may rejoin at either a venule or a metarteriole (I Figure 10-18a).

Wisps of spiraling smooth muscle cells form **precapillary sphincters**, each of which consists of a ring of smooth muscle around the entrance to a capillary as it arises from a metarteriole or an arteriole.

Role of Precapillary Sphincters Precapillary sphincters are not innervated, but they have a high degree of myogenic tone and are sensitive to local metabolic changes. They act as

Arteriole
Smooth muscle
Precapillary sphincter

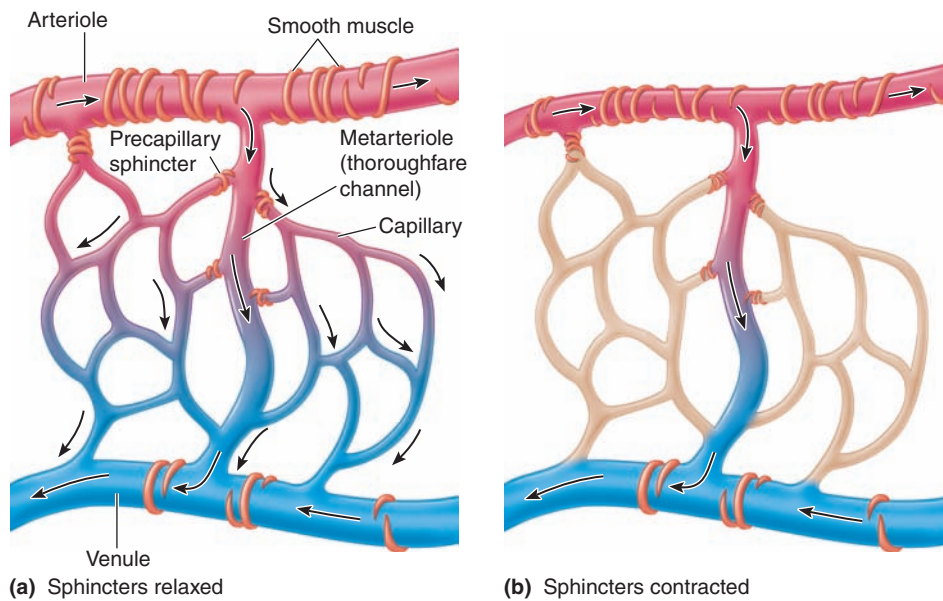
Capillary
Venule
(a) Sphincters relaxed
(b) Sphincters contracted


❙Figure 10-18 **Capillary bed.** Capillaries branch either directly from an arteriole or from a metarteriole, a thoroughfare channel between an arteriole and venule. Capillaries rejoin at either a venule or a metarteriole. Smooth muscle cells form precapillary sphincters that encircle capillaries as they arise from a metarteriole or an arteriole. (a) When the precapillary sphincters are relaxed, blood flows through the entire capillary bed. (b) When the precapillary sphincters are contracted, blood flows only through the metarteriole, bypassing the capillary bed.

Interstitial fluid is a passive intermediary between blood and cells.

Exchanges between blood and tissue cells are not made directly. Interstitial fluid, the true internal environment in immediate contact with the cells, acts as the go-between. Only 20% of the extracellular fluid (ECF) circulates as plasma. The remaining 80% consists of interstitial fluid, which bathes all cells in the body. Cells exchange materials directly with interstitial fluid, with the type and extent of exchange being governed by the properties of cellular plasma membranes. Movement across the plasma membrane may be either passive (that is, by diffusion down electrochemical gradients or by carrier-mediated facilitated diffusion) or active (that is, by carrier-mediated active transport or by vesicular transport) (see ❙Table 3-2, p. 78).

In contrast, exchanges across the capillary wall between the plasma and the interstitial fluid are largely passive. The only transport across this barrier that requires energy is the limited vesicular transport. Because capillary walls are highly permeable, exchange is so thorough that the interstitial fluid takes on essentially the same composition as incoming arterial blood, with the exception of the large plasma proteins that usually do not escape from the blood. Therefore, when we speak of exchanges between blood and tissue cells, we tacitly include interstitial fluid as a passive intermediary.

Exchanges between blood and surrounding tissues across capillary walls are accomplished in two ways: (1) passive diffusion down concentration gradients, the primary mechanism for exchanging individual solutes, and (2) bulk flow, a process that fills the different function of determining the distribution of the ECF volume between the vascular and the interstitial fluid compartments. We now examine each of these mechanisms in more detail.

stopcocks to control blood flow through the particular capillary that each one guards. Capillaries themselves have no smooth muscle, so they cannot actively participate in regulating their own blood flow. When tissue metabolic activity increases, the local metabolic changes bring about relaxation of precapillary sphincters in the vicinity, thereby increasing the number of open capillaries (❙Figure 10-18a). When tissue activity decreases, the local precapillary sphincters contract. As a result, blood bypasses the capillary bed and flows only through the metarteriole (❙Figure 10-18b).

Generally, tissues that are more metabolically active have a greater density of capillaries. Muscles, for example, have relatively more capillaries than their tendinous attachments. Only about 10% or less of the precapillary sphincters in a resting muscle are open at any moment, however, so blood is flowing through only about 10% of the muscle's capillaries or flowing directly through the metarteriole without entering the remaining capillary bed. When the muscle becomes more active, a greater percentage of the precapillary sphincters relax in response to the local chemical changes, simultaneously opening up more capillary beds. Concurrently, arteriolar vasodilation increases total flow to the organ. As a result of more blood flowing through more open capillaries, the total volume and surface area available for exchange increase, and the diffusion distance between the cells and an open capillary decreases. Thus, blood flow through a particular tissue (assuming a constant blood pressure) is regulated by (1) the degree of resistance offered by the arterioles in the organ, controlled by sympathetic activity and local metabolic factors; and (2) the number of open capillaries, controlled by action of the same local factors on precapillary sphincters.

Diffusion across capillary walls is important in solute exchange.

Because most capillary walls have no carrier-mediated transport systems, solutes cross primarily by diffusion down concentration gradients. The chemical composition of arterial blood is carefully regulated to maintain the concentrations of individual solutes at levels that promote each solute's movement in the appropriate direction across the capillary walls. The reconditioning organs continuously add nutrients and O_2 and remove CO_2 and other wastes as blood passes through them. Meanwhile, cells constantly use up supplies and generate metabolic wastes. As cells use up O_2 and glucose, the blood constantly brings in fresh supplies of these
Figure 10-19 Independent exchange of individual solutes down their own concentration gradients across the capillary wall.

vital materials, maintaining concentration gradients that favor the net diffusion of these substances from blood to cells. Simultaneously, ongoing net diffusion of CO_2 and other metabolic wastes from cells to blood is maintained by the continual production of these wastes at the cell level and by their constant removal by the circulating blood (**I** Figure 10-19).

Because the capillary wall does not limit passage of any constituent except plasma proteins, the extent of exchanges for each solute is independently determined by the magnitude of its concentration gradient between blood and surrounding cells. As cells increase their level of activity, they use up more O_2 and produce more CO_2, among other things. This creates larger concentration gradients for O_2 and CO_2 between these cells and

blood, so more O_2 diffuses out of the blood into the cells and more CO_2 proceeds in the opposite direction, to help support the increased metabolic activity.

Bulk flow across the capillary walls is important in extracellular fluid distribution.

The second means by which exchange is accomplished across capillary walls is bulk flow. A volume of protein-free plasma actually filters out of the capillary, mixes with the surrounding interstitial fluid, and then is reabsorbed. This process is called **bulk flow** because the various constituents of the fluid (water and all solutes) are moving in bulk, or as a unit, in contrast to the discrete diffusion of individual solutes down concentration gradients.

The capillary wall acts like a sieve, with fluid moving through its water-filled pores. When pressure inside the capillary exceeds pressure on the outside, fluid is pushed out through the pores in a process known as **ultrafiltration**. Most plasma proteins are retained on the inside during this process because of the pores' filtering effect, although a few do escape. Because all other constituents in plasma are dragged along as a unit with the volume of fluid leaving the capillary, the filtrate is essentially protein-free plasma. When inward-driving pressures exceed outward pressures across the capillary wall, net inward movement of fluid from the interstitial fluid into the capillaries takes place through the pores, a process known as **reabsorption**.

Forces Influencing Bulk Flow Bulk flow occurs because of differences in hydrostatic and colloid osmotic pressures between plasma and interstitial fluid. Even though pressure differences exist between plasma and surrounding fluid elsewhere in the circulatory system, only capillaries have pores that let fluids pass through. Four forces influence fluid movement across the capillary wall (**I** Figure 10-20):

1. **Capillary blood pressure (P_C)** is the fluid or hydrostatic pressure exerted on the inside of the capillary walls by blood.
Figure 10-20 Bulk flow across the capillary wall. Ultrafiltration occurs at the arteriolar end and reabsorption occurs at the venule end of the capillary as a result of imbalances in the physical forces acting across the capillary wall.

FIGURE FOCUS: *If π_P decreases to 23 mm Hg as a result of a reduced plasma protein concentration, calculate the rates of ultrafiltration and reabsorption across the capillaries. What would happen to the volume of interstitial fluid compared to normal?*

This pressure tends to force fluid *out of* the capillaries into the interstitial fluid. By the level of the capillaries, blood pressure has dropped substantially because of frictional losses in pressure in the high-resistance arterioles upstream. On average, the hydrostatic pressure is 37 mm Hg at the arteriolar end of a tissue capillary (compared to a mean arterial pressure of 93 mm Hg). It declines even further, to 17 mm Hg, at the capillary's venular end because of further frictional loss coupled with the exit of fluid through ultrafiltration along the capillary's length (see ❙Figure 10-8, p. 343).

2. **Plasma-colloid osmotic pressure (π_P)**, also known as *oncotic pressure,* is a force caused by colloidal dispersion of plasma proteins (see p. A-7); it encourages fluid movement *into* the capillaries. Because plasma proteins remain in the plasma rather than entering the interstitial fluid, a protein concentration difference exists between plasma and interstitial fluid. Accordingly, a water concentration difference also exists between these two regions. Plasma has a higher protein concentration and a lower water concentration than interstitial fluid does. This difference exerts an osmotic effect that tends to move water from the area of higher water concentration in interstitial fluid to the area of lower water concentration in plasma (see p. 66). The other plasma constituents do not exert an osmotic effect because they readily pass through the capillary wall, so their concentrations are equal in plasma and interstitial fluid. π_P averages 25 mm Hg.

3. **Interstitial fluid hydrostatic pressure (P_{IF})** is the fluid pressure exerted on the outside of the capillary wall by interstitial fluid. This pressure tends to force fluid *into* the capillaries. Because of difficulties measuring P_{IF}, the actual value is controversial. It is either at, slightly above, or slightly below atmospheric pressure. For purposes of illustration, we will say it is 1 mm Hg above atmospheric pressure.

4. **Interstitial fluid–colloid osmotic pressure (π_{IF})** is another force that does not normally contribute significantly to bulk flow. The small fraction of plasma proteins that leak across the capillary walls into the interstitial spaces are normally returned to the blood by the lymphatic system. Therefore, the protein concentration in the interstitial fluid is extremely low, and the interstitial fluid–colloid osmotic pressure is essentially zero. If plasma proteins pathologically leak into the interstitial fluid, however, as they do when histamine widens the capillary pores during tissue injury, the leaked proteins exert an osmotic effect that tends to promote movement of fluid *out of* the capillaries into the interstitial fluid.

Therefore, the two pressures that tend to force fluid out of the capillary are P_C and π_{IF}. The two opposing pressures that tend to force fluid into the capillary are π_P and P_{IF}. Now let us analyze the fluid movement that occurs across a capillary wall because of imbalances in these opposing physical forces (❙Figure 10-20).

Net Exchange of Fluid Across the Capillary Wall Net exchange at a given point across the capillary wall can be calculated using the following equation:

$$\textbf{Net exchange pressure} = (P_C + \pi_{IF}) - (\pi_P + P_{IF})$$

$$\text{(outward pressure)} \quad \text{(inward pressure)}$$

A positive net exchange pressure (when outward pressure exceeds inward pressure) represents an ultrafiltration pressure. A negative net exchange pressure (when inward pressure exceeds outward pressure) represents a reabsorption pressure.

At the arteriolar end of the capillary, outward pressure totals 37 mm Hg, whereas inward pressure totals 26 mm Hg, for a net outward pressure of 11 mm Hg. Ultrafiltration takes place at the beginning of the capillary as this outward pressure gradient forces a protein-free filtrate through the capillary pores.

By the time the venular end of the capillary is reached, capillary blood pressure has dropped but the other pressures have remained essentially constant. At this point, outward pressure has fallen to a total of 17 mm Hg, whereas the total inward pressure is still 26 mm Hg, for a net inward pressure of 9 mm Hg. Reabsorption of fluid takes place as this inward pressure gradient forces fluid back into the capillary at its venular end.

Ultrafiltration and reabsorption, collectively known as *bulk flow,* are thus the result of a shift in the balance between the passive physical forces acting across the capillary wall. No active forces or local energy expenditures are involved in bulk exchange of fluid between plasma and surrounding interstitial fluid. With only minor contributions from interstitial fluid forces, ultrafiltration occurs at the beginning of the capillary because capillary blood pressure exceeds plasma-colloid osmotic pressure, whereas by the end of the capillary, reabsorption takes place because blood pressure has fallen below osmotic pressure.

Note that we have taken "snapshots" at two points—at the beginning and at the end—in a hypothetical capillary. Actually, blood pressure gradually diminishes along the length of the capillary so that progressively diminishing quantities of fluid are filtered out in the first half of the vessel and progressively increasing quantities of fluid are reabsorbed in the last half. Even this situation is idealized. The pressures used in this figure are average values. Some capillaries have such high hydrostatic pressure that filtration actually occurs throughout their entire length, whereas others have such low hydrostatic pressure that reabsorption takes place throughout their length.

Role of Bulk Flow Bulk flow does not play an important role in exchange of individual solutes between blood and tissues because the quantity of solutes moved across the capillary wall by bulk flow is extremely small compared to the larger transfer of solutes by diffusion. The composition of the fluid filtered out of the capillary is essentially the same as the composition of the fluid that is reabsorbed. Thus, ultrafiltration and reabsorption are not important in exchange of nutrients and wastes. Bulk flow is extremely important, however, in regulating the distribution of ECF between plasma and interstitial fluid. Maintenance of proper arterial blood pressure depends in part on an appropriate volume of circulating blood. If plasma volume is reduced (for example, by hemorrhage), blood pressure falls. The resultant lowering of capillary blood pressure alters the balance of forces across the capillary walls. Because net outward pressure is decreased while net inward pressure remains unchanged, extra fluid is shifted from the interstitial compartment into the plasma as a result of reduced filtration and increased reabsorption. The extra fluid soaked up from the interstitial fluid provides addi-

tional fluid for the plasma, temporarily compensating for the blood loss. Meanwhile, reflex mechanisms acting on the heart and blood vessels (described later) also come into play to help maintain blood pressure until long-term mechanisms, such as thirst (and its satisfaction) and reduced urinary output, can restore the fluid volume to completely compensate for the loss.

Conversely, if the plasma volume becomes overexpanded, as with excessive fluid intake, the resulting rise in capillary blood pressure forces extra fluid from the capillaries into the interstitial fluid, temporarily relieving the expanded plasma volume until the excess fluid can be eliminated from the body by long-term measures, such as increased urinary output.

These internal fluid shifts between the two ECF compartments occur automatically and immediately whenever the balance of forces acting across the capillary walls is changed; they provide a temporary mechanism to help keep plasma volume fairly constant. In the process of restoring plasma volume to an appropriate level, interstitial fluid volume fluctuates, but it is more important that plasma volume be kept constant to ensure that the circulatory system functions effectively.

The lymphatic system is an accessory route for return of interstitial fluid to the blood.

Even under normal circumstances, slightly more fluid is filtered out of the capillaries into the interstitial fluid than is reabsorbed from the interstitial fluid back into the plasma. On average, the net ultrafiltration pressure starts at 11 mm Hg at the beginning of the capillary, whereas the net reabsorption pressure only reaches 9 mm Hg by the vessel's end (see ❚Figure 10-20). Because of this pressure differential, on average more fluid is filtered out of the first half of the capillary than is reabsorbed in its last half. The extra fluid filtered out as a result of this filtration–reabsorption imbalance is picked up by the **lymphatic system**. This extensive network of one-way vessels provides an accessory route by which fluid can be returned from the interstitial fluid to the blood. The lymphatic system functions much like a storm sewer that picks up and carries away excess rainwater so that it does not accumulate and flood an area.

Pickup and Flow of Lymph Small, blind-ended terminal lymph vessels known as **initial lymphatics** permeate almost every tissue of the body (❚Figure 10-21a). The endothelial cells forming the walls of initial lymphatics slightly overlap like shingles on a roof, with their overlapping edges being free instead of attached to the surrounding cells. This arrangement creates one-way, valvelike openings in the vessel wall. Fluid pressure on the outside of the vessel pushes the innermost edge of a pair of overlapping edges inward, creating a gap between the edges (that is, opening the valve). This opening permits interstitial fluid to enter (❚Figure 10-21b). Once interstitial fluid enters a lymphatic vessel, it is called **lymph**. Fluid pressure on the inside forces the overlapping edges together, closing the valves so that lymph does not escape. These lymphatic valvelike openings are larger than the pores in blood capillaries. Consequently, large particles in the interstitial fluid, such as escaped plasma proteins and bacteria, can gain access to initial lymphatics but are excluded from blood capillaries.
(a) Relationship between initial lymphatics and blood capillaries

(b) Arrangement of endothelial cells in an initial lymphatic

❚Figure 10-21 **Initial lymphatics.** (a) Blind-ended initial lymphatics pick up excess fluid filtered by blood capillaries and return it to the venous system in the chest. (b) Note that the overlapping edges of the endothelial cells create valvelike openings in the vessel wall.

Initial lymphatics converge to form larger and larger **lymph vessels**, which eventually empty into the venous system near where blood enters the right atrium (❚Figure 10-22a). There is no "lymphatic heart" to provide driving pressure, but lymph is directed from the tissues toward the venous system in the thoracic cavity by two mechanisms. First, lymph vessels beyond the initial lymphatics are surrounded by smooth muscle, which contracts rhythmically as a result of myogenic activity. When this muscle is stretched because the vessel is distended with lymph, the muscle inherently contracts more forcefully, pushing the lymph through the vessel. This intrinsic "lymph pump" is the major force for propelling lymph. Stimulation of lymphatic smooth muscle by the sympathetic nervous system further increases the pumping activity of the lymph vessels. Sec-

(b) Comparison of blood flow and lymph flow per day

❚Figure 10-22 **Lymphatic system.** (a) Lymph empties into the venous system near its entrance to the right atrium. (b) Lymph flow averages 3 liters per day, whereas blood flow averages 7200 liters per day.

ond, because lymph vessels lie between skeletal muscles, contraction of these muscles squeezes the lymph out of the vessels. One-way valves spaced at intervals within the lymph vessels direct the flow of lymph toward its venous outlet in the chest.

Functions of the Lymphatic System Here are the most important functions of the lymphatic system:

■ *Return of excess filtered fluid.* Normally, capillary filtration exceeds reabsorption by about 3 liters per day (20 liters filtered, 17 liters reabsorbed) (❚Figure 10-22b). Yet the entire blood volume is only 5 liters, and only 2.75 liters of that is plasma. (Blood cells make up the rest of the blood volume.) With an average CO of 5 L/min, 7200 liters of blood pass through the capillaries daily under resting conditions (more when CO increases). Even though only a small fraction of the filtered fluid is not reabsorbed by the blood capillaries, the cumulative effect of this process being repeated with every heart-

beat results in the equivalent of more than the entire plasma volume being left behind in the interstitial fluid each day. Obviously, this fluid must be returned to the circulating plasma, and the lymph vessels accomplish this task. The average rate of flow through the lymph vessels is 3 liters per day, compared with 7200 liters per day through the circulatory system.

■ *Defense against disease.* Lymph percolates through **lymph nodes** located en route within the lymphatic system. Passage of this fluid through the lymph nodes is important in the body's defense against disease. For example, bacteria picked up from the interstitial fluid are destroyed by special phagocytes within the lymph nodes (see Chapter 12).

■ *Transport of absorbed fat.* The lymphatic system transports fat absorbed from the digestive tract. The end products of dietary fat digestion are packaged by cells lining the digestive tract into fatty particles that are too large to gain access to the blood capillaries but can easily enter the initial lymphatics (see Chapter 16).

■ *Return of filtered protein.* Most capillaries permit leakage of a small amount of plasma proteins during filtration. These proteins cannot readily be reabsorbed back into the blood capillaries but can easily gain access to the initial lymphatics. If the proteins were allowed to accumulate in the interstitial fluid rather than being returned to the circulation via the lymphatics, π_{IF} (an outward pressure) would progressively increase while π_P (an inward pressure) would progressively fall. As a result, ultrafiltration forces would gradually increase and reabsorption forces would gradually decrease, resulting in progressive accumulation of fluid in the interstitial spaces at the expense of loss of plasma volume.

Edema occurs when too much interstitial fluid accumulates.

Clinical Note Occasionally, excessive interstitial fluid does accumulate when one of the physical forces acting across the capillary walls becomes abnormal for some reason. Swelling of the tissues because of excess interstitial fluid is

known as **edema**. The causes of edema can be grouped into four categories:

1. *A reduced concentration of plasma proteins* decreases π_P. Such a drop in the major inward pressure lets excess fluid filter out, whereas less-than-normal amounts of fluid are reabsorbed; hence, extra fluid remains in the interstitial spaces. Edema can be caused by a decreased concentration of plasma proteins in several ways: excessive loss of plasma proteins in urine, from kidney disease; reduced synthesis of plasma proteins, from liver disease (the liver synthesizes almost all plasma proteins); a diet deficient in protein; or significant loss of plasma proteins from large burned surfaces.

2. *Increased permeability of the capillary walls* allows more plasma proteins than usual to pass from the plasma into the surrounding interstitial fluid—for example, via histamine-induced widening of the capillary pores during tissue injury or allergic reactions. The resultant fall in π_P decreases the effective inward pressure, whereas the resultant rise in π_{IF} caused by excess protein in the interstitial fluid increases the effective outward force. This imbalance contributes in part to the localized edema associated with injuries (for example, blisters) and allergic responses (for example, hives).

3. *Increased venous pressure,* as when blood dams up in the veins, is accompanied by increased P_C. Because the capillaries drain into the veins, damming of blood in the veins leads to a "backlog" of blood in the capillaries because less blood moves out of the capillaries into the overloaded veins than enters from the arterioles. The resultant elevation in outward hydrostatic pressure across the capillary walls is largely responsible for the edema seen with congestive heart failure (see p. 325). Regional edema can also occur because of localized restriction of venous return. An example is the swelling often occurring in the legs and feet during pregnancy. The enlarged uterus compresses the major veins that drain the lower extremities as these vessels enter the abdominal cavity. The resultant damming of blood in these veins raises blood pressure in the capillaries of the legs and feet, which promotes regional edema of the lower extremities.

4. *Blockage of lymph vessels* produces edema because the excess filtered fluid is retained in the interstitial fluid rather than returned to the blood through the lymphatics. Protein accumulation in the interstitial fluid compounds the problem through its osmotic effect. Local lymph blockage can occur, for example, in the arms of women whose major lymphatic drainage channels from the arm have been blocked as a result of lymph node removal during surgery for breast cancer. More widespread lymph blockage occurs with *filariasis,* a mosquito-borne parasitic disease found predominantly in tropical coastal regions. In this condition, small, threadlike filaria worms infect the lymph vessels, where their presence prevents proper lymph drainage. The affected body parts, particularly the scrotum and extremities, become grossly edematous. The condition is often called *elephantiasis* because of the elephant-like appearance of the swollen extremities (❚Figure 10-23).

Whatever the cause of edema, an important consequence is reduced exchange of materials between blood and cells. As

❚Figure 10-23 **Elephantiasis.** Note the pronounced edema in the legs, ankles, and feet of this person with elephantiasis. This tropical condition is caused by a mosquito-borne parasitic worm that invades the lymph vessels. As a result of the interference with lymph drainage, the affected body parts, usually the extremities, become grossly edematous, appearing elephantlike.
Andy Crump/TDR/World Health Organization/Science Source

excess interstitial fluid accumulates, the distance between blood and cells across which nutrients, O_2, and wastes must diffuse increases, so the rate of diffusion decreases. Therefore, cells within edematous tissues may not be adequately supplied.

1. Compare the functions served by diffusion and by bulk flow across the capillary walls.

2. Describe the forces responsible for ultrafiltration at the arteriolar end of a capillary and for reabsorption at the venular end.

3. Define *lymph*.

10.5 Veins

The venous system completes the circulatory circuit. Blood leaving the capillary beds enters the venous system for transport back to the heart.

Venules communicate chemically with nearby arterioles.

At the microcirculatory level, capillaries drain into **venules**, which progressively converge to form small veins that exit the organ. In contrast to arterioles, venules have little tone and resistance. Extensive communication takes place via chemical signals between venules and nearby arterioles. This venuloarteriolar signaling is vital to matching capillary inflow and outflow within an organ.

Veins serve as a blood reservoir and as passageways back to the heart.

Veins have a large radius, so they offer little resistance to flow. Furthermore, because the total cross-sectional area of the venous system gradually decreases as smaller veins converge

into progressively fewer but larger vessels, blood flow speeds up as blood approaches the heart.

In addition to serving as low-resistance passageways to return blood from the tissues to the heart, systemic veins also serve as a *blood reservoir*. Because of their storage capacity, veins are often called **capacitance vessels**. Veins have thinner walls with less smooth muscle than arteries do. Also, in contrast to arteries, veins have little elasticity because venous connective tissue contains considerably more collagen fibers than elastin fibers (see ▌Table 10-1, p. 339). Unlike arteriolar smooth muscle, venous smooth muscle has little inherent myogenic tone. Because of these features, veins are highly distensible, or stretchable, and have little elastic recoil. They easily distend to accommodate additional volumes of blood with only a small increase in venous pressure. Arteries stretched by an excess volume of blood recoil because of the elastin fibers in their walls, driving the blood forward. Veins containing an extra volume of blood simply stretch to accommodate the additional blood without tending to recoil. In this way veins serve as a **blood reservoir**—that is, when demands for blood are low, the veins can store extra blood in reserve because of their passive distensibility. Under resting conditions, the veins contain more than 60% of the total blood volume (▌Figure 10-24).

Contrary to a common misconception, blood stored in the veins is not being held in a stagnant holding tank. Normally all the blood is circulating all the time. When the body is at rest and many of the capillary beds are closed, the capacity of the venous reservoir is increased as extra blood bypasses the closed capillaries and enters the veins. When this extra volume of blood stretches the veins, the blood moves forward through the veins more slowly because the total cross-sectional area of the veins has been increased as a result of the stretching. Therefore, the blood spends more time in the veins. As a result of this slower transit time through the veins, the veins are essentially storing the extra volume of blood because it is not moving forward as quickly to the heart to be pumped out again.

When the stored blood is needed, such as during exercise, extrinsic factors (soon to be described) reduce the capacity of the venous reservoir and drive the extra blood from the veins to the heart so that it can be pumped to the tissues. Increased venous return leads to an increased stroke volume, in accordance with the Frank–Starling law of the heart (see p. 322). In contrast, if too much blood pools in the veins instead of being returned to the heart, CO is abnormally diminished. Thus, a delicate balance exists among the capacity of the veins, the extent of venous return, and CO. We now turn attention to the factors that affect venous capacity and contribute to venous return.

Venous return is enhanced by several extrinsic factors.

Venous capacity (the volume of blood that the veins can accommodate) depends on the distensibility of the vein walls (how much they can stretch to hold blood) and the influence of any externally applied pressure squeezing inwardly on the veins. At a constant blood volume, as venous capacity increases, more blood remains in the veins instead of being returned to
▌Figure 10-24 **Percentage of total blood volume in different parts of the circulatory system**.

the heart. Such venous storage decreases the **effective circulating blood volume**, the volume of blood being returned to and pumped out of the heart. Conversely, when venous capacity decreases, more blood is returned to the heart and is subsequently pumped out. Thus, changes in venous capacity directly influence the magnitude of venous return, which in turn is an important (although not the only) determinant of effective circulating blood volume. The effective circulating blood volume is also influenced short term by passive shifts in bulk flow between plasma and interstitial fluid and long term by factors that control total ECF volume, such as salt and water balance.

The term **venous return** refers to the volume of blood per minute entering each atrium from the veins. Recall that the magnitude of flow through a vessel is directly proportional to the pressure gradient. Much driving pressure imparted to the blood by cardiac contraction has been lost by the time the blood reaches the venous system because of frictional losses along the way, especially during passage through the high-resistance arterioles. By the time the blood enters the venous system, blood pressure averages only 17 mm Hg (see ▌Figure 10-8, p. 343). However, because atrial pressure is near 0 mm Hg, a small but adequate driving pressure still exists to promote flow of blood through the large-radius, low-resistance veins.

In addition to the driving pressure imparted by cardiac contraction, five other factors enhance venous return: sympathetically induced venous vasoconstriction, skeletal muscle pump, venous valves, respiratory pump, and cardiac suction (▌Figure 10-25). Most of these secondary factors affect venous return by increasing the pressure gradient between the veins and the heart. We examine each in turn.

Effect of Sympathetic Activity on Venous Return
Veins are not very muscular and have little inherent tone, but venous smooth muscle is abundantly supplied with sympathetic nerve fibers. Sympathetic stimulation produces venous vasoconstriction, which modestly elevates venous pressure; this, in turn, increases the pressure gradient to drive more of the stored blood from the veins into the right atrium, thus enhancing venous

return. Veins normally have such a large radius that the moderate vasoconstriction from sympathetic stimulation has little effect on resistance to flow. Even when constricted, veins still have a relatively large radius and are still low-resistance vessels.

Note the different outcomes of vasoconstriction in arterioles and veins. Arteriolar vasoconstriction immediately *reduces* flow through these vessels because of their increased resistance (less blood can enter and flow through a narrowed arteriole), whereas venous vasoconstriction immediately *increases* flow through these vessels because of their decreased capacity (narrowing of veins squeezes out more of the blood already in the veins, increasing blood flow through these vessels). In addition to mobilizing the stored blood, venous vasoconstriction sustains increased venous return. With the filling capacity of the veins reduced, less blood draining from the capillaries remains in the veins but continues to flow instead toward the heart.

The increased venous return initiated by sympathetic stimulation leads to increased CO because of the increase in end-diastolic volume. Sympathetic stimulation of the heart also increases CO by increasing the heart rate and increasing the heart's contractility (see pp. 320 and 322). Thus, as long as sympathetic activity remains elevated, as during exercise, the heart pumps out more blood than usual for use by the exercising muscles.

Effect of Skeletal Muscle Activity on Venous Return
Many large veins in the extremities lie between skeletal muscles, so muscle contraction compresses the veins. This external venous compression decreases venous capacity and increases venous pressure, in effect squeezing blood in the veins forward toward the heart (I Figure 10-26a). This pumping action, known as the **skeletal muscle pump**, is another way extra blood stored

in the veins is returned to the heart during exercise. The skeletal muscle pump also counters the effect of gravity on the venous system. Let us see how.

Countering the Effects of Gravity on the Venous System The average pressures mentioned thus far for various regions of the vascular tree are for a person in the horizontal position. When a person is lying down, the force of gravity is uniformly applied, so it need not be considered. When a person stands up, however, gravitational effects are not uniform. In addition to the usual pressure from cardiac contraction, vessels below heart level are subject to pressure from the weight of the column of blood extending from the heart to the level of the vessel (I Figure 10-26b).

This increased pressure has two major consequences. First, the distensible veins yield under the increased hydrostatic pressure, further expanding so that their capacity is increased. Even though the arteries are subject to the same gravitational effects, they are not nearly as distensible and do not expand like the veins. Much of the blood entering from the capillaries tends to pool in the expanded lower-leg veins instead of returning to the heart. Because venous return is reduced, CO decreases and the effective circulating volume shrinks. Second, the marked increase in P_C resulting from the effect of gravity causes excessive fluid to filter out of capillary beds in the lower extremities, producing localized edema (that is, swollen feet and ankles) (I Figure 10-26c).

Two compensatory measures normally counteract these gravitational effects. First, the resultant fall in MAP that occurs when a person moves from a lying-down to an upright position triggers sympathetically induced venous vasoconstriction, which drives some of the pooled blood forward. Second, when

(d) Effect of contraction of skeletal muscles of legs in counteracting the effects of gravity

❚Figure 10-26 **Skeletal muscle pump enhancing venous return and countering effect of gravity on venous pressure.** (a) Compression of veins by contraction of nearby skeletal muscles squeezes extra blood out of the veins, increasing venous return. (b) In an upright adult, the blood in the vessels extending between the heart and the foot is equivalent to a 1.5-m column of blood. The pressure exerted by this column of blood as a result of the effect of gravity is 90 mm Hg. The pressure imparted to the blood by the heart has declined to about 10 mm Hg in the lower-leg veins because of frictional losses in preceding vessels. Together these pressures produce a venous pressure of 100 mm Hg in the ankle and foot veins. The capillaries in the region are subjected to these same gravitational effects. (c) Because of the increased pressure caused by gravity, blood pools in the distended veins, resulting in decreased venous return. Ultrafiltration also increases across capillary walls, resulting in swollen ankles and feet, unless compensatory measures can counteract the effect of gravity. (d) Contraction of skeletal muscles (as in walking) completely empties given vein segments, interrupting the column of blood that the lower veins must support.

a person moves around, the skeletal muscle pump "interrupts" the column of blood by completely emptying given vein segments intermittently so that a particular portion of a vein is not subjected to the weight of the entire venous column from the heart to that portion's level (❙Figure 10-26d). Reflex venous vasoconstriction cannot completely compensate for gravitational effects without skeletal muscle activity. When a person stands still for a long time, therefore, blood flow to the brain is reduced because of the decline in effective circulating volume, despite reflexes aimed at maintaining MAP. Reduced flow of blood to the brain, in turn, leads to fainting, which returns the person to a horizontal position, eliminating the gravitational effects on

(a) Fluid moving in both directions on squeezing a fluid-filled tube

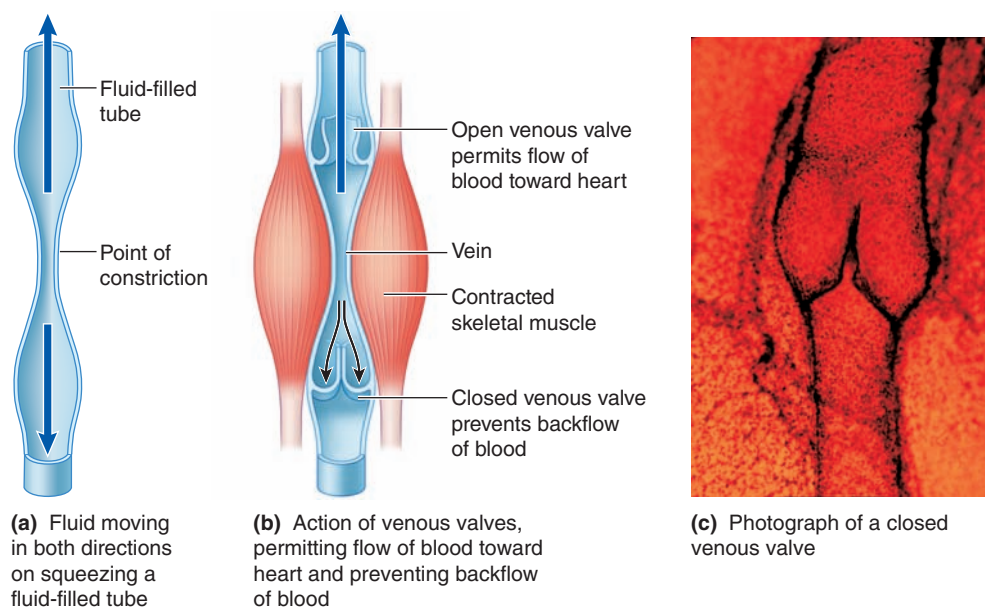
(c) Photograph of a closed venous valve

❙Figure 10-27 **Function of venous valves.**

the vascular system and restoring effective circulation. For this reason, it is counterproductive to try to hold upright someone who has fainted. Fainting is a remedy to the problem, not the problem itself.

Because the skeletal muscle pump facilitates venous return and helps counteract the detrimental effects of gravity on the circulatory system, when you are working at a desk it's a good idea to get up periodically and, when you are on your feet, you should move around. The mild muscular activity "gets the blood moving." It is further recommended that people who must be on their feet for long periods wear elastic stockings that apply a continuous gentle external compression, similar to the effect of skeletal muscle contraction, to further counter the effect of gravitational pooling of blood in the leg veins.

Effect of Venous Valves on Venous Return Venous vasoconstriction and external venous compression both drive blood toward the heart. Yet if you squeeze a fluid-filled tube in the middle, fluid is pushed in both directions from the point of constriction (❙Figure 10-27a). Then why isn't blood driven backward, as well as forward, by venous vasoconstriction and the skeletal muscle pump? Blood can only be driven forward because the large veins are equipped with one-way valves spaced at 2- to 4-cm intervals; these valves let blood move forward toward the heart but keep it from moving back toward the tissues (❙Figure 10-27b and c). These venous valves also play a role in counteracting the gravitational effects of upright posture by helping minimize the backflow of blood that tends to occur when a person stands up and by temporarily supporting portions of the column of blood when the skeletal muscles are relaxed.

Clinical Note **Varicose veins** occur when the venous valves become incompetent and can no longer support the column of blood above them. People predisposed to this condition usually have inherited an overdistensibility and weakness of their vein walls. Aggravated by frequent, prolonged standing,


the veins become so distended as blood pools in them that the edges of the valves can no longer meet to form a seal. Varicosed superficial leg veins become visibly overdistended and tortuous. Contrary to what might be expected, chronic pooling of blood in the pathologically distended veins does not reduce CO because of a compensatory increase in total circulating blood volume. Instead, the most serious consequence of varicose veins is the possibility of abnormal clot formation in the sluggish, pooled blood. Particularly dangerous is the risk that these clots may break loose and block small vessels elsewhere, especially the pulmonary capillaries.

Effect of Respiratory Activity on Venous Return As a result of respiratory activity, the pressure within the chest cavity averages 5 mm Hg less than atmospheric pressure. As the venous system returns blood to the heart from the lower regions of the body, it travels through the chest cavity, where it is exposed to this subatmospheric pressure. Because the venous system in the limbs and abdomen is subject to normal atmospheric pressure, an externally applied pressure gradient exists between the lower veins (at atmospheric pressure) and the chest veins (at less than atmospheric pressure). This pressure difference pushes blood from the lower veins to the chest veins, promoting increased venous return (❙Figure 10-28). This mechanism of facilitating venous return is called the **respiratory pump** because it results from respiratory activity. Increased respiratory activity, the skeletal muscle pump, and venous vasoconstriction, all enhance venous return during exercise.

