Symptoms of immediate hypersensitivity vary depending on the site, allergen, and mediators involved. Most frequently, the reaction is localized to the body site in which the IgE-bearing cells first come into contact with the allergen. If the reaction is limited to the upper respiratory passages after a person inhales an allergen such as ragweed pollen, the released chemicals bring about the symptoms characteristic of **hay fever**—nasal congestion caused by histamine-induced localized edema and sneezing and runny nose caused by increased mucus secretion. If the reaction is concentrated primarily within the bronchioles (the small respiratory airways that lead to the tiny air sacs within the lungs), **asthma** results. Contraction of the smooth muscle in the walls of the bronchioles in response to SRS-A narrows or constricts these passageways, making breathing difficult. Localized swelling in

1 Allergens (antigens) enter the body for the first time.

2 Allergens bind to matching BCRs; B cells now process the allergens and, with stimulation by helper T cells (not shown), proceed through the steps leading to clonal expansion of activated plasma cells.

Histamine granules

4 Fc tail portion of all IgE antibodies, regardless of the specificity of their Fab arm regions, binds to IgE tail receptors on mast cells and basophils. Unlike B cells, each mast cell can have a variety of antibody surface receptors for binding different allergens.

5 When an allergen enters the body on subsequent exposure, it binds with its matching IgE antibodies on mast cells; binding stimulates the mast cell to release histamine and other substances by exocytosis. Any allergen for which preformed, matching IgE are attached to the mast cell can trigger histamine release.

6 Histamine and other released chemicals elicit the allergic response.

❙Figure 12-23 Role of IgE antibodies and mast cells in immediate hypersensitivity. B-cell clones are converted into plasma cells, which secrete IgE antibodies on contact with the allergen for which they are specific. All IgE antibodies, regardless of their antigen specificity, bind to mast cells or basophils. When an allergen combines with the IgE receptor specific for it on the surface of a mast cell, the mast cell releases histamine and other chemicals from preformed granules by exocytosis. These chemicals elicit the allergic response.

the skin because of allergy-induced histamine release causes **hives**. An allergic reaction in the digestive tract in response to an ingested allergen can lead to diarrhea.

Treatment of Immediate Hypersensitivity Treatment of localized immediate allergic reactions with antihistamines often offers only partial relief of the symptoms because some manifestations are invoked by other chemical mediators not blocked by these drugs. For example, antihistamines are not particularly effective in treating asthma, the most serious symptoms of which are invoked by SRS-A. Adrenergic drugs (which mimic the sympathetic nervous system; see p. 241) are helpful through their vasoconstrictor–bronchodilator actions in counteracting the effects of both histamine and SRS-A. Anti-inflammatory drugs such as cortisol derivatives are often used as the primary treatment for ongoing allergen-induced inflammation, such as that associated with asthma. Newer drugs such as *Singulair* that inhibit leukotrienes, including SRS-A, have been added to the arsenal for combating immediate allergies.

Anaphylactic Shock A life-threatening systemic (involving the entire body) reaction known as **anaphylactic shock** can occur if the allergen becomes blood borne or if very large amounts of chemicals are released from the localized site into the circulation. Severe hypotension that can lead to circulatory shock (see p. 374) results from histamine-induced widespread vasodilation and a massive shift of plasma fluid into the interstitial spaces as a result of a generalized increase in capillary permeability. Concurrently, pronounced bronchiolar constriction occurs via SRS-A action and can lead to respiratory failure. The person may suffocate from an inability to move air through the narrowed airways. Unless countermeasures, such as injecting a vasoconstrictor–bronchodilator drug, are undertaken immediately, anaphylactic shock is often fatal. This reaction is the reason even a single bee sting or eating a peanut can be so dangerous in people sensitized to these allergens.

Immediate Hypersensitivity and Absence of Parasitic Worms Although the immediate hypersensitivity response differs considerably from the typical IgG antibody response to bacterial infections, it is strikingly similar to the immune response elicited by parasitic worms. Shared characteristics of the immune reactions to allergens and parasitic worms include IgE antibody production and increased basophil and eosinophil activity. This finding has led to the proposal that harmless allergens somehow trigger an immune response designed to fight worms. Mast cells are concentrated in areas where parasitic worms (and allergens) could contact the body. Parasitic worms can penetrate the skin or penetrate or attach to the digestive tract lining. Some worms migrate through the lungs during a part of their life cycle. Scientists suspect the IgE response helps ward off these invaders as follows. The inflammatory response in the skin could wall off parasitic worms attempting to burrow in. Coughing and sneezing could expel worms that migrated to the lungs. Diarrhea could help flush out worms before they could penetrate or attach to the digestive tract lining. Epidemiological studies suggest that the incidence of allergies in a country rises as the presence of parasites decreases. Thus,

superfluous immediate hypersensitivity responses to normally harmless allergens may represent a pointless marshaling of a honed immune-response system "with nothing better to do" in the absence of parasitic worms. The proposal that lack of early childhood exposure to parasites because of a sanitary lifestyle leads to increased susceptibility to allergic diseases is known as the **hygiene hypothesis.**

Delayed Hypersensitivity Some allergens invoke delayed hypersensitivity, a T-cell-mediated immune response, rather than an immediate, B cell–IgE antibody response. Among these allergens are poison ivy toxin and certain chemicals to which the skin is frequently exposed, such as cosmetics and household cleaning agents. Most commonly, the response is characterized by a delayed skin eruption that reaches its peak intensity 1 to 3 days after contact with an allergen to which the T-cell system has previously been sensitized. To illustrate, poison ivy toxin does not harm the skin on contact, but it activates T cells specific for the toxin, including formation of a memory component. On subsequent exposure to the toxin, activated T cells diffuse into the skin within a day or two, combining with the poison ivy toxin that is present. The resulting interaction gives rise to the tissue damage and discomfort typical of the condition. The best relief is obtained from application of anti-inflammatory preparations, such as those containing cortisol derivatives.

▮Table 12-5 summarizes the distinctions between immediate and delayed hypersensitivities. This completes our discussion of the immune defense system. We now turn to external defenses that thwart entry of foreign invaders.

Check Your Understanding 12.6

1. Name the three categories of inappropriate adaptive immune attacks.
2. Compare the type of immune response and immune effectors involved in immediate hypersensitivity and delayed hypersensitivity.
3. Discuss how the mechanism of action of IgE antibodies differs from that of IgG antibodies.

12.7 External Defenses

The body's defenses against foreign microbes are not limited to the intricate, interrelated immune mechanisms that destroy microorganisms that have actually invaded the body. In addition to the internal immune defense system, the body is equipped with external defense mechanisms designed to prevent microbial penetration wherever body tissues are exposed to the external environment. All of our epithelial surfaces, namely the skin and the linings of the digestive tract, the urogenital (urinary and reproductive) tracts, and respiratory airways and lungs, are protected by antimicrobial peptides called **defensins**. Epithelial cells of these surfaces secrete defensins on attack by microbial pathogens, thereby killing the would-be invaders by disrupting their membranes.

Characteristic	Immediate Hypersensitivity Reaction	Delayed Hypersensitivity Reaction
Time of onset of symptoms after exposure to the allergen	Within 20 minutes	Within 1 to 3 days
Type of immune response	Antibody-mediated immunity against the allergen	Cell-mediated immunity against the allergen
Immune effectors involved	B cells, IgE antibodies, mast cells, basophils, histamine, slow-reactive substance of anaphylaxis, and eosinophil chemotactic factor	T cells
Allergies commonly involved	Hay fever, asthma, hives, and (in extreme cases) anaphylactic shock	Contact allergies, such as allergies to poison ivy, cosmetics, and household cleaning agents

The most obvious external defense is the **skin**, or **integument**, which covers the outside of the body (*integere* means "to cover").

The skin consists of an outer protective epidermis and an inner, connective tissue dermis.

The skin, which is the largest organ of the body, not only is a mechanical barrier between the external environment and the underlying tissues but is dynamically involved in defense mechanisms and other important functions as well. The skin in an average adult weighs 9 pounds and covers a surface area of about 20 square feet (1.86 m²). Its deeper layer contains an abundance of blood vessels, which if laid end to end would extend more than 11 miles. The skin consists of two layers, an outer *epidermis* and an inner *dermis* (▮Figure 12-24).

Epidermis The **epidermis** consists of numerous layers of epithelial cells. On average, the epidermis replaces itself about every 2.5 months. The inner epidermal layers are composed mostly of cube-shaped cells that are living and rapidly dividing, whereas the cells in the outer layers are dead and flattened. The epidermis has no direct blood supply. Its cells are nourished only by diffusion of nutrients from the rich vascular network in the underlying dermis. The newly forming cells in the
▮Figure 12-24 **Anatomy of the skin.** The skin consists of two layers, a keratinized outer epidermis and a richly vascularized inner connective tissue dermis. Special infoldings of the epidermis form the sweat glands, sebaceous glands, and hair follicles. The epidermis contains four types of cells: keratinocytes, melanocytes, Langerhans cells, and Granstein cells. The skin is anchored to underlying muscle or bone by the hypodermis, a loose, fat-containing layer of connective tissue

FIGURE FOCUS*: Note what layer(s) of the skin are directly supplied by blood. What are the implications of this vascular pattern?*

inner layers constantly push the older cells closer to the surface and ever farther from their nutrient supply. This, coupled with the continuous subjection of the outer layers to pressure and "wear and tear," causes these older cells to die and become flattened. Epidermal cells are riveted tightly together by desmosomes (see p. 61), which interconnect with intracellular keratin filaments (see p. 51) to form a strong, cohesive covering. During maturation of a keratin-producing cell, keratin filaments progressively accumulate and cross-link with one another within the cytosol. As the outer cells die, this fibrous keratin core remains, forming flattened, hardened scales that provide a tough, protective **keratinized layer**. As the scales of the outermost keratinized layer slough or flake off through abrasion, they are continuously replaced by means of cell division in the deeper epidermal layers. The rate of cell division, and consequently the thickness of this keratinized layer, varies in different regions of the body. It is thickest in the areas where the skin is subjected to the most pressure, such as the bottom of the feet. The keratinized layer is airtight, fairly waterproof, and impervious to most substances. It resists anything passing in either direction between the body and the external environment.

Clinical Note The skin minimizes loss of water and other vital constituents from the body. This protective layer's value in holding in body fluids becomes obvious after severe burns. Bacterial infections can occur in the unprotected underlying tissue, but even more serious are the systemic consequences of losing body water and plasma proteins from the exposed, burned surface. The resulting circulatory disturbances can be life threatening.

Likewise, the skin barrier impedes passage into the body of most materials that come into contact with the body surface, including bacteria and toxic chemicals. In many instances, the skin modifies compounds that come into contact with it. For example, epidermal enzymes can convert many potential carcinogens into harmless compounds. Some materials, however, especially lipid-soluble substances, can penetrate intact skin through the lipid bilayers of the plasma membranes of the epidermal cells. Drugs that can be absorbed by the skin, such as nicotine or estrogen, are sometimes used in the form of a cutaneous "patch" impregnated with the drug.

Dermis Under the epidermis is the **dermis**, a connective tissue layer that contains many elastin fibers (for stretch) and collagen fibers (for strength) and an abundance of blood vessels and specialized nerve endings. The dermal blood vessels not only supply both the dermis and the epidermis but also play a major role in temperature regulation. The caliber of these vessels, and hence the volume of blood flowing through them, is subject to control to vary the amount of heat exchange between these skin surface vessels and the external environment (see p. 632). Receptors at the peripheral endings of afferent nerve fibers in the dermis detect pressure, temperature, pain, and other somatosensory input (see p. 182). Efferent nerve endings in the dermis control blood vessel caliber, hair erection, and secretion by the skin's exocrine glands.

Skin's Exocrine Glands and Hair Follicles Special infoldings of the epidermis into the underlying dermis form the skin's exocrine glands—the sweat glands and the sebaceous glands—as well as the hair follicles. **Sweat glands** of the most common type, which are distributed over most of the body, release a dilute salt solution through small openings, the sweat pores, onto the skin surface (❚ Figure 12-24). Evaporation of this sweat cools the skin and is important in regulating temperature.

The amount of sweat produced is subject to regulation and depends on the environmental temperature, the amount of heat-generating skeletal muscle activity, and various emotional factors (for example, a person often sweats when nervous). A special type of sweat gland located in the axilla (armpit) and pubic region produces a protein-rich sweat that supports the growth of surface bacteria, which give rise to a characteristic odor. In contrast, most sweat, as well as the secretions from the sebaceous glands, contains chemicals that are generally highly toxic to bacteria.

The cells of the **sebaceous glands** produce **sebum**, an oily secretion released into adjacent hair follicles. From there sebum flows to the skin surface, oiling both the hairs and the outer keratinized layers of the skin, helping to waterproof them and prevent them from drying and cracking. Chapped hands or lips indicate insufficient protection by sebum. The sebaceous glands are particularly active during adolescence, causing the oily skin common among teenagers.

Each **hair follicle** is lined by special keratin-producing cells, which secrete keratin and other proteins that form the hair shaft. Hairs increase the sensitivity of the skin's surface to tactile (touch) stimuli. In some other species, this function is more finely tuned. For example, the whiskers on a cat are exquisitely sensitive in this regard. An even more important role of hair in hairier species is heat conservation, but this function is not significant in us relatively hairless humans. Like hair, the **nails** are another special keratinized product derived from living epidermal structures, the nail beds.

Hypodermis The skin is anchored to the underlying tissue (muscle or bone) by the **hypodermis** (*hypo* means "below"), also known as **subcutaneous tissue** (*sub* means "under"; *cutaneous* means "skin"), a loose layer of connective tissue. Most fat cells are housed within the hypodermis. These fat deposits throughout the body are collectively referred to as **adipose tissue**.

Specialized cells in the epidermis produce melanin, keratin, and vitamin D and participate in immune defense.

The epidermis contains four resident cell types— *melanocytes, keratinocytes, Langerhans cells,* and *Granstein cells*—plus transient T lymphocytes scattered throughout the epidermis and dermis. Each of these resident cell types performs specialized functions.

Melanocytes **Melanocytes** produce the pigment **melanin**, which they disperse to surrounding skin cells. The amount and type of melanin, which can vary among black, brown, yellow, and red pigments, are responsible for the shades of skin color of the various races. Fair-skinned people have about the same number of melanocytes as dark-skinned people; the difference in skin

color depends on the amount of melanin produced by each melanocyte. Melanin is produced through complex biochemical pathways in which the melanocyte enzyme *tyrosinase* plays a key role. Most people, regardless of skin color, have enough tyrosinase that, if fully functional, could result in enough melanin to make their skin very black. In those with lighter skin, however, two genetic factors prevent this melanocyte enzyme from functioning at full capacity: (1) much of the tyrosinase produced is in an inactive form, and (2) various inhibitors that block tyrosinase action are produced. As a result, less melanin is produced.

In addition to hereditary determination of melanin content, the amount of this pigment can be increased transiently in response to exposure to ultraviolet (UV) light rays from the sun. On exposure to UV light, keratinocytes secrete **α-melanocyte stimulating hormone (α-MSH)**, which acts as a paracrine on neighboring melanocytes to darken the skin. This additional melanin, the outward appearance of which constitutes a "tan," performs the protective function of absorbing harmful UV rays.

Keratinocytes By far the most abundant epidermal cells are the **keratinocytes**, which, as the name implies, are specialists in keratin production. As they die, they form the outer protective keratinized layer. They also generate keratin-rich hair and nails.

Keratinocytes also synthesize vitamin D in the presence of sunlight. Vitamin D, which is derived from a precursor molecule closely related to cholesterol, promotes the absorption of Ca^{2+} from the digestive tract into the blood (Chapter 16). Dietary supplements of vitamin D are usually required because typically the skin is not exposed to sufficient sunlight to produce adequate amounts of this essential chemical.

Furthermore, keratinocytes are important immunologically. They secrete IL-1 (a product also secreted by macrophages), which influences the maturation of T cells that tend to localize in the skin. Interestingly, the epithelial cells of the thymus bear anatomic, molecular, and functional similarities to those of the skin. Some post-thymic steps in T-cell maturation take place in the skin under keratinocyte guidance.

Other Immune Cells of the Skin The two other epidermal cell types also play a role in immunity. **Langerhans cells**, which migrate to the skin from bone marrow, are dendritic cells that serve as antigen-presenting cells. Thus, the skin not only is a mechanical barrier but actually alerts lymphocytes if the barrier is breached by invading microorganisms. Langerhans cells present antigen to helper T cells, facilitating their responsiveness to skin-associated antigens. In contrast, **Granstein cells** act as a "brake" on skin-activated immune responses. They are antigen-presenting cells to skin-associated T_{regs}, thus exerting an immune suppressor effect. Significantly, Langerhans cells are more susceptible to damage by UV radiation than Granstein cells are. Losing Langerhans cells as a result of exposure to UV radiation can detrimentally lead to a predominant suppressor signal rather than the normally dominant helper signal, leaving the skin more vulnerable to microbial invasion and cancer cells.

The various epidermal components of the immune system are collectively termed **skin-associated lymphoid tissue**, or **SALT**. SALT plays an important protective role, because the skin is a major interface with the external environment.

Protective measures within body cavities discourage pathogen invasion into the body.

The human body's defense system must guard against entry of potential pathogens not only through the outer surface of the body but also through the internal cavities that communicate directly with the external environment—namely, the digestive system, the urogenital system, and the respiratory system. These systems use various tactics to destroy microorganisms entering through these routes.

Defenses of the Digestive System Saliva secreted into the mouth at the entrance of the digestive system contains an enzyme that lyses certain ingested bacteria. "Friendly" bacteria that live on the back of the tongue convert food-derived nitrate into nitrite, which is swallowed. Acidification of nitrite on reaching the highly acidic stomach generates nitric oxide, which is toxic to a variety of microorganisms. Furthermore, many of the surviving bacteria that are swallowed are killed directly by the strongly acidic gastric juice in the stomach. Farther down the tract, the intestinal lining is endowed with gut-associated lymphoid tissue. These defensive mechanisms are not 100% effective, however. Some bacteria do manage to survive and reach the large intestine (the last portion of the digestive tract), where they continue to flourish. Surprisingly, this normal microbial population provides a natural barrier against infection within the lower intestine. These harmless resident microbes competitively suppress the growth of potential pathogens that have managed to escape the antimicrobial measures of earlier parts of the digestive tract.

Clinical Note Occasionally, orally administered antibiotic therapy against an infection elsewhere within the body may induce an intestinal infection. By knocking out some normal intestinal bacteria, an antibiotic may permit an antibiotic-resistant pathogenic species to overgrow in the intestine.

Defenses of the Urogenital System Within the urogenital system, would-be invaders encounter hostile conditions in the acidic urine and acidic vaginal secretions. The urogenital organs also produce a sticky mucus, which, like flypaper, entraps small invading particles. Subsequently, the particles are either engulfed by phagocytes or are swept out as the organ empties (for example, they are flushed out with urine flow).

Defenses of the Respiratory System The respiratory system is likewise equipped with several important defense mechanisms against inhaled particulate matter. The respiratory system is the largest surface of the body that comes into direct contact with the increasingly polluted external environment. The surface area of the respiratory system exposed to the air is about 40 times that of the skin. Larger airborne particles are filtered out of the inhaled air by hairs at the entrance of the nasal passages. Lymphoid tissues, the *tonsils* and *adenoids,* provide immunological protection against inhaled pathogens near the beginning of the respiratory system. Farther down in the respiratory airways, millions of tiny hairlike projections known as *cilia* constantly beat in an outward direction (see p. 48). The respiratory airways are coated with a layer of thick, sticky

mucus secreted by epithelial cells within the airway lining. This mucus sheet, laden with any inspired particulate debris (such as dust) that adheres to it, is constantly moved upward to the throat by ciliary action. This moving "staircase" of mucus is known as the **mucus escalator**. The dirty mucus is either expectorated (spit out) or, in most cases, is swallowed without the person even being aware of it; any indigestible foreign particulate matter is later eliminated in the feces. Besides keeping the lungs clean, this mechanism is an important defense against bacterial infection because many bacteria enter the body on dust particles. Also contributing to defense against respiratory infections are IgA antibodies secreted in the mucus. In addition, an abundance of phagocytic specialists called **alveolar macrophages** scavenge within the air sacs (alveoli) of the lungs. Further respiratory defenses include coughs and sneezes. These commonly experienced reflex mechanisms involve forceful outward expulsion of material in an attempt to remove irritants from the trachea *(coughs)* or nose *(sneezes)*. A sneeze can propel air and particles from the respiratory airways up to 30 feet away at rates more than 90 miles per hour.

Clinical Note Cigarette smoking suppresses these normal respiratory defenses. The smoke from a single cigarette can paralyze the cilia for several hours, with repeated exposure eventually leading to ciliary destruction. Failure of ciliary activity to sweep out a constant stream of particulate-laden mucus enables inhaled carcinogens to remain in contact with the respiratory airways for prolonged periods. Furthermore, cigarette smoke incapacitates alveolar macrophages. In addition, noxious agents in tobacco smoke irritate the mucous linings of the respiratory tract, resulting in excess mucus production, which may partially obstruct the airways. "Smoker's cough" is an attempt to dislodge this excess stationary mucus. These and other direct toxic effects on lung tissue lead to the increased incidence of lung cancer and chronic respiratory diseases associated with cigarette smoking. Air pollutants include some of the same substances found in cigarette smoke and can similarly affect the respiratory system.

We examine the respiratory system in greater detail in the next chapter.

Check Your Understanding 12.7

1. Describe the epidermis, dermis, and hypodermis.
2. List and state the functions of the four resident cell types in the skin.
3. Tell how the mucus escalator works.

Homeostasis: Chapter in Perspective

We could not survive beyond early infancy were it not for the body's defense mechanisms. These mechanisms resist and eliminate potentially harmful foreign agents with which we continuously come into contact in our hostile external environment and also destroy abnormal cells that often arise within the body. Homeostasis can be optimally maintained, and thus life sustained, only if the body cells are not physically injured or functionally disrupted by pathogenic microorganisms or are not replaced by abnormally functioning cells, such as traumatized cells or cancer cells. The immune defense system—a complex, multifaceted, interactive network of leukocytes, their secretory products, and plasma proteins—contributes indirectly to homeostasis by keeping other cells alive so that they can perform their specialized activities to maintain a stable internal environment. The immune system protects the other healthy cells from foreign agents that have gained entrance to the body, clears away dead and injured cells to pave the way for replacement with healthy new cells, and eliminates newly arisen cancer cells.

The skin contributes indirectly to homeostasis by serving as a protective barrier between the external environment and the rest of the body cells. It helps prevent harmful foreign agents such as pathogens and toxic chemicals from entering the body and helps prevent the loss of precious internal f uids from the body. The skin also contributes directly to homeostasis by helping maintain body temperature by means of the sweat glands and adjustments in skin blood f ow. The amount of heat carried to the body surface for dissipation to the external environment is determined by the volume of warmed blood f owing through the skin.

Other systems that have internal cavities in contact with the external environment, such as the digestive, urogenital, and respiratory systems, also have defense capabilities to prevent harmful external agents from entering the body through these avenues.

Review Exercises Answers begin on p. A-38

Reviewing Terms and Facts

1. The complement system can be activated only by antibodies. *(True or false?)*

2. Specific adaptive immune responses are accomplished by neutrophils. *(True or false?)*

3. Damaged tissue is always replaced by scar tissue. *(True or false?)*

4. Active immunity against a particular disease can be acquired only by actually having the disease. *(True or false?)*

5. A secondary response has a more rapid onset, is more potent, and has a longer duration than a primary response. *(True or false?)*

6. _____ are receptors on the plasma membrane of phagocytes that recognize and bind with telltale molecular patterns present on the surface of microorganisms but absent from human cells.

7. The complement system's _____ forms a doughnut-shaped complex that embeds in a microbial surface membrane, causing osmotic lysis of the victim cell.

8. _____ is a collection of phagocytic cells, necrotic tissue, and bacteria.

9. _____ is the localized response to microbial invasion or tissue injury that is accompanied by swelling, heat, redness, and pain.

10. A chemical that enhances phagocytosis by serving as a link between a microbe and the phagocytic cell is known as a(n) _____.

11. All the chemical messengers other than antibodies secreted by lymphocytes that regulate immune process are categorized as _____.

12. _____ molecules released by killer cells form porelike channels that punch holes in a victim cell, and _____ released by killer cells trigger apoptosis of victim cells.

13. Which of the following statements concerning leukocytes is/are *incorrect*?
   a. Monocytes are transformed into macrophages.
   b. T lymphocytes are transformed into plasma cells that secrete antibodies.
   c. Neutrophils are highly mobile phagocytic specialists.
   d. Basophils release histamine.
   e. Lymphocytes arise in large part from lymphoid tissues.

14. Match the following:
   1. a family of proteins that nonspecifically defend against viral infection
   2. a response to tissue injury in which neutrophils and macrophages play a major role
   3. a group of plasma proteins that, when activated, bring about destruction of foreign cells by attacking their plasma membranes
   4. lymphocytelike entities that spontaneously lyse tumor cells and virus-infected host cells

   (a) complement system
   (b) natural killer (NK) cells
   (c) interferon
   (d) inflammation

15. Using the answer code on the right, indicate whether the numbered characteristics of the adaptive immune system apply to antibody-mediated immunity or cell-mediated immunity (or both):
   1. involves secretion of antibodies
   2. mediated by B cells
   3. mediated by T cells
   4. accomplished by thymus-educated lymphocytes
   5. triggered by the binding of specific antigens to complementary lymphocyte receptors
   6. involves formation of memory cells in response to initial exposure to an antigen
   7. primarily aimed against virus-infected host cells
   8. protects primarily against bacterial invaders
   9. directly destroys targeted cells
   10. involved in rejection of transplanted tissue
   11. requires binding of a lymphocyte to a free extracellular antigen
   12. requires dual binding of a lymphocyte with both foreign antigen and self-antigens present on the surface of a host cell

   (a) antibody-mediated immunity
   (b) cell-mediated immunity
   (c) both antibody-mediated and cell-mediated immunity

16. Using the answer code on the right, indicate whether the numbered characteristics apply to the epidermis or dermis:
   1. is the inner layer of skin
   2. has layers of epithelial cells that are dead and flattened
   3. has no direct blood supply
   4. contains sensory nerve endings
   5. contains keratinocytes
   6. contains melanocytes
   7. contains rapidly dividing cells
   8. is mostly connective tissue

   (a) epidermis
   (b) dermis

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Distinguish between bacteria and viruses.
2. Summarize the functions of each of the lymphoid tissues.

Body Defenses | **443**

3. Distinguish between innate and adaptive immune responses.

4. Compare the life histories of B cells and T cells.

5. Describe the structure of an antibody. List and describe the five subclasses of immunoglobulins.

6. In what ways do antibodies exert their effect?

7. Describe the clonal selection theory.

8. Compare the functions of B cells and T cells. What are the roles of the three types of T cells?

9. Summarize the functions of macrophages in immune defense.

10. What mechanisms are involved in self-tolerance?

11. What is the importance of class I and class II MHC glycoproteins?

12. Describe the factors that contribute to immune surveillance against cancer cells.

13. Distinguish among immunodeficiency disease, autoimmune disease, immune complex disease, immediate hypersensitivity, and delayed hypersensitivity.

14. What are the immune functions of the skin?

Solving Quantitative Exercises

1. As a result of the innate immune response to an infection—for example, from a cut on the skin—capillary walls near the site of infection become very permeable to plasma proteins that normally remain in the blood. These proteins diffuse into the interstitial fluid, raising the interstitial fluid–colloid osmotic pressure (π_{IF}). Increased π_{IF} causes fluid to leave the circulation and accumulate in the tissue, forming a welt, or wheal. This process is referred to as the *wheal response.* The wheal response is mediated in part by histamine secreted from mast cells in the area of infection. The histamine binds to receptors, called *H-1 receptors,* on capillary endothelial cells. The histamine signal is transduced via the Ca^{2+} second-messenger pathway involving phospholipase C (see p. 124). In response to this signal, the capillary endothelial cells contract (via internal actin–myosin interaction), which causes a widening of the intercellular gaps (pores) between the capillary endothelial cells (see p. 354). In addition, substance P (see p. 190) also contributes to pore widening. Plasma proteins can pass through these widened pores and leave the capillaries. Looking at ▌Figure 10-20,

p. 356, compare the magnitude of the wheal response (that is, the extent of localized edema) if π_{IF} were raised (a) from 0 mm Hg to 5 mm Hg and (b) from 0 mm Hg to 10 mm Hg. In both cases, compare the net exchange pressure (NEP) at the arteriolar end of the capillary, the venular end of the capillary, and the average NEP. (Assume the other forces acting across the capillary wall remain unchanged.)

Applying Clinical Reasoning

Linda P. is allergic to molds and dust mites. She takes allergy medication as needed to keep her symptoms under control, but in the hopes of ridding herself of the troublesome allergies, she has been taking allergy (desensitization) shots. Allergy shots consist of weekly injections of minute, gradually increasing doses of the offending allergens. How can deliberately injecting the offending agent lead to a reduction in allergic response to the allergen? The leading theory regarding the mechanism of action of allergy shots is that the immune response to the allergen is gradually shifted from production of IgE antibodies to production of IgG antibodies against this antigen. How would this switch lead to a reduction in allergic symptoms on environmental exposure to higher doses of the antigen?

Thinking at a Higher Level

1. Compare the defense mechanisms that come into play in response to bacterial and viral pneumonia.

2. Three decades have passed since the first cases of AIDS were reported in the United States and millions of research dollars have been spent studying this disease. Much has been learned, and drugs have been developed that delay or manage the condition, but no AIDS vaccine has been approved despite many unsuccessful attempts. Why does the frequent mutation of HIV (the AIDS virus) make it difficult to develop a vaccine against this virus?

3. What effect would failure of the thymus to develop embryonically have on the immune system after birth?

4. Medical researchers are currently working on ways to "teach" the immune system to view foreign tissue as "self." What useful clinical application will the technique have?

5. When someone looks at you, are the cells of your body that person is viewing dead or alive?

The Respiratory System

13
A scanning electron micrograph of an alveolus in the lung. An alveolus (air sac; *blue cavity*) enclosed by an extremely thin membrane (*white*) is surrounded by pulmonary capillaries (*red*). O_2 and CO_2 are exchanged across this thin barrier between air and blood. The large blue ridges at the rear of the alveolus denote the position of underlying capillaries.

CHAPTER AT A GLANCE

Homeostasis Highlights

Energy is essential for sustaining life-supporting cellular activities, such as protein synthesis and active transport across plasma membranes. Body cells need a continuous supply of O_2 to support their energy-generating chemical reactions. The CO_2 produced during these reactions must be eliminated from the body at the same rate as it is produced to prevent dangerous fluctuations in pH (that is, to maintain acid–base balance) because CO_2 generates carbonic acid.

   Respiration involves the sum of the processes that accomplish ongoing passive movement of O_2 from the atmosphere to the tissues to support cell metabolism and the continual passive movement of metabolically produced CO_2 from the tissues to the atmosphere. The **respiratory system** contributes to homeostasis by exchanging O_2 and CO_2 between the atmosphere and blood. The blood transports O_2 and CO_2 between the respiratory system and the tissues.

13.1 Respiratory Anatomy

The primary function of respiration is to obtain O_2 for use by the body cells and to eliminate the CO_2 the cells produce.

The respiratory system does not participate in all steps of respiration.

Most people think of respiration as the process of breathing in and breathing out. In physiology, however, respiration has a broader meaning. Respiration encompasses two separate but related processes: cellular respiration and external respiration.

Cellular Respiration The term **cellular respiration** refers to the intracellular metabolic processes carried out within the mitochondria, which use O_2 and produce CO_2 while deriving energy from nutrient molecules (see p. 35). The **respiratory quotient (RQ)**, the ratio of CO_2 produced to O_2 consumed, varies depending on the foodstuff consumed. When carbohydrate is being used, the RQ is 1—that is, for every molecule of O_2 consumed, one molecule of CO_2 is produced. For fat utilization, the RQ is 0.7; for protein, it is 0.8. On a typical American diet consisting of a mixture of these three nutrients, resting O_2 consumption averages about 250 mL/min, and CO_2 production averages about 200 mL/min, for an average RQ of 0.8:

$$RQ = \frac{CO_2 \text{ produced}}{O_2 \text{ consumed}} = \frac{(200 \text{ mL/min})}{(250 \text{ mL/min})} = 0.8$$
External Respiration The term **external respiration** refers to the entire sequence of events in exchange of O_2 and CO_2 between the external environment and tissue cells. External respiration, the topic of this chapter, encompasses four steps (Figure 13-1):

Step **1** Air is alternately moved into and out of the lungs so that air can be exchanged between the atmosphere (external environment) and air sacs (*alveoli*) of the lungs. This exchange is accomplished by the mechanical act of **breathing**, or **ventilation**. The rate of ventilation is regulated to adjust the flow of air between the atmosphere and alveoli according to the body's metabolic needs for O_2 uptake and CO_2 removal.

Step **2** O_2 and CO_2 are exchanged between air in the alveoli and blood within the pulmonary (*pulmonary* means "lung") capillaries by the process of diffusion.

Step **3** The blood transports O_2 and CO_2 between the lungs and the tissues.

Step **4** O_2 and CO_2 are exchanged between the tissue cells and blood by the process of diffusion across the systemic (tissue) capillaries.

The respiratory system does not accomplish all steps of respiration; it is involved only

Figure 13-1 External and cellular respiration. External respiration encompasses the steps involved in exchange of O_2 and CO_2 between the external environment and tissue cells (steps 1 through 4). Cellular respiration encompasses the intracellular metabolic reactions involving the use of O_2 to derive energy (ATP) from food, producing CO_2 as a by-product.

with ventilation and exchange of O_2 and CO_2 between the lungs and blood (steps ❶ and ❷). The circulatory system is involved in step ❷ and carries out steps ❸ and ❹.

Nonrespiratory Functions of the Respiratory System

The respiratory system also fills these nonrespiratory functions:

■ It is a route for water loss and heat elimination. Inspired (inhaled) atmospheric air is humidified and warmed by the respiratory airways before it is expired. Moistening of inspired air is essential to prevent the alveolar linings from drying out. O_2 and CO_2 cannot diffuse through dry membranes.

■ It enhances venous return (see "respiratory pump," p. 364).

■ It helps maintain normal acid–base balance by altering the amount of H^+-generating CO_2 exhaled (see p. 553).

■ It enables speech, singing, and other vocalization.

■ It defends against inhaled foreign matter (see p. 441).

■ It removes, modifies, activates, or inactivates various materials passing through the pulmonary circulation. All blood returning to the heart from the tissues must pass through the lungs before being returned to the systemic circulation. Thus the lungs are uniquely situated to act on specific materials that have been added to the blood at the tissue level before these substances have a chance to reach other parts of the body by means of the arterial system. For example, prostaglandins, a collection of chemical messengers released in many tissues to mediate particular local responses (see p. 119), may spill into the blood, but they are *inactivated* during passage through the lungs so that they cannot exert systemic effects. By contrast, the lungs *activate* angiotensin II, which is part of the renin–angiotensin–aldosterone hormonal pathway that plays an important role in regulating Na^+ concentration in the ECF (see p. 508).

■ The nose, a part of the respiratory system, is the organ of smell (see p. 227).

The respiratory airways conduct air between the atmosphere and alveoli.

The **respiratory system** includes the respiratory airways leading into the lungs, the lungs themselves, and the respiratory muscles of the thorax (chest) and abdomen involved in producing movement of air through the airways into and out of the lungs. The **respiratory airways** are tubes that carry air between the atmosphere and the air sacs, the latter being the only site where gases can be exchanged between air and blood. If all the airways were lined up end to end, they would extend 1500 miles. The airways begin with the **nasal passages (nose)** (❘Figure 13-2a). The nasal passages open into the **pharynx (throat)**, which serves as a common passageway for both the respiratory and digestive systems. Two tubes lead from the pharynx—the **trachea (windpipe)**, through which air is conducted to the lungs, and the **esophagus**, the tube through which food passes to the stomach. Air normally enters the pharynx through the nose, but it can enter by the mouth as well when the nasal passages are congested—that is, you can breathe through your mouth when you have a cold. Because the pharynx serves as a common passageway for food and air, reflex mechanisms close

off the trachea during swallowing so that food does not enter the airways. The esophagus stays closed except during swallowing to keep air from entering the stomach during breathing.

The **larynx**, or **voice box**, is located at the entrance of the trachea. The anterior protrusion of the larynx forms the "Adam's apple." The **vocal folds**, two bands of elastic tissue that lie across the opening of the larynx, can be stretched and positioned in different shapes by laryngeal muscles (❘Figure 13-3a). Air passes into the larynx through the space between the vocal folds. This laryngeal opening is known as the **glottis**. As air moves through the open glottis past the variably positioned, taut vocal folds, they vibrate to produce the many sounds of speech. The lips, tongue, and soft palate modify the sounds into recognizable sound patterns. During swallowing, the vocal folds assume a function not related to speech: They close the glottis. That is, laryngeal muscles bring the vocal folds into tight apposition to each other to close off the entrance to the trachea so that food does not get into the airways (❘Figure 13-3b).

Beyond the larynx, the trachea divides into two main branches, the right and left **bronchi**, which enter the right and left lungs, respectively. Within each lung the bronchus continues to branch into progressively narrower, shorter, and more numerous airways, like the branching of a tree. The smaller branches are known as **bronchioles**. Clustered at the ends of the terminal bronchioles are the **alveoli**, the tiny air sacs where gases are exchanged between air and blood (see ❘Figure 13-2b).

To permit airflow into and out of the gas-exchanging portions of the lungs, the continuum of conducting airways from the entrance through the terminal bronchioles to the alveoli must remain open. The trachea and larger bronchi are fairly rigid, nonmuscular tubes encircled by a series of cartilaginous rings that prevent these tubes from compressing. The smaller bronchioles have no cartilage to hold them open. Their walls contain smooth muscle that is innervated by the autonomic nervous system and is sensitive to certain hormones and local chemicals. These factors, by varying the degree of contraction of bronchiolar smooth muscle and hence the caliber of these small terminal airways, regulate the amount of air passing between the atmosphere and each cluster of alveoli.

The gas-exchanging alveoli are thin-walled air sacs encircled by pulmonary capillaries.

The lungs are ideally structured for gas exchange. According to Fick's law of diffusion, the shorter the distance and the greater the surface area through which diffusion takes place, the greater the rate of diffusion (see p. 65).

The alveoli are clusters of thin-walled, inflatable, grapelike sacs at the terminal branches of the conducting airways. The alveolar walls consist of a single layer of flattened, **Type I alveolar cells** (❘Figure 13-4a and b). Each alveolus is surrounded by a network of pulmonary capillaries, the walls of which are also only one cell thick (❘Figure 13-4a, b, and c and chapter opener photo). The interstitial space between an alveolus and the surrounding capillary network is extremely thin. Thus, only a 0.5 μm barrier known as the **alveolar–capillary membrane** separates air in the alveoli from blood in the pulmonary capillaries. (A sheet of tracing paper is about 50 times thicker than

this air-to-blood barrier.) The thinness of this barrier facilitates gas exchange.

Furthermore, the alveolar air–pulmonary blood interface presents a tremendous surface area for exchange. The lungs contain about 500 million alveoli, each about 200 µm to 300 µm in diameter. So dense are the pulmonary capillary networks that an almost continuous sheet of blood encircles each alveolus. The pulmonary capillaries if laid end to end would

extend 620 miles. The total surface area thus exposed between alveolar air and pulmonary capillary blood is about 75 m² (about the size of one side of a volleyball court). In contrast, if the lungs consisted of a single hollow chamber of the same dimensions instead of being divided into a multitude of alveolar units, the total surface area would be only about 0.01 m².

In addition to the thin, wall-forming Type I cells, 5% of the alveolar surface epithelium is covered by **Type II alveolar cells** (❙Figure 13-4a and b). These cells secrete *pulmonary surfactant,* a phospholipoprotein complex that facilitates lung expansion (described later). Furthermore, defensive alveolar macrophages stand guard within the lumen of the air sacs (see p. 442).

Minute **pores of Kohn** exist in the walls between adjacent alveoli (see ❙Figure 13-2b). Their presence permits airflow between adjoining alveoli. These passageways are especially important in allowing fresh air to enter an alveolus whose terminal conducting airway is blocked because of disease.

The lungs occupy much of the thoracic cavity.

The two **lungs** are each divided into several lobes and each is supplied by one of the bronchi. The lung tissue itself consists of the series of highly branched airways, the alveoli, the pulmo-

nary blood vessels, and large quantities of elastic connective tissue. The only muscle within the lungs is the smooth muscle in the walls of the arterioles and the walls of the bronchioles, both of which are subject to control. No muscle is present within the alveolar walls to cause them to inflate and deflate during the breathing process. Instead, changes in lung volume (and accompanying changes in alveolar volume) are brought about through changes in the dimensions of the thoracic (chest) cavity. You will learn about this mechanism after we finish discussing respiratory anatomy.

The lungs occupy most of the volume of the **thoracic (chest) cavity**, the only other structures in the chest being the heart and associated vessels, the esophagus, the thymus, and some nerves. The outer chest wall **(thorax)** is formed by 12 pairs of curved **ribs**, which join the **sternum** (breastbone) anteriorly and the **thoracic vertebrae** (backbone) posteriorly. The rib cage provides bony protection for the lungs and heart. Skeletal muscles connect these bony structures and enclose the thoracic cavity. The **diaphragm**, which forms the floor of the thoracic cavity, is a large, dome-shaped sheet of skeletal muscle that separates the thoracic cavity from the
abdominal cavity. It is penetrated only by the esophagus and blood vessels traversing the thoracic and abdominal cavities. At the neck, muscles and connective tissue enclose the thoracic cavity. The only communication between the atmosphere and the thoracic cavity is through the respiratory airways into the alveoli.

A pleural sac separates each lung from the thoracic wall.

A double-walled, closed sac called the **pleural sac** separates each lung from the thoracic wall and other surrounding structures (❚Figure 13-5). The interior of the pleural sac is known as the **pleural cavity**. In the illustration, the dimensions of the pleural cavity are greatly exaggerated to aid visualization; in reality, the layers of the pleural sac are in close contact with one another. The surfaces of the pleura secrete a thin **intrapleural fluid** (*intra* means "within"), which lubricates the pleural surfaces as they slide past each other during respiratory movements.

Pleurisy, an inflammation of the pleural sac, is accompanied by painful breathing because each inflation and each deflation of the lungs cause a "friction rub."

(b) Relationship of lungs to pleural sacs, thoracic wall, and diaphragm
Figure 13-5 **Pleural sac.** (a) Pushing a lollipop into a small water-filled balloon produces a relationship analogous to that between each double-walled, closed pleural sac and the lung that it surrounds and separates from the thoracic wall. (b) One layer of the pleural sac, the *visceral pleura,* closely adheres to the surface of the lung (*viscus* means "organ") and then reflects back on itself to form another layer, the *parietal pleura,* which lines the interior surface of the thoracic wall (*paries* means "wall"). The relative size of the pleural cavity between these two layers is grossly exaggerated for the purpose of visualization.

Check Your Understanding 13.1

1. List the steps of external respiration accomplished by the respiratory system and those carried out by the circulatory system.

2. Discuss how the alveolar air–pulmonary blood interface is ideally structured for gas exchange.

3. State the functions of Type I alveolar cells, Type II alveolar cells, and alveolar macrophages.

13.2 Respiratory Mechanics

Air tends to move from a region of higher pressure to a region of lower pressure—that is, down a **pressure gradient**.

Interrelationships among pressures inside and outside the lungs are important in ventilation.

Air flows into and out of the lungs during the act of breathing by moving down alternately reversing pressure gradients established between the alveoli and the atmosphere by cyclic respira-

tory muscle activity. Three pressure considerations are important in ventilation (**Figure 13-6**):

1. **Atmospheric (barometric) pressure** is the pressure exerted by the weight of the air in the atmosphere on objects on Earth's surface. At sea level it equals 760 mm Hg. Atmospheric pressure diminishes with increasing altitude above sea level as the layer of air above Earth's surface correspondingly decreases in thickness. Minor fluctuations in atmospheric pressure occur at any height because of changing weather conditions (that is, when barometric pressure is rising or falling).

2. **Intra-alveolar pressure** is the pressure within the alveoli. Because the alveoli communicate with the atmosphere through the conducting airways, air quickly flows down its pressure gradient any time intra-alveolar pressure differs from atmospheric pressure; air flow continues until the two pressures equilibrate (become equal).

3. **Intrapleural pressure** is the pressure within the pleural sac. It is the pressure exerted outside the lungs within the thoracic cavity. The intrapleural pressure is usually less than atmospheric pressure, averaging 756 mm Hg at rest. Just as blood pressure is recorded using atmospheric pressure as a reference point (that is, a systolic blood pressure of 120 mm Hg is 120 mm Hg greater than the atmospheric pressure of 760 mm Hg or, in reality, 880 mm Hg), 756 mm Hg is sometimes referred to as a pressure of -4 mm Hg. However, there is really no such thing as an absolute negative pressure. A pressure of -4 mm Hg is just negative when compared with the normal atmospheric pressure of 760 mm Hg. To avoid confusion, we use absolute positive values throughout our discussion of respiration.

Intrapleural pressure does not equilibrate with atmospheric or intra-alveolar pressure because the pleural sac is a closed sac with no openings, so air cannot enter or leave despite any pressure gradients that might exist between the pleural cavity and the atmosphere or lungs.

The transmural pressure gradient stretches the lungs to fill the larger thoracic cavity.

The thoracic cavity is larger than the unstretched lungs because the thoracic wall grows more rapidly than the lungs during development. However, a *transmural pressure gradient* across the lung wall holds the lungs and thoracic wall in close apposition, stretching the lungs to fill the larger thoracic cavity.

Transmural Pressure Gradient The intra-alveolar pressure, equilibrated with atmospheric pressure at 760 mm Hg, is greater than the intrapleural pressure of 756 mm Hg, so a greater pressure is pushing outward than is pushing inward across the lung wall. This net outward pressure differential, the **transmural pressure gradient**, pushes out on the lungs, stretching, or distending, them (*trans* means "across"; *mural* means "wall") (**Fig-**

ure 13-7). Because of this pressure gradient, the lungs are always forced to expand to fill the thoracic cavity, no matter its size. As the thoracic cavity enlarges, the lungs enlarge—that is, the lungs follow the movements of the chest wall.

Why the Intrapleural Pressure Is Subatmospheric

Because of the lungs' elasticity, they try to pull inward away from the thoracic wall as they are stretched to fill the larger thoracic cavity. The transmural pressure gradient, however, prevents the lungs from pulling away except to the slightest degree. The resultant ever-so-slight expansion of the pleural cavity is sufficient to drop the pressure in this cavity by 4 mm Hg, bringing the intrapleural pressure to the subatmospheric level of 756 mm Hg. This pressure drop occurs because the pleural cavity is filled with fluid, which cannot expand to fill the slightly larger volume. Therefore, a vacuum exists in the infinitesimal space in the slightly expanded pleural cavity not occupied by intrapleural fluid, producing a small drop in intrapleural pressure below atmospheric pressure.

Note the interrelationship between the transmural pressure gradient and the subatmospheric intrapleural pressure. The lungs are stretched by the transmural pressure gradient that exists across their walls because the intrapleural pressure is less than atmospheric pressure. The intrapleural pressure, in turn, is subatmospheric because the stretched lungs tend to pull away from the larger thoracic wall, slightly expanding the pleural cavity and dropping the intrapleural pressure below atmospheric pressure.

Pneumothorax Normally, air does not enter the pleural cavity because there is no communication between the cavity and either the atmosphere or the alveoli. However, if the chest wall is punctured (for example, by a stab wound or a broken rib), air flows down its pressure gradient from the higher atmospheric pressure and rushes into the cavity (I Figure

13-8a). The abnormal condition of air in the pleural cavity is known as **pneumothorax** ("air in the chest"). Intrapleural and intra-alveolar pressure are now both equilibrated with atmospheric pressure, so a transmural pressure gradient no longer exists across the lung wall. With no force present to stretch the lung, it collapses to its unstretched size (I Figure 13-8b). Similarly, pneumothorax and lung collapse can occur if air enters the pleural cavity through a hole in the lung produced, for

760

Transmural pressure gradient across lung wall = intra-alveolar pressure minus intrapleural pressure

Numbers are mm Hg pressure.

I Figure 13-7 **Transmural pressure gradient.** Across the lung wall, the intra-alveolar pressure of 760 mm Hg pushes outward, while the intrapleural pressure of 756 mm Hg pushes inward. This 4 mm Hg difference in pressure constitutes a transmural pressure gradient that pushes out on the lungs, stretching them to fill the larger thoracic cavity.

(a) In *traumatic pneumothorax,* a puncture in the chest wall permits air from the atmosphere to flow down its pressure gradient and enter the pleural cavity, abolishing the transmural pressure gradient. (b) When the transmural pressure gradient is abolished, the lung collapses to its unstretched size, and the chest wall springs outward. (c) In *spontaneous pneumothorax,* a hole in the lung wall permits air to move down its pressure gradient and enter the pleural cavity from the lungs, abolishing the transmural pressure gradient. As with traumatic pneumothorax, the lung collapses to its unstretched size.

the lungs during **inspiration** (a breath in) and must be greater than atmospheric pressure for air to flow out of the lungs during **expiration** (a breath out). Altering the volume of the lungs can change intra-alveolar pressure, in accordance with Boyle's law. **Boyle's law** states that, at any constant temperature, the pressure exerted by a gas in a closed container varies inversely with the volume of the gas (❙ Figure 13-9)—that is, as the volume of a gas increases, the pressure exerted by the gas decreases proportionately. Conversely, the pressure increases proportionately as the volume decreases. Changes in lung volume, and accordingly intra-alveolar pressure, are brought about indirectly by respiratory muscle activity.

The respiratory muscles that accomplish breathing do not act directly on the lungs to change their volume. Instead, these muscles change the volume of the thoracic cavity, causing a corresponding change in lung volume because the thoracic wall and lungs are linked by the transmural pressure gradient.

Let us follow the changes that occur during one respiratory cycle—that is, one inspiration and expiration.

Onset of Inspiration: Contraction of Inspiratory Muscles The major **inspiratory muscles**—the muscles that contract to accomplish an inspiration during quiet breathing—include the *diaphragm* and *external intercostal muscles* (❙ Figure 13-10). Before the beginning of inspiration, all respiratory muscles are

example, by a disease process (❙ Figure 13-8c).

Air Alternately Flows Into and Out of the Lungs Due to Cyclic Changes in Intra-Alveolar Pressure. Because air flows down a pressure gradient, the intra-alveolar pressure must be less than atmospheric pressure for air to flow into

❙ Figure 13-9 Boyle's law. Each container has the same number of gas molecules. Given the random motion of gas molecules, the likelihood of a gas molecule striking the interior wall of the container and exerting pressure varies inversely with the volume of the container at any constant temperature. The gas in container B exerts more pressure than the same gas in larger container C but less pressure than the same gas in smaller container A. This relationship is stated as Boyle's law: $P_1V_1 = P_2V_2$. As the volume of a gas increases, the pressure of the gas decreases proportionately; conversely, the pressure increases proportionately as the volume decreases.

relaxed (▮Figure 13-11a). At the onset of inspiration, contraction of the inspiratory muscles enlarges the thoracic cavity. The major inspiratory muscle is the **diaphragm**, which is innervated by the **phrenic nerve**. The relaxed diaphragm has a dome shape that protrudes upward into the thoracic cavity. The diaphragm descends downward when it contracts on stimulation by the phrenic nerve, enlarging the volume of the thoracic cavity by increasing its vertical (top-to-bottom) dimension (▮Figure 13-11b). During quiet breathing, the diaphragm descends about 1 cm during inspiration, but during heavy breathing, it may descend as much as 10 cm. The abdominal wall, if relaxed, bulges outward during inspiration as the descending diaphragm pushes the abdominal contents downward and forward. Diaphragm contraction accomplishes 75% of thoracic cavity enlargement during quiet inspiration.

Two sets of **intercostal muscles** lie between the ribs (*inter* means "between"; *costa* means "rib"). The *external intercostal muscles* lie on top of the *internal intercostal muscles.* Contraction of the **external intercostal muscles**, whose fibers run downward and forward between adjacent ribs, enlarges the thoracic cavity in both the lateral (side-to-side) and the anteroposterior (front-to-back) dimensions. When the external intercostals contract, they elevate the ribs and subsequently the sternum upward and outward (▮Figure 13-11b). **Intercostal nerves** activate these intercostal muscles during inspiration.

Before inspiration, at the end of the preceding expiration, intra-alveolar pressure is equal to atmospheric pressure, so no air is flowing into or out of the lungs (▮Figure 13-12a). As the thoracic cavity enlarges during inspiration on contraction of the diaphragm and external intercostals, the lungs are also forced to expand to fill the larger thoracic cavity. As the lungs enlarge, the intra-alveolar pressure drops because the same number of air molecules now occupies a larger lung volume. In

a typical inspiratory excursion, the intra-alveolar pressure drops 1 mm Hg to 759 mm Hg (▮Figure 13-12b). Because the intra-alveolar pressure is now less than atmospheric pressure, air flows into the lungs down this pressure gradient. Air continues to enter the lungs until no further gradient exists—that is, until intra-alveolar pressure equals atmospheric pressure. Thus, movement of air into the lungs does not cause lung expansion; instead, air flows into the lungs because of the fall in intra-alveolar pressure brought about by lung expansion.

During inspiration, the intrapleural pressure falls to 754 mm Hg because the more highly stretched lungs tend to pull away a bit more from the thoracic wall.

Role of Accessory Inspiratory Muscles Deeper inspirations (more air breathed in) can be accomplished by contracting the diaphragm and external intercostal muscles more forcefully and by bringing the **accessory inspiratory muscles** into play to further enlarge the thoracic cavity. Contracting these accessory muscles, which are in the neck (see ▮Figure 13-10), raises the sternum and elevates the first two ribs, enlarging the upper portion of the thoracic cavity. As the thoracic cavity increases even further in volume than under resting conditions, the lungs likewise expand more, dropping the intra-alveolar pressure further. Consequently, a larger inward flow of air occurs before equilibration with atmospheric pressure is achieved—that is, a deeper breath occurs.

Onset of Expiration: Relaxation of Inspiratory Muscles At the end of inspiration, the inspiratory muscles relax. The diaphragm assumes its original dome-shaped position when it relaxes. The elevated rib cage falls because of gravity when the external intercostals relax (see ▮Figure 13-11c). With no forces expanding the chest wall (and accordingly, expanding the lungs), the chest wall and stretched lungs recoil to their preinspiratory size because of their elastic properties, much as a stretched balloon would on release. As the lungs recoil and become smaller in volume, the intra-alveolar pressure rises because the greater number of air molecules contained within the larger lung volume at the end of inspiration are now compressed into a smaller volume. In a resting expiration, the intra-alveolar pressure increases about 1 mm Hg above atmospheric pressure to 761 mm Hg (▮Figure 13-12c), and air leaves the lungs down this pressure gradient. Outward flow of air ceases when intra-alveolar pressure becomes equal to atmospheric pressure and a pressure gradient no longer exists. ▮Figure 13-13 summarizes the intra-alveolar and intrapleural pressure changes that take place during one respiratory cycle.

Clinical Note Because the diaphragm is the major inspiratory muscle and its relaxation also causes expiration, paralysis of the intercostal muscles alone does not seriously influence quiet breathing. Disruption of diaphragm activity caused by nerve or muscle disorders, however, leads to respiratory paralysis. Fortunately, the phrenic nerve arises from the spinal cord in the neck region (cervical segments 3, 4, and 5) and then descends to the diaphragm at the floor of the thorax, instead of arising from the thoracic region of the cord as might be expected. For this reason, individuals completely paralyzed below the neck by traumatic severance of the spinal cord are

Relaxation of external intercostal muscles

Relaxation of diaphragm

Return of diaphragm, ribs, and sternum to resting position on relaxation of inspiratory muscles restores thoracic cavity to preinspiratory size

(d) Active expiration

Contraction of internal intercostal muscles flattens ribs and sternum, further reducing side-to-side and front-to-back dimensions of thoracic cavity

Contraction of internal intercostal muscles

Contraction of abdominal muscles

Position of relaxed abdominal muscles

Contraction of abdominal muscles causes diaphragm to be pushed upward, further reducing vertical dimension of thoracic cavity

❙ Figure 13-11 **Respiratory muscle activity during inspiration and expiration.** (a) Before inspiration, all respiratory muscles are relaxed. (b) During *inspiration,* the diaphragm descends on contraction, increasing the vertical dimension of the thoracic cavity. Contraction of the external intercostal muscles elevates the ribs and subsequently the sternum to enlarge the thoracic cavity from front to back and from side to side. (c) During *quiet passive expiration,* the diaphragm relaxes, reducing the volume of the thoracic cavity from its peak inspiratory size. As the external intercostal muscles relax, the elevated rib cage falls because of the force of gravity. This also reduces the volume of the thoracic cavity. (d) During *active expiration,* contraction of the abdominal muscles increases the intra-abdominal pressure, exerting an upward force on the diaphragm. This reduces the vertical dimension of the thoracic cavity further than it is reduced during quiet passive expiration. Contraction of the internal intercostal muscles decreases the front-to-back and side-to-side dimensions by flattening the ribs and sternum.

❙Figure 13-12 **Changes in lung volume and intra-alveolar pressure during inspiration and expiration.** (a) Before inspiration, at the end of the preceding expiration, intra-alveolar pressure is equilibrated with atmospheric pressure, and no air is flowing. (b) As the lungs increase in volume during inspiration, the intra-alveolar pressure decreases, establishing a pressure gradient that favors the flow of air into the alveoli from the atmosphere—that is, an inspiration occurs. (c) As the lungs recoil to their preinspiratory size on relaxation of the inspiratory muscles, the intra-alveolar pressure increases, establishing a pressure gradient that favors the flow of air out of the alveoli into the atmosphere—that is, an expiration occurs.

FIGURE FOCUS: *Compare the airflow into the lungs if intra-alveolar pressure is reduced to 758 mm Hg instead of the typical 759 mm Hg as a result of more forceful contraction of inspiratory muscles.*

still able to breathe, even though they have lost use of all other skeletal muscles in their trunk and limbs.