Effect of Cardiac Suction on Venous Return The extent of cardiac filling does not depend entirely on factors affecting the veins. The heart plays a role in its filling. During ventricular contraction, the AV valves are drawn downward, enlarging the atrial cavities. As a result, atrial pressure transiently drops below 0 mm Hg, thus increasing the vein-to-atria pressure gradient so
Figure 10-28 Respiratory pump enhancing venous return. As a result of respiratory activity, the pressure surrounding the chest veins is lower than the pressure surrounding the veins in the extremities and abdomen. This establishes an externally applied pressure gradient on the veins, which drives blood toward the heart.

that venous return is enhanced. In addition, rapid expansion of the ventricular chambers during ventricular relaxation creates a transient negative pressure in the ventricles so that blood is "sucked in" from the atria and veins—that is, the negative ventricular pressure increases the vein-to-atria-to-ventricle pressure gradient, further enhancing venous return. Thus, the heart functions as a "suction pump" to facilitate cardiac filling.

Check Your Understanding 10.5

1. Explain how veins have the capacity to store an extra volume of blood with little change in venous pressure.
2. Define *effective circulating blood volume.*
3. List the factors that enhance venous return.

10.6 Blood Pressure

Mean arterial pressure is the blood pressure that is monitored and regulated in the body. Routine blood pressure measurements record the arterial systolic and diastolic pressures, which can be used as a yardstick for assessing MAP.

Blood pressure is regulated by controlling cardiac output, total peripheral resistance, and blood volume.

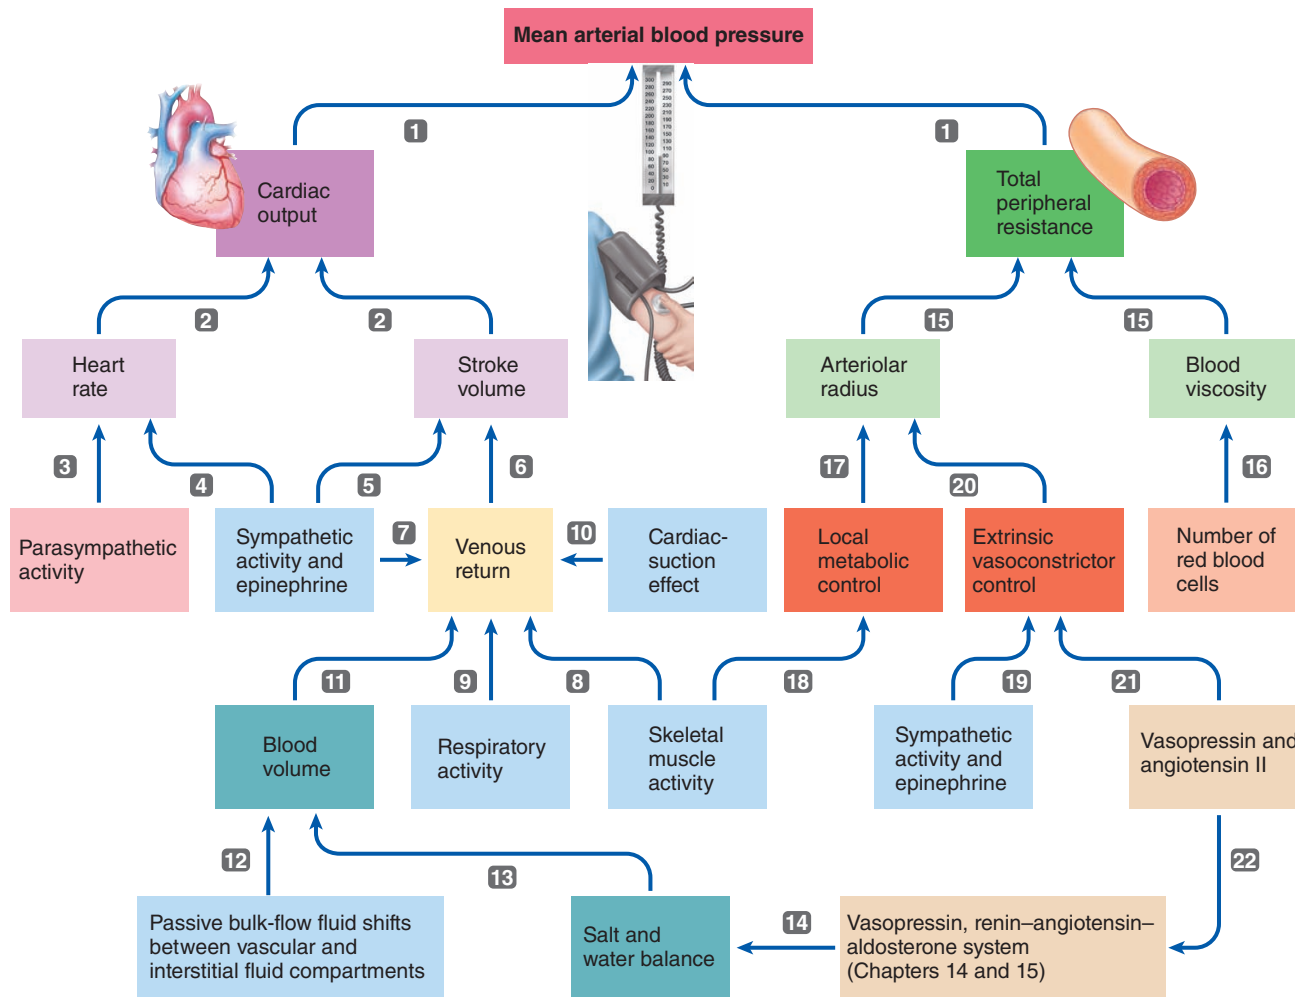
Mean arterial pressure is the main driving force for propelling blood to the tissues. This pressure must be closely regulated for two reasons. First, it must be high enough to ensure sufficient driving pressure; without this pressure, the brain and other organs do not receive adequate flow, no matter what local adjustments are made in the resistance of the arterioles supplying them. Second, the pressure must not be so high that it creates extra work for the heart and increases the risk of vascular damage and possible rupture of small blood vessels.

Determinants of Mean Arterial Pressure Elaborate mechanisms involving the integrated action of the various components of the circulatory system and other body systems are vital in regu-

lating this all-important mean arterial pressure (**Figure 10-29**). Remember that the two determinants of MAP are CO and TPR:

$$MAP = CO \times TPR$$

Recall that a number of factors, in turn, determine CO and TPR (see **Figure 9-24**, p. 324; **Figure 10-13**, p. 351; and **Figure 10-25**, p. 362). Thus, you can quickly appreciate the complexity of blood pressure regulation. Let us work through **Figure 10-29**, reviewing all the factors that affect MAP. Even though we have covered all these factors before, it is useful to pull them together. The numbers in the text correspond to the numbers in the figure.

- MAP depends on CO and TPR (**1** on Figure 10-29).
- CO depends on heart rate and stroke volume **2**.
- Heart rate depends on the relative balance of parasympathetic activity **3**, which decreases heart rate, and sympathetic activity **4** (including epinephrine throughout this discussion), which increases heart rate.
- Stroke volume increases in response to sympathetic activity **5** (extrinsic control of stroke volume).
- Stroke volume also increases as venous return increases **6** (intrinsic control of stroke volume according to the Frank–Starling law of the heart).
- Venous return is enhanced by sympathetically induced venous vasoconstriction **7**, the skeletal muscle pump **8**, the respiratory pump **9**, and cardiac suction **10**.
- The effective circulating blood volume also influences how much blood is returned to the heart **11** and therefore ultimately on how much blood is pumped out by the heart. Blood volume depends in the short term on the size of passive bulk-flow fluid shifts between the plasma and the interstitial fluid across the capillary walls **12**. In the long term, blood volume depends on salt and water balance **13**, which are hormonally controlled by the renin–angiotensin–aldosterone system and vasopressin, respectively **14**.
- The other major determinant of mean arterial pressure, TPR, depends on the radius of all arterioles and on blood viscosity **15**. The main factor determining blood viscosity is the number of red blood cells **16**. However, arteriolar radius is the more important factor determining TPR.


IFigure 10-29 Determinants of mean arterial blood pressure. Note that this figure is basically a composite of Figure 9-24, p. 324, "Control of cardiac output"; Figure 10-13, p. 351, "Factors affecting total peripheral resistance"; and Figure 10-25, p. 362, "Factors that facilitate venous return." See the text for a discussion of the numbers.

FIGURE FOCUS: *State the pathway on this flow diagram by which drugs that interfere with the salt-conserving renin–angiotensin–aldosterone system act to bring down blood pressure in patients with high blood pressure.*

- Arteriolar radius is influenced by local (intrinsic) metabolic controls that match blood flow with metabolic needs **17**. For example, local changes that take place in active skeletal muscles cause local arteriolar vasodilation and increased blood flow to these muscles **18**.

- Arteriolar radius is also influenced by sympathetic activity **19**, an extrinsic control mechanism that causes arteriolar vasoconstriction **20** to increase TPR and subsequently MAP.

- Arteriolar radius is also extrinsically controlled by the hormones vasopressin and angiotensin II, which are potent vasoconstrictors **21** as well as being important in salt and water balance **22**.

Altering any of the pertinent factors that influence MAP changes this pressure, unless a compensatory change in another variable keeps the blood pressure constant. Blood flow to any given organ depends on the driving force of the MAP and on the degree of vasoconstriction of the organ's arterioles. Because MAP depends on CO and the degree of arteriolar vasoconstriction, if the arterioles in one organ

dilate, the arterioles in other organs must constrict to maintain an adequate MAP. An adequate pressure is needed to provide a driving force to push blood not only to the vasodilated organ but also to the brain, which depends on a constant blood supply. Thus, the cardiovascular variables must be continuously juggled to maintain a constant blood pressure despite organs' varying needs for blood.

Short-Term and Long-Term Control Measures Mean arterial pressure is constantly monitored by **baroreceptors** (pressure sensors) within the circulatory system. When deviations from normal are detected, multiple reflex responses are initiated to return MAP to its normal value. *Short-term* (within seconds) adjustments are made by alterations in CO and TPR, mediated by means of autonomic nervous system influences on the heart, veins, and arterioles. *Long-term* (requiring minutes to days) control involves adjusting total blood volume by restoring normal salt and water balance through mechanisms that regulate urine output and thirst (see Chapters 14 and 15). The size of the total blood volume, in turn, has a profound effect on CO

and, thereby, MAP. For now we will focus on the short-term mechanisms involved in ongoing regulation of blood pressure.

The baroreceptor reflex is a short-term mechanism for regulating blood pressure.

Any change in MAP triggers an autonomically mediated **baroreceptor reflex** that influences the heart and blood vessels to adjust CO and TPR in an attempt to restore blood pressure toward normal. Like any reflex, the baroreceptor reflex includes a receptor, an afferent pathway, an integrating center, an efferent pathway, and effector organs.

The most important receptors involved in the moment-to-moment regulation of blood pressure, the **carotid sinus** and **aortic arch baroreceptors**, are mechanoreceptors sensitive to changes in MAP. These baroreceptors are strategically located (Figure 10-30) to provide critical information about arterial blood pressure in the vessels leading to the brain (the carotid sinus baroreceptor) and in the major arterial trunk before it gives off branches that supply the rest of the body (the aortic arch baroreceptor).

The baroreceptors constantly provide information about MAP; in other words, they continuously generate action potentials in response to the ongoing pressure within the arteries. When MAP increases, the receptor potential of these baroreceptors increases, thus increasing the rate of firing in the corresponding afferent neurons. Conversely, a decrease in MAP slows the rate of firing generated in the afferent neurons by the baroreceptors (Figure 10-31).

The integrating center that receives the afferent impulses about the state of the mean arterial pressure is the **cardiovascular control center**, located in the medulla within the brain stem. The efferent pathway is the autonomic nervous system. The cardiovascular control center alters the ratio between sympathetic and parasympathetic activity to the effector organs (the heart and blood vessels). To review how autonomic changes alter arterial blood pressure, study Figure 10-32, which summarizes the major effects of parasympathetic and sympathetic stimulation on the heart and blood vessels.

Let us fit all the pieces of the baroreceptor reflex together by tracing the reflex activity that compensates for an elevation or fall in arterial blood pressure. If for any reason MAP transiently rises above normal (for example, caused by anxiety or taking vasoconstricting decongestants), the carotid sinus and aortic arch baroreceptors increase the rate of firing in their respective afferent neurons (Figure 10-33a). On being informed by increased afferent firing that blood pressure has become too high, the cardiovascular control center responds by decreasing sympathetic and increasing parasympathetic activity to the cardiovascular system. These efferent signals decrease heart rate, decrease stroke volume, and produce arteriolar and venous vasodilation, which in turn lead to a decrease in CO and a decrease in TPR, with a subsequent fall in blood pressure back toward normal.
Figure 10-30 **Location of the arterial baroreceptors.** The arterial baroreceptors are strategically located to monitor the mean arterial blood pressure in the arteries that supply blood to the brain (carotid sinus baroreceptor) and to the rest of the body (aortic arch baroreceptor).

Conversely, when blood pressure falls below normal (for example caused by blood pooling in the leg veins when a person gets up from bed or by blood loss from a traumatic injury), baroreceptor activity decreases, inducing the cardiovascular center to increase sympathetic cardiac and vasoconstrictor nerve activity while decreasing its parasympathetic output (Figure 10-33b). This efferent pattern of activity leads to an increase in heart rate and stroke volume, coupled with arteriolar and venous vasoconstriction. These changes increase both CO and TPR, raising blood pressure back toward normal.
Figure 10-31 **Firing rate in the afferent neuron from the carotid sinus baroreceptor in relation to the magnitude of mean arterial pressure.**
⌐Figure 10-32 Summary of the effects of the parasympathetic and sympathetic nervous systems on factors that influence mean arterial blood pressure.

(b) Baroreceptor reflex in response to a fall in blood pressure

⌐Figure 10-33 Baroreceptor reflexes to restore blood pressure to normal.

Other reflexes and responses influence blood pressure.

Besides the baroreceptor reflex, whose sole function is blood pressure regulation, several other reflexes and responses influence the cardiovascular system and blood pressure even though they primarily regulate other body functions. These factors include the following:

1. Left atrial volume receptors and hypothalamic osmoreceptors are primarily important in water and salt balance in the body; they thus affect long-term regulation of blood pressure by controlling blood volume.

2. Chemoreceptors located in the carotid and aortic arteries, in close association with but distinct from the baroreceptors, are sensitive to low O_2 or high acid levels in the blood. These chemoreceptors' main function is to reflexly increase respiratory activity to bring in more O_2 or to blow off more acid-forming CO_2, but they also reflexly increase blood pressure by sending excitatory impulses to the cardiovascular center.

3. Cardiovascular responses associated with certain behaviors and emotions are mediated through the cerebral cortex–hypothalamic pathway and appear preprogrammed. These responses include the widespread changes in cardiovascular activity accompanying the generalized sympathetic fight-or-flight response, the characteristic marked increase in heart rate and blood pressure associated with sexual orgasm, and the localized cutaneous (skin) vasodilation characteristic of blushing.

4. Hypothalamic control over cutaneous arterioles for the purpose of temperature regulation takes precedence over control that the cardiovascular center has over these same vessels for the purpose of blood pressure regulation. As a result, blood pressure can fall when the skin vessels are widely dilated to eliminate excess heat from the body, even though the baroreceptor responses are calling for cutaneous vasoconstriction to help maintain adequate TPR.

5. Marked cardiovascular changes occur in response to exercise, mediated by exercise centers in the brain at the onset of exercise or even in anticipation of exercise. In moderate exercise, CO more than doubles (and increases up to fivefold in heavy exercise). CO not only is larger but also is redistributed compared to resting; whereas skeletal muscles receive 15% of the CO at rest, during moderate exercise their share of the CO goes up to 64%. As a result, exercising skeletal muscles receive more than a 1000% increase in blood flow. (Details of these and other cardiovascular changes during exercise can be found in the boxed feature on pp. 370–371, ▌A Closer Look at Exercise Physiology.)

We next examine blood pressure abnormalities.

Hypertension is a national public-health problem, but its causes are largely unknown.

Clinical Note Sometimes blood pressure control mechanisms do not function properly or are unable to completely compensate for changes that have taken place. Blood pressure may be too high (**hypertension** if above 140/90 mm Hg) or too low (**hypotension** if below 90/60 mm Hg). Hypotension in its extreme form is *circulatory shock.* We first examine hypertension, which is by far the most common of blood pressure abnormalities, and then conclude this chapter with a discussion of hypotension and shock.

Types of Hypertension There are two broad types of hypertension, secondary hypertension and primary hypertension, depending on the cause. A definite cause for hypertension can be established in only 10% of cases. Hypertension that occurs secondary to another known primary problem is called **secondary hypertension**. For example, hypertension can occur secondary to kidney disease. If the kidneys are unable to eliminate the normal salt load, retention of salt and accompanying water expands the blood volume, thus chronically increasing blood pressure. The underlying cause is unknown in the remaining 90% of hypertension cases. Such hypertension is known as **primary**, or **essential**, **hypertension**. Primary hypertension is a catchall category for blood pressure elevated by a variety of unknown causes rather than by a single disease entity. People show a strong genetic tendency to develop primary hypertension, which can be hastened or worsened by contributing factors such as obesity, chronic stress, smoking, excessive alcohol consumption, or dietary habits. For example, excessive salt intake can contribute to development of primary hypertension, especially in salt-sensitive individuals. (For further discussion of the range of known causes for secondary hypertension and potential causes for primary hypertension, see the boxed feature on pp. 372–373, ▌Concepts, Challenges, and Controversies.)

Whatever the underlying defect, once initiated, hypertension appears to be self-perpetuating. Constant exposure to elevated blood pressure damages vessel walls and predisposes them to development of atherosclerosis (see p. 327). The resultant narrowing of vessel lumens by atherosclerotic plaques increases TPR, which further elevates blood pressure. Thus a detrimental positive-feedback cycle ensues where hypertension and atherosclerosis each promote development of the other.

Baroreceptor Adaptation During Hypertension The baroreceptors do not respond to bring blood pressure back to normal during hypertension because they adapt, or are "reset," to operate at a higher level. In the presence of chronically elevated blood pressure, the baroreceptors still function to regulate blood pressure, but they maintain it at a higher mean pressure.

Complications of Hypertension Hypertension imposes stresses on both the heart and the blood vessels. The heart has an increased workload because it is pumping blood out against an increased TPR, and the high internal pressure may damage blood vessels, particularly when the vessel wall is weakened by the degenerative process of atherosclerosis. Complications of hypertension include (1) *left ventricular hypertrophy* in the early stages as the heart muscle thickens to pump a normal stroke volume against an elevated blood pressure, followed in later stages by *systolic heart failure* as the heart weakens and becomes unable to pump continuously against a sustained elevation in arterial pressure (see p. 324); (2) *strokes* caused by rupture of brain vessels (see p. 142); and (3) *heart attacks* caused by

The Body Gets a Jump on Jogging:
Cardiovascular Changes during Exercise

PRONOUNCED CARDIOVASCULAR CHANGES ACCOMPANY EXERCISE. Not only does cardiac output (CO) increase significantly during exercise but the distribution of CO is adjusted to support the heightened physical activity. For example, CO jumps from its resting value of 5 L/min to 12.5 L/min during moderate exercise and may increase up to 25 L/min (or more in trained athletes) during heavy exercise. The exercising skeletal muscles receive a substantially greater percentage of the larger-than-normal CO, thereby obtaining the extra O_2 and nutrients needed to support these muscles' stepped-up rate of ATP consumption (see the accompanying figure for the magnitude and distribution of CO at rest and during moderate exercise). Heart muscle likewise receives a greater proportion of the CO than usual to support its increased contractile activity during exercise. The percentage going to the skin also increases as a way to eliminate from the body surface the extra heat generated by the exercising muscles. The share of the CO going to most other organs shrinks. Only the magnitude of blood flow to the brain remains unchanged as the distribution of CO is readjusted during exercise. Other noteworthy cardiovascular changes during exercise are a fall in total peripheral resistance (TPR) (because of widespread vasodilation in skeletal muscles despite generalized arteriolar vasoconstriction in most organs), and a modest increase in mean arterial pressure (see the accompanying table for a summary of these cardiovascular changes).

Discrete exercise centers yet to be identified in the brain induce the appropriate cardiac and vascular changes at the onset of exercise or even in feedforward fashion in anticipation of exercise. These effects are then reinforced by afferent inputs to the medullary cardiovascular center from chemoreceptors in exercising muscles and by local mechanisms important in maintaining vasodilation in active muscles. The baroreceptor reflex further modulates these cardiovascular responses.

Cardiovascular Changes during Exercise

Cardiovascular Variable	Change	Comment
Heart rate	Increases	Occurs as a result of increased sympathetic and decreased parasympathetic activity to the SA node
Venous return	Increases	Occurs as a result of sympathetically induced venous vasoconstriction and increased activity of the skeletal muscle pump and respiratory pump
Stroke volume	Increases	Occurs both as a result of increased venous return by means of the Frank-Starling mechanism and as a result of a sympathetically induced increase in myocardial contractility
Cardiac output (CO)	Increases	Occurs as a result of increases in both heart rate and stroke volume
Blood flow to active skeletal muscles and heart muscle	Increases	Occurs as a result of locally controlled arteriolar vasodilation, which is reinforced by the vasodilatory effects of epinephrine and overpowers the weaker sympathetic vasoconstrictor effect
Blood flow to the brain	Unchanged	Occurs because sympathetic stimulation has no effect on brain arterioles; local control mechanisms maintain constant cerebral blood flow
Blood flow to the skin	Increases	Occurs because the hypothalamic temperature control center induces vasodilation of skin arterioles; increased skin blood flow brings heat produced by exercising muscles to the body surface where the heat can be lost to the external environment
Blood flow to the digestive system, kidneys, and other organs	Decreases	Occurs via generalized sympathetically induced arteriolar vasoconstriction
Total peripheral resistance (TPR)	Decreases	Occurs because resistance in the skeletal muscles, heart, and skin decreases to a greater extent than resistance in the other organs increases
Mean arterial blood pressure	Increases (modest)	Occurs because CO increases more than TPR decreases

Percent change in flow

	Percent cardiac output	Flow (mL/min)

The Ups (Causes) and Downs (Treatments) of Hypertension

HYPERTENSION, OR HIGH BLOOD PRESSURE, falls into two types, depending on the cause. Ten percent of hypertension cases are classified as *secondary hypertension* because they occur secondary to an identifiable primary cause. For the other 90% of cases, known as *primary hypertension,* a specific underlying cause cannot be established.

Causes of Secondary Hypertension

The pathological causes of secondary hypertension fall into four categories:

1. *Renal (kidney) hypertension* may occur as a result of either partial occlusion of the renal arteries that supply the kidneys or diseases of the kidney tissue itself.

■ Atherosclerotic lesions protruding into the lumen of a renal artery (see p. 327) or external compression of the vessel by a tumor may reduce blood flow through the kidney. The kidney responds by initiating the renin–angiotensin–aldosterone system (RAAS). This pathway promotes salt and water retention during urine formation, thus increasing blood volume to compensate for the reduced renal blood flow. Recall that angiotensin II, a part of this pathway, is also a powerful vasoconstrictor. Although these effects are compensatory mechanisms to improve blood flow through the narrowed renal artery, they also are responsible for elevating arterial blood pressure as a whole.

■ Renal hypertension also occurs if diseased kidneys are unable to eliminate salt normally in the urine. The resultant salt retention induces water retention, which expands blood volume and leads to hypertension.

2. *Cardiovascular hypertension* is usually associated with chronically elevated total peripheral resistance (TPR) caused by advanced atherosclerosis.

3. *Endocrine hypertension* arises from the following endocrine disorders:

■ A *pheochromocytoma* is a tumor of the adrenal medulla that secretes excessive epinephrine and norepinephrine. Abnormally elevated levels of these hormones bring about a high cardiac output (CO) and generalized peripheral vasoconstriction that increases TPR, both of which contribute to hypertension.

■ With *Conn's syndrome,* the adrenal cortex produces too much aldosterone. Being part of the salt- and water-conserving RAAS, excess aldosterone leads to an elevation of blood pressure.

4. *Neurogenic hypertension* occurs secondary to neural lesions.

■ The problem may be erroneous blood-pressure control caused by a defect in the cardiovascular control center or in the baroreceptors.

■ Neurogenic hypertension may also occur as a compensatory response to a reduction in cerebral blood flow—for example, because a major cerebral vessel is compressed by a tumor. Reflexes are initiated that elevate blood pressure in an attempt to provide sufficient driving pressure to adequately supply the O_2-dependent brain tissue with blood.

Potential Causes of Primary Hypertension

Consider the following range of potential causes for primary hypertension currently being investigated:

■ *Defects in salt management by the kidneys.* Many identified gene variations associated with hypertension in humans are linked in some way to the blood-pressure raising RAAS. For example, a variation in the gene that encodes for angiotensinogen, the precursor for angiotensin II, was the first gene–hypertension link discovered in humans. Individuals with hypertension-producing defects in this pathway appear to be salt sensitive—that is, they do not eliminate salt in the urine as they should, leading to gradual accumulation of salt and water in the body, resulting in progressive elevation of arterial pressure.

■ *Excessive salt intake.* Because salt osmotically retains water, thus expanding blood volume and contributing to the long-term control of blood pressure, excessive ingestion of salt can contribute to hypertension, especially in salt-sensitive individuals.

■ *Diets low in fruits, vegetables, and dairy products (that is, low in K^+ and Ca^{2+}).* Dietary factors other than salt have been shown to markedly affect blood pressure. The DASH (Dietary Approaches to Stop Hypertension) studies found that a low-fat diet rich in fruits, vegetables, and dairy products lowers blood pressure in people with mild hypertension as much as any single drug treatment. The high K^+ intake associated with eating abundant fruits and vegetables may lower blood pressure by relaxing arteries. Furthermore, inadequate Ca^{2+} intake from dairy products has been identified as the most prevalent dietary pattern among individuals with untreated hypertension, although the role of Ca^{2+} in regulating blood pressure is unclear.

■ *Plasma membrane abnormalities such as defective Na^+–K^+ pumps.* Such defects, by altering the electrochemical gradient across plasma membranes, could change the excitability and contractility of the heart and the smooth muscle in blood vessel walls in such a way as to lead to high blood pressure. In addition, the Na^+–K^+ pump is crucial to salt management by the kidneys. A genetic defect in the Na^+–K^+ pump of hypertensive-prone laboratory rats was the first gene–hypertension link to be discovered.

■ *Abnormalities in NO, endothelin, or other locally acting vasoactive paracrines.* For example, a shortage of NO has been discovered in the blood vessel walls of some hypertensive patients, leading to an impaired ability to accomplish blood-pressure-lowering vasodilation. Furthermore, an underlying abnormality in the gene that codes for endothelin, a locally acting vasoconstrictor, has been strongly implicated as a possible cause of hypertension.

- *Excess vasopressin.* Evidence suggests that hypertension may result from a malfunction of the vasopressin-secreting cells of the hypothalamus. Vasopressin is a potent vasoconstrictor and also promotes water retention.

Lifestyle Changes for Treatment of Hypertension

The following lifestyle modifications are recommended for reducing blood pressure in all patients with hypertension and prehypertension:

- *Lose weight if overweight.* Because most obese people are hypertensive, losing weight helps bring blood pressure down in these individuals. Even losing 10 pounds helps improve blood pressure, but the more excess weight lost, the better the improvement. Weight loss is the most important behavioral step in reducing hypertension.

- *Restrict salt intake.* Because cutting down on salt intake can reduce blood pressure, and because a high salt intake, independent of its effect on blood pressure, is linked with an increased lifetime risk of heart attack, strokes, and kidney disease, experts now recommend no more than 1.5 g of sodium (Na^+) (equivalent to 3.8 g of salt) per day for those who already have high blood pressure or are at high risk (African American or older than 40 years old) and an average of 2.3 g of Na^+ (5.8 g of salt) per day for everyone else. Yet Americans currently consume 3.4 to 4 g of Na^+ (or 8.5 to 10 g of salt) per day. One teaspoon of salt has 2.3 g of Na^+. Most salt consumption is not from our saltshakers but hidden in processed foods (such as lunch meats, canned soups, frozen dinners, and potato chips); fast foods; and many restaurant meals.

- *Follow the DASH eating plan.*

- *Exercise regularly.* Moderate aerobic exercise performed for 30 minutes per day on at least four days per week can help reduce blood pressure. If more convenient, the total exercise time on a given day may even be split up into smaller sessions and still provide the same benefits.

- *Limit alcohol consumption.* Limiting alcohol intake to one drink per day for women and men older than 65, or two per day for men younger than 65, is recommended for optimal blood pressure control.

- *Avoid tobacco products.* Smokers are advised to quit smoking and everyone is urged to avoid secondhand smoke. Nicotine in smoke raises blood pressure by activating the sympathetic nervous system and promoting epinephrine release.

- *Reduce stress.* Preventing, reducing, and/or successfully coping with stressful situations (such as through relaxation techniques) can move blood pressure toward normal by cutting down on stress-induced sympathetic discharge.

Antihypertensive Drugs for Treatment of Hypertension

Blood pressure depends on CO and TPR. When needed, a variety of drugs that manipulate salt and water management (to reduce blood volume and venous return, thus reducing CO) or that modify autonomic activity on the heart (to reduce heart rate and cardiac contractility, thus reducing CO) and on the blood vessels (to reduce TPR) can be used to treat hypertension, as follows:

- *Diuretic drugs that increase urinary output* (for example, hydrochlorothiazide) lower blood pressure by increasing urinary output, thereby reducing blood volume. Salt and water that normally would have been retained in the plasma are excreted in the urine.

- *Drugs that block Ca^{2+} channels* (for example, verapamil) reduce the entry of contraction-inducing Ca^{2+} into vascular smooth muscle cells from the ECF in response to excitatory input. Even though cardiac muscle also depends on Ca^{2+} entry to trigger contraction, vascular smooth muscle is more sensitive than cardiac muscle to Ca^{2+} channel blockers. Because the level of contractile activity in vascular smooth muscle cells depends on their cytosolic Ca^{2+} concentration, drugs that block Ca^{2+} channels reduce the contractile activity of these cells, thereby decreasing TPR.

- *Drugs called ACE inhibitors that interfere with production of angiotensin II* (for example, benazepril) block action of RAAS, resulting in more salt and water being lost in the urine and less fluid being retained in the plasma. The resultant reduction in blood volume lowers blood pressure. Also, angiotensin II, a vasoconstrictor, is not formed, thereby decreasing TPR and further reducing blood pressure.

- *Drugs that block angiotensin receptors* (for example, losartan) prevent angiotensin II from causing arteriolar vasoconstriction, thereby decreasing TPR, and also reduce the action of RAAS, thereby decreasing blood volume.

- *Drugs that block β_1-adrenergic receptors* (for example, metoprolol) act by decreasing CO. Because activation of β_1-adrenergic receptors, which are found primarily in the heart (see p. 240), increases the rate and strength of cardiac contraction, drugs that block these receptors decrease heart rate and stroke volume.

- *Drugs that block α_1-adrenergic receptors* (for example, phentolamine) reduce blood pressure by decreasing TPR. Because activation of α_1-adrenergic receptors in vascular smooth muscle brings about vasoconstriction, blockage of α_1-adrenergic receptors reduces arteriolar vasoconstrictor activity, thereby lowering TPR.

- *Drugs that directly relax arteriolar smooth muscle* (for example, hydralazine) promote arteriolar vasodilation, thus reducing TPR.

- *Drugs that block release of norepinephrine from sympathetic endings* (for example, guanethidine) prevent sympathetically induced generalized arteriolar vasoconstriction, thereby lowering TPR.

- *Drugs that act on the brain to reduce sympathetic output* (for example, clonidine) prevent sympathetically induced arteriolar vasoconstriction, thereby precluding the resultant increase in TPR.

rupture of coronary vessels, especially those damaged by atherosclerosis (see p. 314). (Recall that heart attacks can also occur as a result of blocked coronary vessels through thromboembolism; see p. 330.) Hypertension underlies an estimated 47% of all coronary artery disease and 54% of all strokes worldwide. Another serious complication of hypertension is (4) *kidney failure* caused by progressive impairment of blood flow through damaged renal blood vessels. Furthermore, retinal damage from changes in the blood vessels supplying the eyes may result in (5) *progressive loss of vision*.

Until complications occur, hypertension is symptomless because the tissues are adequately supplied with blood. Therefore, unless blood pressure measurements are made routinely, the condition can go undetected until a precipitous complicating event occurs. When you become aware of these potential complications of hypertension and consider that one third of all adults in America are estimated to have chronic elevated blood pressure, you can appreciate the magnitude of this national health problem.

Treatment of Hypertension Once hypertension (or prehypertension) is detected, therapeutic intervention can reduce the course and severity of the problem. By making lifestyle modifications that eliminate or minimize contributing factors, people with hypertension may be able to avoid, delay, or reduce the need for antihypertensive drugs. The most common nondrug therapies to reduce blood pressure are weight reduction, salt restriction, and exercise. Antihypertensive drugs may be employed as needed. No matter what the original cause, agents that reduce blood volume or TPR (or both) decrease blood pressure toward normal. Sometimes a combination of several drugs that act by different mechanisms may be required to achieve normal blood pressure. (To learn more about treatment of hypertension, see the boxed feature on pp. 372–373, ▌Concepts, Challenges, and Controversies.)

Prehypertension In its recent guidelines, the National Institutes of Health identified **prehypertension** as a new category for blood pressures in the range between normal (120/80) and hypertension (140/90). Blood pressures in the prehypertension range can usually be reduced by appropriate dietary and exercise measures, whereas those in the hypertension range typically must be treated with blood pressure medication in addition to changing health habits. The goal in managing blood pressures in the prehypertension range is to take action before the pressure climbs into the hypertension range, where serious complications may develop.

We now examine the other extreme, hypotension, looking first at transient orthostatic hypotension, then at (the more serious) circulatory shock.

Orthostatic hypotension results from transient inadequate sympathetic activity.

Hypotension, or low blood pressure, occurs either when there is a disproportion between vascular capacity and blood volume (in essence, too little blood to fill the vessels) or when the heart is too weak to drive the blood.

The most common situation in which hypotension occurs transiently is orthostatic hypotension. **Orthostatic (postural) hypotension** results from insufficient compensatory responses to the gravitational shifts in blood when a person moves from a horizontal to a vertical position. When a person moves from lying down to standing up, pooling of blood in the leg veins from gravity reduces venous return, decreasing stroke volume and thus lowering CO and blood pressure. This fall in blood pressure is normally detected by the baroreceptors, which initiate immediate compensatory responses to restore blood pressure to its proper level. In some people this reflex adaptation to standing is impaired, as in those taking certain antihypertension drugs that interfere with the reflex or in long-bedridden patients in whom the reflex is temporarily reduced because of disuse. When someone with impaired reflex adaptation first stands up, sympathetic control of the leg veins is inadequate. Consequently, blood pools in the lower extremities without sufficient compensatory responses coming into play to counter the gravity-induced fall in blood pressure. The resultant orthostatic hypotension and decrease in blood flow to the brain cause dizziness or actual fainting.

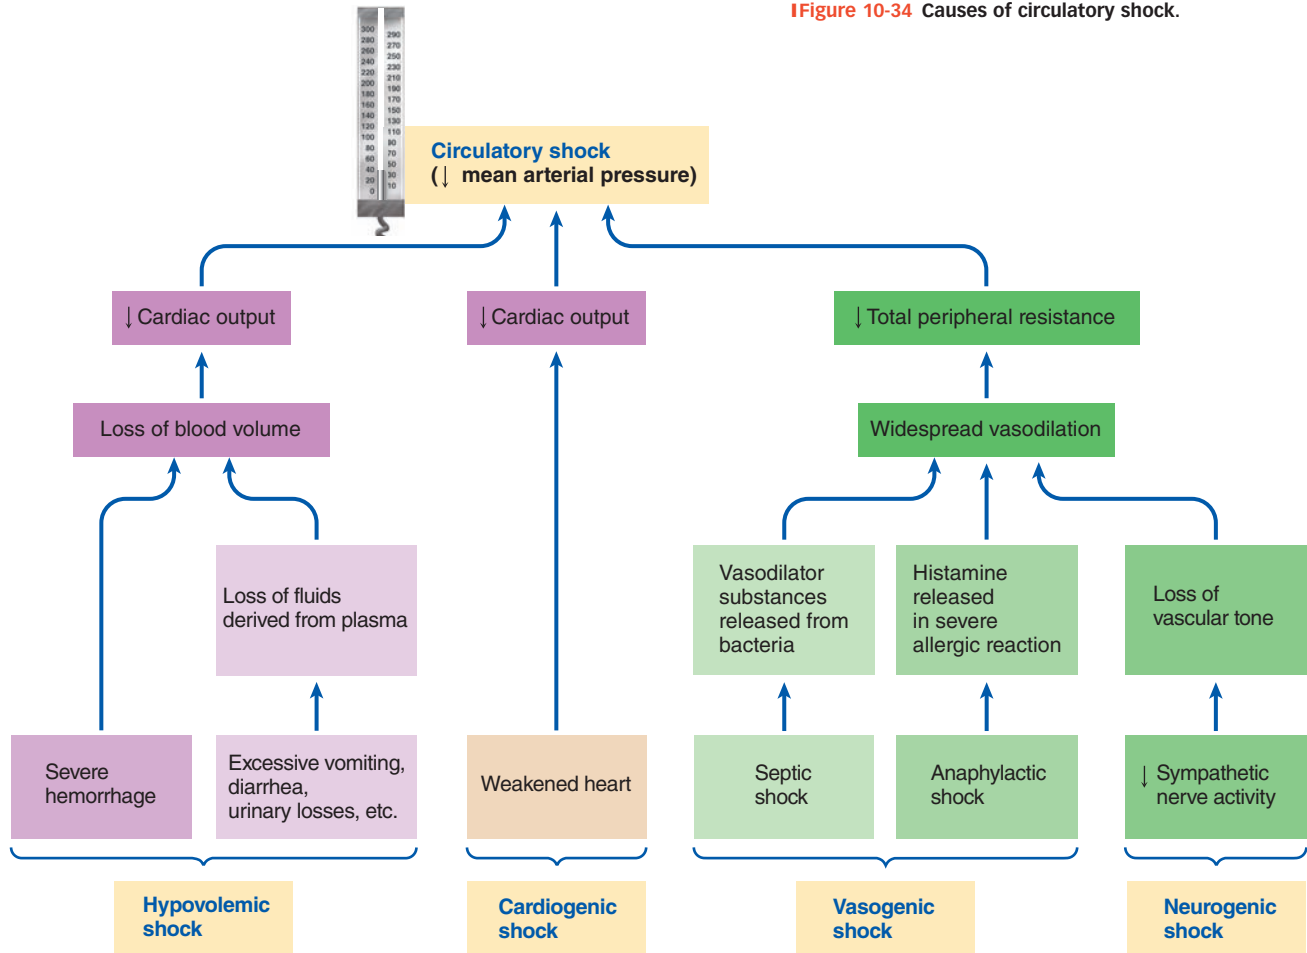
Circulatory shock can become irreversible.

When blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained, the condition known as **circulatory shock** occurs. Circulatory shock may result from (1) extensive loss of blood volume as through hemorrhage *(hypovolemic shock);* (2) failure of a weakened heart to pump blood adequately *(cardiogenic shock);* (3) widespread arteriolar vasodilation *(vasogenic shock)* triggered by vasodilator substances (such as extensive histamine release in severe allergic reactions); or (4) neurally defective vasoconstrictor tone *(neurogenic shock)* (▌Figure 10-34).

We now examine the consequences of and compensations for shock, using hemorrhage as an example (▌Figure 10-35). This figure may look intimidating, but we will work through it step by step. It is an important example that pulls together many of the principles discussed in this and the preceding chapter. As before, the numbers in the text and the figure correspond.

Consequences and Compensations of Shock Following severe loss of blood, the resultant reduction in circulating blood volume leads to a decrease in venous return ❶ and stroke volume and a subsequent fall in CO and mean arterial blood pressure. (Note the *blue* boxes, which indicate consequences of hemorrhage.)

Compensatory measures immediately attempt to maintain adequate blood flow to the brain by increasing blood pressure toward normal, followed by longer-range measures aimed at restoring plasma volume and replacing lost red blood cells, as follows: (Note the *pink* boxes, which indicate compensations for hemorrhage.)

▪ In the short term, the baroreceptor reflex response to the fall in blood pressure brings about decreased parasympathetic activity to the heart and increased sympathetic activity to the heart and the innervated vessels (arterioles and veins) ❷. The resultant increase in heart rate ❸ offsets the reduced stroke


volume **4** brought about by the loss of blood volume. With severe fluid loss, the pulse is weak because of reduced stroke volume but rapid because of increased heart rate.

■ Increased sympathetic activity to the veins produces generalized venous vasoconstriction **5**, increasing venous return and thereby stroke volume by means of the Frank–Starling mechanism **6**.

■ Simultaneously, sympathetic stimulation of the heart increases the heart's contractility **7** so that it beats more forcefully and ejects a greater volume of blood, likewise increasing the stroke volume.

■ The increase in heart rate and in stroke volume collectively increase CO **8**.

■ Sympathetically induced generalized arteriolar vasoconstriction **9** leads to an increase in TPR **10**.

■ Together, the increase in CO and TPR lead to a compensatory increase in arterial pressure **11**.

■ The original fall in arterial pressure is accompanied by a fall in capillary blood pressure **12**, which results in immediate fluid shifts from the interstitial fluid into the capillaries to expand the plasma volume **13**. This response is sometimes termed *autotransfusion* because it restores the plasma volume as a transfusion does.

■ This ECF shift is enhanced by plasma protein synthesis by the liver during the next few days following hemorrhage **14**. The plasma proteins exert a colloid osmotic pressure that helps retain extra fluid in the plasma.

■ Urinary output is reduced, thereby conserving water that normally would have been lost from the body **15**. This additional fluid retention helps expand the reduced plasma volume **16**. Expansion of plasma volume further augments the increase in CO brought about by the baroreceptor reflex **17**. Reduction in urinary output results from decreased renal blood flow caused by compensatory renal arteriolar vasoconstriction **18**. The initial reduction in plasma/blood volume resulting from hemorrhage also triggers increased secretion of the hormone vasopressin and activation of the salt- and water-conserving renin–angiotensin–aldosterone hormonal pathway, which further reduces urinary output **19**.

■ Increased thirst is also stimulated by the initial fall in plasma/blood volume that occurs with hemorrhage **20**. The resultant increased fluid intake helps restore plasma volume.

■ Over a longer course (a week or more), lost red blood cells are replaced through increased red blood cell production triggered by a reduction in O_2 delivery to the kidneys **21** (see p. 385 for further details).

KEY

Consequences   Compensations

Figure 10-35 Consequences and compensations of hemorrhage. The reduction in blood volume resulting from hemorrhage leads to a fall in mean arterial pressure. (Note the *blue boxes,* representing consequences of hemorrhage.) A series of compensations ensue (*light pink boxes*) that ultimately restore plasma volume, arterial pressure, and the number of red blood cells toward normal (*dark pink boxes*). See the text for an explanation of the numbers and a detailed discussion of the compensations.

FIGURE FOCUS: *Describe all pathways that lead to a compensatory increase in cardiac output in response to hemorrhage.*

Irreversible Shock These compensatory mechanisms are often not enough to counteract substantial blood loss. Even if they can maintain an adequate blood pressure level, the short-term measures cannot continue indefinitely. Ultimately, fluid volume must be replaced from the outside through drinking, transfusion, or a combination of both. Blood supply to the kidneys, digestive tract, skin, and other organs can be compromised to maintain blood flow to the brain only so long before organ damage begins to occur. A point may be reached at which blood pressure continues to drop rapidly because of tissue damage, despite vigorous therapy. This condition is often termed *irreversible shock,* in contrast to *reversible shock,* which can be corrected by compensatory mechanisms and effective therapy.

Although the exact mechanism underlying irreversibility is not currently known, many logical possibilities could contribute to the unrelenting, progressive circulatory deterioration that characterizes irreversible shock. Metabolic acidosis arises when lactate (lactic acid) production increases as blood-deprived tissues resort to anaerobic metabolism. Acidosis deranges the enzymatic systems responsible for energy production, limiting the capability of the heart and other tissues to produce ATP. Prolonged depression of kidney function results in electrolyte imbalances that may lead to cardiac arrhythmias. The blood-deprived pancreas releases a chemical that is toxic to the heart (*myocardial toxic factor*), further weakening the heart. Vasodilator substances build up within ischemic organs, inducing local vasodilation that overrides the generalized reflex vasoconstriction. As CO progressively declines because of the heart's diminishing effectiveness as a pump and TPR continues to fall, hypotension becomes increasingly severe. This causes further cardiovascular failure, which leads to a further decline in blood pressure. Thus, when shock progresses to the point that the cardiovascular system itself starts to fail, a vicious positive-feedback cycle ensues that ultimately results in death.

Check Your Understanding 10.6

1. Prepare a flow diagram showing the baroreceptor reflex response to a fall in MAP.

2. Define *secondary hypertension, primary hypertension, orthostatic hypertension,* and *circulatory shock.*

3. Explain why the baroreceptors do not reduce blood pressure to normal during hypertension.

Homeostasis: Chapter in Perspective

Homeostatically, the blood vessels are passageways to transport blood to and from the cells for O_2 and nutrient delivery, waste removal, distribution of fluid and electrolytes, elimination of excess heat, and hormonal signaling, among other things. Cells soon die if deprived of their blood supply; brain cells succumb within 4 minutes. Blood is constantly recycled and reconditioned as it travels through the various organs via the vascular highways. Hence, the body needs only a small volume of blood to maintain the appropriate chemical composition of the entire internal fluid environment on which the cells depend for their survival. For example, O_2 is continually picked up by blood in the lungs and constantly delivered to all body cells.

The smallest blood vessels, the capillaries, are the actual site of exchange between blood and surrounding cells. Capillaries bring homeostatically maintained blood within 0.1 mm of every cell in the body; this proximity is critical because beyond a few millimeters materials cannot diffuse rapidly enough to support life-sustaining activities. O_2 that would take months to years to diffuse from the lungs to all the cells of the body is continuously delivered to the "doorstep" of every cell, where diffusion can efficiently accomplish short local exchanges between capillaries and surrounding cells. Likewise, hormones must be rapidly transported through the circulatory system from their sites of production in endocrine glands to their sites of action in other parts of the body. These chemical messengers could not diffuse nearly rapidly enough to their target organs to effectively exert their controlling effects, many of which are aimed toward maintaining homeostasis.

The rest of the circulatory system is designed to transport blood to and from the capillaries. The arteries and arterioles distribute blood pumped by the heart to the capillaries for life-sustaining exchanges to take place, and the venules and veins collect blood from the capillaries and return it to the heart, where the process is repeated.

Review Exercises   Answers begin on p. A-34

Reviewing Terms and Facts

1. In general, the parallel arrangement of the vascular system enables each organ to receive its separate arterial blood supply. *(True or false?)*

2. More blood flows through the capillaries during cardiac systole than during diastole. *(True or false?)*

3. The capillaries contain only 5% of the total blood volume at any point in time. *(True or false?)*

4. The same volume of blood passes through the capillaries in a minute as passes through the aorta, even though blood flow is much slower in the capillaries. *(True or false?)*

The Blood Vessels and Blood Pressure   **377**

5. Because capillary walls have no carrier transport systems, all capillaries are equally permeable. *(True or false?)*

6. Because of gravitational effects, venous pressure in the lower extremities is greater when a person is standing up than when the person is lying down. *(True or false?)*

7. _____ is a measure of the hindrance to blood flow through a vessel caused by friction between the moving fluid and the stationary vascular walls.

8. Local mechanisms that keep tissue blood flow fairly constant despite wide deviations in mean arterial driving pressure is termed _____.

9. _____ refers to the volume of blood per unit of time flowing through a given segment of the circulatory system, whereas _____ is the speed, or distance per unit of time, with which the blood flows forward through a given segment of the circulatory system.

10. _____ is the term applied to vessel narrowing that increases resistance to flow, whereas _____ is the term applied to vessel widening that decreases resistance to flow.

11. Which of the following functions is or are attributable to arterioles? *(Indicate all correct answers.)*
   a. produce a significant decline in mean pressure, which helps establish the driving pressure gradient between the heart and the organs
   b. serve as the site of exchange of materials between blood and surrounding tissue cells
   c. act as the main determinant of total peripheral resistance
   d. determine the pattern of distribution of cardiac output
   e. help regulate mean arterial blood pressure
   f. convert the pulsatile nature of arterial blood pressure into a smooth, nonfluctuating pressure in the vessels farther downstream
   g. act as a pressure reservoir

12. Using the answer code on the right, indicate whether the following factors increase or decrease venous return:

1. sympathetically induced venous vasoconstriction	(a) increases venous return
2. skeletal muscle activity	(b) decreases venous return
3. gravitational effects on the venous system	(c) has no effect on venous return
4. respiratory activity	
5. increased atrial pressure associated with a leaky AV valve	
6. ventricular pressure change associated with diastolic recoil	

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Compare blood flow through reconditioning organs and through organs that do not recondition the blood.

2. Discuss the relationships among flow rate, pressure gradient, and vascular resistance. What is the major determinant of resistance to flow?

3. Describe the structure and major functions of each segment of the vascular tree.

4. How do the arteries serve as a pressure reservoir?

5. Describe the indirect technique of measuring arterial blood pressure by means of a sphygmomanometer.

6. Compare the consequences of vasoconstriction and vasodilation each on distribution of cardiac output and on control of mean arterial blood pressure.

7. Discuss the local and extrinsic controls that regulate arteriolar resistance.

8. What is the primary means by which individual solutes are exchanged across capillary walls? What forces produce bulk flow across capillary walls? Of what importance is bulk flow?

9. How is lymph formed? What are the functions of the lymphatic system?

10. Define *edema*, and discuss its possible causes.

11. How do veins serve as a blood reservoir?

12. Compare the effect of vasoconstriction on the rate of blood flow in arterioles and in veins.

13. Discuss the factors that determine mean arterial pressure.

14. Review the effects on the cardiovascular system of parasympathetic and sympathetic stimulation.

15. Differentiate between secondary hypertension and primary hypertension. What are the potential consequences of hypertension?

16. Define circulatory shock. What are its consequences and compensations? What is irreversible shock?

Solving Quantitative Exercises

1. Recall that the flow rate of blood equals the pressure gradient divided by the total peripheral resistance (TPR) of the vascular system. The conventional unit of resistance in physiological systems is expressed in PRU (peripheral resistance unit), which is defined as (1 L/min)/(1 mm Hg). At rest, Tom's TPR is about 20 PRU. Last week while playing racquetball, his cardiac output increased to 30 L/min and his mean arterial pressure (MAP) increased to 120 mm Hg. What was his TPR during the game?

2. Systolic pressure rises as a person ages. By age 85, an average male (untreated for hypertension) has a systolic pressure of 180 mm Hg and a diastolic pressure of 90 mm Hg.
   a. What is the MAP of this average 85-year-old male?
   b. Considering capillary dynamics, predict the result at the capillary level of this age-related change in MAP if no homeostatic mechanisms were operating. (Recall that MAP is about 93 mm Hg at age 20.)

3. Compare the flow rates in the systemic and the pulmonary circulations of an individual with the following measurements:

   a. systemic mean arterial pressure = 95 mm Hg

   b. systemic resistance = 19 PRU

   c. pulmonary mean arterial pressure = 20 mm Hg

   d. pulmonary resistance = 4 PRU

4. Which of the following changes would increase the resistance in an arteriole? Explain.

   a. a longer length

   b. a smaller caliber

   c. increased sympathetic stimulation

   d. increased blood viscosity

   e. all of the above

Applying Clinical Reasoning

Li-Ying C. has just been diagnosed as having hypertension secondary to a *pheochromocytoma*, a tumor of the adrenal medulla that secretes excessive epinephrine. Explain how this condition leads to secondary hypertension by describing the effect that excessive epinephrine would have on various factors that determine arterial blood pressure.

Thinking at a Higher Level

1. During coronary bypass surgery, a piece of vein is often removed from the patient's leg and surgically attached within the coronary circulatory system so that blood detours, through the vein, around an occluded coronary artery segment. Why must the patient wear, for an extended period after surgery, an elastic support stocking on the limb from which the vein was removed?

2. A classmate who has been standing still for several hours working on a laboratory experiment suddenly faints. What is the probable explanation? What would you do if the person next to him tried to get him up?

3. A drug applied to a piece of excised arteriole causes the vessel to relax, but an isolated piece of arteriolar muscle stripped from the other layers of the vessel fails to respond to the same drug. What is the probable explanation?

4. Children who suffer from protein malnutrition because their diets are high in starch and low in protein (as in poor countries with limited food supply) often develop *kwashiorkor*. This condition is characterized among other things by a pronounced, protruding belly caused by a fluid-filled abdominal cavity (called *ascites*), although the rest of the body is "skin and bones." What causes the markedly distended abdomen?

5. Why is the risk for developing *deep venous thrombosis (DVT)* (abnormal formation of blood clots, especially in the deep veins of the legs) increased during a long airplane flight? What can you do while onboard to decrease your risk?
11 The Blood

A scanning electron micrograph of cellular elements in the blood. Erythrocytes (*red*) carry oxygen. Leukocytes (*blue*) are vital to immune defense. Platelets (*pink*) help stop bleeding. The light brown threads are fibrin, which is not normally present in the blood but, once produced during vessel injury, forms the meshwork of a clot.

CHAPTER AT A GLANCE

Homeostasis Highlights

Blood is the vehicle for long-distance, mass transport of materials between the cells and external environment or between the cells themselves. Such transport is essential for maintaining homeostasis. Blood consists of a complex liquid **plasma** in which the cellular elements—*erythrocytes, leukocytes,* and *platelets*—are suspended. **Erythrocytes** (**red blood cells**, or **RBCs**) are essentially plasma membrane–enclosed bags of hemoglobin that transport O_2 in the blood. **Leukocytes** (**white blood cells**, or **WBCs**), the immune system's mobile defense units, are transported in the blood to sites of injury or of invasion by disease-causing microorganisms. **Platelets (thrombocytes)** are important in hemostasis, the stopping of bleeding from an injured vessel.

11.1 Plasma

The hematocrit is the packed cell volume of blood; the rest of the volume is plasma.

Blood represents about 8% of total body weight and has an average volume of 5 liters in women and 5.5 liters in men. It consists of three types of specialized cellular elements, *erythrocytes (red blood cells), leukocytes (white blood cells),* and *platelets (thrombocytes),* suspended in the complex liquid *plasma* (❙Figure 11-1, chapter opener photo, and ❙Table 11-1). Erythrocytes and leukocytes are both whole cells, whereas platelets are cell fragments.

The constant movement of blood as it flows through the blood vessels keeps the cellular elements rather evenly dispersed within the plasma. However, if you put a sample of whole blood in a test tube and treat it to prevent clotting, the heavier cells slowly settle to the bottom and the lighter plasma rises to the top. This process can be hastened by centrifuging, which quickly packs the cells in the bottom of the tube (❙Figure 11-1). Because more than 99% of the cells are erythrocytes, the **hematocrit**, or **packed cell volume**, essentially represents the percentage of erythrocytes in the total blood volume. The hematocrit averages about 42% for women and slightly higher, 45%, for men. Plasma accounts for the remaining volume. Accordingly, the average volume of plasma in the blood is about 58% for women and 55% for men. White blood cells and platelets, which are colorless and less dense than red cells, are packed in a thin, cream-colored layer, the *buffy coat,* on top of the packed red cell column. They are less than 1% of the total blood volume.

Let us first consider the largest portion of the blood, the plasma, before turning to the cellular elements.

Plasma (55% of whole blood)

Buffy coat: platelets and leukocytes (<1% of whole blood)

Platelets

Leukocytes (white blood cells)

Erythrocytes (45% of whole blood)

Erythrocytes (red blood cells)

Packed cell volume, or hematocrit
❙**Figure 11-1 Hematocrit and types of blood cells.** The values given are for men. The average hematocrit for women is 42%, with plasma occupying 58% of the blood volume. Note the biconcave shape of the erythrocytes.

FIGURE FOCUS: *If the hematocrit is 37, what percentage of the whole blood is occupied by plasma? Would O₂-carrying capacity be at, above, or below normal?*

Plasma water is a transport medium for many inorganic and organic substances.

Plasma, being a liquid, consists of 90% water. Plasma water is a medium for materials being carried in the blood. Also, plasma absorbs and distributes much of the heat generated metabolically within tissues, with only minimal changes in the temperature of the blood itself. As blood travels close to the surface of the skin, heat energy not needed to maintain body temperature is eliminated to the environment.

A large number of inorganic and organic substances are dissolved in the plasma. Inorganic constituents account for about 1% of plasma weight. The most abundant electrolytes (ions) in the plasma are Na^+ and Cl^-, the components of common salt. Smaller amounts of HCO_3^-, K^+, Ca^{2+}, and other ions are present. The most notable functions of these ions are their roles in membrane excitability, osmotic distribution of fluid between the extracellular fluid (ECF) and the cells, and buffering of pH changes; these functions are discussed elsewhere.

The most plentiful organic constituents by weight are the plasma proteins, which make up 6% to 8% of plasma weight. We examine them more thoroughly in the next section. The remaining small percentage of plasma consists of other organic substances, including nutrients (such as glucose, amino acids, lipids, and vitamins), waste products (creatinine, bilirubin, and nitrogenous substances such as urea), dissolved gases (O_2 and CO_2), and hormones. Most of these substances are merely being transported in the plasma. For example, endocrine glands secrete hormones into the plasma, which transports these chemical messengers to their sites of action.

Many of the functions of plasma are carried out by plasma proteins.

Plasma proteins are the one group of plasma constituents that are not along just for the ride. These important components normally stay in the plasma, where they perform many valuable functions. Here are the most important of these functions, which are elaborated on elsewhere in the text:

1. Unlike other plasma constituents that are dissolved in the plasma water, plasma proteins are dispersed as a colloid (see p. A-7). Furthermore, because they are the largest of the plasma constituents, plasma proteins usually do not exit through the narrow pores in the capillary walls to enter the interstitial fluid. By their presence as a colloidal dispersion in the plasma and their absence in the interstitial fluid, plasma proteins establish

Blood Constituents and Their Functions

Constituent	Functions
Plasma	
Water	Acts as a transport medium; carries heat
Electrolytes	Are important in membrane excitability; distribute fluid by osmosis between ECF and ICF; buffer pH changes
Nutrients, wastes, gases, hormones	Are transported in blood; blood CO_2 plays a role in acid–base balance
Plasma proteins	In general, exert an osmotic effect important in the distribution of the ECF between the vascular and interstitial compartments; buffer pH changes
Albumins	Transport many substances; contribute most to colloid osmotic pressure
Globulins	
Alpha and beta	Transport many water-insoluble substances; include clotting factors and inactive precursor molecules
Gamma	Are antibodies
Fibrinogen	Is an inactive precursor for a clot's fibrin meshwork
Cellular elements	
Erythrocytes	Transport O_2 and CO_2 (mainly O_2)
Leukocytes	
Neutrophils	Engulf bacteria and debris
Eosinophils	Attack parasitic worms; play a role in allergic reactions
Basophils	Release histamine, which is important in allergic reactions, and heparin, which helps clear fat from the blood
Monocytes	Are in transit to become tissue macrophages
Lymphocytes	
B lymphocytes	Produce antibodies
T lymphocytes	Produce cell-mediated immune responses
Platelets	Contribute to hemostasis

an osmotic gradient between the blood and the interstitial fluid. This colloid osmotic pressure is the primary force preventing excessive loss of plasma from the capillaries into the interstitial fluid and thus helps maintain plasma volume (see p. 357).

2. Plasma proteins are partially responsible for plasma's capacity to buffer changes in pH (see p. 552).

3. The three groups of plasma proteins—*albumins, globulins,* and *fibrinogen*—are classified according to their various physical and chemical properties. In addition to the general functions just listed, each type of plasma protein performs specific tasks as follows:

    a. **Albumins**, the most abundant plasma proteins, contribute most extensively to the colloid osmotic pressure by virtue of their numbers. They also nonspecifically bind substances that are poorly soluble in plasma (such

as bilirubin, bile salts, and penicillin) for transport in the plasma.

    b. There are three subclasses of **globulins: alpha (α), beta (β),** and **gamma (γ).**

      (1) Like albumins, some α and β globulins bind poorly water-soluble substances for transport in the plasma, but these globulins are highly specific as to which passenger they bind and carry. Examples of substances carried by specific globulins include thyroid hormone (see p. 668), cholesterol (see p. 328), and iron (see p. 608).

      (2) Many of the factors involved in the blood-clotting process are α or β globulins.

      (3) Some plasma proteins are inactive, circulating precursor molecules, which are activated as needed by specific regulatory inputs. For example, the α glob-

ulin *angiotensinogen* is activated to *angiotensin,* which plays an important role in regulating salt balance in the body (see p. 508).

(4) The γ globulins are *antibodies,* or *immunoglobulins,* which are crucial to the body's defense mechanism (see p. 417).

c. **Fibrinogen** is a key factor in blood clotting.

Plasma proteins are synthesized by the liver, with the exception of antibodies, which are produced by lymphocytes, one of the types of white blood cells.

Check Your Understanding 11.1

1. Draw a centrifuged tube of whole blood, showing the packed cell volume and indicating the percentage in a normal man occupied by plasma, by erythrocytes, and by the buffy coat.

2. Define *hematocrit.*

3. List the functions of plasma proteins.

11.2 Erythrocytes

Each milliliter of blood on average contains about 5 billion **erythrocytes (red blood cells,** or **RBCs**), commonly reported clinically in a **red blood cell count** as 5 million cells per cubic millimeter (mm^3).

Erythrocytes are well designed for their main function of O_2 transport in the blood.

The shape and content of erythrocytes are ideally suited to carry out their primary function, transporting O_2 in the blood.
Erythrocyte Structure Three anatomic features of erythrocytes contribute to the efficiency with which they transport O_2. First, erythrocytes are flat, disc-shaped cells indented in the middle on both sides, like a doughnut with a flattened center instead of a hole (that is, they are biconcave discs 8 μm in diameter, 2 μm thick at the outer edges, and 1 μm thick in the center) (see ❙ Figure 11-1 and chapter opener photo). The biconcave shape provides a larger surface area for diffusion of O_2 from the plasma across the membrane into the erythrocyte than a spherical cell of the same volume would. Also, the thinness of the cell enables O_2 to diffuse rapidly between the exterior and innermost regions of the cell.

A second structural feature that facilitates RBCs' transport function is their flexible membrane. Red blood cells, whose diameter is normally 8 μm, can deform amazingly as they squeeze single file through capillaries as narrow as 3 μm in diameter. Because they are extremely pliant, RBCs can travel through the narrow, tortuous capillaries to deliver their O_2 cargo at the tissue level without rupturing in the process.

The third and most important anatomic feature that enables RBCs to transport O_2 is the hemoglobin they contain.

Role of Hemoglobin Hemoglobin is found only in red blood cells. A **hemoglobin** molecule has two parts: (1) the **globin** portion, a protein made up of four highly folded polypeptide chains (two α subunits and two β subunits), and (2) four iron-containing, nonprotein groups known as **heme groups**, each of which is bound to one of the polypeptides (❙ Figure 11-2). Each of the four iron atoms can combine reversibly with one molecule of O_2; thus, each hemoglobin molecule can pick up four O_2 passengers in the lungs. Because O_2 is poorly soluble in the plasma, 98.5% of the O_2 carried in the blood is bound to hemoglobin (see p. 472).

Hemoglobin is a pigment (that is, it is naturally colored). Because of its iron content, it appears reddish when combined with O_2 and bluish when deoxygenated. Thus, fully oxygenated

(a) Hemoglobin molecule
(b) Iron-containing heme group

❙**Figure 11-2 Hemoglobin molecule.** A hemoglobin molecule consists of four highly folded polypeptide chains (the globin portion) and four iron-containing heme groups.

The Blood | **383**

arterial blood is red, and venous blood, which has lost some of its O_2 load at the tissue level, has a bluish cast.

In addition to carrying O_2, hemoglobin can combine with the following:

1. *Carbon dioxide (CO_2)*. Hemoglobin helps transport this gas from the tissue cells back to the lungs (see p. 476).

2. *The acidic hydrogen-ion portion (H^+) of ionized carbonic acid,* which is generated at the tissue level from CO_2. Hemoglobin buffers this acid so that it minimally alters the pH of the blood (see p. 477).

3. *Carbon monoxide (CO)*. This gas is not normally in the blood, but if inhaled, it preferentially occupies the O_2-binding sites on hemoglobin, causing CO poisoning (see p. 475).

4. *Nitric oxide (NO)*. In the lungs, the vasodilator nitric oxide binds to hemoglobin. This NO is released at the tissues, where it relaxes and dilates the local arterioles (see p. 346). Vasodilation helps ensure that the O_2-rich blood can make its vital rounds and helps stabilize blood pressure.

Therefore, hemoglobin plays the key role in O_2 transport while contributing significantly to CO_2 transport and the pH-buffering capacity of blood. Furthermore, by toting along its own vasodilator, hemoglobin helps deliver the O_2 it is carrying.

Lack of Nucleus and Organelles To maximize its hemoglobin content, a single erythrocyte is stuffed with more than 250 million hemoglobin molecules, excluding almost everything else. (That means each RBC can carry more than 1 billion O_2 molecules.) Red blood cells contain no nucleus or organelles. During the cell's development, these structures are extruded to make room for more hemoglobin (❙Figure 11-3). Thus, an RBC is mainly a plasma membrane–enclosed sac full of hemoglobin.

Key Erythrocyte Enzymes Only a few crucial, nonrenewable enzymes remain within a mature erythrocyte: *glycolytic enzymes* and *carbonic anhydrase*. The **glycolytic enzymes** are necessary for generating the energy needed to fuel the active-transport mechanisms involved in maintaining proper ionic concentrations within the cell. Ironically, even though erythrocytes are the vehicles for transporting O_2 to all other tissues of the body, for energy production erythrocytes themselves cannot use the O_2 they are carrying. Lacking the mitochondria that house the enzymes for oxidative phosphorylation, erythrocytes must rely entirely on glycolysis for ATP formation (see p. 35).

The other important enzyme within RBCs, **carbonic anhydrase**, is critical in CO_2 transport. This enzyme catalyzes a key reaction that leads to the conversion of metabolically produced CO_2 into **bicarbonate ion (HCO_3^-)**, which is the primary form in which CO_2 is transported in the blood. Thus, erythrocytes contribute to CO_2 transport in two ways—by means of its carriage on hemoglobin and its carbonic anhydrase–induced conversion to HCO_3^-.

The bone marrow continuously replaces worn-out erythrocytes.

Each of us has a total of 25 trillion to 30 trillion RBCs streaming through our blood vessels at any given time (100,000 times more in number than the entire U.S. population). Yet these vital gas-transport vehicles are short-lived and must be replaced at the average rate of 2 million to 3 million cells per second.

Erythrocytes' Short Life Span The price erythrocytes pay for their generous content of hemoglobin to the exclusion of the usual specialized intracellular machinery is a short life span. Without DNA, RNA, and ribosomes, red blood cells cannot synthesize proteins for cell repair, growth, and division or for renewing enzyme supplies. Equipped only with initial supplies synthesized before they extrude their nucleus and organelles, RBCs survive an average of only 120 days, in contrast to nerve and muscle cells, which last a person's entire life. During its short life span of 4 months, each erythrocyte travels about 700 miles as it circulates through the vasculature.

As a red blood cell ages, its plasma membrane, which cannot be repaired, becomes fragile and prone to rupture as the cell squeezes through tight spots in the vascular system. Most old RBCs meet their final demise in the **spleen** because this organ's narrow, winding capillary network is a tight fit for these fragile cells. The spleen lies in the upper left part of the abdomen. In addition to removing most of the old erythrocytes from circulation, the spleen has a limited ability to store healthy erythrocytes in its pulpy interior, is a reservoir for platelets, and contains an abundance of lymphocytes, a type of white blood cell.

Erythropoiesis Because erythrocytes cannot divide to replenish their own numbers, the old ruptured cells must be replaced by new cells produced in an erythrocyte factory—the **bone marrow**—which is the soft, highly cellular tissue that fills the internal cavities of bones. The bone marrow normally generates new red blood cells, a process known as **erythropoiesis**, at a rate to keep pace with the demolition of old cells.

❙Figure 11-3 **Major steps in erythrocyte production (erythropoiesis).** Erythrocytes are derived in the red bone marrow from pluripotent stem cells that give rise to all the types of blood cells. Myeloid stem cells are partially differentiated cells that give rise to erythrocytes and several other types of blood cells. Nucleated erythroblasts are committed to becoming mature erythrocytes. These cells extrude their nucleus and organelles, making more room for hemoglobin. Reticulocytes are immature red blood cells that contain organelle (mostly ribosome) remnants. Mature erythrocytes are released into the abundant capillaries in the bone marrow.

Nucleus and organelles — Remnants of organelles — No nucleus or organelles

Pluripotent stem cell — Myeloid stem cell — Erythroblast — Reticulocyte — Erythrocyte

During intrauterine development, RBCs are produced first by the yolk sac and then by the developing liver and spleen, until the bone marrow is formed and takes over erythrocyte production exclusively. In children, most bones are filled with **red bone marrow** capable of blood cell production. As a person matures, fatty **yellow bone marrow** incapable of erythropoiesis gradually replaces red marrow, which remains only in a few places, such as the sternum (breastbone), ribs, pelvis, and upper ends of the limb bones. These are sites where bone marrow is extracted for examination or for bone marrow transplants.

Red marrow not only produces RBCs but also is the ultimate source for leukocytes and platelets. Undifferentiated **pluripotent stem cells**, the source of all blood cells, reside in the red marrow, where they continuously divide and differentiate to give rise to each of the types of blood cells (❙Figure 11-3; also see ❙Figure 11-9, p. 394). The different types of immature blood cells, along with the stem cells, are intermingled in the red marrow at various stages of development. Once mature, the blood cells are released into the rich supply of capillaries that permeate the red marrow. Bone marrow capillaries are of the less common discontinuous type that has large gaps between the endothelial cells (see p. 353). Mature red blood cells can pass through these very large pores to enter the blood, but, once circulating, these cells cannot exit the blood through the much narrower pores in ordinary capillaries. Regulatory factors act on the *hemopoietic* ("blood-producing") red marrow to govern the type and number of cells generated and discharged into the blood. The mechanism for regulating RBC production is the best understood. We consider it next.

Erythropoiesis is controlled by erythropoietin from the kidneys.

Because O_2 transport in the blood is the erythrocytes' main function, you might logically suspect that the primary stimulus for increased erythrocyte production would be reduced O_2 delivery to the tissues. You would be correct, but low O_2 levels do not stimulate erythropoiesis by acting directly on the red marrow. Instead, reduced O_2 delivery to the kidneys stimulates them to secrete the hormone **erythropoietin (EPO)** into the blood, and this hormone in turn stimulates erythropoiesis by the red marrow (❙Figure 11-4). The magnitude of EPO release reflects the degree of O_2 insufficiency detected by the kidneys.

Undifferentiated stem cells continuously generate derivatives that are already committed to becoming RBCs (see ❙Figure 11-3). Erythropoietin acts on these erythrocyte forerunners, stimulating their proliferation and maturation into mature erythrocytes that are released into the blood. This increased erythropoietic activity elevates the number of circulating RBCs, thereby increasing O_2-carrying capacity of the blood and restoring O_2 delivery to the tissues to normal. Once normal O_2 delivery to the kidneys is achieved, EPO secretion is turned down until needed again. In this way, erythrocyte production is normally balanced against destruction or loss of these cells so that O_2-carrying capacity in the blood stays fairly constant. In severe loss of RBCs, as in hemorrhage or abnormal destruction of young circulating erythrocytes, the rate of erythropoiesis can be increased to more than six times the normal level. (For a discussion of erythropoietin abuse by some athletes, see the boxed feature on p. 386, ❙A Closer Look at Exercise Physiology.)

The preparation of an erythrocyte for its departure from the marrow involves several steps, such as synthesis of hemoglobin and extrusion of the nucleus and organelles. Cells closest to maturity need a few days to be "finished off" and released into the blood in response to erythropoietin, and less developed and newly proliferated cells may take up to several weeks to reach maturity. Therefore, the time required for complete replacement of lost RBCs depends on how many are needed
❙Figure 11-4 **Control of erythropoiesis**.

Erythrocytes

❶ Kidneys detect reduced O_2-carrying capacity of blood.

❷ When less O_2 is delivered to the kidneys, they secrete erythropoietin into blood.

❸ Erythropoietin stimulates erythropoiesis by red bone marrow.

❹ Additional circulating erythrocytes increase O_2-carrying capacity of blood.

❺ Increased O_2-carrying capacity relieves initial stimulus that triggered erythropoietin secretion.

Blood Doping: Is More of a Good Thing Better?

EXERCISING MUSCLES NEED A CONTINUAL supply of O_2 for generating energy to sustain endurance activities (see p. 271). **Blood doping** is a technique used to temporarily increase the O_2-carrying capacity of blood in an attempt to gain a competitive advantage. Blood doping involves removing blood from an athlete, then promptly reinfusing the plasma but freezing the RBCs for reinfusion one to seven days before a competitive event. One to four units of blood (one unit equals 450 mL) are usually withdrawn at three- to eight-week intervals before the competition. In the periods between blood withdrawals, increased erythropoietin activity restores the RBC count to normal. Reinfusion of the stored RBCs artificially increases the RBC count and hemoglobin level above normal before competing. Theoretically, blood doping would benefit endurance athletes by improving the blood's O_2-carrying capacity. If too many red cells were infused, however, performance could suffer because the increased blood viscosity would decrease blood flow.

Research indicates that athletes who have used blood doping may realize a 5% to 13% increase in aerobic capacity; a reduction in heart rate during exercise compared to the rate during the same exercise in the absence of blood doping; improved performance; and reduced lactate levels in the blood. (Lactate is produced when muscles resort to less efficient anaerobic glycolysis for energy production; see page 272.)

Blood doping, although effective, is illegal in collegiate athletics and Olympic competition for ethical and medical reasons. Of concern, as with use of any banned performance-enhancing product, is loss of fair competition. Furthermore, the practice can lead to high blood pressure and has been implicated in the deaths of some athletes. The development of synthetic erythropoietin (EPO) exacerbates the problem of blood doping. Injection of this product stimulates RBC production and thus temporarily increases the O_2-carrying capacity of the blood. Injected EPO may improve an endurance athlete's performance by 7% to 10%. Although formally banned, a black market for EPO developed among sports cheats when this product became available as a drug to treat anemia. Erythropoietin is now widely used among competitors in cycling, cross-country skiing, and long-distance running and swimming. This practice is ill advised, however, not only because of legal and ethical implications, but also because of the dangers of increasing blood viscosity. Synthetic EPO is believed responsible for the deaths of a number of cyclists. Unfortunately, too many athletes are willing to take the risks.

It is hoped that recent development of tests to detect blood doping and illegal erythropoietin use, coupled with recent public scorn and medal stripping related to their abuse, will curb their use in the future.

to return the number to normal. (When you donate blood, your circulating erythrocyte supply is replenished in less than a week.)

Reticulocytes When demands for RBC production are high (for example, following hemorrhage), the bone marrow may release large numbers of immature erythrocytes, known as **reticulocytes**, into the blood to quickly meet the need (see ▮ Figure 11-3). These immature cells are recognized by staining techniques that make visible the residual organelle remnants (mostly ribosomes) that have not yet been extruded. Their presence above the normal level of 0.5% to 1.5% of the total number of circulating erythrocytes indicates a high rate of erythropoietic activity. At very rapid rates, more than 30% of circulating RBCs may be at the immature reticulocyte stage.

Clinical Note **Laboratory-produced Erythropoietin** Synthetic erythropoietin (*Epogen, Procrit*) has currently become biotechnology's single-biggest moneymaker, with sales exceeding $1 billion annually. This hormone is often used to boost RBC production in patients with suppressed erythropoietic activity, such as those with kidney failure or those undergoing chemotherapy for cancer. (Chemotherapy drugs interfere with the rapid cell division characteristic of both cancer cells and developing RBCs.)

Anemia can be caused by a variety of disorders.

Clinical Note Despite control measures, O_2-carrying capacity cannot always be maintained to meet tissue needs. A below-normal O_2-carrying capacity of the blood is known as **anemia**, which is characterized by a low hematocrit (▮ Figure 11-5a and b). Anemia can be brought about by a decreased rate of erythropoiesis, excessive losses of erythrocytes, or a deficiency in the hemoglobin content of erythrocytes. The various causes of anemia can be grouped into six categories:

1. **Nutritional anemia** is caused by a dietary deficiency of a factor needed for erythropoiesis, which depends on an adequate supply of essential raw ingredients, some of which are not synthesized in the body, so must be provided by food intake. For example, *iron deficiency anemia* occurs when not enough iron is available for synthesizing hemoglobin.