Forced Expiration: Contraction of Expiratory Muscles

During quiet breathing, expiration is normally a passive process because it is accomplished by elastic recoil of the lungs on relaxation of the inspiratory muscles, with no muscular exertion or energy expenditure required. In contrast, inspiration is *always* active because it is brought about only by contraction of inspiratory muscles at the expense of energy use. Expiration can become active to empty the lungs more completely and more rapidly than is accomplished during quiet breathing, as during the deeper breaths accompanying exercise. To force more air out, the intra-alveolar pressure must be increased even further above atmospheric pressure than can be accomplished by simple relaxation of the inspiratory muscles and elastic recoil of the lungs. To produce such a **forced**, or **active**, **expiration**, expiratory muscles must contract to further reduce the volume of the thoracic cavity and lungs (see ❙Figures 13-10 and 13-11d). The most important **expiratory muscles** are (unbelievable as it may seem at first) the *muscles of the abdominal wall*. As the abdominal muscles contract, the resultant increase in intra-abdominal pressure exerts an upward force on the diaphragm, pushing it farther up into the thoracic cavity than its relaxed position, thus decreasing the vertical dimension of the thoracic cavity even more. The other expiratory muscles are the **internal intercostal muscles,** whose contraction pulls the ribs downward and inward, flattening the chest wall and further decreasing the size of the thoracic cavity; this action is just the opposite of that of the external intercostal muscles.

As active contraction of the expiratory muscles further reduces the volume of the thoracic cavity, the lungs also become further reduced in volume because they do not have to be stretched as much to fill the smaller thoracic cavity—that is, they are permitted to recoil to an even smaller volume. The intra-alveolar pressure increases further as the air in the lungs
❶ During inspiration, intra-alveolar pressure is less than atmospheric pressure.

❷ During expiration, intra-alveolar pressure is greater than atmospheric pressure.

❸ At the end of both inspiration and expiration, intra-alveolar pressure is equal to atmospheric pressure because the alveoli are in direct communication with the atmosphere, and air continues to flow down its pressure gradient until the two pressures equilibrate.

❹ Throughout the respiratory cycle, intrapleural pressure is less than intra-alveolar pressure.

❺ Thus, a transmural pressure gradient always exists, and the lung is always stretched to some degree, even during expiration.

❙Figure 13-13 **Intra-alveolar and intrapleural pressure changes throughout the respiratory cycle.**

The Respiratory System **455**

is confined within this smaller volume. The differential between intra-alveolar and atmospheric pressure is even greater now than during passive expiration, so more air leaves down the pressure gradient before equilibration is achieved. In this way, the lungs are emptied more completely during forceful, active expiration than during quiet, passive expiration.

During forceful expiration, the intrapleural pressure exceeds atmospheric pressure, but the lungs do not collapse. Because the intra-alveolar pressure is also increased correspondingly, a transmural pressure gradient still exists across the walls of the lungs, keeping them stretched to fill the thoracic cavity. For example, if the pressure within the thorax increases 10 mm Hg, the intrapleural pressure becomes 766 mm Hg and the intra-alveolar pressure becomes 770 mm Hg—still a 4–mm Hg pressure difference.

Airway resistance influences airflow rates.

Thus far, we have discussed airflow in and out of the lungs as a function of the magnitude of the pressure gradient between the alveoli and the atmosphere. However, just as flow of blood through the blood vessels depends not only on the pressure gradient but also on the resistance to the flow offered by the vessels, so it is with airflow:

$$F = \frac{\Delta P}{R}$$

where

F = airflow rate
ΔP = difference between atmospheric and intra-alveolar
　　　pressure (pressure gradient)
R = resistance of airways, determined by their radius

The primary determinant of resistance to airflow is the radius of the conducting airways. We ignored airway resistance in our preceding discussion of pressure gradient–induced airflow rates because, in a healthy respiratory system, the radius of the conducting system is large enough that resistance remains extremely low. Therefore, the pressure gradient between the alveoli and the atmosphere is usually the primary factor determining airflow rate. Indeed, the airways normally offer such low resistance that only small pressure gradients of 1 to 2 mm Hg are needed to achieve adequate rates of airflow into and out of the lungs. (By comparison, it would take a pressure gradient 250 times greater to move air through a smoker's pipe than through the respiratory airways at the same flow rate.)

Normally, modest adjustments in airway size can be accomplished by autonomic nervous system regulation to suit the body's needs. Parasympathetic stimulation, which occurs in quiet, relaxed situations when the demand for airflow is low, promotes bronchiolar smooth muscle contraction, which increases airway resistance by producing **bronchoconstriction** (a decrease in the radius of bronchioles). In contrast, sympathetic stimulation and to a greater extent its associated hormone, epinephrine, bring about **bronchodilation** (an increase in bronchiolar radius) and decreased airway resistance by promoting bronchiolar smooth muscle relaxation (❙Table 13-1). Thus, during periods of sympathetic domination, when increased demands for O_2 uptake are actually or potentially placed on the body, bronchodilation ensures that the pressure gradients established by respiratory muscle activity can achieve maximum airflow rates with minimum resistance. Because of this bronchodilator action, epinephrine or related drugs (such as *albuterol,* which is a more selective β_2-adrenergic agonist that relaxes bronchiolar smooth

❙**TABLE 13-1** Factors Affecting Airway Resistance

Status of Airways	Effect on Resistance	Factors Producing the Effect
Bronchoconstriction	↓ Radius, ↑ resistance to airflow	*Physiological control factors:*
		Neural control: parasympathetic stimulation
		Local chemical control: ↓ CO_2 concentration
		Pathological factors:
		Allergy-induced spasm of the airways caused by
		Slow-reactive substance of anaphylaxis (leukotrienes)
		Histamine
		Physical blockage of the airways caused by
		Excess mucus
		Edema of the walls
		Airway collapse
Bronchodilation	↑ Radius, ↓ resistance to airflow	*Physiological control factors:*

		Hormonal control: epinephrine
		Local chemical control: ↑ CO_2 concentration
		Pathological factors: none

muscle without affecting β_1-adrenergic targets like the heart; see p. 240) are useful therapeutic tools to counteract airway constriction in patients with bronchial spasms.

Resistance becomes an extremely important impediment to airflow when airway lumens become abnormally narrowed by disease. We have all transiently experienced the effect that increased airway resistance has on breathing when we have a cold. We know how difficult it is to produce an adequate airflow rate through a "stuffy nose" when the nasal passages are narrowed by swelling and mucus accumulation. More serious is chronic obstructive pulmonary disease, to which we now turn attention.

Airway resistance is abnormally increased with chronic obstructive pulmonary disease.

Clinical Note **Chronic obstructive pulmonary disease (COPD)** is a group of lung diseases characterized by increased airway resistance resulting from narrowing of the lumen of the lower airways. When airway resistance increases, a larger pressure gradient must be established to maintain even a normal airflow rate. For example, if resistance is doubled by narrowing of airway lumens, ΔP must be doubled through increased respiratory muscle exertion to induce the same flow rate of air in and out of the lungs as a healthy person accomplishes during quiet breathing. Accordingly, patients with COPD must work harder to breathe.

COPD, which is the fourth leading cause of death worldwide, encompasses three chronic (long-term) diseases: *chronic bronchitis, asthma,* and *emphysema.*

Chronic Bronchitis **Chronic bronchitis** is a long-term inflammatory condition of the lower respiratory airways, generally triggered by frequent exposure to irritating cigarette smoke, polluted air, or allergens. In response to the chronic irritation, the airways become narrowed by prolonged edematous thickening of the airway linings, coupled with overproduction of thick mucus. Despite frequent coughing associated with the chronic irritation, the plugged mucus often cannot be satisfactorily removed, especially because the irritants immobilize the ciliary mucus escalator (see p. 442). Pulmonary bacterial infections frequently occur because the accumulated mucus is an excellent medium for bacterial growth.

Asthma In **asthma**, airway obstruction is the result of (1) thickening of airway walls, brought about by inflammation and histamine-induced edema (see p. 409); (2) plugging of the airways by excessive secretion of thick mucus; and (3) airway hyperresponsiveness, characterized by profound constriction of the smaller airways caused by trigger-induced spasm of the smooth muscle in the walls of these airways (see p. 436). In severe asthmatic attacks, pronounced clogging and narrowing of the airways can cut off all airflow, leading to death. Asthma has a variety of causes. Triggers that lead to these inflammatory changes, the exaggerated bronchoconstrictor response, or both, include repeated exposure to allergens (such as dust mites or pollen), irritants (as in cigarette smoke or polluted air), respiratory infections, and vigorous exercise. Long-term infections with *Chlamydia pneumoniae,* a common cause of lung infections, may underlie up

to half of the adult cases of asthma. An estimated 15 million people in the United States have asthma, with the number steadily climbing. Asthma is the most common chronic childhood disease; 9.5% of children in the United States as a whole have asthma, with that number rising to 22% in heavily polluted cities.

Emphysema **Emphysema** is characterized by (1) collapse of the smaller airways and (2) breakdown of alveolar walls. This irreversible condition can arise in two ways. Most commonly, emphysema results from excessive release of protein-digesting enzymes such as *trypsin* from alveolar macrophages as a defense mechanism in response to chronic exposure to inhaled cigarette smoke or other irritants. The lungs are normally protected from damage by these enzymes by α_1-*antitrypsin,* a protein that inhibits trypsin. Excessive secretion of these destructive enzymes in response to chronic irritation, however, can overwhelm the protective capability of α_1-antitrypsin so that these enzymes destroy not only foreign materials but lung tissue as well. Loss of lung tissue leads to the breakdown of alveolar walls and collapse of small airways, which characterize emphysema.

Less frequently, emphysema arises from a genetic inability to produce α_1-antitrypsin so that the lung tissue has no protection from trypsin. The unprotected lung tissue gradually disintegrates under the influence of even small amounts of macrophage-released enzymes, in the absence of chronic exposure to inhaled irritants.

Difficulty in Expiring When COPD of any type increases airway resistance, expiration is more difficult than inspiration. The smaller airways, lacking the cartilaginous rings that hold the larger airways open, are kept open by the same transmural pressure gradient that distends the alveoli. Expansion of the thoracic cavity during inspiration indirectly dilates the airways even further than their expiratory dimensions, like alveolar expansion, so airway resistance is lower during inspiration than during expiration. In a healthy individual, the airway resistance is always so low that the slight variation between inspiration and expiration is not noticeable. When airway resistance has substantially increased, however, as during an asthmatic attack, the difference is quite noticeable. Thus, a person with asthma has more difficulty expiring than inspiring, giving rise to the characteristic "wheeze" as air is forced out through the narrowed airways.

Normally the smaller airways stay open during quiet breathing and even during active expiration when intrapleural pressure is elevated, as during exercise. During normal quiet breathing, because airway resistance is low, little frictional loss of pressure occurs within the airways. Airway pressure is the same as intra-alveolar pressure as air exits the alveoli and drops only slightly as air flows outward through airways. Thus, airway pressure remains higher than intrapleural pressure throughout the length of the airways, so the airways remain open. Even though intrapleural pressure is elevated during the active expiration accompanying routine vigorous activity, intra-alveolar pressure is also elevated and airway resistance is still low, so pressure in the small airways does not fall below the elevated intrapleural pressure. Therefore, collapse of the smaller airways does not occur under typical circumstances.

The smaller airways do collapse and further outflow of air is halted only during maximal forced expiration in people without COPD. Because of this airway collapse, the lungs can never be emptied completely. What causes airway collapse? During maximal forced expiration, both intra-alveolar and intrapleural pressures are markedly increased. The slight frictional losses of pressure as air exits through the airways cause the airway pressure to fall below the surrounding elevated intrapleural pressure before the exiting air reaches the level at which the airways are held open by cartilaginous rings. As a result, the small nonrigid airways are compressed closed by the surrounding higher intrapleural pressure, blocking further expiration of air. In healthy individuals, this dynamic compression of airways occurs only at very low lung volumes during maximal forced expiration. By contrast, in people who have COPD, especially emphysema, the smaller airways often collapse at high lung volumes during routine expiration, preventing further outflow of air through these passageways. This detrimental premature airway collapse occurs for two reasons: (1) the pressure drop along the airways is magnified as a result of increased airway resistance, and (2) the intrapleural pressure is higher than normal because of the loss, as in emphysema, of lung tissue that is responsible for the stretched lung's tendency to recoil and thereby lower the intrapleural pressure. Excessive air trapped in the alveoli behind the compressed bronchiolar segments in COPD reduces the amount of gas exchanged between the alveoli and the atmosphere. Therefore, less alveolar air is "freshened" with each breath when airways collapse at higher lung volumes. Furthermore, because of the extra air trapped behind these collapsed airways, people with emphysema have enlarged lungs and tend to appear barrelchested. Compared to normal, those with pronounced emphysema suffer an ironic twist of having more air in the lungs but less gas exchange (because of the loss of surface area resulting from the breakdown of alveolar walls) and decreased ability to bring in fresh air (because the chest wall cannot expand as much from its larger-than-normal resting position to reduce the intraalveolar pressure enough to accomplish adequate inspiration).

The lungs' elastic behavior results from elastin fibers and alveolar surface tension.

During the respiratory cycle, the lungs alternately expand during inspiration and recoil during expiration. What properties of the lungs enable them to behave like balloons, being stretchable and then snapping back to their resting position when the stretching forces are removed? Two interrelated concepts are involved in pulmonary elasticity: compliance and elastic recoil.

Compliance and Elastic Recoil The term **compliance** refers to how much effort is required to stretch or distend the lungs and is analogous to how easy or hard it is to blow up a balloon. (By comparison, 100 times more distending pressure is required to inflate a toy balloon than to inflate the lungs.) Specifically, compliance is a measure of how much change in lung volume results from a given change in the transmural pressure gradient, the force that stretches the lungs. A highly compliant lung stretches further for a given increase in the pressure difference than a less compliant lung does. Stated another way, the lower the compli-

ance of the lungs, the larger the transmural pressure gradient that must be created during inspiration to produce normal lung expansion. In turn, a greater-than-normal transmural pressure gradient during inspiration can be achieved only by making the intrapleural pressure more subatmospheric than usual. This is accomplished by greater expansion of the thoracic cavity through more vigorous contraction of the inspiratory muscles. Therefore, the less compliant the lungs are, the more work is required to produce a given degree of inflation. A poorly compliant lung is referred to as a "stiff" lung because it lacks normal stretchability.

Clinical Note Respiratory compliance can be decreased by several factors, as in *pulmonary fibrosis,* where normal lung tissue is replaced with scar-forming fibrous connective tissue as a result of chronically breathing in asbestos fibers or similar irritants.

The term **elastic recoil** refers to how readily the lungs rebound after having been stretched. It is responsible for the lungs returning to their preinspiratory volume when the inspiratory muscles relax at the end of inspiration.

Pulmonary elastic behavior depends mainly on two factors: large quantities of stretchy *elastin fibers* in the lung connective tissue (see ▮Figure 13-4a, p. 449; also see p. 60) and, more important, *alveolar surface tension.*

Alveolar Surface Tension The thin liquid film that lines each alveolus displays **alveolar surface tension**. At an air–water interface, the water molecules at the surface are more strongly attracted to other surrounding water molecules (by means of hydrogen bonds; see p. A-5) than to the air above the surface. This unequal attraction produces a force known as *surface tension* at the surface of the liquid. Surface tension has a twofold effect. First, the liquid layer resists any force that increases its surface area—that is, it opposes expansion of the alveolus because the surface water molecules oppose being pulled apart. Accordingly, the greater the alveolar surface tension is, the less compliant the lungs are. Second, the liquid surface area tends to shrink as small as possible because the surface water molecules, being preferentially attracted to one another, try to get as close together as possible. Thus, the surface tension of the liquid lining an alveolus tends to reduce alveolus size, squeezing in on the air inside. This property, along with the rebound of the stretched elastin fibers, produces the lungs' elastic recoil back to their preinspiratory size when inspiration is over.

Clinical Note With emphysema, elastic recoil is decreased by loss of elastin fibers and the reduction in alveolar surface tension resulting from the breakdown of alveolar walls. The decrease in elastic recoil contributes, along with the increased airway resistance, to the patient's difficulty expiring.

Pulmonary surfactant decreases surface tension and contributes to lung stability.

The cohesive forces between water molecules are so strong that if the alveoli were lined with water alone, alveolar surface tension would be so great that the lungs would collapse. The recoil force attributable to the elastin fibers and high surface tension would exceed the opposing stretching force of the transmural pressure gradient. Furthermore, the lungs would be poorly compliant, so exhausting muscular efforts would be required to accomplish

stretching and inflation of the alveoli. The tremendous surface tension of pure water is normally counteracted by pulmonary surfactant.

Pulmonary Surfactant **Pulmonary surfactant** is a complex mixture of lipids and proteins secreted by Type II alveolar cells (see **I** Figure 13-4a and b, p. 449). It intersperses between the water molecules in the fluid lining the alveoli and lowers alveolar surface tension (the term *surfactant* is derived from "*surface active agent*"). Because the cohesive force between a water molecule and an adjacent pulmonary surfactant molecule is very low, pulmonary surfactant decreases the extent of hydrogen bonding between molecules at the alveolar air–water interface. By lowering alveolar surface tension, pulmonary surfactant provides two important benefits: (1) It increases pulmonary compliance, reducing the work of inflating the lungs, and (2) it reduces the lungs' tendency to recoil so that they do not collapse as readily.

Pulmonary surfactant's role in reducing the tendency of alveoli to recoil, thereby discouraging alveolar collapse, is important in helping maintain lung stability. The division of the lung into myriad tiny air sacs provides the advantage of a tremendously increased surface area for exchange of O_2 and CO_2, but it also presents the problem of maintaining the stability of all these alveoli. Recall that the pressure generated by alveolar surface tension is directed inward, squeezing in on the air in the alveolus. If you visualize the alveoli as spherical bubbles, according to the **law of LaPlace**, the magnitude of the inward-directed collapsing pressure is directly proportional to the surface tension and inversely proportional to the radius of the bubble:

$$P = \frac{2T}{r}$$

where

P = inward-directed collapsing pressure
T = surface tension
r = radius of bubble (alveolus)

Law of LaPlace:
Magnitude of inward-directed pressure (P) in a bubble (alveolus) = $\dfrac{2 \times \text{Surface tension } (T)}{\text{Radius } (r) \text{ of bubble (alveolus)}}$

Airways

$P_1 = \dfrac{2 \times T}{r}$

(b) With pulmonary surfactant

I Figure 13-14 Role of pulmonary surfactant in counteracting the tendency for small alveoli to collapse into larger alveoli. (a) According to the law of LaPlace, if two alveoli of unequal size but the same surface tension are connected by the same terminal airway, the smaller alveolus—because it generates a larger inward-directed collapsing pressure—has a tendency (without pulmonary surfactant) to collapse and empty its air into the larger alveolus. (b) Pulmonary surfactant reduces the surface tension of a smaller alveolus more than that of a larger alveolus. This reduction in surface tension offsets the effect of the smaller radius in determining the inward-directed pressure. Consequently, the collapsing pressures of the small and large alveoli are comparable. Therefore, in the presence of pulmonary surfactant a small alveolus does not collapse and empty its air into the larger alveolus.

Because the collapsing pressure is inversely proportional to the radius, the smaller the alveolus, the smaller its radius and the greater its tendency to collapse at a given surface tension. Accordingly, if two alveoli of unequal size but the same surface tension are connected by the same terminal airway, the smaller alveolus—because it generates a larger collapsing pressure—has a tendency to collapse and empty its air into the larger alveolus (**I** Figure 13-14a).

Small alveoli normally do not collapse and blow up larger alveoli, however, because pulmonary surfactant reduces the surface tension of small alveoli more than that of larger alveoli. Pulmonary surfactant decreases surface tension to a greater degree in small alveoli than in larger alveoli because the surfactant molecules are crowded closer together in the smaller alveoli. The larger an alveolus, the more spread out are its surfactant molecules and the less effect they have on reducing surface tension. The surfactant-induced lower surface tension of small alveoli offsets the effect of their smaller radius in determining the inward-directed pressure. Therefore, the presence of surfactant causes the collapsing pressure of small alveoli to become comparable to that of larger alveoli and minimizes the tendency for small alveoli to collapse and empty their contents into larger alveoli (❙Figure 13-14b). Pulmonary surfactant therefore helps stabilize the sizes of the alveoli and helps keep them open and available to participate in gas exchange.

The opposing forces acting on the lung (that is, the forces keeping the alveoli open and the countering forces that promote alveolar collapse) are summarized in ❙Table 13-2.

Newborn Respiratory Distress Syndrome Developing fetal lungs normally cannot synthesize pulmonary surfactant until late in pregnancy. Especially in an infant born prematurely, not enough pulmonary surfactant may be produced to reduce the alveolar surface tension to manageable levels. The resulting collection of symptoms is termed **newborn respiratory distress syndrome**. The infant must make strenuous inspiratory efforts to overcome the high surface tension in an attempt to inflate the poorly compliant lungs. Moreover, the work of breathing is further increased because the alveoli, in the absence of surfactant, tend to collapse almost completely during each expiration. It is more difficult (requires a greater transmural pressure differential) to expand a collapsed alveolus by a given volume than to increase an already partially expanded alveolus by the same volume. The situation is analogous to blowing up a new balloon. It takes more effort to blow in that first breath of air when starting to blow up a new balloon than to blow additional breaths into the already partially expanded balloon. With newborn respiratory distress syndrome, it is as though with every breath the infant must start blowing up a new balloon. Lung expansion may require transmural pressure gradients of 20 to 30 mm Hg (compared to the normal 4 to 6 mm Hg) to overcome the tendency of surfactant-deprived alveoli to collapse. Worse yet, the newborn's muscles are still weak. The respiratory distress from surfactant deficiency may soon lead to death if breathing efforts become exhausting or inadequate to support sufficient gas exchange.

This life-threatening condition affects 30,000 to 50,000 newborns, primarily premature infants, each year in the United States. Until the surfactant-secreting cells mature sufficiently, the condition is treated by surfactant replacement. In addition, drugs can hasten the maturation process.

The work of breathing normally requires only about 3% of total energy expenditure.

During normal quiet breathing, the respiratory muscles must work during inspiration to expand the lungs against their elastic forces and to overcome airway resistance, whereas expiration is passive. Normally, the lungs are highly compliant and airway resistance is low, so only about 3% of the total energy expended by the body is used for quiet breathing. The work of breathing may be increased in four different situations:

1. *When pulmonary compliance is decreased,* such as with pulmonary fibrosis, more work is required to expand the lungs.

2. *When airway resistance is increased,* such as with COPD, more work is required to achieve the greater pressure gradients necessary to overcome the resistance so that adequate airflow can occur.

3. *When elastic recoil is decreased,* as with emphysema, passive expiration may be inadequate to expel the volume of air normally exhaled during quiet breathing. Thus, the abdominal muscles must work to aid in emptying the lungs, even when the person is at rest.

4. *When there is a need for increased ventilation,* such as during exercise, more work is required to accomplish both a greater depth of breathing (a larger volume of air moving in and out with each breath) and a faster rate of breathing (more breaths per minute).

During strenuous exercise, the amount of energy required to power pulmonary ventilation may increase up to 25-fold. However, because total energy expenditure by the body increases up to 15- to 20-fold during heavy exercise, the energy used for increased ventilation still represents only about 5% of total energy expended. In contrast, in patients with poorly compliant lungs or obstructive lung disease, the energy required for breathing even at rest may be as much as 30% of total energy expenditure. In such cases, the individual's exercise ability is severely limited, as breathing itself becomes exhausting.

The lungs normally operate about "half full."

On average, in healthy young adults, the maximum air that the lungs can hold is about 5.7 liters in males (4.2 liters in females). Anatomic build, age, the distensibility of the lungs, and the presence or absence of respiratory disease affect this total lung

capacity. Normally, during quiet breathing, the lungs are nowhere near maximally inflated, nor are they deflated to their minimum volume. Thus, the lungs normally remain moderately inflated throughout the respiratory cycle. At the end of a normal quiet expiration, the lungs still contain about 2200 mL of air. During each typical breath under resting conditions, about 500 mL of air are inspired and the same quantity is expired, so during quiet breathing the lung volume varies from 2200 mL at the end of expiration to 2700 mL at the end of inspiration (I Figure 13-15a). During maximal expiration, lung volume can decrease to 1200 mL in males (1000 mL in females), but the lungs can never be completely deflated because the small airways collapse during forced expirations at low lung volumes, blocking further outflow.

A beneficial outcome of not being able to empty the lungs completely is that even during maximal expiratory efforts, gas exchange can continue between the blood flowing through the lungs and the remaining alveolar air. As a result, the gas content of the blood leaving the lungs for delivery to the tissues normally remains remarkably constant throughout the respiratory cycle. By contrast, if the lungs completely filled and emptied with each breath, the amount of O_2 taken up and CO_2 dumped off by the blood would fluctuate widely. Another advantage of the lungs not completely emptying with each breath is the

reduced work of breathing. Recall that it takes less effort to inflate a partially inflated alveolus than a totally collapsed one.

The changes in lung volume that occur with different respiratory efforts can be determined by a spirometer. A traditional wet **spirometer** consists of an air-filled drum floating in a water-filled chamber. As the person breathes air in and out of the drum through a tube connecting the mouth to the air chamber, the drum rises and falls in the water chamber. This rise and fall can be recorded as a **spirogram**, which is calibrated to changes in lung volume. Inspiration is recorded as an upward deflection and expiration as a downward deflection. Today, less cumbersome computerized spirometers have replaced the wet spirometer for clinical use, but the principles of the lung volumes and capacities determined by the older instrument are the same.

Lung Volumes and Capacities I Figure 13-15b is a hypothetical example of a spirogram in a healthy young adult male. Generally, the values are lower for females. The following lung volumes and capacities (a lung capacity is the sum of two or more lung volumes) can be determined:

■ **Tidal volume (TV):** The volume of air entering or leaving the lungs during a single breath. Average value under resting conditions = 500 mL.

■ **Inspiratory reserve volume (IRV):** The extra volume of air that can be maximally inspired over and above the typical resting tidal volume. The IRV is accomplished by maximal contraction of the diaphragm, external intercostal muscles, and accessory inspiratory muscles. Average value = 3000 mL.

■ **Inspiratory capacity (IC):** The maximum volume of air that can be inspired at the end of a normal quiet expiration (IC = IRV + TV). Average value = 3500 mL.

■ **Expiratory reserve volume (ERV):** The extra volume of air that can be actively expired by maximally contracting the expiratory muscles beyond that normally passively expired at the end of a typical resting tidal volume. Average value = 1000 mL.

■ **Residual volume (RV):** The minimum volume of air remaining in the lungs even after a maximal expiration. Average value = 1200 mL. The residual volume cannot be measured directly with a spirometer because this volume of air does not move into and out of the lungs. It can be determined indirectly, however, through gas-dilution techniques involving inspiration of a known quantity of a harmless tracer gas such as helium.

■ **Functional residual capacity (FRC):** The volume of air in the lungs at the end of a normal passive expiration (FRC = ERV + RV). Average value = 2200 mL.

■ **Vital capacity (VC):** The maximum volume of air that can be moved out during a single breath following a maximal inspiration. The subject first inspires maximally and then expires maximally (VC = IRV + TV + ERV). The VC represents the maximum volume change possible within the lungs (❙Figure 13-16). It is rarely used because the maximal muscle contractions involved become exhausting, but it is valuable in determining the functional capacity of the lungs. Average value = 4500 mL.

■ **Total lung capacity (TLC):** The maximum volume of air that the lungs can hold (TLC = VC + RV). Average value = 5700 mL.

■ **Forced expiratory volume in 1 second (FEV_1):** The volume of air that can be expired during the first second of expiration in a VC determination. Usually, FEV_1 is about 80% of VC—that is, normally 80% of the air that can be forcibly expired from maximally inflated lungs can be expired within 1 second. This measurement indicates the maximal airflow rate possible from the lungs.

Clinical Note **Respiratory Dysfunction** Two general categories of respiratory dysfunction yield abnormal results during spirometry—*obstructive lung disease* (difficulty in emptying the lungs) and *restrictive lung disease* (difficulty in filling the lungs) (❙Figure 13-17). However, these are not the only categories of respiratory dysfunction, nor is spirometry the only pulmonary function test. Other conditions affecting respiratory function include (1) diseases impairing diffusion of O_2 and CO_2 across the pulmonary membranes; (2) reduced ventilation because of mechanical failure, as with neuromuscular disorders affecting the respiratory muscles; (3) inadequate perfusion (failure of adequate pulmonary blood flow); or (4) ventilation–perfusion imbalances involving a poor matching of air and blood so that efficient gas exchange cannot occur. Some lung diseases are actually a complex mixture of different types of functional disturbances. To determine what abnormalities are present, the diagnostician relies on a variety of pulmonary function tests in addition to spirometry, including X-ray examination, blood-gas determinations, and tests to measure the diffusion capacity of the alveolar–capillary membrane.

Alveolar ventilation is less than pulmonary ventilation because of dead space.

Various changes in lung volume represent only one factor in determining **pulmonary**, or **minute**, **ventilation**, which is the volume of air breathed in and out in 1 minute. The other important factor is **respiratory rate**, which averages 12 breaths per minute:

$$\underset{\text{(mL/min)}}{\text{Pulmonary ventilation}} = \underset{\text{(mL/breath)}}{\text{tidal volume}} \times \underset{\text{(breaths/min)}}{\text{respiratory rate}}$$

At an average tidal volume of 500 mL/breath and a respiratory rate of 12 breaths/min, pulmonary ventilation is 6000 mL, or 6 liters, of air breathed in and out in 1 minute under resting conditions. For a brief period, a healthy young adult male can voluntarily increase his total pulmonary ventilation 25-fold, to 150 liters/min. To increase pulmonary ventilation, both tidal volume and respiratory rate increase, but depth of breathing increases more than frequency of breathing. It is usually more advantageous to have a greater increase in tidal volume than in respiratory rate because of anatomic dead space, discussed next.

Anatomic Dead Space Not all the inspired air gets down to the site of gas exchange in the alveoli. Part remains in the conducting airways, where it is not available for gas exchange. The volume of the conducting passages in an adult averages about 150 mL. This volume is considered **anatomic dead space** because air within these conducting airways is useless for exchange. Anatomic dead space greatly affects the efficiency of pulmonary ventilation. In effect, even though 500 mL of air are moved in and out with each breath, only 350 mL are actually

❙Figure 13-16 **X-rays of lungs showing maximum volume change.** The difference between (a) the maximum lung volume at maximum inspiration and (b) the minimum lung volume at maximum expiration is the vital capacity, the maximum volume change possible during a single breath.
(a) Spirogram in obstructive lung disease
(b) Spirogram in restrictive lung disease

❚Figure 13-17 **Abnormal lung volumes and capacities with obstructive and restrictive lung diseases.** (a) Because a patient with obstructive lung disease experiences more difficulty emptying the lungs than filling them, the total lung capacity (TLC) is essentially normal, but the functional residual capacity (FRC) and the residual volume (RV) are elevated as a result of the additional air trapped in the lungs following expiration. Because the RV is increased, the vital capacity (VC) is reduced. With more air remaining in the lungs, less of the TLC is available to be used in exchanging air with the atmosphere. Another common finding is a markedly reduced forced expiratory volume in one second (FEV$_1$) because the airflow rate is reduced by the airway obstruction. Even though both the VC and the FEV$_1$ are reduced, the FEV$_1$ is reduced more markedly than the VC is. As a result, the FEV$_1$/VC% is much lower than the normal 80%—that is, much less than 80% of the reduced VC can be blown out during the first second. (b) In restrictive lung disease, the lungs are less compliant than normal. Total lung capacity, inspiratory capacity, and VC are reduced because the lungs cannot be expanded as normal. The percentage of the VC that can be exhaled within one second is the normal 80% or an even higher percentage because air can flow freely in the airways. Therefore, the FEV$_1$/VC% is particularly useful in distinguishing between obstructive and restrictive lung disease. Also, in contrast to obstructive lung disease, the RV is usually normal in restrictive lung disease.

FIGURE FOCUS: *Use the graphs to explain why vital capacity is reduced in obstructive lung disease and in restrictive lung disease compared to normal in Figure 13-15.*

exchanged between the atmosphere and the alveoli because of the 150 mL occupying the anatomic dead space.

Looking at Figure 13-18, note that at the end of inspiration the respiratory airways are filled with 150 mL of fresh atmospheric air from the inspiration. During the subsequent expiration, 500 mL of air are expired to the atmosphere. The first 150 mL expired are the fresh air that was retained in the airways and never used. The remaining 350 mL expired are "old" alveolar air that has participated in gas exchange with the blood. During the same expiration, 500 mL of gas also leave the alveoli. The first 350 mL are expired to the atmosphere; the other 150 mL of old alveolar air never reach the outside but remain in the conducting airways.

On the next inspiration, 500 mL of gas enter the alveoli. The first 150 mL to enter the alveoli are the old alveolar air that remained in the dead space during the preceding expiration. The other 350 mL entering the alveoli are fresh air inspired from the atmosphere. Simultaneously, 500 mL of air enter from the atmosphere. The first 350 mL of atmospheric air reach the alveoli; the other 150 mL remain in the conducting airways to be expired without benefit of being exchanged with the blood, as the cycle repeats itself.

Alveolar Ventilation Because the amount of atmospheric air that reaches the alveoli and is actually available for exchange with blood is more important than the total amount breathed in and out, **alveolar ventilation**—the volume of air exchanged between the atmosphere and the alveoli per minute—is more important than pulmonary ventilation. In determining alveolar

ventilation, the amount of wasted air moved in and out through the anatomic dead space must be taken into account, as follows:

Alveolar ventilation = (tidal volume − dead space volume) × respiratory rate

With average resting values,

Alveolar ventilation = (500 mL/breath − 150 mL dead space volume) × 12 breaths/min = 4200 mL/min

Thus, with quiet breathing, alveolar ventilation is 4200 mL/min, whereas pulmonary ventilation is 6000 mL/min.

Effect of Breathing Patterns on Alveolar Ventilation
To understand how important dead space volume is in determining the magnitude of alveolar ventilation, examine the effect of various breathing patterns on alveolar ventilation in ❚Table 13-3. If a person deliberately breathes deeply (for example, a tidal volume of 1200 mL) and slowly (for example, a respiratory rate of 5 breaths/min), pulmonary ventilation is 6000 mL/min, the same as during quiet breathing at rest, but alveolar ventilation increases to 5250 mL/min compared to the resting rate of 4200 mL/min. In contrast, if a person deliberately breathes shallowly (for example, a tidal volume of 150 mL) and rapidly (a frequency of 40 breaths/min), pulmonary ventilation would still be 6000 mL/min; however, alveolar ventilation would be 0 mL/min. In effect, the person would only be drawing air in and out of the anatomic dead space without any atmospheric air being exchanged with the alveoli, where it could be useful. The individual could voluntarily maintain such a breath-

❚ Figure 13-18 Effect of dead space volume on exchange of tidal volume between the atmosphere and the alveoli. Even though 500 mL of air move in and out between the atmosphere and the respiratory system and 500 mL move in and out of the alveoli with each breath, only 350 mL are actually exchanged between the atmosphere and the alveoli because of the anatomic dead space (the volume of air in the respiratory airways).

❚ TABLE 13-3 Effect of Different Breathing Patterns on Alveolar Ventilation

ing pattern for only a few minutes before losing consciousness, at which time normal breathing would resume.

The value of reflexly bringing about a larger increase in depth of breathing than in rate of breathing when pulmonary ventilation increases during exercise should now be apparent. It is the most efficient means of elevating alveolar ventilation. When tidal volume increases, the entire increase in pulmonary ventilation goes toward elevating alveolar ventilation. In contrast, when pulmonary ventilation increases as a result of an increase in respiratory rate, the frequency with which air is wasted in the dead space also increases because a portion of *each breath* must move in and out of the dead space. Thus not all of the increase in pulmonary ventilation goes toward elevating alveolar ventilation. As needs vary, ventilation is normally

adjusted to a tidal volume and respiratory rate that meet those needs most efficiently in terms of energy cost.

Alveolar Dead Space We have assumed that all the atmospheric air entering the alveoli participates in exchanges of O_2 and CO_2 with pulmonary blood. However, the match between air and blood is not always perfect because not all alveoli are equally ventilated with air and perfused with blood. Any ventilated alveoli that do not participate in gas exchange with blood because they are inadequately perfused are considered **alveolar dead space**. In healthy people, alveolar dead space is quite small and of little importance, but it can increase to even lethal levels in several types of pulmonary disease.

Next you will learn why alveolar dead space is minimal in healthy individuals.

Local controls act on bronchiolar and arteriolar smooth muscle to match airflow to blood flow.

When discussing the role of airway resistance in determining airflow rate into and out of the lungs, we were referring to the overall resistance of all the airways collectively. However, the resistance of individual airways supplying specific alveoli can be adjusted independently in response to changes in the airway's local environment. This situation is comparable to the control of systemic arterioles. Recall that overall systemic arteriolar resistance (that is, total peripheral resistance) is an important determinant of the blood pressure gradient that drives blood flow throughout the systemic circulatory system (see p. 349). Yet the radius of individual arterioles supplying various tissues can be adjusted locally to match the tissues' differing metabolic needs (see p. 345).

Effect of CO_2 on Bronchiolar Smooth Muscle Similar to arteriolar smooth muscle, bronchiolar smooth muscle is sensitive to local changes within its immediate environment, particularly to local CO_2 levels. If an alveolus is receiving too little airflow in comparison to its blood flow, CO_2 levels will increase in the alveolus and surrounding tissue as the blood drops off more CO_2 than is exhaled into the atmosphere. This local increase in CO_2 directly promotes relaxation of the bronchiolar smooth muscle, bringing about dilation of the airway supplying the underaerated alveolus. The resultant decrease in airway resistance leads to an increased airflow (for the same ΔP) to the involved alveolus, so its airflow now matches its blood supply (❚ Figure 13-19a). The converse is also true. A localized decrease in CO_2 associated with an alveolus that is receiving too much air for its blood supply directly increases contractile activity of the airway smooth muscle involved, constricting the airway supplying this overaerated alveolus. The result is reduced airflow to the overaerated alveolus (❚ Figure 13-19b).

Effect of O_2 on Pulmonary Arteriolar Smooth Muscle Simultaneously, a similar locally induced effect on pulmonary vascular smooth muscle takes place to maximally match blood flow to airflow. The two mechanisms for matching airflow and

blood flow function concurrently, so normally very little air or blood is wasted in the lung. In the pulmonary circulation, just as in the systemic circulation, distribution of the cardiac output to different alveolar capillary networks can be controlled by adjusting the resistance to blood flow through specific pulmonary arterioles. If blood flow is greater than airflow to a given alveolus, the O_2 level in the alveolus and surrounding tissues falls below normal as the overabundance of blood extracts more O_2 than usual from the alveolus. The local decrease in O_2 concentration causes vasoconstriction of the pulmonary arteriole supplying this particular capillary bed, thus reducing blood flow to match the smaller airflow (❚ Figure 13-19a). Conversely, an increase in alveolar O_2 concentration caused by a mismatched large airflow and small blood flow brings about pulmonary vasodilation, which increases blood flow to match the larger airflow (❚ Figure 13-19b).

This local effect of O_2 on pulmonary arteriolar smooth muscle is, appropriately, just the opposite of its effect on systemic arteriolar smooth muscle (❚ Table 13-4). In the systemic circulation, a decrease in O_2 in a tissue causes localized vasodilation to increase blood flow to the deprived area, and vice versa, which is important in matching blood supply to local metabolic needs.

Because of gravitational effects, some regional differences in ventilation and perfusion exist from the top to the bottom of the lung. When a person is standing upright, ventilation and perfusion are both less at the top of the lung and greater at the bottom of the lung, but gravity exerts a more marked effect on blood flow than on airflow. Therefore, the ventilation–perfusion ratio (the rate of airflow compared to the rate of blood flow) decreases from the top to the bottom of the lung (❚ Figure 13-20). In other words, the top of the lung receives less air and blood than the bottom of the lung, but it receives relatively more air than blood; the bottom of the lung receives more air and blood than the top of the lung, but it receives relatively less air than blood. In healthy lungs, the effect of this mismatch between air and blood has a negligible effect on overall O_2 uptake and CO_2 elimination. Airflow and blood flow at a particular alveolar interface are usually matched as much as possible by local controls to accomplish efficient exchange of O_2 and CO_2. However, in pathologic conditions, ventilation–perfusion mismatches can exceed the capability of local controls to compensate, so the effect on O_2 uptake and CO_2 elimination can become significant, as with widespread plugging of airways with inflammatory mucus secretion or widespread damage to pulmonary vessels.

We have now finished discussing respiratory mechanics—all the factors involved in ventilation. We next examine gas exchange between alveolar air and blood and then between blood and systemic tissues.

13.3 Gas Exchange

The purpose of breathing is to provide a continual supply of fresh O_2 for pickup by blood and to constantly remove CO_2 unloaded from blood. Blood acts as a transport system for O_2 and CO_2 between the lungs and the tissues, with the tissue cells extracting O_2 from blood and eliminating CO_2 into it.

Gases move down partial pressure gradients.

Gas exchange at both the pulmonary capillary and the tissue capillary levels involves simple passive diffusion of O_2 and CO_2 down *partial pressure gradients.* No active transport mechanisms exist for these gases. Let us see what partial pressure gradients are and how they are established.

Partial Pressures Atmospheric air is a mixture of gases; typical dry air contains about 79% nitrogen (N_2) and 21% O_2, with almost negligible percentages of CO_2, H_2O vapor, other gases, and pollutants. Altogether, these gases exert a total atmospheric pressure of 760 mm Hg at sea level. This total pressure is equal to the sum of the pressures that each gas in the mixture partially contributes. The pressure exerted by a particular gas is directly proportional to the percentage of that gas in the total air mixture. Every gas molecule, no matter what its size, exerts the same amount of pressure; for example, a N_2 molecule exerts the same

Effects of Local Changes in O_2 on Pulmonary and Systemic Arterioles

Composition and partial pressures in atmospheric air

Total atmospheric pressure = 760 mm Hg

79% N_2

Partial pressure of N_2 = 600 mm Hg

Partial pressure of N_2 in atmospheric air:
P_{N_2} = 760 mm Hg × 0.79 = 600 mm Hg

21% O_2

Partial pressure of O_2 = 160 mm Hg

Partial pressure of O_2 in atmospheric air:
P_{O_2} = 760 mm Hg × 0.21 = 160 mm Hg

IFigure 13-21 Concept of partial pressures. The partial pressure exerted by each gas in a mixture equals the total pressure times the fractional composition of the gas in the mixture.

FIGURE FOCUS: *If a person lives 1 mile above sea level in Denver, Colorado (the "mile-high city"), where the atmospheric pressure is 630 mm Hg, what would the P_{O_2} of inspired air be?*

pressure as an O_2 molecule. Because 79% of the air consists of N_2 molecules, 79% of the 760 mm Hg atmospheric pressure, or 600 mm Hg, is exerted by the N_2 molecules. Similarly, because O_2 represents 21% of the atmosphere, 21% of the 760 mm Hg atmospheric pressure, or 160 mm Hg, is exerted by O_2 (IFigure 13-21). The individual pressure exerted independently by a particular gas within a mixture of gases is known as its **partial pressure**, designated by P_{gas}. Thus, the partial pressure of O_2 in atmospheric air, P_{O_2}, is normally 160 mm Hg. The atmospheric partial pressure of CO_2, P_{CO_2}, is negligible at 0.23 mm Hg.

Gases dissolved in a liquid such as blood or another body fluid also exert a partial pressure. The greater the partial pressure of a gas in a liquid is, the more of that gas is dissolved.

Partial Pressure Gradients A difference in partial pressure between the capillary blood and the surrounding structures is known as a **partial pressure gradient**. Partial pressure gradients exist between the alveolar air and the pulmonary capillary blood. Similarly, partial pressure gradients exist between the systemic capillary blood and the surrounding tissues. A gas always diffuses down its partial pressure gradient from the area of higher partial pressure to the area of lower partial pressure, similar to diffusion down a concentration gradient.
(a) Regional ventilation and perfusion rates and ventilation–perfusion ratios in the lungs

	Ventilation (airflow) (L/min)	Perfusion (blood flow) (L/min)	Ventilation–perfusion ratio

(b) Ventilation and perfusion rates and ventilation–perfusion ratios at top and bottom of lungs

IFigure 13-20 Differences in ventilation, perfusion, and ventilation–perfusion ratios at the top and bottom of the lungs as a result of gravitational effects. Note that the top of the lungs receives less air and blood than the bottom of the lungs, but the top of the lungs receives relatively more air than blood and the bottom of the lungs receives relatively less air than blood.

FIGURE FOCUS: *(1) Is the top or bottom of the lung better ventilated? (2) Which region is better perfused? (3) Which has a higher ventilation–perfusion ratio?*

O2 enters and CO2 leaves the blood in the lungs down partial pressure gradients.

We first consider the magnitude of alveolar P_{O_2} and P_{CO_2} and then look at the partial pressure gradients that move these two gases between the alveoli and the incoming pulmonary capillary blood.

Alveolar P_{O_2} and P_{CO_2} Alveolar air is not of the same composition as inspired atmospheric air, for two reasons. First, as soon as atmospheric air enters the respiratory passages, exposure to the moist airways saturates it with H_2O. Like any other gas, water vapor exerts a partial pressure. At body temperature, the partial pressure of H_2O vapor is 47 mm Hg. Humidification of inspired air in effect "dilutes" the partial pressure of the inspired gases by 47 mm Hg because the sum of the partial pressures must total the atmospheric pressure of 760 mm Hg. In moist air, P_{H_2O} = 47 mm Hg, P_{N_2} = 563 mm Hg, and P_{O_2} = 150 mm Hg.

Second, alveolar P_{O_2} is also lower than atmospheric P_{O_2} because fresh inspired air (average equals 350 mL out of a tidal volume of 500 mL) is mixed with the large volume of old air that remained in the lungs at the end of the preceding expiration (average functional residual capacity equals 2200 mL). At the end of inspiration, only about 13% of the air in the alveoli is fresh air. As a result of humidification and the small turnover of alveolar air, the average alveolar P_{O_2} is 100 mm Hg, compared to the atmospheric P_{O_2} of 160 mm Hg.

You might logically think that alveolar P_{O_2} would increase during inspiration with the arrival of fresh air and would decrease during expiration. Only small fluctuations in alveolar P_{O_2} occur, however, for two reasons. First, only a small proportion of the total alveolar air is exchanged with each breath. The relatively small volume of inspired, high-P_{O_2} air is quickly mixed with the larger volume of retained alveolar air, which has a lower P_{O_2}. Thus, the O2 in the inspired air can only slightly elevate the level of the total alveolar P_{O_2}. Even this potentially small elevation of P_{O_2} is diminished for another reason. O2 continually moves by passive diffusion down its partial pressure gradient from the alveoli into the blood. The O2 arriving in the alveoli in the newly inspired air simply replaces the O2 diffusing out of the alveoli into the pulmonary capillaries. Therefore, alveolar P_{O_2} remains relatively constant around 100 mm Hg throughout the respiratory cycle. Because pulmonary blood P_{O_2} equilibrates with alveolar P_{O_2}, the P_{O_2} of the blood leaving the lungs likewise remains fairly constant at this same value. Accordingly, the amount of O2 in the blood available to the tissues varies only slightly during the respiratory cycle.

A similar situation exists in reverse for CO2, which is continuously produced by the body tissues as a metabolic waste product and constantly added to the blood at the level of the systemic capillaries. In the pulmonary capillaries, CO2 diffuses down its partial pressure gradient from the blood into the alveoli and is removed from the body during expiration. As with O2, alveolar P_{CO_2} remains fairly constant throughout the respiratory cycle but at a lower value of 40 mm Hg.

P_{O_2} and P_{CO_2} Gradients Across the Pulmonary Capillaries As blood passes through the lungs, it picks up O2 and gives up CO2 by diffusion down partial pressure gradients between blood and alveoli. Ventilation constantly replenishes alveolar O2 and removes CO2, thus maintaining the appropriate gradients to ensure this diffusion. Blood entering the pulmonary capillaries is systemic venous blood pumped to the lungs through the pulmonary arteries. This blood, having just returned from the body tissues, is relatively low in O2, with a P_{O_2} of 40 mm Hg, and is relatively high in CO2, with a P_{CO_2} of 46 mm Hg. As this blood flows through the pulmonary capillaries, it is exposed to alveolar air (❙Figure 13-22). Because the alveolar P_{O_2} at 100 mm Hg is higher than the P_{O_2} of 40 mm Hg in the blood entering the lungs, O2 diffuses down its partial pressure gradient from the alveoli into the blood until no further gradient exists. As blood leaves the pulmonary capillaries, it has a P_{O_2} equal to alveolar P_{O_2} at 100 mm Hg.

The partial pressure gradient for CO2 is in the opposite direction. Blood entering the pulmonary capillaries has a P_{CO_2} of 46 mm Hg, whereas alveolar P_{CO_2} is only 40 mm Hg. CO2 diffuses from the blood into the alveoli until blood P_{CO_2} equilibrates with alveolar P_{CO_2}. Thus, blood leaving the pulmonary capillaries has a P_{CO_2} of 40 mm Hg. After leaving the lungs, the blood, which now has a P_{O_2} of 100 mm Hg and a P_{CO_2} of 40 mm Hg, is returned to the heart and then pumped out to the body tissues as systemic arterial blood.

Note that blood returning to the lungs from the tissues still contains O2 (P_{O_2} of systemic venous blood = 40 mm Hg) and that blood leaving the lungs still contains CO2 (P_{CO_2} of systemic arterial blood = 40 mm Hg). The extra O2 carried in the blood beyond that normally given up to the tissues represents an immediately available O2 reserve that can be tapped by tissue cells whenever their O2 demands increase. The CO2 remaining in the blood even after passage through the lungs plays an important role in the acid–base balance of the body because CO2 generates carbonic acid. Furthermore, arterial P_{CO_2} is important in driving respiration, as described later.

The amount of O2 picked up in the lungs matches the amount extracted and used by the tissues. When the tissues metabolize more actively (for example, during exercise), they extract more O2 from the blood, reducing the systemic venous P_{O_2} even lower than 40 mm Hg—for example, to a P_{O_2} of 30 mm Hg. When this blood returns to the lungs, a larger-than-normal P_{O_2} gradient exists between the newly entering blood and the alveolar air. Therefore, more O2 diffuses from the alveoli into the blood down the larger partial pressure gradient before blood P_{O_2} equals alveolar P_{O_2}. This additional transfer of O2 into the blood replaces the increased amount of O2 consumed, so O2 uptake matches O2 use even when O2 consumption increases. As more O2 is diffusing from the alveoli into the blood because of the increased partial pressure gradient, ventilation is stimulated so that O2 enters the alveoli more rapidly from the atmosphere to replace the O2 diffusing into the blood. Similarly, the amount of CO2 given up to the alveoli from the blood matches the amount of CO2 picked up at the tissues.

Factors other than the partial pressure gradient influence the rate of gas transfer.

We have been discussing diffusion of O2 and CO2 between alveoli and blood as if these gases' partial pressure gradients were the sole determinants of their rates of diffusion. According

Figure 13-22 O_2 and CO_2 exchange across pulmonary and systemic capillaries caused by partial pressure gradients.

Net diffusion gradients for O_2 and CO_2, between the lungs and tissues

High P_{O_2} | Low P_{CO_2}

Low P_{O_2} | High P_{CO_2}

1 Alveolar P_{O_2} remains relatively high and alveolar P_{CO_2} remains relatively low because a portion of the alveolar air is exchanged for fresh atmospheric air with each breath.

2 In contrast, the systemic venous blood entering the lungs is relatively low in O_2 and high in CO_2, having given up O_2 and picked up CO_2 at the systemic capillary level.

3 The partial pressure gradients established between the alveolar air and pulmonary capillary blood induce passive diffusion of O_2 into the blood and CO_2 out of the blood until the blood and alveolar partial pressures become equal.

4 The blood leaving the lungs is thus relatively high in O_2 and low in CO_2. It arrives at the tissues with the same blood-gas content as when it left the lungs.

5 The partial pressure of O_2 is relatively low and that of CO_2 is relatively high in the O_2-consuming, CO_2-producing tissue cells.

6 Consequently, partial pressure gradients for gas exchange at the tissue level favor the passive movement of O_2 out of the blood into cells to support their metabolic requirements and also favor the simultaneous transfer of CO_2 into the blood.

7 Having equilibrated with the tissue cells, the blood leaving the tissues is relatively low in O_2 and high in CO_2.

8 The blood then returns to the lungs to once again fill up on O_2 and dump off CO_2.

to Fick's law of diffusion, the diffusion rate of a gas through a sheet of tissue also depends on the surface area and thickness of the membrane through which the gas is diffusing and on the diffusion constant of the particular gas (Table 13-5). Changes in the rate of gas exchange normally are determined primarily by changes in partial pressure gradients between blood and alveoli because these other factors are relatively constant under resting conditions. However, under circumstances when these other factors do change, these changes alter the rate of gas transfer in the lungs.

Effect of Surface Area on Gas Exchange The rate of gas exchange is directly proportional to the surface area across which exchange takes place. During exercise, the surface area available for exchange can be increased to enhance the rate of gas transfer. During resting conditions, some of the pulmonary capillaries are typically closed because the normally low pressure of the pulmonary circulation is inadequate to keep all the capillaries open. During exercise, when pulmonary blood pressure is raised by increased cardiac output, many of the previously closed pulmonary capillaries are forced open. This increases the surface area of blood available for exchange. Furthermore, the alveolar walls are stretched further than normal during exercise because of the larger tidal volumes (deeper breathing). Such stretching increases the alveolar surface area and decreases the thickness of the alveolar walls. Collectively, these changes expedite gas exchange across the alveolar–capillary membrane during exercise.

Clinical Note By contrast, several pathological conditions can markedly reduce pulmonary surface area and, in turn, decrease the rate of gas exchange. Most notably, in *emphysema* surface area is reduced because many alveolar walls are lost,

Factors That Influence the Rate of Gas Transfer Across the Alveolar–Capillary Membrane

Factor	Influence on the Rate of Gas Transfer Between Air and Blood	Comments
Partial pressure gradients of O_2 and CO_2	Rate of transfer ↑ as partial pressure gradient ↑	Major determinant of the rate of transfer
Surface area of the alveolar–capillary membrane	Rate of transfer ↑ as surface area ↑	Surface area remains constant under resting conditions Surface area ↑ during exercise Surface area ↓ with pathological conditions such as emphysema and lung collapse
Thickness of the alveolar–capillary membrane	Rate of transfer ↓ as thickness ↑	Thickness normally remains constant Thickness ↑ with pathological conditions such as pulmonary edema, pulmonary fibrosis, and pneumonia
Diffusion constant	Rate of transfer ↑ as diffusion constant ↑	Diffusion constant for CO_2 is 20 times that of O_2, offsetting the smaller partial pressure gradient for CO_2; therefore, approximately equal amounts of CO_2 and O_2 are transferred across the membrane

resulting in larger but fewer chambers (IFigure 13-23). Loss of surface area for exchange is likewise associated with collapsed regions of the lung and also results when part of the lung tissue is surgically removed—for example, in treating lung cancer.

Clinical Note **Effect of Thickness on Gas Exchange** Inadequate gas exchange can also occur when the thickness of the barrier separating the air and blood is pathologically increased. As the thickness increases, the rate of gas transfer decreases because a gas takes longer to diffuse through the greater thickness. Thickness increases in (1) *pulmonary edema,* an excess accumulation of interstitial fluid between the alveoli and the pulmonary capillaries caused by pulmonary inflammation or left-sided congestive heart failure (see p. 325); (2) *pulmonary fibrosis,* involving replacement of delicate lung tissue with thick, fibrous tissue in response to certain chronic irritants; and (3) *pneumonia,* which is characterized by inflammatory fluid accumulation within or around the alveoli. Most commonly, pneumonia is caused by bacterial or viral infection of the lungs, but it may also arise from accidental *aspiration* (breathing in) of food or vomit.

Effect of Diffusion Constant on Gas Exchange
The rate of gas transfer is directly proportional to the diffusion constant, a constant value related to the solubility of a particular gas in the lung tissues and to its molecular weight ($D \propto sol/\sqrt{MW}$). The diffusion constant for CO_2 is 20 times that of O_2 because CO_2 is much more soluble in body tissues than O_2 is. The rate of CO_2 diffusion across the respiratory membranes is therefore 20 times more rapid than that of O_2 for a given partial pressure gradient. This difference in diffusion constants is normally offset by the difference in partial pressure gradients that exist for O_2 and CO_2 across the alveolar–capillary membrane. The CO_2 partial pressure gradient is 6 mm Hg (P_{CO_2} of 46 mm Hg in the blood; P_{CO_2} of 40 mm Hg in the alveoli), compared to the O_2 gradient of 60 mm Hg (P_{O_2} of 100 mm Hg in the alveoli; P_{O_2} of 40 mm Hg in the blood).

Normally, approximately equal amounts of O_2 and CO_2 are exchanged—a respiratory quotient's worth. Even though a given volume of blood spends three fourths of

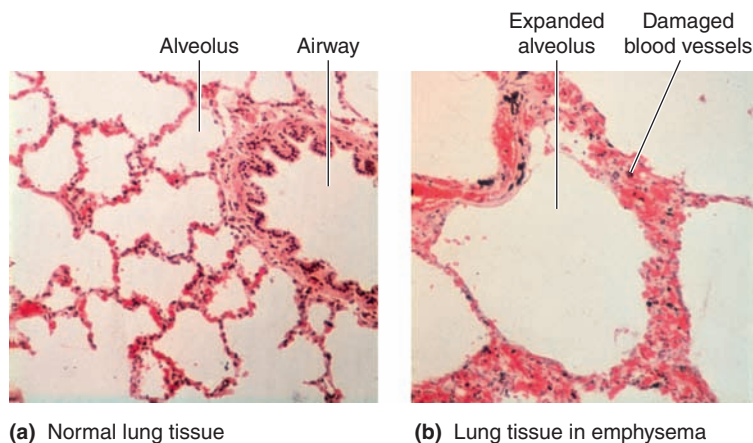
(a) Normal lung tissue   **(b)** Lung tissue in emphysema


IFigure 13-23 **Comparison of normal and emphysematous lung tissue.** (a) Each of the smallest clear spaces is an alveolar lumen in normal lung tissue. (b) Note the loss of alveolar walls in the emphysematous lung tissue, resulting in larger but fewer alveolar chambers.

a second passing through the pulmonary capillary bed, P_{O_2} and P_{CO_2} are usually both equilibrated with alveolar partial pressures by the time the blood has traversed only one third the length of the pulmonary capillaries. This means that the lung normally has enormous diffusion reserves, a fact that becomes extremely important during heavy exercise. The time the blood spends in transit in the pulmonary capillaries is decreased as pulmonary blood flow increases with the greater cardiac output that accompanies exercise. Even when less time is available for exchange, blood P_{O_2} and P_{CO_2} are normally able to equilibrate with alveolar levels because of the lungs' diffusion reserves.

Clinical Note In a diseased lung in which diffusion is impeded because the surface area is decreased or the blood–air barrier is thickened, O_2 transfer is usually more seriously impaired than CO_2 transfer because of the larger CO_2 diffusion constant. By the time the blood reaches the end of the pulmonary capillary network, it is more likely to have equilibrated with alveolar P_{CO_2} than with alveolar P_{O_2} because CO_2 can diffuse more rapidly through the respiratory barrier. In milder conditions, diffusion of both O_2 and CO_2 might remain adequate at rest, but during exercise, when pulmonary transit time is decreased, the blood gases, especially O_2, may not have completely equilibrated with the alveolar gases before the blood leaves the lungs.

Gas exchange across the systemic capillaries also occurs down partial pressure gradients.

Just as they do at the pulmonary capillaries, O_2 and CO_2 move between the systemic capillary blood and the tissue cells by simple passive diffusion down partial pressure gradients. Refer again to ❙ Figure 13-22. The arterial blood that reaches the systemic capillaries is essentially the same blood that left the lungs by means of the pulmonary veins because the only two places in the entire circulatory system at which gas exchange can take place are the pulmonary and the systemic capillaries. The arterial P_{O_2} is 100 mm Hg, and the arterial P_{CO_2} is 40 mm Hg, the same as alveolar P_{O_2} and P_{CO_2}.

P$_{O_2}$ and *P*$_{CO_2}$ Gradients Across the Systemic Capillaries
Cells constantly consume O_2 and produce CO_2 through oxidative metabolism. Cellular P_{O_2} averages about 40 mm Hg and P_{CO_2} about 46 mm Hg, although these values are highly variable, depending on the level of cellular metabolic activity. O_2 moves by diffusion down its partial pressure gradient from the entering systemic capillary blood (P_{O_2} = 100 mm Hg) into the adjacent cells (P_{O_2} = 40 mm Hg) until equilibrium is reached. Therefore, the P_{O_2} of venous blood leaving the systemic capillaries is equal to the tissue P_{O_2} at an average of 40 mm Hg.

The reverse situation exists for CO_2, which rapidly diffuses out of the cells (P_{CO_2} = 46 mm Hg) into the entering capillary blood (P_{CO_2} = 40 mm Hg) down the partial pressure gradient created by the ongoing production of CO_2. Transfer of CO_2 continues until blood P_{CO_2} equilibrates with tissue P_{CO_2}.[1] Accordingly, blood leaving the systemic capillaries has an average P_{CO_2} of 46 mm Hg. This systemic venous blood, which is relatively low in O_2 (P_{CO_2} = 40 mm Hg) and relatively high in

CO_2 (P_{CO_2} = 46 mm Hg), returns to the heart and is subsequently pumped to the lungs as the cycle repeats itself.

The more actively a tissue is metabolizing, the lower the cellular P_{O_2} falls and the higher the cellular P_{CO_2} rises. As a consequence of the larger blood-to-cell partial pressure gradients, more O_2 diffuses from blood into cells, and more CO_2 moves from cells into blood before blood P_{O_2} and P_{CO_2} achieve equilibrium with the surrounding cells. Thus, the amount of O_2 transferred to the cells and the amount of CO_2 carried away from the cells both depend on the rate of cellular metabolism.

Net Diffusion of O_2 and CO_2 Between the Alveoli and Tissues
Net diffusion of O_2 occurs first between alveoli and blood and then between blood and tissues because of the O_2 partial pressure gradients created by continuous replenishment of fresh alveolar O_2 provided by alveolar ventilation and continuous use of O_2 in the cells. Net diffusion of CO_2 occurs in the reverse direction, first between tissues and blood and then between blood and alveoli because of the CO_2 partial pressure gradients created by continuous production of CO_2 in the cells and continuous removal of alveolar CO_2 through the process of alveolar ventilation (see ❙ Figure 13-22).

Now let us see how O_2 and CO_2 are transported in the blood.

13.4 Gas Transport

Oxygen picked up by the blood at the lungs must be transported to the tissues for cell use. Conversely, CO_2 produced at the cell level must be transported to the lungs for elimination.

Most O_2 in the blood is transported bound to hemoglobin.

Oxygen is present in the blood in two forms: physically dissolved and chemically bound to hemoglobin (❙ Table 13-6).

Physically Dissolved O_2
Little O_2 physically dissolves in plasma water because O_2 is poorly soluble in body fluids. The amount dissolved is directly proportional to the P_{O_2} of the

---

[1]Actually, the partial pressures of the systemic blood gases never completely equilibrate with tissue P_{O_2} and P_{CO_2}. Because cells constantly consume O_2 and produce CO_2, the tissue P_{O_2} is always slightly less than the P_{O_2} of the blood leaving the systemic capillaries, and the tissue P_{CO_2} always slightly exceeds the systemic venous P_{CO_2}.

Methods of Gas Transport in the Blood

Gas	Method of Transport in Blood	Percentage Carried in This Form
O_2	Physically dissolved	1.5
	Bound to hemoglobin	98.5
CO_2	Physically dissolved	10
	Bound to hemoglobin	30
	As bicarbonate (HCO_3^-)	60

blood: The higher the P_{O_2}, the more O_2 dissolved. At a normal arterial P_{O_2} of 100 mm Hg, only 3 mL of O_2 can dissolve in 1 liter of blood. Thus, only 15 mL of O_2 can dissolve per minute in the normal pulmonary blood flow of 5 liters/min (the resting cardiac output). Even under resting conditions, the cells consume 250 mL of O_2 per minute, and consumption may increase up to 25-fold during strenuous exercise. To deliver the O_2 needed by the tissues even at rest, the cardiac output would have to be 83.3 liters/min if O_2 could only be transported in dissolved form. Obviously, there must be an additional mechanism for transporting O_2 to the tissues. This mechanism is *hemoglobin (Hb)*. Only 1.5% of the O_2 in the blood is dissolved; the remaining 98.5% is transported in combination with Hb. *The O_2 bound to Hb does not contribute to the P_{O_2} of the blood*; thus, blood P_{O_2} is not a measure of the total O_2 content of the blood but only of the dissolved portion of O_2.

Oxygen Bound to Hemoglobin Hemoglobin, an iron-bearing protein molecule contained within the red blood cells, can form a loose, easily reversible combination with O_2 (see p. 383). When not combined with O_2, Hb is referred to as **reduced hemoglobin**, or **deoxyhemoglobin**; when combined with O_2, it is called **oxyhemoglobin (HbO$_2$)**:

$$\underset{\text{reduced hemoglobin}}{Hb} + O_2 \rightleftharpoons \underset{\text{oxyhemoglobin}}{HbO_2}$$
We need to answer several questions about the role of Hb in O_2 transport. What determines whether O_2 and Hb are combined or dissociated (separated)? Why does Hb combine with O_2 in the lungs and release O_2 at the tissues? How can a variable amount of O_2 be released at the tissues, depending on the level of tissue activity? How can we talk about O_2 transfer between blood and surrounding tissues in terms of O_2 partial pressure gradients when 98.5% of the O_2 is bound to Hb and thus does not contribute to the P_{O_2} of the blood?

The P_{O_2} is the primary factor determining the percent hemoglobin saturation.

Each of the four atoms of iron within the heme portions of a Hb molecule can combine with an O_2 molecule, so each Hb molecule can carry up to four molecules of O_2. Hemoglobin is considered *fully saturated* when all the Hb present is carrying its maximum O_2 load. The **percent hemoglobin (% Hb) saturation**, a measure of the extent to which the Hb present is combined with O_2, can vary from 0% to 100%.

The most important factor determining the % Hb saturation is the P_{O_2} of the blood, which in turn is related to the concentration of O_2 physically dissolved in the blood. According to the **law of mass action**, if the concentration of one substance involved in a reversible reaction is increased, the reaction is driven toward the opposite side. Conversely, if the concentration of one substance is decreased, the reaction is driven toward that side. Applying this law to the reversible reaction involving Hb and O_2 (Hb + $O_2 \rightleftharpoons HbO_2$), when blood P_{O_2} increases, as in the pulmonary capillaries, the reaction is driven toward the right side of the equation, increasing formation of HbO_2 (increased % Hb saturation). When blood P_{O_2} decreases, as in the systemic capillaries, the reaction is driven toward the left side of the equation, and oxygen is released from Hb as HbO_2 dissociates (decreased % Hb saturation). Thus, because of the difference in P_{O_2} at the lungs and other tissues, Hb automatically "loads up" on O_2 in the lungs, where ventilation is continually providing fresh supplies of O_2, and "unloads" it in the tissues, which are constantly using up O_2.

O_2–Hb Dissociation Curve The relationship between blood P_{O_2} and % Hb saturation is not linear, however, a point that is important physiologically. Doubling the partial pressure does not double the % Hb saturation. Rather, the relationship between these variables follows an S-shaped curve, the **O_2–Hb dissociation (or saturation) curve** (IFigure 13-24). At the upper end, between a blood P_{O_2} of 60 mm Hg and one of 100 mm Hg, the curve flattens off, or plateaus. Within this pressure range, a rise in P_{O_2} produces only a small increase in the extent to which Hb is bound with O_2. In the P_{O_2} range of 0 to 60 mm Hg, in contrast, a small change in P_{O_2} results in a large change in the extent to which Hb is combined with O_2, as shown by the steep lower part of the curve. Both the upper plateau and the lower steep portion of the curve have physiological significance.

Significance of the Plateau Portion of the O_2–Hb Curve The plateau portion of the curve is in the blood P_{O_2} range at the pulmonary capillaries where O_2 is being loaded onto Hb. The systemic arterial blood leaving the lungs, having equilibrated with alveolar P_{O_2}, normally has a P_{O_2} of 100 mm Hg. Looking at the O_2–Hb curve, note that at a blood P_{O_2} of 100 mm Hg, Hb is 97.5% saturated. Therefore, Hb in the systemic arterial blood normally is almost fully saturated.

If the alveolar P_{O_2} and, consequently, the arterial P_{O_2} fall below normal, there is little reduction in the total amount of O_2 transported by the blood until the P_{O_2} falls below 60 mm Hg. This is because of the plateau region of the curve. If the arterial P_{O_2} falls 40%, from 100 to 60 mm Hg, the concentration of dissolved O_2 as reflected by the P_{O_2} is likewise reduced 40%. At a blood P_{O_2} of 60 mm Hg, however, the % Hb saturation is still remarkably high, at 90%. Accordingly, the total O_2 content of the blood is only slightly decreased despite the 40% reduction in P_{O_2} because Hb is still carrying an almost full load of O_2, and, as mentioned before, most O_2 is transported by Hb rather than dissolved. However, even if the blood P_{O_2} is greatly increased—

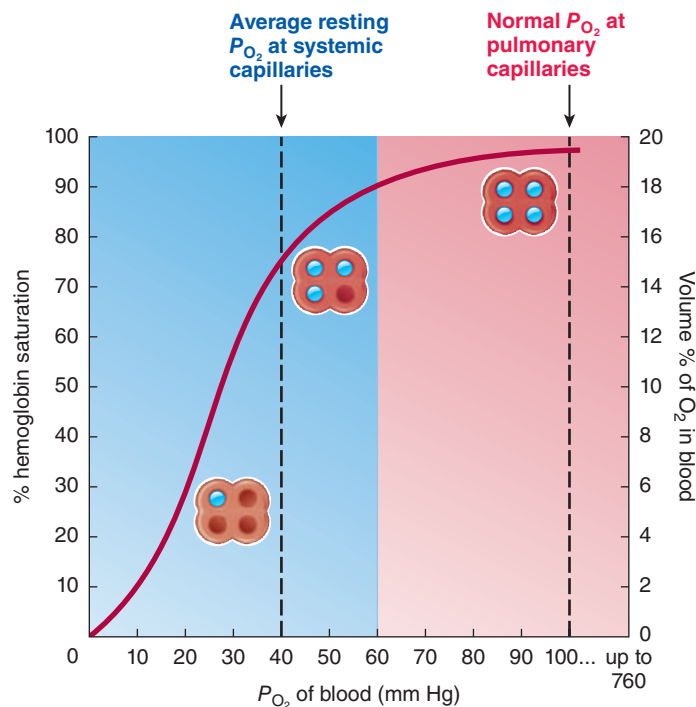
KEY

⬤ = O_2 molecule

= Partially saturated hemoglobin molecule

= Fully saturated hemoglobin molecule


❙ **Figure 13-24 Oxygen–hemoglobin (O_2–Hb) dissociation (saturation) curve.** The % hemoglobin saturation (the scale on the left side of the graph) depends on the P_{O_2} of the blood. The relationship between these two variables is depicted by an S-shaped curve with a plateau region between a blood P_{O_2} of 60 and 100 mm Hg and a steep portion between 0 and 60 mm Hg. Another way of expressing the effect of blood P_{O_2} on the amount of O_2 bound with hemoglobin is the volume % of O_2 in the blood (mL of O_2 bound with hemoglobin in each 100 mL of blood). The scale on the right side of the graph represents that relationship.
FIGURE FOCUS: *Looking at the graph, compare the changes in % Hb saturation if P_{O_2} decreases by 25 mm Hg (1) from its normal value of 100 mm Hg in the pulmonary capillaries and (2) from its normal value of 40 mm Hg in the systemic capillaries.*

say, to 600 mm Hg—by breathing pure O_2, little additional O_2 is added to the blood. A small extra amount of O_2 dissolves, but the % Hb saturation can be maximally increased by only another 2.5%, to 100% saturation. Therefore, in the P_{O_2} range between 60 and 600 mm Hg or even higher, there is only a 10% difference in the amount of O_2 carried by Hb. Thus, the plateau portion of the O_2–Hb curve provides a good margin of safety in O_2-carrying capacity of the blood.

Clinical Note Arterial P_{O_2} may be reduced by pulmonary diseases accompanied by inadequate ventilation or defective gas exchange or by circulatory disorders that result in inadequate blood flow to the lungs. It may also fall in healthy people under two circumstances: (1) at high altitudes, where total atmospheric pressure and hence the P_{O_2} of the inspired air are reduced, or (2) in O_2-deprived environments at sea level, such

as if someone were accidentally locked in a vault. Unless the arterial P_{O_2} becomes markedly reduced (falls below 60 mm Hg) in either pathological conditions or abnormal circumstances, near-normal amounts of O_2 can still be carried to the tissues.

Significance of the Steep Portion of the O_2–Hb Curve

The steep portion of the curve between 0 and 60 mm Hg is in the blood P_{O_2} range at the systemic capillaries, where O_2 is unloaded from Hb. In the systemic capillaries, the blood equilibrates with the surrounding tissue cells at an average P_{O_2} of 40 mm Hg. Note in ❙ Figure 13-24 that at a P_{O_2} of 40 mm Hg the % Hb saturation is 75%. The blood arrives in the tissue capillaries at a P_{O_2} of 100 mm Hg with 97.5% Hb saturation. Because Hb can only be 75% saturated at the P_{O_2} of 40 mm Hg in the systemic capillaries, nearly 25% of the HbO_2 must dissociate, yielding reduced Hb and O_2. This released O_2 is free to diffuse down its partial pressure gradient from the red blood cells through the plasma and the interstitial fluid into the tissue cells.

The Hb in the venous blood returning to the lungs is still normally 75% saturated. If the tissue cells are metabolizing more actively, the P_{O_2} of the systemic capillary blood falls (for example, from 40 to 20 mm Hg) because the cells are consuming O_2 more rapidly. Note on the curve that this drop of 20 mm Hg in P_{O_2} decreases the % Hb saturation from 75% to 30%— that is, about 45% more of the total HbO_2 than normal gives up its O_2 for tissue use. The normal 60 mm Hg drop in P_{O_2} from 100 to 40 mm Hg in the systemic capillaries causes about 25% of the total HbO_2 to unload its O_2. In comparison, a further drop in P_{O_2} of only 20 mm Hg results in an additional 45% of the total HbO_2 unloading its O_2 because the O_2 partial pressures in this range are operating in the steep portion of the curve. In this range, only a small drop in systemic capillary P_{O_2} can automatically make large amounts of O_2 immediately available to meet the O_2 needs of more actively metabolizing tissues, such as exercising muscles. As much as 85% of the Hb may give up its O_2 to active muscle cells during strenuous exercise. In addition to this more thorough withdrawal of O_2 from the blood, even more O_2 is made available to actively metabolizing cells by circulatory and respiratory adjustments that increase the flow rate of oxygenated blood through the active tissues.

Hemoglobin promotes the net transfer of O_2 at both the alveolar and the tissue levels.

We still have not really clarified the role of Hb in gas exchange. Because blood P_{O_2} depends entirely on the concentration of *dissolved* O_2, we could ignore the O_2 bound to Hb in our earlier discussion of O_2 being driven from the alveoli to the blood by a P_{O_2} gradient. However, Hb does play a crucial role in permitting the transfer of large quantities of O_2 before blood P_{O_2} equilibrates with the surrounding tissues (❙ Figure 13-25).

Role of Hb at the Alveolar Level Hemoglobin acts as a "storage depot" for O_2, removing O_2 from solution as soon as it enters the blood from the alveoli. Because only dissolved O_2 contributes to P_{O_2}, the O_2 stored in Hb cannot contribute to blood P_{O_2}. When systemic venous blood enters the pulmonary capillaries, its P_{O_2} is considerably lower than alveolar P_{O_2}, so O_2

(a) Alveolar P_{O_2} = blood P_{O_2} **(b)** Alveolar P_{O_2} > blood P_{O_2} **(c)** Alveolar P_{O_2} = blood P_{O_2}

KEY

● = O_2 molecule   = Partially saturated hemoglobin molecule   = Fully saturated hemoglobin molecule
❙**Figure 13-25 Hemoglobin facilitating a large net transfer of O_2 by acting as a storage depot to keep P_{O_2} low.** (a) In the hypothetical situation in which no Hb is present in the blood, the alveolar P_{O_2} and the pulmonary capillary blood P_{O_2} are at equilibrium. (b) Hemoglobin has been added to the blood. As the Hb starts to bind with O_2, it removes O_2 from solution. Because only dissolved O_2 contributes to blood P_{O_2}, the blood P_{O_2} falls below that of the alveoli, even though the same number of O_2 molecules are present in the blood as in part (a). By "soaking up" some of the dissolved O_2, Hb favors the net diffusion of more O_2 down its partial pressure gradient from the alveoli to the blood. (c) Hemoglobin is fully saturated with O_2 and the alveolar and blood P_{O_2} are at equilibrium again. The blood P_{O_2} resulting from dissolved O_2 is equal to the alveolar P_{O_2}, despite the fact that the total O_2 content in the blood is much greater than in part (a) when blood P_{O_2} was equal to alveolar P_{O_2} in the absence of Hb.

immediately diffuses into the blood, raising blood P_{O_2}. As soon as the blood P_{O_2} increases, the percentage of Hb that can bind with O_2 likewise increases, as indicated by the O_2–Hb curve. Consequently, most of the O_2 that has diffused into the blood combines with Hb and no longer contributes to blood P_{O_2}. As O_2 is removed from solution by combining with Hb, blood P_{O_2} falls to about the same level it was when the blood entered the lungs, even though the total quantity of O_2 in the blood actually has increased. Because blood P_{O_2} is again considerably below alveolar P_{O_2}, more O_2 diffuses from the alveoli into the blood, only to be soaked up by Hb again.

Even though we have considered this process stepwise for clarity, net diffusion of O_2 from alveoli to blood occurs continuously until Hb becomes as saturated with O_2 as it can be at that particular P_{O_2}. At a normal P_{O_2} of 100 mm Hg, Hb is 97.5% saturated. Thus, by soaking up O_2, Hb keeps blood P_{O_2} low and prolongs the existence of a partial pressure gradient so that a large net transfer of O_2 into the blood can take place. Not until Hb can store no more O_2 (that is, Hb is maximally saturated for that P_{O_2}) does all the O_2 transferred into the blood remain dissolved and directly contribute to the P_{O_2}. Only now does blood P_{O_2} rapidly equilibrate with alveolar P_{O_2} and bring further O_2 transfer to a halt, but this point is not reached until Hb is already loaded to the maximum extent possible. Once blood P_{O_2} equilibrates with alveolar P_{O_2}, no further O_2 transfer can take place, no matter how little or how much total O_2 has already been transferred.

Role of Hb at the Tissue Level The reverse situation occurs at the tissue level. Because the P_{O_2} of blood entering the systemic capillaries is considerably higher than the P_{O_2} of the surrounding tissue, O_2 immediately diffuses from the blood into

the tissues, lowering blood P_{O_2}. When blood P_{O_2} falls, Hb must unload some stored O_2 because the % Hb saturation is reduced. As the O_2 released from Hb dissolves in the blood, blood P_{O_2} increases and again exceeds the P_{O_2} of the surrounding tissues. This favors further movement of O_2 out of the blood, although the total quantity of O_2 in the blood has already fallen. Only when Hb can no longer release any more O_2 into solution (when Hb is unloaded to the greatest extent possible for the P_{O_2} existing at the systemic capillaries) can blood P_{O_2} fall as low as in surrounding tissue. At this time, further transfer of O_2 stops. Hemoglobin, because it stores a large quantity of O_2 that can be freed by a slight reduction in P_{O_2} at the systemic capillary level, permits the transfer of tremendously more O_2 from the blood into the cells than would be possible in its absence.

Thus, Hb plays an important role in the *total quantity* of O_2 that the blood can pick up in the lungs and drop off in the tissues. If Hb levels fall to one half of normal, as in a severely anemic patient (see p. 386), the O_2-carrying capacity of the blood falls by 50% even though the arterial P_{O_2} is the normal 100 mm Hg with 97.5% Hb saturation. Only half as much Hb is available to be saturated, emphasizing again how critical Hb is in determining how much O_2 can be picked up at the lungs and made available to tissues.

Factors at the tissue level promote unloading of O_2 from hemoglobin.

Even though the main factor determining the % Hb saturation is the P_{O_2} of the blood, other factors can affect the affinity, or bond strength, between Hb and O_2 and, accordingly, can shift the O_2–Hb curve (that is, change the % Hb saturation at a given P_{O_2}). These other factors are CO_2, acidity, temperature, and

2,3-bisphosphoglycerate, which we examine separately. The O_2–Hb dissociation curve with which you are already familiar (see ❙Figure 13-24) is a typical curve at normal arterial CO_2 and acidity levels, normal body temperature, and normal 2,3-bisphosphoglycerate concentration.

Effect of CO_2 on % Hb Saturation An increase in P_{CO_2} shifts the O_2–Hb curve to the right (❙Figure 13-26). The % Hb saturation still depends on the P_{O_2}, but for any given P_{O_2} less O_2 and Hb can be combined. This effect is important because the P_{CO_2} of the blood increases in the systemic capillaries as CO_2 diffuses down its gradient from cells into blood. The presence of this additional CO_2 in the blood in effect decreases the affinity of Hb for O_2, so Hb unloads even more O_2 at the tissue level than it would if the reduction in P_{O_2} in the systemic capillaries was the only factor affecting % Hb saturation.

Effect of Acid on % Hb Saturation An increase in acidity also shifts the curve to the right. Because CO_2 generates carbonic acid, the blood becomes more acidic at the systemic capillary level as it picks up CO_2 from the tissues. The resulting reduction in Hb affinity for O_2 in the presence of increased acidity aids in releasing even more O_2 at the tissue level for a given P_{O_2}. In actively metabolizing cells, such as exercising muscles, not only is more carbonic acid–generating CO_2 produced, but lactate (lactic acid) also may be produced if the cells resort to anaerobic metabolism (see pp. 39 and 272). The resultant local elevation of acid in the working muscles facilitates further unloading of O_2 in the very tissues that need the most O_2.

❙Figure 13-26 **Effect of increased P_{CO_2}, H^+, temperature, and 2,3-bisphosphoglycerate on the O_2–Hb curve.** Increased P_{O_2}, acid, and temperature, as found at the tissue level, shift the O_2–Hb curve to the right. As a result, less O_2 and Hb can be combined at a given P_{O_2} so that more O_2 is unloaded from Hb for use by the tissues. Similarly, 2,3-bisphosphoglycerate, whose production is increased in red blood cells when arterial HbO_2 is chronically below normal, shifts the O_2–Hb curve to the right, making more of the limited O_2 available at the tissue level.

Bohr Effect The influence of CO_2 and acid on the release of O_2 is known as the **Bohr effect**. Both CO_2 and the hydrogen ion (H^+) component of acids can combine reversibly with Hb at sites other than the O_2-binding sites. The result is a change in the molecular structure of Hb that reduces its affinity for O_2. (Note that the % Hb saturation refers only to the extent to which Hb is combined with O_2, not the extent to which it is bound with CO_2, H^+, or other molecules. Indeed, the % Hb saturation decreases when CO_2 and H^+ bind with Hb, because their presence on Hb facilitates increased release of O_2 from Hb.)

Effect of Temperature on % Hb Saturation In a similar manner, a rise in temperature shifts the O_2–Hb curve to the right, resulting in more unloading of O_2 at a given P_{O_2}. An exercising muscle or other actively metabolizing cell produces heat. The resulting local rise in temperature enhances O_2 release from Hb for use by more active tissues.

Comparison of These Factors at the Tissue and Pulmonary Levels As you just learned, increases in CO_2, acidity, and temperature at the tissue level, all of which are associated with increased cellular metabolism and increased O_2 consumption, enhance the effect of a drop in P_{O_2} in facilitating the release of O_2 from Hb. These effects are largely reversed at the pulmonary level, where the extra acid-forming CO_2 is blown off and the local aerated environment is cooler. Appropriately, therefore, Hb has a higher affinity for O_2 in the pulmonary capillary environment, enhancing the effect of raised P_{O_2} in loading O_2 onto Hb.

Effect of 2,3-Bisphosphoglycerate on % Hb Saturation The preceding changes take place in the *environment* of the red blood cells, but a factor *inside* the red blood cells can also affect the degree of O_2–Hb binding: **2,3-bisphosphoglycerate (BPG)**. This erythrocyte constituent, which is produced during red blood cell metabolism, can bind reversibly with Hb and reduce its affinity for O_2, just as CO_2 and H^+ do. Thus, an increased level of BPG, like the other factors, shifts the O_2–Hb curve to the right, enhancing O_2 unloading as the blood flows through the tissues.

BPG production by red blood cells gradually increases whenever Hb in the arterial blood is chronically undersaturated—that is, when arterial HbO_2 is below normal. This condition may occur in people living at high altitudes or in those suffering from certain types of circulatory or respiratory diseases or anemia. By helping unload O_2 from Hb at the tissue level, increased BPG helps maintain O_2 availability for tissue use even though arterial O_2 supply is chronically reduced.

Hemoglobin has a much higher affinity for carbon monoxide than for O_2.

Clinical Note **Carbon monoxide (CO)** and O_2 compete for the same binding sites on Hb, but Hb's affinity for CO is 240 times that of its affinity for O_2. The combination of CO and Hb is known as **carboxyhemoglobin (HbCO)**. Because Hb preferentially latches onto CO, even small amounts of CO can tie up a disproportionately large share of Hb, making Hb unavailable for

O_2 transport. Even though the Hb concentration and P_{O_2} are normal, the O_2 content of the blood is seriously reduced.

Fortunately, CO is not a normal constituent of inspired air. It is a poisonous gas produced during the incomplete combustion (burning) of carbon products such as automobile gasoline, coal, wood, and tobacco. Carbon monoxide is especially dangerous because it is so insidious. If CO is being produced in a closed environment so that its concentration continues to increase (for example, in a parked car with the motor running and windows closed), it can reach lethal levels without the victim ever being aware of the danger. Because it is odorless, colorless, tasteless, and nonirritating, CO is not detectable. Furthermore, for reasons described later, the victim has no sensation of breathlessness and makes no attempt to increase ventilation, even though the cells are O_2 starved.

Most CO_2 is transported in the blood as bicarbonate.

When arterial blood flows through the tissue capillaries, CO_2 diffuses down its partial pressure gradient from the tissue cells into the blood. CO_2 is transported in the blood in three ways (as described in the following list and shown with corresponding numbers in ❙Figure 13-27; see also ❙Table 13-6, p. 472):

1. *Physically dissolved.* As with dissolved O_2, the amount of CO_2 physically dissolved in the blood depends on the P_{CO_2}. Because CO_2 is more soluble than O_2 in plasma water, a greater proportion of the total CO_2 than of O_2 in the blood is physically dissolved. Even so, only 10% of the blood's total CO_2 content is carried this way at the normal systemic venous P_{CO_2} level.

2. *Bound to hemoglobin.* Another 30% of the CO_2 combines with Hb to form **carbamino hemoglobin (HbCO$_2$)**. CO_2 binds with the globin portion of Hb, in contrast to O_2, which combines with the heme portions. Reduced Hb has a greater affinity for CO_2 than HbO_2 does. The unloading of O_2 from Hb in the tissue capillaries therefore facilitates the picking up of CO_2 by Hb.

3. *As bicarbonate.* By far the most important means of CO_2 transport is as **bicarbonate (HCO_3^-)**, with 60% of the CO_2 being converted into HCO_3^- by the following chemical reaction:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H + HCO_3^-$$

In the first step, CO_2 combines with H_2O to form carbonic acid (H_2CO_3). As is characteristic of acids, some of the H_2CO_3 mol-
❙Figure 13-27 **Carbon dioxide transport in the blood.** Carbon dioxide picked up at the tissue level is transported in the blood to the lungs in three ways: (1) physically dissolved, (2) bound to hemoglobin (Hb), and (3) as bicarbonate ion (HCO_3^-). Hemoglobin is present only in the red blood cells, as is carbonic anhydrase, the enzyme that catalyzes the production of HCO_3^-. The H^+ generated during the production of HCO_3^- also binds to Hb. HCO_3^- moves by facilitated diffusion down its concentration gradient out of the red blood cell into the plasma, and chloride (Cl^-) moves by means of the same passive carrier into the red blood cell down the electrical gradient created by the outward diffusion of HCO_3^-. The reactions that occur at the tissue level are reversed at the pulmonary level, where CO_2 diffuses out of the blood to enter the alveoli.

FIGURE FOCUS: *Study the figure to identify three chemicals with which hemoglobin binds.*

ecules spontaneously dissociate into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). The one carbon and two oxygen atoms of the original CO_2 molecule are thus present in the blood as an integral part of HCO_3^-. This is beneficial because HCO_3^- is more soluble in the blood than CO_2 is.

This reaction takes place slowly in the plasma, but it proceeds swiftly within the red blood cells because of the presence of the erythrocyte enzyme **carbonic anhydrase**, which catalyzes (speeds up) the reaction. In fact, under the influence of carbonic anhydrase, the reaction proceeds directly from CO_2 + H_2O to H^+ + HCO_3^- without the intervening H_2CO_3 step:

$$CO_2 + H_2O \xrightarrow{\text{carbonic anhydrase}} H^+ \ HCO_3^-$$
Chloride Shift As this reaction proceeds, HCO_3^- and H^+ start to accumulate within the red blood cells in the systemic capillaries. The red blood cell membrane has a HCO_3^-–Cl^- carrier that passively facilitates the diffusion of these ions in opposite directions across the membrane. The membrane is relatively impermeable to H^+. Consequently, HCO_3^-, but not H^+, diffuses down its concentration gradient out of the erythrocytes into the plasma. Because HCO_3^- is a negatively charged ion, the efflux of HCO_3^- unaccompanied by a comparable outward diffusion of positively charged ions creates an electrical gradient (see p. 66). Chloride ions (Cl^-), the dominant plasma anions, diffuse into the red blood cells down this electrical gradient to restore electric neutrality. This inward shift of Cl^- in exchange for the efflux of CO_2-generated HCO_3^- is known as the **chloride (Cl^-) shift**.

Haldane Effect Hemoglobin binds with most of the H^+ formed within the erythrocytes. As with CO_2, reduced Hb has a greater affinity for H^+ than HbO_2 does. Therefore, unloading of O_2 facilitates Hb pickup of CO_2 and CO_2-generated H^+, an influence known as the **Haldane effect**. Because only free, dissolved H^+ contributes to the acidity of a solution, venous blood would be considerably more acidic than arterial blood if Hb did not mop up most of the H^+ generated at the tissue level.

Note how Hb's unloading of O_2 and its uptake of CO_2 and CO_2-generated H^+ at the tissue level work in synchrony. Increased CO_2 and H^+ cause increased O_2 release from Hb by the Bohr effect; increased O_2 release from Hb in turn causes increased CO_2 and H^+ uptake by Hb through the Haldane effect. The entire process is efficient. Reduced Hb must be carried back to the lungs to refill on O_2 anyway. After O_2 is released, Hb picks up new passengers—CO_2 and H^+—that are going in the same direction to the lungs.

The reactions at the tissue level as CO_2 enters the blood from the tissues are reversed once the blood reaches the lungs and CO_2 leaves the blood to enter the alveoli (❚Figure 13-27).

Various respiratory states are characterized by abnormal blood-gas levels.

❚Table 13-7 is a glossary of terms used to describe various states associated with respiratory abnormalities, most of which are discussed in more detail here or later in the chapter.

❚**TABLE 13-7** Mini Glossary of Clinically Important Respiratory States

Apnea   Transient cessation of breathing

Asphyxia O_2 starvation of tissues, caused by a lack of O_2 in the air, respiratory impairment, or inability of the tissues to use O_2

Cyanosis   Blueness of the skin resulting from insufficiently oxygenated blood in the arteries

Dyspnea   Difficult or labored breathing

Eupnea   Normal breathing

Hypercapnia   Excess CO_2 in the arterial blood

Hyperpnea   Increased pulmonary ventilation that matches increased metabolic demands, as in exercise

Hyperventilation   Increased pulmonary ventilation in excess of metabolic requirements, resulting in decreased P_{CO_2} and respiratory alkalosis

Hypocapnia   Below-normal CO_2 in the arterial blood

Hypoventilation   Underventilation in relation to metabolic requirements, resulting in increased P_{CO_2} and respiratory acidosis

Hypoxia   Insufficient O_2 at the cellular level

Anemic hypoxia   Reduced O_2-carrying capacity of the blood

Circulatory hypoxia   Too little oxygenated blood delivered to the tissues; also known as stagnant hypoxia

Histotoxic hypoxia   Inability of the cells to use available O_2

Hypoxic hypoxia   Low arterial blood P_{O_2} accompanied by inadequate Hb saturation

Respiratory arrest   Permanent cessation of breathing (unless clinically corrected)

Suffocation O_2 deprivation as a result of an inability to breathe oxygenated air

---

Clinical Note **Abnormalities in Arterial P_{O_2}**   The term **hypoxia** refers to the condition of having insufficient O_2 at the cell level. Following are the four general categories of hypoxia:

1. *Hypoxic hypoxia* is characterized by a low arterial blood P_{O_2} accompanied by inadequate Hb saturation. It is caused by (a) a respiratory malfunction involving inadequate gas exchange, typified by a normal alveolar P_{O_2} but a reduced arterial P_{O_2}, or (b) exposure to high altitude or to a suffocating environment where atmospheric P_{O_2} is reduced so that alveolar and arterial P_{O_2} are likewise reduced.

2. *Anemic hypoxia* is a reduced O_2-carrying capacity of the blood. It can result from (a) a decrease in circulating red blood cells, (b) an inadequate amount of Hb within the red blood cells, or (c) CO poisoning. In all cases of anemic hypoxia, arterial P_{O_2} is normal but the O_2 content of the arterial blood is lower than normal because of inadequate available Hb.

3. *Circulatory hypoxia* arises when too little oxygenated blood is delivered to the tissues. Circulatory hypoxia can be restricted to a limited area by a local vascular blockage. Or the body may experience circulatory hypoxia in general from con-

gestive heart failure or circulatory shock. Arterial P_{O_2} and O_2 content are typically normal, but too little oxygenated blood reaches the cells.

4. In *histotoxic hypoxia,* O_2 delivery to the tissues is normal, but the cells cannot use the O_2 available to them. The classic example is *cyanide poisoning.* Cyanide blocks enzymes essential for cellular respiration (enzymes in the electron transport system; see p. 37).

Hyperoxia, an above-normal arterial P_{O_2}, cannot occur when a person is breathing atmospheric air at sea level. However, breathing supplemental O_2 can increase alveolar and consequently, arterial P_{O_2}. Because more of the inspired air is O_2, more of the total pressure of the inspired air is attributable to the O_2 partial pressure, so more O_2 dissolves in the blood before arterial P_{O_2} equilibrates with alveolar P_{O_2}. Even though arterial P_{O_2} increases, the total blood O_2 content does not significantly increase because Hb is nearly fully saturated at the normal arterial P_{O_2}. In certain pulmonary diseases associated with a reduced arterial P_{O_2}, however, breathing supplemental O_2 can help establish a larger alveoli-to-blood driving gradient, improving arterial P_{O_2}. Far from being advantageous, a markedly elevated arterial P_{O_2} can be dangerous. If arterial P_{O_2} is too high, **oxygen toxicity** can occur. Even though the total O_2 content of the blood is only slightly increased, exposure to a high P_{O_2} can cause brain damage and blindness-causing damage to the retina. Therefore, O_2 therapy must be administered cautiously.

Clinical Note **Abnormalities in Arterial P_{CO_2}** The term **hypercapnia** refers to the condition of having excess CO_2 in arterial blood; it is caused by **hypoventilation** (ventilation inadequate to meet metabolic needs for O_2 delivery and CO_2 removal). With most lung diseases, CO_2 accumulates in arterial blood concurrently with an O_2 deficit because both O_2 and CO_2 exchange between lungs and atmosphere are affected (❙Figure 13-28).

Hypocapnia, below-normal arterial P_{CO_2} levels, is brought about by hyperventilation. **Hyperventilation** occurs when a person "overbreathes"—that is, when the rate of ventilation exceeds the body's metabolic needs for CO_2 removal. As a result, CO_2 is blown off to the atmosphere more rapidly than it is produced in the tissues, and arterial P_{CO_2} falls. Hyperventilation can be triggered by anxiety states, fever, and aspirin poisoning. Alveolar P_{O_2} increases during hyperventilation as more fresh O_2 is delivered to the alveoli from the atmosphere than the blood extracts from the alveoli for tissue consumption, and arterial P_{O_2} increases correspondingly (❙Figure 13-28). However, because Hb is almost fully saturated at the normal arterial P_{O_2}, very little additional O_2 is added to the blood. Except for the small extra amount of dissolved O_2, blood O_2 content remains essentially unchanged during hyperventilation.

Increased ventilation is not synonymous with hyperventilation. Increased ventilation that matches an increased metabolic demand, such as the increased need for O_2 delivery and CO_2 elimination during exercise, is termed **hyperpnea**. During exercise, alveolar and arterial P_{O_2} and P_{CO_2} remain constant, with
❙Figure 13-28 **Effects of hyperventilation and hypoventilation on arterial P_{O_2} and P_{CO_2}.**

the increased atmospheric exchange just keeping pace with the increased O_2 consumption and CO_2 production.

Clinical Note **Consequences of Abnormalities in Arterial Blood Gases** The consequences of reduced O_2 availability to the tissues during hypoxia are apparent. The cells need adequate O_2 to sustain energy-generating metabolic activities. The consequences of abnormal blood CO_2 levels are less obvious. Changes in blood CO_2 concentration primarily affect acid–base balance. Hypercapnia elevates production of CO_2-generated H^+. The subsequent generation of excess H^+ produces an acidic condition termed *respiratory acidosis*. Conversely, less-than-normal amounts of H^+ are generated from CO_2 in conjunction with hypocapnia. The resultant alkalotic (less acidic than normal) condition is called *respiratory alkalosis* (see Chapter 15). (To learn about the effects of mountain climbing and deep sea diving on blood gases, see the boxed feature on pp. 480–481, ❙Concepts, Challenges, and Controversies.)

Check Your Understanding 13.4

1. State the percentage of O_2 and CO_2 carried in the blood by each of the methods of transport.

2. Draw a graph showing the O_2–Hb dissociation curve and label the parts of the curve that operate in the blood P_{O_2} range at the pulmonary capillaries and at the systemic capillaries.

3. Discuss the effect of hypoventilation and of hyperventilation on acid–base balance.

13.5 Control of Respiration

Like the heartbeat, breathing must occur in a continuous, cyclic pattern to sustain life processes. Cardiac muscle must rhythmically contract and relax to alternately pump blood from the heart and fill it again. Similarly, inspiratory muscles must rhythmically contract and relax to alternately fill the lungs with air and empty them. Both these activities are accomplished automatically, without conscious effort. However, the underlying mechanisms and control of these two systems are remarkably different.

Respiratory centers in the brain stem establish a rhythmic breathing pattern.

Whereas the heart can generate its own rhythm by means of its intrinsic pacemaker activity, the respiratory muscles, being skeletal muscles, contract only when stimulated by their nerve supply. The rhythmic pattern of breathing is established by cyclic neural activity to the respiratory muscles. In other words, the pacemaker activity that establishes breathing rhythm resides in the respiratory control centers in the brain, not in the lungs or respiratory muscles themselves. The nerve supply to the heart, not being needed to initiate the heartbeat, only modifies the rate and strength of cardiac contraction. In contrast, the nerve supply to the respiratory system is essential in maintaining breathing and in reflexly adjusting the level of ventilation to match changing needs for O_2 uptake and CO_2 removal. Furthermore, unlike cardiac activity, which is not subject to voluntary control, respiratory activity can be voluntarily modified, as when you are talking.

Components of Neural Control of Respiration Neural control of respiration involves three distinct components: (1) factors that generate the alternating inspiration–expiration rhythm, (2) factors that regulate the magnitude of ventilation (that is, the rate and depth of breathing) to match body needs, and (3) factors that modify respiratory activity to serve other purposes. The latter modifications may be either involuntary, as in the respiratory maneuvers involved in a cough, or voluntary, as in the breath control required for speech.

Respiratory control centers housed in the brain stem generate the rhythmic pattern of breathing. The primary respiratory control center, the *medullary respiratory center,* consists of several aggregations of neuronal cell bodies within the medulla that provide output to the respiratory muscles. In addition, two other respiratory centers lie higher in the brain stem in the pons—the *pneumotaxic center* and the *apneustic center.* These pontine centers influence output from the medullary respiratory center (❙Figure 13-29). Here is how these various regions interact to establish respiratory rhythmicity.

Inspiratory and Expiratory Neurons in the Medullary Center We rhythmically breathe in and out during quiet breathing because of alternate contraction and relaxation of the major inspiratory muscles (the diaphragm and external intercostal muscles). Contraction and relaxation of these muscles in turn is commanded by the **medullary respiratory center**,
❙Figure 13-29 **Respiratory control centers in the brain stem**.

which sends impulses to the cell bodies (located in the spinal cord) of the motor neurons supplying these muscles.

The medullary respiratory center consists of two neuronal clusters known as the *dorsal respiratory group* and the *ventral respiratory group* (❙Figure 13-29).

■ The **dorsal respiratory group (DRG)** consists mostly of *inspiratory neurons* whose descending fibers terminate on the motor neurons that supply the inspiratory muscles. When the DRG inspiratory neurons fire, they stimulate the inspiratory muscles and inspiration takes place; when they cease firing, the inspiratory muscles relax and passive expiration occurs. Expiration is brought to an end as the inspiratory neurons fire again. The DRG has important interconnections with the ventral respiratory group.

■ The **ventral respiratory group (VRG)** is composed of *inspiratory neurons* and *expiratory neurons,* both of which remain inactive during normal quiet breathing. This region is called into play by the DRG as an "overdrive" mechanism during periods when demands for ventilation are increased. It is especially important in active expiration. No impulses are generated in the descending pathways from the expiratory neurons during quiet breathing. Only during active expiration do the expiratory neurons stimulate the motor neurons supplying the expiratory muscles (the abdominal and internal intercostal muscles). Furthermore, the VRG inspiratory neurons, when stimulated by the DRG, rev up inspiratory activity when demands for ventilation are high.

Generation of Respiratory Rhythm Contrary to a long-held belief, the DRG does not generate the basic rhythm of

Effects of Heights and Depths on the Body

OUR BODIES ARE OPTIMALLY EQUIPPED for existence at normal atmospheric pressure. Ascent into mountains high above sea level or descent into the depths of the ocean can have adverse effects on the body.

Effects of High Altitude on the Body

Atmospheric pressure progressively declines as altitude increases. At 18,000 feet above sea level, atmospheric pressure is only 380 mm Hg—half of its normal sea-level value. Because the proportion of O_2 and N_2 in the air remains the same, the P_{O_2} of inspired air at this altitude is 21% of 380 mm Hg, or 80 mm Hg, with alveolar P_{O_2} being even lower at 45 mm Hg. At any altitude above 10,000 feet, the arterial P_{O_2} falls into the steep portion of the O_2–Hb curve, below the safety range of the plateau region. As a result, the % Hb saturation in arterial blood declines precipitously with further increases in altitude.

People who rapidly ascend to altitudes of 10,000 feet or more experience symptoms of **acute mountain sickness** attributable to hypoxic hypoxia and the resultant hypocapnia-induced alkalosis. The increased ventilatory drive to obtain more O_2 causes respiratory alkalosis because acid-forming CO_2 is blown off more rapidly than it is produced. Symptoms of mountain sickness include fatigue, nausea, loss of appetite, labored breathing, rapid heart rate (triggered by hypoxia as a compensatory measure to increase circulatory delivery of available O_2 to the tissues), and nerve dysfunction characterized by poor judgment, dizziness, and incoordination.

Despite these acute responses to high altitude, millions of people live at elevations above 10,000 feet, with some villagers even residing in the Andes at altitudes higher than 16,000 feet. How do they live and function normally? They do so through the process of **acclimatization**. When a person remains at high altitude, the acute compensatory responses of increased ventilation and increased cardiac output are gradually replaced over a period of days by more slowly developing compensatory measures that permit adequate oxygenation of the tissues and restoration of normal acid–base balance. Red blood cell (RBC) production increases, stimulated by erythropoietin in response to reduced O_2 delivery to the kidneys (see p. 385). The rise in the number of RBCs increases the O_2-carrying capacity of the blood. Hypoxia also promotes synthesis of BPG within the RBCs so that O_2 is unloaded from Hb more easily at the tissues (see p. 475). The number of capillaries within the tissues increases, reducing the distance that O_2 must diffuse from the blood to reach the cells. Furthermore, acclimatized cells are able to use O_2 more eff ciently by increasing the number of mitochondria, the energy organelles. In addition, the kidneys restore arterial pH to nearly normal by conserving acid that normally would have been lost in the urine (see p. 554).

These compensatory measures come with undesirable trade-offs. For example, the greater number of RBCs increases blood viscosity (makes the blood "thicker"), thereby increasing resistance to blood

ventilation. Generation of respiratory rhythm is now known to lie in the **pre-Bötzinger complex**, a region located in the upper (head) end of the VRG (❙Figure 13-29). A network of neurons in this region display pacemaker activity, undergoing self-induced action potentials similar to those of the SA node of the heart. The rate at which the DRG inspiratory neurons rhythmically fire is driven by synaptic input from this complex.

Influences From the Pneumotaxic and Apneustic Centers The respiratory centers in the pons exert "fine-tuning" influences over the medullary center to help produce normal, smooth inspirations and expirations. The **pneumotaxic center** sends impulses to the DRG that help "switch off" the inspiratory neurons, limiting the duration of inspiration. In contrast, the **apneustic center** prevents the inspiratory neurons from being switched off, thus providing an extra boost to the inspiratory drive. In this check-and-balance system, the pneumotaxic center dominates over the apneustic center, helping halt inspiration and letting expiration occur normally. Without the pneumotaxic brakes, the breathing pattern consists of prolonged inspiratory gasps abruptly interrupted by brief expirations. This abnormal breathing pattern is known as **apneusis**; hence, the center that promotes this type of breathing is the apneustic center. Apneusis occurs in certain types of severe brain damage.

Hering–Breuer Reflex When the tidal volume is large (greater than 1 liter), as during exercise, the **Hering–Breuer reflex** is triggered to prevent overinflation of the lungs. **Pulmo-**

flow (see p. 337). As a result, the heart has to work harder to pump blood through the vessels.

Recent studies suggest that genetic selection has led to healthier normal red blood cell and hemoglobin levels among populations that have lived at high altitudes for thousands of years, thus bypassing the risks of thick blood. Instead, these peoples have evolved to rely on other means to live with permanently low arterial P_{O_2}. For example, the high-altitude inhabitants' endothelial cells release up to 10 times more nitric oxide (NO) than is released in those dwelling near sea level (see p. 346). This extra NO dilates the arterioles, more than doubling blood flow to the tissues, helping these high dwellers move suff cient O_2 to their tissues despite sustained low arterial O_2 levels.

Effects of Deep-Sea Diving on the Body

When a deep-sea diver, with the help of a *self-*c*ontained u*nderwater *b*reathing *a*pparatus *(scuba)*, descends underwater, the body is exposed to greater than atmospheric pressure. Pressure rapidly increases with sea depth as a result of the weight of the water. Pressure is already doubled about 30 feet below sea level. The air provided by scuba equipment is delivered to the lungs at these high pressures. Recall that (1) the amount of a gas in solution is directly proportional to the partial pressure of the gas and (2) air is composed of 79% N_2. Nitrogen is poorly soluble in body tissues, but the high P_{N_2} that occurs during deep-sea diving causes more of this gas than normal to dis-

solve in the body tissues. The small amount of N_2 dissolved in the tissues at sea level has no known effect, but as more N_2 dissolves at greater depths, **nitrogen narcosis,** or **"rapture of the deep,"** develops. Nitrogen narcosis is believed to result from reduced excitability of neurons when the lipid-soluble N_2 dissolves in their lipid membranes. At 150 feet underwater, divers experience a feeling of euphoria and become drowsy, similar to the effect of having a few cocktails. At lower depths, divers become weak and clumsy, and at 350 to 400 feet, they lose consciousness. Oxygen toxicity resulting from the high P_{O_2} is another possible detrimental effect of descending deep underwater.

Another problem associated with deep-sea diving occurs during ascent. If a diver who has been submerged long enough for a signif cant amount of N_2 to dissolve in the tissues suddenly ascends to the surface, the rapid reduction in P_{N_2} causes N_2 to quickly come out of solution and form bubbles of gaseous N_2 in the body, much as bubbles of gaseous CO_2 form in a bottle of champagne when the cork is popped. The consequences depend on the amount and location of N_2 bubble formation in the body. This condition is called **decompression sickness** or **"the bends"** because the victim often bends over in pain. Decompression sickness can be prevented by ascending slowly to the surface or by decompressing gradually in a decompression tank so that the excess N_2 can slowly escape through the lungs without bubble formation.

nary stretch receptors within the smooth muscle layer of the small airways are activated by stretching of the lungs at large tidal volumes. Action potentials from these stretch receptors travel through afferent nerve fibers to the medullary center and inhibit the inspiratory neurons. This negative feedback from the highly stretched lungs helps cut inspiration short before the lungs become overinflated.

Ventilation magnitude is adjusted in response to three chemical factors: P_{O_2}, P_{CO_2}, and H^+.

No matter how much O_2 is extracted from the blood or how much CO_2 is added to it at the tissue level, the P_{O_2} and P_{CO_2} of the systemic arterial blood leaving the lungs are normally held remarkably constant, indicating that arterial blood-gas content is precisely regulated. Arterial blood gases are maintained within the normal range by varying the magnitude of ventilation (rate and depth of breathing) to match the body's needs for O_2 uptake and CO_2 removal. If the blood extracts more O_2 from the alveoli and drops off more CO_2 because the tissues are metabolizing more actively, ventilation increases correspondingly to bring in more fresh O_2 and blow off more CO_2.

The medullary respiratory center receives inputs that provide information about the body's needs for gas exchange. It responds by sending appropriate signals to the motor neurons supplying the respiratory muscles, to adjust the rate and depth of ventilation to meet those needs. The two most obvious signals to increase ventilation are a decreased arterial P_{O_2} or an

Chemical Factor	Effect on the Peripheral Chemoreceptors	Effect on the Central Chemoreceptors
↓ P_{O_2} in the arterial blood	Stimulates only when the arterial P_{O_2} has fallen to the point of being life threatening (<60 mm Hg); an emergency mechanism	Directly depresses the central chemoreceptors and the respiratory center itself when <60 mm Hg
↑ P_{CO_2} in the arterial blood (↑ H^+ in the brain ECF)	Weakly stimulates	Strongly stimulates; is the dominant control of ventilation
		(Levels >70–80 mm Hg directly depress the respiratory center and central chemoreceptors)
↑ H^+ in the arterial blood	Stimulates; important in acid–base balance	Does not affect; cannot penetrate the blood–brain barrier

increased arterial P_{CO_2}. These two factors do indeed influence the magnitude of ventilation, but not to the same degree nor through the same pathway. Also, a third chemical factor, H^+, notably influences the level of respiratory activity. We examine the role of each of these important chemical factors in the control of ventilation (▮Table 13-8).

Decreased arterial P_{O_2} increases ventilation only as an emergency mechanism.

Arterial P_{O_2} is monitored by **peripheral chemoreceptors** known as the **carotid bodies** and **aortic bodies**, which lie at the fork of the common carotid arteries (that supply the brain) on both the right and the left sides and in the arch of the aorta, respectively (▮Figure 13-30). These chemoreceptors respond to specific changes in the chemical content of the arterial blood that bathes them. They are distinctly different from the carotid sinus and aortic arch baroreceptors located in the same vicinity. The latter monitor pressure changes rather than chemical changes and are important in regulating systemic arterial blood pressure (see p. 367).

Effect of a Large Decrease in P_{O_2} on the Peripheral Chemoreceptors The peripheral chemoreceptors are not sensitive to modest reductions in arterial P_{O_2}. Arterial P_{O_2} must fall below 60 mm Hg (>40% reduction) before the peripheral chemoreceptors respond by sending afferent impulses to the medullary inspiratory neurons, thereby reflexly increasing ventilation. Because arterial P_{O_2} falls below 60 mm Hg only in the unusual circumstances of severe pulmonary disease or reduced atmospheric P_{O_2}, it does not play a role in the normal ongoing regulation of respiration. This fact may seem surprising at first because a primary function of ventilation is to provide enough O_2 for uptake by the blood. However, there is no need to increase ventilation until arterial P_{O_2} falls below 60 mm Hg because of the safety margin in % Hb saturation afforded by the plateau portion of the O_2–Hb curve. Hemoglobin is still 90% saturated at an arterial P_{O_2} of 60 mm Hg, but the % Hb saturation drops precipitously when P_{O_2} falls below this level. Therefore, reflex stimulation of respiration by the peripheral chemoreceptors is an important emergency mechanism in dangerously

low arterial P_{O_2} states. Indeed, this reflex mechanism is a life-saver because a low arterial P_{O_2} directly depresses the respiratory center, as it does all the rest of the brain.

Clinical Note Because the peripheral chemoreceptors respond to the P_{O_2} of the blood, *not* the total O_2 content of the blood, O_2 content in the arterial blood can fall to dangerously low or even fatal levels without the peripheral chemoreceptors ever responding to reflexly stimulate respiration. Remember that only physically dissolved O_2 contributes to blood P_{O_2}. The total O_2 content in the arterial blood can be reduced in anemic
▮Figure 13-30 **Location of the peripheral chemoreceptors.** The carotid bodies are located in the carotid sinus, and the aortic bodies are located in the aortic arch.

states, in which O_2-carrying Hb is reduced, or in CO poisoning, when Hb preferentially binds to this molecule rather than to O_2. In both cases, arterial P_{O_2} is normal, so respiration is not stimulated, even though O_2 delivery to the tissues may be so reduced that the person dies from cellular O_2 deprivation.

Direct Effect of a Large Decrease in P_{O_2} on the Respiratory Center
Except for the peripheral chemoreceptors, the activity level in all nervous tissue falls in O_2 deprivation. Were it not for stimulatory intervention of the peripheral chemoreceptors when arterial P_{O_2} falls threateningly low, a vicious cycle ending in cessation of breathing would ensue. Direct depression of the respiratory center by the markedly low arterial P_{O_2} would further reduce ventilation, leading to an even greater fall in arterial P_{O_2}, which would even further depress the respiratory center until ventilation ceased and death occurred.

CO$_2$-generated H$^+$ in the brain is normally the main regulator of ventilation.

In contrast to arterial P_{O_2}, which does not contribute to the minute-to-minute regulation of respiration, arterial P_{CO_2} is the most important input regulating the magnitude of ventilation under resting conditions. This role is appropriate because changes in alveolar ventilation have an immediate and pronounced effect on arterial P_{CO_2}. By contrast, changes in ventilation have little effect on % Hb saturation and O_2 availability to the tissues until arterial P_{O_2} falls by more than 40%. Even slight alterations from normal in arterial P_{CO_2} bring about a significant reflex effect on ventilation. An increase in arterial P_{CO_2} reflexly stimulates the respiratory center, with the resultant increase in ventilation promoting elimination of the excess CO_2 to the atmosphere. Conversely, a fall in arterial P_{CO_2} reflexly reduces the respiratory drive. The subsequent decrease in ventilation lets metabolically produced CO_2 accumulate so that P_{CO_2} can return normal.

Effect of Increased P_{CO_2} on the Central Chemoreceptors
It is surprising that, given the key role of arterial P_{CO_2} in regulating respiration, no important receptors monitor arterial P_{CO_2} per se. The carotid and aortic bodies are only weakly responsive to changes in arterial P_{CO_2}, so they play only a minor role in reflexly stimulating ventilation in response to an elevation in arterial P_{CO_2}. More important in linking changes in arterial P_{CO_2} to compensatory adjustments in ventilation are the **central chemoreceptors**, located in the medulla near the respiratory center. These central chemoreceptors do not monitor CO_2 itself; however, they are sensitive to changes in CO_2-induced H$^+$ concentration in the brain extracellular fluid (ECF) that bathes them.

Movement of materials across the brain capillaries is restricted by the blood–brain barrier (see p. 141). Because this barrier is readily permeable to CO_2, any increase in arterial P_{CO_2} causes a similar rise in brain-ECF P_{CO_2} as CO_2 diffuses down its pressure

gradient from the cerebral blood vessels into the brain ECF. Under the influence of carbonic anhydrase, the increased P_{CO_2} within the brain ECF correspondingly raises the concentration of H$^+$ according to the law of mass action as it applies to this reaction: $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$. An elevation in H$^+$ concentration in the brain ECF directly stimulates the central chemoreceptors, which in turn increase ventilation by stimulating the respiratory center through synaptic connections (❙Figure 13-31). As the excess CO_2 is subsequently blown off, arterial P_{CO_2} and brain-ECF P_{CO_2} and H$^+$ concentration return to normal. Conversely, a decline in arterial P_{CO_2} below normal is paralleled by a fall in P_{CO_2} and H$^+$ in the brain ECF, the result of which is a central chemoreceptor–mediated decrease in ventilation. As CO_2 produced by cell metabolism is consequently allowed to accumulate, arterial P_{CO_2} and brain-ECF P_{CO_2} and H$^+$ are restored toward normal.