2. **Pernicious anemia** is caused by an inability to absorb enough ingested vitamin B_{12} from the digestive tract. Vitamin B_{12} is essential for normal RBC production and maturation. It is abundant in various foods and thus is rarely deficient in the diet. The problem is a deficiency of *intrinsic factor*, a special substance secreted by the lining of the stomach (see p. 585). Vitamin B_{12} can be absorbed from the intestinal tract only when this nutrient is bound to intrinsic factor.
KEY

= Plasma	= Erythrocytes

3. **Aplastic anemia** is caused by the bone marrow failing to produce enough RBCs, even though all ingredients needed for erythropoiesis are available. Reduced erythropoietic capability can be caused by destruction of red marrow by toxic chemicals (such as benzene), heavy exposure to ionizing radiation, invasion of the marrow by cancer cells, or chemotherapy for cancer. The destructive process may selectively reduce the marrow's output of erythrocytes, or it may also reduce the productive capability for leukocytes and platelets. The anemia's severity depends on the extent to which erythropoietic tissue is destroyed; severe losses are fatal.

4. **Renal anemia** may result from kidney disease. Because erythropoietin from the kidneys is the primary stimulus for promoting erythropoiesis, inadequate erythropoietin secretion by diseased kidneys leads to insufficient RBC production.

5. **Hemorrhagic anemia** is caused by losing a lot of blood. The loss can be either acute, such as a bleeding wound, or chronic, such as excessive menstrual flow.

6. **Hemolytic anemia** is caused by rupture of too many circulating erythrocytes. **Hemolysis**, the rupture of RBCs, occurs either because an external factor brings about rupture of otherwise normal cells, as in invasion of RBCs by malaria parasites, or because the cells are defective, as in sickle cell disease.

Malaria is caused by protozoan parasites introduced into a victim's blood by the bite of a carrier mosquito (hence the use of mosquito nets over beds at night in tropical regions to reduce the incidence of malaria). These parasites selectively invade RBCs, where they multiply to the point that the mass of malarial organisms ruptures the cells, releasing hundreds of new active parasites that quickly invade other RBCs. As this cycle continues and more erythrocytes are destroyed, the anemic condition progressively worsens and leads to death if not treated.

Sickle cell disease is the best-known example among various hereditary abnormalities of erythrocytes that make these cells fragile. It affects about 1 in 650 African Americans. Sickle cell disease is caused by a genetic mutation that changes a single amino acid in the 146-long amino acid chain that makes up the β chain of hemoglobin (valine replaces glutamate at position 6 in this amino acid chain). This defective type of hemoglobin joins together to form rigid chains that make the RBC stiff and unnaturally shaped, like a crescent or sickle (Figure 11-6). Unlike normal erythrocytes, these deformed RBCs tend to clump together. The resultant "logjam" blocks blood flow through small vessels, leading to pain and tissue damage at the affected site. Furthermore, the defective erythrocytes are fragile and prone to rupture, even as young cells, as they travel through the narrow splenic capillaries. Despite an accelerated rate of erythropoiesis triggered by the constant excessive loss of RBCs, production may not be able to keep pace with the rate of destruction, and anemia may result. Interestingly, patients who have sickle cell anemia are more likely to survive malaria because defective cells invaded by malaria parasites are more apt to be destroyed as they travel through the spleen, eliminating the infected cells before the parasites have a chance to multiply and spread. This advantage may explain the increased incidence of sickle cell disease among descendants of people who lived in tropical regions where malaria is prevalent. In an evolutionary

Sickle-shaped red blood cell   Normal-shaped red blood cell
Figure 11-6 Sickle-shaped red blood cell. A scanning electron micrograph comparing a sickle cell and normal red blood cell.

"trade-off," the benefit conferred by surviving malaria may have offset the disadvantages of sickle cell disease.

Polycythemia is an excess of circulating erythrocytes.

Polycythemia, in contrast to anemia, is characterized by too many circulating RBCs and an elevated hematocrit (see Figure 11-5c). There are two general types of polycythemia, depending on what causes the excess RBC production: primary polycythemia and secondary polycythemia.

Primary polycythemia is caused by a tumorlike condition of the bone marrow in which erythropoiesis proceeds at an excessive, uncontrolled rate instead of being subject to the normal erythropoietin regulatory mechanism. The RBC count may reach 11 million cells/mm^3 (normal is 5 million cells/mm^3), and the hematocrit may be as high as 70% to 80% (normal is 42% to 45%). No benefit is derived from the extra O_2-carrying capacity of the blood, because O_2 delivery is more than adequate with normal RBC numbers. Inappropriate polycythemia has harmful effects, however. The excessive number of red cells increases blood's viscosity up to five to seven times normal (that is, makes the blood "thicker"), causing the blood to flow sluggishly, which may actually reduce O_2 delivery to the tissues (see p. 337). The increased viscosity also increases total peripheral resistance, which may elevate blood pressure, thus increasing the workload of the heart, unless blood-pressure control mechanisms can compensate (see Figure 10-13, p. 351).

Secondary polycythemia, in contrast, is an appropriate erythropoietin-induced adaptive mechanism to improve the blood's O_2-carrying capacity in response to a prolonged reduction in O_2 delivery to the tissues. It occurs normally in people living at high altitudes, where less O_2 is available in the air, or in people for whom O_2 delivery to the tissues is impaired by chronic lung disease or cardiac failure. The red cell count in secondary polycythemia is usually lower than that in primary polycythemia, typically averaging 6 million to 8 million cells/mm^3. The price paid for improved O_2 delivery is an increased viscosity of the blood.

An elevated hematocrit can occur when the body loses fluid but not erythrocytes, as in dehydration accompanying heavy sweating or profuse diarrhea (see Figure 11-5d). This is not a true polycythemia, however, because the number of circulating RBCs is not increased. A normal number of erythrocytes are simply concentrated in a smaller plasma volume. This condition is sometimes termed **relative polycythemia**.

We next shift attention to blood types, which depend on erythrocyte antigens.

Blood types depend on surface antigens on erythrocytes.

An **antigen** is a large, complex molecule that triggers a specific immune response against itself when it gains entry to the body. For example, antigens are found on the surface of foreign cells such as bacterial invaders. Certain types of white blood cells recognize antigens and produce specific antibodies against them. An **antibody** binds with the specific antigen against which it is produced and leads to the antigen's destruction by various means. Thus, the

body rejects cells bearing antigens that do not match its own. You will learn more about these immune responses in the next chapter on body defenses. For now, we focus on the special antigen–antibody reaction that forms the basis of different blood types.

ABO Blood Types The surface membranes of human erythrocytes contain inherited antigens that vary depending on blood type. Within the major blood group system, the **ABO system**, the erythrocytes of people with type A blood contain A antigens, those with type B blood contain B antigens, those with type AB blood have both A and B antigens, and those with type O blood do not have any A or B red blood cell surface antigens.

Antibodies against erythrocyte antigens not present on the body's erythrocytes begin to appear in human plasma after a baby is about 6 months of age. Accordingly, the plasma of type A blood contains anti-B antibodies, type B blood contains anti-A antibodies, no antibodies related to the ABO system are present in type AB blood, and both anti-A and anti-B antibodies are present in type O blood (Table 11-2). Typically, one would expect antibody production against A or B antigen to be induced only if blood containing the alien antigen were injected into the body. However, high levels of these antibodies are found in the plasma of people who have never been exposed to a different type of blood. Consequently, these were considered naturally occurring antibodies—that is, produced without any known exposure to the antigen. Scientists now know that people are routinely exposed at an early age to small amounts of A- and B-like antigens associated with common, harmless intestinal bacteria. Antibodies produced against these foreign antigens coincidentally also interact with a nearly identical antigen for a foreign blood group, even on first exposure to it.

Transfusion Reaction If a person is given blood of an incompatible type, two antigen–antibody interactions take place. By far, the more serious consequences arise from the effect of the antibodies in the recipient's plasma on the incoming donor erythrocytes. The effect of the donor's antibodies on the recipient's erythrocyte-bound antigens is less important unless a large amount of blood is transfused, because the donor's antibodies are so diluted by the recipient's plasma that little RBC damage takes place in the recipient.

Antibody interaction with an erythrocyte-bound antigen may result in agglutination (clumping) or hemolysis (rupture) of the attacked RBCs. Agglutination and hemolysis of donor RBCs

TABLE 11-2 ABO Blood Types

Blood Type	Antigens on Erythrocytes	Antibodies in Plasma
A	A	Anti-B
B	B	Anti-A
AB	A and B	No antibodies
O	No antigens	Both anti-A and anti-B

by antibodies in the recipient's plasma can lead to a sometimes fatal **transfusion reaction** (❙Figure 11-7). Agglutinated clumps of incoming donor cells can plug small blood vessels. In addition, one of the most lethal consequences of mismatched transfusions is acute kidney failure caused by the release of large amounts of hemoglobin from ruptured donor erythrocytes. If the free hemoglobin in the plasma rises above a critical level, it precipitates in the kidneys and blocks the urine-forming structures, leading to acute kidney shutdown.

Universal Blood Donors and Recipients Because type O individuals have no A or B antigens, their erythrocytes are not attacked by either anti-A or anti-B antibodies, so they are considered **universal donors**. Their blood can be transfused into people of any blood type. However, type O individuals can receive only type O blood, because the anti-A and anti-B antibodies in their plasma attack either A or B antigens in incoming blood. In contrast, type AB individuals are called **universal recipients**. Lacking both anti-A and anti-B antibodies, they can accept donor blood of any type, although they can donate blood only to other AB people. Because their erythrocytes have both A and B antigens, their cells would be attacked if transfused into individuals with antibodies against either of these antigens.

The terms *universal donor* and *universal recipient* are misleading, however. In addition to the ABO system, many other erythrocyte antigens and plasma antibodies can cause transfusion reactions, the most important of which is the Rh factor.
❙Figure 11-7 **Transfusion reaction**. A transfusion reaction resulting from type B blood being transfused into a recipient with type A blood.

FIGURE FOCUS: *(1) Describe what would happen to donor red blood cells if type B blood were transfused into a recipient with type O blood? (2) How about if type O donor blood were transfused into a recipient with type B blood?*

According to the American Association of Blood Banking, following are the percentages of blood types in the ABO and Rh blood systems in the United States population: A+, 34%; A−, 6%; B+, 9%; B−, 2%; AB+, 3%; AB−, 1%; O+, 38%; and O−, 7%.

Clinical Note Anti-Rh antibodies are produced only by Rh-negative individuals when (and if) such people are first exposed to the foreign Rh antigen present in Rh-positive blood. A subsequent transfusion of Rh-positive blood could produce a transfusion reaction in such a sensitized Rh-negative person. Rh-positive individuals, in contrast, never produce antibodies against the Rh factor that they themselves possess. Therefore, Rh-negative people should be given only Rh-negative blood, whereas Rh-positive people can safely receive either Rh- negative or Rh-positive blood. The Rh factor is of particular medical importance when an Rh-negative mother develops antibodies against the erythrocytes of an Rh-positive fetus she is carrying, a condition known as **erythroblastosis fetalis**, or **hemolytic disease of the newborn**. Because the maternal antibodies destroy many fetal RBCs, the fetal bone marrow cannot keep pace with the rate of destruction and releases immature precursors of erythrocytes, such as reticulocytes and eventually erythroblasts (see ❙Figure 11-3), hence the name of the condition. (See Applying Clinical Reasoning on p. 402 for further discussion of this disorder.)

Except in extreme emergencies, it is safest to individually cross-match blood before a transfusion is undertaken even though the ABO and Rh typing is already known, because there are approximately 23 other minor human erythrocyte antigen systems, with hundreds of subtypes. Compati-

Rh Blood-Group System People who have the **Rh factor** (an erythrocyte antigen first observed in rhesus monkeys, hence the designation Rh) are said to have *Rh-positive* blood, whereas those lacking the Rh factor are considered *Rh-negative*. In contrast to the ABO system, no naturally occurring antibodies develop against the Rh factor.

bility is determined by mixing the RBCs from the potential donor with plasma from the recipient. If no clumping occurs, the blood is considered an adequate match for transfusion. (See the boxed feature on pp. 390–391, ❙Concepts, Challenges, and Controversies, for an update on alternatives to whole-blood transfusions under investigation.)

In Search of a Blood Substitute

ONE OF THE HOTTEST MEDICAL contests of the past three decades has been the race to develop a universal substitute for human blood that is safe, inexpensive, and disease free and that has a long shelf life.

Need for a Blood Transfusion

A blood transfusion is administered, on average, every two seconds in the United States alone. As a general rule, a transfusion is warranted when the hemoglobin concentration falls below 7 g/100 mL whole blood (normal range is 13 to 18 g/100 mL for men and 12 to 16 g/100 mL for women) or when another specific component of the blood, such as platelets or clotting factors, is in short supply. The need can arise with victims of traumatic emergencies, such as automobile accidents or gunshot wounds; with surgery patients; with cancer patients on chemotherapy that suppresses blood cell production; with people who have blood disorders like leukemia or sickle cell anemia; with patients undergoing bone marrow transplants; and with other illnesses. Some patients need ongoing transfusions to survive, such as those with hemophilia. Sometimes whole blood is separated so that different components may be used for multiple recipients. Collection specialists have even developed a technique known as *apheresis* in which blood is collected into an instrument that separates the blood into separate portions, then the rest of the blood is returned to the donor after a selected portion, such as platelets, is recovered.

Need for a Blood Substitute

With only about 5% of the population now donating blood, regional shortages of particular blood types necessitate the shipping and sharing of blood among areas. (Almost everyone older than 17 years of age who weighs more than 110 pounds, is healthy, and has not donated blood in the last 8 weeks is eligible to be a blood donor, but most people do not take this opportunity to give the gift of life.) Medical personnel anticipate widespread shortages of blood in the near future because the number of blood donors continues to decline at the same time that the number of senior citizens, the group of people who most often need transfusions, continues to grow. The benefits for society of a safe blood substitute that could be administered without regard for the recipient's blood type are great, as will be the profits for the manufacturer of the first successful product. Experts estimate that the world market for a good blood substitute, more accurately called an *oxygen therapeutic,* may be $10 billion per year.

Researchers began working on blood substitutes in the 1960s, but the search for an alternative to whole-blood transfusions was given new impetus in the 1980s by the rising incidence of AIDS and the concomitant concern over the safety of the nation's blood supply. Infectious diseases such as AIDS, viral hepatitis, and West Nile virus infection can be transmitted from infected blood donors to recipients of blood transfusions. Although careful screening of our blood supply minimizes the possibility that infectious diseases will be transmitted through transfusion, the public remains wary and would welcome a safe substitute.

Eliminating the risk of disease transmission is only one advantage of an alternative to whole-blood transfusion. Whole blood must be kept refrigerated, and even then its shelf life is only 42 days. Also, transfusion of whole blood requires blood typing and cross matching, which cannot be done at the scene of an accident or on a battlefield.

Major Approaches

The goal is not to find a replacement for whole blood but to duplicate its O_2-carrying capacity. The biggest need for blood transfusions is to replace acute blood loss in surgical patients, accident victims, and wounded soldiers. These individuals require short-term replenishment of blood's O_2-carrying capacity until their bodies synthesize replacement erythrocytes. The many other important elements in blood are not as immediately critical in sustaining life as the hemoglobin within the RBCs is. Unfortunately, RBCs are the whole-blood component that requires refrigeration, has a short shelf life, and bears the markers for the various blood types.

Therefore, the search for a blood substitute has focused on two major possibilities: (1) hemoglobin products that exist outside an RBC and can be stored at room temperature for up to a year, and (2) chemically synthesized products that serve as artificial hemoglobin by dissolving large amounts of O_2 when O_2 levels are high (as in the lungs) and releasing it when O_2 levels are low (as in the tissues). A variety of potential blood substitutes are in various stages of development and clinical trials. No products have yet reached the market, although they are getting close. Let us examine each of the major approaches.

Hemoglobin Products

By far the greatest number of research efforts have focused on manipulating the structure of hemoglobin so that it can be effectively and safely administered as a substitute for whole-blood transfusions. If appropriately stabilized and suspended in saline solution, hemoglobin could be injected to bolster O_2-carrying capacity of the recipients' blood no matter what their blood type. The following strategies are among those being pursued to develop a hemoglobin product:

■ One problem is that hemoglobin behaves differently when it is outside RBCs. "Naked" hemoglobin splits into halves that do not re-

lease O_2 for tissue use as readily as normal hemoglobin does. Also, these hemoglobin fragments can cause kidney damage. A cross-binding reagent has been developed that keeps hemoglobin molecules intact when they are outside RBCs, thus surmounting one major obstacle to administering free hemoglobin.

■ Some products under investigation are derived from outdated, donated human blood. Instead of the blood being discarded, its hemoglobin is extracted, purified, sterilized, and chemically stabilized. However, this strategy relies on the continued practice of collecting human blood donations.

■ Several products use cows' blood as a starting point. Bovine hemoglobin is readily available from slaughterhouses, is cheap, and can be treated for administration to humans. A big concern with these products is the potential of introducing into humans unknown disease-causing microbes that might be lurking in the bovine products.

■ A potential candidate as a blood substitute is genetically engineered hemoglobin, which bypasses the ongoing need for human donors or the risk of spreading disease from cows to humans. Genetic engineers can insert the gene for human hemoglobin into bacteria, which act as a "factory" to produce the desired hemoglobin product. A drawback for genetically engineered hemoglobin is the high cost involved in operating the facilities.

■ One promising strategy encapsulates hemoglobin within liposomes—membrane-wrapped containers—similar to real hemoglobin-stuffed, plasma membrane–enclosed RBCs. These so-called neo red cells (*neo* means "new") await further investigation.

Synthetic O_2 Carriers

Other researchers are pursuing chemical-based strategies that rely on *perfluorocarbons (PFCs),* which are artificial O_2-carrying compounds composed of carbon and fluorine. PFCs are completely inert, chemically synthesized molecules that can dissolve large quantities of O_2 in direct proportion to the amount of O_2 breathed in. Because they are derived from a nonbiological source, PFCs cannot transmit disease. This, coupled with their low cost, makes them attractive as a blood substitute. Yet use of PFCs is not without risk. Their administration can cause flulike symptoms, and because of poor excretion, they may be retained and accumulate in the body. Ironically, PFC administration poses the danger of causing O_2 toxicity by delivering too much O_2 to the tissues in uncontrolled fashion.

A more recent strategy under development is a water-soluble, synthetic plastic version of hemoglobin. The molecule has the same size and shape of hemoglobin, reversibly binds with O_2, and is made from a substance known to be safe in the body, but it has not yet undergone biological testing.

Red Blood Cells Produced from Stem Cells

The newest technique being explored is using hemopoietic stem cells to "grow" a supply of transfusable red blood cells. One rich source of hemopoietic stem cells under investigation is umbilical cord blood after birth. The umbilical cord is the connection between mother and fetus during gestation but is cut when the baby is born. Hemopoietic stem cells from cord blood that normally would have been discarded can be used to produce mass quantities of new red blood cells of the O negative type (universal donor type; see p. 389) in a machine that mimics the bone marrow environment. This process is called *blood pharming.* These laboratory-produced RBCs are functionally indistinguishable from body-produced erythrocytes. However, as of now the process is cost prohibitive for general use and is being explored for more limited battlefield application.

Tactics to Reduce Need for Donated Blood

Other tactics aimed toward reducing the need for donated blood include the following:

■ By changing surgical practices, the medical community has reduced the need for transfusions. These blood-saving methods include recycling a patient's blood during surgery (collecting lost blood, then reinfusing it); using less invasive and therefore less bloody surgical techniques; and treating the patient with blood-enhancing erythropoietin before surgery.

■ The necessity of matching blood types for transfusions is a major reason for waste at blood banks. Transfusion of mismatched blood causes a serious, even fatal reaction (see p. 389). Therefore, a blood bank may be discarding stocks of one blood type that has gone unused, while facing a serious shortage of another type. Researchers have zeroed in on a way to use enzymes to cleave A and B antigens from RBCs, thus converting all donated blood into "universal donor" type O blood. If clinical trials using this enzyme-converted blood are successful, such a product would reduce the current waste and would be highly beneficial to battlefield surgeons who often do not have time to type blood.

■ Other investigators are seeking ways to prolong the life of RBCs, either in a blood bank or in patients, thus reducing the need for fresh blood that can be transfused.

As this list of strategies attests, considerable progress has been made toward developing a safe, effective alternative to whole-blood transfusions. After three decades of intense effort, however, considerable challenges remain, and no ideal solution has been found.

1. Describe the anatomic features of erythrocytes that contribute to the efficiency with which they transport O_2.
2. List the chemicals with which hemoglobin can combine.
3. Discuss the source, control, and function of erythropoietin.

11.3 Leukocytes

Leukocytes (white blood cells, or **WBCs)** are the mobile units of the body's immune defense system. **Immunity** is the body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells. Leukocytes and their derivatives, along with a variety of plasma proteins, make up the **immune system**, an internal defense system that recognizes and either destroys or neutralizes materials that are foreign to the "normal self." Specifically, the immune system (1) defends against invading disease-producing microorganisms (such as bacteria and viruses); (2) functions as a "cleanup crew" that removes worn-out cells (such as aged red blood cells) and tissue debris (for example, tissue damaged by trauma or disease), paving the way for wound healing and tissue repair; and (3) identifies and destroys cancer cells that arise in the body.

Leukocytes primarily function as defense agents outside the blood.

To carry out their functions, WBCs largely use a "seek out and attack" strategy—that is, they go to sites of invasion or tissue damage. The main reason WBCs are in the blood is for rapid transport from their site of production or storage to wherever they are needed. Unlike erythrocytes, leukocytes are able to exit the blood by assuming amoebalike behavior to wriggle through narrow capillary pores and crawl to assaulted areas (see ❚Figure 12-2, p. 408). As a result, the immune system's effector cells are widely dispersed throughout the body and can defend in any location. For this reason, we introduce the specific circulating WBCs here to round out our discussion of blood but leave the details of their phagocytic and immunologic functions, which take place primarily in the tissues, for the next chapter.

There are five types of leukocytes.

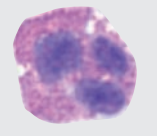
Leukocytes lack hemoglobin, so they are colorless (that is, "white") unless specifically stained for microscopic visibility. Unlike red blood cells, which are of uniform structure, identical function, and constant number, white blood cells vary in structure, function, and number. There are five types of circulating WBCs—neutrophils, eosinophils, basophils, monocytes, and lymphocytes—each with a characteristic structure and function. They are all somewhat larger than RBCs.

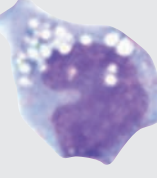
Granulocytes and Agranulocytes The five types of leukocytes fall into two main categories, depending on the appearance of their nuclei and the presence or absence of granules in their cytoplasm when viewed microscopically (❚Figure 11-8). Neutrophils, eosinophils, and basophils are categorized as **poly-** morphonuclear (meaning "many-shaped nucleus") **granulocytes** (meaning "granule-containing cells"). Their nuclei are segmented into several lobes of varying shapes, and their cytoplasm contains an abundance of membrane-enclosed granules. The granules contain preformed, stored chemicals that are released by exocytosis on appropriate stimulation for carrying out the granulocyte's functions. The three types of granulocytes are distinguished on the basis of the varying affinity of their granules for dyes: *Eosinophils* have an affinity for the red dye eosin, *basophils* preferentially take up a basic blue dye, and *neutrophils* are neutral, showing no dye preference. Monocytes and lymphocytes are known as **mononuclear** (meaning "single nucleus") **agranulocytes** (meaning "cells lacking granules"). Both have a single, large, nonsegmented nucleus and few granules. *Monocytes* are the larger of the two and have an oval or kidney-shaped nucleus. *Lymphocytes,* the smallest of the leukocytes, characteristically have a large spherical nucleus that occupies most of the cell.

Functions and Life Spans of Leukocytes The following are the functions and life spans of the granulocytes:

■ **Neutrophils** are phagocytic specialists; they engulf and destroy bacteria intracellularly (see ❚Figure 2-9c, p. 32). Neutrophil granules, which contain an arsenal of antimicrobial proteins, fuse with invading bacteria ingested by phagocytosis and kill them inside the cell. Neutrophils can also release the bacteria-killing chemicals into the ECF by exocytosis of granule contents to the cell exterior, a process called *degranulation*. As a further assault, neutrophils can act like "suicide bombers" by undergoing an unusual type of programmed cell death called *NETosis,* during which they kill nearby bacteria. During NETosis, neutrophils use vital cellular materials to prepare a web of fibers dubbed **neutrophil extracellular traps (NETs)**, which they release into the ECF on their death. These fibers consist of chromatin from the neutrophil's nucleus studded with antimicrobial proteins from its cytoplasmic granules. NETs bind with bacteria, trapping and then destroying these foreign invaders extracellularly. Neutrophils invariably are the first defenders on the scene of bacterial invasion. Furthermore, they scavenge to clean up debris.

Clinical Note As might be expected in view of these functions, an increase in circulating neutrophils (**neutrophilia**) typically accompanies acute bacterial infections. In fact, a differential WBC count (a determination of the proportion of each type of leukocyte present) can be used to make an immediate, reasonably accurate prediction of whether an infection, such as pneumonia or meningitis, is of bacterial or viral origin. Obtaining a definitive answer as to the causative agent by culturing a sample of the infected tissue's fluid takes several days. Because an elevated neutrophil count is highly indicative of bacterial infection, antibiotic therapy can be initiated long before the causative agent is actually known. (Bacteria generally succumb to antibiotics, whereas viruses do not.)

■ **Eosinophils** are specialists of another type. An increase in circulating eosinophils (**eosinophilia**) is associated with allergic conditions (such as asthma and hay fever) and with internal parasite infestations (for example, worms). Eosinophils ob-




Leukocytes					Erythrocyte	Platelets
Polymorphonuclear granulocytes			Mononuclear agranulocytes

viously cannot engulf a larger parasitic worm, but they do attach to the worm and secrete substances that kill it.

■ **Basophils** are the least numerous of the leukocytes. They are quite similar structurally and functionally to *mast cells,* which never circulate in the blood but instead are dispersed in connective tissue throughout the body. Both basophils and mast cells synthesize and store *histamine* and *heparin,* powerful chemical substances that can be released on appropriate stimulation. Histamine release is important in allergic reactions, whereas heparin speeds up removal of fat particles from the blood after a fatty meal and plays a role in certain immune responses. Heparin can also prevent clotting (coagulation) of blood samples drawn for clinical analysis and is used extensively as an anticoagulant drug, but it does not appear to play a physiologic role as an anticoagulant.

Once released into the blood from the bone marrow, a granulocyte usually stays in transit in the blood for less than a day before leaving to enter the tissues, where it survives another 3 to 4 days unless it dies sooner in the line of duty.

By comparison, the functions and life spans of the agranulocytes are as follows:

■ **Monocytes**, like neutrophils, become professional phagocytes. They emerge from the bone marrow while still immature and circulate for only a day or two before settling down in various tissues throughout the body. At their new residences, monocytes continue to mature and greatly enlarge, becoming large tissue phagocytes known as **macrophages** (*macro* means "large"; *phage* means "eater"). A macrophage's life span ranges from months to years unless it dies sooner while performing phagocytosis. A phagocytic cell can ingest only a limited amount of foreign material before it succumbs.

■ **Lymphocytes** provide immune defense against targets for which they are specifically programmed. There are two types of lymphocytes, B and T lymphocytes (B and T cells), which look alike. **B lymphocytes** produce antibodies, which circulate in the blood and are responsible for *antibody-mediated,* or hu-

moral, immunity. An antibody binds with and marks for destruction (by phagocytosis or other means) the specific kinds of antigen-containing foreign matter, such as bacteria, that induced production of the antibody. **T lymphocytes** do not produce antibodies; instead, they directly destroy their specific target cells by releasing chemicals that punch holes in the victim cell, a process called *cell-mediated immunity.* The target cells of T cells include body cells invaded by viruses and cancer cells. Lymphocytes live for about 100 to 300 days. Only a small part of the total lymphocytes are in transit in the blood at any given moment. Most continually recycle among the blood, lymph and lymphoid tissues, spending only a few hours at a time in the blood. *Lymphoid tissues* are lymphocyte-containing tissues such as the lymph nodes and tonsils.

Leukocytes are produced at varying rates depending on the body's changing needs.

All leukocytes ultimately originate from common precursor undifferentiated pluripotent stem cells in bone marrow that also give rise to erythrocytes and platelets (I Figure 11-9). The cells destined to become WBCs eventually differentiate into various committed cell lines and proliferate under the influence of appropriate stimulating factors. Granulocytes and monocytes are produced only in bone marrow, which releases these mature leukocytes into the blood. Lymphocytes are originally derived from precursor cells in bone marrow, but most new lymphocytes actually come from lymphocyte colonies already in lymphoid tissues originally populated by cells derived from bone marrow.

The total number of white blood cells normally ranges from 5 million to 10 million cells per milliliter of blood, with an average of 7 million/mL, expressed as an average **white blood cell count** of 7000/mm^3. Leukocytes are the least numerous of the blood cells (about 1 white blood cell for every 700 red blood cells), not because fewer are produced but because they are merely in transit while in the blood. Normally, about two thirds

of the circulating leukocytes are granulocytes, mostly neutrophils, whereas one third are agranulocytes, predominantly lymphocytes (see ❙Figure 11-8). However, the total number of white cells and the percentage of each type may vary considerably to meet changing defense needs. Depending on the type and extent of assault the body is combating, different types of leukocytes are selectively produced at varying rates, as in neutrophilia for example. Chemical messengers arising from invaded or damaged tissues or from activated leukocytes themselves govern the rates of production of the various WBCs. Specific messengers analogous to erythropoietin direct the differentiation and proliferation of each cell type. Some of these messengers have been identified and can be produced in the laboratory; an example is **granulocyte colony–stimulating factor**, which stimulates increased replication and release of granulocytes, especially neutrophils, from bone marrow. Marketed under the name *Neulasta,* this synthetic agent is a powerful new therapeutic tool that can be used to bolster defense and thus decrease the incidence of infection in cancer patients being treated with chemotherapy drugs. These drugs suppress all rapidly dividing cells, including hemopoietic cells in bone marrow, and the targeted cancer cells.

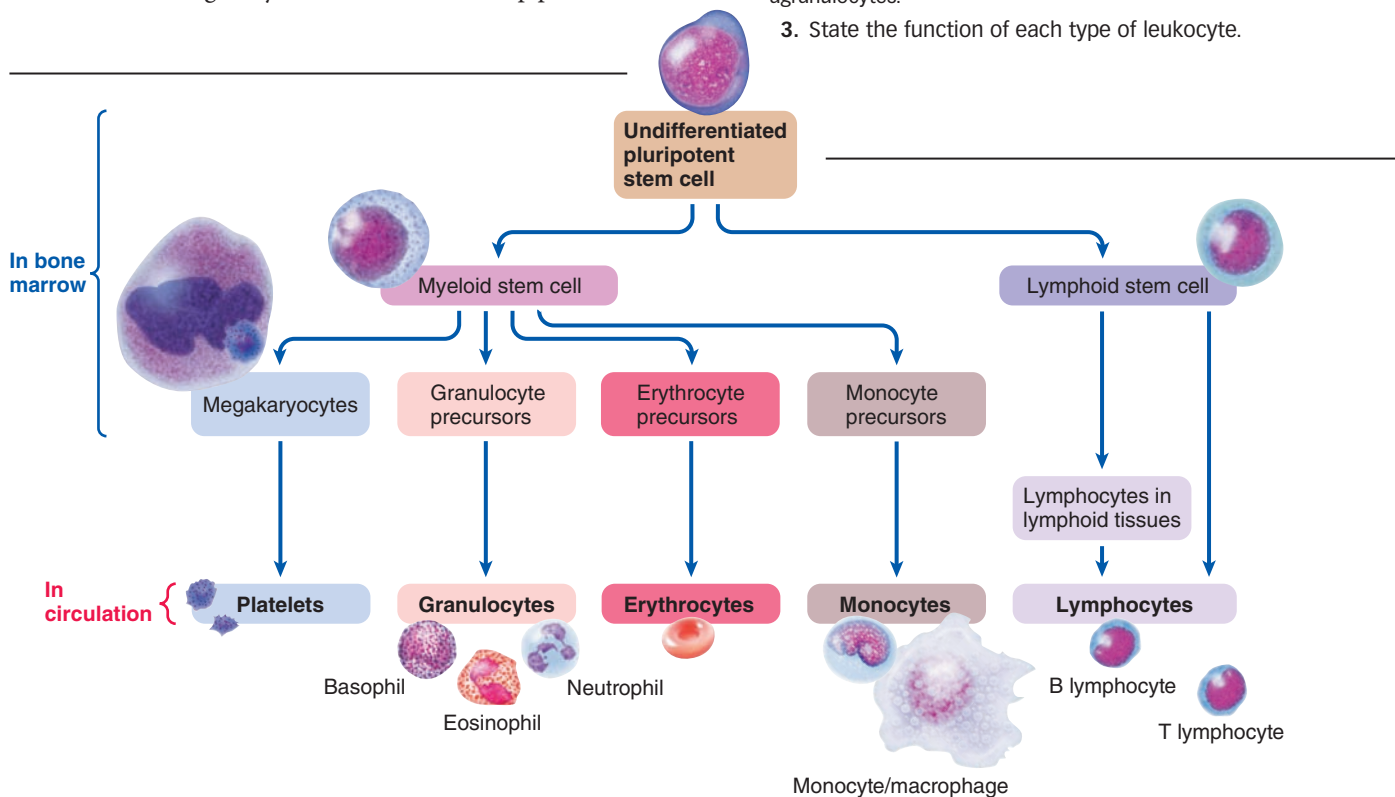
Clinical Note

Abnormalities in Leukocyte Production Even though levels of circulating WBCs may vary, changes in these levels are normally controlled and adjusted according to the body's needs. However, abnormalities in leukocyte production can occur that are not subject to control—that is, either too few or too many WBCs can be produced. Bone marrow can greatly slow down or even stop production

of white blood cells when it is exposed to certain toxic chemical agents (such as benzene and anticancer drugs) or to excessive radiation. The most serious consequence is the reduction in professional phagocytes (neutrophils and macrophages), which greatly diminishes the body's defense capabilities against invading microorganisms. The only defense still available when bone marrow fails is the immune capabilities of the lymphocytes produced by lymphoid tissues.

Surprisingly, one of the major consequences of **leukemia**, a cancerous condition involving uncontrolled proliferation of WBCs, is inadequate defense capabilities against foreign invasion. In leukemia, the WBC count may reach as high as $500,000/\text{mm}^3$, compared with the normal $7000/\text{mm}^3$, but because most of these cells are abnormal or immature, they cannot perform their normal defense functions. Another devastating consequence of leukemia is displacement of the other blood cell lines in bone marrow. This results in anemia because of reduced erythropoiesis and in internal bleeding because of a platelet deficit. Platelets play a critical role in preventing bleeding from myriad tiny breaks that normally occur in small blood vessel walls. Consequently, overwhelming infections or hemorrhage are the most common causes of death in leukemic patients. The next section examines platelets' role in minimizing the threat of bleeding.

Check Your Understanding 11.3

1. Define *immunity* and list the functions of the immune system.
2. Name the polymorphonuclear granulocytes and the mononuclear agranulocytes.
3. State the function of each type of leukocyte.


❙Figure 11-9 **Blood cell production (hemopoiesis).** All the blood cell types ultimately originate from the same undifferentiated pluripotent stem cells in the red bone marrow.

FIGURE FOCUS: *Name all of the blood cellular elements derived from myeloid stem cells.*

11.4 Platelets and Hemostasis

An average of 250 million platelets are normally present in each milliliter of blood (range of 150,000 to 350,000/mm³).

Platelets are cell fragments shed from megakaryocytes.

Platelets, or **thrombocytes**, are not whole cells but small cell fragments (about 2 to 4 μm in diameter) shed from the outer edges of extraordinarily large (up to 60 μm in diameter) bone marrow–bound cells known as **megakaryocytes** (❙ Figure 11-10). A single megakaryocyte typically produces about 1000 platelets. Megakaryocytes are derived from the same undifferentiated stem cells that give rise to the erythrocytic and leukocytic cell lines (see ❙ Figure 11-9). Platelets are essentially detached vesicles containing pieces of megakaryocyte cytoplasm wrapped in plasma membrane.

Platelets remain functional for an average of 10 days, at which time they are removed from circulation by tissue macrophages, especially those in the spleen and liver, and are replaced by newly released platelets from bone marrow. The hormone **thrombopoietin**, produced by the liver, increases the number of megakaryocytes in bone marrow and stimulates each megakaryocyte to produce more platelets as needed. The factors that control thrombopoietin secretion and regulate the platelet level are currently under investigation.

Because platelets are cell fragments, they lack nuclei. However, they have organelles and cytosolic enzyme systems for generating energy and synthesizing secretory products, which they store in numerous granules dispersed throughout the cytosol. Furthermore, platelets contain high concentrations of actin and myosin, which enable them to contract. Their secretory and contractile abilities are important in hemostasis, a topic to which we now turn.

Hemostasis prevents blood loss from damaged small vessels.

Hemostasis is the arrest of bleeding from a broken blood vessel—that is, the stopping of hemorrhage (*hemo* means "blood"; *stasis* means "standing"). For bleeding to take place from a vessel, a break must be present in the vessel wall and the pressure inside must be greater than the pressure outside the vessel to force blood out through the defect.

The small capillaries, arterioles, and venules are often ruptured by minor traumas of everyday life; such traumas are the most common source of bleeding, although we often are not even aware that any damage has taken place. The body's inherent hemostatic mechanisms normally are adequate to seal defects and stop blood loss through these small microcirculatory vessels. *Clinical Note* The rarer occurrence of bleeding from medium to large vessels usually cannot be stopped by hemostatic mechanisms alone. Bleeding from a severed artery is more profuse and therefore more dangerous than venous bleeding, because the outward driving pressure is greater in arteries (that is, arterial blood pressure is higher than venous pressure). First-
❙Figure 11-10 A megakaryocyte forming platelets.

aid measures for a severed artery include applying external pressure to the wound that is greater than the arterial pressure to temporarily halt bleeding until the torn vessel can be surgically closed. Hemorrhage from a severed vein can often be stopped simply by elevating the bleeding body part to reduce gravity's effects on pressure in the vein (see p. 362). If the accompanying drop in venous pressure is not enough to stop bleeding, mild external compression is usually adequate.