Unlike CO_2, H$^+$ cannot readily permeate the blood–brain barrier, so H$^+$ in the plasma cannot gain access to the central chemoreceptors. Accordingly, the central chemoreceptors respond only to H$^+$ generated within the brain ECF itself as a result of CO_2 entry. Thus, the major mechanism controlling ventilation under resting conditions is specifically aimed at regulating the brain-ECF H$^+$ concentration, which in turn directly reflects the arterial P_{CO_2}. Unless there are extenuating circumstances such as reduced availability of O_2 in the inspired
❙ Figure 13-31 **Effect of increased arterial P_{CO_2} on ventilation.**

ca = Carbonic anhydrase

air, arterial P_{O_2} is coincidentally also maintained at its normal value by the brain-ECF H^+ ventilatory driving mechanism.

The powerful influence of the central chemoreceptors on the respiratory center is widely believed to be responsible for your inability to deliberately hold your breath for more than about a minute. While you hold your breath, metabolically produced CO_2 continues to accumulate in your blood and then to build up the H^+ concentration in your brain ECF. Finally, the increased P_{CO_2}–H^+ stimulant to respiration becomes so powerful that central chemoreceptor excitatory input overrides voluntary inhibitory input to respiration, so breathing resumes despite deliberate attempts to prevent it. Breathing resumes long before arterial P_{O_2} falls to the threateningly low levels that trigger the peripheral chemoreceptors. Therefore, you cannot deliberately hold your breath long enough to create a dangerously high level of CO_2 or low level of O_2 in the arterial blood. (As an alternate theory, recent evidence suggests that the break point at which a breath-holding person is driven to gasp for air might depend on signals resulting from prolonged contraction of the diaphragm, not on elevated P_{CO_2}–H^+.)

Direct Effect of a Large Increase in P_{CO_2} on the Respiratory Center In contrast to the normal reflex stimulatory effect of the increased P_{CO_2}–H^+ mechanism on respiratory activity, very high levels of CO_2 directly depress the entire brain, including the respiratory center, just as very low levels of O_2 do. Up to a P_{CO_2} of 70 to 80 mm Hg, progressively higher P_{CO_2} levels promote correspondingly more vigorous respiratory efforts in an attempt to blow off the excess CO_2. A further increase in P_{CO_2} beyond 70 to 80 mm Hg, however, does not further increase ventilation but actually depresses the respiratory neurons. For this reason, CO_2 must be removed and O_2 supplied in closed environments such as closed-system anesthesia machines, submarines, or space capsules. Otherwise, CO_2 could reach lethal levels, not only because it depresses respiration but also because it produces severe respiratory acidosis.

Clinical Note **Loss of Sensitivity to P_{CO_2} with Lung Disease** During prolonged hypoventilation caused by certain types of chronic lung disease, an elevated P_{CO_2} occurs simultaneously with a markedly reduced P_{O_2}. In most cases, the elevated P_{CO_2} (acting via the central chemoreceptors) and the reduced P_{O_2} (acting via the peripheral chemoreceptors) are *synergistic*—that is, the combined stimulatory effect on respiration exerted by these two inputs together is greater than the sum of their independent effects.

However, some patients with severe chronic lung disease lose their sensitivity to an elevated arterial P_{CO_2}. In a prolonged increase in H^+ generation in the brain ECF, from long-standing CO_2 retention, enough HCO_3^- may cross the blood–brain barrier to buffer, or "neutralize," the excess H^+. The additional HCO_3^- combines with the excess H^+, removing it from solution so that it no longer contributes to free H^+ concentration. When brain-ECF HCO_3^- concentration rises, brain-ECF H^+ concentration returns to normal, although arterial P_{CO_2} and brain-ECF P_{CO_2} remain high. The central chemoreceptors are no longer aware of the elevated P_{CO_2} because the brain-ECF H^+

is normal. Because the central chemoreceptors no longer reflexly stimulate the respiratory center in response to the elevated P_{CO_2}, the drive to eliminate CO_2 is blunted in such patients—that is, their level of ventilation is abnormally low considering their high arterial P_{CO_2}. In these patients, the hypoxic drive to ventilation becomes their primary respiratory stimulus, in contrast to normal individuals, in whom the arterial P_{CO_2} level is the dominant factor governing the magnitude of ventilation. Ironically, administering O_2 to such patients to relieve the hypoxic condition can markedly depress their drive to breathe by elevating the arterial P_{O_2} and removing the primary driving stimulus for respiration. Thus, O_2 therapy must be administered cautiously in patients with long-term pulmonary diseases.

Adjustments in ventilation in response to changes in arterial H^+ are important in acid–base balance.

Changes in arterial H^+ concentration cannot influence the central chemoreceptors because H^+ does not readily cross the blood–brain barrier. However, the aortic and carotid body peripheral chemoreceptors are highly responsive to fluctuations in arterial H^+ concentration, in contrast to their weak sensitivity to deviations in arterial P_{CO_2} and their unresponsiveness to arterial P_{O_2} until it falls 40% below normal.

Any change in arterial P_{CO_2} brings about a corresponding change in the H^+ concentration of the blood as well as of the brain ECF. These CO_2-induced H^+ changes in the arterial blood are detected by the peripheral chemoreceptors; the result is reflexly stimulated ventilation in response to increased arterial H^+ concentration and depressed ventilation in association with decreased arterial H^+ concentration. However, these changes in ventilation mediated by the peripheral chemoreceptors are far less important than the powerful central-chemoreceptor mechanism in adjusting ventilation in response to changes in CO_2-generated H^+ concentration.

The peripheral chemoreceptors do play a major role in adjusting ventilation in response to alterations in arterial H^+ concentration unrelated to fluctuations in P_{CO_2}. In many situations, even though P_{CO_2} is normal, arterial H^+ concentration is changed by the addition or loss of non-CO_2-generated acid from the body. For example, arterial H^+ concentration increases during untreated diabetes mellitus because excess H^+-generating keto acids are abnormally produced and added to the blood. A rise in arterial H^+ concentration reflexly stimulates ventilation by means of the peripheral chemoreceptors. Conversely, the peripheral chemoreceptors reflexly suppress respiratory activity in response to a fall in arterial H^+ concentration resulting from nonrespiratory causes, such as occurs during excessive vomiting. During vomiting, the acid-rich digestive juice that is secreted into the stomach and subsequently reabsorbed back into the blood when digestion is complete is instead lost from the body. Changes in ventilation by this mechanism are extremely important in regulating the body's acid–base balance. Changing the magnitude of ventilation can vary the amount of H^+-generating CO_2 eliminated. The resulting adjustment in the

amount of H^+ added to the blood from CO_2 can compensate for the nonrespiratory-induced abnormality in arterial H^+ concentration that first elicited the respiratory response. (See Chapter 15 for further details.)

Exercise profoundly increases ventilation by unclear mechanisms.

Alveolar ventilation may increase up to 20-fold during heavy exercise to keep pace with the increased demand for O_2 uptake and CO_2 output. (ITable 13-9 highlights changes in O_2- and CO_2-related variables during exercise.) The cause of increased ventilation during exercise is still largely speculative. It would seem logical that changes in the "big three" chemical factors—decreased P_{O_2}, increased P_{CO_2}, and increased H^+—could account for the increase in ventilation. This does not appear to be the case, however.

■ Despite the marked increase in O_2 use during exercise, arterial P_{O_2} does not decrease but remains normal or may actually increase slightly because the increase in alveolar ventilation keeps pace with or even slightly exceeds the stepped-up rate of O_2 consumption.

■ Likewise, despite the marked increase in CO_2 production during exercise, arterial P_{CO_2} does not increase but remains normal or decreases slightly because the extra CO_2 is removed as rapidly or even more rapidly than it is produced by the increase in ventilation.

■ During mild or moderate exercise, H^+ concentration does not increase because H^+-generating CO_2 is held constant. During heavy exercise, H^+ concentration does increase somewhat from release of H^+-generating lactate (lactic acid) into the blood by anaerobic metabolism in the exercising muscles. Even so, the elevation in H^+ concentration resulting from lactic acid formation is not enough to account for the large increase in ventilation accompanying exercise.

Some investigators argue that the constancy of the three chemical regulatory factors during exercise shows that ventilatory responses to exercise are actually being controlled by these factors—particularly by P_{CO_2} because it is normally the dominant control during resting conditions. According to this reasoning, how else could alveolar ventilation be increased in exact proportion to CO_2 production, thereby keeping the P_{CO_2} constant? This proposal, however, cannot account for the observation that during heavy exercise, alveolar ventilation may increase relatively more than CO_2 production increases, thereby actually causing a slight decline in P_{CO_2}. Also, ventilation increases abruptly at the onset of exercise (within seconds), long before changes in arterial blood gases could become important influences on the respiratory center (which requires a matter of minutes).

ITABLE 13-9 Changes in Variables Related to O_2 and CO_2 during Exercise

Variable	Change	Comment
O_2 use	Marked ↑	Active muscles oxidize nutrient molecules more rapidly to meet their increased energy needs.
CO_2 production	Marked ↑	More actively metabolizing muscles produce more CO_2.
Alveolar ventilation	Marked ↑	By mechanisms not completely understood, alveolar ventilation keeps pace with or even slightly exceeds the increased metabolic demands during exercise.
Arterial P_{O_2}	Normal or slight ↑	Despite a marked increase in O_2 use and CO_2 production during exercise, alveolar ventilation keeps pace with or even slightly exceeds the stepped-up rate of O_2 consumption and CO_2 production.
Arterial P_{CO_2}	Normal or slight ↓	
O_2 delivery to muscles	Marked ↑	Although arterial P_{O_2} remains normal, O_2 delivery to muscles greatly increases as a result of the increased blood flow to exercising muscles accomplished by increased cardiac output coupled with local vasodilation of active muscles.
O_2 extraction by muscles	Marked ↑	Increased use of O_2 lowers the P_{O_2} at the tissue level, which results in more O_2 unloading from hemoglobin; this is enhanced by ↑ P_{CO_2}, ↑ H^+, and ↑ temperature.
CO_2 removal from muscles	Marked ↑	The increased blood flow to exercising muscles removes the excess CO_2 produced by these more actively metabolizing tissues.
Arterial H^+ Concentration		
Mild to moderate exercise	Normal	Because H^+-generating CO_2 is held constant in arterial blood, arterial H^+ concentration does not change.
Heavy exercise	Modest ↑	In heavy exercise, when muscles resort to anaerobic metabolism, lactic acid is added to the blood.

The Respiratory System **485**

Researchers have suggested that a number of other factors, including the following, play a role in the ventilatory response to exercise:

1. *Reflexes originating from body movements.* Joint and muscle receptors excited during muscle contraction reflexly stimulate the respiratory center, abruptly increasing ventilation. Even passive movement of the limbs (for example, someone else alternately flexing and extending a person's knee) may increase ventilation several-fold through activation of these receptors, although no actual exercise is occurring. Thus, the mechanical events of exercise are believed to play an important role in coordinating respiratory activity with the increased metabolic requirements of the active muscles.

2. *Increase in body temperature.* Much of the energy generated during muscle contraction is converted to heat rather than to actual mechanical work. Heat-loss mechanisms such as sweating frequently cannot keep pace with the increased heat production that accompanies increased physical activity, so body temperature often rises slightly during exercise (see p. 632). Because raised body temperature stimulates ventilation, this exercise-related heat production undoubtedly contributes to the respiratory response to exercise. For the same reason, increased ventilation often accompanies a fever.

3. *Epinephrine release.* The adrenal medullary hormone epinephrine also stimulates ventilation. The level of circulating epinephrine rises during exercise in response to the sympathetic nervous system discharge that accompanies increased physical activity.

4. *Impulses from the cerebral cortex.* Especially at the onset of exercise, the motor areas of the cerebral cortex are believed to simultaneously stimulate the medullary respiratory neurons and activate the motor neurons of the exercising muscles. This is similar to the cardiovascular adjustments initiated by the motor cortex at the onset of exercise. In this way, the motor region of the brain calls forth increased ventilatory and circulatory responses to support the increased physical activity it is about to orchestrate. These anticipatory adjustments are feedforward regulatory mechanisms—that is, they occur before any homeostatic factors actually change (see p. 18).

None of these factors or combinations of factors are fully satisfactory in explaining the abrupt and profound effect exercise has on ventilation, nor can they completely account for the high degree of correlation between respiratory activity and the body's needs for gas exchange during exercise. (For a discussion of how O_2 consumption during exercise can be measured to determine a person's maximum work capacity, see the accompanying boxed feature, ▮A Closer Look at Exercise Physiology.)

Ventilation can be influenced by factors unrelated to the need for gas exchange.

Ventilation can be modified for reasons other than the need to supply O_2 or remove CO_2. Here are some examples of involuntary influences in this category:

■ Protective reflexes such as sneezing and coughing temporarily govern respiratory activity in an effort to expel irritant materials from respiratory passages.

■ The respiratory center is reflexly inhibited during swallowing, when the airways are closed to prevent food from entering the lungs (see p. 576).

■ Pain originating anywhere in the body reflexly stimulates the respiratory center (for example, one "gasps" with pain).

■ Involuntary modification of breathing also occurs during the expression of various emotional states, such as laughing, crying, sighing, and groaning. The emotionally induced modifications are mediated through connections between the limbic system in the brain (which is responsible for emotions) and the respiratory center.

■ Hiccups occur when involuntary, spasmodic contractions of the diaphragm take place, each causing rapid intake of air, which is suddenly halted by abrupt closure of the glottis, resulting in the "hic" sound. The underlying trigger for hiccups is not known.

Humans also have considerable voluntary control over ventilation. Voluntary control of breathing is accomplished by the cerebral cortex, which does not act on the respiratory center in the brain stem but instead sends impulses directly to the motor neurons in the spinal cord that supply the respiratory muscles. We deliberately control our breathing to perform such voluntary acts as speaking, singing, whistling, playing wind instruments, or swimming. Also, we can voluntarily hyperventilate ("overbreathe") or, at the other extreme, hold our breath, but only for a brief period before reflex control mechanisms take over.

During apnea, a person "forgets to breathe"; during dyspnea, a person feels "short of breath."

Apnea is the transient interruption of ventilation, with breathing resuming spontaneously. If breathing does not resume, the condition is called **respiratory arrest**. Because ventilation is normally decreased and the central chemoreceptors are less sensitive to the arterial P_{CO_2} drive during sleep, especially paradoxical sleep (see p. 169), apnea is most likely to occur during this time. Victims of sleep apnea may stop breathing for a few seconds or up to 1 or 2 minutes as many as 500 times a night. Mild sleep apnea is not dangerous unless the sufferer has pulmonary or circulatory disease, which can be worsened by recurrent bouts of apnea.

Clinical Note **Sudden Infant Death Syndrome** In exaggerated cases of sleep apnea, the victim may be unable to recover from an apneic period, and death results. This is the case in **sudden infant death syndrome (SIDS)**, or "crib death," the leading cause of death in the first year of life. With this tragic form of sleep apnea, a previously healthy 2- to 4-month-old infant is found dead in his or her crib for no apparent reason. The underlying cause of SIDS is the subject of intense investigation. Most evidence suggests that the baby "forgets to breathe" because the respiratory control mechanisms are immature, either in the brain stem or in the chemoreceptors that monitor the body's respiratory status. For example, on autopsy more than half the victims have poorly developed

How to Find Out How Much Work You're Capable of Doing

THE BEST SINGLE PREDICTOR OF a person's work capacity is the determination of **maximal O_2 consumption**, or **max VO_2**, which is the maximum volume of O_2 the person is capable of using per minute to oxidize nutrient molecules for energy production. Max VO_2 is measured by having the person engage in exercise, usually on a treadmill or bicycle ergometer (a stationary bicycle with variable resistance). The workload is incrementally increased until the person becomes exhausted. Expired air samples collected during the last minutes of exercise, when O_2 consumption is at a maximum because the person is working as hard as possible, are analyzed for the percentage of O_2 and CO_2 they contain. Furthermore, the volume of air expired is measured. Equations are then used to determine the amount of O_2 consumed, taking into account the percentages of O_2 and CO_2 in the inspired air, the total volume of air expired, and the percentages of O_2 and CO_2 in the exhaled air.

Maximal O_2 consumption depends on three systems. The respiratory system is essential for ventilation and exchange of O_2 and CO_2 between air and blood in the lungs. The circulatory system is required to deliver O_2 to the working muscles. Finally, the muscles must have the oxidative enzymes available to use the O_2 once it has been delivered.

Regular aerobic exercise can improve max VO_2 by making the heart and respiratory system more eff cient, thereby delivering more O_2 to the working muscles. Exercised muscles themselves become better equipped to use O_2 once it is delivered. The number of functional capillaries increases, as do the number and size of mitochondria, which contain the oxidative enzymes.

Maximal O_2 consumption is measured in liters per minute and then converted into milliliters per kilogram of body weight per minute so that large and small people can be compared. As would be expected, athletes have the highest values for maximal O_2 consumption. The max VO_2 for male cross-country skiers has been recorded to be as high as 94 mL O_2/kg/min. Distance runners maximally consume between 65 and 85 mL O_2/kg/min, and football players have max VO_2 values between 45 and 65 mL O_2/kg/min, depending on the position they play. Sedentary young men maximally consume between 25 and 45 mL O_2/kg/min. Female values for max VO_2 are 20% to 25% lower than for males when expressed as mL/kg/min of total body weight. The difference in max VO_2 between females and males is only 8% to 10% when expressed as mL/kg/min of lean body weight, however, because females generally have a higher percentage of body fat (the female sex hormone estrogen promotes fat deposition).

Available norms are used to classify people as being low, fair, average, good, or excellent in aerobic capacity for their age group. Exercise physiologists use max VO_2 measurements to prescribe or adjust training regimens to help people achieve their optimal level of aerobic conditioning.

---

carotid bodies, the more important of the peripheral chemoreceptors. Abnormal lung development has been suggested as being responsible for at least some cases. Some infants who died of SIDS were found to have reduced levels of a growth factor critical for the lungs. Alternatively, some researchers believe the condition may be triggered by an initial cardiovascular failure rather than by an initial cessation of breathing. Still other investigators propose that some cases may result from aspiration of stomach juice containing the bacterium *Helicobacter pylori.* In one study, this microorganism was present in 88% of infants who died of SIDS. Scientists speculate that *H. pylori* may lead to the production of ammonia, which can be lethal if it gains access to the blood from the lungs. Perhaps a combination of factors might be involved, or maybe SIDS is a collection of early infancy deaths from a variety of causes.

Whatever the underlying cause, certain risk factors make babies more vulnerable to SIDS. Among them are sleeping position (an almost 40% higher incidence of SIDS is associated with sleeping on the abdomen rather than on the back or side) and exposure to nicotine during fetal life or after birth. Infants whose mothers smoked during pregnancy or who breathe cigarette smoke in the home are three times more likely to die of SIDS than those not exposed to smoke.

Clinical Note **Dyspnea** People who have dyspnea have the subjective sensation that they are not getting enough air—that is, they feel "short of breath." **Dyspnea** is the mental anguish associated with the unsatiated desire for more adequate ventilation. It often accompanies the labored breathing characteristic of obstructive lung disease or the pulmonary edema associated with congestive heart failure. In contrast, during exercise a person can breathe very hard without experiencing dyspnea because such exertion is not accompanied by a sense of anxiety over the adequacy of ventilation. Surprisingly, dyspnea is not directly related to chronic elevation of arterial P_{CO_2} or reduction of P_{O_2}. The subjective feeling of air hunger may occur even when alveolar ventilation and the blood gases are normal. Some people experience dyspnea when they *perceive* that they are short of air even though this is not actually the case, such as in a crowded elevator.

Check Your Understanding 13.5

1. Briefly describe how the following brain regions contribute to control of respiration: the medullary respiratory center (including the roles of the DRG and VRG), the pneumotaxic center, the apneustic center, and the pre-Bötzinger complex.

2. Discuss the role of the peripheral chemoreceptors.

3. Tell how the magnitude of ventilation is regulated under resting conditions.

Homeostasis: Chapter in Perspective

The respiratory system contributes to homeostasis by obtaining O_2 from and eliminating CO_2 to the external environment. All body cells ultimately need an adequate supply of O_2 to use in oxidizing nutrient molecules to generate ATP. Brain cells, which especially depend on a continual supply of O_2, die if deprived of O_2 for more than 4 minutes. Even cells that can resort to anaerobic ("without O_2") metabolism for energy production, such as strenuously exercising muscles, can do so only transiently by incurring an O_2 deficit that must be made up during the period of excess postexercise O_2 consumption (see p. 272).

As a result of these energy-yielding metabolic reactions, the body produces large quantities of CO_2 that must be eliminated. Because CO_2 and H_2O form carbonic acid, adjustments in the rate of CO_2 elimination by the respiratory system are important in regulating acid–base balance in the internal environment. Cells can survive only within a narrow pH range.

Review Exercises Answers begin on p. A-39

Reviewing Terms and Facts

1. Breathing is accomplished by alternate contraction and relaxation of muscles within the lung tissue. *(True or false?)*

2. Normally, the alveoli empty completely during maximal expiratory efforts. *(True or false?)*

3. Alveolar ventilation does not always increase when pulmonary ventilation increases. *(True or false?)*

4. O_2 and CO_2 have equal diffusion constants. *(True or false?)*

5. Hemoglobin has a higher affinity for O_2 than for any other substance. *(True or false?)*

6. Rhythmicity of breathing is brought about by pacemaker activity displayed by the respiratory muscles. *(True or false?)*

7. The expiratory neurons send impulses to the motor neurons controlling the expiratory muscles during normal quiet breathing. *(True or false?)*

8. The two forces that tend to keep the alveoli open are _____ and _____.

9. The two forces that promote alveolar collapse are _____ and _____.

10. _____ is a measure of the magnitude of change in lung volume accomplished by a given change in the transmural pressure gradient.

11. _____ is the phenomenon of the lungs snapping back to their resting size after having been stretched.

12. _____ is the erythrocytic enzyme that catalyzes the conversion of CO_2 into HCO_3^-.

13. Which of the following reactions take(s) place at the pulmonary capillaries?
   a. $Hb + O_2 \rightarrow HbO_2$
   b. $CO_2 + H_2O \rightarrow H^+ + HCO_3^-$
   c. $Hb + CO_2 \rightarrow HbCO_2$
   d. $Hb + H^+ \rightarrow HbH$

14. Indicate the O_2 and CO_2 partial pressure relationships important in gas exchange by circling > (greater than), < (less than), or = (equal to) as appropriate in each of the following statements:
   a. P_{O_2} in blood entering the pulmonary capillaries is (>, <, or =) P_{O_2} in the alveoli.
   b. P_{CO_2} in blood entering the pulmonary capillaries is (>, <, or =) P_{CO_2} in the alveoli.
   c. P_{O_2} in the alveoli is (>, <, or =) P_{O_2} in blood leaving the pulmonary capillaries.
   d. P_{CO_2} in the alveoli is (>, <, or =) P_{CO_2} in blood leaving the pulmonary capillaries.
   e. P_{O_2} in blood leaving the pulmonary capillaries is (>, <, or =) P_{O_2} in blood entering the systemic capillaries.
   f. P_{CO_2} in blood leaving the pulmonary capillaries is (>, <, or =) P_{CO_2} in blood entering the systemic capillaries.
   g. P_{O_2} in blood entering the systemic capillaries is (>, <, or =) P_{O_2} in the tissue cells.
   h. P_{CO_2} in blood entering the systemic capillaries is (>, <, or =) P_{CO_2} in the tissue cells.
   i. P_{O_2} in the tissue cells is (>, <, or approximately =) P_{O_2} in blood leaving the systemic capillaries.
   j. P_{CO_2} in the tissue cells is (>, <, or approximately =) P_{CO_2} in blood leaving the systemic capillaries.
   k. P_{O_2} in blood leaving the systemic capillaries is (>, <, or =) P_{O_2} in blood entering the pulmonary capillaries.
   l. P_{CO_2} in blood leaving the systemic capillaries is (>, <, or =) P_{CO_2} in blood entering the pulmonary capillaries.

15. Using the answer code on the right, indicate which chemoreceptors are being described:

1. stimulated by an arterial P_{O_2} of 80 mm Hg
2. stimulated by an arterial P_{O_2} of 55 mm Hg
3. directly depressed by an arterial P_{O_2} of 55 mm Hg
4. weakly stimulated by an elevated arterial P_{O_2}
5. strongly stimulated by an elevated brain-ECF H^+ concentration induced by an elevated arterial P_{CO_2}
6. stimulated by an elevated arterial H^+ concentration

(a) peripheral chemoreceptors
(b) central chemoreceptors
(c) both peripheral and central chemoreceptors
(d) neither peripheral nor central chemoreceptors

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Distinguish between cellular and external respiration. List the steps in external respiration.
2. Describe the components of the respiratory system. What is the site of gas exchange?
3. Compare atmospheric, intra-alveolar, and intrapleural pressures.
4. Why are the lungs normally stretched even during expiration?
5. Explain why air enters the lungs during inspiration and leaves during expiration.
6. Why is inspiration normally active and expiration normally passive?
7. Why does airway resistance become an important determinant of airflow rates in chronic obstructive pulmonary disease?
8. Explain pulmonary elasticity in terms of compliance and elastic recoil.
9. State the source and function of pulmonary surfactant.
10. Define the various lung volumes and capacities.
11. Compare pulmonary and alveolar ventilation. What is the consequence of anatomic and alveolar dead space?
12. Compare ventilation, perfusion, and the ventilation–perfusion ratio at the top and the bottom of the lung. Explain what accounts for these differences.
13. What determines the partial pressures of a gas in air and in blood?
14. List the methods of O_2 transport and CO_2 transport in the blood.
15. What is the primary factor that determines the percent hemoglobin saturation? What are the significances of the plateau and the steep portions of the O_2–Hb dissociation curve?
16. How does hemoglobin promote the net transfer of O_2 from the alveoli to the blood?
17. Explain the Bohr and Haldane effects.

18. Define the following: *hypoxic hypoxia, anemic hypoxia, circulatory hypoxia, histotoxic hypoxia, hypercapnia, hypocapnia, hyperventilation, hypoventilation, hyperpnea, apnea,* and *dyspnea.*
19. What are the locations and functions of the three respiratory control centers? Distinguish between the dorsal respiratory group (DRG) and the ventral respiratory group (VRG).
20. What brain region establishes the rhythmicity of breathing?

Solving Quantitative Exercises

1. The two curves in ❚Figure 13-28 (p. 478) show partial pressures for O_2 and CO_2 at various alveolar ventilation rates. These curves can be calculated from the following two equations:

$$P_{AO_2} = P_{IO_2} - (V_{O_2}/V_A) \; 863 \text{ mm Hg}$$

$$P_{ACO_2} = (V_{CO_2}/V_A) \; 863 \text{ mm Hg}$$

In these equations, P_{AO_2} = the partial pressure of O_2 in the alveoli, P_{ACO_2} = the partial pressure of CO_2 in the alveoli, P_{IO_2} = the partial pressure of O_2 in the inspired air, V_{O_2} = the rate of O_2 consumption by the body, V_{CO_2} = the rate of CO_2 production by the body, V_A = the rate of alveolar ventilation, and 863 mm Hg is a constant that accounts for atmospheric pressure and temperature.

John is in training for a marathon tomorrow and just ate a meal of pasta (assume this is pure carbohydrate, which is metabolized with an RQ of 1). His alveolar ventilation rate is 3.0 L/min, and he is consuming O_2 at a rate of 300 mL/min. What is the value of John's P_{ACO_2}?

2. Assume you are flying in an airplane that is cruising at 18,000 feet, where the pressure outside the plane is 380 mm Hg.
   a. Calculate the partial pressure of O_2 in the air outside the plane, ignoring water vapor pressure.
   b. If the plane depressurized, what would be the value of your P_{AO_2}? Assume that the ratio of your O_2 consumption to ventilation was not changed (that is, equaled 0.06), and note that under these conditions the constant in the equation that accounts for atmospheric pressure and temperature decreases from 863 mm Hg to 431.5 mm Hg.
   c. Calculate your P_{ACO_2}, assuming that your CO_2 production and ventilation rates remained unchanged at 200 mL/min and 4.2 L/min, respectively.

3. A student has a tidal volume of 350 mL. While breathing at a rate of 12 breaths/min, her alveolar ventilation is 80% of her pulmonary ventilation. What is her anatomic dead space volume?

Applying Clinical Reasoning

Keith M., a former heavy cigarette smoker, has severe emphysema. How does this condition affect his airway resistance? How does this change in airway resistance influence Keith's inspiratory and expiratory efforts? Describe how his respiratory muscle activity and intra-alveolar pressure changes compare to normal to accomplish a normal tidal volume. How would his

spirogram compare to normal? What influence would Keith's condition have on gas exchange in his lungs? What blood-gas abnormalities are likely to be present? Would it be appropriate to administer O_2 to Keith to relieve his hypoxic condition?

Thinking at a Higher Level

1. Why is it important that airplane interiors are pressurized (that is, the pressure is maintained at sea-level atmospheric pressure even though the atmospheric pressure surrounding the plane is substantially lower)? Explain the physiological value of using O_2 masks if the pressure in the airplane interior cannot be maintained.

2. If a severely anemic person has normal lungs, indicate whether each of the following factors will be normal, below normal, or above normal: (a) alveolar P_{O_2}, (b) arterial P_{O_2}, (c) percent hemoglobin saturation, (d) total O_2 content of arterial blood, (e) tissue P_{O_2}, (f) total O_2 transferred from blood to tissues

3. Would hypercapnia accompany the hypoxia produced in each of the following situations? Why or why not?

   a. cyanide poisoning
   b. pulmonary edema

   c. restrictive lung disease
   d. high altitude
   e. severe anemia
   f. congestive heart failure
   g. obstructive lung disease

4. Based on what you know about the control of respiration, explain why it is dangerous to voluntarily hyperventilate to lower the arterial P_{CO_2} before going underwater. The purpose of the hyperventilation is to stay under longer before P_{CO_2} rises above normal and drives the swimmer to surface for a breath of air.

5. If a person whose alveolar–capillary membranes are thickened by disease has an alveolar P_{O_2} of 100 mm Hg and an alveolar P_{CO_2} of 40 mm Hg, which of the following values of systemic arterial blood gases are most likely to exist?

   a. P_{O_2} = 105 mm Hg, P_{CO_2} = 35 mm Hg
   b. P_{O_2} = 100 mm Hg, P_{CO_2} = 40 mm Hg
   c. P_{O_2} = 80 mm Hg, P_{CO_2} = 45 mm Hg

If the person is administered 100% O_2, will the arterial P_{O_2} increase, decrease, or remain the same? Will the arterial P_{CO_2} increase, decrease, or remain the same?

The Urinary System

Steve Gschmeissner/Science Source

CHAPTER AT A GLANCE

A scanning electron micrograph of glomeruli and blood vessels in the kidney. The glomeruli (*yellow*) are balls of highly coiled capillaries through which protein-free plasma is filtered as the first step in urine formation. The kidney tubules (stripped away to reveal the glomeruli) collect the filtered fluid and convert it into urine by making selected exchanges with peritubular capillaries that wrap around the tubules.

Homeostasis Highlights

The survival and proper functioning of cells depend on maintaining stable concentrations of salt, acids, and other electrolytes in the internal fluid environment. Cell survival also depends on continuous removal of toxic metabolic wastes that cells produce as they perform life-sustaining chemical reactions. The **kidneys** play a major role in maintaining homeostasis by regulating the concentration of many plasma constituents, especially electrolytes and water, and by eliminating all metabolic wastes (except CO_2, which is removed by the lungs). As plasma repeatedly filters through the kidneys, they retain constituents of value for the body and eliminate undesirable or excess materials in the urine. Of special importance is the kidneys' ability to regulate the volume and osmolarity (solute concentration) of the internal fluid environment by controlling salt and water balance. Also crucial is their ability to help regulate pH by controlling elimination of acid and base in the urine.

14.1 Kidneys: Functions, Anatomy, and Basic Processes

The composition of the fluid bathing all the cells could be notably altered by exchanges between the cells and this internal fluid environment if mechanisms did not exist to keep the extracellular fluid (ECF) stable.

The kidneys perform a variety of functions aimed at maintaining homeostasis.

The **kidneys**, in concert with hormonal and neural inputs that control their function, are primarily responsible for maintaining stable volume, electrolyte composition, and osmolarity (solute concentration) of the ECF. By adjusting the quantity of water and various plasma constituents that are either conserved for the body or eliminated in the urine, the kidneys can maintain water and electrolyte balance within the narrow range compatible with life despite a wide range of intake and losses of these constituents through other avenues. The kidneys not only adjust for variations in ingestion of water, salt, and other electrolytes, but also adjust urinary output of these ECF constituents to compensate for abnormal losses through heavy sweating, vomiting, diarrhea, or hemorrhage. Thus, as the kidneys do what they can to maintain homeostasis, urine composition varies greatly.

When the ECF has a surplus of water or a particular electrolyte such as salt, the kidneys can eliminate the excess in the urine. If a deficit exists, the kidneys cannot provide additional quantities of the depleted constituent, but they can limit urinary losses of the material in short supply and thus conserve it until the person can take in more of the depleted substance. Accordingly, the kidneys can compensate more efficiently for excesses than for deficits. In fact, in some instances the kidneys cannot halt the loss of a valuable substance in the urine, even though the substance may be in short supply. A prime example is a water deficit. Even if a person is not consuming any water, the kidneys must put out about half a liter of water in the urine each day to fill another major role as the body's "cleaners."

In addition to the kidneys' important regulatory role in maintaining fluid and electrolyte balance, they are the main route for eliminating potentially toxic metabolic wastes and foreign compounds from the body. These wastes cannot be eliminated as solids; they must be excreted in solution, thus obligating the kidneys to produce a minimum volume of around 500 mL of waste-filled urine per day. Because water eliminated in the urine is derived from the blood plasma, a person stranded without water eventually urinates to death: The plasma volume falls to a fatal level as water is unavoidably removed to accompany the wastes.

Overview of Kidney Functions The kidneys perform the following specific functions, most of which help preserve constancy of the internal fluid environment and most of which will be discussed in this and the next chapter:

1. *Maintaining water (H_2O) balance in the body.*

2. *Maintaining the proper osmolarity of body fluids, primarily through regulating H_2O balance.* This function prevents osmotic fluxes into or out of the cells, which could lead to detrimental swelling or shrinking of the cells, respectively. Brain cells are particularly sensitive to volume changes.

3. *Regulating the quantity and concentration of most ECF ions,* including sodium (Na^+), chloride (Cl^-), potassium (K^+), calcium (Ca^{2+}), hydrogen ion (H^+), bicarbonate (HCO_3^-), phosphate (PO_4^{3-}), sulfate (SO_4^{2-}), and magnesium (Mg^{2+}). Even minor fluctuations in the ECF concentrations of some of these electrolytes can have profound influences. For example, changes in the ECF concentration of K^+ can potentially lead to fatal cardiac dysfunction.

4. *Maintaining proper plasma volume,* which is important in the long-term regulation of arterial blood pressure. This function is accomplished through the kidneys' regulatory role in salt (NaCl) and H_2O balance.

5. *Helping maintain the proper acid–base balance* of the body by adjusting urinary output of H^+ and HCO_3^-.

6. *Excreting (eliminating) the end products (wastes) of bodily metabolism,* such as urea (from proteins), uric acid (from nucleic acids), creatinine (from muscle creatine), bilirubin (from hemoglobin), and hormone metabolites. If allowed to accumulate, many of these wastes are toxic, especially to the brain.

7. *Excreting many foreign compounds,* such as drugs, food additives, pesticides, and other exogenous nonnutritive materials that have entered the body.

8. *Producing renin,* an enzymatic hormone that triggers a chain reaction important in salt conservation by the kidneys.

9. *Producing erythropoietin,* a hormone that stimulates red blood cell production (see Chapter 11).

10. *Converting vitamin D into its active form* (see Chapter 19).

The kidneys form urine; the rest of the urinary system carries it to the outside.

The **urinary system** consists of the urine-forming organs—the kidneys—and the structures that carry the urine from the kidneys to the outside for elimination from the body (❙ Figure 14-1a). The kidneys are a pair of bean-shaped organs about 4 to 5 inches long that lie behind the abdominal cavity (between the abdominal cavity and the back muscles), one on each side of the vertebral column, slightly above the waistline. Each kidney is supplied by a **renal artery** and a **renal vein**, which, respectively, enters and leaves the kidney at the medial indentation that gives this organ its beanlike form. The kidney acts on the plasma flowing through it to produce urine, conserving materials to be retained in the body and eliminating unwanted materials into the urine.

After urine is formed, it drains into a central collecting cavity, the **renal pelvis**, located at the medial inner core of each kidney (❙ Figure 14-1b). From there urine is channeled into the **ureter**, a duct that exits at the medial border close to the renal artery and vein. There are two ureters, one carrying urine from each kidney to the single urinary bladder.

The **urinary bladder**, which temporarily stores urine, is a hollow, distensible, smooth muscle–walled sac. Periodically,

urine is emptied from the bladder to the outside through another tube, the **urethra**, as a result of bladder contraction. The urethra in females is straight and short, passing directly from the neck of the bladder to the outside (IFigure 14-2a; see also IFigure 20-2, p. 719). In males, the urethra is longer and follows a curving course from the bladder to the outside, passing through both the prostate gland and the penis (see IFigures 14-1a and 14-2b; see also IFigure 20-1, p. 717). The male urethra serves the dual function of providing both a route for eliminating urine from the bladder and a passageway for semen from the reproductive organs. The prostate gland lies below the neck of the bladder and completely encircles the urethra.

Clinical Note Prostatic enlargement, which often occurs during middle to older age, can partially or completely occlude the urethra, impeding the flow of urine.

The parts of the urinary system beyond the kidneys merely serve as "ductwork" to transport urine to the outside. Once formed by the kidneys, urine is not altered in composition or volume as it moves downstream through the rest of the tract.

The nephron is the functional unit of the kidney.

Each kidney consists of about 1 million microscopic functional units known as **nephrons**, which are bound together by connective tissue (see IFigure 14-1c). Recall that a functional unit is the smallest unit within an organ capable of performing all of that organ's functions. Because the main function of the kidneys is to produce urine and, in so doing, maintain constancy in the
IFigure 14-2 **Comparison of the urethra in females and males.** (a) In females, the urethra is straight and short. (b) In males, the urethra, which is much longer, passes through the prostate gland and penis.

ECF composition, a nephron is the smallest unit capable of forming urine.

The arrangement of nephrons within the kidneys gives rise to two distinct regions—an outer region called the **renal cortex**, which looks granular, and an inner region, the **renal medulla**, which is made up of striated triangles, the **renal pyramids** (see IFigure 14-1b and c).

Knowledge of the structural arrangement of an individual nephron is essential for understanding the distinction between the cortical and the medullary regions of the kidney and, more important, for understanding renal function. Each nephron consists of a *vascular component* and a *tubular component,* which are intimately related structurally and functionally (IFigure 14-3).

Vascular Component of the Nephron The dominant part of the nephron's vascular component is the **glomerulus**, a ball-like tuft of capillaries through which part of the water and solutes is filtered from blood passing through (IFigure 14-4 and chapter opener photo). This filtered

Overview of Functions of Parts of a Nephron

Vascular component
- Afferent arteriole—carries blood to the glomerulus
- Glomerulus—a tuft of capillaries that filters a protein-free plasma into the tubular component
- Efferent arteriole—carries blood from the glomerulus
- Peritubular capillaries—supply the renal tissue; involved in exchanges with the fluid in the tubular lumen

Tubular component
- Bowman's capsule—collects the glomerular filtrate
- Proximal tubule—uncontrolled reabsorption and secretion of selected substances occur here
- Loop of Henle (of juxtamedullary nephrons only; not shown)—establishes an osmotic gradient in the renal medulla that is important in the kidney's ability to produce urine of varying concentration
- Distal tubule and collecting duct—variable, controlled reabsorption of Na^+ and H_2O and secretion of K^+ and H^+ occur here; fluid leaving the collecting duct is urine, which enters the renal pelvis

Combined vascular/tubular component
- Juxtaglomerular apparatus—produces substances involved in the control of kidney function

IFigure 14-3 **A nephron.** Components of a cortical nephron, the most abundant type of nephron in humans.

fluid, which is almost identical in composition to plasma, then passes through the nephron's tubular component, where various transport processes convert it into urine.

On entering the kidney, the renal artery subdivides to ultimately form many small vessels known as **afferent arterioles**, one of which supplies each nephron. The afferent arteriole delivers blood to the glomerulus. The glomerular capillaries rejoin to form another arteriole, the **efferent arteriole**, through which blood that was not filtered into the tubular component leaves the glomerulus (see ❙Figures 14-3 and 14-4). The efferent arterioles are the only arterioles in the body that drain from capillaries. Typically, arterioles break up into capillaries that rejoin to form venules. At the glomerular capillaries, no O_2 or nutrients are extracted from the blood for use by the kidney tissues, nor are waste products picked up from the surrounding tissue. Thus, arterial blood enters the glomerular capillaries through the afferent arteriole, and arterial blood leaves the glomerulus through the efferent arteriole.

The efferent arteriole subdivides into a second set of capillaries, the **peritubular capillaries**, which supply the renal tissue with blood and are important in exchanges between the tubular system and blood during conversion of the filtered fluid into urine. These peritubular capillaries, as their name implies, are intertwined around the tubular system (*peri* means "around"). The peritubular capillaries rejoin to form venules that ultimately drain into the renal vein, by which blood leaves the kidney.

Tubular Component of the Nephron The nephron's tubular component is a hollow, fluid-filled tube formed by a single layer of epithelial cells. Even though the tubule is continuous from its beginning near the glomerulus to its ending at the renal pelvis, it is arbitrarily divided into various segments based on differences in structure and function along its length (see ❙Figure 14-3). The tubular component begins with **Bowman's capsule**, an expanded, double-walled "cup" that surrounds the glomerulus to collect fluid filtered from the glomerular capillaries.

From Bowman's capsule, the filtered fluid passes into the **proximal tubule**, which lies within the cortex and is highly coiled or convoluted throughout much of its course. The next segment, the **loop of Henle**, forms a sharp U-shaped or hairpin loop that dips into the renal medulla. The *descending limb* of the loop of Henle plunges from the cortex into the medulla; the *ascending limb* traverses back up into the cortex. The ascending limb returns to the glomerular region of the same nephron, where it passes through the fork formed by the afferent and efferent arterioles. Both the tubular and the vascular cells at this point are specialized to form the **juxtaglomerular apparatus**, a structure that lies next to the glomerulus (*juxta* means "next to"). This specialized region plays an important role in regulating kidney function. Beyond the juxtaglomerular apparatus, the tubule again coils tightly to form the **distal tubule**, which also lies entirely within the cortex. The distal tubule empties into a **collecting duct** or **tubule**, with each collecting duct draining fluid from up to eight separate nephrons. Each collecting duct plunges down through the medulla to empty its fluid contents (now converted into urine) into the renal pelvis.

Cortical and Juxtamedullary Nephrons Two types of nephrons—*cortical nephrons* and *juxtamedullary nephrons*—are distinguished by the location and length of some of their structures (❙Figures 14-1 and 14-5). All nephrons originate in the cortex, but the glomeruli of **cortical nephrons** lie in the outer layer of the cortex, whereas the glomeruli of **juxtamedullary nephrons** lie in the inner layer of the cortex, next to the medulla. The presence of all glomeruli and associated Bowman's capsules in the cortex is responsible for this region's granular appearance. These two nephron types differ most markedly in their loops of Henle. The hairpin loop of cortical nephrons dips only slightly into the medulla. In contrast, the loop of juxtamedullary nephrons plunges through the entire depth of the medulla. Furthermore, the peritubular capillaries of juxtamedullary nephrons form hairpin vascular loops known as **vasa recta** ("straight vessels"), which run in close association with the long loops of Henle. In cortical nephrons, the peritubular capillaries do not form vasa recta but instead entwine around these nephrons' short loops of Henle in the same manner as the peritubular capillaries wrap around the proximal and distal tubules in both types of nephrons. As they course through the medulla, the collecting ducts of both cortical and juxtamedullary nephrons run parallel to the ascending and descending limbs of the juxtamedullary nephrons' long loops of Henle and vasa recta. The parallel arrangement of tubules and vessels in the medulla creates this region's striated appearance. More important, as you will see, this arrangement—coupled with the permeability and transport characteristics of the long loops of Henle and vasa recta—plays a key role in the kidneys' ability to produce urine of varying concentrations, depending on the needs of the body. About 80% of the nephrons in humans are of the cortical type. Species with greater urine-concentrating abilities than humans, such as the desert rat, have a greater proportion of juxtamedullary nephrons.

I Figure 14-5 Comparison of juxtamedullary and cortical nephrons. The glomeruli of cortical nephrons lie in the outer cortex, whereas the glomeruli of juxtamedullary nephrons lie in the inner part of the cortex next to the medulla. The loops of Henle of cortical nephrons dip only slightly into the medulla, but the juxtamedullary nephrons have long loops of Henle that plunge deep into the medulla. The juxtamedullary nephrons' peritubular capillaries form hairpin loops known as *vasa recta.* (For better visualization, the kidney is rotated 90° from its normal position in an upright person, the nephrons are grossly exaggerated in size, and the peritubular capillaries have been omitted, except for the vasa recta.)

The three basic renal processes are glomerular filtration, tubular reabsorption, and tubular secretion.

Three basic processes are involved in forming urine: *glomerular filtration, tubular reabsorption,* and *tubular secretion.* To aid in visualizing the relationships among these renal processes, it is useful to unwind the nephron schematically, as in **I** Figure 14-6.

Glomerular Filtration As blood flows through the glomerulus, protein-free plasma filters through the glomerular capillaries into Bowman's capsule. Normally, about 20% of the plasma that enters the glomerulus is filtered. This process, known as **glomerular filtration**, is the first step in urine formation. On average, 125 mL of glomerular filtrate (filtered fluid) are formed collectively through all the glomeruli each minute. This amounts to 180 liters (about 47.5 gallons) each day. Considering that the

average plasma volume in an adult is 2.75 liters, this means that the kidneys filter the entire plasma volume about 65 times per day. If everything filtered passed out in the urine, the total plasma volume would be urinated in less than half an hour! This does not happen, however, because the kidney tubules and peritubular capillaries are intimately related throughout their lengths so that the tubular cells can transfer materials as needed between the fluid inside the tubules and the blood within the peritubular capillaries.

Tubular Reabsorption As the filtrate flows through the tubules, substances of value to the body are returned to the peritubular capillary plasma. This selective movement of substances from inside the tubule (the tubular lumen) into the blood is called **tubular reabsorption**. Reabsorbed substances are not lost from the body in the urine but instead are carried by the peritubular capillaries to the venous system and then to

TS = **Tubular secretion**—selective movement of nonfiltered substances from the peritubular capillaries into the tubular lumen

❙Figure 14-6 **Basic renal processes.** Anything filtered or secreted but not reabsorbed is excreted in the urine and lost from the body. Anything filtered and subsequently reabsorbed, or not filtered at all, enters the venous blood and is saved for the body.

FIGURE FOCUS: *Name two ways that substances can* enter *and two ways that substances can* leave *the tubular fluid*.

the heart to be recirculated. Of the 180 liters of plasma filtered per day, 178.5 liters, on average, are reabsorbed. The remaining 1.5 liters of filtered fluid left in the tubules pass into the renal pelvis to be eliminated as urine. In general, substances the body needs to conserve are selectively reabsorbed, whereas unwanted substances that must be eliminated stay in the tubular fluid, which becomes urine after tubular modification is complete.

Tubular Secretion The third renal process, **tubular secretion**, is the selective transfer of substances from the peritubular capillary blood into the tubular lumen. It provides a second route for substances to enter the renal tubules from the blood, the first being by glomerular filtration. Only about 20% of the plasma flowing through the glomerular capillaries is filtered into Bowman's capsule; the remaining 80% flows on through the efferent arteriole into the peritubular capillaries. Tubular secretion provides a mechanism for more rapidly eliminating selected substances from the plasma by extracting an additional

quantity of a particular substance from the 80% of unfiltered plasma in the peritubular capillaries and adding it to the quantity of the substance already present in the tubule as a result of filtration.

Urine Excretion **Urine excretion** is the elimination of substances from the body in the urine. It is not a separate process but the result of the first three processes. All plasma constituents filtered or secreted but not reabsorbed remain in the tubules and pass into the renal pelvis to be excreted as urine and eliminated from the body (❙Figure 14-6). (Do not confuse excretion with secretion.) Note that anything filtered and subsequently reabsorbed, or not filtered at all, enters the venous blood from the peritubular capillaries and thus is conserved for the body instead of being excreted in the urine, despite passing through the kidneys.

The Big Picture of the Basic Renal Processes Glomerular filtration is largely an indiscriminate process. With the exception of blood cells and plasma proteins, all constituents within the blood—H_2O, nutrients, electrolytes, wastes, and so on—nonselectively enter the tubular lumen as a bulk unit during filtration—that is, of the 20% of the plasma filtered at the glomerulus, everything in that part of the plasma enters Bowman's capsule except for the plasma proteins. The highly discriminating tubular processes then work on the filtrate to return to the blood a fluid of the composition and volume necessary to maintain constancy of the internal fluid environment. The unwanted filtered material is left behind in the tubular fluid to be excreted as urine. Glomerular filtration can be thought of as pushing a part of the plasma, with all its essential components and those that need to be eliminated from the body, onto a tubular "conveyor belt" that terminates at the renal pelvis, which is the collecting point for urine within the kidney. All plasma constituents that enter this conveyor belt and are not subsequently returned to the plasma by the end of the line are spilled out of the kidney as urine. It is up to the tubular system to salvage by reabsorption the filtered materials that need to be preserved for the body while leaving behind substances that must be excreted. In addition, some substances not only are filtered, but also are secreted onto the tubular conveyor belt, so the amounts of these substances excreted in the urine are greater than the amounts that were filtered. For many substances, these renal processes are subject to physiologic control. Thus, the kidneys handle each constituent in the plasma by a particular combination of filtration, reabsorption, and secretion.

The kidneys act only on the plasma, yet the ECF consists of both plasma and interstitial fluid. The interstitial fluid is the true internal fluid environment of the body because it is the only component of the ECF that comes into direct contact with the cells. However, because of the free exchange between plasma and interstitial fluid across the capillary walls (with the exception of plasma proteins), interstitial fluid composition reflects the composition of plasma. Thus, by performing their regulatory and excretory roles on plasma, the kidneys maintain the proper interstitial fluid environment for optimal cell function. Most of the rest of this chapter is devoted to considering how the basic renal processes are accomplished and the mecha-

To be filtered, a substance must pass through

nisms by which they are carefully regulated to help maintain homeostasis.

Check Your Understanding 14.1

1. Name and describe the functional unit of the kidneys.

2. Schematically draw an "unwound" nephron and use arrows to show the direction of movement between its vascular and tubular components during the three basic renal processes.

3. Distinguish between cortical and juxtamedullary nephrons.

14.2 Glomerular Filtration

Fluid filtered from the glomerulus into Bowman's capsule must pass through the three layers that make up the **glomerular membrane** (I Figure 14-7): (1) the glomerular capillary wall, (2) the basement membrane, and (3) the inner layer of Bowman's capsule. Collectively, these layers function as a fine molecular sieve that retains the blood cells and plasma proteins but permits H_2O and solutes of small molecular dimension to filter through. Let us consider each layer in more detail.

The glomerular membrane is considerably more permeable than capillaries elsewhere.

The *glomerular capillary wall* consists of a single layer of flattened endothelial cells. It is perforated by many large pores that make it more than 100 times more permeable to H_2O and solutes than capillaries elsewhere in the body. The glomerular capillaries not only have the traditional pores found between the endothelial cells that form the capillary walls, but the endothelial cells themselves also are perforated by large holes or fenestrations (see p. 353).

The *basement membrane* is an acellular (lacking cells) gelatinous layer composed of collagen and glycoproteins that is sandwiched between the glomerulus and Bowman's capsule. The collagen provides structural strength, and the glycoproteins discourage the filtration of small plasma proteins. The larger plasma proteins cannot be filtered because they cannot fit through the capillary pores, but the pores are just barely large enough to permit passage of albumin, the smallest of plasma proteins. However, because the glycoproteins are negatively charged, they repel albumin and other plasma proteins, which are also negatively charged. Therefore, plasma proteins are almost completely excluded from the filtrate, with less than 1% of the albumin molecules escaping into Bowman's capsule. The small proteins that do slip into the filtrate are picked up by the proximal tubule by receptor-mediated endocytosis (see p. 31), then degraded into constituent amino acids that are returned to the blood. Thus, urine is normally protein free.

Clinical Note Some renal diseases characterized by excessive albumin in the urine (*albuminuria*) are the result of disruption of the negative charges within the basement membrane, which makes the glomerular membrane more permeable to albumin even though the size of the capillary pores remains constant. (Urinary loss of proteins can also fol-

When Protein in the Urine
Does Not Mean Kidney Disease

URINARY LOSS OF PROTEINS (MOSTLY albumin) usually signifies kidney disease *(nephritis).* However, a urinary protein loss similar to that of nephritis often occurs following exercise, but the condition is harmless, transient, and reversible. The term *athletic pseudonephritis* (*pseudo* means "false") is used to describe this postexercise (after exercise) proteinuria (protein in the urine). Studies indicate that 70% to 80% of athletes have proteinuria after very strenuous exercise. This condition occurs in participants in both noncontact and contact sports, so it does not arise from physical trauma to the kidneys.

Usually, only a very small fraction of the plasma proteins that enter the glomerulus is filtered; these filtered plasma proteins are subsequently reabsorbed in the tubules, so normally no plasma proteins appear in the urine. Two basic mechanisms can cause proteinuria: (1) increased glomerular permeability with no change in tubular reabsorption or (2) impairment of tubular reabsorption. Research has shown that the proteinuria occurring during mild to moderate exercise results from changes in glomerular permeability, whereas the proteinuria occurring during short-term exhaustive exercise is caused by both increased glomerular permeability and tubular dysfunction.

This reversible kidney dysfunction is believed to result from circulatory and hormonal changes that occur with exercise. Renal blood flow is reduced during exercise as the renal vessels are constricted and blood is diverted to the exercising muscles. This reduction is positively correlated with exercise intensity. With intense exercise, renal blood flow may be reduced to 20% of normal. As a result, glomerular blood flow is also reduced, but not to the same extent as renal blood flow, because of autoregulation (see p. 501). Investigators propose that decreased glomerular blood flow enhances diffusion of proteins into the tubular lumen because as the more slowly flowing blood spends more time in the glomerulus, a greater proportion of the plasma proteins have time to escape through the glomerular membrane. Hormonal changes that occur with exercise may also affect glomerular permeability. For example, injection of the kidney hormone renin is a well-recognized way to experimentally induce proteinuria. Plasma renin activity increases during strenuous exercise and may contribute to postexercise proteinuria. Researchers also hypothesize that maximal tubular reabsorption is reached during severe exercise, which could impair protein reabsorption.

low exercise, but it is transient and harmless. For further discussion, see the accompanying boxed feature, ❙ A Closer Look at Exercise Physiology.)

The final layer of the glomerular membrane is the *inner layer of Bowman's capsule.* It consists of **podocytes**, octopuslike epithelial cells that encircle the glomerular tuft. A podocyte bears multiple elongated primary foot processes (*podo* means "foot"; a *process* is a projection or appendage), each of which has many side branches, or secondary foot processes, protruding from it to the right and to the left, similar to the fronds of a fern plant. The secondary foot processes of one podocyte interdigitate with the secondary foot processes of adjacent podocytes as they cup around a glomerular capillary, much as you interlace your fingers when you cup your hands around a ball (❙ Figure 14-8). The narrow slits between the interdigitating secondary foot processes of adjacent podocytes are known as **filtration slits**, which provide a pathway through which fluid leaving the glomerular capillaries can enter the lumen of Bowman's capsule.

Thus, the route that filtered substances take across the glomerular membrane is completely extracellular—first through capillary pores, then through the acellular basement membrane, and finally through capsular filtration slits (see ❙ Figure 14-7).

Glomerular capillary blood pressure is the major force that causes glomerular filtration.

To accomplish glomerular filtration, a force must drive a part of the plasma in the glomerulus through the openings in the glomerular membrane. No local energy is used to move fluid from the plasma across the glomerular membrane into Bowman's capsule. Passive physical forces similar to those acting across capillaries elsewhere accomplish glomerular filtration.

Because the glomerulus is a tuft of capillaries, the same principles of fluid dynamics apply here that cause ultrafiltration across other capillaries (see p. 356), except for two important differences: (1) The glomerular capillaries are more permeable than capillaries elsewhere, so more fluid is filtered for a given

filtration pressure, and (2) the balance of forces across the glomerular membrane is such that filtration occurs the entire length of the capillaries. In contrast, the balance of forces in other capillaries shifts so that filtration occurs in the beginning part of the vessel but reabsorption occurs toward the vessel's end (see ▌Figure 10-20, p. 356).

Forces Involved in Glomerular Filtration Three physical forces are involved in glomerular filtration: glomerular capillary blood pressure, plasma-colloid osmotic pressure, and Bowman's capsule hydrostatic pressure. Glomerular capillary blood pressure *favors* filtration, whereas the two other forces acting across the glomerular membrane *oppose* filtration, as follows (▌Table 14-1):

1. *Glomerular capillary blood pressure* is the fluid (hydrostatic) pressure exerted by the blood within the glomerular capillaries. It ultimately depends on contraction of the heart (the source of energy that produces glomerular filtration) and the resistance to blood flow offered by the afferent and efferent arterioles. Glomerular capillary blood pressure, at an estimated average value of 55 mm Hg, is higher than capillary blood pressure elsewhere. The reason for the higher pressure is the larger diameter of the afferent arteriole compared to that of the efferent arteriole (see ▌Figure 14-4, p. 495). Because blood can flow more rapidly into the glomerulus through the wide afferent arteriole than it can leave through the narrower

efferent arteriole, glomerular capillary blood pressure is maintained high as a result of blood damming up in the glomerular capillaries. Also, because of the high resistance offered by the efferent arterioles, blood pressure does not fall along the length of the glomerular capillaries as it does along other capillaries. This elevated, nondecremental glomerular blood pressure tends to push fluid out of the glomerulus into Bowman's capsule along the glomerular capillaries' entire length, and it is the major force producing glomerular filtration.

2. *Plasma-colloid osmotic pressure* (π_P) is caused by the unequal distribution of plasma proteins across the glomerular membrane. Because plasma proteins cannot be filtered, they are in the glomerular capillaries but not in Bowman's capsule. Accordingly, the concentration of H_2O is higher in Bowman's capsule than in the glomerular capillaries. The resulting tendency for H_2O to move by osmosis down its concentration gradient from Bowman's capsule into the glomerulus opposes glomerular filtration. This opposing osmotic force averages 30 mm Hg, which is slightly higher than across other capillaries. It is higher because more H_2O is filtered out of the glomerular blood, so the concentration of plasma proteins is higher than elsewhere.