Hemostasis involves three major steps: (1) *vascular spasm,* (2) *formation of a platelet plug,* and (3) *blood coagulation (clotting).* Platelets play a pivotal role in hemostasis. They obviously play a major part in forming a platelet plug, but they also contribute significantly to the other two steps.

Vascular spasm reduces blood flow through an injured vessel.

A cut or torn blood vessel immediately constricts. The underlying mechanism is thought to be an intrinsic response triggered by a paracrine released locally from the injured vessel's endothelial lining (see p. 345). This constriction, or **vascular spasm**, slows blood flow through the defect and thus minimizes blood loss. Also, as the opposing endothelial surfaces of the vessel are pressed together by this initial vascular spasm, they become sticky and adhere to each other, further sealing off the damaged vessel. These physical measures alone cannot completely prevent further blood loss, but they minimize blood flow through the break in the vessel until other hemostatic measures can actually plug the hole.

Platelets aggregate to form a plug at a vessel injury.

Platelets normally do not adhere to the smooth endothelial lining of blood vessels, but they do stick to damaged vessels. When the endothelial lining is disrupted because of vessel injury, *von Willebrand factor (vWF)*, a plasma protein secreted by mega-

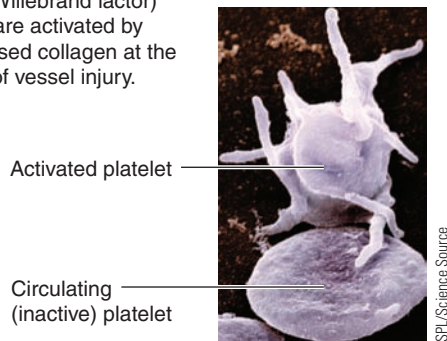
1 Circulating platelets adhere to (by means of the plasma protein von Willebrand factor) and are activated by exposed collagen at the site of vessel injury.

2 Activated platelets release ADP and thromboxane A₂.

3 These chemical messengers work together to activate other platelets passing by.

4 Newly activated platelets aggregate onto the growing platelet plug and release even more platelet-attracting chemicals.

5 Normal (uninjured) endothelium releases prostacyclin and nitric oxide, which inhibit platelet aggregation, so the platelet plug is confined to the site of injury.


❚ Figure 11-11 Platelet activation, formation of a platelet plug, and prevention of platelet aggregation at adjacent normal vessel lining.

karyocytes, platelets, and endothelial cells and always present in the plasma, adheres to the exposed collagen. *Collagen* is a fibrous protein in the connective tissue underlying the endothelial lining (see p. 60 and p. 340). vWF has binding sites to which the fast-moving platelets attach by means of their cell-surface receptors specific for this plasma protein. Thus vWF serves as a bridge between platelets and the injured vessel wall. This adhesion prevents these platelets from being swept forward in the circulation. This layer of stuck platelets forms the foundation of a hemostatic **platelet plug** at the site of the defect. Collagen activates the bound platelets. Normally platelets are disc-shaped and have a smooth surface, but activated platelets quickly reorganize their actin cytoskeletal elements to develop spiky processes, which help them adhere to the collagen and to other platelets (❚ Figure 11-11). Activated platelets also release several important chemicals from their storage granules. Among these

chemicals is *adenosine diphosphate (ADP)*, which causes the surfaces of nearby circulating platelets to become sticky so that they adhere to the first layer of aggregated platelets and are activated. These newly aggregated platelets release more ADP, which causes more platelets to pile on, and so on; thus, a plug of platelets is rapidly built up at the defect site in a positive-feedback fashion (❚ Figure 11-11). This aggregating process is reinforced by the ADP-stimulated formation of an eicosanoid paracrine similar to prostaglandins, *thromboxane A₂*, from a component of the platelet plasma membrane (see p. 119). Thromboxane A₂ directly promotes platelet aggregation and further enhances it indirectly by triggering the release of even more ADP from the platelet granules. Thus, formation of a platelet plug involves the three successive, closely integrated events of adhesion, activation, and aggregation.

Given the self-perpetuating nature of platelet aggregation, why does the platelet plug not continue to expand over the surface of the adjacent normal vessel lining? The reason is that ADP discharged by activated platelets stimulates release of *prostacyclin* and *nitric oxide* from the adjacent normal endothelium. Both these chemicals profoundly inhibit platelet aggregation. Thus, the platelet plug is limited to the defect and does not spread to the nearby undamaged vascular tissue (❚ Figure 11-11).

The aggregated platelet plug not only physically seals the break in the vessel but also performs three other important roles. (1) The actin–myosin complex within the aggregated platelets contracts to compact and strengthen what was origi-

nally a fairly loose plug. (2) The platelet plug releases several powerful vasoconstrictors that induce profound constriction of the affected vessel to reinforce the initial vascular spasm. (3) The platelet plug releases other chemicals that enhance blood coagulation, the next step of hemostasis. Although the platelet-plugging mechanism alone is often enough to seal the myriad minute tears in capillaries and other small vessels that occur many times daily, larger holes in these vessels require the formation of a blood clot to completely stop the bleeding.

Scientists continue to discover other platelet functions besides thwarting blood loss, such as releasing growth factors to help damaged tissue rebuild, inducing inflammation, serving as detectors of disease-causing microorganisms, and promoting NET release by neutrophils. Thus, platelets are not mere "band-aids" in the blood.

Clot formation results from a triggered chain reaction involving plasma clotting factors.

Blood coagulation, or **clotting**, is the transformation of blood from a liquid into a solid gel. Formation of a clot on top of the platelet plug reinforces the seal over a break in a vessel. Furthermore, as blood in the vicinity of the vessel defect solidifies, it can no longer flow. Clotting is the body's most powerful hemostatic mechanism. It is required to stop bleeding from all but the minutest defects.

Clot Formation The ultimate step in clot formation is conversion of **fibrinogen**, a large, soluble plasma protein produced by the liver and normally always present in the plasma, into **fibrin**, an insoluble, threadlike molecule. This conversion into fibrin is catalyzed by the enzyme **thrombin** at the site of the injury. Fibrin molecules adhere to the damaged vessel surface, forming a loose, netlike meshwork that traps blood cells, including aggregating platelets. The resulting mass, or **clot**, typically appears red because of the abundance of trapped RBCs, but the foundation of the clot is formed of fibrin derived from the plasma (❚Figure 11-12). Except for platelets, which help bring about the conversion of fibrinogen to fibrin, clotting can take place in the absence of all other blood cells.

Fibrin is the stretchiest natural protein that scientists have ever studied. On average fibrin fibers can be passively stretched nearly 3 times their original length and still snap back to their starting length and can be stretched more than 4 times their original length before they break. This highly elastic property accounts for the extraordinary stretchiness of blood clots.

The original fibrin web is rather weak, because the fibrin strands are only loosely interlaced. However, chemical linkages rapidly form between adjacent strands to strengthen and stabilize the clot meshwork. This cross-linkage is catalyzed by a clotting factor known as *factor XIII (fibrin-stabilizing factor),* which normally is present in the plasma in inactive form.

Roles of Thrombin Multitasking thrombin, in addition to (1) converting fibrinogen into fibrin, also (2) activates factor XIII to stabilize the resultant fibrin mesh, (3) acts in a positive-feedback fashion to facilitate its own formation, and (4) enhances platelet aggregation, which in turn is essential to the clotting process.
❚Figure 11-12 **Erythrocytes trapped in the fibrin meshwork of a clot**.

Because thrombin converts the ever-present fibrinogen molecules in the plasma into a blood-stanching clot, thrombin must normally be absent from the plasma except in the vicinity of vessel damage. Otherwise, blood would always be coagulated—a situation incompatible with life. How can thrombin normally be absent from the plasma, yet be readily available to trigger fibrin formation when a vessel is injured? The answer is that thrombin exists in the plasma in the form of an inactive precursor called **prothrombin**, which is converted into thrombin by the clotting cascade when blood clotting is desirable.

The Clotting Cascade Yet another activated plasma clotting factor, **factor X**, converts prothrombin to thrombin; factor X itself is normally present in the blood in inactive form and must be converted into its active form by still another activated factor, and so on. Altogether, 12 plasma clotting factors participate in essential steps that lead to the final conversion of fibrinogen into a stabilized fibrin mesh (❚Figure 11-13). These factors are designated by roman numerals in the order in which the factors were discovered, not the order in which they participate in the clotting process.[1] Most of these clotting factors are plasma proteins synthesized by the liver. Normally, they are always present in the plasma in an inactive form, such as fibrinogen and prothrombin. In contrast to fibrinogen, which is converted into insoluble fibrin strands, prothrombin and the other precursors, when converted to their active form, act as proteolytic (protein-splitting) enzymes. These enzymes activate another specific factor in the clotting sequence. Once the first factor in the sequence is activated, it in turn activates the next factor, and so on, in a series of sequential reactions known as the **clotting cascade**, until thrombin catalyzes the final conversion of fibrinogen into fibrin. Several of these steps require the presence of plasma Ca^{2+} and *platelet factor 3 (PF3)*, a chemical secreted by the aggregated platelet plug. Thus, platelets also contribute to clot formation.

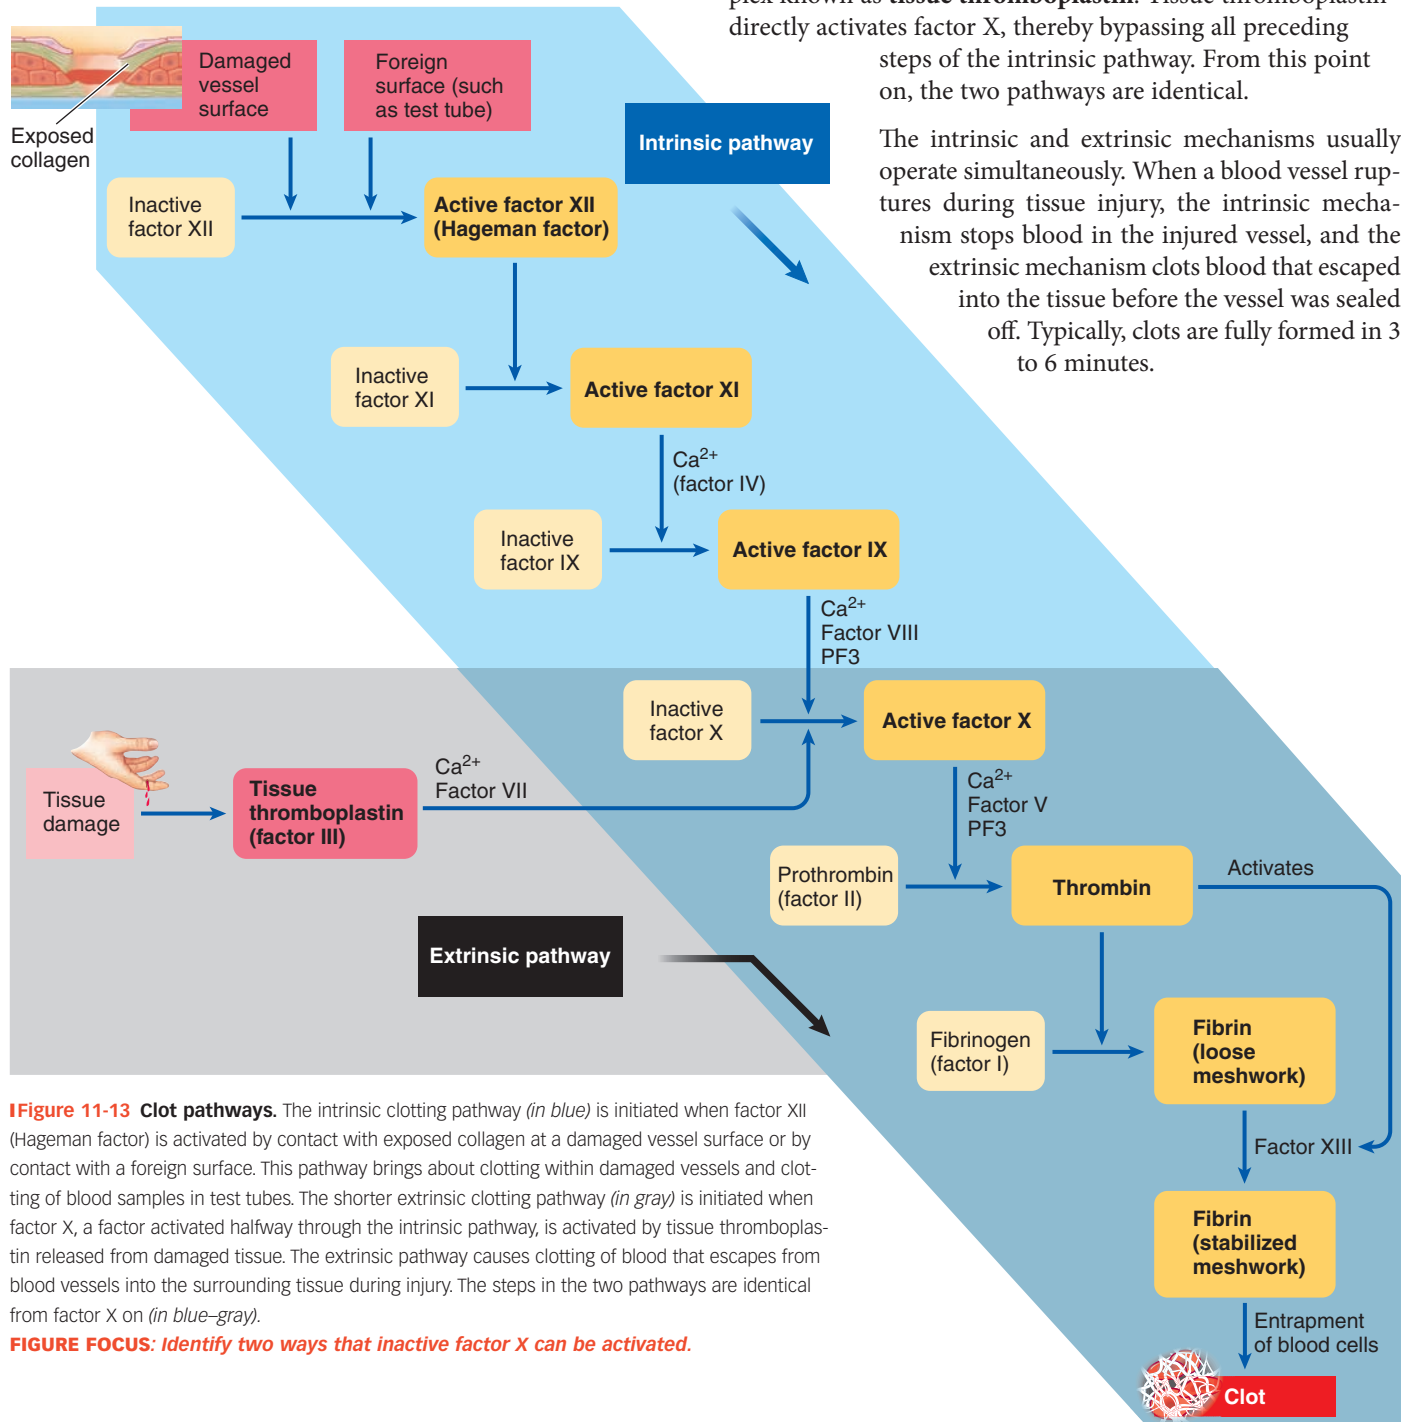
[1]The term *factor VI* is no longer used. What once was considered a separate factor VI has now been determined to be an activated form of factor V.

Intrinsic and Extrinsic Pathways The clotting cascade may be triggered by the *intrinsic pathway* or the *extrinsic pathway*:

■ The **intrinsic pathway** precipitates clotting within damaged vessels, and clotting of blood samples in test tubes. All elements necessary to bring about clotting by means of the intrinsic pathway are present in the blood. This pathway, which involves seven separate steps (shown in *blue* in ❙Figure 11-13), is set off when **factor XII (Hageman factor)** is activated by coming into contact with either exposed collagen in an injured vessel or a foreign surface such as a glass test tube. Remember

that exposed collagen also initiates platelet aggregation. Thus, formation of a platelet plug and the chain reaction leading to clot formation are simultaneously set in motion when a vessel is damaged. Furthermore, these complementary hemostatic mechanisms reinforce each other. The aggregated platelets secrete PF3, which is essential for the clotting cascade that in turn enhances further platelet aggregation.

■ The **extrinsic pathway** takes a shortcut and requires only four steps (shown in *gray* in ❙Figure 11-13). This pathway, which requires contact with tissue factors external to the blood, initiates clotting of blood that has escaped into the tissues. When a tissue is traumatized, it releases a protein complex known as **tissue thromboplastin**. Tissue thromboplastin directly activates factor X, thereby bypassing all preceding steps of the intrinsic pathway. From this point on, the two pathways are identical.

The intrinsic and extrinsic mechanisms usually operate simultaneously. When a blood vessel ruptures during tissue injury, the intrinsic mechanism stops blood in the injured vessel, and the extrinsic mechanism clots blood that escaped into the tissue before the vessel was sealed off. Typically, clots are fully formed in 3 to 6 minutes.


❙Figure 11-13 **Clot pathways.** The intrinsic clotting pathway *(in blue)* is initiated when factor XII (Hageman factor) is activated by contact with exposed collagen at a damaged vessel surface or by contact with a foreign surface. This pathway brings about clotting within damaged vessels and clotting of blood samples in test tubes. The shorter extrinsic clotting pathway *(in gray)* is initiated when factor X, a factor activated halfway through the intrinsic pathway, is activated by tissue thromboplastin released from damaged tissue. The extrinsic pathway causes clotting of blood that escapes from blood vessels into the surrounding tissue during injury. The steps in the two pathways are identical from factor X on *(in blue–gray).*

FIGURE FOCUS: *Identify two ways that inactive factor X can be activated.*

Clot Retraction Once a clot is formed, **clot retraction** occurs as platelets trapped within the clot contract and shrink the fibrin mesh, pulling the edges of the damaged vessel closer together. During clot retraction, fluid is squeezed from the clot. This fluid, which is essentially plasma minus fibrinogen and other clotting precursors that have been removed during the clotting process, is called **serum**.

Fibrinolytic plasmin dissolves clots.

A clot is not meant to be a permanent solution to vessel injury. It is a transient device to stop bleeding until the vessel can be repaired.

Vessel Repair The aggregated platelets secrete a chemical that helps promote the invasion of fibroblasts ("fiber formers") from the surrounding connective tissue into the wounded area of the vessel. Fibroblasts form a scar at the vessel defect.

Clot Dissolution Simultaneous with the healing process, the clot, which is no longer needed to prevent hemorrhage, is slowly dissolved by a fibrinolytic (fibrin-splitting) enzyme called **plasmin**. If clots were not removed after they performed their hemostatic function, their accumulation would eventually obstruct the vessels, especially the small ones that regularly endure tiny ruptures. Plasmin, like the clotting factors, is a plasma protein produced by the liver and present in the blood in an inactive precursor form, **plasminogen**. Plasmin is activated in a fast cascade of reactions involving many factors, among them factor XII (Hageman factor), which also triggers the rapid chain reaction leading to clot formation (❙Figure 11-14). Fast-activated plasmin becomes trapped in the clot and later dissolves it by slowly breaking down the fibrin meshwork.

Phagocytic white blood cells gradually remove the products of clot dissolution. You have observed the slow removal of blood that has clotted after escaping into the tissue layers of your skin following an injury. The black-and-blue marks of bruised skin result from deoxygenated clotted blood within the skin; this blood is eventually cleared by plasmin action, followed by the phagocytic "cleanup crew."

Preventing Inappropriate Clot Formation In addition to removing clots that are no longer needed, plasmin functions continually to prevent clots from forming inappropriately. Throughout the vasculature, small amounts of fibrinogen are constantly being converted into fibrin, triggered by unknown mechanisms. Clots do not develop, however, because the fibrin is quickly disposed of by plasmin activated by **tissue plasminogen activator (tPA)** from the tissues, especially the lungs. Normally, the low level of fibrin formation is counterbalanced by a low level of fibrinolytic activity, so inappropriate clotting does not occur. Only when a vessel is damaged do additional factors precipitate the explosive chain reaction that leads to more extensive fibrin formation and results in local clotting at the site of injury.

Clinical Note Genetically engineered tPA and other similar chemicals that trigger clot dissolution are frequently used to limit damage to cardiac muscle during heart attacks. Administering a clot-busting drug within the first hours after a clot has blocked a coronary (heart) vessel often dissolves the clot in time to restore blood flow to the cardiac muscle supplied by the blocked
❙Figure 11-14 **Role of factor XII in clot formation and dissolution.** Activation of factor XII (Hageman factor) simultaneously initiates a fast cascade of reactions that result in clot formation and a fast cascade of reactions that result in plasmin activation. Plasmin, which is trapped in the clot, subsequently slowly dissolves the clot. This action removes the clot when it is no longer needed after the vessel has been repaired.

vessel before the muscle dies of O_2 deprivation. tPA and related drugs can also be administered to promptly dissolve a stroke-causing clot within a cerebral (brain) blood vessel within 3 hours of onset of symptoms to minimize loss of irreplaceable brain tissue.

Inappropriate clotting produces thromboembolism.

Clinical Note Despite protective measures, clots occasionally form in intact vessels. Abnormal or excessive clot formation within blood vessels—that is, hemostasis in the wrong place—can compromise blood flow to vital organs. The body's clotting and anticlotting systems normally function in a check-and-balance manner. Acting in concert, they permit prompt formation of "good" blood clots, thus minimizing blood loss from damaged vessels, while preventing "bad" clots from forming and blocking blood flow in intact vessels. To review, an abnormal intravascular clot attached to a vessel wall is known as a **thrombus**, and freely floating clots are called **emboli** (singular, *embolus*). An enlarging thrombus narrows and can eventually completely occlude the vessel in which it forms. By entering and completely plugging a smaller vessel, a circulating embolus can suddenly block blood flow (see ❙Figure 9-28, p. 330).

Several factors, acting independently or simultaneously, can cause *thromboembolism*: (1) Roughened vessel surfaces associated with atherosclerosis can lead to thrombus formation (see p. 327). (2) Imbalances in the clotting–anticlotting systems can trigger clot formation. (3) Slow-moving blood is more apt to clot, probably because small quantities of fibrin accumulate in the stagnant blood, for example, in blood pooled in varicosed leg veins (see p. 364) or pooled in ineffectively pumping atria during atrial fibrillation (see p. 313). (4) Widespread clotting is occasionally triggered by release of tissue thromboplastin into the blood from large amounts of traumatized tissue. Similar

The Blood | **399**

widespread clotting can occur in **septicemic shock**, in which bacteria or their toxins initiate the clotting cascade.

Anticoagulant drugs ("blood thinners") are sometimes given to prevent thromboembolism in people with conditions that make them more prone to developing clots. For example, *heparin,* which must be injected, accelerates the action of a normal blood-borne inhibitor of thrombin, halting this clot promoter. *Warfarin* (Coumadin), which can be taken orally, interferes with vitamin K's action. Vitamin K, commonly known as the *blood-clotting vitamin*, is essential for normal clot formation. In recent years several new classes of oral anticoagulants have become available. *Dabigatran* (Pradaxa) is a direct thrombin inhibitor, thereby preventing conversion of fibrinogen to fibrin. *Rivaroxaban* (Xarelto) and related drugs inhibit active factor X, thus blocking conversion of prothrombin to thrombin. *Clopidogrel* (Plavix) works by inhibiting the platelet plasma-membrane receptor for ADP.

Hemophilia is the primary condition that produces excessive bleeding.

Clinical Note In contrast to inappropriate clot formation in intact vessels, the opposite hemostatic disorder is failure of clots to form promptly in injured vessels, resulting in life-threatening hemorrhage from even relatively mild traumas. The most common cause of excessive bleeding is **hemophilia** resulting from a deficiency of one of the factors in the clotting cascade (low or no factor VIII in 80% of cases).

People with a platelet deficiency, in contrast to the more profuse bleeding that accompanies defects in the clotting mechanism, continuously develop hundreds of small, confined hemorrhagic areas throughout the body as blood leaks from tiny breaks in the small blood vessels before coagulation takes place. Platelets normally are the primary sealers of these ever-occurring minute ruptures. In the skin of a platelet-deficient person, the diffuse capillary hemorrhages are visible as small, purplish blotches, giving rise to the term **thrombocytopenia purpura** ("the purple of thrombocyte deficiency") for this condition. (Recall that *thrombocyte* is another name for *platelet.*)

Vitamin K deficiency can also cause a bleeding tendency because of incomplete activation of vitamin K–dependent clotting factors.

Check Your Understanding 11.4

1. Describe how a platelet plug forms at the site of a vessel defect.
2. Draw a flow diagram showing the intrinsic and extrinsic pathways of the clotting cascade.
3. Explain how a clot is dissolved after it is no longer needed.

Homeostasis: Chapter in Perspective

Blood contributes to homeostasis in a variety of ways. First, the composition of interstitial fluid, the true internal environment that surrounds and directly exchanges materials with the cells, depends on the composition of blood plasma. Because of the thorough exchange that occurs between the interstitial and vascular compartments, interstitial fluid has the same composition as plasma with the exception of plasma proteins, which cannot escape through the capillary walls. Thus, blood serves as the vehicle for rapid, long-distance, mass transport of materials to and from the cells, and interstitial fluid serves as the go-between.

Homeostasis depends on the blood carrying essential supplies such as O_2 and nutrients to the cells as rapidly as the cells consume them and carrying materials such as metabolic wastes away from the cells as rapidly as the cells produce these products. It also depends on the blood carrying hormonal messengers from their site of production to their distant site of action. Once a substance enters the blood, it can be transported throughout the body within seconds, whereas diffusion of the substance over long distances in a large multicellular organism such as a human would take months to years—a situation incompatible with life. Diffusion can, however, effectively accomplish short local exchanges of materials between blood and surrounding cells through the intervening interstitial fluid.

Blood has special transport capabilities that enable it to move its cargo efficiently throughout the body. For example, life-sustaining O_2 is poorly soluble in water, but blood is equipped with O_2-carrying specialists, the erythrocytes (red blood cells), which are stuffed full of hemoglobin, a complex molecule that transports O_2. Likewise, homeostatically important water-insoluble hormonal messengers are shuttled in the blood by plasma protein carriers.

Specific components of the blood perform the following additional homeostatic activities unrelated to blood's transport function:

■ Blood helps maintain the proper pH in the internal environment by buffering changes in the body's acid–base load.

■ Blood helps maintain body temperature by absorbing heat produced by heat-generating tissues such as contracting skeletal muscles and distributing it throughout the body. Excess heat is carried by blood to the body surface for elimination to the external environment.

■ Electrolytes (mostly Na^+ and K^+) carried by plasma are important in membrane excitability, which is critical for nerve and muscle function.

■ Plasma electrolytes (mostly Na^+ and Cl^-) are important in osmotic distribution of water between the ECF and ICF. Plasma proteins play a critical role in distributing the ECF between the plasma and interstitial fluid.

■ Through their hemostatic functions the platelets and clotting factors minimize the loss of life-sustaining blood after vessel injury.

■ The leukocytes (white blood cells), their secretory products, and certain types of plasma proteins, such as antibodies, constitute the immune defense system. This system defends the body against invading disease-causing agents, paves the way for wound healing and tissue repair by clearing away debris from dead or injured cells, and destroys cancer cells. These actions indirectly contribute to homeostasis by helping organs that directly maintain homeostasis stay healthy. We could not survive beyond early infancy were it not for the body's defense mechanisms.

Review Exercises Answers begin on p. A-35

Reviewing Terms and Facts

1. Blood can absorb metabolic heat while undergoing only small changes in temperature. *(True or false?)*

2. Hemoglobin can carry only O_2. *(True or false?)*

3. Erythrocytes, leukocytes, and platelets all originate from the same undifferentiated stem cells. *(True or false?)*

4. Erythrocytes are unable to use the O_2 they contain for their own ATP formation. *(True or false?)*

5. White blood cells spend most of their time in the blood. *(True or false?)*

6. The type of leukocyte produced primarily in lymphoid tissue is _____.

7. Most clotting factors are synthesized by the _____.

8. Which of the following is *not* a function of plasma proteins?
   a. facilitating retention of fluid in the blood vessels
   b. playing an important role in blood clotting
   c. transporting water-insoluble substances in the blood
   d. transporting O_2 in the blood
   e. serving as antibodies
   f. contributing to the buffering capacity of the blood

9. Which of the following is *not* directly triggered by exposed collagen in an injured vessel?
   a. initial vascular spasm
   b. platelet aggregation
   c. activation of the clotting cascade
   d. activation of plasminogen

10. Match the following *(an answer may be used more than once)*:

1. causes platelets to aggregate in positive-feedback fashion	(a) prostacyclin
2. activates prothrombin	(b) plasmin
3. fibrinolytic enzyme	(c) ADP
4. inhibits platelet aggregation	(d) fibrin
5. first factor activated in intrinsic clotting pathway	(e) thrombin
6. forms meshwork of the clot	(f) factor X
7. stabilizes the clot	(g) factor XII
8. activates fibrinogen	(h) factor XIII
9. activated by tissue thromboplastin	

11. Match the following blood abnormalities with their causes:

1. deficiency of intrinsic factor	(a) hemolytic anemia
2. insufficient amount of iron to synthesize adequate hemoglobin	(b) aplastic anemia
3. destruction of bone marrow	(c) nutritional anemia
4. abnormal loss of blood	(d) hemorrhagic anemia
5. tumorlike condition of bone marrow	(e) pernicious anemia
6. inadequate erythropoietin secretion	(f) renal anemia
7. excessive rupture of circulating erythrocytes	(g) primary polycythemia
8. associated with living at high altitudes	(h) secondary polycythemia

Understanding Concepts

(Answers at www.cengagebrain.com)

1. What is the average blood volume in women and in men? What is the normal percentage of blood occupied by erythrocytes and by plasma in women and in men? What is the hematocrit? What is the buffy coat?

2. What is the composition of plasma?

3. List the three major groups of plasma proteins, and state their functions.

4. Describe the structure and functions of erythrocytes.

5. Why can erythrocytes survive for only about 120 days?

6. Describe the process and control of erythropoiesis.

7. List the antigens and antibodies present in the blood of the four major ABO blood types. Describe what happens in a transfusion reaction. Does the recipient have to have had prior exposure to incompatible blood of the ABO type for a transfusion reaction to occur? Does the recipient have to have had prior exposure to incompatible blood of the Rh type for a transfusion reaction to occur? Explain.

8. Compare the structure, functions, and life spans of the five types of leukocytes.

9. Discuss the derivation of platelets.

10. Describe the three steps of hemostasis, including a comparison of the intrinsic and extrinsic pathways by which the clotting cascade is triggered.

11. Compare plasma and serum.

12. What normally prevents inappropriate clotting in vessels?

Solving Quantitative Exercises

1. The normal concentration of hemoglobin in blood (as measured clinically) is 15 g/100 mL of blood.

   a. Given that 1 mole of hemoglobin weighs 66,000 grams, what is the concentration of hemoglobin in millimoles (mM)?

   b. Each hemoglobin molecule can bind four molecules of O_2. What is the concentration of O_2 bound to hemoglobin at maximal saturation (in mM)?

   c. Given that 1 mole of an ideal gas occupies 22.4 liters, what is the maximal carrying capacity of normal blood for O_2 (usually expressed in mL of O_2/liter of blood)?

2. Assume that the blood sample in ❙Figure 11-5b, p. 387, is from a patient with hemorrhagic anemia. Given a normal blood volume of 5 liters, a normal red blood cell concentration of 5 billion/mL, and an RBC production rate of 3 million cells/second, how long will it take the body to return the hematocrit to normal?

3. Note that in the blood sample in ❙Figure 11-5c from a patient with polycythemia, the hematocrit has increased to 70%. An increased hematocrit increases blood viscosity, which in turn increases total peripheral resistance and increases the workload on the heart. The effect of hematocrit (h) on relative blood viscosity (v, viscosity relative to that of water) is given approximately by the following equation:

$$v = 1.5 \times \exp(2h)$$

Note that in this equation, h is the hematocrit as a fraction, not a percentage. Given a normal hematocrit of 0.40, what percent increase in viscosity would result from the polycythemia in ❙Figure 11-5c? What percent change would this cause in total peripheral resistance?

Applying Clinical Reasoning

Heather L., who has Rh-negative blood, has just given birth to her first child, who has Rh-positive blood. Both mother and baby are fine, but the doctor administers an Rh immunoglobulin preparation (short-lived antibodies against the Rh factor antigen) so that any future Rh-positive babies Heather has will not suffer from erythroblastosis fetalis (hemolytic disease of the newborn) (see p. 389). During gestation (pregnancy), fetal and maternal blood do not mix. Instead, materials are exchanged between these two circulatory systems across the placenta, a special organ that develops during gestation from both maternal and fetal structures (see p. 757). Red blood cells are unable to cross the placenta, but antibodies can cross. Dur-

ing the birthing process, a small amount of the infant's blood may enter the maternal circulation.

1. Why did Heather's first-born child not have erythroblastosis fetalis—that is, why didn't maternal antibodies against the Rh factor attack the fetal Rh-positive RBCs during gestation?

2. Why would any subsequent Rh-positive babies Heather might carry be likely to develop erythroblastosis fetalis if she were not treated with Rh immunoglobulin?

3. How would administering Rh immunoglobulin immediately following Heather's first pregnancy with an Rh-positive child prevent erythroblastosis fetalis in a later pregnancy with another Rh-positive child? Similarly, why must Rh immunoglobulin be given to Heather after the birth of each Rh-positive child she bears?

4. Suppose Heather were not treated with Rh immunoglobulin after the birth of her first Rh-positive child, and a second Rh-positive child developed erythroblastosis fetalis. Would administering Rh immunoglobulin to Heather immediately after the second birth prevent this condition in a third Rh-positive child? Why or why not?

Thinking at a Higher Level

1. A person has a hematocrit of 62. Can you conclude from this finding that the person has polycythemia? Explain.

2. There are different forms of hemoglobin. *Hemoglobin A* is normal adult hemoglobin, which has two α chains and two β chains. The abnormal form *hemoglobin S,* which has a single "typographical error" in the genetic code for the β chains, causes RBCs to warp into fragile, sickle-shaped cells (see p. 387). Fetal RBCs contain *hemoglobin F,* the production of which stops soon after birth. Hemoglobin F contains two γ chains instead of two β chains, along with the two α chains. This substitution increases hemoglobin's affinity for O_2. Now researchers are trying to goad the genes that direct hemoglobin F synthesis back into action as a means of treating sickle cell anemia. Explain how turning on these fetal genes could be a useful remedy. (Indeed, the first effective drug therapy for treating sickle cell anemia, *hydroxyurea,* acts on the bone marrow to boost production of fetal hemoglobin.)

3. What types of blood in the ABO and Rh blood systems could safely be transfused into a person with Type A+ blood?

4. Low on the list of popular animals are vampire bats, leeches, and ticks, yet these animals may someday indirectly save your life. Scientists are currently examining the "saliva" of these blood-sucking creatures in search of new chemicals that might limit cardiac muscle damage in heart attack victims. What do you suspect the nature of these sought-after chemicals is?

5. *Porphyria* is a genetic disorder that shows up in about one in every 25,000 individuals. Affected individuals lack certain enzymes that are part of a metabolic pathway leading to formation of heme, which is the iron-containing group of hemoglobin. An accumulation of porphyrins, which are intermediates of the pathway, causes a variety of symptoms, especially after exposure to sunlight. Lesions and scars form on the skin. Hair grows thickly on the face and hands. As gums retreat from teeth, the elongated canine teeth take on a fanglike appearance. Symptoms worsen on exposure to a variety of substances, including garlic and alcohol. Affected individuals avoid sunlight and aggravating substances and get injections of heme from normal red blood cells. If you are familiar with vampire stories, which date from the Middle Ages or earlier, speculate on how they may have evolved among superstitious folk who did not have medical knowledge of porphyria.

12 Body Defenses
A scanning electron micrograph of a macrophage at work. A macrophage (*green*), a large tissue phagocyte, extends projections to surround and engulf tuberculosis bacteria (*purple*). After internalizing the bacteria, the macrophage will destroy them by lysosomal enzymes. The macrophage will also present bacterial antigens (protein fragments) on its surface that will activate specific helper lymphocytes, setting in motion events leading to production of antibodies against the tuberculosis bacteria.

CHAPTER AT A GLANCE

Homeostasis Highlights

Humans constantly come into contact with external agents that could be harmful if they entered the body. The most serious are disease-causing microorganisms. If bacteria or viruses do gain entry, the body is equipped with a complex, multifaceted internal defense system—the **immune system**—that provides continual protection against invasion by foreign agents. Furthermore, body surfaces exposed to the external environment, such as the **integumentary system (skin)**, serve as a first line of defense to resist penetration by foreign microorganisms. The immune system also protects against cancer and paves the way for repair of damaged tissues.

The immune system indirectly contributes to homeostasis by helping maintain the health of organs that directly contribute to homeostasis.

404

12.1 Immune System: Targets, Effectors, Components

Immunity is the body's ability to protect itself by resisting or eliminating potentially harmful foreign invaders (such as bacteria and viruses) or abnormal cells (such as cancer cells). The first line of defense against foreign invaders is the epithelial barriers that surround the outer surface of the body (the skin) and line the body cavities (such as the digestive tract and lungs) that are in contact with the external environment. These epithelial barriers are not part of the immune system. We will discuss their roles in the body's overall defense mechanisms after examining the immune system in detail. As an overview, the following activities are attributable to the immune system, an internal defense system that plays a key role in recognizing and either destroying or neutralizing things that are not "normal self":

1. Defending against invading **pathogens** (disease-producing microorganisms)
2. Removing worn-out cells and tissue damaged by trauma or disease, paving the way for wound healing and tissue repair
3. Identifying and destroying abnormal cancer cells that have originated in the body, a function termed *immune surveillance*

Pathogenic bacteria and viruses are the major targets of the immune system.

The primary foreign enemies against which the immune system defends are bacteria and viruses. Comparing their relative sizes, if an average bacterium were the size of a pitcher's mound, a virus would be the size of a baseball. **Bacteria** are nonnucleated, single-celled microorganisms self-equipped with all the machinery essential for their survival and reproduction. Pathogenic bacteria that invade the body cause tissue damage and produce disease largely by releasing enzymes or toxins that physically injure or functionally disrupt affected cells and organs. The disease-producing power of a pathogen is known as its **virulence**.