3. *Bowman's capsule hydrostatic pressure,* the pressure exerted by the fluid in this initial part of the tubule, is estimated to be about 15 mm Hg. This pressure, which tends to push fluid out of Bowman's capsule, opposes the filtration of fluid from the glomerulus into Bowman's capsule.

Glomerular Filtration Rate As can be seen in ▌Table 14-1, the forces acting across the glomerular membrane are not in balance. The total force favoring filtration is the glomerular capillary blood pressure at 55 mm Hg. The total of the two forces opposing filtration is 45 mm Hg. The net difference favoring filtration (10 mm Hg of pressure) is called the **net filtration pressure**. This modest pressure forces large volumes of fluid from the blood through the highly permeable glomerular membrane. The actual rate of filtration, the **glomerular filtration rate (GFR)**, depends not only on the net filtration pressure, but also on how much glomerular surface area is available for penetration and how permeable the glomerular membrane is (that is, how "holey" it is). These properties of the glomerular membrane are collectively referred to as the **filtration coefficient (K_f)**. Accordingly,

$$\text{GFR} = K_f \times \text{net filtration pressure}$$

Normally, about 20% of the plasma that enters the glomerulus is filtered at the net filtration pressure of 10 mm Hg, producing collectively through all glomeruli 180 liters of glomerular filtrate each day for an average GFR of 125 mL/min in males (160 L/day, 115 mL/min in females).

Changes in GFR result mainly from changes in glomerular capillary blood pressure.

Because the net filtration pressure that accomplishes glomerular filtration is simply the result of an imbalance of opposing physical forces between the glomerular capillary plasma and Bowman's capsule fluid, alterations in any of these physical forces can affect the GFR, as discussed next.

▌**TABLE 14-1** Forces Involved in Glomerular Filtration

Force	Effect	Magnitude (mm Hg)
Glomerular capillary blood pressure	Favors filtration	55
Plasma-colloid osmotic pressure	Opposes filtration	30
Bowman's capsule hydrostatic pressure	Opposes filtration	15
Net filtration pressure (difference between force favoring filtration and forces opposing filtration)	Favors filtration	10

Unregulated Influences on the GFR Plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure normally do not vary much and cannot be regulated.

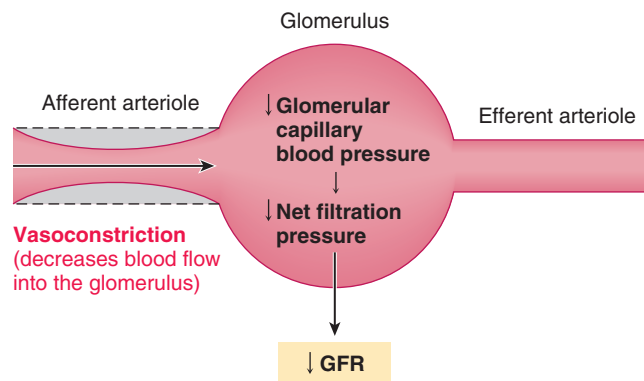
Clinical Note However, these forces can change pathologically and thus inadvertently affect the GFR. Because π_P opposes filtration, a decrease in plasma protein concentration, by reducing this pressure, leads to an increased GFR. Plasma protein concentration might uncontrollably drop, for example, in severely burned patients who lose a large quantity of protein-rich, plasma-derived fluid through the exposed burned surface of their skin. Conversely, when π_P rises, such as in cases of dehydrating diarrhea, the GFR falls.

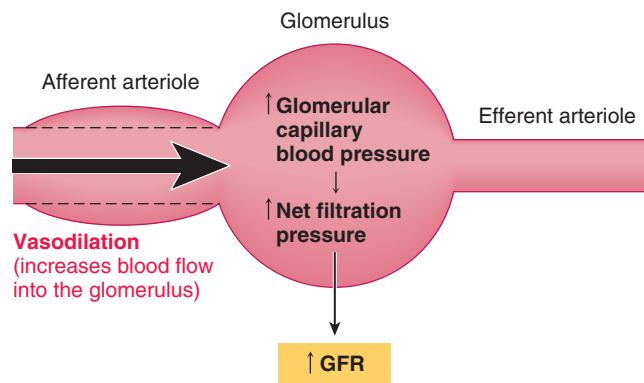
Bowman's capsule hydrostatic pressure can become uncontrollably elevated, and filtration subsequently can decrease, given a urinary tract obstruction, such as a kidney stone or enlarged prostate. The damming up of fluid behind the obstruction elevates capsular hydrostatic pressure.

Controlled Adjustments in the GFR Unlike plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure—which may be uncontrollably altered in various disease states and thereby may inappropriately alter the GFR—glomerular capillary blood pressure can be controlled to adjust the GFR to suit the body's needs. Assuming that all other factors stay constant, as glomerular capillary blood pressure rises, net filtration pressure goes up and the GFR increases correspondingly. The magnitude of the glomerular capillary blood pressure depends on the rate of blood flow within each of the glomeruli. The amount of blood flowing into a glomerulus per minute is determined largely by the magnitude of the mean systemic arterial blood pressure and the resistance offered by the afferent arteriole. If afferent arteriolar resistance increases, less blood flows into the glomerulus, decreasing the GFR. Conversely, if afferent arteriolar resistance decreases, more blood flows into the glomerulus and the GFR increases. Two major control mechanisms regulate the GFR, both directed at adjusting glomerular blood flow by regulating the radius and thus the resistance of the afferent arteriole. These mechanisms are (1) autoregulation, which is aimed at preventing spontaneous changes in GFR; and (2) extrinsic sympathetic control, which is aimed at long-term regulation of arterial blood pressure.

Mechanisms Responsible for Autoregulation of the GFR Because arterial blood pressure is the force that drives blood into the glomerulus, the glomerular capillary blood pressure and, accordingly, the GFR would increase in direct proportion to an increase in arterial pressure if everything else remained constant (▌Figure 14-9). Similarly, a fall in arterial blood pressure would cause a decline in GFR. Such spontaneous, inadvertent changes in GFR are largely prevented by intrinsic regulatory mechanisms initiated by the kidneys themselves, a process known as **autoregulation** (*auto* means "self"). The kidneys can, within limits, maintain a constant blood flow into the glomerular capillaries (and thus a constant glomerular capillary blood pressure and a stable GFR) despite changes in the driving arterial pressure. They do so primarily by altering
▌Figure 14-9 **Direct effect of arterial blood pressure on the glomerular filtration rate (GFR).**

afferent arteriolar caliber, thereby adjusting resistance to flow through these vessels. For example, if the GFR increases as a direct result of a rise in arterial pressure, the net filtration pressure and GFR can be reduced to normal by constriction of the afferent arteriole, which decreases the flow of blood into the glomerulus (▌Figure 14-10a). This local adjustment lowers glomerular blood pressure and GFR to normal.

Conversely, when GFR falls in the presence of a decline in arterial pressure, glomerular pressure can be increased to normal by vasodilation of the afferent arteriole, which allows more


(a) Arteriolar vasoconstriction decreases the GFR


(b) Arteriolar vasodilation increases the GFR

▌Figure 14-10 **Adjustments of afferent arteriole caliber to alter the GFR.**

blood to enter despite the reduction in driving pressure (Figure 14-10b). The resultant buildup of glomerular blood volume increases glomerular blood pressure, which in turn brings the GFR back up to normal.

Two mechanisms contribute to autoregulation of the GFR: (1) a *myogenic* mechanism, which responds to changes in pressure within the nephron's vascular component; and (2) a *tubuloglomerular feedback* mechanism, which senses changes in salt level in the fluid flowing through the nephron's tubular component.

■ The **myogenic** mechanism is a common property of vascular smooth muscle (*myogenic* means "muscle produced"). Arteriolar vascular smooth muscle contracts inherently in response to the stretch accompanying increased pressure within the vessel (see p. 348). Accordingly, the afferent arteriole automatically constricts on its own when it is stretched because of an increased arterial driving pressure. This response helps limit blood flow into the glomerulus to normal despite the elevated arterial pressure. Conversely, inherent relaxation of an unstretched afferent arteriole when pressure within the vessel is reduced increases blood flow into the glomerulus despite the fall in arterial pressure.

■ The **tubuloglomerular feedback (TGF)** mechanism involves the *juxtaglomerular apparatus,* which is the specialized combination of tubular and vascular cells where the tubule, after having bent back on itself, passes through the angle formed by the afferent and efferent arterioles as they join the glomerulus (Figure 14-11; see also Figure 14-3, p. 494). The smooth muscle cells within the wall of the afferent arteriole in this region are specialized to form **granular cells**, so called because they contain many secretory granules. Specialized tubular cells

in this region are collectively known as the **macula densa**. The macula densa cells detect changes in the salt level of the fluid flowing past them through the tubule.

If the GFR is increased secondary to an elevation in arterial pressure, more fluid than normal is filtered and flows through the distal tubule. In response to the resultant rise in salt delivery to the distal tubule, the macula densa cells release *ATP* and *adenosine,* both of which act locally as a paracrine on the adjacent afferent arteriole, causing it to constrict, thus reducing glomerular blood flow and returning GFR to normal. In the opposite situation, when less salt is delivered to the distal tubule because of a spontaneous decline in GFR accompanying a fall in arterial pressure, less ATP and adenosine are released by the macula densa cells. The resultant afferent arteriolar vasodilation increases the glomerular flow rate, restoring the GFR to normal. To exert even more exquisite control over tubuloglomerular feedback, the macula densa cells also secrete the vasodilator *nitric oxide,* which puts the brakes on the action of ATP and adenosine at the afferent arteriole. By means of the TGF mechanism, the tubule of a nephron is able to monitor the salt level in the fluid flowing through it and adjust the rate of filtration through the glomerulus of the same nephron accordingly to keep the early distal tubular fluid and salt delivery constant.

Importance of Autoregulation of the GFR The myogenic and tubuloglomerular feedback mechanisms work in unison to autoregulate the GFR within the mean arterial blood
Figure 14-11 The juxtaglomerular apparatus. The juxtaglomerular apparatus consists of specialized vascular cells (the granular cells) and specialized tubular cells (the macula densa) at a point where the distal tubule passes through the fork formed by the afferent and efferent arterioles of the same nephron.

pressure range of 80 to 180 mm Hg. Within this wide range, intrinsic autoregulatory adjustments of afferent arteriolar resistance can compensate for changes in arterial pressure, thus preventing inappropriate fluctuations in GFR, even though glomerular pressure tends to change in the same direction as arterial pressure. Normal mean arterial pressure is 93 mm Hg, so this range encompasses the transient changes in blood pressure that accompany daily activities unrelated to the need for the kidneys to regulate H_2O and salt excretion, such as the normal elevation in blood pressure accompanying exercise. Autoregulation is important because unintentional shifts in GFR could lead to dangerous imbalances of fluid, electrolytes, and wastes. Because at least a certain portion of the filtered fluid is always excreted, the amount of fluid excreted in the urine is automatically increased as the GFR increases. If autoregulation did not occur, the GFR would increase and H_2O and solutes would be lost needlessly as a result of the rise in arterial pressure accompanying heavy exercise. If, by contrast, the GFR were too low, the kidneys could not eliminate enough wastes, excess electrolytes, and other materials that should be excreted. Autoregulation thus greatly blunts the direct effect that changes in arterial pressure would otherwise have on GFR and subsequently on H_2O, solute, and waste excretion.

When changes in mean arterial pressure fall outside the autoregulatory range, these mechanisms cannot compensate. Therefore, dramatic changes in mean arterial pressure (<80 mm Hg or >180 mm Hg) directly cause the glomerular capillary pressure and, accordingly, the GFR to decrease or increase in proportion to the change in arterial pressure.

Importance of Extrinsic Sympathetic Control of the GFR In addition to the intrinsic autoregulatory mechanisms designed to keep the GFR constant in the face of fluctuations in arterial blood pressure, the GFR can be *changed on purpose*—even when the mean arterial blood pressure is within the autoregulatory range—by extrinsic control mechanisms that override the autoregulatory responses. Extrinsic control of GFR, which is mediated by sympathetic nervous system input to the afferent arterioles, is aimed at long-term regulation of arterial blood pressure. The parasympathetic nervous system does not exert any influence on the kidneys.

If plasma volume is decreased—for example, by hemorrhage—the resulting fall in arterial blood pressure is detected by the arterial carotid sinus and aortic arch baroreceptors, which initiate neural reflexes to raise blood pressure toward normal (see p. 367). These reflex responses are coordinated by the cardiovascular control center in the brain stem and are mediated primarily through increased sympathetic activity to the heart and blood vessels. Although the resulting increase in both cardiac output and total peripheral resistance helps raise blood pressure toward normal in the short term, plasma volume is still

reduced. In the long term, plasma volume must be restored to normal. One compensation for a depleted plasma volume is reduced urine output so that more fluid than normal is conserved for the body. Urine output is reduced in part by reducing the GFR; if less fluid is filtered, less is available to excrete.

Role of the Baroreceptor Reflex in Extrinsic Control of the GFR No new mechanism is needed to decrease the GFR. It is reduced by the baroreceptor reflex response to a fall in blood pressure (Figure 14-12). During this reflex, sympathetically induced vasoconstriction occurs in most arterioles throughout the body (including the afferent arterioles) as a compensatory mechanism to increase total peripheral resistance. The afferent arterioles have α_1-adrenergic receptors (see p. 240) and are innervated with sympathetic vasoconstrictor
Figure 14-12 Baroreceptor reflex influence on GFR in long-term regulation of blood pressure.

fibers to a far greater extent than the efferent arterioles are. When the afferent arterioles carrying blood to the glomeruli constrict from increased sympathetic activity, less blood flows into the glomeruli than normal, lowering glomerular capillary blood pressure (see ❚Figure 14-10a). The resulting decrease in GFR, in turn, reduces urine volume. In this way, some of the H_2O and salt that would otherwise have been lost in the urine are saved for the body, helping restore plasma volume to normal in the long term so that short-term cardiovascular adjustments that have been made are no longer necessary. Other mechanisms, such as increased tubular reabsorption of H_2O and salt, and increased thirst (described more thoroughly elsewhere), also contribute to long-term maintenance of blood pressure, despite a loss of plasma volume, by helping restore plasma volume.

Conversely, if blood pressure is elevated (for example, because of an expansion of plasma volume following ingestion of excessive fluid), the opposite responses occur. When the baroreceptors detect a rise in blood pressure, sympathetic vasoconstrictor activity to the arterioles, including the renal afferent arterioles, is reflexly reduced, allowing afferent arteriolar vasodilation to occur. As more blood enters the glomeruli through the dilated afferent arterioles, glomerular capillary blood pressure rises, increasing the GFR (see ❚Figure 14-10b). As more fluid is filtered, more fluid is available to be eliminated in the urine. A hormonally adjusted reduction in the tubular reabsorption of H_2O and salt also contributes to the increase in urine volume. These two renal mechanisms—increased glomerular filtration and decreased tubular reabsorption of H_2O and salt—increase urine volume and eliminate the excess fluid from the body. Reduced thirst and fluid intake also help restore an elevated blood pressure to normal in the long term.

The GFR can be influenced by changes in the filtration coefficient.

Thus far we have discussed changes in the GFR as a result of changes in net filtration pressure. The rate of glomerular filtration, however, depends on the filtration coefficient (K_f) as well as on the net filtration pressure. For years K_f was considered a constant, except in disease situations in which the glomerular membrane becomes leakier than usual. Research to the contrary indicates that K_f is subject to change under physiologic control. Both factors on which K_f depends—the surface area and the permeability of the glomerular membrane—can be modified by contractile activity within the membrane.

The surface area available for filtration within the glomerulus is represented by the inner surface of the glomerular capillaries that comes into contact with blood. Each tuft of glomerular capillaries is held together by **mesangial cells** (see ❚Figure 14-11). These cells contain contractile elements (that is, actinlike filaments). Contraction of these mesangial cells closes off a portion of the filtering capillaries, reducing the surface area available for filtration within the glomerular tuft, thus lowering the K_f and decreasing the GFR. Sympathetic stimulation causes the mesangial cells to contract, thereby providing a second mechanism (besides promoting afferent arteriolar vasoconstriction) by which sympathetic activity can decrease the GFR.

Podocytes also possess actinlike filaments, whose contraction or relaxation can, respectively, decrease or increase the number of filtration slits open in the inner membrane of Bowman's capsule by changing the shapes and proximities of the secondary foot processes (❚Figure 14-13). The number of slits is a determinant of permeability; the more open slits, the greater the permeability. Contractile activity of the podocytes, which in turn affects permeability and the K_f, is under physiologic control by poorly understood mechanisms.

The kidneys normally receive 20% to 25% of the cardiac output.

At the average net filtration pressure and K_f, 20% of the plasma that enters the kidneys is converted into glomerular filtrate. That means at an average GFR of 125 mL/min, the total renal plasma flow must average about 625 mL/min. Because 55% of whole blood consists of plasma (that is, hematocrit = 45; see p. 381), the total flow of blood through the kidneys averages 1140 mL/min. This quantity is about 22% of the total cardiac
(a) Increased K_f on podocyte relaxation
(b) Decreased K_f on podocyte contraction

❚Figure 14-13 **Change in the number of open filtration slits caused by podocyte relaxation and contraction.** (a) Podocyte relaxation narrows the bases of the fine secondary foot processes, increasing the number of fully open intervening filtration slits spanning a given area. (b) Podocyte contraction flattens the foot process branches and thus decreases the number of intervening filtration slits.

output of 5 liters (5000 mL)/min, although the kidneys compose less than 1% of total body weight.

The kidneys receive such a seemingly disproportionate share of the cardiac output because they must continuously perform their regulatory and excretory functions on the huge volumes of plasma delivered to them to maintain stability in the internal fluid environment. Most of the blood goes to the kidneys not to supply the renal tissue but to be adjusted and purified by the kidneys. On average, 20% to 25% of the blood pumped out by the heart each minute "goes to the cleaners" instead of serving its normal purpose of exchanging materials with the tissues. Only by continuously processing such a large proportion of the blood can the kidneys precisely regulate the volume and electrolyte composition of the internal environment and adequately eliminate the large quantities of metabolic waste products that are constantly produced.

We next consider how the tubules act on this large volume of filtered plasma, first considering the process of tubular reabsorption.

<div style="background:green;color:white;">**Check Your Understanding 14.2**</div>

1. Prepare a table showing the effect and magnitude of the physical forces involved in glomerular filtration.

2. Discuss the mechanisms and importance of autoregulation of the GFR.

3. Discuss the mechanism and importance of extrinsic control of the GFR.

14.3 Tubular Reabsorption

All plasma constituents except the plasma proteins are indiscriminately filtered together through the glomerular capillaries. In addition to waste products and excess materials that the body must eliminate, the filtered fluid contains nutrients, electrolytes, and other substances that the body cannot afford to lose in the urine. Indeed, through ongoing glomerular filtration, greater quantities of these materials are filtered per day than are even present in the entire body. The essential materials that are filtered are returned to the blood by *tubular reabsorption,* the discrete transfer of substances from the tubular lumen into the peritubular capillaries.

Tubular reabsorption is tremendous, highly selective, and variable.

Tubular reabsorption is a highly selective process. All constituents except plasma proteins are at the same concentration in the glomerular filtrate as in plasma. In most cases, the quantity reabsorbed of each substance is the amount required to maintain the proper composition and volume of the internal fluid environment. In general, the tubules have a high reabsorptive capacity for substances needed by the body and little or no reabsorptive capacity for substances of no value. Accordingly, only a small percentage, if any, of filtered plasma constituents that are useful to the body are present in the urine, most having

been reabsorbed and returned to the blood. Of the 125 mL of fluid filtered per minute, typically 124 mL/min are reabsorbed. Considering the magnitude of glomerular filtration, the extent of tubular reabsorption is tremendous: The tubules typically reabsorb 99% of the filtered water (47 gallons per day), 100% of the filtered sugar (0.4 pound per day), and 99.5% of the filtered salt (3.5 pounds per day). Only excess amounts of essential materials such as electrolytes are excreted in the urine. For the essential plasma constituents regulated by the kidneys, absorptive capacity may vary depending on the body's needs. In contrast, a large percentage of filtered waste products are present in the urine. These wastes, which are useless or even potentially harmful to the body if allowed to accumulate, generally are not reabsorbed. Instead, they stay in the tubules to be eliminated in the urine. For example, creatinine, a waste produced during muscle metabolism, is not reabsorbed at all, so 100% of filtered creatinine is excreted in the urine. As H_2O and other valuable constituents are reabsorbed, the waste products remaining in the tubular fluid become highly concentrated.

Tubular reabsorption involves transepithelial transport.

Throughout its length, the tubule wall is one cell thick and is close to a surrounding peritubular capillary (❚ Figure 14-14). Adjacent tubular cells do not come into contact with each other except where they are joined by tight junctions (see p. 61) at their lateral edges near their *luminal membranes,* which face the tubular lumen. Interstitial fluid lies in the gaps between adjacent cells—the **lateral spaces**—as well as between the tubules and the capillaries. The *basolateral membrane* faces the interstitial fluid at the base and lateral edges of the cell. The tight junctions largely prevent substances from moving *between* the cells, so materials must pass *through* the cells to leave the tubular lumen and gain entry to the blood.

Transepithelial Transport To be reabsorbed, a substance must go across the following five distinct barriers (the numbers correspond to the numbered barriers in ❚ Figure 14-14):

1 Leave the tubular fluid by crossing the luminal membrane of the tubular cell.

2 Pass through the cytosol from one side of the tubular cell to the other.

3 Cross the basolateral membrane of the tubular cell to enter the interstitial fluid.

4 Diffuse through the interstitial fluid.

5 Penetrate the capillary wall to enter the plasma.

This entire sequence of steps is known as **transepithelial transport** (*transepithelial* means "across the epithelium").

Passive Versus Active Reabsorption The two types of tubular reabsorption—passive and active—depend on whether local energy expenditure is needed for reabsorbing a particular substance. In **passive reabsorption**, all steps in the transepithelial transport of a substance from the tubular lumen to the plasma are passive—that is, no energy is spent for the substance's net movement, which occurs down electrochemical or

❙Figure 14-14 **Steps of transepithelial transport.**

osmotic gradients. In contrast, **active reabsorption** takes place if any step in the transepithelial transport of a substance requires energy, even if the four other steps are passive. With active reabsorption, net movement of the substance from the tubular lumen to the plasma occurs *against* an electrochemical gradient. Substances that are actively reabsorbed are of particular importance to the body, such as glucose, amino acids, and other organic nutrients, as well as Na^+ and other electrolytes, such as PO_4^{3-}. Rather than specifically describing the reabsorptive process for each of the many filtered substances returned to the plasma, we provide illustrative examples of the general mechanisms involved, after first highlighting the unique and important case of Na^+ reabsorption.

Na^+ reabsorption depends on the Na^+–K^+ ATPase pump in the basolateral membrane.

Sodium reabsorption is unique and complex. Of the total energy spent by the kidneys, 80% is used for Na^+ transport, indicating the importance of this process. Unlike most filtered solutes, Na^+ is reabsorbed throughout most of the tubule, but this occurs to varying extents in different regions. Of the Na^+ filtered, 99.5% is normally reabsorbed. Of the Na^+ reabsorbed, on average 67% is reabsorbed in the proximal tubule, 25% in the loop of Henle, and 8% in the distal and collecting tubules. Sodium reabsorption plays different important roles in each of these segments, as will become apparent as our discussion continues. Here is a preview of these roles:

■ Sodium reabsorption in the *proximal tubule* plays a pivotal role in reabsorbing glucose, amino acids, H_2O, Cl^-, and urea.

■ Sodium reabsorption in the ascending limb of the *loop of Henle,* along with Cl^- reabsorption, plays a critical role in the

kidneys' ability to produce urine of varying concentrations and volumes, depending on the body's need to conserve or eliminate H_2O.

■ Sodium reabsorption in the *distal and collecting tubules* is variable and subject to hormonal control. It plays a key role in regulating ECF volume, which is important in long-term control of arterial blood pressure, and is linked in part to K^+ secretion.

Sodium is reabsorbed throughout the tubule with the exception of the descending limb of Henle's loop. You will learn about the significance of this exception later. Throughout all Na^+-reabsorbing tubular segments, the active step in Na^+ reabsorption involves the energy-dependent Na^+–K^+ ATPase carrier located in the tubular cell's basolateral membrane (❙Figure 14-15). This carrier is the same Na^+–K^+ pump present in all cells that actively extrudes Na^+ from the cell (see p. 73). As this basolateral pump transports Na^+ out of the tubular cell into the lateral space, it keeps the intracellular Na^+ concentration low while simultaneously building up the Na^+ concentration in the lateral space—that is, it moves Na^+ against a concentration gradient. Because the intracellular Na^+ concentration is kept low by basolateral pump activity, a concentration gradient is established that favors passive movement of Na^+ from its higher concentration in the tubular lumen across the luminal border into the tubular cell. The nature of the luminal Na^+ channels and transport carriers that permit Na^+ movement from the lumen into the cell varies for different parts of the tubule, but in each case, Na^+ movement across the luminal membrane is always a passive step. For example, in the proximal tubule, Na^+ crosses the luminal border by a symport carrier that simultaneously moves Na^+ and an organic nutrient such as glucose from the lumen into the cell. You will learn more about
Figure 14-15 Sodium reabsorption. The basolateral Na⁺–K⁺ pump actively transports Na⁺ from the tubular cell into the interstitial fluid within the lateral space. This process establishes a concentration gradient for passive movement of Na⁺ from the lumen into the tubular cell and from the lateral space into the peritubular capillary, accomplishing net transport of Na⁺ from the tubular lumen into the blood at the expense of energy.

this cotransport process shortly. By contrast, in the collecting duct, Na^+ crosses the luminal border through a Na^+ leak channel (see p. 58). Once Na^+ enters the cell across the luminal border by whatever means, it is actively extruded to the lateral space by the basolateral Na^+–K^+ pump. This step is the same throughout the tubule. Na^+ continues to diffuse down a concentration gradient from its high concentration in the lateral space into the surrounding interstitial fluid and finally into the peritubular capillary blood. Thus, net transport of Na^+ from the tubular lumen into the blood occurs at the expense of energy.

First, we consider the importance and mechanism of regulating Na^+ reabsorption in the distal portion of the nephron.

Aldosterone stimulates Na⁺ reabsorption in the distal and collecting tubules.

In the proximal tubule and loop of Henle, a constant percentage of the filtered Na^+ is reabsorbed regardless of the **Na⁺ load** (*the total amount* of Na^+ in the body fluids, *not the concentration* of Na^+ in the body fluids). In the distal and collecting tubules, the reabsorption of a small percentage of the filtered Na^+ is subject to hormonal control. The extent of this controlled, discretionary reabsorption is inversely related to the magnitude of the Na^+ load in the body. If there is too much Na^+, little of this controlled Na^+ is reabsorbed; instead, it is lost in the urine, thereby removing excess Na^+ from the body. If Na^+ is depleted, most or all of this controlled Na^+ is reabsorbed, conserving for the body Na^+ that otherwise would be lost in the urine.

The Na^+ load in the body is reflected by ECF volume. Sodium and its accompanying anion Cl^- account for more than

90% of the ECF's osmotic activity. Whenever we speak of Na^+ load, we tacitly mean salt load, too, because Cl^- goes along with Na^+. (NaCl is common table salt.) The Na^+ load is subject to regulation; Cl^- passively follows along. Recall that osmotic pressure can be thought of loosely as a "pulling" force that attracts and holds H_2O (see p. 67). When the Na^+ load is above normal and the ECF's osmotic activity is therefore increased, the extra Na^+ "holds" extra H_2O, expanding ECF volume. Conversely, when the Na^+ load is below normal, thereby decreasing ECF osmotic activity, less H_2O than normal can be held in the ECF, so ECF volume is reduced. Because plasma is part of the ECF, the most important result of a change in ECF volume is the matching change in blood pressure with expansion (increased blood pressure) or reduction (decreased blood pressure) of the plasma volume. Thus, long-term control of arterial blood pressure ultimately depends on Na^+-regulating mechanisms. We now turn attention to these mechanisms.

Activation of the Renin–Angiotensin–Aldosterone System The most important and best-known hormonal system involved in regulating Na^+ is the **renin–angiotensin–aldosterone system (RAAS)**. The granular cells of the *juxtaglomerular apparatus* (see Figure 14-11) secrete an enzymatic hormone, **renin**, into the blood in response to a fall in NaCl, ECF volume, and arterial blood pressure. This function is in addition to the role the macula densa cells of the juxtaglomerular apparatus play in autoregulation. Specifically, the following three inputs to the granular cells increase renin secretion:

1. The granular cells themselves function as *intrarenal baroreceptors.* They are sensitive to pressure changes within the afferent arteriole. When the granular cells detect a fall in blood pressure, they secrete more renin.

2. The macula densa cells in the tubular portion of the juxtaglomerular apparatus are sensitive to the NaCl moving past them through the tubular lumen. In response to a fall in NaCl, the macula densa cells trigger increased renin secretion.

3. The granular cells are innervated by the sympathetic nervous system. When blood pressure falls below normal, the baroreceptor reflex increases sympathetic activity. As part of this reflex response, increased sympathetic activity stimulates the granular cells to secrete more renin.

These interrelated signals for increased renin secretion all indicate the need to expand plasma volume to increase arterial pressure to normal in the long term. Through a complex series of events involving RAAS, increased renin secretion brings about increased Na^+ reabsorption by the distal and collecting tubules (with Cl^- passively following Na^+'s active movement). The ultimate benefit of this salt retention is osmotically induced H_2O retention, which helps restore plasma volume.

Let us examine in further detail the RAAS mechanism that ultimately leads to increased Na^+ reabsorption (❙Figure 14-16). Once secreted into the blood, renin acts as an enzyme to activate **angiotensinogen** into **angiotensin I**. Angiotensinogen is a plasma protein synthesized by the liver and always present in the plasma in high concentration. On passing through the lungs via the pulmonary circulation, angiotensin I is converted into **angiotensin II** by **angiotensin-converting enzyme (ACE)**, which is abundant in the pulmonary capillaries. ACE is located in small pits in the luminal surface of the pulmonary capillary endothelial cells. Angiotensin II is the main stimulus for secretion of the hormone *aldosterone* from the adrenal cortex. The *adrenal cortex* is an endocrine gland that produces several hormones, each secreted in response to different stimuli.

Functions of the Renin–Angiotensin–Aldosterone System Two distinct types of tubular cells are located in the distal and collecting tubules: *principal cells* and *intercalated cells*. The more abundant **principal cells** are the site of action of aldosterone and vasopressin, a H_2O-conserving hormone, and thus are involved in Na^+ reabsorption and K^+ secretion (both regulated by aldosterone) and in H_2O reabsorption (regulated by vasopressin). **Intercalated cells**, by contrast, are concerned with acid–base balance.

Among its actions, **aldosterone** increases Na^+ reabsorption by the principal cells of the distal and collecting tubules. It does so by promoting insertion of additional Na^+ leak channels into the luminal membranes and additional Na^+–K^+ pumps into the basolateral membranes of these cells. The net result is greater
❙Figure 14-16 **Renin–angiotensin–aldosterone system (RAAS).** The kidneys secrete the enzymatic hormone renin in response to reduced NaCl, ECF volume, and arterial blood pressure. Renin activates angiotensinogen, a plasma protein produced by the liver, into angiotensin I. Angiotensin I is converted into angiotensin II by angiotensin-converting enzyme (ACE) produced in the lungs. Angiotensin II stimulates the adrenal cortex to secrete the hormone aldosterone, which stimulates Na^+ reabsorption by the kidneys. The resulting retention of Na^+ exerts an osmotic effect that holds more H_2O in the ECF. Together, the conserved Na^+ and H_2O help correct the original stimuli that activated this hormonal system. Angiotensin II also exerts other effects that help rectify the original stimuli, such as by promoting arteriolar vasoconstriction.

FIGURE FOCUS: *If a person's blood pressure falls because of loss of fluid and salt through heavy sweating, summarize the short-term and long-term compensatory measures shown in this figure and Figure 14-12 to help restore blood pressure to normal.*

passive movement of Na^+ into these distal and collecting tubular cells from the lumen and increased active pumping of Na^+ out of the cells into the plasma—that is, an increase in Na^+ reabsorption, with Cl^- following passively. RAAS thus promotes salt retention and a resulting H_2O retention and rise in arterial blood pressure. Acting in a negative-feedback fashion, this system alleviates the factors that triggered the initial release of renin—namely, salt depletion, plasma volume reduction, and decreased arterial blood pressure (❙Figure 14-16).

In addition to stimulating aldosterone secretion, angiotensin II is a potent constrictor of the systemic arterioles, directly increasing blood pressure by increasing total peripheral resistance (see p. 349). Furthermore, it stimulates thirst (increasing fluid intake) and stimulates vasopressin (increasing H_2O retention by the kidneys), both of which contribute to plasma volume expansion and elevation of arterial pressure. (As you will learn later, other mechanisms related to long-term regulation of blood pressure and ECF osmolarity are also important in controlling thirst and vasopressin secretion.)

The opposite situation exists when the Na^+ load, ECF and plasma volume, and arterial blood pressure are above normal. Under these circumstances, renin secretion is inhibited. Therefore, because angiotensinogen is not activated to angiotensin I and II, aldosterone secretion is not stimulated. Without aldosterone, the small aldosterone-dependent part of Na^+ reabsorption in the distal segments of the tubule does not occur. Instead, this nonreabsorbed Na^+ is lost in the urine. In the absence of aldosterone, the ongoing loss of this small percentage of filtered Na^+ can rapidly remove excess Na^+ from the body. Even though only about 8% of the filtered Na^+ depends on aldosterone for reabsorption, this small loss, multiplied many times as the entire plasma volume is filtered through the kidneys many times per day, can lead to a sizable loss of Na^+.

The amount of aldosterone secreted, and consequently the relative amount of salt conserved versus salt excreted, varies depending on the body's needs. For example, an average salt consumer typically excretes nearly 10 g of salt per day in the urine, a heavy salt consumer excretes more, and someone who has lost considerable salt during heavy sweating excretes less urinary salt. With maximum aldosterone secretion, all the filtered Na^+ (and, accordingly, all the filtered Cl^-) is reabsorbed, so salt excretion in the urine is zero. By varying the amount of renin and aldosterone secreted in accordance with the salt-determined fluid load in the body, the kidneys can finely adjust the amount of salt conserved or eliminated. In doing so, they maintain the salt load, ECF volume, and arterial blood pressure at a relatively constant level despite wide variations in salt consumption and abnormal losses of salt-laden fluid.

Role of the Renin–Angiotensin–Aldosterone System in Various Diseases Some cases of hypertension (high blood pressure) are the result of abnormal increases in RAAS activity. This system is also responsible in part for the fluid retention and edema accompanying congestive heart failure. Because of the failing heart, cardiac output is reduced and blood pressure is low despite a normal or even expanded plasma volume. When a fall in blood pressure is the result of a failing heart rather than a reduced salt and fluid load in the body, the salt- and fluid-retaining reflexes triggered by the low blood pressure are inappropriate. Sodium excretion may fall to zero despite continued salt ingestion and accumulation in the body. The resulting ECF expansion produces edema and intensifies the congestive heart failure because the weakened heart cannot pump the additional plasma volume.

Drugs that Affect Na^+ Reabsorption Because their salt-retaining mechanisms are being inappropriately triggered, patients with congestive heart failure are placed on low-salt diets. Often they are treated with **diuretics**, therapeutic agents that cause **diuresis** (increased urinary output) and thus promote fluid loss from the body. Many of these drugs function by inhibiting tubular reabsorption of Na^+. For example, *thiazide diuretics* such as hydrochlorothiazide inhibit Na^+ reabsorption in the distal tubule. As more Na^+ is excreted, more H_2O is also lost from the body, helping remove excess ECF. **ACE inhibitor drugs**, which block the action of ACE, and **aldosterone receptor blockers (ARBs)**, which block the binding of aldosterone with its renal receptors, are both also beneficial in treating hypertension and congestive heart failure. These two classes of drugs halt the ultimate salt- and fluid-conserving actions and arteriolar constrictor effects of RAAS.

The natriuretic peptides inhibit Na^+ reabsorption.

Whereas RAAS exerts the most powerful influence on renal handling of Na^+, this Na^+-retaining, blood pressure–raising system is opposed by a Na^+-losing, blood pressure–lowering system that involves the hormones **atrial natriuretic peptide (ANP)** and **brain natriuretic peptide (BNP)**. These peptides produce **natriuresis**, or excretion of large amounts of sodium in the urine. The heart, in addition to its pump action, produces ANP and BNP. As its name implies, ANP is produced in the atrial cardiac muscle cells. BNP was first discovered in the brain (hence its name) but is produced primarily in the ventricular cardiac muscle cells. ANP and BNP are stored in granules and released when the heart muscle cells are mechanically stretched by an expansion of the circulating plasma volume when ECF volume is increased. This expansion, which occurs as a result of Na^+ and H_2O retention, increases blood pressure. In turn, the NPs promote natriuresis and accompanying diuresis, decreasing the plasma volume, and also directly influence the cardiovascular system to lower blood pressure (❙Figure 14-17).

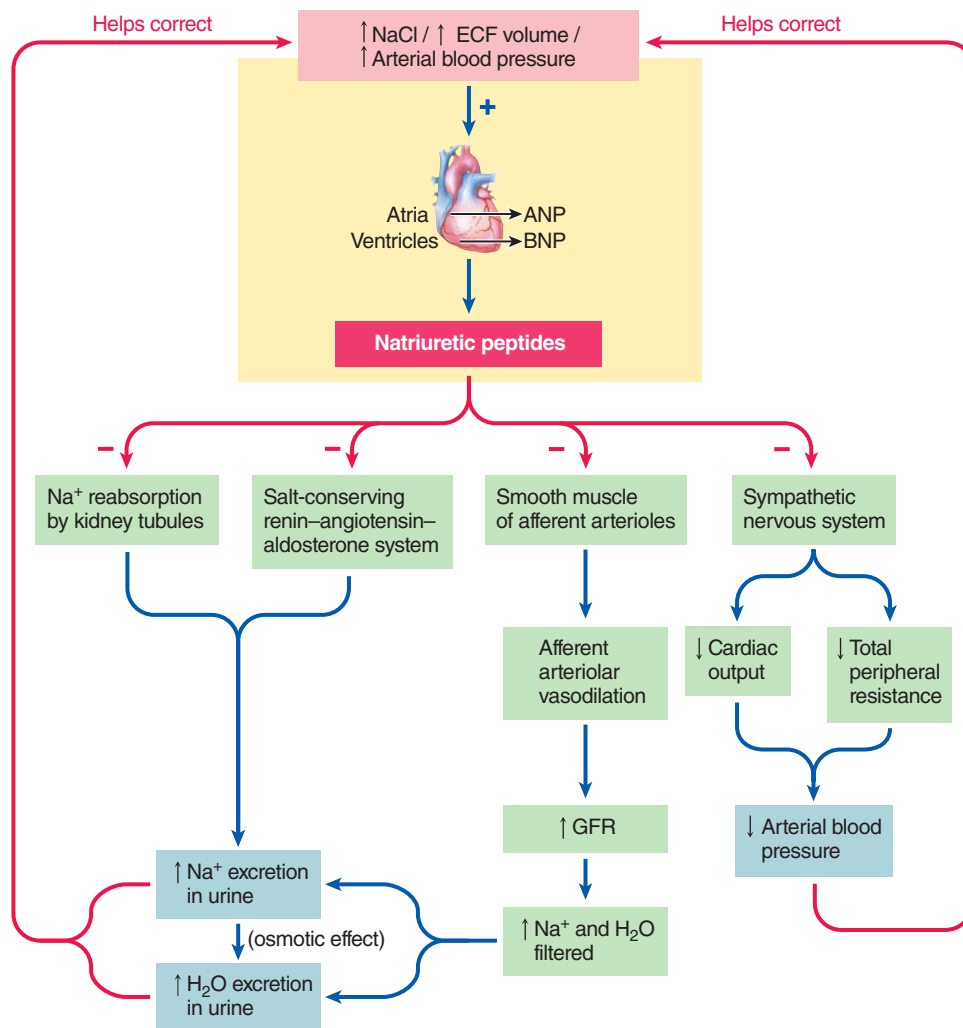
The main action of ANP and BNP is to directly inhibit Na^+ reabsorption in the distal parts of the nephron, thus increasing Na^+ excretion and accompanying osmotic H_2O excretion in the urine. They further increase Na^+ excretion in the urine by inhibiting two steps of the Na^+-conserving RAAS. The NPs inhibit renin secretion by the kidneys and act on the adrenal cortex to inhibit aldosterone secretion. In addition, they inhibit the secretion and actions of vasopressin, the H_2O-conserving hormone. ANP and BNP also promote natriuresis and accompanying diuresis by increasing the GFR.


Figure 14-17 Atrial and brain natriuretic peptide. The cardiac atria secrete the hormone atrial natriuretic peptide (ANP) and the cardiac ventricles secrete brain natriuretic peptide (BNP) in response to being stretched by Na^+ retention, expansion of the ECF volume, and increase in arterial blood pressure. ANP and BNP, in turn, promote natriuretic, diuretic, and hypotensive effects to help correct the original stimuli that resulted in their release.

They dilate the afferent arterioles and constrict the efferent arterioles, thus raising glomerular capillary blood pressure and increasing the GFR. They further increase the GFR by relaxing the glomerular mesangial cells, leading to an increase in K_f. As more salt and water are filtered, more salt and water are excreted in the urine. Besides indirectly lowering blood pressure by reducing the Na^+ load and hence the fluid load in the body, ANP and BNP directly lower blood pressure by decreasing cardiac output and reducing total peripheral resistance by inhibiting sympathetic nervous activity to the heart and blood vessels, respectively.

The relative contributions of ANP and BNP in maintaining salt and H_2O balance and blood pressure regulation are presently being intensively investigated. A deficiency of the counterbalancing natriuretic system may underlie some cases of long-term hypertension by leaving the powerful Na^+-conserving system unopposed. The resulting salt retention, especially in association with high salt intake, could expand ECF volume and elevate blood pressure.

We now shift attention to the reabsorption of other filtered solutes. Nevertheless, we continue to discuss Na^+ reabsorption because the reabsorption of many other solutes is linked in some way to Na^+ reabsorption.

Glucose and amino acids are reabsorbed by Na^+-dependent secondary active transport.

Large quantities of nutritionally important organic molecules such as glucose and amino acids are filtered each day. Because these molecules normally are completely reabsorbed into the blood by energy- and Na^+-dependent mechanisms located in the proximal tubule, none of these nutrients are usually excreted in the urine, thus protecting against their loss.

Glucose and amino acids are reabsorbed by **secondary active transport**. With this process, specialized *symport carriers,* such as the *sodium and glucose cotransporter (SGLT),* simultaneously transfer both Na^+ and the specific organic molecule from the lumen into the cell (see ❚Figure 3-18, p. 76). Within the kidney, SGLT is located only in the proximal tubule. This luminal cotransport carrier is the means by which Na^+ passively crosses the luminal membrane in the proximal tubule. Once transported into the tubular cell, glucose and amino acids passively diffuse down their concentration gradients across the basolateral membrane into the plasma, facilitated by a carrier, such as the *glucose transporter (GLUT),* which does not depend on energy (see p. 72).

In general, actively reabsorbed substances exhibit a tubular maximum.

All actively reabsorbed substances bind with plasma membrane carriers that transfer them across the membrane against a concentration gradient. Each carrier is specific for the types of substances it can transport; for example, SGLT can transport glucose but not amino acids. Because a limited number of each carrier type is present in the tubular cells, an upper limit exists on how much of a particular substance can be actively transported from the tubular fluid in a given period. The maximum reabsorption rate is reached when all of the carriers specific for a particular substance are fully occupied or saturated so that they cannot handle additional passengers at that time (see p. 71). This maximum reabsorption rate is designated as the

tubular maximum, or T_m.[1] Any quantity of a substance filtered beyond its T_m is not reabsorbed and escapes instead into the urine. With the exception of Na^+, all actively reabsorbed substances have a T_m. (Even though individual Na^+ transport carriers can become saturated, the tubules as a whole do not display a T_m for Na^+ because aldosterone promotes the insertion of more active Na^+–K^+ carriers in the distal and collecting tubular cells as needed.)

The plasma concentrations of some but not all substances that display carrier-limited reabsorption are regulated by the kidneys. How can the kidneys regulate some actively reabsorbed substances but not others, when the renal tubules limit the quantity of each of these substances that can be reabsorbed and returned to the plasma? We compare glucose, a substance that has a T_m but *is not regulated* by the kidneys, with phosphate, a T_m-limited substance that *is regulated* by the kidneys.

Glucose is an actively reabsorbed substance not regulated by the kidneys.

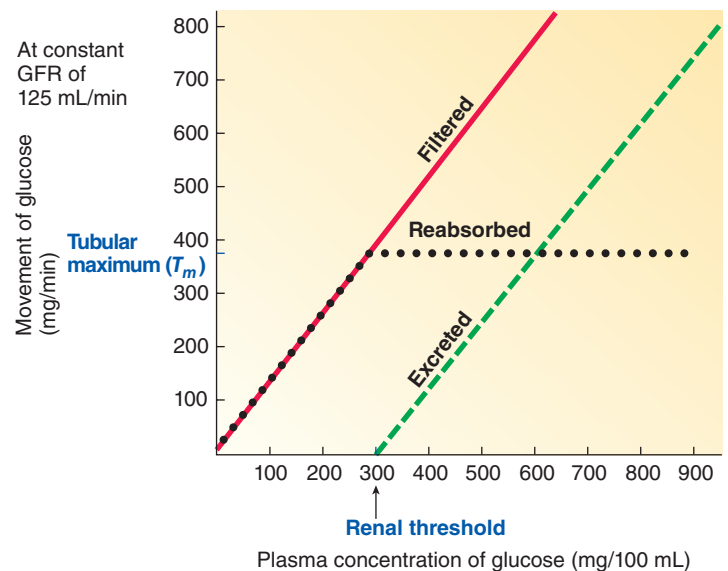
The normal plasma concentration of glucose is 100 mg of glucose for every 100 mL of plasma. Because glucose is freely filterable at the glomerulus, it passes into Bowman's capsule at the same concentration it has in the plasma. Accordingly, 100 mg of glucose are present in every 100 mL of plasma filtered. With 125 mL of plasma normally being filtered each minute (average GFR = 125 mL/min), 125 mg of glucose pass into Bowman's capsule with this filtrate every minute. The quantity of any substance filtered per minute, known as its **filtered load**, can be calculated as follows:

Filtered load of a substance = plasma concentration × GFR of the substance

Filtered load of glucose = 100 mg/100 mL × 125 mL/min

= 125 mg/min

At a constant GFR, the filtered load of glucose is directly proportional to the plasma glucose concentration. Doubling the plasma glucose concentration to 200 mg/100 mL doubles the filtered load of glucose to 250 mg/min, and so on (❚ Figure 14-18).

Tubular Maximum for Glucose The T_m for glucose averages 375 mg/min—that is, the glucose carrier mechanism is capable of actively reabsorbing up to 375 mg of glucose per minute before it reaches its maximum transport capacity. At a normal plasma glucose concentration of 100 mg/100 mL, the 125 mg of glucose filtered per minute can readily be reabsorbed by the glucose carrier mechanism because the filtered load is well below the T_m for glucose. Ordinarily, therefore, no glucose appears in the urine. Not until the filtered load of glucose exceeds 375 mg/min is the T_m reached. When more


❚Figure 14-18 **Renal handling of glucose as a function of plasma glucose concentration.** At a constant GFR, the quantity of glucose filtered per minute is directly proportional to the plasma concentration of glucose. All the filtered glucose can be reabsorbed up to the tubular maximum (T_m). If the amount of glucose filtered per minute exceeds the T_m, the maximum amount of glucose is reabsorbed (a T_m worth) and the rest stays in the filtrate to be excreted in urine. The renal threshold is the plasma concentration at which the T_m is reached and glucose first starts appearing in the urine.

FIGURE FOCUS: *Use the graph to determine how much glucose is filtered, reabsorbed, and excreted at plasma glucose concentrations of (1) 200 mg/100 mL, (2) 300 mg/100mL, and (3) 400 mg/100mL.*

glucose is filtered per minute than can be reabsorbed because the T_m has been exceeded, the maximum amount is reabsorbed, and the rest stays in the filtrate to be excreted. Accordingly, the plasma glucose concentration must be greater than 300 mg/100 mL—more than three times normal—before the amount filtered exceeds 375 mg/min and glucose starts spilling into the urine.

Renal Threshold for Glucose The plasma concentration at which the T_m of a particular substance is reached and the substance first starts appearing in the urine is called the **renal threshold**. At the average T_m of 375 mg/min and GFR of 125 mL/min, the renal threshold for glucose is 300 mg/100 mL.[2] Beyond the T_m, reabsorption stays constant at its maximum rate, and any further increase in the filtered load leads to a directly proportional increase in the amount of the substance excreted. For example, at a plasma glucose concentration of 400 mg/100 mL, the filtered load of glucose is 500 mg/min, 375 mg/min of which can be reab-

---

[1]For clarification, although both are designated as T_m, *transport maximum* refers to the upper limit on transport of a particular substance across a cell's plasma membrane that occurs when all of the carriers specific for the substance are saturated (see p. 71), whereas *tubular maximum* refers to the upper limit on transepithelial transport across the kidney tubules when all of the carriers specific for the substance are saturated.

[2]This is an idealized situation. In reality, glucose often starts spilling into the urine at glucose concentrations of 180 mg/100 mL and above. Glucose is often excreted before the average renal threshold of 300 mg/100 mL is reached for two reasons. First, not all nephrons have the same T_m, so some nephrons may have exceeded their T_m and be excreting glucose while others have not yet reached their T_m. Second, the efficiency of the glucose cotransport carrier may not be working at its maximum capacity at elevated values less than the true T_m, so some of the filtered glucose may fail to be reabsorbed and spill into the urine even though the average renal threshold has not been reached.

sorbed (a T_m worth) and 125 mg/min of which are excreted in the urine. At a plasma glucose concentration of 500 mg/100 mL, the filtered load is 625 mg/min, still only 375 mg/min can be reabsorbed, and 250 mg/min spill into the urine (❚Figure 14-18).

Clinical Note The plasma glucose concentration can become extremely high in *diabetes mellitus,* an endocrine disorder involving inadequate insulin action. Insulin is a pancreatic hormone that facilitates transport of glucose into many body cells. When cellular glucose uptake is impaired, glucose that cannot gain entry into cells stays in the plasma, elevating the plasma glucose concentration. Consequently, although glucose does not normally appear in urine, it is found in the urine of people with untreated diabetes when the plasma glucose concentration exceeds the renal threshold, even though renal function has not changed.

What happens when plasma glucose concentration falls below normal? The renal tubules reabsorb all filtered glucose because the glucose reabsorptive capacity is far from being exceeded. The kidneys cannot do anything to raise a low plasma glucose level to normal. They simply return all filtered glucose to the plasma.

Reason Why the Kidneys Do Not Regulate Glucose The kidneys do not influence plasma glucose concentration over a range of values, from abnormally low levels up to three times the normal level. Because the T_m for glucose is well above the normal filtered load, the kidneys usually conserve all the glucose, thereby protecting against loss of this important nutrient in the urine. The kidneys do not regulate glucose because they do not maintain glucose at some specific plasma concentration. Instead, this concentration is normally regulated by endocrine and liver mechanisms, with the kidneys merely maintaining whatever plasma glucose concentration is set by these other mechanisms (except when excessively high levels overwhelm the kidneys' reabsorptive capacity). The same principle holds true for other organic plasma nutrients, such as amino acids and water-soluble vitamins.

Phosphate is an actively reabsorbed substance regulated by the kidneys.

The kidneys do directly contribute to the regulation of many electrolytes, such as phosphate and calcium, because the renal thresholds of these inorganic ions equal their normal plasma concentrations. The transport carriers for these electrolytes are located in the proximal tubule. We use PO_4^{3-} as an example. Our diets are generally rich in PO_4^{3-}, but because the tubules can reabsorb up to the normal plasma concentration's worth of PO_4^{3-} and no more, the excess ingested PO_4^{3-} is quickly spilled into the urine, restoring the plasma concentration to normal. The greater the amount of PO_4^{3-} ingested beyond the body's needs, the greater the amount excreted. In this way, the kidneys maintain the desired plasma PO_4^{3-} concentration while eliminating any excess PO_4^{3-} ingested.

Unlike the reabsorption of organic nutrients, the reabsorption of PO_4^{3-} and Ca^{2+} is also subject to hormonal control. Parathyroid hormone can alter the renal thresholds for PO_4^{3-} and Ca^{2+}, thus adjusting the quantity of these electrolytes conserved, depending on the body's momentary needs (see Chapter 19).

Active Na⁺ reabsorption is responsible for passive reabsorption of Cl⁻, H₂O, and urea.

Not only is secondary active reabsorption of glucose and amino acids linked to the basolateral Na^+–K^+ pump, but passive reabsorption of Cl^-, H_2O, and urea also depends on this active Na^+ reabsorption mechanism.

Chloride Reabsorption Negatively charged Cl^- is passively reabsorbed down the electrical gradient created by active reabsorption of positively charged Na^+. For the most part, Cl^- passes between, not through, the tubular cells (through "leaky" tight junctions). The amount of Cl^- reabsorbed is determined by the rate of active Na^+ reabsorption instead of being directly controlled by the kidneys.

Water Reabsorption Water is passively reabsorbed throughout the length of the tubule as H_2O osmotically follows actively reabsorbed Na^+. Of the H_2O filtered, 65%—117 liters per day—is passively reabsorbed in the proximal tubule. Another 15% of the filtered H_2O is passively reabsorbed in the loop of Henle. This 80% of the filtered H_2O is obligatorily reabsorbed in the early parts of the nephron regardless of the H_2O load in the body and is not subject to regulation. Variable amounts of the remaining 20% are reabsorbed in the distal portions of the tubule; the extent of reabsorption in the distal and collecting tubules is under direct hormonal control, depending on the body's state of hydration. No part of the tubule directly requires energy for this tremendous reabsorption of H_2O.

During reabsorption, H_2O passes primarily through **aquaporins (AQPs)**, or **water channels**, formed by specific plasma membrane proteins in the tubular cells. Different types of water channels are present in various parts of the nephron. The water channels in the proximal tubule, AQP-1, are always open, accounting for the high H_2O permeability of this region. The AQP-2 channels in the principal cells in the distal parts of the nephron, in contrast, are regulated by the hormone *vasopressin,* accounting for the variable H_2O reabsorption in this region.

The main driving force for H_2O reabsorption in the proximal tubule is a compartment of hypertonicity in the lateral spaces between the tubular cells established by the basolateral pump's active extrusion of Na^+ (❚Figure 14-19). As a result of this pump activity, the concentration of Na^+ rapidly diminishes in the tubular fluid and tubular cells while it simultaneously increases in the localized region within the lateral spaces. This osmotic gradient induces the passive net flow of H_2O from the lumen into the lateral spaces, either through the cells or intercellularly through "leaky" tight junctions. The accumulation of fluid in the lateral spaces results in a buildup of hydrostatic (fluid) pressure, which flushes H_2O out of the lateral spaces into the interstitial fluid and finally into the peritubular capillaries. Water also osmotically follows other preferentially reabsorbed solutes such as glucose (which is also Na^+ dependent), but the direct influence of Na^+ reabsorption on passive H_2O reabsorption is quantitatively more important.

This return of filtered H_2O to the plasma is enhanced by the fact that the plasma-colloid osmotic pressure is greater in the peritubular capillaries than elsewhere. The concentration of plasma proteins, which is responsible for π_P, is elevated in the blood enter-

ing the peritubular capillaries because of the extensive filtration of H_2O through the glomerular capillaries upstream. The plasma proteins left behind in the glomerulus are concentrated into a smaller volume of plasma H_2O, increasing π_P of the unfiltered blood that leaves the glomerulus and enters the peritubular capillaries. This force tends to "pull" H_2O into the peritubular capillaries simultaneously with the "push" of the hydrostatic pressure in the lateral spaces that drives H_2O toward the capillaries. By these means, 65% of the filtered H_2O—117 liters per day—is passively reabsorbed by the end of the proximal tubule.

The mechanisms responsible for H_2O reabsorption beyond the proximal tubule will be described later.

Urea Reabsorption Passive reabsorption of urea, in addition to Cl^- and H_2O, is indirectly linked to active Na^+ reabsorption. **Urea** is a waste product from the breakdown of protein. The osmotically induced reabsorption of H_2O in the proximal tubule secondary to active Na^+ reabsorption produces a concentration gradient for urea that favors passive reabsorption of this waste (❙Figure 14-20). Extensive reabsorption of H_2O in the proximal tubule gradually reduces the original 125 mL/min of filtrate until only 44 mL/min of fluid remain in the lumen by the end of the proximal tubule (65% of the H_2O in the original filtrate, or 81 mL/min, has been reabsorbed). Substances that have been filtered but not reabsorbed become progressively more concentrated in the tubular fluid as H_2O is reabsorbed while they are left behind. Urea is one such substance. Urea's concentration as it is filtered at the glomerulus is identical to its concentration in the plasma entering the peritubular capillaries. The quantity of urea present in the 125 mL of filtered fluid at the beginning of the proximal tubule, however, is concentrated almost threefold in the 44 mL left at the end of the proximal tubule. As a result, the urea concentration within the tubular fluid becomes greater than the urea concentration in the adjacent capillaries. Therefore, a concentration gradient is created for urea to passively diffuse from the tubular lumen into the peritubular capillary plasma. Because the walls of the proximal tubules are only somewhat permeable to urea, only about 50% of the filtered urea is passively reabsorbed by this means.

Clinical Note Even though only half of the filtered rea is eliminated from the plasma with each pass through the nephrons, this removal rate is adequate. The urea concentration

❙**Figure 14-19 Water reabsorption in the proximal tubule.** The force for osmotic H_2O reabsorption is the compartment of hypertonicity in the lateral spaces established by active extrusion of Na^+ by the basolateral pump. The resultant accumulation of H_2O in the lateral spaces creates a hydrostatic pressure that drives the H_2O into the peritubular capillaries.
❙**Figure 14-20 Passive reabsorption of urea at the end of the proximal tubule.** (a) In Bowman's capsule and at the beginning of the proximal tubule, urea is at the same concentration as in the plasma and surrounding interstitial fluid. (b) By the end of the proximal tubule, 65% of the original filtrate has been reabsorbed, concentrating the filtered urea in the remaining filtrate. This establishes a concentration gradient favoring passive reabsorption of urea.