In contrast to bacteria, **viruses** are not self-sustaining cellular entities. They consist only of nucleic acids (genetic material—DNA or RNA) enclosed by a protein coat. Because they lack cellular machinery for energy production and protein synthesis, viruses cannot carry out metabolism and reproduce unless they invade a **host cell** (a body cell of the infected individual) and take over the cell's biochemical facilities for their own uses. Not only do viruses sap the host cell's energy resources, but the viral nucleic acids also direct the host cell to synthesize proteins needed for viral replication.

When a virus becomes incorporated into a host cell, the body's defense mechanisms may destroy the cell because they no longer recognize it as a normal-self cell. Other ways in which viruses can lead to cell damage or death are by depleting essential cell components, dictating that the cell produce substances toxic to the cell, or transforming the cell into a cancer cell.

Leukocytes are the effector cells of the immune system.

Leukocytes (white blood cells, or WBCs) and their derivatives, along with a variety of plasma proteins, are responsible for immune defense.

Leukocyte Functions As a brief review, the functions of the five types of leukocytes are as follows (see pp. 392–393 and ▌Figure 11-8):

1. **Neutrophils** are highly mobile phagocytic specialists that engulf and destroy unwanted materials.
2. **Eosinophils** secrete chemicals that destroy parasitic worms and are involved in allergic reactions.
3. **Basophils** release histamine and heparin and also are involved in allergic reactions.
4. **Monocytes** are transformed into **macrophages**, which are large, tissue-bound phagocytic specialists.
5. **Lymphocytes** are of two types:
   a. **B lymphocytes (B cells)** produce antibodies that indirectly lead to the destruction of foreign material (antibody-mediated immunity).
   b. **T lymphocytes (T cells)** directly destroy virus-invaded cells and mutant cells by releasing chemicals that punch lethal holes in the victim cells (cell-mediated immunity).

A given leukocyte is present in the blood only transiently. Most leukocytes are out in the tissues on defense missions.

Lymphoid Tissues Almost all leukocytes originate from common precursor stem cells in the bone marrow and are subsequently released into the blood. The only exception is lymphocytes, which arise in part from lymphocyte colonies in various lymphoid tissues originally populated by cells derived from bone marrow (see ▌Figure 11-9, p. 394).

Lymphoid tissues, collectively, are the tissues that produce, store, or process lymphocytes. These include the bone marrow, lymph nodes, spleen, thymus, tonsils, adenoids, appendix, and aggregates of lymphoid tissue in the lining of the digestive tract called **Peyer's patches** or **gut-associated lymphoid tissue (GALT)** (▌Figure 12-1 and ▌Table 12-1). Lymphoid tissues are strategically located to intercept invading microorganisms before they have a chance to spread very far. For example, lymphocytes populating the *tonsils* and *adenoids* are situated advantageously to respond to inhaled microbes, whereas microorganisms invading through the digestive system immediately encounter lymphocytes in the *appendix* and GALT. Potential pathogens that gain access to lymph are filtered through *lymph nodes,* where they are exposed to lymphocytes as well as to macrophages that line lymphatic passageways. The *spleen,* the largest lymphoid tissue, performs immune functions on blood similar to those that lymph nodes perform on lymph. Through actions of its lymphocyte and macrophage population, the spleen clears blood that passes through it of microorganisms and other foreign matter and also removes worn-out red blood cells

(see p. 384). The *thymus* and *bone marrow* play important roles in processing T and B lymphocytes, respectively, to prepare them to carry out their specific immune strategies.

We now turn attention to the two major components of the immune system's response to foreign invaders and other targets—innate and adaptive immune responses. In the process, we will further examine the roles of each type of leukocyte.

Immune responses may be either innate and nonspecific or adaptive and specific.

Protective immunity is conferred by the complementary actions of two separate but interdependent components of the immune system: the innate immune system and the adaptive, or acquired, immune system. The responses of these two systems differ in timing and in the selectivity of the defense mechanisms.

The **innate immune system** encompasses the body's *nonspecific* immune responses that come into play immediately on exposure to a threatening agent. These nonspecific responses are inherent (innate or built-in) defense mechanisms that nonselectively defend against foreign or abnormal material of any type, even on initial exposure to it. Such responses provide a first line of internal
defense against a range of threats, including infectious agents, chemical irritants, and tissue injury. Everyone is born with essentially the same innate immune-response mechanisms. The **adaptive**, or **acquired**, **immune system**, in contrast, relies on *specific* immune responses selectively targeted against a particular foreign material to which the body has already been exposed and has had an opportunity to prepare for a discriminating attack on the enemy. The adaptive immune system thus takes considerably more time to mount and takes on specific foes. The innate and adaptive immune systems work in harmony to contain, and then eliminate, harmful agents.

Innate Immune System The innate system is always on guard, ready to unleash a limited repertoire of defense mechanisms at any and every invader. Of the immune effector cells, the neutrophils and macrophages—both phagocytic specialists—are especially important in innate defense. Several groups of plasma proteins also play key roles, as you will see shortly.

Nonspecific immune responses are set in motion on exposure to generic molecular patterns associated with threatening agents. Two categories of patterns call forth the innate

| Figure 12-1 **Lymphoid tissues.**

Labels in figure: Adenoid, Tonsil, Thymus, Lymph node, Spleen, Lymphatic vessel, Peyer's patches in small intestine (gut-associated lymphoid tissue), Appendix, Bone marrow

| TABLE 12-1 Functions of Lymphoid Tissues

Lymphoid Tissue	Functions
Bone marrow	Origin of all blood cells
	Site of maturational processing for B lymphocytes
Lymph nodes, tonsils, adenoids, appendix, gut-associated lymphoid tissue	Exchange lymphocytes with the lymph (remove, store, produce, and add them)
	Resident lymphocytes produce antibodies and activated T cells, which are released into the lymph
	Resident macrophages remove microbes and other particulate debris from the lymph
Spleen	Exchanges lymphocytes with the blood (removes, stores, produces, and adds them)
	Resident lymphocytes produce antibodies and activated T cells, which are released into the blood
	Resident macrophages remove microbes and other particulate debris, most notably worn-out red blood cells, from the blood
	Stores a small percentage of red blood cells, which can be added to the blood by splenic contraction as needed
Thymus	Site of maturational processing for T lymphocytes
	Secretes the hormone thymosin

response: exogenous (originating from outside the body) **pathogen-associated molecular patterns (PAMPs)**, such as the carbohydrates typically found in bacterial cell walls but not found in human cells, and endogenous (originating from within the body) **damage-associated molecular patterns (DAMPs;** also known as **alarmins)**, such as extracellular adenosine triphosphate (ATP) released from trauma-damaged cells. Both patterns trigger identical innate pathways leading to inflammation, a multistep process involving phagocytic removal of offending agents and tissue debris and promoting tissue repair. In addition, the response to PAMPs includes augmenting adaptive immunity. We will focus on the response called forth by PAMPs. The responding phagocytic cells possess *pattern recognition receptors* on their surface membrane or in their cytosol for detecting the patterns associated with threatening agents. For example, phagocytes are studded with plasma membrane proteins known as **toll-like receptors (TLRs)**, which recognize PAMPs. About a dozen distinct TLRs each recognize a different specific set of molecular patterns. For example, some recognize gram-positive bacteria (bacteria that can be stained with Gram stain), others recognize gram-negative bacteria (bacteria whose cell wall does not pick up Gram stain), still others recognize viral DNA or RNA, and so on. TLRs have been dubbed the "eyes of the innate immune system" because these immune sensors recognize and bind with the unique, telltale pathogen markers, allowing the effector cells of the innate system to "see" pathogens as distinct from normal-self cells.

A TLR's recognition of a pathogen triggers the phagocyte to engulf and destroy the infectious microorganism. Moreover, activation of the TLR induces the phagocytic cell to secrete chemicals, some of which contribute to inflammation. TLRs link the innate and adaptive branches of the immune system because still other chemicals secreted by the phagocytes recruit cells of the adaptive immune system. Because of their pivotal role in the immune system, TLRs are targets for many new drugs and vaccines under development.

As another link between the innate and adaptive branches of the immune system, foreign particles are deliberately marked for phagocytic ingestion by being coated with antibodies produced by the B cells of the adaptive immune system. These are but a few examples of how various components of the immune system are highly interactive and interdependent. The most significant cooperative relationships among the immune effectors are pointed out throughout this chapter.

TLRs function at the cell surface to recognize pathogens in the extracellular fluid (ECF), but most viruses are hidden inside host cells instead of being free in the ECF. Scientists recently discovered intracellular pattern recognition receptors, including several **RLRs,**[1] which recognize viral DNA or RNA within the cytosol, and multiple **NLRs,**[2] which distinguish intracellular PAMPs such as bits of bacterial cell wall engulfed by a phago-

cyte or parasites that have invaded a nonimmune cell. Appropriately, activation of RLRs by viral genetic material triggers synthesis of interferon, an innate mechanism to be described later that defends against viral invasion. Activated NLRs trigger formation of cytosolic, multiprotein complexes termed **inflammasomes**, of which the NLRs themselves are a part. Inflammasomes bring about a potent inflammatory response, complementing the actions triggered by activated TLRs. Thus, the trinity of pathogen receptors—TLRs, RLRs, and NLRs—cooperate to ensure efficient innate immune responses against pathogenic interlopers.

The innate mechanisms give us all a rapid but limited and nonselective response to unfriendly challenges of all kinds, much like medieval guardsmen lashing out with brute-force weapons at any enemy approaching the walls of the castle they are defending. Innate immunity largely contains and limits the spread of infection. These nonspecific responses are important for keeping the foe at bay until the adaptive immune system, with its highly selective weapons, can be prepared to take over and mount strategies to eliminate the villain.

Adaptive Immune System Unlike the innate immune system, the adaptive immune system customizes its defenses for specific pathogens. The responses of the adaptive immune system are mediated by the B and T lymphocytes. Each B and T cell can recognize and defend against only one particular type of foreign material, such as one kind of bacterium. Among the millions of B and T cells in the body, only the ones specifically equipped to recognize the unique molecular features of a particular infectious agent are called into action to discriminatingly defend against this agent. This specialization is similar to modern, specially trained military personnel called into active duty to accomplish a specific task. The chosen lymphocytes multiply, expanding the pool of specialists that can launch a highly targeted attack against the invader.

The adaptive immune system is the ultimate weapon against most pathogens. The repertoire of activated and expanded B and T cells constantly changes, or adapts, to wage battle against the specific pathogens encountered in each person's environment. Thus, the targets of the adaptive immune system vary among people, depending on the types of immune assaults each individual meets. Furthermore, this system acquires an ability to more efficiently eradicate a particular foe when rechallenged by the same pathogen in the future. It does so by establishing a pool of memory cells as a result of an encounter with a given pathogen so that, when later exposed to the same agent, it can more swiftly defend against the invader.

Next we examine in more detail the innate immune responses before looking more closely at adaptive immunity.

> 1. Define *immunity*.
> 2. Explain why innate immune responses are considered nonspecific and adaptive immune responses are said to be specific.
> 3. Distinguish among PAMPs, DAMPs, TLRs, RLRs, and NLRs.

---

[1] *RLRs* stands for *retinoic acid inducible gene I (RIG-I)-like receptors*
[2] *NLRs* stands for *nucleotide-binding oligomerization domain (NOD)-like receptors*

12.2 Innate Immunity

Innate defenses include the following:

1. *Inflammation,* a nonspecific response to tissue injury in which the phagocytic specialists—neutrophils and macrophages—play a major role

2. *Interferon,* a family of proteins that nonspecifically defend against viral infection

3. *Natural killer cells,* a special class of lymphocytelike cells that spontaneously and nonspecifically lyse (rupture) and thereby destroy virus-infected host cells and cancer cells

4. The *complement system,* a group of inactive plasma proteins that, when sequentially activated, bring about destruction of foreign cells by attacking their plasma membranes

We now elaborate on each of these mechanisms in order.

Inflammation is a nonspecific response to foreign invasion or tissue damage.

Inflammation is an innate, nonspecific series of interrelated events set into motion in response to foreign invasion, tissue damage, or both. The goal of inflammation is to bring to the invaded or injured area phagocytes and plasma proteins that can (1) isolate, destroy, or inactivate invaders; (2) remove debris; and (3) prepare for subsequent healing and repair. The overall inflammatory response is remarkably
1 A break in the skin introduces bacteria, which reproduce at the wound site. Activated resident macrophages engulf the pathogens and secrete chemotaxins and other cytokines.

2 Activated mast cells release histamine.

3 Histamine dilates local blood vessels and widens capillary pores. Some cytokines cause neutrophils and monocytes to stick to the blood vessel wall.

4 Chemotaxins attract neutrophils and monocytes, which squeeze out between cells of the blood vessel wall, a process called diapedesis, and migrate to the infection site.

5 Monocytes enlarge into macrophages. Newly arriving macrophages and neutrophils engulf the pathogens and destroy them.

Figure 12-2 **Steps producing inflammation.** Chemotaxins released at the site of damage attract phagocytes to the scene. Note the leukocytes emigrating from the blood into the tissues by assuming amoebalike behavior and squeezing through the capillary pores. Mast cells secrete vessel-dilating, pore-widening histamine. Macrophages secrete cytokines that exert multiple local and systemic effects.

FIGURE FOCUS: *Use the figure (1) to identify the first immune cells to defend at a site of injury and/or infection, and (2) to describe how neutrophils and monocytes exit the blood to enter the site.*

similar no matter what the triggering event (bacterial invasion, chemical injury, or mechanical trauma), although some subtle differences may be evident, depending on the injurious agent or the site of damage. The following sequence of events typically occurs during inflammation. As an example, we use bacterial entry into a break in the skin (❙Figure 12-2).

Defense by Resident Tissue Macrophages When bacteria invade through a break in the external barrier of skin (or enter through another avenue), macrophages already in the area immediately begin phagocytizing the foreign microbes, defending against infection during the first hour or so, before other mechanisms can be mobilized (see chapter opener photo). Resident macrophages also secrete chemical mediators, or *cytokines,* that exert various immune responses, as will be described shortly (❙Figure 12-2, step ❶).

Localized Vasodilation Almost immediately on microbial invasion, arterioles within the area dilate, increasing blood flow to the site of injury. This localized vasodilation is mainly induced by **histamine** released from mast cells in the area of tissue damage (the connective tissue–bound "cousins" of circulating basophils; see p. 393) (steps ❷ and ❸). Increased local delivery of blood brings to the site more phagocytic leukocytes and plasma proteins, both crucial to the defense response.

Increased Capillary Permeability Released histamine also increases the capillaries' permeability by enlarging the capillary pores (the spaces between the endothelial cells) so that plasma proteins normally prevented from leaving the blood can escape into the inflamed tissue (see p. 354).

Localized Edema Accumulation of leaked plasma proteins in the interstitial fluid raises the local interstitial fluid–colloid osmotic pressure. Furthermore, the increased local blood flow elevates capillary blood pressure. Because both these pressures tend to move fluid out of the capillaries, these changes favor enhanced ultrafiltration and reduced reabsorption of fluid across the involved capillaries. The end result of this shift in fluid balance is localized edema (see p. 359). Thus, the familiar

swelling that accompanies inflammation is the result of histamine-induced vascular changes. Likewise, the other well-known gross manifestations of inflammation, such as redness and heat, are largely caused by the enhanced flow of warm arterial blood to the damaged tissue (*inflammare* means "to set on fire"). Pain is caused both by local distension within the swollen tissue and by the direct effect of locally produced substances on the receptor endings of afferent neurons that supply the area. These observable characteristics of the inflammatory process (swelling, redness, heat, and pain) are coincidental to the primary purpose of the vascular changes in the injured area—to increase the number of leukocytic phagocytes and crucial plasma proteins in the area (❙Figure 12-3).
❙Figure 12-3 **Gross manifestations and outcomes of inflammation.**
FIGURE FOCUS: *Trace the pathways by which histamine leads to the undesirable gross manifestations of inflammation. Which box in the diagram designates the desirable outcome of inflammation?*

Walling Off the Inflamed Area The leaked plasma proteins most critical to the immune response are those in the complement system and clotting and anticlotting factors. On exposure to tissue thromboplastin in the injured tissue and to specific chemicals secreted by phagocytes on the scene, fibrinogen—the final factor in the clotting system—is converted into fibrin (see p. 397). Fibrin forms interstitial fluid clots in the spaces around the bacterial invaders and damaged cells. This walling off the injured region from the surrounding tissues prevents, or at least delays, the spread of bacterial invaders and their toxic products. Later, the more slowly acting anticlotting factors gradually dissolve the clots after they are no longer needed (see p. 399).

Emigration of Leukocytes Within an hour after injury, the area is teeming with leukocytes that have left the vessels. Neutrophils arrive first, followed during the next 8 to 12 hours by the slower-moving monocytes. The latter swell and mature into macrophages during another 8- to 12-hour period. Once neutrophils or monocytes leave the bloodstream, they never recycle back to the blood. Leukocytes can emigrate from the blood into the tissues via the following steps:

■ Blood-borne neutrophils and monocytes stick to the inner endothelial lining of capillaries in the affected tissue, an event called **margination** (see ▌Figure 12-2, step ❸). *Selectins,* a type of cell adhesion molecule (CAM; see p. 60) that protrudes from the vessel lining, cause leukocytes flowing by in the blood to slow down and roll along the interior of the vessel, much as the nap of a carpet slows down a child's rolling toy car. This slowing-down allows neutrophils and monocytes enough time to check for local activating factors—"SOS signals", such as certain cytokines released by resident macrophages in nearby infected tissues. When present, these activating factors cause these leukocytes to adhere firmly to the endothelial lining by means of interaction with another type of CAM, the *integrins.*

■ Soon the stuck leukocytes start leaving the vessel by a process called **diapedesis**. During diapedesis, an adhered leukocyte behaves like an amoeba (see p. 50), forming pseudopods to wriggle through a capillary pore even though it is much larger than the pore. After exiting, a leukocyte crawls toward the injured area (step ❹). Neutrophils, the "foot soldiers" on the front lines, arrive on the inflammatory scene earliest, within minutes, because they are more mobile than monocytes.

■ How do leukocytes know where to go? These phagocytic cells are attracted to **chemotaxins**, chemical mediators released at the site of damage (*taxis* means "attraction"). Some cytokines function as chemotaxins, as do certain activated components of the complement system, another innate defense tool. Cytokines that act as chemotaxins are often specifically called **chemokines**. Binding of chemotaxins with protein receptors on the plasma membrane of a phagocytic cell increases Ca^{2+} entry into the cell. Calcium, in turn, switches on the cellular contractile apparatus that leads to amoebalike crawling. Because the concentration of chemotaxins progressively increases toward the site of injury, phagocytic cells move unerringly toward this site along a chemotaxin concentration gradient.

Leukocyte Proliferation Resident tissue macrophages and leukocytes that exited from the blood and migrated to the site are soon joined by new phagocytic recruits from the bone marrow. Within a few hours after onset of the inflammatory response, the number of neutrophils in the blood may increase up to five times that of normal. Mobilization of stored neutrophils and proliferation of new neutrophils and monocytes–macrophages are stimulated by various chemical mediators (*colony–stimulating factors;* see p. 394) released from the inflamed region.

Marking of Bacteria for Destruction by Opsonins Phagocytes must be able to distinguish between normal-self cells and foreign or abnormal cells before accomplishing their destructive mission. Otherwise, they could not selectively engulf and destroy only unwanted materials. First, phagocytes, by means of their TLRs, recognize and subsequently engulf infiltrators that have standard bacterial cell wall components not found in human cells. Second, foreign particles are deliberately marked for phagocytic ingestion by being coated with chemical mediators generated by the immune system. Such body-produced chemicals that make bacteria more susceptible to phagocytosis are known as **opsonins** (*opsonin* means "to prepare for eating"). The most important opsonins are antibodies and one of the activated proteins of the complement system.

An opsonin enhances phagocytosis by linking the foreign cell to a phagocytic cell (▌Figure 12-4). One portion of an opsonin molecule binds nonspecifically to the surface of an invading bacterium, whereas another portion of the opsonin molecule binds to receptor sites specific for it on the phagocytic cell's plasma membrane. This link ensures that the bacterial victim does not have a chance to "get away" before the phagocyte can perform its lethal attack.

Leukocytic Destruction of Bacteria Neutrophils and macrophages clear the inflamed area of infectious and toxic agents, and tissue debris, largely by phagocytosis; this clearing action is the main function of the inflammatory response. Recall that phagocytosis involves engulfment of a bacterium or other foreign particle or tissue debris, which becomes enclosed
Structures are not drawn to scale.

▌**Figure 12-4 Mechanism of opsonin action.** One of the activated complement molecules, C3b, links a foreign cell, such as a bacterium, and a phagocytic cell by nonspecifically binding with the foreign cell and specifically binding with a receptor on the phagocyte. This link ensures that the foreign victim does not escape before it can be engulfed by the phagocyte.

in a membrane-bound intracellular vesicle called a *phagosome.* The phagosome fuses with a lysosome and the entrapped material degrades intracellularly by hydrolytic enzymes within the confines of this organelle (see p. 31). Macrophages can engulf a bacterium in less than 0.01 second. Phagocytes eventually die from accumulation of toxic by-products from foreign particle degradation or from inadvertent release of destructive lysosomal chemicals into the cytosol. Neutrophils usually succumb after phagocytizing from 5 to 25 bacteria, whereas macrophages survive much longer and can engulf up to 100 or more bacteria. Indeed, the longer-lived macrophages even clear the area of dead neutrophils in addition to other tissue debris. The **pus** that forms in an infected wound is a collection of these phagocytic cells, both living and dead; necrotic (dead) tissue liquefied by lysosomal enzymes released from the phagocytes; and bacteria.

Mediation of Inflammation by Cytokines Microbe-stimulated phagocytes release many chemicals that function as mediators of inflammation. All chemicals other than antibodies that leukocytes secrete are categorized as **cytokines**, which are protein signal molecules whose function is to regulate immune responses (see p. 118). Macrophages, monocytes, neutrophils, a type of T cell called a helper T cell, and some nonimmune cells such as endothelial cells and fibroblasts (fiber-formers in the connective tissue) all secrete cytokines. More than 100 cytokines have been identified, and the list continues to grow as researchers unravel the complicated chemical means by which immune effector cells communicate with one another to coordinate their activities. Unlike antibodies, cytokines do not interact directly with the antigen (foreign material) that induces their production. Instead, cytokines largely spur other immune cells into action to help ward off the invader. Cytokines typically act locally as paracrines on cells in the vicinity, but some circulate in the blood to exert endocrine effects at distant sites. Some cytokines have names related to their first identified or most important function, examples being specific *colony–stimulating factors.* Other cytokines are designated as specific numbered *interleukins,* such as interleukin 1 (IL-1), interleukin 2 (IL-2), up to IL-38, numbered in order of their discovery (*interleukin* means "between leukocytes"). Cytokines secreted by phagocytes orchestrate a wide variety of independent and overlapping immune activities, the following being among the most important:

1. Some phagocytic secretions are very destructive and directly kill microbes by nonphagocytic means. For example, macrophages secrete *nitric oxide (NO),* a multipurpose chemical that is toxic to nearby microbes (see p. 346). As a more subtle means of destruction, neutrophils secrete **lactoferrin**, a protein that tightly binds with iron, making it unavailable for use by invading bacteria. Bacterial multiplication depends on high concentrations of available iron.

2. Several chemicals released by macrophages, namely **interleukin 1 (IL-1)**, **interleukin 6 (IL-6)**, and **tumor necrosis factor (TNF)** collectively act to bring about a diverse array of effects locally and throughout the body, all of which are geared toward defending the body against infection or tissue injury. They promote inflammation and are largely responsible for systemic (body-wide) manifestations, such as malaise (not feeling well), accompanying an infection. (*Tumor necrosis factor* was named for its first identified role in killing cancer cells.)

3. The same cytokine trio function together as **endogenous pyrogen (EP)**, which induces development of fever (*endogenous* means "from within the body"; *pyro* means "fire" or "heat"; *gen* means "production"). This response occurs especially when invading organisms have spread into the blood. Endogenous pyrogen causes release within the hypothalamus of *prostaglandins,* locally acting lipid signal molecules (see p. 119) that "turn up" the hypothalamic "thermostat" that regulates body temperature. The function of the resulting elevation in body temperature in fighting infection remains unclear. Fever is a common systemic manifestation of inflammation, suggesting the raised temperature plays an important beneficial role, as supported by recent evidence. Higher temperatures appear to augment phagocytosis, increase the rate of the many enzyme-dependent inflammatory activities, and interfere with bacterial multiplication by increasing bacterial requirements for iron. Resolving the controversial issue of whether a fever can be beneficial is extremely important, given the widespread use of drugs that suppress fever.

Clinical Note Although a mild fever may be beneficial, there is no doubt that an extremely high fever can be detrimental, particularly by harming the central nervous system. Young children, whose temperature-regulating mechanisms are not as stable as those of more mature individuals, occasionally have convulsions in association with high fevers.

4. IL-1, IL-6, and TNF also decrease the plasma concentration of iron by altering iron metabolism within the liver, spleen, and other tissues. This action reduces the amount of iron available to support bacterial multiplication.

5. Furthermore, the same three cytokines stimulate release of **acute phase proteins** from the liver. This collection of proteins, which have not yet been sorted out by scientists, exerts a multitude of wide-ranging effects associated with the inflammatory process, tissue repair, and immune cell activities. One of the better-known acute phase proteins is **C-reactive protein**, considered clinically as a blood-borne marker of inflammation (see p. 329). C-reactive protein serves as a nonspecific opsonin that binds to the surface of many kinds of bacteria.

6. TNF stimulates release of histamine from mast cells in the vicinity. Histamine, in turn, promotes the local vasodilation and increased capillary permeability of inflammation.

7. IL-1 enhances the proliferation and differentiation of both B and T lymphocytes, which, in turn, are responsible for antibody production and cell-mediated immunity, respectively.

8. *Granulocyte-macrophage colony–stimulating factor* from macrophages and other immune and nonimmune cells on the scene stimulates the bone marrow to synthesize and release neutrophils and monocytes–macrophages, an effect especially prominent in response to bacterial infections.

9. Still other phagocytic chemical mediators trigger both the clotting and anticlotting systems to first enhance the walling-off process and then facilitate gradual dissolution of the fibrin clot after it is no longer needed.

10. A chemical secreted by neutrophils, **kallikrein**, converts specific plasma protein precursors produced by the liver into ac-

tivated **kinins**. Activated kinins augment a variety of inflammatory events. For example, the end product of the kinin cascade, **bradykinin**, activates nearby pain receptors and thus partially produces the soreness associated with inflammation. Bradykinin also dilates blood vessels in the area, reinforcing the effects of histamine. In positive-feedback fashion, kinins also act as powerful chemotaxins to entice more neutrophils to join the battle.

This list of events augmented by phagocyte-secreted chemicals is not complete, but it illustrates the diversity and complexity of responses these mediators elicit. Furthermore, other important interactions between macrophages and lymphocytes that do not depend on release of chemicals from phagocytic cells are described later. Thus, the effect that phagocytes, especially macrophages, ultimately have on microbial invaders far exceeds their "engulf and destroy" tactics.

Tissue Repair The ultimate purpose of the inflammatory process is to isolate and destroy injurious agents and to clear the area for tissue repair. In some tissues (for example, skin, bone, and liver), the healthy organ-specific cells surrounding the injured area undergo cell division to replace the lost cells, often repairing the wound perfectly. In typically nonregenerative tissues such as nerve and muscle, however, lost cells are replaced by **scar tissue**. Connective-tissue fibroblasts start to divide rapidly in the vicinity and secrete large quantities of the protein collagen, which fills in the region vacated by the lost cells and results in the formation of scar tissue (see p. 60). Even in a tissue as readily replaceable as skin, scars sometimes form when complex underlying structures, such as hair follicles and sweat glands, are permanently destroyed by deep wounds.

Inflammation is an underlying culprit in many common, chronic illnesses.

Clinical Note Acute (short-term) inflammatory responses serve a useful purpose for eliminating pathogens from the body, but scientists are increasingly becoming aware that chronic (long-term), low-grade inflammation is a unifying theme for many chronic diseases. Chronic inflammation occurs when the triggering agent persists long term, either because it is not entirely eliminated or because it is constantly present or continually renewed. Chronic inflammation has an important role in Alzheimer's disease (p. 164), atherosclerosis and coronary artery disease (see p. 327), asthma (see p. 457), rheumatoid arthritis (see p. 420), obesity (see p. 623), diabetes (see p. 696), and possibly cancer, among other health problems. Collectively, these conditions are responsible for most morbidity (illness) and mortality (death). Reining in this underlying inflammation could have a huge effect on the quality and quantity of life for much of the world's population.

Nonsteroidal anti-inflammatory drugs and glucocorticoids suppress inflammation.

Clinical Note Many drugs can suppress inflammation; the most commonly used are the *nonsteroidal anti-inflammatory drugs,* or *NSAIDs* (aspirin, ibuprofen, and related compounds) and *glucocorticoids* (drugs similar to the steroid hormone cortisol, which is secreted by the adrenal cortex and exerts anti-inflammatory actions; see p. 674). For example, aspirin interferes with the inflammatory response by decreasing histamine release, thus reducing pain, swelling, and redness. Furthermore, aspirin reduces fever by inhibiting production of prostaglandins, the local mediators of endogenous pyrogen–induced fever.

Glucocorticoids, which are potent anti-inflammatory drugs, suppress almost every aspect of the inflammatory response. In addition, they destroy lymphocytes within lymphoid tissue and reduce antibody production. These therapeutic agents are useful for treating undesirable immune responses, such as allergic reactions (for example, poison ivy rash and asthma) and the inflammation associated with arthritis. However, by suppressing inflammatory and other immune responses that localize and eliminate bacteria, such therapy also reduces the body's ability to resist infection. For this reason, glucocorticoids should be used discriminatingly.

Other newer, more specialized classes of anti-inflammatory agents have recently appeared on the market, such as drugs that specifically inhibit TNF, such as adalimumab *(Humira)*. These new drugs are used, for example, in the treatment of rheumatoid arthritis.

Now let us shift from inflammation to interferon, another component of innate immunity.

Interferon transiently inhibits multiplication of viruses in most cells.

Interferon, a group of three related cytokines, is released from virus-infected cells and briefly provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells. Interferon was named for its ability to "interfere" with viral replication.

Antiviral Effect of Interferon When a virus invades a cell, the cell synthesizes and secretes interferon in response to being exposed to viral nucleic acid. Once released into the ECF from a virus-infected cell, interferon binds with receptors on the plasma membranes of healthy neighboring cells or even distant cells that it reaches through the blood, signaling these cells to prepare for possible viral attack. Interferon thus acts as a "whistle-blower," forewarning healthy cells of potential viral attack and helping them prepare to resist. Interferon does not have a direct antiviral effect; instead, it triggers production of virus-blocking enzymes by potential host cells. When interferon binds with these other cells, they synthesize enzymes that can break down viral messenger RNA (see p. 23) and inhibit protein synthesis. Both these processes are essential for viral replication. Although viruses are still able to invade these forewarned cells, the pathogens are unable to govern cellular protein synthesis for their own replication (▐ Figure 12-5).

The newly synthesized inhibitory enzymes remain inactive within the tipped-off potential host cell unless it is actually invaded by a virus, at which time the enzymes are activated by the presence of viral nucleic acid. This activation requirement protects the cell's own messenger RNA and protein-synthesizing machinery from unnecessary inhibition by these

enzymes should viral invasion not occur. Because activation can take place only during a limited time span, this is a short-term defense mechanism.

Interferon is released nonspecifically from any cell infected by any virus and, in turn, can induce temporary self-protective activity against many different viruses in any other cells that it reaches. Thus, it provides a general, rapidly responding defense strategy against viral invasion until more specific but slower-responding immune mechanisms come into play.

In addition to facilitating inhibition of viral replication, interferon reinforces other immune activities. For example, it enhances macrophage phagocytic activity, stimulates production of antibodies, and boosts the power of killer cells.

Anticancer Effects of Interferon Interferon exerts anticancer as well as antiviral effects. It markedly enhances the actions of cell-killing cells—the *natural killer cells,* the component of innate immunity we describe next—and a special type of T lymphocyte, *cytotoxic T cells*—that attack and destroy both virus-infected cells and cancer cells. Furthermore, interferon itself slows cell division and suppresses tumor growth.

Natural killer cells destroy virus-infected cells and cancer cells on first exposure to them.

Natural killer (NK) cells are naturally occurring, lymphocyte-like cells that nonspecifically destroy virus-infected cells and cancer cells by releasing chemicals that directly lyse the membranes of such cells on first exposure to them. NK cells recognize general features of virus-infected cells and cancer cells. Their mode of action and major targets are similar to those of cytotoxic T cells, but the latter can fatally attack only the specific types of virus-infected cells and cancer cells to which they have been previously exposed. Furthermore, after exposure cytotoxic T cells require a maturation period before they can launch their lethal assault. NK cells provide an immediate, non-

specific defense against virus-invaded cells and cancer cells before the more specific and abundant cytotoxic T cells become functional. Antibodies produced as part of the adaptive immune response enhance the killing action of NK cells.

The complement system punches holes in microorganisms.

The **complement system** is another defense mechanism brought into play nonspecifically in response to invading organisms. This system can be activated in two major ways (❙ Figure 12-6a):

1. By exposure to particular carbohydrate chains present on the surfaces of microorganisms but not found on human cells, a nonspecific innate immune response known as the **alternate complement pathway**

2. By exposure to antibodies produced against a specific foreign invader, an adaptive immune response known as the **classical complement pathway**

The system derives its name from its ability to "complement" the action of antibodies; it is the primary mechanism activated by antibodies to kill foreign cells. The complement system

❙Figure 12-5 **Mechanism of action of interferon in preventing viral replication.** Interferon, which is released from virus-infected cells, binds with other uninvaded host cells and induces these cells to produce inactive enzymes capable of blocking viral replication. The inactive enzymes are activated only if a virus subsequently invades one of these prepared cells.

FIGURE FOCUS: *Explain how interferon secreted by virus-infected cells transiently protects all cells against all kinds of viruses.*

Body Defenses | **413**

Alternate complement pathway: Binding directly to a foreign invader nonspecifically activates the complement cascade (an innate immune response).
Classical complement pathway: Binding to antibodies (Y-shaped molecules) produced against and attached to a particular foreign invader specifically activates the complement cascade (an adaptive immune response).

(a) Activation of complement system
Activated complement proteins C5, C6, C7, C8, and a number of C9s aggregate to form a porelike channel in the plasma membrane of the target cell. The resulting leakage leads to destruction of the cell.

(b) Formation of membrane attack complex

❘Figure 12-6 **Complement system.** (a) Activation of complement system via the alternate pathway and the classical pathway. (b) Formation of membrane attack complex of the complement system.

destroys cells by forming *membrane attack complexes* that punch holes in the victim cells. In addition to bringing about direct lysis of the invader, the complement cascade reinforces general inflammatory tactics.

Formation of the Membrane Attack Complex In the same mode as the clotting and anticlotting systems, the complement system consists of an interactive group of more than 30 plasma proteins that are produced by the liver and circulate in the blood in inactive form. Once the first component, C1, is activated, it activates the next component in the sequence, and so on (in the order of C4, C2, C3, then C5 through C9), in a cascade of activation reactions. The five final components, C5 through C9, assemble into a large, doughnut-shaped protein complex, the **membrane attack complex (MAC)**, which embeds itself in the surface membrane of nearby microorganisms, creating a large channel through the membrane (❘Figure 12-6b). In other words, the parts make a hole. This hole-punching technique makes the membrane extremely leaky; the resulting osmotic flux of water into the victim cell causes it to swell and burst. Membrane attack complexes can be formed and lyse a microbe within 30 seconds. Such complement-induced lysis is the major means of directly killing microbes without phagocytizing them.

Augmenting Inflammation Unlike the other cascade systems, in which the sole function of the various components

leading up to the end step is activation of the next precursor in the sequence, several activated proteins in the complement cascade additionally act on their own to augment the inflammatory process by the following methods:

- *Serving as chemotaxins,* which attract and guide professional phagocytes to the site of complement activation (that is, the site of microbial invasion)
- *Acting as opsonins* by binding with microbes and thereby enhancing their phagocytosis
- *Promoting vasodilation and increased vascular permeability,* thus increasing blood flow to the invaded area
- *Stimulating release of histamine* from mast cells in the vicinity, which in turn enhances the local vascular changes characteristic of inflammation
- *Activating kinins,* which further reinforce inflammation

Several activated components in the cascade are very unstable, being able to activate the next component in the sequence for less than 0.1 millisecond before assuming an inactive form. Because these unstable components can carry out the sequence only in the immediate area in which they are activated before they decompose, the complement attack is confined to the surface membrane of the microbe whose presence initiated activation of the system. Nearby host cells are thus spared from lytic attack. However, abnormal complement activity has been impli-

cated in a number of diseases, including osteoarthritis and age-related macular degeneration (see p. 200).

This completes our discussion of innate immunity. Before turning to adaptive immunity, we draw attention to recently found immune effector cells that blur the boundary between innate and adaptive immunity.

Newly discovered immune cells straddle innate and adaptive defenses.

In recent years scientists have identified new immune cell types that have characteristics belonging to both branches of the immune system. For example, **innate lymphoid cells (ILCs)** are innate mirror images of *helper T cells,* a specialized class of adaptive-system T lymphocytes that spurs other immune cells into action. The always-ready ILCs swiftly but less powerfully perform many of the same duties as the slower but stronger tailor-made helper T cells. In the opposite direction, **innate response activator (IRA) B cells** from the adaptive system recognize bacteria by means of TLRs and act quickly to carry out functions that overlap with the innate system, such as producing cytokines that activate other innate immune cells. By contrast, typical B cells do not respond to TLRs and act slowly to produce antibodies.

Check Your Understanding 12.2

1. List and briefly describe the four types of innate defense.
2. Define *chemotaxin* and *opsonin.*
3. Describe the formation and function of a membrane attack complex.

12.3 Adaptive Immunity: General Concepts

A specific adaptive immune response is a selective attack aimed at limiting or destroying a particular offending target for which the body has been specially prepared after exposure to it.

Adaptive immune responses include antibody-mediated immunity and cell-mediated immunity.

There are two classes of adaptive immune responses: **antibody-mediated**, or **humoral**, **immunity**, involving production of antibodies by B lymphocyte derivatives known as *plasma cells,* and **cell-mediated immunity**, involving production of *activated T lymphocytes,* which directly attack unwanted cells. (The term *humoral immunity* is a reference to the ancient Greek classification of body fluids into four *humors,* blood being one of them. Antibodies responsible for humoral immunity are carried by the blood.)