FIGURE FOCUS: *Explain why urea is passively reabsorbed in the late part but not the early part of the proximal tubule.*

in the plasma becomes elevated only in impaired kidney function, when much less than half of the urea is removed. An elevated urea level was one of the first chemical characteristics to be identified in the plasma of patients with severe renal failure. Accordingly, clinical measurement of **blood urea nitrogen (BUN)** came into use as a crude assessment of kidney function. It is now known that the most serious consequences of renal failure are not attributable to the retention of urea, which itself is not especially toxic, but rather to accumulation of H^+ and K^+, which are inadequately secreted (as discussed in a later section about renal failure). Health professionals still often refer to renal failure as *uremia,* in reference to excess urea in the blood, even though urea retention is not this condition's major threat.

In general, unwanted waste products are not reabsorbed.

The other filtered waste products besides urea, such as *uric acid, creatinine,* and *phenols* (derived from many foods) are likewise concentrated in the tubular fluid as H_2O leaves the filtrate to enter the plasma. But urea molecules, being the smallest of the waste products, are the only wastes passively reabsorbed by this concentrating effect. The other wastes cannot leave the lumen down their concentration gradients to be passively reabsorbed because they cannot permeate the tubular wall. Therefore, these waste products generally remain in the tubules and are excreted in the urine in highly concentrated form. This excretion of metabolic wastes is not subject to physiologic control, but when renal function is normal, the excretory processes proceed at a satisfactory rate.

Having completed discussion of tubular reabsorption, we now shift to the other basic renal process carried out by the tubules—tubular secretion.

Check Your Understanding 14.3

1. Show the steps of transepithelial transport on a sketch you make of a kidney tubule and associated peritubular capillary.

2. Describe the sequence of events that take place in the renin–angiotensin–aldosterone system in response to a fall in NaCl, ECF volume, and arterial blood pressure.

3. If the plasma concentration of a substance is 200 mg/100 mL, the substance's T_m is 200 mg/min, and the GFR is 125 mL/min, (1) what is the filtered load of this substance, (2) how much of the substance is reabsorbed, and (3) how much of it is excreted?

14.4 Tubular Secretion

Like tubular reabsorption, tubular secretion involves transepithelial transport, but now the steps are reversed. By providing a second route of entry into the tubules for selected substances, *tubular secretion,* the discrete transfer of substances from the peritubular capillaries into the tubular lumen, is a supplemental mechanism that hastens elimination of these compounds from the body. Anything that gains entry to the tubular fluid, whether by glomerular filtration or tubular secretion, and fails to be reabsorbed is eliminated in the urine.

The most important substances secreted by the tubules are *hydrogen ion, potassium ion,* and *organic anions and cations.* Many of the latter are compounds foreign to the body.

Hydrogen ion secretion is important in acid–base balance.

Renal H^+ secretion is extremely important in regulating acid–base balance in the body. H^+ secreted into the tubular fluid is eliminated from the body in the urine. H^+ can be secreted by the proximal, distal, and collecting tubules, with the extent of H^+ secretion depending on the acidity of the body fluids. When the body fluids are too acidic, H^+ secretion increases. Conversely, when the H^+ concentration in the body fluids is too low, H^+ secretion decreases. (See Chapter 15 for further details.)

Potassium ion secretion is controlled by aldosterone.

Potassium is one of the most abundant cations in the body, but about 98% of the K^+ is in the intracellular fluid because the Na^+–K^+ pump actively transports K^+ into the cells. Because only a relatively small amount of K^+ is in the ECF, even slight changes in the ECF K^+ load can have a pronounced effect on the plasma K^+ concentration. Changes in the plasma K^+ concentration have a marked influence on membrane excitability. Therefore, plasma K^+ concentrations are tightly controlled, primarily by the kidneys.

Renal handling of K^+ is complex. K^+ is selectively moved in opposite directions in different parts of the tubule; it is actively reabsorbed in the proximal tubule and actively secreted by principal cells in the distal and collecting tubules. Furthermore, one type of intercalated cell actively secretes K^+ and another type actively reabsorbs K^+ in the distal and collecting tubules in conjunction with H^+ transport (see Chapter 15). Early in the tubule, K^+ is constantly reabsorbed without regulation, whereas K^+ secretion later in the tubule by the principal cells is variable and subject to regulation. Because the filtered K^+ is almost completely reabsorbed in the proximal tubule, most K^+ in the urine is derived from controlled K^+ secretion in the distal parts of the nephron rather than from filtration.

During K^+ depletion, K^+ secretion in the distal parts of the nephron is reduced to a minimum, so only the small percentage of filtered K^+ that escapes reabsorption in the proximal tubule is excreted in the urine. In this way, K^+ that normally would have been lost in urine is conserved for the body. Conversely, when plasma K^+ levels are elevated, K^+ secretion is adjusted so that just enough K^+ is added to the filtrate for elimination to reduce the plasma K^+ concentration to normal. Thus, K^+ secretion, not the filtration or reabsorption of K^+, is varied in a controlled fashion to regulate the rate of K^+ excretion and maintain the desired plasma K^+ concentration.

Mechanism Of K^+ Secretion K^+ secretion in the principal cells of the distal and collecting tubules is coupled to Na^+ reab-
I Figure 14-21 Potassium ion secretion. The basolateral pump simultaneously transports Na$^+$ into the lateral space and K$^+$ into the tubular cell. In the parts of the tubule that secrete K$^+$, this ion leaves the cell through channels located in the luminal border, thus being secreted. (In the parts of the tubule that do not secrete K$^+$, the K$^+$ pumped into the cell during Na$^+$ reabsorption leaves the cell through channels located in the basolateral border, thus being retained in the body.)

FIGURE FOCUS: *(1) What happens to the Na$^+$ transported by the basolateral Na$^+$–K$^+$ pump during K$^+$ secretion? (2) What happens to the K$^+$ transported by the basolateral Na$^+$–K$^+$ pump during Na$^+$ reabsorption in the segments of the tubule that do not secrete K$^+$?*

sorption by the energy-dependent basolateral Na$^+$–K$^+$ pump (I Figure 14-21). This pump not only moves Na$^+$ out of the cell into the lateral space, but also transports K$^+$ from the lateral space into the tubular cells. The resulting high intracellular K$^+$ concentration favors net movement of K$^+$ from the cells into the tubular lumen. Movement across the luminal membrane occurs passively through the large number of K$^+$ leak channels in this barrier in the distal and collecting tubules. By keeping the interstitial fluid concentration of K$^+$ low as it transports K$^+$ into the tubular cells from the surrounding interstitial fluid, the basolateral pump encourages passive movement of K$^+$ out of the peritubular capillary plasma into the interstitial fluid. A potassium ion leaving the plasma in this manner is later pumped into the cells, from which it passively moves into the lumen. In this way, the basolateral pump actively induces the net secretion of K$^+$ from the peritubular capillary plasma into the tubular lumen in the distal parts of the nephron.

Because K$^+$ secretion is linked with Na$^+$ reabsorption by the Na$^+$–K$^+$ pump, why isn't K$^+$ secreted throughout the Na$^+$-reabsorbing segments of the tubule instead of taking place only in the distal parts of the nephron? The answer lies in the location of the passive K$^+$ leak channels. In the principal cells of the distal and collecting tubules, the K$^+$ channels are concentrated in the luminal membrane, providing a route for K$^+$ pumped into the cell to exit into the tubular lumen, thus being secreted. In the proximal tubule, the K$^+$ leak channels are located primarily in the basolateral membrane. As a result, K$^+$ pumped

into the cell from the lateral space by the Na$^+$–K$^+$ pump simply moves back out into the lateral space through these channels. This K$^+$ recycling permits the ongoing operation of the Na$^+$–K$^+$ pump to accomplish Na$^+$ reabsorption with no local net effect on K$^+$.

Control of K$^+$ Secretion Several factors can alter the rate of K$^+$ secretion, the most important being aldosterone. This hormone stimulates K$^+$ secretion by the principal tubular cells late in the nephron while simultaneously enhancing these cells' reabsorption of Na$^+$. A rise in plasma K$^+$ concentration directly stimulates the adrenal cortex to increase its output of aldosterone, which in turn promotes the secretion and ultimate urinary excretion and elimination of excess K$^+$. Conversely, a decline in plasma K$^+$ concentration causes a reduction in aldosterone secretion and a corresponding decrease in aldosterone-stimulated renal K$^+$ secretion. The amount of K$^+$ excreted in the urine varies from 80% to 1% of the filtered quantity, depending on the body's momentary needs.

Note that a rise in plasma K$^+$ concentration *directly* stimulates aldosterone secretion by the adrenal cortex, whereas a fall in plasma Na$^+$ concentration stimulates aldosterone secretion by means of the complex RAAS pathway. Thus, aldosterone secretion can be stimulated by two separate pathways (I Figure 14-22). No matter what the stimulus, however, increased aldosterone secretion always promotes simultaneous Na$^+$ reabsorption and K$^+$ secretion. For this reason, K$^+$ secretion can be inadvertently stimulated as a result of increased aldosterone activity brought about by Na$^+$ depletion, ECF volume reduction, or a fall in arterial blood pressure totally unrelated to K$^+$ balance. The resulting inappropriate loss of K$^+$ can lead to K$^+$ deficiency.

Effect of H$^+$ Secretion on K$^+$ Secretion Another factor that can inadvertently alter the magnitude of K$^+$ secretion is the acid–base status of the body. The intercalated cells in the distal portions of the nephron secrete either K$^+$ or H$^+$. An increased rate of secretion of either K$^+$ or H$^+$ is accompanied by a decreased rate of secretion of the other ion. Normally the kidneys secrete a preponderance of K$^+$, but when the body fluids are too acidic and H$^+$ secretion is increased as a compensatory measure, K$^+$ secretion is correspondingly reduced. This reduced secretion leads to inappropriate K$^+$ retention in the body fluids.

Importance of Regulating Plasma K$^+$ Concentration Except in the overriding circumstances of K$^+$ imbalances inadvertently induced during renal compensations for Na$^+$ or ECF volume deficits or acid–base imbalances, the kidneys usually exert a fine degree of control over plasma K$^+$ concentration. This is extremely important because even minor fluctuations in plasma K$^+$ concentration can have detrimental consequences.

❙Figure 14-22 Dual control of aldosterone secretion by K⁺ and Na⁺.

Clinical Note K⁺ plays a key role in the membrane electrical activity of excitable tissues. Both increases and decreases in the plasma (ECF) K⁺ concentration can alter the intracellular-to-extracellular K⁺ concentration gradient, which in turn can change the resting membrane potential. The most serious consequences of both K⁺ excess and K⁺ deficiency are related to their effect on the heart. Both conditions result in decreased cardiac excitability, for different reasons. A *rise* in ECF K⁺ concentration reduces resting potential (makes it less negative), which decreases the excitability of neurons; skeletal muscle cells; and, most importantly, cardiac muscle cells, by keeping the voltage-gated Na⁺ channels responsible for the rising phase of the cardiac action potential in their inactive (closed and not capable of opening) state (see p. 92). The cell membrane is unable to repolarize completely after depolarization to return the channel to its closed and capable of opening conformation. Some Na⁺ channels are more sensitive than others to the depolarizing effect. As more and more Na⁺ channels are inactivated by rising K⁺ levels, cardiac excitability progressively decreases. A *fall* in ECF K⁺ concentration results in hyperpolarization of nerve and muscle cell membranes, which also reduces their excitability. A greater depolarization than normal is needed to bring the membrane to threshold potential. Thus, both low and high ECF K⁺ concentrations can lead to abnormalities in cardiac rhythm and even death.

Organic anion and cation secretion hastens elimination of foreign compounds.

The proximal tubule contains two distinct types of secretory carriers, one for secretion of organic anions and a separate system for secretion of organic cations.

Functions of Organic Ion Secretory Systems The organic ion secretory systems serve three important functions:

1. By adding more of a particular type of organic ion to the quantity that has already gained entry to the tubular fluid by glomerular filtration, the organic secretory pathways facilitate excretion of these substances. Included among these organic ions are certain blood-borne chemical messengers such as prostaglandins and epinephrine, which, having served their purpose, must be rapidly removed from the blood so that their biological activity is not unduly prolonged.

2. In some important instances, organic ions are poorly soluble in water. To be transported in blood, they are extensively but not irreversibly bound to plasma proteins. Because they are attached to plasma proteins, these substances cannot be filtered through the glomeruli. Tubular secretion facilitates elimination of these nonfilterable organic ions in urine. Even though a given organic ion is largely bound to plasma proteins, a small percentage of the ion always exists in free or unbound form in the plasma. Removal of this free organic ion by secretion permits "unloading" of some of the bound ion, which is then free to be secreted. This, in turn, encourages the unloading of even more organic ion, and so on.

3. Most important, the proximal tubule organic ion secretory systems play a key role in eliminating many foreign compounds from the body. These systems can secrete a large number of different organic ions, both those produced within the body and those foreign organic ions that have gained access to the body fluids. This nonselectivity permits the organic ion secretory systems to hasten removal of many foreign organic chemicals, including food additives, environmental pollutants (for example, pesticides), drugs, and other nonnutritive organic substances that have entered the body. Even though this mechanism helps rid the body of potentially harmful foreign compounds, it is not subject to physiologic adjustments. The carriers cannot pick up their secretory pace when confronting an elevated load of these organic ions.

The liver plays an important role in helping rid the body of foreign compounds. Many foreign organic chemicals are not ionic in their original form, so they cannot be secreted by the organic ion systems. The liver converts these foreign substances into an anionic form that facilitates their secretion by the organic anion system and thus accelerates their elimination. *Clinical Note* Many drugs, such as penicillin and nonsteroidal anti-inflammatory drugs (NSAIDs), are eliminated from the body by the organic ion secretory systems. To keep the plasma concentration of these drugs at effective levels, the dosage must be repeated frequently to keep pace with the rapid removal of these compounds in the urine.

Because the organic ion secretory carriers are not very selective, different drugs can compete for binding sites on the same carrier. For example, cimetidine (a drug used to treat stomach ulcers; see p. 589) and procainamide (a drug used to treat cardiac arrhythmias) both are secreted by the organic cation secretory carriers. If these drugs were given to the same patient, the urinary excretion rate of both substances would be decreased because they would compete for elimination by the secretory carriers. Thus coadministration of these drugs would lead to much higher blood concentrations of both substances than when each is given alone. Thus, to avoid potential drug toxicity, drugs eliminated by the same secretory pathway should not be taken together.

Summary of Reabsorptive and Secretory Processes

This completes our discussion of the reabsorptive and secretory processes that occur across the proximal and distal portions of the nephron. These processes are summarized in ❚Table 14-2. To generalize, the proximal tubule does most of the reabsorbing. This mass reabsorber transfers much of the filtered water

---

❚**TABLE 14-2** Summary of Transport across Proximal and Distal Portions of the Nephron

PROXIMAL TUBULE

Reabsorption	Secretion
67% of filtered Na^+ actively reabsorbed, not subject to control; Cl^- follows passively	Variable H^+ secretion, depending on acid–base status of body
All filtered glucose and amino acids reabsorbed by secondary active transport; not subject to control	Organic ion secretion; not subject to control
Variable amounts of filtered PO_4^{3-} and other electrolytes reabsorbed; subject to control	
65% of filtered H_2O osmotically reabsorbed; not subject to control	
50% of filtered urea passively reabsorbed; not subject to control	
Almost all filtered K^+ reabsorbed; not subject to control

Variable H_2O reabsorption, controlled by vasopressin	Variable K^+ secretion, controlled by aldosterone

---

and needed solutes back into the blood in unregulated fashion. Similarly, the proximal tubule is the major site of secretion, with the exception of K^+ secretion. The distal and collecting tubules then determine the final amounts of H_2O, Na^+, K^+, and H^+ excreted in the urine and thus eliminated from the body. They do so by fine-tuning the amount of Na^+ and H_2O reabsorbed and the amount of K^+ and H^+ secreted. These processes in the distal part of the nephron are all subject to control, depending on the body's momentary needs. The unwanted filtered waste products are left behind to be eliminated in the urine, along with excess amounts of filtered or secreted nonwaste products that fail to be reabsorbed.

We next focus on the end result of the basic renal processes—what's left in the tubules to be excreted in urine, and, as a consequence, what has been cleared from plasma.

Check Your Understanding 14.4

1. List the three secretory processes accomplished by the kidney tubules.

2. Compare how the proximal tubule cells and the principal cells of the distal and collecting tubules handle K^+ and indicate which of these processes is subject to control.

3. Explain how most foreign organic compounds are eliminated from the body.

14.5 Urine Excretion and Plasma Clearance

Of the 125 mL of plasma filtered per minute, typically 124 mL/min are reabsorbed, so the final quantity of urine formed averages 1 mL/min. Thus, of the 180 liters filtered per day, 1.5 liters of urine are excreted.

Urine contains high concentrations of various waste products plus variable amounts of the substances regulated by the kidneys, with any excess quantities having spilled into the urine. Useful substances are conserved by reabsorption, so they do not appear in the urine.

A relatively small change in the quantity of filtrate reabsorbed can bring about a large change in the volume of urine formed. For example, a reduction of less than 1% in the total reabsorption rate, from 124 to 123 mL/min, increases the urinary excretion rate by 100%, from 1 to 2 mL/min.

Plasma clearance is the volume of plasma cleared of a particular substance per minute.

Compared to plasma entering the kidneys through the renal arteries, plasma leaving the kidneys through the renal veins lacks the materials that were left behind to be eliminated in the urine. By excreting substances in the urine, the kidneys clean or "clear" the plasma flowing through them of these substances. The **plasma clearance** of any substance is defined as the volume of plasma completely cleared of that substance by the kidneys

per minute.[3] It refers not to the *amount of the substance* removed but to the *volume of plasma* from which that amount was removed. Plasma clearance is actually a more useful measure than urine excretion; it is more important to know what effect urine excretion has on removing materials from body fluids than to know the volume and composition of discarded urine. Plasma clearance expresses the kidneys' effectiveness in removing various substances from the internal fluid environment.

Plasma clearance can be calculated for any plasma constituent as follows:

$$\text{Clearance rate of a substance (mL/min)} = \frac{\text{urine concentration of the substance (quantity/mL urine)} \times \text{urine flow rate (mL/min)}}{\text{plasma concentration of the substance (quantity/mL plasma)}}$$

The plasma clearance rate varies for different substances, depending on how the kidneys handle each substance. Let us consider how three common patterns of renal handling influence clearance rates for the involved substances.

Plasma Clearance Rate for a Substance Filtered But Not Reabsorbed or Secreted Assume that a plasma constituent, substance X, is freely filterable at the glomerulus but is not reabsorbed or secreted. As 125 mL/min of plasma are filtered and subsequently reabsorbed, the quantity of substance X originally contained within the 125 mL is left behind in the tubules to be excreted. Thus, 125 mL of plasma are cleared of substance X each minute (❙ Figure 14-23a). (Of the 125 mL/min of plasma filtered, 124 mL/min of the filtered fluid are returned, through reabsorption, to the plasma minus substance X, thus clearing this 124 mL/min of substance X. In addition, the 1 mL/min of fluid lost in urine is eventually replaced by an equivalent volume of ingested H_2O that is already clear of substance X. Therefore, 125 mL of plasma cleared of substance X are, in effect, returned to the plasma for every 125 mL of plasma filtered per minute.) Thus, *the plasma clearance rate of a substance filtered but not reabsorbed or secreted always equals the GFR.*

Clinical Note No normally occurring chemical in the body has the characteristics of substance X. All substances naturally present in the plasma, even wastes, are reabsorbed or secreted to some extent. However, **inulin** (do not confuse with insulin), a harmless foreign carbohydrate produced abundantly by Jerusalem artichokes and to a lesser extent by other root vegetables such as onions and garlic, is freely filtered and not reabsorbed or secreted—an ideal substance X. Inulin can be injected and its plasma clearance determined as a clinical means of finding out the GFR. Because all glomerular filtrate formed is cleared of inulin, the volume of plasma cleared of

inulin per minute equals the volume of plasma filtered per minute—that is, the GFR, as the following example illustrates:

$$\text{Clearance rate for inulin} = \frac{30 \text{ mg/mL urine} \times 1.25 \text{ mL urine/min}}{0.30 \text{ mg/mL plasma}}$$

$$= 125 \text{ mL plasma/min}$$

Although determination of inulin plasma clearance is accurate and straightforward, it is not very convenient because inulin must be infused continuously throughout the determination to maintain a constant plasma concentration. Therefore, the plasma clearance of an endogenous substance, **creatinine**, is often used instead to find a rough estimate of the GFR. Creatinine, an end product of muscle metabolism, is produced at a relatively constant rate. It is freely filtered and not reabsorbed but is slightly secreted. Accordingly, creatinine clearance is not a completely accurate reflection of the GFR, but it does provide a close approximation and can be more readily determined than inulin clearance.

Plasma Clearance Rate for a Substance Filtered and Reabsorbed Some or all of a reabsorbable substance that has been filtered is returned to the plasma. Because less than the filtered volume of plasma is cleared of the substance, *the plasma clearance rate of a reabsorbable substance is always less than the GFR*. For example, the plasma clearance for glucose is normally zero. All the filtered glucose is reabsorbed with the rest of the returning filtrate, so none of the plasma is cleared of glucose (❙ Figure 14-23b).

For a substance that is partially reabsorbed, such as urea, only part of the filtered plasma is cleared of that substance. With about 50% of the filtered urea being passively reabsorbed, only half of the filtered plasma, or 62.5 mL, is cleared of urea each minute (❙ Figure 14-23c).

Clearance Rate for a Substance Filtered and Secreted Tubular secretion allows the kidneys to clear certain materials from the plasma more efficiently. Only 20% of the plasma entering the kidneys is filtered. The remaining 80% passes unfiltered into the peritubular capillaries. The only means by which this unfiltered plasma can be cleared of any substance during the trip through the kidneys before being returned to the general circulation is by secretion. An example is H^+. Not only is filtered plasma cleared of nonreabsorbable H^+, but the plasma from which H^+ is secreted is also cleared of H^+. For example, if the quantity of H^+ secreted is equivalent to the quantity of H^+ present in 25 mL of plasma, the clearance rate for H^+ will be 150 mL/min at the normal GFR of 125 mL/min. Every minute 125 mL of plasma loses its H^+ through filtration and failure of reabsorption, and an additional 25 mL of plasma loses its H^+ through secretion. Thus, *the plasma clearance rate for a secreted substance is always greater than the GFR* (❙ Figure 14-23d).

Clinical Note Just as inulin can be used to determine the GFR, plasma clearance of another foreign compound, the organic anion **para-aminohippuric acid (PAH)**, can be used to measure renal plasma flow. Like inulin, PAH is freely filterable and nonreabsorbable. It differs, however, in that all the PAH in

---

[3]Actually, plasma clearance is an artificial concept because when a particular substance is excreted in the urine, that substance's concentration in the plasma as a whole is uniformly decreased as a result of thorough mixing in the circulatory system. However, it is useful for comparative purposes to consider clearance in effect as the volume of plasma that would have contained the total quantity of the substance (at the substance's concentration prior to excretion) that the kidneys excreted in one minute—that is, the hypothetical volume of plasma completely cleared of that substance per minute.

(a) For a substance filtered and not reabsorbed or secreted, such as inulin, all of the filtered plasma is cleared of the substance.
(b) For a substance filtered, not secreted, and completely reabsorbed, such as glucose, none of the filtered plasma is cleared of the substance.
(c) For a substance filtered, not secreted, and partially reabsorbed, such as urea, only a portion of the filtered plasma is cleared of the substance.
(d) For a substance filtered and secreted but not reabsorbed, such as hydrogen ion, all of the filtered plasma is cleared of the substance, and the peritubular plasma from which the substance is secreted is also cleared.

❙Figure 14-23 **Plasma clearance for substances handled in different ways by the kidneys.**

the plasma that escapes filtration is secreted from the peritubular capillaries by the organic anion secretory pathway in the proximal tubule. Thus, PAH is removed from all the plasma that flows through the kidneys—both from plasma that is filtered and subsequently reabsorbed without its PAH and from unfiltered plasma that continues on in the peritubular capillaries and loses its PAH by active secretion into the tubules. Because all the plasma that flows through the kidneys is cleared of PAH, the plasma clearance for PAH is a reasonable estimate of the rate of plasma flow through the kidneys. Typically, renal plasma flow averages 625 mL/min, for a renal blood flow (plasma plus blood cells) of 1140 mL/min—more than 20% of the cardiac output.

Clearance rates for inulin and PAH can be used to determine the filtration fraction.

If you know the rates of inulin clearance (GFR) and PAH clearance (renal plasma flow) you can easily determine the **filtration fraction**, the fraction of plasma flowing through the glomeruli that is filtered into the tubules:

$$\text{Filtration fraction} = \frac{\text{GFR (plasma inulin clearance)}}{\text{renal plasma flow (plasma PAH clearance)}}$$

$$= \frac{125 \text{ mL/min}}{625 \text{ mL/min}} = 20\%$$

Thus, 20% of the plasma that enters the glomeruli is typically filtered.

The kidneys can excrete urine of varying concentrations depending on body needs.

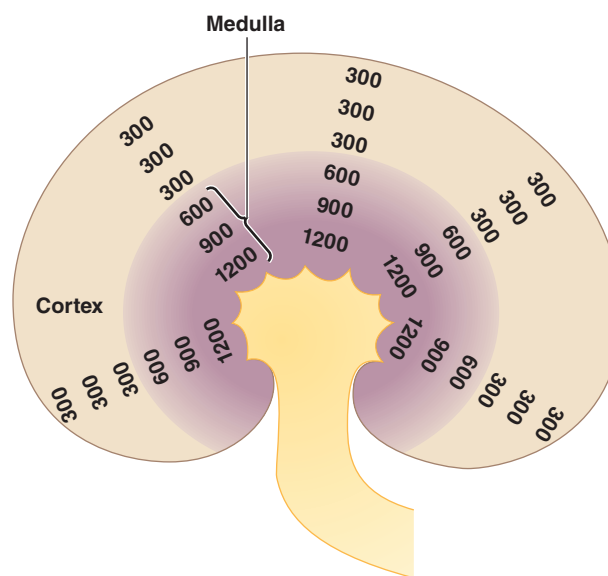
Having considered how the kidneys deal with a variety of solutes in the plasma, we now concentrate on renal handling of plasma H_2O. The ECF osmolarity (solute concentration) depends on the relative amount of H_2O compared to solute. At normal fluid balance and solute concentration, the body fluids are **isotonic** at an osmolarity of 300 milliosmols per liter (mOsm/L) (see pp. 69 and A-7). If too much H_2O is present relative to the solute load, the body fluids are **hypotonic**, which means they are too dilute at an osmolarity less than 300 mOsm/L. However, if a H_2O deficit exists relative to the solute load, the body fluids are too concentrated or are **hypertonic**, having an osmolarity greater than 300 mOsm/L.

Knowing that the driving force for H_2O reabsorption the entire length of the tubules is an osmotic gradient between the tubular lumen and the surrounding interstitial fluid, you would expect, given osmotic considerations, that the kidneys could not excrete urine more or less concentrated than the body fluids. Indeed, this would be the case if the interstitial fluid surrounding the tubules in the kidneys were identical in osmolarity to the rest of the body fluids. Water reabsorption would proceed only until the tubular fluid equilibrated osmotically with the interstitial fluid, and the body would have no way to eliminate excess H_2O when the body fluids were hypotonic or to conserve H_2O in the presence of hypertonicity.

Fortunately, a **vertical osmotic gradient** is uniquely maintained in the medullary interstitial fluid of each kidney. The concentration of the interstitial fluid progressively increases

from the cortical boundary down through the depth of the renal medulla until it reaches a maximum of 1200 mOsm/L in humans at the junction with the renal pelvis (❚Figure 14-24).

By a mechanism described shortly, this gradient enables the kidneys to produce urine that ranges in concentration from 100 to 1200 mOsm/L, depending on the body's state of hydration. When the body is in ideal fluid balance, 1 mL/min of isotonic urine is formed. When the body is overhydrated (too much H_2O), the kidneys can produce a large volume of dilute urine (up to 25 mL/min and hypotonic at 100 mOsm/L), eliminating the excess H_2O in the urine. Conversely, the kidneys can put out a small volume of concentrated urine (down to 0.3 mL/min and hypertonic at 1200 mOsm/L) when the body is dehydrated (too little H_2O), conserving H_2O for the body.

Unique anatomic arrangements and complex functional interactions among various nephron components in the renal medulla establish and use the vertical osmotic gradient. Recall that the hairpin loop of Henle dips only slightly into the medulla in cortical nephrons, but in juxtamedullary nephrons the loop plunges through the entire depth of the medulla so that the tip of the loop lies near the renal pelvis (see ❚Figures 14-1c, p. 493, and 14-5, p. 496). Also, the vasa recta of juxtamedullary nephrons follow the same deep hairpin loop as the long loop of Henle. Flow in both the long loops of Henle and the vasa recta is considered *countercurrent* because the flow in the two closely adjacent limbs of the loop moves in opposite directions. Also running through the medulla in the descending direction only, on their way to the renal pelvis, are the collecting ducts that serve both types of nephrons. This arrangement, coupled with the permeability and transport characteristics of these tubular


❚Figure 14-24 **Vertical osmotic gradient in the renal medulla.** All values are in mOsm/L. The osmolarity of the interstitial fluid throughout the renal cortex is isotonic at 300 mOsm/L, but the osmolarity of the interstitial fluid in the renal medulla increases progressively from 300 mOsm/L at the boundary with the cortex to a maximum of 1200 mOsm/L at the junction with the renal pelvis. (The kidney is rotated 90° from its normal position in an upright person for better visualization of the vertical osmotic gradient in the renal medulla.)

segments, plays a key role in the kidneys' ability to produce urine of varying concentrations, depending on the body's needs for water conservation or elimination. Briefly, the juxtamedullary nephrons' long loops of Henle *establish* the vertical osmotic gradient by means of countercurrent multiplication, their vasa recta *preserve* this gradient while providing blood to the renal medulla by means of countercurrent exchange, and the collecting ducts of all nephrons *use* the gradient, in conjunction with the hormone vasopressin, to produce urine of varying concentrations. We next examine each of these processes in greater detail.

Long Henle's loops establish the vertical osmotic gradient by countercurrent multiplication.

We now follow the filtrate through a long-looped nephron to see how this structure establishes a vertical osmotic gradient in the renal medulla via **countercurrent multiplication** during which an active concentrating mechanism's effect is multiplied as a result of countercurrent flow. Immediately after the filtrate is formed, uncontrolled osmotic reabsorption of filtered H_2O occurs in the proximal tubule secondary to active Na^+ reabsorption. As a result, by the end of the proximal tubule, about 65% of the filtrate has been reabsorbed, but the 35% remaining in the tubular lumen still has the same osmolarity as the body fluids. Therefore, the fluid entering the loop of Henle is still isotonic. An additional 15% of the filtered H_2O is obligatorily reabsorbed from the loop of Henle during the establishment and maintenance of the vertical osmotic gradient, with the osmolarity of the tubular fluid being altered in the process.

Properties of the Descending and Ascending Limbs of a Long Henle's Loop The following functional distinctions between the descending limb of a long Henle's loop (which carries fluid from the proximal tubule down into the depths of the medulla) and the ascending limb (which carries fluid up and out of the medulla into the distal tubule) are crucial for establishing the incremental osmotic gradient in the medullary interstitial fluid.

The *descending limb* (1) is highly permeable to H_2O (via abundant, always-open AQP-1 water channels) and (2) does not actively extrude Na^+—that is, it does not reabsorb Na^+. (It is the only segment of the entire tubule that does not do so.)

The *ascending limb* (1) actively transports NaCl out of the tubular lumen into the surrounding interstitial fluid and (2) is always impermeable to H_2O, so salt leaves the tubular fluid without H_2O osmotically following along.

Mechanism of Countercurrent Multiplication The close proximity and countercurrent flow of the two limbs allow important interactions between them. Even though the flow of fluids is continuous through the loop of Henle, we can visualize what happens step by step, much like an animated film run so slowly that each frame can be viewed.

Initially, before the vertical osmotic gradient is established, the medullary interstitial fluid concentration is uniformly 300 mOsm/L, as are the rest of the body fluids (❙Figure 14-25, Initial scene).

The active salt pump in the ascending limb can transport NaCl out of the lumen until the surrounding interstitial fluid is 200 mOsm/L more concentrated than the tubular fluid in this limb. When the ascending limb pump starts actively extruding NaCl, the medullary interstitial fluid becomes hypertonic. Water cannot follow osmotically from the ascending limb because this limb is impermeable to H_2O. However, net diffusion of H_2O does occur from the descending limb into the interstitial fluid. The tubular fluid entering the descending limb from the proximal tubule is isotonic. Because the descending limb is highly permeable to H_2O, net diffusion of H_2O occurs by osmosis out of the descending limb into the more concentrated interstitial fluid. The passive movement of H_2O out of the descending limb continues until the osmolarities of the fluid in the descending limb and the interstitial fluid become equilibrated. Thus, the tubular fluid entering the loop of Henle immediately starts to become more concentrated as it loses H_2O. At equilibrium, the osmolarity of the ascending limb fluid is 200 mOsm/L and the osmolarities of the interstitial fluid and descending limb fluid are equal at 400 mOsm/L (❙Figure 14-25, step ❶).

If we now advance the entire column of fluid in the loop several frames (step ❷), a mass of 200 mOsm/L fluid exits from the top of the ascending limb into the distal tubule, and a new mass of isotonic fluid at 300 mOsm/L enters the top of the descending limb from the proximal tubule. At the bottom of the loop, a comparable mass of 400 mOsm/L fluid from the descending limb moves forward around the tip into the ascending limb, placing it opposite a 400 mOsm/L region in the descending limb, but the 200 mOsm/L concentration difference has been lost at both the top and the bottom of the loop.

The ascending limb pump again transports NaCl out while H_2O passively leaves the descending limb until a 200 mOsm/L difference is reestablished between the ascending limb and both the interstitial fluid and the descending limb at each horizontal level (step ❸). Note, however, that the concentration of tubular fluid is progressively increasing in the descending limb and progressively decreasing in the ascending limb.

As the tubular fluid is advanced still farther (step ❹), the 200 mOsm/L concentration gradient is disrupted again at all horizontal levels. Again, active extrusion of NaCl from the ascending limb, coupled with the net diffusion of H_2O out of the descending limb, reestablishes the 200 mOsm/L gradient at each horizontal level (step ❺).

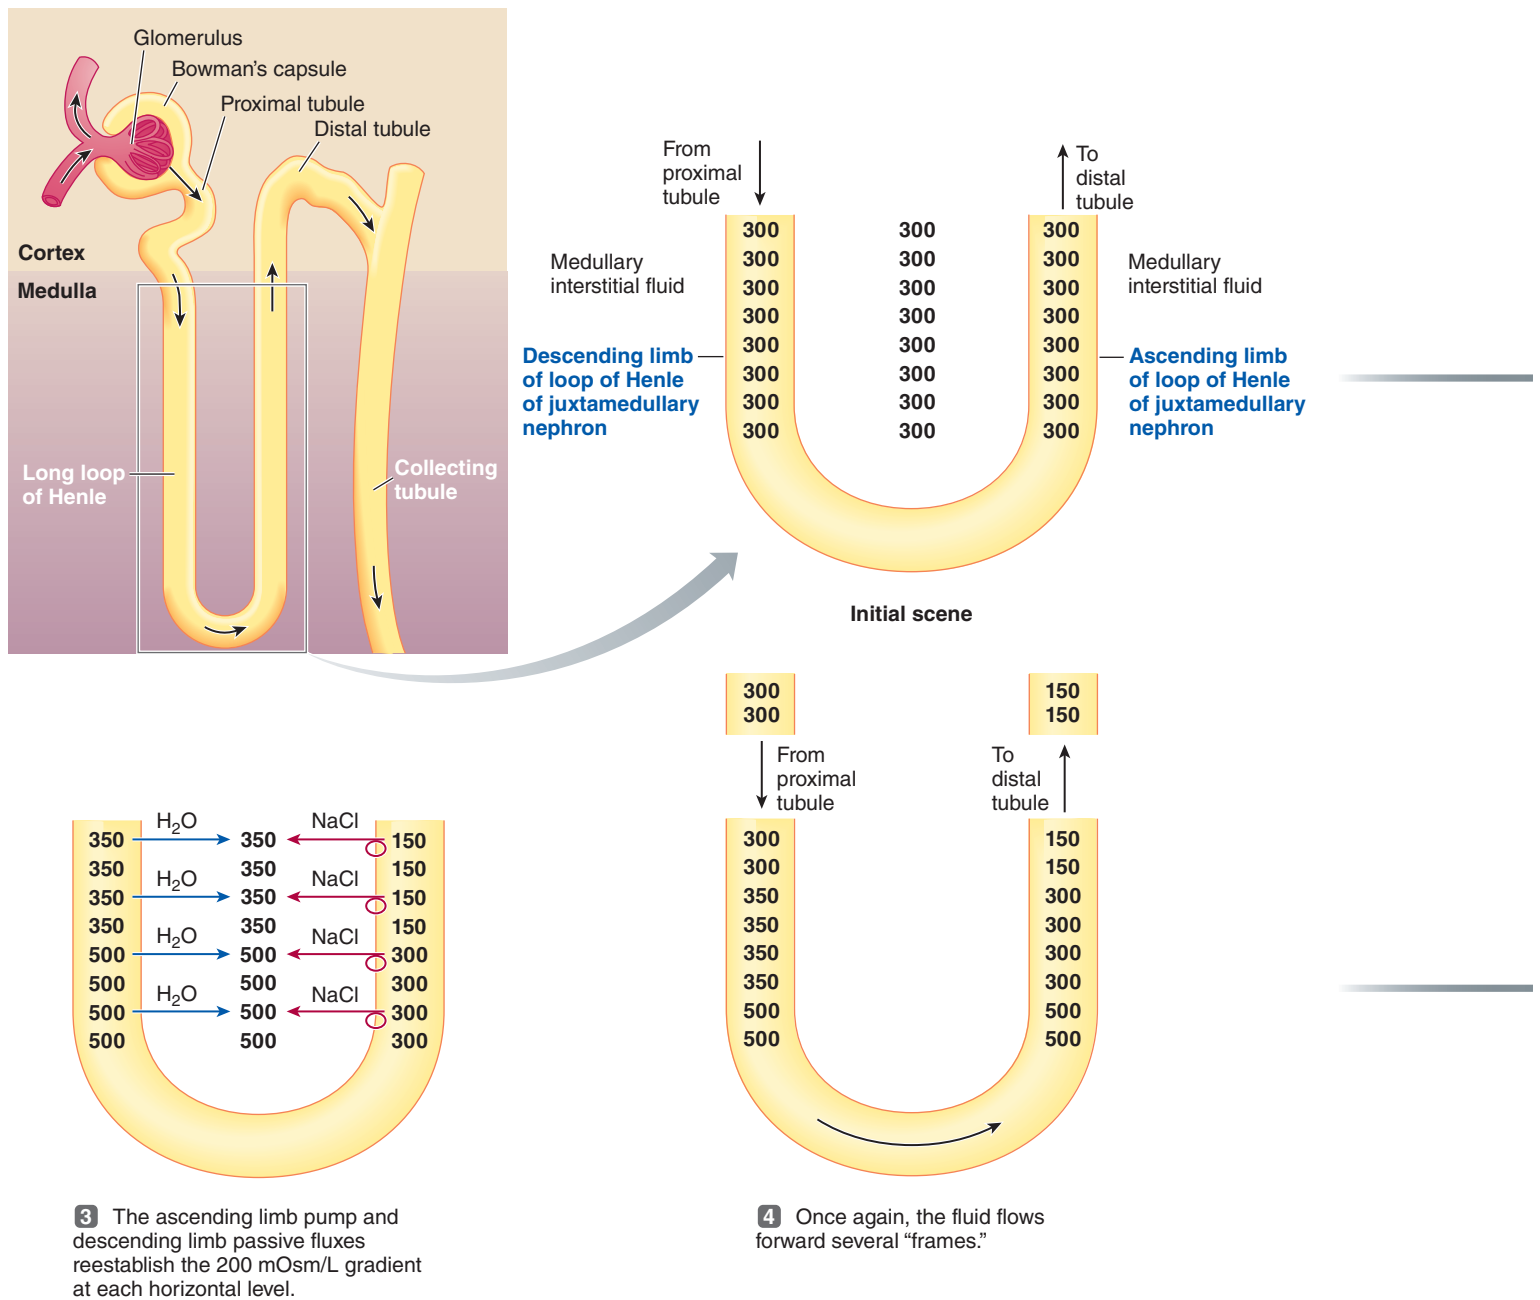
As the fluid flows slightly forward again and this stepwise process continues (step ❻), the fluid in the descending limb becomes progressively more hypertonic until it reaches a maximum concentration of 1200 mOsm/L at the bottom of the loop, four times the normal concentration of body fluids. Because the interstitial fluid always achieves equilibrium with the descending limb, an incremental vertical concentration gradient ranging from 300 to 1200 mOsm/L is likewise established in the medullary interstitial fluid. In contrast, the concentration of the tubular fluid progressively decreases in the ascending limb as NaCl is pumped out but H_2O is unable to follow. In fact, the tubular fluid even becomes hypotonic before leaving the ascending limb to enter the distal tubule at a concentration of 100 mOsm/L, one third the normal concentration of body fluids.


Figure 14-25 Countercurrent multiplication in the renal medulla. All values are in mOsm/L.

Note that although a gradient of only 200 mOsm/L exists between the ascending limb and the surrounding fluids at each medullary horizontal level, a larger vertical gradient exists from the top to the bottom of the medulla. Even though the ascending limb pump can generate a gradient of only 200 mOsm/L, this effect is multiplied into a large vertical gradient because of the countercurrent flow within the loop. Thus, this concentrating mechanism accomplished by the loop of Henle is known as **countercurrent multiplication**.

We have artificially described countercurrent multiplication in a stop-and-flow, stepwise fashion to facilitate understanding. However realize that once the incremental medul-lary gradient is established, it stays constant because of the continuous flow of fluid, coupled with the ongoing ascending limb active transport and the accompanying descending limb passive fluxes.

Benefits of Countercurrent Multiplication If you consider only what happens to the tubular fluid as it flows through the loop of Henle, the whole process seems an exercise in futility. The isotonic fluid that enters the loop becomes progressively more concentrated as it flows down the descending limb, achieving a maximum concentration of 1200 mOsm/L, only to become progressively more diluted as it

KEY

← ○ = Active transport of NaCl
1 The active salt pump in the ascending limb establishes a 200 mOsm/L gradient at each horizontal level.
2 As the fluid flows forward several "frames," a mass of 200 mOsm/L fluid exits into the distal tubule and a new mass of 300 mOsm/L fluid enters from the proximal tubule.
5 The 200 mOsm/L gradient at each horizontal level is established once again.
6 The final vertical osmotic gradient is established and maintained by the ongoing countercurrent multiplication of the long loops of Henle.

flows up the ascending limb, finally leaving the loop at a minimum concentration of 100 mOsm/L. What is the point of concentrating the fluid fourfold and then turning around and diluting it until it leaves at one third the concentration at which it entered? Such a mechanism offers two benefits. First, it establishes a vertical osmotic gradient in the medullary interstitial fluid. This gradient, in turn, is used by the collecting ducts to concentrate the tubular fluid so that a urine *more concentrated* than normal body fluids can be excreted. Second, because the fluid is hypotonic as it enters the distal parts of the tubule, the kidneys can excrete a urine *more dilute* than normal body fluids. Let us see how.

Vasopressin controls variable H₂O reabsorption in the final tubular segments.

After obligatory H₂O reabsorption from the proximal tubule (65% of the filtered H₂O) and loop of Henle (15% of the filtered H₂O), 20% of the filtered H₂O remains in the lumen to enter the distal and collecting tubules for variable reabsorption under hormonal control. This is still a large volume of filtered H₂O subject to regulated reabsorption; 20% × GFR (180 L/day) = 36 L/day to be reabsorbed to varying extents, depending on the body's state of hydration. This is more than 13 times the amount of plasma H₂O in the entire circulatory system.

The fluid leaving the loop of Henle enters the distal tubule at 100 mOsm/L, so it is hypotonic to the surrounding isotonic (300 mOsm/L) interstitial fluid of the renal cortex through which the distal tubule passes. The distal tubule then empties into the collecting duct, which is bathed by progressively increasing concentrations (300 to 1200 mOsm/L) of the surrounding interstitial fluid as it descends through the medulla.

Role of Vasopressin For H_2O absorption to occur across a segment of the tubule, two criteria must be met: (1) an osmotic gradient must exist across the tubule, and (2) the tubular segment must be permeable to H_2O. The distal and collecting tubules are *impermeable* to H_2O except in the presence of **vasopressin**, also known as **antidiuretic hormone** (*antidiuretic* means "against increased urine output"),[4] which increases their permeability to H_2O. Vasopressin is produced by several specific neuronal cell bodies in the *hypothalamus* and then stored in the *posterior pituitary gland,* which is attached to the hypothalamus by a thin stalk (see ❙Figure 18-4, p. 647). The hypothalamus controls release of vasopressin from the posterior pituitary into the blood. In negative-feedback fashion, vasopressin secretion is stimulated by a H_2O deficit when the ECF is too concentrated (that is, hypertonic) and H_2O must be conserved for the body, and it is inhibited by a H_2O excess when the ECF is too dilute (that is, hypotonic) and surplus H_2O must be eliminated in urine.

Vasopressin reaches the basolateral membrane of the principal tubular cells lining the distal and collecting tubules through the circulatory system. Here, it binds with V_2 receptors specific for it (❙Figure 14-26). (Vasopressin binds with different V_1 *receptors* on vascular smooth muscle to exert its vasoconstrictor effects; see p. 350.) Binding of vasopressin with its V_2 receptors, which are G-protein-coupled receptors (see p. 117), activates the cyclic AMP (cAMP) second-messenger system within these tubular cells (see p. 123). This binding ultimately increases permeability of the opposite luminal membrane to H_2O by promoting insertion of aquaporins (specifically, *AQP-2*) in this membrane by means of exocytosis. Without these aquaporins, the luminal membrane is impermeable to H_2O. Once H_2O enters the tubular cells from the filtrate through these vasopressin-regulated luminal water channels, it passively leaves the cells down the osmotic gradient across the cells' basolateral membrane to enter the interstitial fluid. The aquaporins in the basolateral membrane of the distal and collecting tubule (*AQP-3* and *AQP-4*) are

always present and open, so this membrane is always permeable to H_2O. By permitting more H_2O to permeate from the lumen into the tubular cells, the additional vasopressin-regulated luminal channels thus increase H_2O reabsorption from the filtrate into the interstitial fluid. The tubular response to vasopressin is graded: The more vasopressin present, the more luminal water channels inserted, and the greater the permeability of the distal and collecting tubules to H_2O. The increase in luminal membrane water channels is not permanent, however. The channels are retrieved by endocytosis when vasopressin secretion decreases and cAMP activity is similarly decreased. Accordingly, H_2O permeability is reduced when vasopressin secretion decreases. These H_2O channels are stored in internalized vesicles ready for reinsertion in the luminal membrane the next time vasopressin secretion increases. This shuttling of AQP-2 into and out of the luminal membrane under vasopressin command provides a means of rapidly controlling H_2O permeability of the distal and collecting tubules, depending on the body's momentary needs.

Vasopressin influences H_2O permeability only in the distal and collecting tubules. It has no influence over the 80% of the filtered H_2O that is obligatorily reabsorbed without control in the proximal tubule and descending limb of the loop of Henle. The ascending limb of Henle's loop is always impermeable to H_2O, even in the presence of vasopressin.
❶ Blood-borne vasopressin binds with its receptor sites on the basolateral membrane of a principal cell in the distal or collecting tubule.

❷ This binding activates the cyclic AMP (cAMP) second-messenger pathway within the cell.

❸ Cyclic AMP increases the opposite luminal membrane's permeability to H_2O by promoting the insertion of vasopressin-regulated AQP-2 water channels into the membrane. This membrane is impermeable to water in the absence of vasopressin.

❹ Water enters the tubular cell from the tubular lumen through the inserted water channels.

❺ Water exits the cell through different, always open water channels (either AQP-3 or AQP-4) permanently positioned at the basolateral border, and then enters the blood, in this way being reabsorbed.

❙Figure 14-26 **Mechanism of action of vasopressin**.

---

[4]Even though textbooks traditionally have tended to use the name *antidiuretic hormone* for this hormone, especially when discussing its actions on the kidney, investigators in the field now prefer *vasopressin*.

Regulation of H₂O Reabsorption in Response to a H₂O Deficit

Regulation of H$_2$O Reabsorption in Response to a H$_2$O Deficit When vasopressin secretion increases in response to a H$_2$O deficit and the permeability of the distal and collecting tubules to H$_2$O accordingly increases, the hypotonic tubular fluid entering the distal part of the nephron can lose progressively more H$_2$O by osmosis into the interstitial fluid as the tubular fluid first flows through the isotonic cortex and then is exposed to the ever-increasing osmolarity of the medullary interstitial fluid as it plunges toward the renal pelvis (❙Figure 14-27a). As the 100 mOsm/L tubular fluid enters the distal tubule and is exposed to a surrounding interstitial fluid of 300 mOsm/L, H$_2$O leaves the tubular fluid by osmosis across the now-permeable tubular cells until the tubular fluid reaches a maximum concentration of 300 mOsm/L by the end of the distal tubule. As this 300 mOsm/L tubular fluid progresses farther into the collecting duct, it is exposed to even higher osmolarity in the surrounding medullary interstitial fluid. Consequently, the tubular fluid loses more H$_2$O by osmosis and becomes further concentrated; only to move farther forward, be exposed to an even higher interstitial fluid osmolarity, and lose even more H$_2$O; and so on.

Under the influence of maximum levels of vasopressin, the tubular fluid can be concentrated up to 1200 mOsm/L by the end of the collecting ducts. The fluid is not modified any further beyond the collecting duct, so what remains in the tubules at this point is urine. As a result of this extensive vasopressin-promoted reabsorption of H$_2$O in the late segments of the tubule, a small volume of urine concentrated up to 1200 mOsm/L can be excreted. As little as 0.3 mL of urine may be formed each minute, less than one third the normal urine flow rate of 1 mL/min. The reabsorbed H$_2$O entering the medullary interstitial fluid is picked up by the peritubular capillaries and returned to the general circulation, thus being conserved for the body.

Although vasopressin promotes H$_2$O conservation by the body, it cannot halt urine production, even when a person is not taking in any H$_2$O, because a minimum volume of H$_2$O must be excreted with the solute wastes. Collectively, the waste products and other constituents eliminated in the urine average 600 milliosmols each day. Because the maximum urine concentration is 1200 mOsm/L, the minimum volume of urine required to excrete these wastes is 500 mL per day (600 milliosmols of wastes per day ÷ 1200 milliosmols per liter of urine = 0.5 liter, [500 mL] per day, or 0.3 mL/min). Thus, under maximal vasopressin influence, 99.7% of the 180 liters of plasma H$_2$O filtered per day is returned to the blood, with an obligatory H$_2$O loss of 0.5 liter.

The kidneys' ability to tremendously concentrate urine to minimize H$_2$O loss when necessary is possible only because of the presence of the vertical osmotic gradient in the medulla. If this gradient did not exist, the kidneys could not produce a urine more concentrated than the body fluids no matter how much vasopressin was secreted because the only driving force for H$_2$O reabsorp-

tion is a concentration differential between the tubular fluid and the interstitial fluid.

Regulation of H₂O Reabsorption in Response to a H₂O Excess Conversely, when a person consumes large quantities of H_2O, the excess H_2O must be removed from the body without simultaneously losing solutes that are critical for maintaining homeostasis. Under these circumstances, no vasopressin is secreted, so the distal and collecting tubules remain impermeable to H_2O. The tubular fluid entering the distal tubule is hypotonic (100 mOsm/L), having lost salt without an accompanying loss of H_2O in the ascending limb of Henle's loop. As this hypotonic fluid passes through the distal and collecting tubules (❙Figure 14-27b), the medullary osmotic gradient cannot exert any influence because the late tubule is impermeable to H_2O. Thus, in the absence of vasopressin, the 20% of the filtered fluid that reaches the distal tubule is not reabsorbed. Meanwhile, excretion of wastes and other urinary solutes remains constant. The net result is a large volume of dilute urine, which helps rid the body of excess H_2O. Urine osmolarity may be as low as 100 mOsm/L— the same as in the fluid entering the distal tubule. Urine flow may be increased up to 25 mL/min in the absence of vasopressin, compared to the normal urine production of 1 mL/min.

The ability to produce urine less concentrated than the body fluids depends on the tubular fluid being hypotonic as it enters the distal part of the nephron. This dilution is accomplished in the ascending limb, as NaCl is actively extruded but H_2O cannot follow. Therefore, the loop of Henle, by simultaneously establishing the medullary osmotic gradient and diluting the tubular fluid before it enters the distal segments, plays a key role in allowing the kidneys to excrete urine that ranges in concentration from 100 to 1200 mOsm/L.

The vasa recta preserve the vertical osmotic gradient by countercurrent exchange.

The renal medulla must be supplied with blood to nourish the tissues in this area and to transport water that is reabsorbed by the loops of Henle and collecting ducts back to the general circulation. In doing so, however, it is critical that circulation of blood through the medulla does not disturb the vertical gradient of hypertonicity established by the loops of Henle. Consider the situation if blood were to flow straight through from the cortex to the inner medulla and then directly into the renal vein (❙Figure 14-28a). Because capillaries are freely permeable to NaCl and H_2O, the blood would progressively pick up salt and lose H_2O through passive fluxes down concentration and osmotic gradients as it flowed through the depths of the medulla. Isotonic blood entering the medulla, on equilibrating with each medullary level, would leave the medulla very hypertonic at 1200 mOsm/L. It would be impossible to establish and maintain the medullary hypertonic gradient because the NaCl

KEY

⟵ = Passive diffusion of H_2O (osmosis)   ⟶ = Passive diffusion of NaCl

❙Figure 14-28 **Countercurrent exchange in the renal medulla.** All values are in mOsm/L. (a) If the blood supply to the renal medulla flowed straight through from the cortex to the inner medulla, the blood would be isotonic on entering but very hypertonic on leaving, having picked up salt and lost H_2O as it equilibrated with the surrounding interstitial fluid at each incremental horizontal level. It would be impossible to maintain the vertical osmotic gradient because the salt pumped out by the ascending limb of Henle's loop would be continuously flushed away by blood flowing through the medulla. (b) Blood equilibrates with the interstitial fluid at each incremental horizontal level in both the descending limb and the ascending limb of the vasa recta, so blood is isotonic as it enters and leaves the medulla. This countercurrent exchange prevents dissolution of the medullary osmotic gradient while providing blood to the renal medulla.

pumped into the medullary interstitial fluid would continuously be carried away by the circulation.

This dilemma is avoided by the hairpin construction of the vasa recta, which, by looping back through the concentration gradient in reverse, allows the blood to leave the medulla and enter the renal vein essentially isotonic to incoming arterial blood (❚Figure 14-28b). As blood passes down the descending limb of the vasa recta, equilibrating with the progressively increasing concentration of the surrounding interstitial fluid, it picks up salt and loses H_2O until it is very hypertonic by the bottom of the loop. Then, as blood flows up the ascending limb, salt diffuses back out into the interstitial fluid, and H_2O reenters the vasa recta as progressively decreasing concentrations are encountered in the surrounding interstitial fluid. This passive exchange of solutes and H_2O between the two limbs of the vasa recta and the interstitial fluid is known as **countercurrent exchange**. Unlike countercurrent multiplication, it does not *establish* the concentration gradient. Rather, it *preserves* (prevents the dissolution of) the gradient. Because blood enters and leaves the medulla at the same osmolarity as a result of countercurrent exchange, the medullary tissue is nourished with blood, yet the incremental gradient of hypertonicity in the medulla is preserved.

Water reabsorption is only partially linked to solute reabsorption.

It is important to distinguish between H_2O reabsorption that mandatorily follows solute reabsorption and reabsorption of "free" H_2O not linked to solute reabsorption.

■ *In the tubular segments permeable to H_2O, solute reabsorption is* always *accompanied by comparable H_2O reabsorption because of osmotic considerations.* Therefore, the total volume of H_2O reabsorbed is determined in large part by the total mass of solute reabsorbed; this is especially true of NaCl because it is the most abundant solute in the ECF.

■ *Solute excretion is* always *accompanied by comparable H_2O excretion because of osmotic considerations.* This fact is responsible for the obligatory excretion of at least a minimal volume of H_2O to accompany waste excretion, even when a person is severely dehydrated. For the same reason, when excess unreabsorbed solute is present in the tubular fluid, its presence exerts an osmotic effect to hold excessive H_2O in the lumen, leading to osmotic diuresis. There are two types of diuresis: osmotic diuresis and water diuresis. **Osmotic diuresis** involves increased excretion of both H_2O and solute caused by excess unreabsorbed solute in the tubular fluid, such as occurs in untreated diabetes mellitus. The large quantity of unreabsorbed glucose that remains in the tubular fluid in people with diabetes osmotically drags H_2O with it into the urine. **Water diuresis,** in contrast, is increased urinary output of H_2O with little or no increase in excretion of solutes.

■ *A loss or gain of pure H_2O that is not accompanied by comparable solute deficit or excess in the body* (that is, "free" H_2O) *leads to changes in ECF osmolarity.* Such an imbalance between H_2O and solute is corrected by partially dissociating H_2O reabsorption from solute reabsorption in the distal portions of

the nephron through the combined effects of vasopressin secretion and the medullary osmotic gradient. Through this mechanism, free H_2O can be reabsorbed without comparable solute reabsorption to correct for hypertonicity of the body fluids. Conversely, a large quantity of free H_2O can be excreted unaccompanied by comparable solute excretion (that is, water diuresis) to rid the body of excess pure H_2O, thus correcting for hypotonicity of the body fluids. Water diuresis is normally a compensation for ingesting too much H_2O.

Excessive water diuresis follows alcohol ingestion. Because alcohol inhibits vasopressin secretion, the kidneys inappropriately lose too much H_2O. Typically, more fluid is lost in the urine than is consumed in the alcoholic beverage, so the body becomes dehydrated despite substantial fluid ingestion.

❚Table 14-3 summarizes how various tubular segments of the nephron handle Na^+ and H_2O and the significance of these processes.

Renal failure has wide-ranging consequences.