Lymphocytes can specifically recognize and selectively respond to an almost limitless variety of foreign agents, as well as cancer cells. The recognition and response processes are dif-

ferent in B and in T cells. B cells recognize free-existing foreign invaders such as bacteria and their toxins and a few viruses, which they combat by secreting antibodies specific for the invaders. T cells specialize in recognizing and destroying body cells gone awry, including virus-infected cells and cancer cells. Before we examine each of these processes in detail, we explore the different life histories of B and T cells.

Origins of B and T Cells Both types of lymphocytes, like all blood cells, are derived from common stem cells in the bone marrow (see ❚ Figure 11-9, p. 394). Whether a lymphocyte and all its progeny are destined to be B or T cells depends on the site of final differentiation and maturation of the original cell in the lineage (❚ Figure 12-7). B cells differentiate and mature in the bone marrow. As for T cells, during fetal life and early childhood, some immature lymphocytes from the bone marrow migrate through the blood to the thymus, where they undergo further processing to become T lymphocytes (named for their site of maturation). The **thymus** is a lymphoid tissue located
❚ **Figure 12-7 Origins of B and T cells.** B cells are derived from lymphocytes that matured and differentiated in the bone marrow, whereas T cells are derived from lymphocytes that originated in the bone marrow but matured and differentiated in the thymus. After early childhood, new B and T cells are produced primarily by colonies of B and T cells established in peripheral lymphoid tissues during fetal life and early childhood.

midline within the chest cavity above the heart in the space between the lungs (see ❙Figure 12-1, p. 406).

On being released into the blood from either the bone marrow or the thymus, mature B and T cells take up residence and establish lymphocyte colonies in the peripheral lymphoid tissues. Here, on appropriate stimulation, they undergo cell division to produce new generations of either B or T cells, depending on their ancestry. After early childhood, most new lymphocytes are derived from these peripheral lymphocyte colonies rather than from the bone marrow.

Each of us has an estimated 2 trillion lymphocytes, which, if aggregated in a mass, would be about the size of the brain. At any one time, most of these lymphocytes are concentrated in the various strategically located lymphoid tissues, but both B and T cells continually circulate among the lymph, blood, and body tissues, where they remain on constant surveillance.

Role of Thymosin Because most of the migration and differentiation of T cells occurs early in development, the thymus gradually atrophies and becomes less important as a person matures. It does, however, continue to produce **thymosin**, a hormone important in maintaining the T-cell lineage. Thymosin enhances proliferation of new T cells within the peripheral lymphoid tissues and augments the immune capabilities of existing T cells. Thymosin secretion starts to decline after about 30 to 40 years of age. Scientists speculate that diminishing T-cell capacity with advancing age may be linked to increased susceptibility to viral infections and cancer because T cells play an especially important role in defense against viruses and cancer.

Let us now see how lymphocytes detect their selected target.

An antigen induces an immune response against itself.

Both B and T cells must be able to specifically recognize unwanted cells and other material to be destroyed as being distinct from the body's normal cells. The presence of antigens enables lymphocytes to make this distinction. An **antigen** is a large, unique molecule that triggers a specific immune response against itself, such as generation of antibodies that lead to its destruction, when it gains entry into the body (*antigen* means *anti*body *gen*erator, although some antigens trigger cell-mediated immune responses instead of antibody production). In general, the more complex a molecule is, the greater its antigenicity. Foreign proteins are the most common antigens because of their size and structural complexity, although other macromolecules, such as large

polysaccharides (carbohydrates) and lipids (fats), can also act as antigens. Antigens may exist as isolated molecules, such as bacterial toxins, or they may be an integral part of a multimolecular structure, as when they are on the surface of an invading foreign microbe.

We'll first see how B cells respond to their targeted antigen, after which we'll look at T cells' response to their antigen.

<div style="border:1px solid green; padding:8px;">

12.4 B Lymphocytes: Antibody-Mediated Immunity

Each B and T cell has receptors—**B-cell receptors (BCRs)** and **T-cell receptors (TCRs)**—on its surface for binding with one particular type of the multitude of possible antigens (❙Figure 12-8). These receptors are the "eyes of the adaptive immune system," although a given lymphocyte can "see" only one unique antigen. This is in contrast to the TLRs of the innate effector cells, which recognize generic "trademarks" found on the surface of all microbial invaders.

(a) B-cell receptor (BCR)

(b) T-cell receptor (TCR)
❙**Figure 12-8** **B-cell and T-cell receptors.**

The antigens to which B cells respond can be T-independent or T-dependent.

T-independent antigens stimulate production of antibody without any assistance from T cells. For example, B cells can bind with and be directly activated by T-independent polysaccharide antigens without T-cell help. By contrast, **T-dependent antigens**, which are typically protein antigens, do not directly stimulate production of antibody without the help of a *helper T cell.* Most antigens to which B cells respond are T-dependent antigens. For now we will consider activation of B cells by binding with antigen without regard to whether helper T cells must be present. We will discuss how helper T cells are involved in the response of B cells to T-dependent antigens when we consider the different types of T cells later.
(a) Unactivated B cell

Endoplasmic reticulum

(b) Plasma cell

Figure 12-9 Comparison of an unactivated B cell and a plasma cell. Electron micrographs at the same magnification of (a) an unactivated B cell, or small lymphocyte, and (b) a plasma cell. A plasma cell is an activated B cell. It is filled with an abundance of rough endoplasmic reticulum distended with antibody molecules.

Antigens stimulate B cells to convert into plasma cells that produce antibodies.

When BCRs (Figure 12-8a) bind with an antigen, most B cells differentiate into active *plasma cells,* whereas others become dormant *memory cells.* We first examine the role of plasma cells and their antibodies and then later in the chapter turn attention to memory cells.

Plasma Cells A **plasma cell** produces **antibodies** that can combine with the specific type of antigen that stimulated activation of the plasma cell. During differentiation into a plasma cell, a B cell swells as the rough endoplasmic reticulum (the site for synthesis of proteins to be exported; see p. 25) greatly expands (Figure 12-9). Because antibodies are proteins, plasma cells essentially become prolific protein factories, producing up to 2000 antibody molecules per second. So great is the commitment of a plasma cell's protein-synthesizing machinery to antibody production that it cannot maintain protein synthesis for its own viability and growth. Consequently, it dies after a brief (5- to 7-day), highly productive life span.

Antibody Subclasses Antibodies (also known as γ *globulins* or *immunoglobulins*; see p. 383) are grouped into five subclasses based on differences in their biological activity:

- **IgM** serves as the BCR for antigen attachment and is produced in the early stages of plasma cell response.
- **IgG**, the most abundant immunoglobulin in the blood, is produced and secreted copiously when the body is subsequently re-exposed to the same antigen. IgG produces most specific immune responses against bacterial invaders.
- **IgE** helps protect against parasitic worms and is the antibody mediator for common allergic responses, such as hay fever, asthma, and hives.

- **IgA** is found in secretions of the digestive, respiratory, and urogenital (urinary and reproductive) systems and in milk and tears.
- **IgD** is present on the surface of many B cells, but its function is unclear.

Recognize that within each of these five functional subclasses are millions of different antibodies, each able to bind with only one specific antigen.

Antibodies are Y shaped and classified according to properties of their tail portion.

Antibodies of all five subclasses are composed of four interlinked polypeptide chains—two long, heavy chains and two short, light chains—arranged in the shape of a Y (Figure 12-10). Characteristics of the arm regions of the Y determine the *specificity* of the antibody (that is, with what antigen the antibody can bind). Properties of the tail portion of the antibody determine the *functional properties* of the antibody (what the antibody does once it binds with an antigen).

An antibody has two identical antigen-binding sites, one at the tip of each arm. These **antigen-binding fragments (Fab)** are unique for each antibody, so each antibody can interact only with an antigen that specifically matches it, much like a lock and key. The tremendous variation in the antigen-binding fragments of different antibodies leads to the extremely large number of unique antibodies that can bind specifically with only one of millions of different antigens.

In contrast to these variable Fab regions at the arm tips, the tail portion of every antibody within each immunoglobulin subclass is identical. The tail, the antibody's **constant (Fc) region**, contains binding sites for particular mediators of antibody-induced activities, which vary among the subclasses.
Figure 12-10 Antibody structure. An antibody is Y-shaped. It is able to bind only with the specific antigen that "fits" its antigen-binding sites (Fab) on the arm tips. The tail region (Fc) binds with particular mediators of antibody-induced activities.

In fact, differences in the constant region are the basis for distinguishing among the immunoglobulin subclasses. For example, the constant tail region of IgG antibodies, when activated by antigen binding in the Fab region, binds with phagocytic cells and serves as an opsonin to enhance phagocytosis. In comparison, the constant tail region of IgE antibodies attaches to mast cells and basophils, even in the absence of antigens. When the appropriate antigen gains entry to the body and binds with the attached antibodies, this triggers the release of histamine from the affected mast cells and basophils. Histamine, in turn, induces the allergic manifestations that follow.

Antibodies largely amplify innate immune responses to promote antigen destruction.

Antibodies cannot directly destroy foreign organisms or other unwanted materials on binding with antigens on their surfaces. Instead, they exert their protective influence by physically hindering antigens or, more commonly, by amplifying innate immune responses.

Physical Hindrance of an Antigen Through neutralization and agglutination, antibodies can physically hinder some antigens from exerting their detrimental effects.

■ In **neutralization**, antibodies combine with bacterial toxins, preventing these harmful chemicals from interacting with susceptible cells. Similarly, antibodies can neutralize some types of viruses by binding with their surface antigens and preventing these viruses from entering cells, where they could exert their damaging effects.

■ In **agglutination**, multiple antibody molecules cross-link numerous antigen molecules into chains or lattices of antigen–antibody complexes (∎Figure 12-11a). Through this means, foreign cells, such as bacteria or mismatched transfused red blood cells, bind together in a clump (see p. 389). When soluble antigens such as tetanus toxin are involved instead of foreign cells that can clump together, the dissolved antigen–antibody lattices become so large that they *precipitate* (separate from solution).

Within the body, these physical hindrance mechanisms play only a minor protective role against invading agents. *Clinical Note* However, the tendency for certain antigens to agglutinate or precipitate on forming large complexes with antibodies specific for them is useful for detecting the presence of particular antigens or antibodies. Pregnancy diagnosis tests, for example, use this principle to detect, in urine, the presence of a hormone secreted soon after conception.

Amplification of Innate Immune Responses The most important function of antibodies is to profoundly augment the innate immune responses already initiated by the invaders. Antibodies mark foreign material as targets for actual destruction by the complement system, phagocytes, or NK cells as follows:

1. *Activating the complement system.* When an appropriate antigen binds with an antibody, receptors on the tail portion of the antibody bind with and activate C1, the first component of the complement system. This sets off the cascade of events leading to formation of the membrane attack complex, which is specifically directed at the membrane of the invading cell that bears the antigen that initiated the activation process (∎Figure 12-11b). Antibodies are the most powerful activators of the complement system (the classical complement pathway). The biochemical attack subsequently unleashed against the invader's membrane is the most important means by which antibodies exert their protective influence. Furthermore, various activated complement components enhance every aspect of inflammation. The same complement system is activated by an antigen–antibody complex regardless of the type of antigen. Although binding of antigen to antibody is highly specific, the outcome, which is determined by the antibody's constant tail region, is identical for all activated antibodies within a given subclass; for example, all IgG antibodies activate the same complement system.

2. *Enhancing phagocytosis.* Antibodies, especially IgG, act as opsonins. The tail portion of an antigen-bound IgG antibody binds with a receptor on the surface of a phagocyte and subsequently promotes phagocytosis of the antigen-containing victim attached to the antibody (∎Figure 12-11c).

3. *Stimulating NK cells.* Binding of antibody to antigen also induces attack of the antigen-bearing target cell by NK cells. NK cells have receptors for the constant tail portion of antibodies. In this case, when the target cell is coated with antibodies, the tail portions of the antibodies link the target cell to NK cells, which destroy the target cell by releasing chemicals that lyse its plasma membrane (∎Figure 12-11d). This process is known as **antibody-dependent cellular cytotoxicity (ADCC).**

❙Figure 12-11 **How antibodies help eliminate invading microbes.** Antibodies may physically hinder antigens, such as through neutralization or (a) agglutination. More commonly, antibodies amplify innate immune responses by (b) activating the complement system, (c) enhancing phagocytosis by acting as opsonins, and (d) stimulating natural killer cells.
FIGURE FOCUS: *A friend has bacterial pneumonia. Describe three means by which antibodies against the causative microorganism indirectly lead to destruction of the bacteria.*

By amplifying other nonspecific lethal defenses in these ways, antibodies, although unable to directly destroy invading bacteria or other undesirable material, bring about destruction of the antigens to which they are specifically attached.

Clinical Note **Immune Complex Disease** Occasionally, an over-zealous antigen–antibody response inadvertently causes damage to normal cells, as well as to invading foreign cells. Typically, antigen–antibody complexes, formed in response to foreign invasion, are removed by phagocytic cells after having revved up nonspecific defense strategies. If large numbers of these complexes are continuously produced, how-

ever, the phagocytes cannot clear away all the immune complexes formed. Antigen–antibody complexes that are not removed continue to activate the complement system, among other things. Excessive amounts of activated complement and other inflammatory agents may "spill over," damaging the surrounding normal cells, as well as the unwanted cells. Furthermore, destruction is not necessarily restricted to the initial site of inflammation. Antigen–antibody complexes may circulate freely and become trapped in the kidneys, joints, brain, small vessels of the skin, and elsewhere, causing widespread inflammation and tissue damage. Such damage produced by immune complexes is referred to as an **immune complex disease**, which

Body Defenses | **419**

can be a complicating outcome of bacterial, viral, or parasitic infection.

More insidiously, immune complex disease can stem from overzealous inflammatory activity prompted by immune complexes formed by "self-antigens" (proteins synthesized by the person's body) and antibodies erroneously produced against them. *Rheumatoid arthritis* develops in this way.

Clonal selection accounts for the specificity of antibody production.

Consider the diversity of foreign molecules a person can potentially encounter during a lifetime. Despite this, each B cell is preprogrammed to respond to only 1 of probably more than 100 million different antigens. Other antigens cannot combine with the same B cell and induce it to secrete different antibodies. The astonishing implication is that each of us is equipped with about 100 million kinds of preformed B lymphocytes, at least one "matching" B lymphocyte for every possible antigen that we might ever encounter.

Early researchers in immunologic theory believed antibodies were "made to order" whenever a foreign antigen gained entry to the body. In contrast, the currently accepted **clonal selection theory** proposes that diverse B lymphocytes are produced during fetal development, each capable of synthesizing an antibody against a particular antigen before ever being exposed to it. All offspring of a particular ancestral B lymphocyte form a family of identical cells, or a **clone**, committed to producing the same specific antibody. B cells remain dormant, not actually secreting their particular antibody product or undergoing rapid division until (or unless) they come into contact with the appropriate antigen. Lymphocytes that have not yet been exposed to their specific antigen are known as **naive lymphocytes**. When an antigen gains entry to the body, the particular clone of B cells that bear receptors (BCRs) on their surface uniquely specific for that antigen is activated or "selected" by the antigen binding with the BCRs, hence the term *clonal selection theory* (❙Figure 12-12).

The first antibodies produced by a newly formed B cell are IgM immunoglobulins, which are inserted into the cell's plasma membrane rather than secreted. Here they serve as BCRs for binding with a specific kind of antigen, almost like "advertisements" for the kind of antibody that the cell can produce. Binding of the appropriate antigen to a B cell amounts to "placing an order" for the manufacture and secretion of large quantities of that particular antibody.
❙Figure 12-12 **Clonal selection theory.** The B-cell clone specific to the antigen proliferates and differentiates into plasma cells and memory cells. Plasma cells secrete antibodies that bind with free antigen not attached to B cells. Memory cells are primed and ready for subsequent exposure to the same antigen.

Selected clones differentiate into active plasma cells and dormant memory cells.

Antigen binding causes the activated B-cell clone to multiply (the clone expands at the rate of two to three cell divisions per day) and differentiate into two cell types—the previously described plasma cells and memory cells, which we focus on next. Most progeny are transformed into active plasma cells, which are prolific producers of customized antibodies that contain the same antigen-binding sites as the surface receptors. However, plasma cells switch to producing IgG antibodies, which are secreted rather than remaining membrane bound. In the blood, the secreted antibodies combine with the invading, free extracellular antigen (such as on the surface of a bacterium), marking it for destruction by the complement system, phagocytic ingestion, or NK cells.

Memory Cells Not all new B lymphocytes produced by the specifically activated clone differentiate into short-lived antibody-secreting plasma cells. A small proportion become long-lived **memory cells**, which do not participate in the current immune attack against the antigen but instead remain

dormant and expand this specific clone. If the person is ever re-exposed to the same antigen, these memory cells are primed and ready for even more immediate action than the original lymphocytes in the clone were.

Even though each of us has essentially the same original pool of different naive B-cell clones, the pool gradually becomes appropriately biased to respond most efficiently to each person's particular antigenic environment. Those clones specific for antigens to which a person is never exposed remain dormant for life, whereas those specific for antigens in the individual's environment typically become expanded and enhanced by forming highly responsive memory cells. The different naive clones provide protection against new pathogens, and the evolving populations of memory cells protect against the recurrence of infections encountered in the past.

I Figure 12-13 Primary and secondary immune responses. (a) Primary response on first exposure to a microbial antigen. (b) Secondary response on subsequent exposure to the same microbial antigen. The primary response does not peak for a couple of weeks, whereas the secondary response peaks in a week. The magnitude of the secondary response is 100 times that of the primary response.

Primary and Secondary Responses During initial contact with a microbial antigen, the antibody response is delayed for several days until plasma cells are formed and does not reach its peak for a couple of weeks. This response is known as the **primary response**, which is mediated by IgM antibodies (I Figure 12-13a). Meanwhile, symptoms characteristic of the particular microbial invasion persist until either the invader succumbs to the mounting specific immune attack against it or the infected person dies. After reaching the peak, the antibody levels gradually decline over time. If the same antigen ever reappears, the long-lived memory cells launch a more rapid, more potent, and longer-lasting **secondary response** than occurred during the primary response (I Figure 12-13b). This swifter, more powerful immune attack, which is mediated by IgM antibodies, is frequently adequate to prevent overt infection on subsequent exposures to the same microbe, forming the basis of long-term immunity against a specific disease.

Clinical Note The original antigenic exposure that induces the formation of memory cells can occur through the person either having the disease or being vaccinated. **Vaccination (immunization)** deliberately exposes the person to a pathogen that has been stripped of its disease-inducing capability (that is, the pathogen is *attenuated*) but that can still induce antibody formation against itself. (For the early history of vaccination development, see the boxed feature on p. 422, I Concepts, Challenges, and Controversies.)

Active immunity is self-generated; passive immunity is "borrowed."

The production of antibodies as a result of exposure to an antigen is referred to as **active immunity** against that antigen. A second way in which an individual can acquire antibodies is by direct transfer of antibodies actively formed by another person (or animal). The immediate "borrowed" immunity conferred on receipt of preformed antibodies is known as **passive immunity**. Such transfer of antibodies of the IgG class normally

occurs from the mother to the fetus across the placenta during intrauterine development. In addition, a mother's colostrum (first milk) contains IgA antibodies that provide further protection for breast-fed babies. Passively transferred antibodies are usually broken down in less than a month, but meanwhile the newborn is provided important immune protection (essentially the same as the mother's) until he or she can begin actively mounting immune responses. Antibody-synthesizing ability does not develop for about a month after birth.

Clinical Note Passive immunity is sometimes used clinically to provide immediate protection or to bolster resistance against an extremely virulent infectious agent or potentially lethal toxin to which a person has been exposed (for example, rabies virus, tetanus toxin in nonimmunized individuals, and poisonous snake venom). The administered preformed antibodies are harvested from another source (often nonhuman) that has been exposed to an attenuated form of the antigen. Frequently, horses or sheep are used in the deliberate production of antibodies to be collected for passive immunizations. Although injection of serum containing these antibodies (**antiserum** or **antitoxin**) is beneficial in providing immediate protection against the specific disease or toxin, the recipient may develop an immune response against the injected antibodies themselves because they are foreign proteins. The result may be a severe allergic reaction to the treatment, a condition known as **serum sickness**.

The huge repertoire of B cells is built by reshuffling a small set of gene fragments.

How is it possible for each person to have such a tremendous diversity of B lymphocytes that all individuals (with healthy immune systems) have the ability to produce specific antibodies against every one of the 100 million different antigens that we potentially might encounter? Antibodies are proteins synthesized in accordance with a nuclear DNA blueprint. Because all cells of the body, including the antibody-producing cells,

Vaccination: A Victory Over Many Dreaded Diseases

MODERN SOCIETY HAS COME TO hope and even expect that vaccines can be developed to protect us from almost any dreaded infectious disease. This expectation has been brought into sharp focus by our current frustration over the inability to date to develop a successful vaccine against HIV, the virus that causes AIDS.

Nearly 2500 years ago, our ancestors were aware of the existence of immune protection. Writing about a plague that struck Athens in 430 BC, Thucydides observed that the same person was never attacked twice by this disease. However, the ancients did not understand the basis of this protection, so they could not manipulate it to their advantage.

Early attempts to deliberately acquire lifelong protection against smallpox, a dreaded disease that was highly infectious and frequently fatal (up to 40% of the sick died), consisted of intentionally exposing oneself by coming into direct contact with a person suffering from a milder form of the disease. The hope was to protect against a future fatal bout of smallpox by deliberately inducing a mild case of the disease. By the beginning of the 17th century, this technique had evolved into using a needle to extract small amounts of pus from active smallpox pustules (the f uid-filled bumps on the skin, which leave a characteristic depressed scar or "pock" mark after healing) and introducing this infectious material into healthy individuals. This inoculation process was done by applying the pus directly to slight cuts in the skin or by inhaling dried pus.

Edward Jenner, an English physician, was the first to demonstrate that immunity against cowpox, a disease similar to but less serious than smallpox, could also protect humans against smallpox. Having observed that milkmaids who got cowpox seemed to be protected from smallpox, Jenner in 1796 inoculated a healthy boy with pus he had extracted from cowpox boils (*vacca,* as in *vaccination,* means

"cow"). After the boy recovered, Jenner (not being restricted by modern ethical standards of research on human subjects) deliberately inoculated him with what was considered a normally fatal dose of smallpox infectious material. The boy survived.

Jenner's results were not taken seriously, however, until a century later when, in the 1880s, Louis Pasteur, the first great experimental immunologist, extended Jenner's technique. Pasteur demonstrated that the disease-inducing capability of organisms could be greatly reduced (attenuated) so that they could no longer produce disease but would still induce antibody formation when introduced into the body—the basic principle of modern vaccines. His first vaccine was against anthrax, a deadly disease of sheep and cows. Pasteur isolated and heated anthrax bacteria and then injected these attenuated organisms into a group of healthy sheep. A few weeks later, at a gathering of fellow scientists, Pasteur injected these vaccinated sheep and a group of unvaccinated sheep with fully potent anthrax bacteria. The result was dramatic—all the vaccinated sheep survived, but all the unvaccinated sheep died. Pasteur's notorious public demonstrations such as this, coupled with his charismatic personality, caught the attention of physicians and scientists of the time, sparking the development of modern immunology.

Today preventive vaccines save an estimated 3 million lives annually. Now scientists are striving to develop therapeutic vaccines aimed not at preventing disease but at squelching established diseases and addictions. New kinds of vaccines at various stages of development include those for the following conditions: cancer, coronary artery disease (by targeting LDL, the "bad" cholesterol); allergies; obesity (by targeting ghrelin, the "hunger hormone"); and addictions, such as for nicotine and cocaine.

---

contain the same nuclear DNA, it is hard to imagine how enough DNA could be packaged within the nuclei of every cell to code for the 100 million different antibodies (a different portion of the genetic code being used by each B-cell clone), along with all the other genetic instructions used by other cells. Actually, only a relatively small number of gene fragments code for antibody synthesis, but during B-cell development these fragments are cut, reshuffled, and spliced in a vast number of different combinations. Each different combination gives rise to a unique B-cell clone. Antibody genes of already-formed B cells are later even further diversified by mutations, to which the region that codes for the antibody's variable antigen-binding sites are highly prone. Each different mutant cell in turn gives rise to a new clone. In this way, a huge antibody repertoire is possible using only a modest share of the genetic blueprint.

We now turn our attention to T cells.

12.5 T Lymphocytes: Cell-Mediated Immunity

As important as B lymphocytes and their antibody products are in specific defense against invading bacteria and other foreign material, they represent only half of the body's specific immune

defenses. The T lymphocytes are equally important in defense against most viral infections and also play an important regulatory role in immune mechanisms.

T cells bind directly with their targets.

Whereas B cells defend against conspicuous invaders in the ECF, T cells defend against covert invaders that hide inside cells where antibodies and the complement system cannot reach them. Unlike B cells, which secrete antibodies that can attack antigens at long distances, T cells must directly contact their targets, a process known as *cell-mediated immunity*. T cells of the killer type release chemicals that destroy the targeted cells they contact, such as virus-infected cells and cancer cells.

Like B cells, T cells are clonal and exquisitely antigen specific. On its plasma membrane, each T cell bears unique receptor proteins called *T-cell receptors (TCRs)*, similar although not identical to the surface receptors on B cells (see ▐ Figure 12-8b, p. 416). Immature lymphocytes acquire their TCRs in the thymus during their differentiation into T cells. Unlike B cells, T cells are activated by a foreign antigen only when it is on the surface of a cell that also carries a marker of the individual's identity; that is, both foreign antigens and **self-antigens** known as **major histocompatibility complex (MHC) molecules** must be on a cell's surface before a T cell can bind with it. During thymic education, T cells learn to recognize foreign antigens only in combination with the person's own tissue antigens—a lesson passed on to all T cells' future progeny. The importance of this dual antigen requirement and the nature of the MHC self-antigens are described shortly.

A delay of a few days generally follows exposure to the appropriate antigen before **activated T cells** are prepared to launch a cell-mediated immune attack. When exposed to a specific antigen combination, cells of the complementary T-cell clone proliferate and differentiate for several days, yielding large numbers of activated effector T cells that carry out various cell-mediated responses.

Like B cells, T cells form a memory pool and display both primary and secondary responses. Primary responses tend to be initiated in the lymphoid tissues. During a few-week period after the infection is cleared, more than 90% of the huge number of effector T cells generated during the primary response die by means of *apoptosis* (cell suicide; see p. 42). To stay alive, activated T lymphocytes require the continued presence of their specific antigen and appropriate stimulatory signals. Once the foe succumbs, most of the now superfluous T lymphocytes commit suicide because their supportive antigen and stimulatory signals are withdrawn. Elimination of most of the effector T cells following a primary response is essential to prevent congestion in the lymphoid tissues. (Such paring down is not needed for B cells—those that become plasma cells and not memory B cells on antigen stimulation rapidly work themselves to death producing antibodies.) The remaining surviving effector T cells become long-lived memory T cells that migrate to all areas of the body, where they are poised for a swift secondary response to the same pathogen in the future.

The three types of T cells are cytotoxic, helper, and regulatory T cells.

The three subpopulations of T cells can be designated in two ways: by their roles when activated by an antigen or by specific proteins associated with their outer membrane. By role, the three types of T cells are *cytotoxic T cells, helper T cells,* and *regulatory T cells.* By specific membrane protein type, these same cells are *CD8+ T cells, CD4+ T cells,* and *CD4+CD25+ T cells,* respectively. The various types of immune cells each have an assortment of specific immune-related surface membrane proteins given official *cluster designation (CD) numbers* that help characterize them.

■ **Cytotoxic**, or **killer**, **T cells** destroy host cells harboring anything foreign and thus bearing a foreign antigen, such as body cells invaded by viruses, cancer cells that have mutated proteins resulting from malignant transformations, and transplanted cells. The T-cell receptors for cytotoxic T cells are associated with **coreceptors** designated CD8, which are inserted into the plasma membrane as these cells pass through the thymus. Therefore, these cells are also known as **CD8+ T cells**.

■ **Helper T cells** do not directly participate in immune destruction of invading pathogens. Instead, they modulate activities of other immune cells. Because of the important role they play in "turning on" the full power of all the other activated lymphocytes and macrophages, helper T cells constitute the immune system's "master switch." Helper T cells are by far the most numerous T cells, making up 60% to 80% of circulating T cells. The T-cell receptors for helper T cells are associated with coreceptors designated CD4. Accordingly, helper T cells are also called **CD4+ cells**.

■ **Regulatory T cells (T$_{regs}$)** are a recently identified small subset of CD4+ cells. They have the same CD4 coreceptors as helper T cells, but in addition they also have CD25, a component of a receptor for IL-2, which promotes T$_{reg}$ activities. Thus, these cells are also called **CD4+CD25+ T cells**.

We now further examine these T cell types.

Cytotoxic T cells secrete chemicals that destroy target cells.

Cytotoxic T cells are microscopic "hit men." The targets of these destructive cells most frequently are host cells infected with viruses. When a virus invades a body cell, as it must to survive (▐ Figure 12-14, step ❶), the cell breaks down the envelope of proteins surrounding the virus and loads a fragment of this viral antigen piggyback onto a newly synthesized MHC self-antigen. This self-antigen–viral antigen complex is inserted into the host cell's surface membrane, where it serves as a red flag indicating the cell is harboring the invader (step ❷). To attack the intracellular virus, cytotoxic T cells must destroy the infected host cell in the process. Cytotoxic T cells of the clone specific for this particular virus recognize and bind to the viral antigen and self-antigen on the surface of an infected cell (step ❸). Thus activated by the viral antigen, a cytotoxic T cell can kill the infected cell by either direct or indirect means, depending

4 Cytotoxic T cell releases chemicals that destroy the attacked cell before the virus can enter its nucleus and start to replicate.

❙Figure 12-14 **A cytotoxic T cell lysing a virus-invaded cell.**

on the type of lethal chemicals the activated T cell releases. Let us elaborate.

■ An activated cytotoxic T cell may directly kill the victim cell by releasing chemicals that lyse the attacked cell before viral replication can begin (step ❹). Specifically, cytotoxic T cells, as well as NK cells, destroy a targeted cell by releasing **perforin** molecules, which penetrate the target cell's surface membrane and join to form porelike channels (❙Figure 12-15). This technique of killing a cell by punching holes in its membrane is similar to the method employed by the membrane attack complex of the complement cascade. This contact-dependent mechanism of killing has been nicknamed the "kiss of death."

■ A cytotoxic T cell can also indirectly bring about death of an infected host cell by releasing **granzymes**, which are enzymes similar to digestive enzymes. Granzymes enter the target cell through the perforin channels. Once inside, these chemicals trigger the virus-infected cell to self-destruct through apoptosis.

The virus released on destruction of the host cell by either of these methods is directly destroyed in the ECF by phagocytic cells, neutralizing antibodies, and the complement system. Meanwhile, the cytotoxic T cell, which has not been harmed in the process, can move on to kill other infected host cells. Recall that other defense mechanisms including interferon and NK cells also come into play to combat viral infections. As usual, an intricate interplay exists among the immune defenses that are launched against viruses, as summarized in ❙Table 12-2.

When virus-infected cells are destroyed, surrounding healthy cells replace the lost cells by means of cell division. Usually, to halt a viral infection, only some of the host cells must be destroyed. If the virus has had a chance to multiply, however, with replicated virus leaving the original cell and spreading to other host cells, the cytotoxic T-cell defense mechanism may sacrifice so many of the host cells that serious malfunction may ensue.

Hybrid Natural Killer T Cells A recently discovered subclass of cytotoxic T cells, **natural killer T (NKT) cells**, have properties of both NK cells and cytotoxic T cells. Constituting only 0.2% of all circulating T cells, the hybrid NKT cells have both NK-cell markers and T-cell receptors and thus are another cell type that sits at the crossroads of innate and adaptive immunity. Scientists are scrambling to identify the physiological roles of these multifunctional cells. They seem to be important in suppression of autoimmunity (erroneous production of antibodies against self-antigens) and in tumor rejection.

Defense in the Nervous System The usual method of destroying virus-infected host cells is not appropriate for the nervous system. If cytotoxic T cells destroyed virus-infected neurons, the lost cells could not be replaced because neurons cannot reproduce. Fortunately, virus-infected neurons are spared from extermination by the immune system, but how, then, are neurons protected from viruses? Immunologists long thought that the only antiviral defenses for neurons were those aimed at free viruses in the ECF. Surprising new research has revealed, however, that antibodies not only target viruses for destruction in the ECF but can also eliminate viruses inside neurons. It is unclear whether antibodies actually enter the
1 Killer cell binds to its target.

2 As a result of binding, killer cell's perforin-containing granules fuse with plasma membrane.

3 Granules disgorge their perforin by exocytosis into a small pocket of intercellular space between killer cell and its target.

4 On exposure to Ca^{2+} in this space, individual perforin molecules change from spherical to cylindrical shape.

5 Remodeled perforin molecules bind to target cell membrane and insert into it.

6 Individual perforin molecules group together like staves of a barrel to form pores.

7 Pores admit salt and H_2O, causing target cell to swell and burst.
(a) Details of the killing process for cytotoxic T cells and NK cells
(b) Enlargement of perforin-formed pores in a target cell

ıFigure 12-15 Mechanism of killing by killer cells.

---

neurons and interfere directly with viral replication (neurons have been shown to take up antibodies near their synaptic endings) or bind with the surface of nerve cells and trigger intracellular changes that stop viral replication.

Clinical Note The fact that some viruses, such as the herpes virus, persist for years in nerve cells, occasionally "flaring up" to produce symptoms, demonstrates that the antibodies' intraneuronal mechanism does not provide a foolproof antiviral defense for neurons.

Helper T cells secrete chemicals that amplify the activity of other immune cells.

In contrast to cytotoxic T cells, helper T cells are not killer cells. Instead, helper T cells secrete cytokines that "help," or augment, nearly all aspects of the immune response. Most cytokines are produced by helper T cells. The following are among the best known of helper T-cell cytokines:

1. Helper T cells secrete several interleukins *(IL-4, IL-5,* and *IL-6)* that serve collectively as a **B-cell growth factor**, which contributes to B-cell function in concert with the IL-1 secreted by macrophages. Antibody secretion is greatly reduced or absent without the assistance of helper T cells, especially in defense against T-dependent antigen.

2. Helper T cells similarly secrete **T-cell growth factor** *(IL-2),* which augments the activity of cytotoxic T cells and even of other helper T cells responsive to the invading antigen. In typical interplay fashion, IL-1 secreted by macrophages not only enhances the activity of both the appropriate B- and T-cell clones but also stimulates secretion of IL-2 by activated helper T cells.

ITABLE 12-2 Defenses Against Viral Invasion

When the virus is free in the ECF,

Macrophages

Destroy the free virus by phagocytosis.

Process and present the viral antigen to helper T cells.

Secrete IL-1, which activates B- and T-cell clones specific to the viral antigen.

Antibodies

Are secreted by plasma cells derived from B cells specific to the viral antigen.

Neutralize the virus to prevent its entry into a host cell.

Act as opsonins to enhance phagocytosis of the virus.

Activate the lethal complement cascade as part of adaptive immunity.

The Complement System

Directly destroys the free virus by forming a hole-punching membrane attack complex.

Acts as an opsonin to enhance phagocytosis of the virus.

When the virus has entered a host cell (which it must do to survive and multiply, with the replicated viruses leaving the original host cell to enter the ECF in search of other host cells),

Interferon

Is secreted by virus-infected cells.

Binds with and prevents viral replication in other host cells.

Enhances the killing power of macrophages, natural killer cells, and cytotoxic T cells.

Natural Killer (NK) Cells

Nonspecifically lyse virus-infected host cells.

Cytotoxic T Cells

Are specifically activated by the viral antigen and lyse the infected host cells before the virus has a chance to replicate.

Helper T Cells

Secrete cytokines, which enhance cytotoxic T-cell activity and B-cell antibody production.

When a virus-infected cell is destroyed, the free virus is released into the ECF, where it is attacked directly by macrophages, antibodies, and the activated complement components.

IFigure 12-16 **AIDS virus.** Human immunodeficiency virus (HIV) (*red*), the AIDS-causing virus, on a helper (CD4+) T lymphocyte, HIV's primary target.

3. Some helper T-cell cytokines act as *chemotaxins* to lure more neutrophils and macrophages-to-be to the invaded area.

4. Once macrophages are attracted to the area, **macrophage-migration inhibition factor**, another cytokine released from helper T cells, keeps these large phagocytic cells in the region by inhibiting their outward migration. As a result, many chemotactically attracted macrophages accumulate in the infected area. This factor also confers greater phagocytic power on the gathered macrophages. These so-called **angry macrophages** have more powerful destructive ability. They are especially important in defending against the bacteria that cause tuberculosis because such microbes can survive simple phagocytosis by nonactivated macrophages (see chapter opener photo).

5. One cytokine secreted by helper T cells *(IL-5)* activates eosinophils, and another *(IL-4)* promotes the development of IgE antibodies for defense against parasitic worms.

Clinical Note This variety of immune activities helped by helper T cells is why **acquired immunodeficiency syndrome (AIDS)**, caused by the **human immunodeficiency virus (HIV)**, is so devastating to the immune defense system. The AIDS virus selectively invades helper (CD4+) T cells, destroying or incapacitating the cells that normally orchestrate much of the immune response (IFigure 12-16). The virus also invades macrophages, further crippling the immune system, and sometimes enters brain cells, leading to the dementia (severe impairment of intellectual capacity) noted in some AIDS victims.

HIV infections are still incurable, and efforts to develop a vaccine against HIV have been only slightly successful to date because the virus rapidly mutates. However, a variety of drugs are now available to control HIV. For example, some classes of drugs disable HIV from making copies of itself, whereas others block HIV entry into CD4+ cells. The most successful therapy is a three-drug "cocktail" that typically changes the course of the disease from a short-term death sentence to a long-term, often manageable condition. The triple combination of drugs from different classes slows progression of the condition and allows the body to replenish its CD4+ population while reducing the likelihood that the virus develops drug resistance. A recent novel treatment with promising preliminary results involves disabling by means of new gene-editing technology the receptor on CD4+ cells that HIV uses to gain entry into these cells. Another new tactic under investigation to thwart the spread of HIV entails treatment as prevention (that is, giving drugs to

individuals not infected) for those at high risk of acquiring the virus.

T Helper 1 and T Helper 2 Cells Not all helper cells secrete the same cytokines. Two subsets of helper T cells—**T helper 1 (TH1)** and **T helper 2 (TH2)** cells—augment different patterns of immune responses by secreting different types of cytokines. TH1 cells rally a cell-mediated (cytotoxic T-cell) response, which is appropriate for infections with intracellular microbes, such as viruses. By contrast, TH2 cells promote antibody-mediated immunity, especially IgE production, by B cells and rev up eosinophil activity for defense against parasitic worms.

Helper T cells produced in the thymus are in a naive state until they encounter the antigen they are primed to recognize. Whether a naive helper T cell becomes a TH1 or TH2 cell depends on which cytokines are secreted by macrophages and dendritic cells (macrophagelike cells) of the innate immune system that "present" the antigen to the uncommitted T cell. You will learn about antigen presentation in an upcoming section. **IL-12** drives a naive T cell specific for the antigen to become a TH1 cell, whereas **IL-4** favors the development of a naive cell into a TH2 cell. Thus, the antigen-presenting cells of the nonspecific immune system can influence the whole tenor of the specific immune response by determining whether the TH1 or TH2 cellular subset dominates. In the usual case, the secreted cytokines promote the appropriate specific immune response against the particular threat at hand.

Scientists have also recently discovered much smaller subsets of helper T cells: TH17 cells and T follicular helper (TFH) cells. **TH17 cells** produce *IL-17* (accounting for the name of this subset). They promote inflammation and are effector cells in the development of inflammatory autoimmune diseases (immune attack against a body tissue), such as the attack against myelin in multiple sclerosis (see p. 103). The newest discovered **TFH cells** specifically interact with B cells in lymph node follicles (hence the name of this subset) to help them secrete antibodies in response to T-dependent antigens and also promote differentiation of memory B cells.

Regulatory T cells suppress immune responses.

Representing 5% to 10% of CD4+ T cells, regulatory T cells suppress immune responses, thus keeping the rest of the immune system under tight control. They are specialized to inhibit both innate and adaptive immune responses in a check-and-balance fashion to minimize harmful immune pathology. T_{regs} contain large amounts of the intracellular protein **Foxp3**, which is essential for turning developing T cells into T_{regs} and gives these suppressor cells the ability to quiet other immune cells. Researchers hope that the ability of T_{regs} to put the brakes on helper T cells, B cells, NK cells, and dendritic cells can somehow be used therapeutically to curb autoimmune diseases and prevent rejection of transplanted organs.

A newly discovered subset of B cells, **regulatory B cells (B_{regs})**, performs a similar role in suppressing harmful immune responses instead of turning into plasma cells that churn out antibodies as most B cells do. Constituting only about 1% to 2% of all B cells, B_{regs} help squelch autoimmunity and dampen innate-immunity directed inflammatory responses.

We next examine how T cells are activated by antigen-presenting cells and the roles of MHC molecules.

T cells respond only to antigens presented to them by antigen-presenting cells.

T cells cannot perform their tasks without assistance from antigen-presenting cells. That is, relevant T cells cannot recognize "raw" foreign antigens entering the body; before reacting to it, a T-cell clone must be formally "introduced" to the antigen. **Antigen-presenting cells (APCs)** handle the formal introduction; they engulf, then process and present antigens, complexed with MHC self-antigen molecules, on their surface to the T cells. APCs include macrophages and closely related dendritic cells, both of which not only are phagocytic effector cells of the innate defense system but also play a key role in activating cell-mediated adaptive immunity. You are already familiar with macrophages. **Dendritic cells** are specialized APCs that act as sentinels in almost every tissue. They are so named because they have many surface projections, or branches, that resemble the dendrites of neurons (*dendros* means "tree") (▮Figure 12-17). Dendritic cells are especially abundant in the skin and mucosal linings of the lungs and digestive tract—strategic locations where microbes are likely to enter the body. After exposure to the appropriate antigen, dendritic cells leave their tissue home and migrate through the lymphatic system to nearby lymph nodes, where they cluster and activate T cells.

We will use a dendritic cell engulfing a bacterium and presenting it to a helper T cell as an example of an APC. Invading bacteria are phagocytized by dendritic cells (or macrophages) (▮Figure 12-18, step ❶). Within the dendritic cell, the phagosome containing the engulfed bacterium fuses with a lysosome, which enzymatically breaks down the bacterium's proteins into antigenic peptides (small protein fragments) (step ❷). Each antigenic peptide then binds to an MHC molecule, which has been newly synthesized within the endoplasmic reticulum–

▮Figure 12-17 **Dendritic cell**.

1 Dendritic cell engulfs a bacterium.

2 Large molecules of engulfed bacterium are broken down by lysosomes to produce antigenic peptides.

3 New MHC molecule has been synthesized by endoplasmic reticulum–Golgi complex.

4 Antigenic peptides bind to newly formed MHC molecules.

5 Antigen is displayed on cell surface bound to MHC molecule—the cell is now an antigen-presenting cell (APC).

❙Figure 12-18 **Generation of an antigen-presenting cell when a dendritic cell engulfs a bacterium.**

Golgi complex (steps **3** and **4**). An MHC molecule has a deep groove into which a variety of antigenic peptides can bind, depending on what the macrophage has engulfed. The MHC molecule then transports the bound antigen to the cell surface, where it is presented to passing T lymphocytes (step **5**). The dendritic cell is now an antigen-presenting cell. Once displayed at the cell surface, the combined presence of these self- and nonself-antigens alerts the immune system to the presence of an undesirable agent within the cell. Unlike B cells, T cells cannot bind with foreign antigen that is not in association with self-antigen. It would be futile for T cells to bind with free, extracellular antigen—they cannot defend against foreign material unless it is intracellular. Only a specific helper T cell with a T-cell receptor that fits the displayed antigen-MHC complex in complementary fashion can bind with the APC.

When the helper T cell binds to the APC, the APC secretes cytokines that activate the associated T cell, among other effects. The activated T cell then secretes various other cytokines, which act in an autocrine manner to stimulate clonal expansion of this particular helper T cell and act in a paracrine manner on adjacent B cells, cytotoxic T cells, and NK cells to enhance their responses to the same foreign antigen.

What is the nature of the MHC self-antigens that the immune system learns to recognize as markers of a person's cells? That is the topic of the next section.

The major histocompatibility complex is the code for self-antigens.

Self-antigens are plasma membrane–bound glycoproteins (proteins with sugar attached) known as **MHC molecules** because their synthesis is directed by a group of genes called the **major histocompatibility complex**, or **MHC.** The MHC genes are the most variable ones in humans. More than 100 different MHC

molecules have been identified in human tissue, but each individual has a code for only 3 to 6 of these possible antigens. Because of the tremendous number of combinations possible, the exact pattern of MHC molecules varies from one individual to another, much like a "biochemical fingerprint" or "molecular identification card."

The major histocompatibility complex (*histo* means "tissue"; *compatibility* means "ability to get along") was so named because these genes and the self-antigens they encode were first discerned in relation to tissue typing (similar to blood typing), which is done to obtain the most compatible matches for tissue grafting and transplantation. However, the transfer of tissue from one individual to another does not normally occur in nature. The natural function of MHC antigens lies in their ability to direct the responses of T cells, not in their artificial role in rejecting transplanted tissue.

Class I and Class II MHC Glycoproteins

T cells become active only when they match a given MHC–foreign antigen combination. In addition to having to fit a specific foreign antigen, the T-cell receptor must match the appropriate MHC molecule. Each person has two main classes of MHC-encoded molecules that are differentially recognized by cytotoxic and helper T cells—*class I* and *class II MHC glycoproteins,* respectively (❙Figure 12-19). The class I and II markers serve as signposts to guide cytotoxic and helper T cells to the precise cellular locations where their immune capabilities can be most effective. The coreceptors (either CD8 or CD4) on the T cells bind with the MHC molecules on the target molecule, linking the two cells together.

Cytotoxic (CD8+) T cells can respond to foreign antigens only in association with **class I MHC glycoproteins**, which are found on the surface of all nucleated body cells. This binding specificity occurs because the cytotoxic T cell's CD8 coreceptor can interact only with class I MHC molecules. To carry out their role of dealing with pathogens that have invaded host cells, it is appropriate that cytotoxic T cells bind only with body cells that viruses have infected—that is, with foreign antigens in association with self-antigens. Furthermore, these deadly T cells can link up with any cancerous body cell because class I MHC molecules also display mutated (and thus "foreign" appearing) cellular proteins characteristic of these abnormal cells. Because any nucleated body cell can be invaded by viruses or become cancerous, essentially all cells display class I MHC glycoproteins, enabling cytotoxic T cells to attack any virus-invaded host cell or any cancer cell. In the case of cytotoxic T cells, the outcome of this binding is destruction of the infected body cell. Because cytotoxic T cells do not bind to MHC self-antigens in the absence of foreign antigens, normal body cells are protected from lethal immune attack.

In contrast, **class II MHC glycoproteins**, which are recognized by helper (CD4+) T cells, are restricted to the surface of a few special types of immune cells. The CD4 coreceptor associated with these helper T cells can interact only with class II MHC molecules. A helper T cell can bind with a foreign antigen only when it is found on the surfaces of immune cells with

(a) **Class I MHC self-antigens**

2 Cytotoxic (CD8+) T cell

3 CD8 coreceptor — T-cell receptor
— Foreign antigen
1 Class I MHC molecule (self-antigen)

4 Invaded host cell

1 Class I MHC molecules are found on the surface of all cells.

2 They are recognized only by cytotoxic (CD8+) T cells.

3 CD8 coreceptor links the two cells together.

4 Linked in this way, cytotoxic T cells can destroy body cells if invaded by foreign (viral) antigen.

(b) **Class II MHC self-antigens**

2 Helper (CD4+) T cell

3 CD4 coreceptor — T-cell receptor
— Foreign antigen
1 Class II MHC molecule (self-antigen)

4 Dendritic cell (APC)

1 Class II MHC molecules are found on the surface of immune cells with which helper T cells interact: dendritic cells, macrophages, and B cells.

2 They are recognized only by helper (CD4+) T cells.

3 CD4 coreceptor links the two cells together.

4 To be activated, helper T cells must bind with a class II MHC-bearing APC (dendritic cell or macrophage). To activate B cells, helper T cell must bind with a class II MHC-bearing B cell with displayed foreign antigen.

❙Figure 12-19 **Distinctions between class I and class II major histocompatibility complex (MHC) glycoproteins.** Specific binding requirements for the two types of T cells ensure that these cells bind only with the target cells with which they can interact. Cytotoxic (CD8+) T cells can recognize and bind with foreign antigen only when the antigen is in association with class I MHC glycoproteins, which are found on the surface of all body cells. This requirement is met when a virus invades a body cell, whereupon the cell is destroyed by the cytotoxic T cells. Helper (CD4+) T cells, which are activated by or enhance the activities of dendritic cells, macrophages, and B cells, can recognize and bind with foreign antigen only when it is in association with class II MHC glycoproteins, which are found only on the surface of these other immune cells. The CD8+ or CD4+ T-cell's coreceptor CD8 or CD4 links these cells to the target cell's class I or class II MHC molecules, respectively.

which the helper T cell directly interacts—*macrophages, dendritic cells,* and *B cells.* Class II MHC molecules are found on macrophages and dendritic cells, which present antigens to helper T cells and on B cells, whose activities are enhanced by cytokines secreted by helper T cells. B cells do not phagocytize antigenic particles like macrophages and dendritic cells do, but they can internalize T-dependent antigen bound to their surface receptor by receptor-mediated endocytosis (see p. 31), then display the antigens complexed with class II MHC on their surface. Binding of the antigen-bearing B cell with the matching helper T cell causes the T cell to secrete cytokines that activate this specific B cell, leading to clonal expansion and conversion of this B-cell clone into antibody-producing plasma cells and memory cells (❙ Figure 12-20). The capabilities of helper T cells would be squandered if these cells were able to bind with body cells other than these special APC and B immune cells. This is the primary pathway by which the adaptive immune system fights bacteria. ❙ Table 12-3 summarizes

the innate and adaptive immune strategies that defend against bacterial invasion.

Clinical Note **Transplant Rejection** T cells bind with MHC antigens present on the surface of transplanted cells in the absence of a foreign viral antigen. The ensuing destruction of the transplanted cells triggers the rejection of transplanted or grafted tissues. Presumably, some of the recipient's T cells "mistake" the MHC antigens of the donor cells for a closely resembling combination of a conventional viral foreign antigen complexed with the recipient's MHC self-antigens.

To minimize the rejection phenomenon, technicians match the tissues of donor and recipient according to MHC antigens as closely as possible. Therapeutic procedures to suppress the immune system then follow. In recent years, new therapeutic agents have become extremely useful in selectively depressing T-cell-mediated immune activity while leaving B-cell antibody-mediated immunity essentially intact. For example, *cyclosporin*

Activation of helper T cells by antigen presentation

1. Bacterium is taken up by phagocytosis and degraded in a lysosome.

2. Bacterial antigenic peptides are displayed on APC cell surface bound to class II MHC molecules and presented to helper (CD4+) T cells with TCRs that recognize the antigen.

3. APC secretes cytokines that activate T cell.

4. Activated T cell secretes cytokines that stimulate T cell to proliferate to expand clone of selected cells.

5. Cloned helper T cells are ready to activate B cells and enhance other immune activities.

❙Figure 12-20 **Interactions among large phagocytic cells (APCs), helper T cells, and B cells responsive to T-dependent antigen.**
FIGURE FOCUS: *In this sequence of events, with what two immune cell types do helper T cells bind and what is the outcome of each binding?*

❙**TABLE 12-3** Innate and Adaptive Immune Responses to Bacterial Invasion

Innate Immune Mechanisms	Adaptive Immune Mechanisms
Roles of Inflammation	**Roles of B Cells and Helper T Cells**
Resident tissue macrophages engulf invading bacteria.	B cells specific to T-independent antigen are activated on binding with the antigen.
Histamine-induced vascular responses increase blood flow to the area, bringing in additional immune effector cells and plasma proteins.	B cells specific to T-dependent antigen present antigen to helper T cells. On binding with the B cells, helper T cells activate the B cells.
A fibrin clot walls off the invaded area.	The activated B-cell clone proliferates and differentiates into plasma cells and memory cells.
Neutrophils and monocytes–macrophages migrate from the blood to the area to engulf and destroy foreign invaders and to remove cell debris.	Plasma cells secrete customized antibodies, which specifically bind to the invading bacteria. Plasma cell activity is enhanced by
Phagocytic cells secrete cytokines, which enhance both innate and adaptive immune responses and induce local and systemic symptoms associated with an infection.	IL-1 secreted by macrophages.
	Helper T cells, which have been activated by the same bacterial antigen processed and presented to them by macrophages or dendritic cells.
Roles of the Complement System	
The complement system is nonspecifically activated by exposure to PAMPs (alternate complement pathway).	Antibodies bind to invading bacteria and enhance innate mechanisms that lead to the bacteria's destruction. Specifically, antibodies
Complement components form a hole-punching membrane attack complex that lyses bacterial cells.	Act as opsonins to enhance phagocytic activity.
Complement components enhance many steps of inflammation.	Activate the lethal complement system (classical complement pathway).
	Stimulate natural killer (NK) cells, which directly lyse bacteria.
	Memory cells persist that are capable of responding more rapidly and more forcefully should the same bacteria be encountered again.

Activation of B cells responsive to T-dependent antigen
6 BCR binds to antigen. Antigen is internalized by receptor-mediated endocytosis and its macromolecules degraded. Antigenic peptides produced are displayed on cell surface bound to class II MHC molecules.

7 TCR of a helper T cell recognizes specific antigen on B cell, and CD4 coreceptor links the two cells together.

8 Helper T cell secretes cytokines that stimulate B cell proliferation to produce clone of selected cells.

9 Some cloned B cells differentiate into plasma cells, which secrete antibodies specific for the antigen, while a few differentiate into memory B cells.

10 Antibodies bind with antigen, targeting antigenic invader for destruction by the innate immune system.

blocks IL-2, the cytokine secreted by helper T cells that is required for expansion of the selected cytotoxic T-cell clone.

What factors normally prevent the adaptive immune system from unleashing its powerful defense capabilities against the body's self-antigens? We examine this issue next.

The immune system is normally tolerant of self-antigens.

Self-tolerance refers to preventing the immune system from attacking the person's own tissues. During the genetic "cut, shuffle, and paste process" that goes on during lymphocyte development, some B and T cells are by chance formed that could react against the body's own tissue antigens. If these lymphocyte clones were allowed to function, they would destroy the individual's body. Fortunately, the immune system normally does not produce antibodies or activated T cells against the body's self-antigens. A variety of mechanisms are involved in self-tolerance, including the following:

1. *Clonal deletion.* In response to continuous exposure to body antigens early in development, B and T lymphocyte clones specifically capable of attacking these self-antigens in most cases are permanently destroyed within the thymus. This **clonal deletion** is accomplished by triggering apoptosis of immature cells that would react with the body's proteins. This physical elimination is the major mechanism by which self-tolerance is developed.

2. *Clonal anergy.* Self-reactive lymphocyte clones that escape destruction in the thymus are rendered nonfunctional in the periphery by various means, the most important of which is clonal anergy. The premise of clonal anergy is that

a T lymphocyte must receive two specific simultaneous signals to be activated ("turned on"), one from its compatible antigen and a stimulatory cosignal molecule found only on the surface of an APC. Both signals are present for foreign antigens, which are introduced to T cells by APCs. In contrast, these dual signals—antigen plus cosignal—never are present for self-antigens because these antigens are not handled by cosignal-bearing APCs. The first exposure to a single signal from a self-antigen "turns off" the compatible T cell, rendering the cell unresponsive to further exposure to the antigen. This reaction is referred to as **clonal anergy** (*anergy* means "lack of energy") because T cells are inactivated (that is, "become lazy") rather than activated by their antigens. Anergized T lymphocyte clones survive, but they cannot function.

3. *Active suppression by regulatory cells.* T_{regs} (and maybe B_{regs}) play a role in self-tolerance by inhibiting throughout life some lymphocyte clones specific for the body's tissues.

4. *Receptor editing.* With **receptor editing**, once a B cell that bears a receptor for one of the body's antigens encounters the self-antigen, the B cell escapes death by swiftly changing its antigen receptor to a nonself version. In this way, an originally self-reactive B cell survives but is "rehabilitated" so that it never targets the body's tissues again.

5. *Immunological ignorance,* alternatively known as *antigen sequestering.* Some self-molecules are normally hidden from the immune system because they never come into direct contact with the ECF in which the immune cells and their products circulate. An example is thyroglobulin, a complex protein sequestered within the hormone-secreting structures of the thyroid gland (see p. 666).

Autoimmune diseases arise from loss of tolerance to specific self-antigens.

Clinical Note Occasionally, the immune system fails to distinguish between self-antigens and foreign antigens and unleashes its deadly powers against one or more of the body's tissues. A condition in which the immune system fails to recognize and tolerate self-antigens associated with particular tissues is known as an **autoimmune disease** (*auto* means "self"). Autoimmunity underlies more than 80 diseases, many of which are well known. Examples include *multiple sclerosis, rheumatoid arthritis, Type 1 diabetes mellitus,* and *psoriasis* (a skin condition). About 50 million Americans suffer from some type of autoimmune disease, with the incidence being about three times higher in females than in males.

Autoimmune diseases may arise from various causes:

1. Normal-self antigens may be modified by factors such as drugs, environmental chemicals, viruses, or genetic mutations so that they are no longer recognized and tolerated by the immune system.

2. Exposure of normally inaccessible self-antigens sometimes induces an immune attack against these antigens. Because the immune system is usually never exposed to hidden self-antigens, it does not "learn" to tolerate them. Inadvertent exposure of these normally inaccessible antigens to the immune system because of tissue disruption caused by injury or disease can lead to a rapid immune attack against the affected tissue, just as if these self-proteins were foreign invaders. *Hashimoto's disease,* which involves production of antibodies against thyroglobulin and destruction of the thyroid gland's hormone-secreting capacity, is one such example.

3. Exposure of the immune system to a foreign antigen structurally almost identical to a self-antigen may induce the production of antibodies or activated T lymphocytes that not only interact with the foreign antigen but also cross-react with the closely similar body antigen. An example of this molecular mimicry is the streptococcal bacteria responsible for "strep throat." The bacteria possess antigens structurally very similar to self-antigens in the tissue covering the heart valves of some individuals, in which case the antibodies produced against the streptococcal organisms may also bind with this heart tissue. The resultant inflammatory response is responsible for the heart-valve lesions associated with *rheumatic fever*.

4. New studies hint at a possible trigger of autoimmune diseases that could explain why a whole host of these disorders are more common in women than in men. Scientists have long speculated that the sex bias of autoimmune diseases was somehow related to hormonal differences. Recent findings suggest, however, that the higher incidence of these self-destructive conditions in females may be a legacy of pregnancy. Researchers have learned that fetal cells, which often gain access to the mother's bloodstream during the trauma of labor and delivery, sometimes linger in the mother for decades after the pregnancy. The immune system typically clears these cells from the mother's body following childbirth, but studies have demonstrated that women with autoimmune conditions are more likely than healthy women to have persistent fetal cells in their

blood. The persistence of similar but not identical fetal antigens that were not wiped out early on as being foreigners may somehow trigger a gradual, more subtle immune attack that eventually turns against the mother's closely related antigens. For example, this phenomenon might be the underlying trigger for *systemic lupus erythematosus,* an autoimmune attack against DNA, a condition that can affect many organs, most commonly skin, joints, and kidneys.

We now turn to T cells' role in defending against cancer.

An interplay among immune cells and interferon defends against cancer.

Besides destroying virus-infected host cells, an important function of the T-cell system is recognizing and destroying newly arisen, potentially cancerous tumor cells before they have a chance to multiply and spread, a process known as **immune surveillance**. At least once a day, on average, your immune system destroys a mutated cell that could potentially become cancerous. Any normal cell may be transformed into a cancer cell if mutations occur within its genes that govern cell division and growth. Such mutations may occur by chance or, more frequently, by exposure to **carcinogenic** (cancer-causing) **factors** such as ionizing radiation, certain environmental chemicals, or physical irritants. Alternatively, a few cancers are caused by tumor viruses, which turn the cells they invade into cancer cells, an example being the *human papillomavirus* that causes cervical cancer. The immune system recognizes cancer cells because they bear new and different surface antigens alongside the cell's normal-self antigens because of either genetic mutation or invasion by a tumor virus.

Clinical Note **Benign and Malignant Tumors** Cell multiplication and growth are normally under strict control by largely unknown regulatory mechanisms. Cell multiplication in an adult is generally restricted to replacing lost cells. Furthermore, cells normally respect their place and space in the body's society of cells. If a cell that has transformed into a tumor cell manages to escape immune destruction, however, it defies the normal controls on its proliferation and position. Unrestricted multiplication of a single tumor cell results in a **tumor** that consists of a clone of cells identical to the original mutated cell. If the mass is slow growing, stays put in its original location, and does not infiltrate the surrounding tissue, it is considered a **benign tumor**. In contrast, the transformed cell may multiply rapidly and form an invasive mass that lacks the "altruistic" behavior characteristic of normal cells. Such invasive tumors are **malignant tumors**, or **cancer**. Malignant tumor cells usually do not adhere well to the neighboring normal cells, so often some of the cancer cells break away from the parent tumor. These "emigrant" cancer cells are transported through the blood to new territories, where they continue to proliferate, forming multiple malignant tumors. The term **metastasis** is applied to this spreading of cancer to other parts of the body.

If a malignant tumor is detected early, before it has metastasized, it can be removed surgically. Once cancer cells have dispersed and seeded multiple cancerous sites, surgical elimination of the malignancy is impossible. In this case, agents that

interfere with rapidly dividing and growing cells, such as certain *chemotherapy drugs*, are used in an attempt to destroy the malignant cells. Unfortunately, these agents also harm normal body cells, especially rapidly proliferating cells such as blood cells and the cells lining the digestive tract.

Untreated cancer is eventually fatal in most cases, for several interrelated reasons. The uncontrollably growing malignant mass crowds out normal cells by vigorously competing with them for space and nutrients, yet the cancer cells cannot take over the functions of the cells they are destroying. Cancer cells typically remain immature and do not become specialized, often resembling embryonic cells instead (❚ Figure 12-21). Such poorly differentiated malignant cells lack the ability to perform the specialized functions of the normal cell type from which they mutated. Affected organs gradually become disrupted to the point that they can no longer perform their life-sustaining functions, and the person dies.

Genetic Mutations that Do Not Lead to Cancer Even though many body cells undergo mutations throughout a person's lifetime, most of these mutations do not result in malignancy for three reasons:

1. Only a fraction of the mutations involve loss of control over the cell's growth and multiplication. More frequently, other facets of cellular function are altered.

2. A cell usually becomes cancerous only after an accumulation of multiple independent mutations. This requirement contributes at least in part to the much higher incidence of cancer in older individuals, in whom mutations have had more time to accumulate in a single cell lineage.

3. Potentially cancerous cells that do arise are usually destroyed by the immune system early in their development.

Effectors of Immune Surveillance Immune surveillance against cancer depends on interplay among three types of immune cells—*cytotoxic T cells, NK cells,* and *macrophages*—and *interferon.* These three immune cell types not only can attack and destroy cancer cells directly but also secrete interferon. Interferon, in turn, inhibits multiplication of cancer cells and increases the killing ability of the immune cells (❚ Figure 12-22). Because NK cells do not require prior exposure and activation in response to a cancer cell before being able to launch a lethal attack, they are the first line of defense against cancer. Cytotoxic T cells take aim at cancer cells after being activated by mutated surface proteins alongside normal class I MHC molecules. On contacting a cancer cell, both these killer cells release perforin and other toxic chemicals that destroy the targeted mutant cell. Macrophages, in addition to clearing away the remains of the dead victim cell, can engulf and destroy cancer cells intracellularly.

Still, cancer does sometimes occur because cancer cells occasionally escape these immune

Cancer cell | Normal ciliated respiratory airway cell
❚Figure 12-21 **Comparison of normal and cancerous cells in the large respiratory airways.** The normal cells display specialized cilia (*blue*), which constantly contract in whiplike motion to sweep debris and microorganisms from the respiratory airways so that they do not gain entrance to the deeper portions of the lungs. The cancerous cells are not ciliated, so they are unable to perform this specialized defense task.

mechanisms. Some cancer cells are believed to survive by evading immune detection—for example, by failing to display identifying antigens on their surface or by being surrounded by counterproductive **blocking antibodies** that interfere with T-cell function. Although B cells and antibodies are not believed to play a direct role in cancer defense, B cells, on viewing a

mutant cancer cell as an alien to "normal self," may produce antibodies against it. These antibodies, for unknown reasons, do not activate the complement system, which could destroy the cancer cells. Instead, the antibodies bind with the antigenic sites on the cancer cell, "hiding" these sites from recognition by cytotoxic T cells. The coating of a tumor cell, by blocking antibodies, thus protects the harmful cell from attack by deadly T cells. Still other successful cancer cells thwart immune attack by turning on their pursuers. They induce the cytotoxic T cells that bind with them to commit suicide. In addition, some cancer cells secrete large amounts of a specific chemical messenger that recruits T_{regs} and programs them to suppress cytotoxic T cells.

We have finished discussing B cells and T cells, the effector cells of adaptive immunity. ❙Table 12-4 compares these two types of lymphocytes.

A regulatory loop links the immune system with the nervous and endocrine systems.

Even though complex controlling factors operate within the immune system itself, scientists traditionally thought that the immune system functioned independently of other control systems in the body. However, they now know that the immune system both influences and is influenced by the two major regulatory systems, the nervous and endocrine systems. Neurons have receptors for specific cytokines. For example, IL-1 can turn on the stress response by activating a sequence of nervous and endocrine events that result in secretion of cortisol, one of the major hormones released during stress. This linkage between a mediator of the immune response and a mediator of the stress response is appropriate. Cortisol mobilizes the body's nutrient stores so that metabolic fuel is readily available to keep pace with the body's energy demands at a time when the person is sick and may not be eating enough (or, in the case of an animal, may not be able to search for food). Furthermore, cortisol mobilizes amino acids, which serve as building blocks to repair any tissue damage sustained during the encounter that triggered the immune response.

In the reverse direction, lymphocytes and macrophages are responsive to blood-borne signals from the nervous system and from certain endocrine glands. These immune cells possess receptors for a wide variety of neurotransmitters, hormones, and other chemical mediators. For example, cortisol and other chemical mediators of the stress response have a profound immunosuppressive effect, inhibiting many functions of lymphocytes and macrophages and decreasing the production of cytokines. Thus, a negative-feedback loop exists among the immune system and the nervous and endocrine systems. Cytokines released by immune cells enhance the neurally and hormonally controlled stress response, whereas cortisol and related chemical mediators released during the stress response suppress the immune system. For example, the anti-inflammatory effect of cortisol modulates stress-activated immune responses, preventing them from overshooting, and thus protecting us against damage by potentially overreactive defense mechanisms.

However, in large part because stress suppresses the immune system, stressful physical, psychological, and social life events are sometimes linked with increased susceptibility to infections and cancer. Thus, the body's resistance to disease can be influenced by the person's mental state—a case of "mind over matter."

Other important links exist between the immune and nervous systems besides the cortisol connection. For example, many immune system organs, such as the thymus, spleen, and lymph nodes, are innervated by the sympathetic nervous system, the branch of the nervous system called into play during stress-related "fight-or-flight" situations (see p. 238). Also, a parasympathetic anti-inflammatory pathway helps rein in the inflammatory response. The vagus nerve, the main nerve of the parasympathetic nervous system, supplies the spleen and other

❙TABLE 12-4 B versus T Lymphocytes

Characteristic	B Lymphocytes	T Lymphocytes
Ancestral origin	Bone marrow	Bone marrow
Site of maturational processing	Bone marrow	Thymus
Receptors for antigen	B-cell receptors are antibodies inserted in the plasma membrane; highly specific	T-cell receptors present in the plasma membrane are not the same as antibodies; highly specific
Bind with	Extracellular antigens such as bacteria, free viruses, and other circulating foreign material	Foreign antigen in association with self-antigen, such as virus-infected cells
Types of active cells	Plasma cells	Cytotoxic T cells, helper T cells, regulatory T cells
Formation of memory cells	Yes	Yes
Type of immunity	Antibody-mediated immunity	Cell-mediated immunity
Secretory product	Antibodies	Cytokines
Functions	Help eliminate free foreign invaders (mostly bacteria) by enhancing innate immune responses against them	Lyse virus-infected cells and cancer cells; aid B cells in antibody production; modulate immune responses
Life span	Short	Long

Exercise: A Help or Hindrance to Immune Defense?

FOR YEARS PEOPLE WHO ENGAGE in moderate exercise regimens have claimed they have fewer colds when they are in good aerobic condition. In contrast, elite athletes and their coaches have often complained about the number of upper respiratory infections that the athletes seem to contract at the height of their competitive seasons. The results of recent scientific studies lend support to both these claims. The effect of exercise on immune defense depends on the intensity of the exercise.

Animal studies have shown that high-intensity exercise after experimentally induced infection results in more severe infection. Moderate exercise performed before infection or to tumor implantation, in contrast, results in less severe infection and slower tumor growth in experimental animals.

Studies on humans lend further support to the hypothesis that exhaustive exercise suppresses immune defense, whereas moderate exercise stimulates the immune system. A survey of 2300 runners competing in a major marathon indicated that those who ran more than 60 miles a week had twice the number of respiratory infections as those who ran less than 20 miles a week in the two months preceding the race. In another study, 10 elite athletes were asked to run

on a treadmill for 3 hours at the same pace they would run in competition. Blood tests after the run indicated that natural killer (NK) cell activity had decreased by 25% to 50%, and this decrease lasted for 6 hours. The runners also showed a 60% increase in the stress hormone cortisol, which is known to suppress immunity. Other studies have shown that athletes have lower resting salivary IgA levels compared with control subjects and that their respiratory mucosal immunoglobulins are decreased after prolonged exhaustive exercise. These results suggest a lower resistance to respiratory infection following high-intensity exercise. Because of these results, researchers in the field recommend that athletes keep exposure to respiratory viruses to a minimum by avoiding crowded places or anyone with a cold or f u for the first 6 hours after strenuous competition.

However, a study evaluating the effects of a moderate exercise program in which a group of women walked 45 minutes a day, 5 days a week, for 15 weeks found that the walkers' antibody levels and NK cell activity increased throughout the exercise program. Other studies using moderate exercise on stationary bicycles in subjects older than age 65 showed increases in NK cell activity as large as those found in young people.

sites where macrophages are abundant. Cytokine-secreting macrophages, the orchestrators of many aspects of inflammation, have receptors for acetylcholine (ACh). Even though ACh is typically the parasympathetic postganglionic neurotransmitter, vagal nerve endings in the spleen are adrenergic, not cholinergic. What is the source then of the ACh to which splenic macrophages respond? In an interesting twist, vagal stimulation of a population of memory T cells in the spleen causes these immune cells to produce the ACh that inhibits cytokine secretion by the splenic macrophages, in this way suppressing inflammation. In the reverse direction (immune system influencing nervous system), immune system secretions act on the brain to produce fever and other general symptoms that accompany infections. Furthermore, immune cells secrete some traditional hormones once thought to be produced only by the endocrine system. For example, many of the hormones secreted by the pituitary gland are produced by lymphocytes as well. Scientists are only beginning to sort out the mechanisms and implications of the many complex neuro–endocrine–immune interactions. (For a discussion of the possible effects of exercise on immune defense, see the accompanying boxed feature, ❙A Closer Look at Exercise Physiology.)

Check Your Understanding 12.5

1. List the three major types of T cells and state their functions.
2. Describe the role of antigen-presenting cells.
3. By what means is self-tolerance achieved?
4. Define *immune surveillance* and discuss how it is accomplished.

12.6 Immune Diseases

Abnormal functioning of the immune system can lead to immune diseases in two general ways: *immunodeficiency diseases* (too little immune response) and *inappropriate immune attacks* (too much or mistargeted immune response).

Immunodeficiency diseases result from insufficient immune responses.

Clinical Note **Immunodeficiency diseases** occur when the immune system fails to respond adequately to foreign invasion. The condition may be congenital (present at birth) or acquired (nonhereditary), and it may involve impairment of antibody-mediated or cell-mediated immunity, or both.

In a rare hereditary condition known as **severe combined immunodeficiency**, both B and T cells are lacking. Such people have extremely limited defenses against pathogenic organisms and die in infancy unless maintained in a germ-free environment (that is, live in a "bubble"). However, that verdict has changed with recent successes using gene therapy to cure the disease in some patients.

Acquired (nonhereditary) immunodeficiency states can arise from inadvertent destruction of lymphoid tissue during prolonged therapy with anti-inflammatory agents, such as cortisol derivatives, or from cancer therapy aimed at destroying rapidly dividing cells (which unfortunately include lymphocytes as well as cancer cells). The most recent and tragically the most common acquired immunodeficiency disease is AIDS, which, as described earlier, is caused by HIV, a virus that invades and incapacitates the critical helper T cells.

Let us now look at inappropriate immune attacks.

Allergies are inappropriate immune attacks against harmless environmental substances.

Clinical Note **Inappropriate immune attacks** cause reactions harmful to the body. These include (1) *autoimmune diseases,* in which the immune system turns against one of the body's tissues; (2) *immune complex diseases,* which involve overexuberant antibody responses that "spill over" and damage normal tissue; and (3) allergies. The first two conditions have been described earlier in this chapter, so we now concentrate on allergies.

An **allergy** is the acquisition of an inappropriate specific immune reactivity, or **hypersensitivity**, to a normally harmless environmental substance, such as dust or pollen. The offending agent is known as an **allergen**. Subsequent re-exposure of a sensitized individual to the same allergen elicits an immune attack, which may vary from a mild, annoying reaction to a severe, body-damaging reaction that may even be fatal.

Allergic responses are classified into two categories: immediate hypersensitivity and delayed hypersensitivity. In **immediate hypersensitivity**, the allergic response appears within about 20 minutes after a sensitized person is exposed to an allergen. In **delayed hypersensitivity**, the reaction does not generally show up until a day or so following exposure. The difference in timing is the result of the different mediators involved. A particular allergen may activate either a B- or a T-cell response. Immediate allergic reactions involve B cells and are elicited by antibody interactions with an allergen; delayed reactions involve T cells and the more slowly responding process of cell-mediated immunity against the allergen. Let us examine the causes and consequences of each of these reactions in more detail.

Triggers for Immediate Hypersensitivity

In immediate hypersensitivity, the antibodies involved and the events that ensue on exposure to an allergen differ from the typical antibody-mediated response to bacteria. The most common allergens that provoke immediate hypersensitivities are pollen grains, bee stings, penicillin, certain foods, molds, dust, feathers, and animal fur. (Actually, people allergic to cats are not allergic to the fur itself. The true allergen is in the cat's saliva, which is deposited on the fur during licking. Likewise, people are not allergic to dust or feathers per se but to tiny mites that inhabit the dust or feathers.) For unclear reasons, these allergens bind to and elicit the synthesis of IgE antibodies rather than the IgG antibodies associated with bacterial antigens. IgE antibodies are the least plentiful immunoglobulin, but their

presence spells trouble. Without IgE antibodies, there would be no immediate hypersensitivity. When a person with an allergic tendency is first exposed to a particular allergen, compatible helper T cells secrete IL-4, a cytokine that prods compatible B cells to synthesize IgE antibodies specific for the allergen. During this initial **sensitization period** no symptoms are evoked, but memory cells form that are primed for a more powerful response on subsequent re-exposure to the same allergen.

In contrast to the antibody-mediated response elicited by bacterial antigens, IgE antibodies do not freely circulate. Instead, their tail portions attach to mast cells and basophils, both of which produce and store an arsenal of potent inflammatory chemicals, such as histamine, in preformed granules. Mast cells are most plentiful in regions that come into contact with the external environment, such as the skin, the outer surface of the eyes, and the linings of the respiratory system and digestive tract. Binding of an appropriate allergen with the outreached arm regions of the IgE antibodies that are lodged tail-first in a mast cell or basophil triggers the rupture of the cell's granules. As a result, histamine and other chemical mediators spew forth into the surrounding tissue.

A single mast cell (or basophil) may be coated with several different IgE antibodies, each able to bind with a different allergen. Thus, the mast cell can be triggered to release its chemical products by any one of several allergens (❙Figure 12-23).

Chemical Mediators of Immediate Hypersensitivity

Following are among the most important reaction-causing chemicals released during immediate allergic reactions:

1. *Histamine,* which brings about vasodilation and increased capillary permeability and increased mucus production.

2. **Slow-reactive substance of anaphylaxis (SRS-A)**, which induces prolonged and profound contraction of smooth muscle, especially of the small respiratory airways. SRS-A is a collection of three related *leukotrienes,* locally acting eicosanoids similar to prostaglandins (see p. 119).

3. **Eosinophil chemotactic factor**, which specifically attracts eosinophils to the area. Interestingly, eosinophils release enzymes that inactivate SRS-A and may inhibit histamine, perhaps serving as an "off switch" to limit the allergic response.

Symptoms of Immediate Hypersensitivity