Urine excretion and the resulting clearance of wastes and excess electrolytes from the plasma are crucial for maintaining homeostasis. When the functions of both kidneys are so disrupted that they cannot perform their regulatory and excretory functions sufficiently to maintain homeostasis, **renal failure** has set in. Renal failure has a variety of causes, some of which begin elsewhere in the body and affect renal function secondarily. Among the causes are the following:

1. *Infectious organisms,* either blood-borne or gaining entrance to the urinary tract through the urethra
2. *Toxic agents,* such as lead, arsenic, pesticides, or even long-term exposure to high doses of aspirin
3. *Inappropriate immune responses,* such as **glomerulonephritis**, which occasionally follows streptococcal throat infections as antigen–antibody complexes leading to localized inflammatory damage are deposited in the glomeruli (see p. 419)
4. *Obstruction of urine flow* by kidney stones, tumors, or an enlarged prostate gland, with back pressure reducing glomerular filtration and damaging renal tissue
5. An *insufficient renal blood supply* that leads to inadequate filtration pressure, which can occur secondary to circulatory disorders such as heart failure, hemorrhage, shock, or narrowing and hardening of the renal arteries by atherosclerosis

The glomeruli or tubules may be independently affected, or both may be dysfunctional. Regardless of cause, renal failure can manifest itself either as *acute renal failure,* characterized by a sudden onset with rapidly reduced urine formation until less than the essential minimum of around 500 mL of urine is being produced per day, or as *chronic renal failure,* characterized by slow, progressive, insidious loss of renal function. A person may die from acute renal failure, or the condition may be reversible and lead to full recovery. Chronic renal failure, in contrast, is not reversible. Gradual, permanent destruction of renal tissue eventually proves fatal. Chronic renal failure is insidious because up to 75% of the kidney tissue can be destroyed before the loss of kidney function is even noticeable. Because of the

	Na+ REABSORPTION		H2O REABSORPTION	
Tubular Segment	Percentage of Reabsorption in This Segment	Distinguishing Features	Percentage of Reabsorption in This Segment	Distinguishing Features
Proximal tubule	67	Active; uncontrolled; plays a pivotal role in the reabsorption of glucose, amino acids, Cl^-, H_2O, and urea	65	Passive; obligatory osmotic reabsorption following active Na^+ reabsorption
Loop of Henle	25	Active, uncontrolled; NaCl reabsorption from the ascending limb helps establish the medullary interstitial vertical osmotic gradient, which is important in the kidneys' ability to produce urine of varying concentrations and volumes, depending on the body's needs	15	Passive; obligatory osmotic reabsorption from the descending limb as the ascending limb extrudes NaCl into the interstitial fluid (that is, reabsorbs NaCl)
Distal and collecting tubules	8	Active; variable and subject to aldosterone control; important in the regulation of ECF volume and long-term control of blood pressure; linked to K^+ secretion and H^+ secretion	20	Passive; not linked to solute reabsorption; variable quantities of "free" H_2O reabsorption subject to vasopressin control; driving force is the vertical osmotic gradient in the medullary interstitial fluid established by the long loops of Henle; important in regulating ECF osmolarity

abundant reserve of kidney function, only 25% of kidney tissue is needed to adequately maintain all the essential renal excretory and regulatory functions. With less than 25% of functional kidney tissue remaining, however, renal insufficiency becomes apparent. *End-stage renal failure* results when 90% of kidney function has been lost. More than 26 million people in the United States have some extent of kidney disease, which leads to more than 80,000 deaths per year.

We will not sort out the stages and symptoms associated with various renal disorders, but ❙Table 14-4, which summarizes the potential consequences of renal failure, gives you an idea of the broad effects that kidney impairment can have. When the kidneys cannot maintain a normal internal environment, widespread disruption of cell activities can bring about abnormal function in other organ systems as well. By the time end-stage renal failure occurs, literally every body system has become impaired to some extent. The most life-threatening consequences of renal failure are retention of H^+ (causing metabolic acidosis) and K^+ (leading to cardiac malfunction) because these ions are not adequately secreted and eliminated in the urine.

Because chronic renal failure is irreversible and eventually fatal, treatment is aimed at maintaining renal function by alternative methods, such as dialysis and kidney transplantation. (For further explanation of these procedures, see the boxed feature on p. 530, ❙Concepts, Challenges, and Controversies.)

This finishes our discussion of kidney function. For the remainder of the chapter, we focus on the plumbing that stores and carries the urine formed by the kidneys to the outside.

Urine is temporarily stored in the bladder, from which it is emptied by micturition.

Once urine has been formed by the kidneys, it is transmitted through the smooth–muscle walled ureters to the urinary bladder. Urine does not flow through the ureters by gravitational pull alone. Peristaltic (forward-pushing) contractions of the smooth muscle within the ureteral wall propel the urine forward from the kidneys to the bladder. The ureters penetrate the wall of the bladder obliquely, coursing through the wall several centimeters before they open into the bladder cavity. This anatomic arrangement prevents backflow of urine from the bladder to the kidneys when pressure builds up in the bladder. As the bladder fills, the ureteral ends within its wall are compressed closed. Urine can still enter, however, because ureteral contractions generate enough pressure to overcome the resistance and push urine through the occluded ends.

Role of the Bladder The bladder can accommodate large fluctuations in urine volume. The bladder wall consists of smooth muscle lined by a special type of epithelium. It was once assumed that the bladder was an inert sac. However, both the epithelium and the smooth muscle actively participate in the bladder's ability to accommodate large changes in urine volume. The epithelial lining can increase and decrease in surface area by the orderly process of membrane recycling as the bladder alternately fills and empties. Membrane-enclosed cytoplasmic vesicles are inserted by exocytosis into the surface area

▮TABLE 14-4 Potential Ramifications of Renal Failure

Uremic toxicity caused by retention of waste products

    Nausea, vomiting, diarrhea, and ulcers caused by a toxic effect on the digestive system

    Bleeding tendency arising from a toxic effect on platelet function

    Mental changes—such as reduced alertness, insomnia, and shortened attention span, progressing to convulsions and coma—caused by toxic effects on the central nervous system

    Abnormal sensory and motor activity caused by a toxic effect on the peripheral nerves

Metabolic acidosis caused by the inability of the kidneys to adequately secrete H^+ that is continually being added to the body fluids as a result of metabolic activity (*among most life-threatening consequences of renal failure*)

    Altered enzyme activity caused by the action of too much acid on enzymes

    Depression of the central nervous system caused by the action of too much acid interfering with neuronal excitability

Potassium retention resulting from inadequate tubular secretion of K^+ (*among most life-threatening consequences of renal failure*)

    Altered cardiac and neural excitability as a result of changing the resting membrane potential of excitable cells

Sodium imbalances caused by inability of the kidneys to adjust Na^+ excretion to balance changes in Na^+ consumption

    Elevated blood pressure, generalized edema, and congestive heart failure if too much Na^+ is consumed

    Hypotension and, if severe enough, circulatory shock if too little Na^+ is consumed

Phosphate and calcium imbalances arising from impaired reabsorption of these electrolytes

    Disturbances in skeletal structures caused by abnormalities in deposition of calcium phosphate crystals, which harden bone

Loss of plasma proteins as a result of increased "leakiness" of the glomerular membrane

    Edema caused by a reduction in plasma-colloid osmotic pressure

Inability to vary urine concentration as a result of impairment of the countercurrent system

    Hypotonicity of body fluids if too much H_2O is ingested

    Hypertonicity of body fluids if too little H_2O is ingested

Hypertension arising from the combined effects of salt and fluid retention and vasoconstrictor action of excess angiotensin II

Anemia caused by inadequate erythropoietin production

Depression of the immune system caused by toxic levels of wastes and acids

    Increased susceptibility to infections

---

during bladder filling; then the vesicles are withdrawn by endocytosis to shrink the surface area following emptying (see pp. 29, 31 and 77). As is characteristic of smooth muscle, bladder muscle can stretch tremendously without building up bladder wall tension (see p. 293). In addition, the highly folded bladder wall flattens out during filling to increase bladder storage capacity. Because the kidneys continuously form urine, the bladder must have enough storage capacity to preclude the need to continuously get rid of the urine.

Bladder smooth muscle is richly supplied by parasympathetic fibers, stimulation of which causes bladder contraction. If the passageway through the urethra to the outside is open, contraction empties urine from the bladder. The exit from the bladder, however, is guarded by two sphincters, the *internal urethral sphincter* and the *external urethral sphincter.*

Role of the Urethral Sphincters A *sphincter* is a ring of muscle that can variably close off or permit passage through an opening (see p. 264). The **internal urethral sphincter** is smooth muscle and, accordingly, under involuntary control. It

is not really a separate muscle but instead consists of the last part of the bladder. When the bladder is relaxed, the anatomic arrangement of the internal urethral sphincter region closes the bladder outlet.

Farther down the passageway, the urethra is encircled by a layer of skeletal muscle, the **external urethral sphincter**. This sphincter is reinforced by the entire **pelvic diaphragm**, a skeletal muscle sheet that forms the floor of the pelvis and helps support the pelvic organs (see ▮Figure 14-2, p. 494). The motor neurons that supply the external sphincter and pelvic diaphragm fire continuously at a moderate rate unless they are inhibited, keeping these muscles tonically contracted so that they prevent urine from escaping through the urethra. Normally, when the bladder is relaxed and filling, both the internal and the external urethral sphincters are closed to keep urine from dribbling out. Furthermore, because the external sphincter and pelvic diaphragm are skeletal muscle and thus under voluntary control, the person can deliberately tighten them to prevent urination from occurring even when the bladder is contracting and the internal sphincter is open.

Dialysis: Cellophane Tubing or Abdominal Lining as an Artificial Kidney

BECAUSE CHRONIC RENAL FAILURE IS irreversible and eventually fatal, treatment is aimed at maintaining renal function by alternative methods, such as dialysis and kidney transplantation. More than 300,000 people in the United States are currently undergoing dialysis, and this number is expected to climb as the population ages and the incidence of diabetes mellitus, one of the leading causes of kidney failure, continues to rise. End-stage renal failure (less than 10% kidney function) caused by diabetes mellitus is increasing at a rate of more than 11% annually.

The process of dialysis bypasses the kidneys to maintain normal fluid and electrolyte balance and remove wastes artificially. In the original method of dialysis, **hemodialysis**, a patient's blood is pumped through cellophane tubing that is surrounded by a large volume of fluid similar in composition to normal plasma. After dialysis, the blood is returned to the patient's circulatory system. During hemodialysis, about 250 mL of blood is outside of the body at any given time.

Like capillaries, cellophane is highly permeable to most plasma constituents but is impermeable to plasma proteins. As blood flows through the tubing, solutes move across the cellophane down their individual concentration gradients; plasma proteins, however, stay in the blood. Urea and other wastes, which are absent in the dialysis fluid, diffuse out of the plasma into the surrounding fluid, cleaning the blood of these wastes. Plasma constituents that are not regulated by the kidneys and are at normal concentration, such as glucose, do not move across the cellophane into the dialysis fluid because there is no driving force to produce their movement. (The dialysis fluid's glucose concentration is the same as normal plasma glucose concentration.) Electrolytes, such as K^+ and PO_4^{3-}, which are higher than their normal plasma concentrations because the diseased kidneys cannot eliminate excess quantities of these substances, move out of the plasma until equilibrium is achieved between the plasma and the dialysis fluid. Because the dialysis fluid's solute concentrations are maintained at normal plasma values, the solute concentration of the blood returned to the patient after dialysis is essentially normal.

Hemodialysis is repeated as often as necessary to maintain the plasma composition within an acceptable level. Conventionally, it is done three times per week for up to five hours at each session at a treatment center, but newer, more user-friendly, at-home methods dialyze the blood up to six times per week during the day or at night while the person is sleeping. The more frequent methods maintain better stability in plasma constituents than the less frequent methods do.

Another method of dialysis, **continuous ambulatory peritoneal dialysis (CAPD)**, uses the peritoneal membrane (the lining of the abdominal cavity) as the dialysis membrane. With this method, 2 liters of dialysis fluid are inserted into the patient's abdominal cavity through a permanently implanted catheter. Urea, K^+, and other wastes and excess electrolytes diffuse from the plasma across the peritoneal membrane into the dialysis fluid, which is drained off and replaced several times a day. The CAPD method offers several advantages: The patient can self-administer it, the patient's blood is continuously purified and adjusted, and the patient can engage in normal activities while dialysis is being accomplished. One drawback is increased risk of peritoneal infections.

Although dialysis can remove metabolic wastes and foreign compounds and help maintain fluid and electrolyte balance within acceptable limits, this plasma-cleansing technique cannot make up for the failing kidneys' reduced ability to produce hormones (erythropoietin and renin) and to activate vitamin D. One promising new technique under investigation incorporates living kidney cells derived from pigs within a dialysislike machine. Standard ultrafiltration technology like that used in hemodialysis purifies and adjusts the plasma as usual. Importantly, the living cells not only help maintain even better control of plasma constituents, especially K^+, but also add the deficient renal hormones to the plasma passing through the machine and activate vitamin D.

For now, transplanting a healthy kidney from a donor is another option for treating chronic renal failure. A kidney is one of the few transplants that can be provided by a living donor. Because 25% of the total kidney tissue can maintain the body, both the donor and the recipient have ample renal function with only one kidney each. The biggest problem with transplants is the possibility that the patient's immune system rejects the organ. Risk of rejection can be minimized by matching the tissue types of the donor and the recipient as closely as possible (the best donor choice is usually a close relative), coupled with immunosuppressive drugs. More than 15,000 kidney transplants are performed in the United States each year, with 60,000 more people on waiting lists for a donor kidney.

Another new technique on the horizon for treating end-stage renal failure is a continuously functioning artificial kidney that mimics natural renal function. Using nanotechnology (very small-scale devices), researchers are working on a device that contains two membranes, the first for filtering blood like the glomerulus does and the second for mimicking the renal tubules by selectively altering the filtrate. The device, which will directly process the blood on an ongoing basis without using dialysis fluid, will return important substances to the body while discharging unneeded substances to a disposable bag that will serve as an external bladder. Scientists have developed computer models for such a device and thus far have created the filtering membrane.

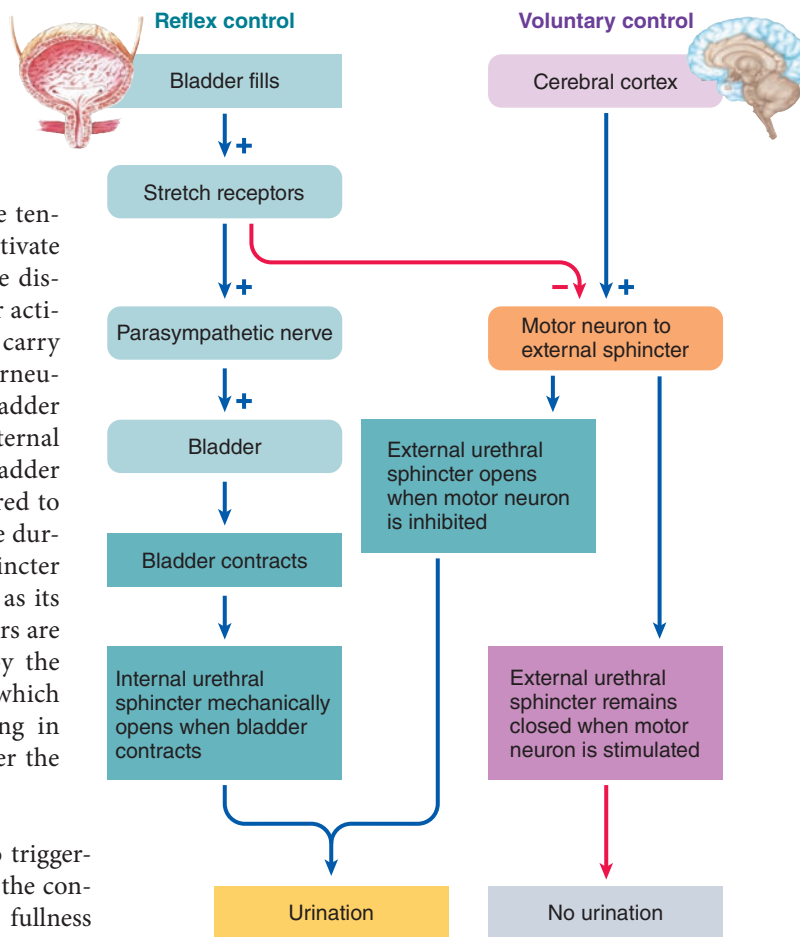
Micturition Reflex **Micturition**, or **urination**, the process of bladder emptying, is governed by two mechanisms: the micturition reflex and voluntary control. The **micturition reflex** is initiated when stretch receptors within the bladder wall are stimulated (❙Figure 14-29). The bladder in an adult can accommodate 250 to 400 mL of urine before the tension within its walls begins to rise sufficiently to activate the stretch receptors (❙Figure 14-30). The greater the distension beyond this, the greater the extent of receptor activation. Afferent fibers from the stretch receptors carry impulses into the spinal cord and eventually, via interneurons, stimulate the parasympathetic supply to the bladder and inhibit the motor-neuron supply to the external sphincter. Parasympathetic stimulation of the bladder causes it to contract. No special mechanism is required to open the internal sphincter; changes in bladder shape during contraction mechanically pull the internal sphincter open. Simultaneously, the external sphincter relaxes as its motor neuron supply is inhibited. Now both sphincters are open, and urine is expelled through the urethra by the force of bladder contraction. This micturition reflex, which is entirely a spinal reflex, governs bladder emptying in infants. As soon as the bladder fills enough to trigger the reflex, the baby automatically wets.

Voluntary Control of Micturition In addition to triggering the micturition reflex, bladder filling gives rise to the conscious urge to urinate. The perception of bladder fullness appears before the external sphincter reflexly relaxes, warning that micturition is imminent. As a result, voluntary control of micturition, learned during toilet training in early childhood, can override the micturition reflex so that bladder emptying can take place at your convenience rather than when bladder filling first activates the stretch receptors. If the time when the micturition reflex is initiated is inopportune for urination, you can voluntarily prevent bladder emptying by deliberately tightening your external sphincter and pelvic diaphragm. Voluntary excitatory impulses from the cerebral cortex override the reflex inhibitory input from the stretch receptors to the involved motor neurons (the relative balance of excitatory and inhibitory postsynaptic potentials [EPSPs and IPSPs]; see p. 106), keeping these muscles contracted so that no urine is expelled.

Urination cannot be delayed indefinitely. As the bladder continues to fill, reflex input from the stretch receptors increases with time. Finally, reflex inhibitory input to the external sphincter motor neuron becomes so powerful that it can no longer be overridden by voluntary excitatory input, so the sphincter relaxes and the bladder uncontrollably empties.

Micturition can also be deliberately initiated, even though the bladder is not distended, by voluntarily relaxing the external sphincter and pelvic diaphragm. Lowering of the pelvic floor allows the bladder to drop downward, which simultaneously pulls open the internal urethral sphincter and stretches the bladder wall. The subsequent activation of the stretch receptors brings about bladder contraction by the micturition reflex. Voluntary bladder emptying may be further assisted by contracting the abdominal wall and respiratory diaphragm. The resulting

increase in intra-abdominal pressure squeezes down on the bladder to facilitate its emptying.

Clinical Note **Urinary Incontinence** **Urinary incontinence**, or inability to prevent discharge of urine, occurs when descending pathways in the spinal cord that mediate voluntary control of the external sphincter and pelvic dia-


❙Figure 14-29 **Reflex and voluntary control of micturition**.
❙Figure 14-30 **Pressure changes within the urinary bladder as the bladder fills with urine.**

The Urinary System | **531**

phragm are disrupted, as in spinal-cord injury. Because the components of the micturition reflex arc are still intact in the lower spinal cord, bladder emptying is governed by an uncontrollable spinal reflex, as in infants. A lesser degree of incontinence characterized by urine escaping when bladder pressure suddenly increases transiently, such as during coughing or sneezing, can result from impaired sphincter function. This is common in women who have borne children or in men whose sphincters have been injured during prostate surgery.

Check Your Understanding 14.5

1. State how the plasma clearance rate for each of the following substances compares with the GFR: (1) a substance that is filtered but not reabsorbed or secreted, (2) a substance that is filtered and reabsorbed, and (3) a substance that is filtered and secreted.

2. Tell which nephron component establishes, which component preserves, and which component uses the vertical osmotic gradient in the renal medulla.

3. Explain how vasopressin increases the permeability of the distal and collecting tubules to H_2O.

4. Describe the micturition reflex.

Homeostasis: Chapter in Perspective

The kidneys contribute to homeostasis more extensively than any other single organ. They regulate the electrolyte composition, volume, osmolarity, and pH of the internal environment and eliminate all the waste products of bodily metabolism except for respiration-removed CO_2. They accomplish these regulatory functions by eliminating in the urine substances the body doesn't need, such as metabolic wastes and excess quantities of ingested salt or water, while conserving useful substances. The kidneys can maintain the plasma constituents they regulate within the narrow range compatible with life, despite wide variations in intake and losses of these substances through other avenues. Illustrating the magnitude of the kidneys' task, about a quarter of the blood pumped into the systemic circulation goes to the kidneys to be adjusted and purified, with only three quarters of the blood being used to supply all the other tissues.

The kidneys contribute to homeostasis in the following specific ways:

Regulatory Functions

■ The kidneys regulate the quantity and concentration of most ECF electrolytes, including those important in maintaining proper neuromuscular excitability.

■ They help maintain proper pH by eliminating excess H^+ (acid) or HCO_3^- (base) in the urine.

■ They help maintain proper plasma volume, which is important in long-term regulation of blood pressure, by controlling the body's salt balance. The ECF volume, including plasma volume, reflects total salt load in the ECF because Na^+ and its attendant anion, Cl^-, are responsible for more than 90% of the ECF's osmotic (water-holding) activity.

■ The kidneys maintain water balance in the body, which is important in maintaining proper ECF osmolarity (concentration of solutes). This role is essential in maintaining stable cell volume by keeping water from osmotically moving into or out of the cells, thus preventing them from swelling or shrinking, respectively.

Excretory Functions

■ The kidneys excrete metabolic end products in the urine. If allowed to accumulate, these wastes are toxic to cells.

■ The kidneys excrete many foreign compounds that enter the body.

Hormonal Functions

■ The kidneys produce erythropoietin, the hormone that stimulates bone marrow to produce red blood cells. This action contributes to homeostasis by helping maintain the optimal O_2 content of blood. More than 98% of O_2 in the blood is bound to hemoglobin within red blood cells.

■ They produce renin, the hormone that initiates the renin–angiotensin–aldosterone pathway for controlling renal tubular Na^+ reabsorption, which is important in long-term maintenance of plasma volume and blood pressure.

Metabolic Functions

■ The kidneys help activate vitamin D, which is essential for Ca^{2+} absorption from the digestive tract. Calcium, in turn, exerts a variety of homeostatic functions.

Review Exercises

Reviewing Terms and Facts

1. Part of the kidneys' energy supply is used to accomplish glomerular filtration. *(True or false?)*

2. Sodium reabsorption is under hormonal control throughout the length of the tubule. *(True or false?)*

3. Glucose and amino acids are reabsorbed by secondary active transport. *(True or false?)*

4. Solute excretion is always accompanied by comparable H_2O excretion. *(True or false?)*

5. Water excretion can occur without comparable solute excretion. *(True or false?)*

6. The functional unit of the kidneys is the _____.

7. _____ is the only ion actively reabsorbed in the proximal tubule and actively secreted in the distal and collecting tubules.

8. The daily minimum volume of obligatory H_2O loss that must accompany excretion of wastes is _____ mL.

9. Indicate whether each of the following factors would (a) increase or (b) decrease the GFR if everything else remained constant.
   1. a rise in Bowman's capsule pressure resulting from ureteral obstruction by a kidney stone
   2. a fall in plasma protein concentration resulting from loss of these proteins from a large burned surface of skin
   3. a dramatic fall in arterial blood pressure following severe hemorrhage (<80 mm Hg)
   4. afferent arteriolar vasoconstriction
   5. tubuloglomerular feedback response to decreased salt delivery to the distal tubule
   6. myogenic response of an afferent arteriole stretched as a result of an increased driving blood pressure
   7. ↑ sympathetic activity to the afferent arterioles
   8. contraction of mesangial cells
   9. contraction of podocytes

10. Which of the following filtered substances is normally *not* present in the urine at all?
    a. Na^+
    b. PO_4^{3-}
    c. urea
    d. H^+
    e. glucose

11. Reabsorption of which of the following substances is *not* linked in some way to active Na^+ reabsorption?
    a. glucose
    b. PO_4^{3-}
    c. H_2O
    d. urea
    e. Cl^-

In questions 12–14, indicate, by writing the identifying letters in the proper order in the blanks, the proper sequence through which fluid flows as it traverses the structures in question.

12. a. ureter   ____ ____ ____ ____ ____
    b. kidney
    c. urethra
    d. bladder
    e. renal pelvis

13. a. efferent arteriole   ____ ____ ____ ____ ____ ____
    b. peritubular capillaries
    c. renal artery
    d. glomerulus
    e. afferent arteriole
    f. renal vein

14. a. loop of Henle   ____ ____ ____ ____ ____ ____ ____
    b. collecting duct
    c. Bowman's capsule
    d. proximal tubule
    e. renal pelvis
    f. distal tubule
    g. glomerulus

15. Using the answer code on the right, indicate what the osmolarity of the tubular fluid is at each of the designated points in a nephron:
    1. Bowman's capsule
    2. end of proximal tubule
    3. tip of Henle's loop of juxtamedullary nephron (at the bottom of the U-turn)
    4. end of Henle's loop of juxtamedullary nephron (before entry into distal tubule)
    5. end of collecting duct

    (a) isotonic (300 mOsm/L)
    (b) hypotonic (100 mOsm/L)
    (c) hypertonic (1200 mOsm/L)
    (d) ranging from hypotonic to hypertonic (100 mOsm/L to 1200 mOsm/L)

Understanding Concepts
(Answers at www.cengagebrain.com)

1. List the functions of the kidneys.

2. Describe the anatomy of the urinary system. Describe the components of a nephron.

3. Describe the three basic renal processes; indicate how they relate to urine excretion.

4. Distinguish between *secretion* and *excretion*.

5. Discuss the forces involved in glomerular filtration. What is the average GFR?

6. How is GFR regulated as part of the baroreceptor reflex?

The Urinary System   **533**

7. Why do the kidneys receive a seemingly disproportionate share of the cardiac output? What percentage of renal blood flow is normally filtered?

8. List the steps in transepithelial transport.

9. Distinguish between active and passive reabsorption.

10. Describe all the tubular transport processes that are linked to the basolateral Na^+–K^+ ATPase carrier.

11. Describe the renin–angiotensin–aldosterone system. What are the functions of aldosterone and angiotensin II?

12. Discuss the source and functions of ANP and BNP.

13. Compare two substances that display a T_m, one that *is* and one that *is not* regulated by the kidneys.

14. What is the importance of tubular secretion? What are the most important secretory processes?

15. What is the average rate of urine formation?

16. Define *plasma clearance*.

17. What establishes a vertical osmotic gradient in the medullary interstitial fluid? Of what importance is this gradient?

18. Discuss vasopressin's function and mechanism of action.

19. Compare countercurrent multiplication and countercurrent exchange.

20. Describe the transfer of urine to, the storage of urine in, and the emptying of urine from the bladder.

Solving Quantitative Exercises

1. Two patients are voiding protein in their urine. To determine whether this proteinuria indicates a serious problem, a physician injects small amounts of inulin and PAH into each patient. Recall that inulin is freely filtered and neither secreted nor reabsorbed in the nephron and that PAH at this concentration is completely removed from the blood by tubular secretion. The data collected are given in the following table, where $[I]_u$ and $[PAH]_u$ are the concentrations of inulin or PAH in the urine (in mM), respectively; $[I]_p$ and $[PAH]_p$ are the concentrations of these substances in the plasma; and v_u is the flow rate of urine (in mL/min).

Patient	$[I]_u$	$[I]_p$	$[PAH]_u$	$[PAH]_p$	v_u
1	25	2	186	3	10
2	31	1.5	300	4.5	6

a. Calculate each patient's GFR and renal plasma flow.

b. Calculate the renal blood flow for each patient, assuming both have a hematocrit of 0.45.

c. Calculate the filtration fraction for each patient.

d. Which of the values calculated for each patient are within the normal range?

e. Which values are abnormal? What could be causing these deviations from normal?

2. What is the filtered load of sodium if inulin clearance is 125 mL/min and the sodium concentration in plasma is 145 mM?

3. Calculate a patient's rate of urine production, given that his inulin clearance is 125 mL/min and his urine and plasma concentrations of inulin are 300 mg/liter and 3 mg/liter, respectively.

4. If the urine concentration of a substance is 7.5 mg/mL of urine, its plasma concentration is 0.2 mg/mL of plasma, and the urine flow rate is 2 mL/min, what is the clearance rate of the substance? Is the substance being reabsorbed or secreted by the kidneys?

Applying Clinical Reasoning

Marcus T. has noted a gradual decrease in his urine flow rate and is now experiencing difficulty in initiating micturition. He needs to urinate frequently, and often he feels as if his bladder is not empty even though he has just urinated. Analysis of Marcus's urine reveals no abnormalities. Are his urinary tract symptoms most likely caused by kidney disease, a bladder infection, or prostate enlargement?

Thinking at a Higher Level

1. What would the clinical implications be on finding each of the following substances in a 72-year-old, sedentary person's urine: (1) glucose, (2) protein, (3) sodium?

2. The juxtamedullary nephrons of animals adapted to survive with minimal water consumption, such as desert rats, have relatively much longer loops of Henle than humans have. Of what benefit would these longer loops be?

3. *Conn's syndrome* is an endocrine disorder brought about by a tumor of the adrenal cortex that secretes excessive aldosterone in uncontrolled fashion. Given what you know about the functions of aldosterone, describe what the most prominent features of this condition would be.

4. Because of a mutation, a child was born with an ascending limb of Henle that was water permeable. What would be the minimum/maximum urine osmolarities (in units of mOsm/L) the child could produce?

   a. 100/300

   b. 300/1200

   c. 100/100

   d. 1200/1200

   e. 300/300

5. An accident victim suffers permanent damage of the lower spinal cord and is paralyzed from the waist down. Describe what governs bladder emptying in this individual.

Fluid and Acid–Base Balance

Yellow Dog Productions/Photographer's Choice/Getty Images

Maintaining fluid balance. This woman running a road race grabs a cup of water to replace fluid lost in sweat. A thirst center in the hypothalamus drives fluid ingestion. Input must equal output to keep a body constituent such as water in balance.

CHAPTER AT A GLANCE

15.1 Balance Concept

15.2 Fluid Balance

15.3 Acid–Base Balance

Homeostasis Highlights

Homeostasis depends on maintaining a balance between the input and the output of all constituents in the internal fluid environment. Regulation of **fluid balance** involves two separate components: control of extracellular fluid (ECF) volume, of which circulating plasma volume is a part, and control of ECF osmolarity (solute concentration). The kidneys control ECF volume by maintaining **salt balance** and control ECF osmolarity by maintaining **water balance**. The kidneys maintain this balance by adjusting the output of salt and water in the urine as needed to compensate for variable input and abnormal losses of these constituents.

Similarly, the kidneys help maintain **acid–base balance** by adjusting the urinary output of hydrogen ion (acid) and bicarbonate ion (base) as needed. Also contributing to acid–base balance are the buffer systems in the body fluids, which chemically compensate for changes in hydrogen ion concentration, and the lungs, which can adjust the rate at which they excrete hydrogen ion–generating CO_2.

15.1 Balance Concept

The cells of complex multicellular organisms are able to survive and function only within a narrow range of composition of the ECF, the internal fluid environment that bathes them.

The internal pool of a substance is the amount of that substance in the ECF.

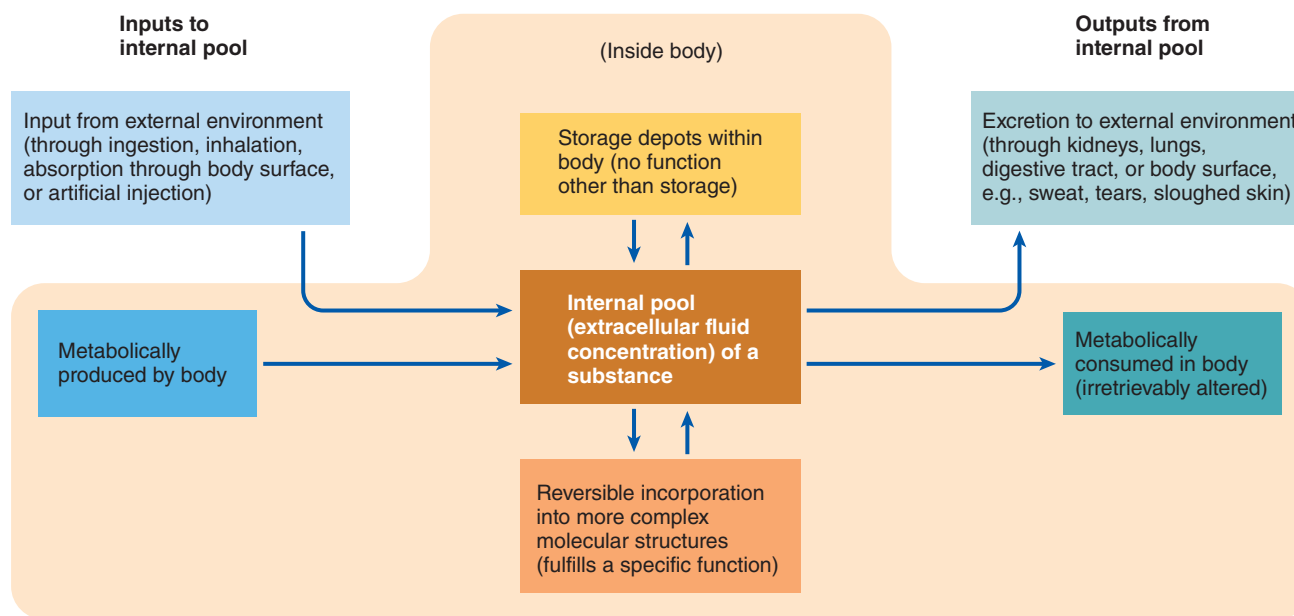
The quantity of any particular substance in the ECF is a readily available internal **pool**. The amount of the substance in the pool may be increased either by transferring more in from the external environment (usually by ingestion) or by metabolically producing it within the body (❚Figure 15-1). Substances may be removed from the body by being excreted to the outside or by being used up in a metabolic reaction. If the quantity of a substance is to remain stable within the body, its **input** through ingestion or metabolic production must be balanced by an equal **output** through excretion or metabolic consumption. This relationship, known as the **balance concept**, is extremely important in maintaining homeostasis. Not all input and output pathways apply to every body-fluid constituent. For example, salt is not synthesized or used up by the body, so maintaining a stable salt concentration in the body fluids depends entirely on a balance between salt ingestion and salt excretion.

For some ECF constituents, the ECF pool is further altered by transferring this specific constituent into or out of storage within the body. If the body as a whole has a surplus or deficit of a particular stored substance, the storage site can be expanded or partially depleted to maintain the ECF concentration of the substance within homeostatically prescribed limits. For example, after absorption of a meal, when more glucose is entering the plasma than is being consumed by the cells, the extra glu-cose can be temporarily stored, in the form of glycogen, in muscle and liver cells. This storage depot can then be tapped between meals as needed to maintain the plasma glucose level when no new nutrients are being added to the blood by eating.

Another possible internal exchange between the pool and the rest of the body is reversible incorporation of a plasma constituent into a more complex molecular structure to serve a specific purpose. For example, iron is incorporated into hemoglobin within the red blood cells but is released intact back into the body fluids when the red blood cells degenerate.

To maintain stable balance of an ECF constituent, its input must equal its output.

When total body input of a particular substance equals its total body output, a **stable balance** exists. When the gains via input for a substance exceed its losses via output, a **positive balance** exists. The result is an increase in the total amount of the substance in the body. In contrast, when losses for a substance exceed its gains, a **negative balance** exists and the total amount of the substance in the body decreases.

Changing the magnitude of any input or output pathways for a given substance can alter its plasma concentration. To maintain homeostasis, any change in input must be balanced by a corresponding change in output (for example, increased salt intake must be matched by a corresponding increase in salt output in the urine), and conversely, increased losses must be compensated for by increased intake. Thus, maintaining a stable balance requires control. However, not all input and output pathways are regulated to maintain balance. Generally, input of various plasma constituents is poorly controlled or not controlled at all. We frequently ingest salt and H_2O, for example, not because we need them but because we want them, so the


❚Figure 15-1 **Inputs to and outputs from the internal pool of a body constituent.**
FIGURE FOCUS: *Indicate which of the pathways into and out of the internal pool shown in the figure are applicable for phosphate (PO_4^{3-}). Review on pp. 512 and 529 what you have already learned about phosphate handling in the body.*

intake of salt and H_2O is highly variable. Likewise, hydrogen ion (H^+) is uncontrollably generated internally and added to the body fluids. Salt, H_2O, and H^+ can also be lost to the external environment to varying degrees through the digestive tract (vomiting), skin (sweating), and elsewhere without regard for the salt, H_2O, or H^+ balance in the body. Compensatory adjustments in the urinary excretion of these substances maintain the body fluids' volume and salt and acid composition within the extremely narrow homeostatic range compatible with life despite the wide variations in input and unregulated losses of these plasma constituents.

The rest of this chapter is devoted to discussing the regulation of fluid balance (maintaining salt and H_2O balance) and acid–base balance (maintaining H^+ balance).

Check Your Understanding 15.1

1. List the possible inputs to and outputs from the internal pool of a given body constituent.

2. Def ne *stable balance, positive balance,* and *negative balance.*

15.2 Fluid Balance

Water is by far the most abundant component of the body, averaging 60% of body weight but ranging from 40% to 80%. The H_2O content of an individual remains fairly constant because the kidneys efficiently regulate H_2O balance, but the percentage of body H_2O varies from person to person. The main reason for the wide range in body H_2O among individuals is their variable amount of adipose tissue (fat). Adipose tissue has a low H_2O percentage compared to other tissues. Plasma, as you might suspect, is more than 90% H_2O. Even the soft tissues such as skin, muscles, and internal organs consist of 70% to 80% H_2O. The relatively drier skeleton is only 22% H_2O. Fat, however, is the driest tissue of all, having only 10% H_2O content. Accordingly, a high body H_2O percentage is associated with leanness and a low body H_2O percentage with obesity because a larger proportion of the overweight body consists of relatively dry fat.

Body water is distributed between the ICF and the ECF compartments.

Body H_2O is distributed between two major fluid compartments: fluid within the cells, or **intracellular fluid (ICF)**, and fluid surrounding the cells, or **extracellular fluid (ECF)** (▮Table 15-1). (The terms *water [H_2O]* and *fluid* are commonly used interchangeably. Although this usage is not entirely accurate, because it ignores the solutes in body fluids, it is acceptable when discussing total volume of fluids because the major proportion of these fluids consists of H_2O.)

Proportion of H_2O in the Major Fluid Compartments
The ICF compartment composes about two thirds of the total body H_2O. Even though each cell contains a unique mixture of constituents, these trillions of minute fluid compartments are

▮TABLE 15-1 Major Body Fluid Compartments

Compartment	Volume of Fluid (in Liters)	Percentage of Body Fluid	Percentage of Body Weight
Total body fluid	42	100	60
Intracellular fluid (ICF)	28	67	40
Extracellular fluid (ECF)	14	33	20
Plasma	2.8	6.6 (20% of ECF)	4
Interstitial fluid	11.2	26.4 (80% of ECF)	16

similar enough to be considered collectively as one large fluid compartment.

The remaining third of the body H_2O found in the ECF compartment is further subdivided into plasma and interstitial fluid. **Plasma**, the fluid portion of blood, makes up about a fifth of the ECF volume. **Interstitial fluid**, the fluid that lies in the spaces between cells and makes exchanges with the cells, represents the other four fifths of the ECF compartment.

Minor ECF Compartments Two other minor categories are included in the ECF: lymph and transcellular fluid. **Lymph** is the fluid being returned from the interstitial fluid to the plasma by means of the lymphatic system, where it is filtered through lymph nodes for immune defense purposes (see pp. 358 and 405). **Transcellular fluid** consists of a number of small, specialized fluid volumes, all of which are secreted by specific cells into a particular body cavity to perform some specialized function. Transcellular fluid includes *cerebrospinal fluid* (surrounding, cushioning, and nourishing the brain and spinal cord); *intraocular fluid* (maintaining the shape of and nourishing the eye); *synovial fluid* (lubricating and serving as a shock absorber for the joints); *pericardial, intrapleural,* and *peritoneal fluids* (lubricating movements of the heart, lungs, and intestines, respectively); and the *digestive juices* (digesting ingested foods).

Although these fluids are extremely important functionally, they represent an insignificant fraction of total body H_2O. Furthermore, the transcellular compartment as a whole usually does not reflect changes in the body's fluid balance. For example, cerebrospinal fluid does not decrease in volume when the body as a whole is experiencing a negative H_2O balance. This is not to say that these fluid volumes never change. Localized changes in a particular transcellular fluid compartment can occur pathologically (such as too much intraocular fluid accumulating in the eyes of people with glaucoma; see p. 193), but such a localized fluid disturbance does not affect the fluid balance of the body. Therefore, the transcellular compartment can usually be ignored when dealing with problems of fluid balance. The main exception to this generalization occurs when diges-

tive juices are abnormally lost from the body during heavy vomiting or diarrhea, which can bring about a fluid imbalance.

Plasma and interstitial fluid are similar in composition, but ECF and ICF differ markedly.

Several barriers separate the body-fluid compartments, limiting the movement of H_2O and solutes among the various compartments to differing degrees.

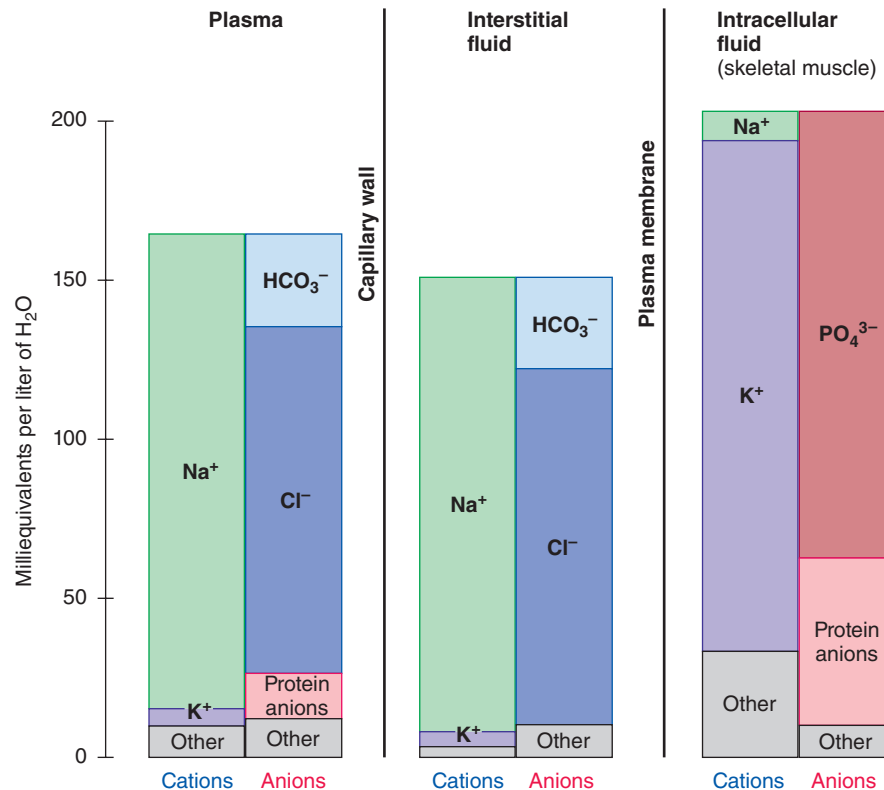
The Barrier Between Plasma and Interstitial Fluid: Blood Vessel Walls

The two components of the ECF—plasma and interstitial fluid—are separated by the walls of the blood vessels. However, H_2O and all plasma constituents except for plasma proteins are continuously and freely exchanged between plasma and interstitial fluid by passive means across the thin, pore-lined capillary walls. Accordingly, plasma and interstitial fluid are nearly identical in composition, except that interstitial fluid lacks plasma proteins. Any change in one of these ECF compartments is quickly reflected in the other compartment because they are constantly mixing.

The Barrier Between ECF And ICF: Cellular Plasma Membranes

In contrast to the similar composition of plasma and interstitial fluid, the composition of the ECF differs considerably from that of the ICF (❚Figure 15-2). Each cell is surrounded by a highly selective plasma membrane that permits passage of certain materials while excluding others. Movement through the membrane barrier occurs by both passive and active means and may be highly discriminating (see ❚Table 3-2, p. 78). Among the major differences between ECF and ICF are (1) the presence of cell proteins in the ICF that cannot permeate the enveloping membranes to leave the cells and (2) the unequal distribution of Na^+ and K^+ and their attendant anions (negatively charged ions) as a result of the action of the membrane-bound Na^+–K^+ pump present in all cells. Because this pump actively transports Na^+ out of and K^+ into cells, Na^+ is the primary ECF cation (positively charged ion) and K^+ is the primary ICF cation (see p. 73; also see ❚Table 3-3, p. 80).

Except for the extremely small, electrically unbalanced portion of the total intracellular and extracellular ions involved in membrane potential, most ECF and ICF ions are electrically balanced. In the ECF, Na^+ is accompanied primarily by the anion chloride (Cl^-) and to a lesser extent by bicarbonate (HCO_3^-). The major intracellular anions are phosphate (PO_4^{3-}) and the negatively charged proteins trapped within the cell.

The movement of H_2O between plasma and interstitial fluid across capillary walls is governed by relative imbalances between capillary blood pressure (a fluid, or hydrostatic, pressure) and colloid osmotic pressure (see pp. 356–357). The net transfer of


❚Figure 15-2 Ionic composition of the major body-fluid compartments.

H_2O between the interstitial fluid and the ICF across the cellular plasma membranes occurs as a result of osmotic effects alone (see p. 68). The hydrostatic pressures of the interstitial fluid and ICF are both extremely low and fairly constant. All cells are freely permeable to H_2O.

Fluid balance is maintained by regulating ECF volume and osmolarity.

All exchanges of H_2O and other constituents between the ICF and the external world must occur through the ECF, so the ECF serves as an intermediary between the cells and the external environment. Water added to the body fluids always enters the ECF first, and fluid always leaves the body via the ECF.

Plasma is the only fluid that can be acted on directly to control its volume and composition. This fluid circulates through all the reconditioning organs that perform homeostatic adjustments (see p. 336). However, because of the free exchange across the capillary walls, if the volume and composition of the plasma are regulated, the volume and composition of the interstitial fluid bathing the cells are likewise regulated. Thus, any control mechanism that operates on plasma in effect regulates the entire ECF. The ICF in turn is influenced by changes in the ECF to the extent permitted by the permeability of membrane barriers surrounding the cells.

Two factors are regulated to maintain **fluid balance** in the body: ECF volume and ECF osmolarity. Although regulation of these two factors is interrelated, both depending on the relative NaCl and H_2O loads in the body, the reasons why and the mechanisms by which they are controlled are notably different:

1. *ECF volume* must be closely regulated to help *maintain blood pressure.* Maintaining *salt balance* is of primary importance in the long-term regulation of ECF volume.

2. *ECF osmolarity* must be closely regulated to *prevent swelling or shrinking of cells.* Maintaining *water balance* is of primary importance in regulating ECF osmolarity.

Control of ECF volume is important in the long-term regulation of blood pressure.

A reduction in ECF volume causes a fall in arterial blood pressure by decreasing plasma volume. Conversely, expanding ECF volume raises arterial blood pressure by increasing plasma volume. Two compensatory measures come into play to transiently adjust blood pressure until the ECF volume can be restored to normal. Let us review them.

Short-Term Control Measures to Maintain Blood Pressure

1. *The baroreceptor reflex alters both cardiac output and total peripheral resistance* to adjust blood pressure in the proper direction through autonomic nervous system effects on the heart and blood vessels (see p. 367). Cardiac output and total peripheral resistance are both increased to raise blood pressure when it falls too low, and conversely, both are decreased to reduce blood pressure when it rises too high.

2. *Fluid shifts occur temporarily and automatically between plasma and interstitial fluid* as a result of changes in the balance of hydrostatic and osmotic forces acting across the capillary walls that arise when plasma volume deviates from normal (see p. 357). A reduction in plasma volume is partially compensated for by a shift of fluid out of the interstitial compartment into the blood vessels, expanding the circulating plasma volume at the expense of the interstitial compartment. Conversely, when plasma volume is too large, much of the excess fluid shifts into the interstitial compartment.

These two measures provide temporary relief to help keep blood pressure fairly constant, but they are not long-term solutions. Furthermore, these short-term compensatory measures have a limited ability to minimize a change in blood pressure. For example, if plasma volume is too inadequate, blood pressure remains too low no matter how vigorous the pump action of the heart, how constricted the resistance vessels, or what proportion of interstitial fluid shifts into the blood vessels.

Long-Term Control Measures to Maintain Blood Pressure
In the long run, other compensatory measures come into play to restore ECF volume to normal. Long-term regulation of blood pressure rests with the kidneys and the thirst mechanism, which control urinary output and fluid intake, respectively. In so doing, they make needed fluid exchanges between the ECF and the external environment to regulate the body's total fluid volume. Accordingly, they have an important long-term influence on arterial blood pressure. Of these measures, control of urinary output by the kidneys is the most crucial for maintaining blood pressure. You will see why as we discuss these long-term mechanisms in more detail.

Control of salt balance is primarily important in regulating ECF volume.

To review, sodium (Na^+) and its accompanying anion chloride (Cl^-) account for more than 90% of the ECF osmotic activity. As the kidneys conserve salt (NaCl) by actively reabsorbing Na^+, with Cl^- passively following, they automatically conserve H_2O because H_2O comes along osmotically. This retained salt solution is isotonic (see p. 69). The more salt in the ECF, the more H_2O in the ECF. The *concentration* of salt is not changed by changing the *total amount* of salt in the body (that is, by changing the Na^+ load) because H_2O always follows salt to maintain osmotic equilibrium—in other words, to maintain the normal concentration of salt. A reduced salt load leads to decreased H_2O retention, so the ECF remains isotonic but reduced in volume. The *Na^+ load* therefore determines the ECF volume, and appropriately, regulation of ECF volume depends primarily on controlling salt balance.

To maintain salt balance at a set level, salt input must equal salt output, thus preventing salt accumulation or deficit in the body. We now look at control of salt input and output.

Poor Control of Salt Intake The only avenue for salt input is ingestion, which typically is well in excess of the body's need for replacing obligatory salt losses. In our example of a typical daily salt balance (ITable 15-2), salt intake is 10 g per day; yet 0.5 g of salt per day is adequate to replace the small amounts of salt usually lost in sweat and feces. (The average American salt intake is about 8.5 to 10 g per day, although many people are consciously reducing their salt intake.)

Because humans typically consume salt in excess of our needs, obviously our salt intake is not well controlled. Carnivores (meat eaters) and omnivores (eaters of meat and plants, like humans), which naturally get enough salt in fresh meat (meat contains an abundance of salt-rich ECF), normally do not display a physiological appetite to seek additional salt. In contrast, herbivores (plant eaters), which lack salt naturally in their diets, develop salt hunger and will travel miles to a salt lick. Humans have a hedonistic (pleasure-seeking) rather than a regulatory appetite for salt; we consume salt because we like it rather than because we have a physiological need.

ITABLE 15-2 Daily Salt Balance

SALT INPUT		SALT OUTPUT	
Avenue	Amount (g/day)	Avenue	Amount (g/day)
Ingestion	10.0	Obligatory loss in sweat and feces	0.5
		Controlled excretion in urine	9.5
Total input	10.0	**Total output**	10.0

Precise Control of Salt Output in the Urine To maintain salt balance, excess ingested salt must be excreted in the urine. The three avenues for salt output are obligatory loss of salt in *sweat* and *feces* and controlled excretion of salt in *urine* (❙Table 15-2). The total amount of sweat produced is unrelated to salt balance, being determined instead by factors that control body temperature. The small salt loss in feces is not subject to control. Except when sweating heavily or during diarrhea, the body uncontrollably loses only about 0.5 g of salt per day. This amount is the only salt that normally needs to be replaced by salt intake.

Because salt consumption is typically far more than the meager amount needed to compensate for uncontrolled losses, the kidneys precisely excrete the excess salt in the urine to maintain salt balance. In our example, 9.5 g of salt are eliminated in the urine per day so that total salt output exactly equals salt input. By regulating the rate of urinary salt excretion (that is, by regulating the rate of Na^+ excretion, with Cl^- following along), the kidneys normally keep the total Na^+ load (tacitly including the total Cl^- load) in the ECF constant despite any notable changes in dietary intake of salt or unusual losses through sweating or diarrhea. As a reflection of keeping the total Na^+ load in the ECF constant, the ECF volume, in turn, is maintained within the narrowly prescribed limits essential for normal circulatory function.

Deviations in ECF volume accompanying changes in the salt load trigger renal compensatory responses that quickly bring the Na^+ load and ECF volume back into line. Na^+ is freely filtered at the glomerulus and actively reabsorbed, but it is not secreted by the tubules, so the amount of Na^+ excreted in the urine represents the amount of Na^+ filtered but not subsequently reabsorbed:

$$Na^+ \text{ excreted} = Na^+ \text{ filtered} - Na^+ \text{ reabsorbed}$$

The kidneys accordingly adjust the amount of salt excreted by controlling two processes: (1) the glomerular filtration rate (GFR) and (2) more important, the tubular reabsorption of Na^+. You have already learned about these regulatory mechanisms, but we are pulling them together here as they relate to long-term control of ECF volume and blood pressure.

■ *The amount of Na^+ filtered is controlled by regulating the GFR.* The amount of Na^+ filtered is equal to the plasma Na^+ concentration times the GFR. At any given plasma Na^+ concentration, any change in the GFR correspondingly changes the amount of Na^+ and accompanying fluid that are filtered. Thus, control of the GFR can adjust the amount of Na^+ filtered each minute. Recall that the GFR is deliberately changed to alter the amount of salt and fluid filtered, as part of the general baroreceptor reflex response to a change in blood pressure (see ❙Figure 14-12, p. 503). Changes in Na^+ load in the body are not sensed as such; instead, they are monitored indirectly through the effect that the Na^+ load ultimately has on blood pressure. It is fitting that baroreceptors that monitor fluctuations in blood pressure bring about adjustments in the amounts of Na^+ filtered and eventually excreted.

■ *The amount of Na^+ reabsorbed is controlled through the renin–angiotensin–aldosterone system.* The amount of Na^+ re-

absorbed also depends on regulatory systems that play an important role in controlling blood pressure. Although Na^+ is reabsorbed throughout most of the tubule's length, only its reabsorption in the late parts of the tubule is subject to control. The main factor controlling the extent of Na^+ reabsorption in the distal and collecting tubules is the powerful renin–angiotensin–aldosterone system (RAAS), which promotes Na^+ reabsorption and thereby Na^+ retention. Sodium retention, in turn, promotes osmotic retention of H_2O and subsequent expansion of plasma volume and elevation of arterial blood pressure. Appropriately, this Na^+-conserving system is activated by a reduction in NaCl, ECF volume, and arterial blood pressure (see ❙Figure 14-16, p. 508).

Thus, control of GFR and Na^+ reabsorption are interrelated, and both are intimately tied in with long-term regulation of ECF volume as reflected by blood pressure. For example, a fall in arterial blood pressure brings about (1) a reflex reduction in the GFR to decrease the amount of Na^+ filtered and (2) a hormonally adjusted increase in the amount of Na^+ reabsorbed (❙Figure 15-3). Together, these effects reduce the amount of Na^+ excreted, thereby conserving for the body the Na^+ and accompanying H_2O needed to compensate for the fall in arterial pressure. (To look at how exercising muscles and cooling mechanisms compete for an inadequate plasma volume, see the boxed feature on p. 542, ❙A Closer Look at Exercise Physiology.)

Controlling ECF osmolarity prevents changes in ICF volume.

Maintaining fluid balance depends on regulating both ECF volume and ECF osmolarity. Regulating ECF osmolarity is important in preventing changes in cell volume. The **osmolarity** of a fluid is a measure of the concentration of the individual solute particles dissolved in it. The higher the osmolarity, the higher the concentration of solutes or, to look at it differently, the lower the concentration of H_2O. Recall that water tends to move by osmosis down its own concentration gradient from an area of lower solute (higher H_2O) concentration to an area of higher solute (lower H_2O) concentration (see p. 66).

Ions Responsible for ECF and ICF Osmolarity Osmosis occurs across the cellular plasma membranes only when a difference in concentration of nonpenetrating solutes exists between the ECF and the ICF. Solutes that can penetrate a barrier separating two fluid compartments quickly become equally distributed between the two compartments and thus do not contribute to osmotic differences.

Na^+ and accompanying Cl^-, being by far the most abundant solutes in the ECF in terms of numbers of particles, account for most ECF osmotic activity. In contrast, K^+ and its accompanying intracellular anions are responsible for ICF osmotic activity. Even though small amounts of Na^+ and K^+ passively diffuse across the plasma membrane all the time, these ions behave as if they were nonpenetrating because of Na^+–K^+ pump activity. Any Na^+ that passively diffuses down its electrochemical gradient into the cell is promptly pumped back outside, so the result is the same as if Na^+ were barred from the cells. In reverse, K^+ in effect remains trapped within the cells.

Normally, the osmolarities of the ECF and ICF are the same because the total concentration of K^+ and other effectively nonpenetrating solutes inside the cells is equal to the total concentration of Na^+ and other effectively nonpenetrating solutes in the fluid surrounding the cells. Even though nonpenetrating solutes in the ECF and ICF differ, their concentrations are normally identical, and the number (not the nature) of the unequally distributed particles per volume determines the fluid's osmolarity. Because the osmolarities of the ECF and ICF are normally equal, no net movement of H_2O usually occurs into or out of the cells. Therefore, cell volume normally remains constant.

Importance of Regulating ECF Osmolarity Any circumstance that results in a loss or gain of *free H_2O* (that is, loss or gain of H_2O that is not accompanied by comparable solute deficit or excess) leads to changes in ECF osmolarity. If there is a deficit of free H_2O in the ECF, the solutes become too concentrated and ECF osmolarity becomes abnormally high—that is, it becomes *hypertonic* (see p. 69). If there is excess free H_2O in the ECF, the solutes become too dilute and ECF osmolarity becomes abnormally low—that is, it becomes *hypotonic.* When ECF osmolarity changes with respect to ICF osmolarity, osmosis takes place, with H_2O either leaving or entering the cells,

depending on whether the ECF is more concentrated or less concentrated, respectively, than the ICF.

The osmolarity of the ECF must therefore be regulated to prevent these undesirable shifts of H_2O out of or into the cells. As far as the ECF itself is concerned, the concentration of its solutes does not really matter. However, it is crucial that ECF osmolarity be maintained within narrow limits to prevent the cells from shrinking (by osmotically losing water to the ECF) or swelling (by osmotically gaining fluid from the ECF).

Let us examine the fluid shifts that occur between the ECF and the ICF when ECF osmolarity becomes hypertonic or hypotonic relative to the ICF.

During ECF hypertonicity, cells shrink as H_2O leaves them.

Hypertonicity of the ECF, the excessive concentration of ECF solutes, is usually associated with **dehydration**, or a negative free H_2O balance.

Causes of Hypertonicity (Dehydration) Dehydration with accompanying hypertonicity can be brought about in three ways:

1. *Insufficient H_2O intake*, such as might occur during desert travel or might accompany difficulty in swallowing

2. *Excessive H_2O loss*, such as might occur during heavy sweating, vomiting, or diarrhea (even though both H_2O and solutes are lost during these conditions, relatively more H_2O is lost, so the remaining solutes become more concentrated)

3. *Diabetes insipidus, a disease characterized by a deficiency of vasopressin*

Clinical Note *Vasopressin (antidiuretic hormone)* increases the permeability of the distal and collecting tubules to H_2O and thus enhances water conservation by reducing urinary output of water (see p. 524). Without adequate vasopressin in **diabetes insipidus**, the kidneys cannot conserve H_2O because they cannot reabsorb H_2O from the late parts of the nephron. Such patients typically produce up to 20 liters of very dilute urine daily, compared to the normal average of 1.5 liters per day. Unless H_2O intake keeps pace with this tremendous loss of H_2O in the urine, the person quickly dehydrates. Such patients complain that they spend an extraordinary amount of time day and night going the bathroom and getting drinks. Fortunately, they can be treated with replacement vasopressin administered by nasal spray.

1 See Figure 14-12 for details of mechanism.

2 See Figure 14-16 for details of mechanism.

Figure 15-3 Dual effect of a fall in arterial blood pressure on renal handling of Na^+.
FIGURE FOCUS: *Describe the two pathways by which an excess Na^+ load is eliminated from the body.*

Clinical Note **Direction and Resulting Symptoms of Water Movement During Hypertonicity** Whenever the ECF compartment becomes hypertonic, H_2O moves out of the cells by osmosis into the more concentrated ECF until the

A Potentially Fatal Clash:
When Exercising Muscles
and Cooling Mechanisms Compete
for an Inadequate Plasma Volume

AN INCREASING NUMBER OF PEOPLE of all ages are participating in walking or jogging programs to improve their level of physical fitness and decrease their risk of cardiovascular disease. For people living in environments that undergo seasonal temperature changes, fluid loss can make exercising outdoors dangerous during the transition from the cool days of spring to the hot, humid days of summer. If exercise intensity is not modified until the participant gradually adjusts to the hotter environmental conditions, dehydration and salt loss can indirectly lead to heat cramps, heat exhaustion, or ultimately heat stroke and death.

The term **acclimatization** refers to the gradual adaptations the body makes to maintain long-term homeostasis in response to a prolonged physical change in the surrounding environment, such as a change in temperature. When a person exercises in the heat without gradually adapting to the hotter environment, the body faces a terrible dilemma. During exercise, large amounts of blood must be delivered to the muscles to supply O_2 and nutrients and to remove the wastes that accumulate from their high rate of activity. Exercising muscles also produce heat. To maintain body temperature in the face of this extra heat, blood flow to the skin is increased so that heat from the warmed blood can be lost through the skin to the surrounding environment. If the environmental temperature is hotter than the body temperature, heat cannot be lost from the blood to the surrounding environment despite maximal skin vasodilation. Instead, the body gains heat from its warmer surroundings, further adding to the dilemma. Because extra blood is diverted to both the muscles and the skin when a person exercises in the heat, less blood is returned to the heart, and the heart pumps less blood per beat in accordance with the Frank–Starling mechanism (see p. 322). Therefore, the heart must beat faster than it would in a cool environment to deliver the same amount of blood per minute. The increased rate of cardiac pumping further contributes to heat production.

The sweat rate also increases so that evaporative cooling can take place to help maintain the body temperature during periods of excessive heat gain. In an unacclimatized person, maximal sweat rate is about 1.5 liters per hour. During sweating, water-retaining salt, as well as water, is lost. The resulting loss of plasma volume through sweating further depletes the blood supply available for muscular exercise and for cooling through skin vasodilation.

The heart has a maximum rate at which it can pump. If exercise continues at a high intensity and this maximal rate is reached, the exercising muscles win the contest for blood supply. Cooling is sacrificed as skin blood flow decreases. If exercise continues, body heat continues to rise, and heat exhaustion (rapid, weak pulse; hypotension; profuse sweating; and disorientation) or heat stroke (failure of the temperature control center in the hypothalamus; hot, dry skin; extreme confusion or unconsciousness; and possibly death) can occur (see p. 634). Every year people die of heat stroke running in marathons during hot, humid weather. (Some people make matters worse by adding a caffeine-containing energy drink to their workout or competition. Caffeine may provide a jolt of energy, but it also acts as a diuretic and can lead to performance-reducing dehydration, the opposite effect of what the people might think they are accomplishing by drinking these beverages.)

By contrast, if a person exercises in the heat for 2 weeks at reduced, safe intensities, the body makes the following adaptations so that after acclimatization the person can do the same amount of work as was possible in a cool environment: (1) The plasma volume is increased by as much as 12%. Expansion of the plasma volume provides enough blood to both supply the exercising muscles and direct blood to the skin for cooling. (2) The person begins sweating at a lower temperature so that the body does not get so hot before cooling begins. (3) The maximal sweat rate increases nearly three times, to 4 liters per hour, with a more even distribution over the body. This increase in evaporative cooling reduces the need for cooling by skin vasodilation. (4) The sweat becomes more dilute so that less salt is lost in the sweat. The retained salt exerts an osmotic effect to hold water in the body and help maintain circulating plasma volume. These adaptations take 14 days and occur only if the person exercises in the heat. Being patient until these changes take place can enable the person to exercise safely throughout the summer months.

ICF osmolarity equilibrates with the ECF. As H_2O leaves them, the cells shrink. Of particular concern is that considerable shrinking of brain neurons disturbs brain function, which can be manifested as mental confusion and irrationality in moderate cases and delirium, convulsions, or coma in more severe hypertonic conditions.

Rivaling the neural symptoms in seriousness are circulatory disturbances that arise from the reduced plasma volume associated with dehydration. Circulatory problems may range from a slight lowering of blood pressure to circulatory shock and death.

Other more common symptoms become apparent even in mild cases of dehydration. For example, dry skin and sunken

eyeballs indicate loss of H_2O from the underlying soft tissues, and the tongue becomes dry and parched because salivary secretion is suppressed.

During ECF hypotonicity, the cells swell as H_2O enters them.

Hypotonicity of the ECF is associated with **overhydration**—that is, excess free H_2O. When a positive free H_2O balance exists, the ECF is less concentrated (more dilute) than normal.

Causes of Hypotonicity (Overhydration) Usually, any surplus free H_2O is promptly excreted in the urine, so hypotonicity generally does not occur. However, hypotonicity arises in three ways:

1. Patients with *renal failure* who cannot excrete dilute urine become hypotonic when they consume relatively more H_2O than solutes.

2. Hypotonicity occurs transiently in healthy people if *H_2O is rapidly ingested* to such an excess that the kidneys cannot respond quickly enough to eliminate the extra H_2O.

3. Hypotonicity occurs when excess H_2O without solute is retained in the body as a result of the *syndrome of inappropriate vasopressin secretion.*

Clinical Note Vasopressin is normally secreted in response to a H_2O deficit, which is relieved by increasing H_2O reabsorption in the distal part of the nephrons. However, vasopressin secretion, and therefore hormonally controlled tubular H_2O reabsorption, can be increased in response to pain, trauma, and other stressful situations, even when the body has no H_2O deficit. The increased vasopressin secretion and resulting H_2O retention elicited by stress are appropriate in anticipation of potential blood loss in the stressful situation. The extra retained H_2O could minimize the effect a loss of blood volume would have on blood pressure. However, because modern-day stressful situations generally do not involve blood loss, the increased vasopressin secretion is inappropriate as far as the body's fluid balance is concerned, leading to the **syndrome of inappropriate vasopressin secretion**. The resultant retention of too much H_2O dilutes the body's solutes. In addition to stress inappropriately promoting vasopressin secretion from its normal source, some types of lung cancer secrete vasopressin, inappropriately diluting the body fluids.

Clinical Note **Direction and Resulting Symptoms of Water Movement During Hypotonicity** Excess free H_2O retention first dilutes the ECF, making it hypotonic. The resulting difference in osmotic activity between the ECF and the ICF causes H_2O to move by osmosis from the more dilute ECF into the cells, with the cells swelling as H_2O moves into them. Like the shrinking of cerebral neurons, pronounced swelling of brain cells also leads to brain dysfunction. Symptoms include confusion, irritability, lethargy, headache, dizziness, vomiting, drowsiness, and in severe cases, convulsions, coma, and death.

Nonneural symptoms of overhydration include weakness caused by swelling of muscle cells and circulatory disturbances,

including hypertension and edema, caused by expansion of plasma volume.

The condition of overhydration, hypotonicity, and cellular swelling resulting from excess free H_2O retention is known as **water intoxication**. It should not be confused with the fluid retention that occurs with excess salt retention. In the latter case, the ECF is still isotonic because the increase in salt is matched by a corresponding increase in H_2O. Because the interstitial fluid is still isotonic, no osmotic gradient exists to drive the extra H_2O into the cells. The excess salt and H_2O burden is therefore confined to the ECF compartment, with circulatory consequences being the most important concern. In water intoxication, in addition to any circulatory disturbances, symptoms caused by cell swelling become a problem.

We now contrast the situations of hypertonicity and hypotonicity with what happens when isotonic fluid is gained or lost.

No water moves into or out of cells during an ECF isotonic fluid gain or loss.

Clinical Note An example of an isotonic fluid gain is therapeutic intravenous administration of an isotonic solution, such as isotonic saline. When isotonic fluid is injected into the ECF compartment, ECF volume increases, but the concentration of ECF solutes remains unchanged; in other words, the ECF is still isotonic. Because the ECF osmolarity has not changed, the ECF and ICF are still in osmotic equilibrium, so no net fluid shift occurs between the two compartments. The ECF compartment has increased in volume without shifting H_2O into the cells.

Similarly, in an isotonic fluid loss such as hemorrhage, the loss is confined to the ECF, with no corresponding loss of fluid from the ICF. Fluid does not shift out of the cells because the ECF remaining within the body is still isotonic, so no osmotic gradient draws H_2O out of the cells. Many other mechanisms counteract loss of blood, but the ICF compartment is not directly affected by the loss.

We now consider how free H_2O balance and consequently ECF osmolarity are normally maintained to minimize harmful changes in cell volume.

Vasopressin control of free H_2O balance is important in regulating ECF osmolarity.

Control of free H_2O balance is crucial for regulating ECF osmolarity. Because increases in free H_2O cause the ECF to become too dilute and deficits of free H_2O cause the ECF to become too concentrated, the osmolarity of the ECF must be immediately corrected by restoring stable free H_2O balance to avoid harmful osmotic fluid shifts into or out of the cells.

To maintain a stable H_2O balance, H_2O input must equal H_2O output.

Sources of H_2O Input

■ In a person's typical daily H_2O balance (Table 15-3), a little more than a liter of H_2O is added to the body by *drinking liquids.*

■ Surprisingly, an amount almost equal to that is obtained from *eating solid food.* Muscles consist of about 75% H_2O;

Fluid and Acid–Base Balance | **543**

TABLE 15-3 Daily Water Balance			
WATER INPUT		**WATER OUTPUT**	
Avenue	Quantity (mL/day)	Avenue	Quantity (mL/day)
Fluid intake	1250	Insensible loss (from lungs and nonsweating skin)	900
H_2O in food intake	1000	Sweat	100
Metabolically produced H_2O	350	Feces	100
		Urine	1500
Total input	2600	**Total output**	2600

meat (animal muscle) is therefore 75% H_2O. Fruits and vegetables consist of 60% to 96% H_2O. Therefore, people normally get almost as much H_2O from solid foods as from liquids.

■ The third source of H_2O input is *metabolically produced H_2O.* Chemical reactions within cells convert food and O_2 into energy, producing CO_2 and H_2O in the process. This **metabolic H_2O** produced during cell metabolism and released into the ECF averages about 350 mL per day.

The average H_2O intake from these three sources totals 2600 mL per day. Another source of H_2O often employed therapeutically is intravenous infusion of fluid.

Sources of H₂O Output

■ On the output side of the H_2O balance tally, you lose nearly a liter of H_2O daily without being aware of it. This **insensible loss** (loss of which the person has no sensory awareness) occurs from the *lungs* and *nonsweating skin.* During respiration, inspired air becomes saturated with H_2O within the airways. This H_2O is lost when the moistened air is subsequently expired (see p. 447). Normally, you are not aware of this H_2O loss, but you can recognize it on cold days, when H_2O vapor condenses so that you can "see your breath." The other insensible loss is continual loss of H_2O from the skin even in the absence of sweating. Water molecules can diffuse through skin cells and evaporate without being noticed. Fortunately, the skin is fairly waterproofed by its keratinized exterior layer, which protects against a greater loss of H_2O by this avenue (see p. 440). When this protective surface layer is lost, such as when a person has extensive burns, increased fluid loss from the burned surface can cause serious problems with fluid balance.

■ Sensible loss (loss of which the person is aware) of H_2O from the skin occurs through *sweating,* which represents another avenue of H_2O output. At an air temperature of 68°F, an average of 100 mL of H_2O is lost daily through sweating. Loss of water from sweating can vary substantially, depending on the environmental temperature and humidity and the degree

of physical activity; it may range from zero up to as much as several liters per hour in very hot weather.

■ Another passageway for H_2O loss from the body is through the *feces.* Normally, only about 100 mL of H_2O are lost this way each day. During fecal formation in the large intestine, most H_2O is absorbed out of the digestive tract lumen into the blood, thereby conserving fluid and solidifying the digestive tract's contents for elimination. Additional H_2O can be lost from the digestive tract through vomiting or diarrhea.

■ By far the most important output mechanism is *urine excretion,* with 1500 mL (1.5 liters) of urine being produced daily on average.

The total H_2O output is 2600 mL/day, the same as the volume of H_2O input in our example. This balance is not by chance. Normally, H_2O input matches H_2O output so that the H_2O in the body remains in balance.

Factors Regulated to Maintain Water Balance Of the many sources of H_2O input and output, only two can be regulated to maintain H_2O balance. On the intake side, thirst influences the amount of fluid ingested; on the output side, the kidneys can adjust how much urine is formed. Controlling H_2O output in the urine is the most important mechanism in controlling H_2O balance.

Some of the other factors are regulated, but not for maintaining H_2O balance. Food intake is subject to regulation to maintain energy balance, and control of sweating is important in maintaining body temperature. Metabolic H_2O production and insensible losses are unregulated.

Control of Water Output in the Urine by Vasopressin Fluctuations in ECF osmolarity caused by imbalances between H_2O input and H_2O output are quickly compensated for by adjusting urinary excretion of H_2O without changing the usual excretion of salt—that is, H_2O reabsorption and excretion are partially dissociated from solute reabsorption and excretion, so the amount of free H_2O retained or eliminated can be varied to quickly restore ECF osmolarity to normal. Free H_2O reabsorption and excretion are adjusted through changes in vasopressin secretion (see ▮Figure 14-27, p. 525). Throughout most of the nephron, H_2O reabsorption is important in regulating ECF volume because salt reabsorption is accompanied by comparable H_2O reabsorption. In the distal and collecting tubules, however, variable free H_2O reabsorption can take place without comparable salt reabsorption because of the vertical osmotic gradient in the renal medulla to which this part of the tubule is exposed. Vasopressin increases the permeability of this late part of the tubule to H_2O. Depending on the amount of vasopressin present, the amount of free H_2O reabsorbed can be adjusted as necessary to restore ECF osmolarity to normal.

Vasopressin is produced by the hypothalamus, stored in the posterior pituitary gland, and released from the posterior pituitary on command from the hypothalamus.

Control of Water Input by Thirst **Thirst** is the subjective sensation that drives you to ingest H_2O. The **thirst center** is located in the hypothalamus close to the vasopressin-secreting cells.

We now elaborate on the mechanisms that regulate vasopressin secretion and thirst.

Vasopressin secretion and thirst are largely triggered simultaneously.

The hypothalamic control centers that regulate vasopressin secretion (and thus urinary output) and thirst (and thus drinking) act in concert. Vasopressin secretion and thirst are both stimulated by a free H_2O deficit and suppressed by a free H_2O excess. Thus, appropriately, the same circumstances that call for reducing urinary output to conserve body H_2O give rise to the sensation of thirst to replenish body H_2O.

Role of Hypothalamic Osmoreceptors The predominant excitatory input for both vasopressin secretion and thirst comes from **hypothalamic osmoreceptors** located near the vasopressin-secreting cells and thirst center. These osmo-receptors monitor the osmolarity of fluid surrounding them, which in turn reflects the concentration of the entire internal fluid environment. As ECF osmolarity increases (too little H_2O) and the need for H_2O conservation increases, vasopressin secretion and thirst are both stimulated (❚Figure 15-4). As a result, reabsorption of H_2O in the distal and collecting tubules is increased so that urinary output is reduced and H_2O is conserved, while H_2O intake is simultaneously encouraged. These actions restore depleted H_2O stores, thus relieving the hypertonic condition by diluting the solutes to normal concentration. In contrast, H_2O excess, manifested by reduced ECF osmolarity, prompts increased urinary output (through decreased vasopressin release) and suppresses thirst, which together reduce the water load in the body.

Role of Left Atrial Volume Receptors Although the major stimulus for vasopressin secretion and thirst is an increase in ECF osmolarity, the vasopressin-secreting cells and thirst center are both influenced to a moderate extent by changes in ECF volume (and therefore plasma volume) mediated by input from the **left atrial volume receptors**. Located in the left atrium, these volume receptors respond to pressure-induced stretch caused by blood flowing through, which reflects the ECF volume—that is, they monitor the "fullness" of the vascular system. In contrast, the aortic arch and carotid sinus baroreceptors monitor the mean driving pressure in the vascular system (see p. 367). In response to a major reduction in ECF volume (>7% loss of volume), and accordingly in arte-

❚Figure 15-4 **Control of increased vasopressin secretion and thirst during a H_2O deficit.**

rial pressure, as during hemorrhage, the left atrial volume receptors reflexly stimulate both vasopressin secretion and thirst. (By comparison, a change as small as a 1% increase in ECF osmolarity triggers increased vasopressin secretion, and an increase in osmolarity of 2% or more produces a strong desire to drink, indicative of the greater influence of the hypothalamic osmoreceptors than the left atrial volume receptors in controlling vasopressin secretion and thirst.) In the face of a marked reduction in ECF volume, the outpouring of vasopressin and the increased thirst lead to decreased urine output and increased fluid intake, respectively. Furthermore, vasopressin, at the circulating levels elicited by a large decline in ECF volume and arterial pressure, exerts a potent vasoconstrictor (that is, a "vaso" "pressor") effect on arterioles (thus giving rise to its name; see p. 350). Both by helping expand the
ECF and plasma volume and by increasing total peripheral resistance, vasopressin helps relieve the low blood pressure that elicited vasopressin secretion. Simultaneously, the low blood pressure is detected by the aortic arch and carotid sinus baroreceptors, which help raise the pressure by increasing sympathetic activity to the heart and blood vessels (see p. 368). Furthermore, sympathetic activity also contributes to the sensation of thirst and increased vasopressin activity.

Conversely, vasopressin and thirst are both inhibited when ECF volume (and, accordingly, plasma volume) and arterial blood pressure are elevated. The resultant suppression of H_2O intake, coupled with elimination of excess ECF and plasma volume in the urine, helps restore blood pressure to normal.

Recall that low NaCl, low ECF volume, and low arterial blood pressure also reflexly increase aldosterone secretion via RAAS. The resulting increase in Na^+ reabsorption leads to osmotic retention of H_2O, expansion of ECF volume, and an increase in arterial blood pressure. Aldosterone-controlled Na^+ reabsorption is the most important factor in regulating ECF volume, with the vasopressin and thirst mechanism playing only a supportive role.

Role of Angiotensin II Yet another stimulus for increasing both thirst and vasopressin is angiotensin II (▮Table 15-4). When RAAS is activated to conserve Na^+, angiotensin II, in addition to stimulating aldosterone secretion, acts directly on the brain to give rise to the urge to drink and concurrently stimulates vasopressin to enhance renal H_2O reabsorption (see p. 508). The resultant increased H_2O intake and decreased urinary output help correct the reduction in ECF volume that triggered RAAS.

Regulatory Factors that Do Not Link Vasopressin and Thirst Several factors affect vasopressin secretion but not thirst. As described earlier, vasopressin is stimulated by stress-related inputs such as pain and trauma that have nothing directly to do with maintaining H_2O balance. In fact, H_2O retention from the inappropriate secretion of vasopressin can bring about a hypotonic H_2O imbalance. In contrast, alcohol and caffeine inhibit vasopressin secretion and can lead to ECF hypertonicity by promoting excessive free H_2O excretion.

One stimulus that promotes thirst but not vasopressin secretion is a direct effect of dryness of the mouth. Nerve endings in the mouth are directly stimulated by dryness, which causes an intense sensation of thirst that can often be relieved merely by moistening the mouth even though no H_2O is actually ingested. A dry mouth can exist when salivation is suppressed by factors unrelated to the body's H_2O content, such as nervousness, excessive smoking, or certain drugs.

Factors that affect vasopressin secretion or thirst but have nothing directly to do with the body's need for H_2O are usually short-lived. The dominant, long-standing control of vasopressin and thirst is directly correlated with the body's state of H_2O—namely, by the status of ECF osmolarity and, to a lesser extent, by ECF volume.

Oral Metering Some kind of "oral H_2O metering" appears to exist, at least in animals. A thirsty animal will rapidly drink only enough H_2O to satisfy its H_2O deficit. It stops drinking before the ingested H_2O has had time to be absorbed from the digestive tract and return the ECF compartment to normal. Receptors in the mouth, pharynx (throat), and upper digestive tract signal that enough H_2O has been consumed. This mechanism seems to be less effective in humans because we frequently drink more than is necessary to meet the needs of our bodies or, conversely, may not drink enough to make up a deficit.

Nonphysiological Influences on Fluid Intake Although the thirst mechanism exists to control H_2O intake, fluid con-

▮**TABLE 15-4** Factors Controlling Vasopressin Secretion and Thirst

Factor	Effect on Vasopressin Secretion	Effect on Thirst	Comment
↑ **ECF osmolarity**	↑	↑	Major stimulus for vasopressin secretion and thirst
↓ **ECF volume**	↑	↑	Important only for large changes in ECF volume/arterial blood pressure
Angiotensin II	↑	↑	Part of dominant pathway for promoting compensatory salt and H_2O retention when ECF volume and arterial blood pressure are reduced
Pain, trauma, and other stress-related inputs	Inappropriate ↑ unrelated to body's H_2O balance	No effect	Promotes excess H_2O retention and ECF hypotonicity (resultant H_2O retention of potential value in maintaining arterial blood pressure in case of blood loss in the stressful situation)
Alcohol and caffeine	Inappropriate ↓ unrelated to body's H_2O balance	No effect	Promote excess H_2O loss and ECF hypertonicity
Dry mouth	No effect	↑	Nerve endings in the mouth that ultimately give rise to the sensation of thirst are directly stimulated by dryness

Regulated Variable	Need to Regulate the Variable	Outcomes If the Variable Is Not Normal	Mechanism for Regulating the Variable
ECF volume	Important in the long-term control of arterial blood pressure	↓ ECF volume → ↓ arterial blood pressure ↑ ECF volume → ↑ arterial blood pressure	Maintenance of salt balance; salt osmotically "holds" H_2O, so the Na^+ load determines the ECF volume. Accomplished primarily by aldosterone-controlled adjustments in urinary Na^+ excretion
ECF osmolarity	Important to prevent detrimental osmotic movement of H_2O between the ECF and ICF	↑ ECF osmolarity (hypertonicity) → H_2O leaves the cells → cells shrink ↓ ECF osmolarity (hypotonicity) → H_2O enters the cells → cells swell	Maintenance of free H_2O balance. Accomplished primarily by vasopressin-controlled adjustments in excretion of H_2O in the urine

sumption by humans is often influenced more by habit and sociological factors than by the need to regulate H_2O balance. Thus, even though H_2O intake is critical in maintaining fluid balance, it is not precisely controlled in humans, who err especially on the side of excess H_2O consumption. We usually drink when we are thirsty, but we often drink even when we are not thirsty because, for example, we are on a coffee break.

With H_2O intake being inadequately controlled and indeed even contributing to H_2O imbalances in the body, the primary factor involved in maintaining H_2O balance is urinary output regulated by the kidneys. Accordingly, *vasopressin-controlled H_2O reabsorption is of primary importance in regulating ECF osmolarity.*

Before we shift to acid–base balance, examine ▮Table 15-5, which summarizes the regulation of ECF volume and osmolarity, the two factors important in maintaining fluid balance.

Check Your Understanding 15.2

1. Make a chart showing the percentage of body H_2O distributed among the major body fluid compartments.

2. Compare how ECF volume and ECF osmolarity are regulated, and discuss the importance of each being regulated.

3. What factors are regulated to maintain salt balance and to maintain water balance?

4. Compare the effect of ECF hypertonicity and hypotonicity on cell volume.

15.3 Acid–Base Balance

The term **acid–base balance** refers to the precise regulation of **free** (that is, unbound) **hydrogen ion (H^+) concentration** in the body fluids. To indicate the concentration of a chemical, its symbol is enclosed in square brackets. Thus, $[H^+]$ designates H^+ concentration.

Acids liberate free hydrogen ions, whereas bases accept them.

Acids are a special group of hydrogen-containing substances that *dissociate,* or separate, when in solution to liberate free H^+ and anions. Many other substances (for example, carbohydrates) also contain hydrogen, but they are not classified as acids because the hydrogen is tightly bound within their molecular structure and is never liberated as free H^+.

A strong acid has a greater tendency to dissociate in solution than a weak acid does—that is, a greater percentage of a strong acid's molecules separate into free H^+ and anions. Hydrochloric acid (HCl) is an example of a strong acid; every HCl molecule dissociates into free H^+ and chloride (Cl^-) when dissolved in H_2O. With a weaker acid such as carbonic acid (H_2CO_3), only a portion of the molecules dissociates in solution into H^+ and bicarbonate anions (HCO_3^-). The remaining H_2CO_3 molecules remain intact. Because only free H^+ contributes to the acidity of a solution, H_2CO_3 is a weaker acid than HCl because H_2CO_3 does not yield as many free H^+ per number of acid molecules present in solution (▮Figure 15-5).

The extent of dissociation for a given acid is always constant—that is, when in solution, the same proportion of a particular acid's molecules always separate to liberate free H^+, with the other portion always remaining intact. The constant degree of dissociation for a particular acid (in this example, H_2CO_3) is expressed by its **dissociation constant (K)** as follows:

$$[H^+][HCO_3^-]/[H_2CO_3] = K$$

where

$[H^+][HCO_3^-]$ represents the concentration of ions resulting from H_2CO_3 dissociation and $[H_2CO_3]$ represents the concentration of intact (undissociated) H_2CO_3.

The dissociation constant varies for different acids.

A **base** is a substance that can combine with a free H^+ and thus remove it from solution. A strong base can bind H^+ more readily than a weak base can.
IFigure 15-5 **Comparison of a strong and a weak acid.**
(a) Five molecules of a strong acid. A strong acid such as HCl (hydrochloric acid) completely dissociates into free H⁺ and anions in solution. (b) Five molecules of a weak acid. A weak acid such as H₂CO₃ (carbonic acid) only partially dissociates into free H⁺ and anions in solution.

KEY

= Undissociated acid

= Free H⁺   = Free anion

The greater the $[H^+]$, the larger the number by which 1 must be divided and the lower the pH.

2. *Every unit change in pH actually represents a 10-fold change in $[H^+]$* because of the logarithmic relationship. A log to the base 10 indicates how many times 10 must be multiplied by itself to produce a given number. For example, the log of 10 = 1, whereas the log of 100 = 2. The number 10 must be multiplied by itself twice to yield 100 ($10 \times 10 = 100$). Numbers less than 10 have logs less than 1. Numbers between 10 and 100 have logs between 1 and 2, and so on. Accordingly, each unit of change in pH indicates a 10-fold change in $[H^+]$. For example, a solution with a pH of 7 has a $[H^+]$ 10 times less than that of a solution with a pH of 6 (a 1 pH-unit difference) and 100 times less than that of a solution with a pH of 5 (a 2 pH-unit difference).

Acidic and Basic Solutions in Chemistry The pH of pure H_2O is 7.0, which is considered chemically neutral. An extremely small proportion of H_2O molecules dissociate into H^+ and hydroxyl (OH^-) ions. Because an equal number of acidic H^+ and basic OH^- are formed, H_2O is neutral, being neither acidic nor basic. Solutions having a pH less than 7.0 contain a higher $[H^+]$ than pure H_2O and are considered **acidic**. Solutions having a pH value greater than 7.0 have a lower $[H^+]$ than pure

The pH designation is used to express [H⁺].

The $[H^+]$ in the ECF is normally 4×10^{-8} or 0.00000004 equivalents per liter, about 3 million times less than the $[Na^+]$ in the ECF. The concept of pH was developed to express the low value of $[H^+]$ more conveniently. Specifically, **pH** equals the logarithm (log) to the base 10 of the reciprocal of $[H^+]$.

$$pH = \log 1/[H^+]$$

Two important points should be noted about this formula:

1. Because $[H^+]$ is in the denominator, *a high $[H^+]$ corresponds to a low pH and a low $[H^+]$ corresponds to a high pH.*

H_2O and are considered **basic**, or **alkaline** (❙Figure 15-6a). ❙Figure 15-7 compares the pH values of common solutions.

Acidosis and Alkalosis in the Body The pH of arterial blood is normally 7.45 and the pH of venous blood is 7.35, for an average blood pH of 7.4. The pH of venous blood is slightly lower (more acidic) than that of arterial blood because H^+ is generated by the formation of H_2CO_3 from CO_2 picked up at the tissue capillaries. **Acidosis** exists whenever blood pH falls below 7.35, whereas **alkalosis** occurs when blood pH is above 7.45 (see ❙Figure 15-6b). Note that the reference point for determining the body's acid–base status is not the chemically neutral pH of 7.0 but the normal blood pH of 7.4. Thus, a blood pH of 7.2 is considered acidotic even though in chemistry a pH of 7.2 is considered basic.

pH	
0	Hydrochloric acid (HCl)
1	Gastric fluid (1.0–3.0)
2	Lemon juice, cola drinks, some acid rain
3	Vinegar, wine, beer, oranges
4	Tomatoes / Bananas / Black coffee

Acidic (pH 0–7); Basic (pH 7–14)

❙**Figure 15-7** Comparison of pH values of common solutions.

An arterial pH of less than 6.8 or greater than 8.0 is not compatible with life. Because death occurs if arterial pH falls outside the range of 6.8 to 8.0 for more than a few seconds, $[H^+]$ in the body fluids must be carefully regulated.

Fluctuations in $[H^+]$ alter nerve, enzyme, and K^+ activity.

Only a narrow pH range is compatible with life because even small changes in $[H^+]$ have dramatic effects on normal cell function, as the following consequences indicate:

1. *Changes in excitability of nerve and muscle cells are among the major clinical manifestations of pH abnormalities.*

■ The major clinical effect of increased $[H^+]$ (acidosis) is depression of the central nervous system (CNS). Acidotic patients become disoriented and, in more severe cases, eventually die in a state of coma.

■ In contrast, the major clinical effect of decreased $[H^+]$ (alkalosis) is overexcitability of the nervous system, first the peripheral nervous system and later the CNS. Peripheral nerves become so excitable that they fire even in the absence of normal stimuli. Such overexcitability of the afferent (sensory) nerves gives rise to abnormal "pins-and-needles" tingling sensations. Overexcitability of efferent (motor) nerves brings about muscle twitches and, in more pronounced cases, severe muscle spasms. Death may occur in extreme alkalosis because spasm of the respiratory muscles seriously impairs breathing. Alternatively, patients with severe alkalosis may die of convulsions resulting from overexcitability of the CNS. In less serious situations, CNS overexcitability is manifested as extreme nervousness.

2. *Hydrogen ion concentration exerts a marked influence on enzyme activity.* Even slight deviations in $[H^+]$ alter the shape and activity of protein molecules. Because enzymes are proteins, a shift in the body's acid–base balance disturbs the normal pattern of metabolic activity catalyzed by these enzymes.

3. *Changes in $[H^+]$ influence K^+ levels in the body.* When reabsorbing Na^+ from the filtrate, the renal tubular cells secrete either K^+ or H^+ in exchange. Normally, they secrete a preponderance of K^+ compared to H^+. Because of the intimate relationship between secretion of H^+ and that of K^+ by the kidneys, when H^+ secretion increases to compensate for acidosis, less K^+ than usual can be secreted; conversely, when H^+ secretion is reduced during alkalosis, more K^+ is secreted than normal. The resulting changes in ECF $[K^+]$ can lead to cardiac abnormalities, among other detrimental consequences (see p. 516).

Hydrogen ions are continually added to the body fluids as a result of metabolic activities.

As with any other constituent, input of hydrogen ions must be balanced by an equal output to maintain a constant $[H^+]$ in the body fluids. On the input side, only a small amount of acid capable of dissociating to release H^+ is taken in with food, such as the weak citric acid found in oranges. Most H^+ in the body fluids is generated internally from metabolic activities.

Sources of H⁺ in the Body Normally, H^+ is continuously added to the body fluids from the three following sources:

1. *Carbonic acid formation.* The major source of H^+ is from metabolically produced CO_2. Cellular oxidation of nutrients yields energy, with CO_2 and H_2O as end products. Without catalyst influence, CO_2 and H_2O slowly form H_2CO_3, which then rapidly partially dissociates to liberate free H^+ and HCO_3^-:

$$CO_2 + H_2O \underset{slow}{\rightleftharpoons} H_2CO_3 \underset{fast}{\rightleftharpoons} H^+ + HCO_3^-$$

The slow first reaction is the rate-limiting step in the plasma, but the hydration (combination with H_2O) of CO_2 is greatly accelerated by the enzyme *carbonic anhydrase,* which is abundant in red blood cells (see p. 477), some special secretory cells of the stomach and pancreas (see pp. 584 and 591), and kidney tubular cells. Under the influence of carbonic anhydrase (represented by *ca* in the next equation), these cells directly convert CO_2 and H_2O into H^+ and HCO_3^- (with no intervening production of H_2CO_3) as follows:

Step 1. Carbonic anhydrase catalyzes the formation of HCO_3^- from metabolically produced CO_2 in the reaction:

$$CO_2 + OH^- \overset{ca}{\rightleftharpoons} HCO_3^-$$
Step 2. Water dissociates, forming more OH^- that can be used in Step 1, yielding H^+ in the process:

$$H_2O \rightleftharpoons OH^- + H^+$$
Collectively, these steps can be summarized as:

$$CO_2 + H_2O \overset{ca}{\rightleftharpoons} H^+ + HCO_3^-$$
The OH^- used up in step 1 is generated by step 2; as a result, there's no net loss or gain of OH^-, so we can ignore it in this summary equation.

These reactions are reversible because they can proceed in either direction, depending on the concentrations of the substances involved as dictated by the *law of mass action* (see p. 472). Within the systemic capillaries, the CO_2 level in the blood increases as metabolically produced CO_2 enters from the tissues. This drives the reaction (with or without carbonic anhydrase) to the H^+ side. In the lungs, the reaction is reversed: CO_2 diffuses from the blood flowing through the pulmonary capillaries into the alveoli (air sacs), from which it is expired to the atmosphere. The resultant reduction in blood CO_2 drives the reaction toward the CO_2 side. H^+ and HCO_3^- form CO_2 and H_2O again. The CO_2 is exhaled while the hydrogen ions generated at the tissue level are incorporated into H_2O molecules.

When the respiratory system can keep pace with the rate of metabolism, there is no net gain or loss of H^+ in the body fluids from metabolically produced CO_2. When the rate of CO_2 removal by the lungs does not match the rate of CO_2 production at the tissue level, however, the resulting accumulation or deficit of CO_2 leads to an excess or shortage, respectively, of free H^+ in the body fluids.

2. *Inorganic acids produced during breakdown of nutrients.* Dietary proteins found abundantly in meat contain a large quantity of sulfur and phosphorus. When these nutrient molecules are broken down, sulfuric acid and phosphoric acid are produced as by-products. Being moderately strong acids, these two inorganic acids largely dissociate, liberating free H^+ into the body fluids. Acids are likewise generated during breakdown of the proteins in grains and dairy products. In contrast, breakdown of fruits and vegetables produces bases that, to some extent, neutralize acids derived from meat, grain, and dairy protein metabolism. Generally, however, more acids than bases are produced during breakdown of ingested food, leading to an excess of these acids.

3. *Organic acids resulting from intermediary metabolism.* Numerous organic acids are produced during normal intermediary metabolism. For example, fatty acids are produced during fat metabolism, and muscles produce lactic acid (lactate) during heavy exercise (see p. 272). These acids partially dissociate to yield free H^+.

Hydrogen ion generation therefore normally goes on continuously, as a result of ongoing metabolic activities. In certain disease states, additional acids may be produced that further contribute to the total body pool of H^+. For example, in diabetes mellitus, large quantities of keto acids may be produced by abnormal fat metabolism (see pp. 689 and 694). Some types of acid-producing medications may also add to the total H^+ load that the body must handle. Thus, input of H^+ is unceasing, highly variable, and essentially unregulated.

Three Lines of Defense Against Changes in [H⁺] The key to H^+ balance is maintaining normal alkalinity of the ECF (pH 7.4) despite this constant onslaught of acid. The generated free H^+ must be largely removed from solution while in the body and ultimately must be eliminated so that the pH of body fluids can remain within the narrow range compatible with life. Mechanisms must also exist to compensate rapidly for the occasional situation in which the ECF becomes too alkaline.

Three lines of defense against changes in $[H^+]$ operate to maintain $[H^+]$ of body fluids at a nearly constant level despite unregulated input: (1) the *chemical buffer systems,* (2) the *respiratory mechanism of pH control,* and (3) the *renal mechanism of pH control.* We now look at each of these methods.

Chemical buffer systems minimize changes in pH by binding with or yielding free H⁺.

A **chemical buffer system** is a mixture in a solution of two chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution. A buffer system consists of a pair of substances involved in a reversible reaction—one substance that can yield free H^+ as the $[H^+]$ starts to fall and another that can bind with free H^+ (thus removing it from solution) when $[H^+]$ starts to rise.

An important example of such a buffer system is the carbonic acid–bicarbonate (H_2CO_3:HCO_3^-) buffer pair, which is involved in the following reversible reaction:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$
When a strong acid such as HCl is added to an unbuffered solution, all the dissociated H^+ remains free in the solution (❚Figure 15-8a). In contrast, when HCl is added to a solution containing the H_2CO_3:HCO_3^- buffer pair, the HCO_3^- immediately binds

with the free H^+ to form H_2CO_3 (❙Figure 15-8b). This weak H_2CO_3 dissociates only slightly compared to the marked reduction in pH that occurred when the buffer system was not present and the additional H^+ remained unbound. In the opposite case, when the pH of the solution starts to rise from the addition of base or loss of acid, the H^+-yielding member of the buffer pair, H_2CO_3, releases H^+ to minimize the rise in pH.

The body has four buffer systems: (1) the H_2CO_3:HCO_3^- buffer system, (2) the protein buffer system, (3) the hemoglobin buffer system, and (4) the phosphate buffer system. Each buffer system serves an important role (❙Table 15-6).

The H_2CO_3:HCO_3^- buffer pair is the primary ECF buffer for noncarbonic acids.

The H_2CO_3:HCO_3^- buffer pair is the most important buffer system in the ECF for buffering pH changes brought about by causes other than fluctuations in CO_2-generated H_2CO_3.

❙Figure 15-8 **Action of chemical buffers.** (a) Addition of HCl to an unbuffered solution. All the added hydrogen ions (H^+) remain free and contribute to the acidity of the solution. (b) Addition of HCl to a buffered solution. Bicarbonate ions (HCO_3^-), the basic member of the buffer pair, bind with some of the added H^+ and remove them from solution so that they do not contribute to its acidity.

It is an effective ECF buffer system for two reasons. First, H_2CO_3 and HCO_3^- are abundant in the ECF, so this system is readily available to resist changes in pH. Second, and more importantly, each component of this buffer pair is closely regulated. The kidneys regulate HCO_3^-, and the respiratory system regulates CO_2, which generates H_2CO_3. Thus, in the body the H_2CO_3:HCO_3^- buffer system includes involvement of CO_2 via the following reaction, with which you are already familiar:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

When new H^+ is added to the plasma from any source other than CO_2 (for example, through lactic acid released into the ECF from exercising muscles), the preceding reaction is driven toward the left side of the equation. As the extra H^+ binds with HCO_3^-, it no longer contributes to the acidity of body fluids, so the rise in $[H^+]$ abates. In the converse situation, when the plasma $[H^+]$ occasionally falls below normal for some reason other than a change in CO_2 (such as the loss during vomiting of plasma-derived HCl in the digestive juices in the stomach), the reaction is driven toward the right side of the equation. Dissolved CO_2 and H_2O in the plasma form H_2CO_3, which generates additional H^+ to make up for the H^+ deficit. In so doing, the H_2CO_3:HCO_3^- buffer system resists the fall in $[H^+]$.

This system cannot buffer changes in pH induced by fluctuations in H_2CO_3. A buffer system cannot buffer itself. Consider, for example, the situation in which the plasma $[H^+]$ is elevated by CO_2 retention from a respiratory problem. The rise in CO_2 drives the reaction to the right according to the law of mass action, elevating $[H^+]$. The increase in $[H^+]$ occurs as a result of the reaction being driven to the *right* by an increase in CO_2, so the elevated $[H^+]$ cannot drive the reaction to the *left* to buffer the increase in $[H^+]$. Only if the increase in $[H^+]$ is brought about by some mechanism other than CO_2 accumulation can this buffer system be shifted to the CO_2 side of the equation and effectively reduce $[H^+]$. Likewise, in the opposite situation, the H_2CO_3:HCO_3^- buffer system cannot compensate for a reduction in $[H^+]$ from a deficit of CO_2 by generating more H^+-yielding H_2CO_3 when the problem in the first place is a shortage of HCO_3^--forming CO_2. Other mechanisms, to be described shortly, are available for resisting fluctuations in pH caused by changes in CO_2 levels.

Henderson–Hasselbalch Equation

The relationship between $[H^+]$ and the members of a buffer pair can be expressed according to the **Henderson–**

TABLE 15-6 Chemical Buffers and Their Primary Roles

Buffer System	Major Functions
$H_2CO_3:HCO_3^-$ buffer system	Primary ECF buffer against noncarbonic acid changes
Protein buffer system	Primary ICF buffer; also buffers ECF
Hemoglobin buffer system	Primary buffer against carbonic acid changes
Phosphate buffer system	Important urinary buffer; also buffers ICF

Hasselbalch equation, which, for the $H_2CO_3:HCO_3^-$ buffer system is as follows:

$$pH = pK + \log[HCO_3^-]/[H_2CO_3]$$

Although you do not need to know the mathematical manipulations involved, it is helpful to understand how this formula is derived. Recall that the dissociation constant K for H_2CO_3 acid is

$$[H^+][HCO_3^-]/[H_2CO_3] = K$$

and that the relationship between pH and $[H^+]$ is

$$pH = \log 1/[H^+]$$

Then, by solving the dissociation constant formula for $[H^+]$ (that is, $[H^+] = K \times [H_2CO_3]/[HCO_3^-]$) and replacing this value for $[H^+]$ in the pH formula, one comes up with the Henderson–Hasselbalch equation.

Practically speaking, $[H_2CO_3]$ directly reflects the concentration of dissolved CO_2, from now on referred to as $[CO_2]$, because most of the CO_2 in the plasma is converted into H_2CO_3. (The dissolved CO_2 concentration is equivalent to P_{CO_2}, as described in Chapter 13.) Therefore, the equation becomes

$$pH = pK + \log[HCO_3^-]/[CO_2]$$

The pK is the logarithm of l/K, and like K, pK always remains a constant for any given acid. For H_2CO_3, pK is 6.1. Because pK is always a constant, changes in pH are associated with changes in the ratio between $[HCO_3^-]$ and $[CO_2]$.

■ Normally, the ratio between $[HCO_3^-]$ and $[CO_2]$ in the ECF is 20 to 1—that is, there is 20 times more HCO_3^- than CO_2. We plug this ratio into our formula:

$$pH = pK + \log[HCO_3^-]/[CO_2]$$
$$= 6.1 + \log 20/1$$

The log of 20 is 1.3. Therefore, pH = 6.1 + 1.3 = 7.4, which is the normal pH of plasma.

■ When the ratio of $[HCO_3^-]$ to $[CO_2]$ increases above 20/1, pH increases. Accordingly, either a rise in $[HCO_3^-]$ or a fall in $[CO_2]$, both of which increase the $[HCO_3^-]/[CO_2]$ ratio if the other component remains constant, shifts the acid–base balance toward the alkaline side.

■ In contrast, when the $[HCO_3^-]/[CO_2]$ ratio decreases below 20/1, pH decreases toward the acid side. This can occur either if the $[HCO_3^-]$ decreases or if the $[CO_2]$ increases while the other component remains constant.

Because $[HCO_3^-]$ is regulated by the kidneys and $[CO_2]$ by the lungs, the pH of the plasma can be shifted up and down by kidney and lung influences. The kidneys and lungs regulate pH (and thus free $[H^+]$) largely by controlling plasma $[HCO_3^-]$ and $[CO_2]$, respectively, to restore their ratio to normal. Accordingly,

$$pH \propto \frac{[HCO_3^-] \text{ controlled by kidney function}}{[CO_2] \text{ controlled by respiratory function}}$$

Because of this relationship, not only do both the kidneys and lungs normally participate in pH control, but renal or respiratory dysfunction can also induce acid–base imbalances by altering the $[HCO_3^-]/[CO_2]$ ratio. We will build on this principle when we examine respiratory and renal control of pH and acid–base abnormalities later in the chapter. For now, we are going to continue our discussion of the roles of the different buffer systems.

The protein buffer system is primarily important intracellularly.

The most plentiful buffers of the body fluids are the proteins, including the intracellular proteins and the plasma proteins. Proteins are excellent buffers because they contain both acidic and basic groups that can give up or take up H^+. Quantitatively, the protein system is most important in buffering changes in $[H^+]$ in the ICF because of the sheer abundance of the intracellular proteins. The more limited number of plasma proteins reinforces the $H_2CO_3:HCO_3^-$ system in extracellular buffering.

The hemoglobin buffer system buffers H^+ generated from CO_2.

Hemoglobin (Hb) buffers the H^+ generated from metabolically produced CO_2 in transit between the tissues and the lungs. At the systemic capillary level, CO_2 continuously diffuses into the blood from the tissue cells where it is being produced. The greatest percentage of this CO_2, along with H_2O, forms H^+ and HCO_3^- under the influence of carbonic anhydrase within the red blood cells. Most H^+ generated from CO_2 at the tissue level becomes bound to reduced Hb and no longer contributes to acidity of body fluids (see p. 477). Were it not for Hb, blood would become too acidic after picking up CO_2 at the tissues. With the tremendous buffering capacity of the Hb system, venous blood is only slightly more acidic than arterial blood despite the large volume of H^+-generating CO_2 carried in venous blood. At the lungs, the reactions are reversed and the resulting CO_2 is exhaled.

The phosphate buffer system is an important urinary buffer.

The phosphate buffer system consists of an acid phosphate salt (NaH_2PO_4) that can donate a free H^+ when the $[H^+]$ falls and a basic phosphate salt (Na_2HPO_4) that can accept a free H^+ when

the [H$^+$] rises. Basically, this buffer pair can alternately switch a H$^+$ for a Na$^+$ as demanded by the [H$^+$]:

$$Na_2HPO_4 + H^+ \rightleftharpoons NaH_2PO_4 + Na^+$$

Even though the phosphate pair is a good buffer, its concentration in the ECF is rather low, so it is not very important as an ECF buffer. Because phosphates are most abundant within the cells, this system contributes significantly to intracellular buffering, being rivaled only by the more plentiful intracellular proteins.

Even more important, the phosphate system serves as an excellent urinary buffer. Humans normally consume more phosphate than needed. The excess phosphate filtered through the kidneys is not reabsorbed but remains in the tubular fluid to be excreted (because the renal threshold for phosphate is exceeded; see p. 512). This excreted phosphate buffers urine as it forms by removing from solution the H$^+$ secreted into the tubular fluid. None of the other body-fluid buffer systems are present in the tubular fluid to play a role in buffering urine during its formation. Most or all of the filtered HCO$_3^-$ and CO$_2$ (alias H$_2$CO$_3$) are reabsorbed, whereas Hb and plasma proteins are not even filtered.

Chemical buffer systems act as the f rst line of defense against changes in [H$^+$].

All chemical buffer systems act immediately, within fractions of a second, to minimize changes in pH. When [H$^+$] is altered, the reversible chemical reactions of the involved buffer systems shift at once (by the law of mass action) to compensate for the change in [H$^+$]. Accordingly, the buffer systems are the *first line of defense* against changes in [H$^+$] because they are the first mechanism to respond.

Through the mechanism of buffering, most hydrogen ions seem to disappear from the body fluids from the time they are generated until the time they are eliminated. Recognize, however, that none of the chemical buffer systems actually eliminate H$^+$ from the body. The buffer systems merely remove hydrogen ions from solution by incorporating them within one member of the buffer pair, thus preventing them from contributing to body-fluid acidity. Because each buffer system has a limited capacity to soak up H$^+$, the H$^+$ that is unceasingly produced must ultimately be removed from the body by another means. If H$^+$ were not eventually eliminated, soon all the body-fluid buffers would already be bound with H$^+$ and there would be no further buffering ability.

The respiratory and renal mechanisms of pH control actually eliminate acid from the body instead of merely suppressing it, but they respond more slowly than chemical buffer systems. We now turn to these other defenses against changes in acid–base balance.

The respiratory system regulates [H$^+$] by controlling the rate of CO$_2$ removal.

The respiratory system plays an important role in acid–base balance through its ability to alter pulmonary ventilation and consequently to alter excretion of H$^+$-generating CO$_2$. The level of respiratory activity is governed in part by arterial [H$^+$], as follows (❚Table 15-7):

■ An increase in arterial [H$^+$] as the result of a *nonrespiratory* (or *metabolic*) cause brings about reflex stimulation of the respiratory center in the brain stem (see p. 479) via the peripheral chemoreceptors to increase pulmonary ventilation (the rate at which gas is exchanged between the lungs and the atmosphere; see p. 484). As the rate and depth of breathing increase, more CO$_2$ than usual is blown off. Because hydration of CO$_2$ generates H$^+$, removal of CO$_2$ in essence removes acid from this source from the body, offsetting extra H$^+$ present from a nonrespiratory source.

■ Conversely, when arterial [H$^+$] falls because of a nonrespiratory cause, pulmonary ventilation is reflexly reduced. As a result of slower, shallower breathing, metabolically produced CO$_2$ diffuses from the cells into the blood faster than it is removed from the blood by the lungs, so higher-than-usual amounts of acid-forming CO$_2$ accumulate in the blood, thus restoring [H$^+$] toward normal.

The lungs are extremely important in maintaining [H$^+$]. Every day they remove from body fluids what amounts to 100 times more H$^+$ derived from CO$_2$ than the kidneys remove from sources other than CO$_2$–H$^+$. Furthermore, the respiratory system, through its ability to regulate arterial [CO$_2$], can adjust the amount of H$^+$ added to body fluids from this source as needed to restore pH toward normal when fluctuations occur in [H$^+$] from sources other than CO$_2$–H$^+$.

The respiratory system serves as the second line of defense against changes in [H$^+$].

Respiratory regulation acts at a moderate speed, coming into play only when chemical buffer systems alone cannot minimize [H$^+$] changes. When deviations in [H$^+$] occur, the buffer sys-

❚**TABLE 15-7** Respiratory Adjustments to Nonrespiratory Acidosis and Alkalosis

Respiratory Compensations	Normal pH	Nonrespiratory (Metabolic) Acidosis	Nonrespiratory (Metabolic) Alkalosis
Ventilation	Normal	↑	↓
Rate of CO$_2$ removal	Normal	↑	↓
Rate of H$^+$ generation from CO$_2$	Normal	↓	↑

tems respond immediately, whereas adjustments in ventilation require a few minutes to be initiated. If a deviation in [H^+] is not swiftly and completely corrected by the buffer systems, the respiratory system comes into action a few minutes later, thus serving as the *second line of defense* against changes in [H^+].

The respiratory system alone can return the pH only 50% to 75% of the way toward normal. Two reasons contribute to the respiratory system's inability to fully compensate for a non-respiratory-induced acid–base imbalance. First, during respiratory compensation for a deviation in pH, the peripheral chemoreceptors, which increase ventilation in response to an elevated arterial [H^+], and the central chemoreceptors, which increase ventilation in response to a rise in [CO_2] (by monitoring CO_2-generated H^+ in the brain ECF; see p. 483), work at odds. Consider what happens in response to acidosis arising from a non-respiratory cause. When the peripheral chemoreceptors detect an increase in arterial [H^+], they reflexly *stimulate* the respiratory center to step up ventilation, causing more acid-forming CO_2 to be blown off. In response to the resultant fall in CO_2, however, the central chemoreceptors start to *inhibit* the respiratory center. By opposing the action of the peripheral chemoreceptors, the central chemoreceptors stop the compensatory increase in ventilation short of restoring pH all the way to normal.

Second, the driving force for the compensatory increase in ventilation is diminished as the pH moves toward normal. Ventilation is increased by the peripheral chemoreceptors in response to a rise in arterial [H^+], but as the [H^+] is gradually reduced by stepped-up removal of H^+-forming CO_2, the enhanced ventilatory response is also gradually reduced.

When changes in [H^+] stem from [CO_2] fluctuations that arise from respiratory abnormalities, the respiratory mechanism cannot contribute to pH control. For example, if acidosis exists because of CO_2 accumulation caused by lung disease, the impaired lungs cannot possibly compensate for acidosis by increasing the rate of CO_2 removal. The buffer systems (other than the H_2CO_3:HCO_3^- pair) plus renal regulation are the only mechanisms available for defending against respiratory-induced acid–base abnormalities.

We next see how the kidneys help maintain acid–base balance.

The kidneys adjust their rate of H^+ excretion by varying the extent of H^+ secretion.

The kidneys control the pH of body fluids by adjusting three interrelated factors: (1) H^+ excretion, (2) HCO_3^- excretion, and (3) ammonia (NH_3) secretion. We examine each of these mechanisms in further detail, starting with H^+ excretion.

Acids are continuously added to body fluids as a result of metabolic activities, yet the generated H^+ must not be allowed to accumulate. Although the body's buffer systems can resist changes in pH by removing H^+ from solution, the persistent production of acidic metabolic products would eventually overwhelm the limits of this buffering capacity. Therefore, the constantly generated H^+ must ultimately be eliminated from the body. The lungs can remove only CO_2-generated H^+ by eliminating CO_2. The task of eliminating H^+ derived from sulfuric,

phosphoric, lactic, and other acids rests with the kidneys. Furthermore, the kidneys can eliminate extra H^+ derived from CO_2.

All of the filtered H^+ is excreted because the kidney tubules are not able to reabsorb H^+, but most excreted H^+ enters the urine via secretion. Recall that the filtration rate of H^+ equals plasma [H^+] times GFR. Because plasma [H^+] is extremely low (less than in pure H_2O except during extreme acidosis, when pH falls below 7.0), the filtration rate of H^+ is likewise extremely low. This minute amount of filtered H^+ is excreted in the urine. However, most excreted H^+ gains entry into the tubular fluid by being actively secreted by the tubular cells from the peritubular capillary plasma into the tubular lumen. The proximal, distal, and collecting tubules all secrete H^+. Because the kidneys normally excrete H^+, urine is usually acidic, having an average pH of 6.0.

The H^+ secretory process begins in the tubular cells with CO_2 from three sources: CO_2 diffused into the tubular cells from (1) plasma or (2) tubular fluid or (3) CO_2 metabolically produced within the tubular cells. Catalyzed by carbonic anhydrase within the tubular cells, CO_2 and H_2O form H^+ and HCO_3^-. To secrete H^+, an energy-dependent carrier in the luminal membrane then transports H^+ out of the cell into the tubular lumen. The luminal-membrane carrier differs in different parts of the nephron.

Mechanism of Renal H^+ Secretion in the Proximal Tubule

In the proximal tubule, H^+ is secreted by both primary active transport via H^+ ATPase pumps (see p. 73) and by secondary active transport via Na^+–H^+ antiporters (see p. 74). The antiporters transport Na^+ derived from glomerular filtrate in the opposite direction of H^+ secretion, so H^+ secretion and Na^+ reabsorption are partially linked in the proximal tubule.

Mechanism of Renal H^+ Secretion in the Distal and Collecting Tubules

Recall that two types of cells are located in the distal and collecting tubules, *principal cells* and *intercalated cells* (see p. 508). Principal cells are the ones with which you are already familiar. These are the cells that play an important role in Na^+ (and subsequently Cl^-—that is, salt) balance and in K^+ balance under the influence of aldosterone. They are also the cells involved in maintaining H_2O balance under the influence of vasopressin.

Intercalated cells, which are interspersed among the principal cells, are involved in fine regulation of acid–base balance. There are two types of intercalated cells, Type A (most abundant) and Type B:

- **Type A intercalated cells** are H^+-secreting, HCO_3^--reabsorbing, K^+-reabsorbing cells. They actively secrete H^+ into the tubular lumen via two types of primary active transport mechanisms: H^+ ATPase pumps and H^+–K^+ ATPase pumps. The latter secrete H^+ in exchange for uptake (reabsorption) of K^+. Both of these types of carriers are located at the luminal membrane in Type A cells (❙ Figure 15-9). The HCO_3^- generated in the process of forming H^+ from CO_2 under the influence of carbonic anhydrase enters the blood (is reabsorbed) in exchange for Cl^- at the basolateral membrane via Cl^-–HCO_3^- antiporters.
Figure 15-9 **Hydrogen ion secretion coupled with bicarbonate reabsorption in a Type A intercalated cell.** The H^+-secreting pumps are located at the luminal membrane, and the HCO_3^--reabsorbing antiporters are located at the basolateral membrane. Because the disappearance of a filtered HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma, HCO_3^- is considered "reabsorbed."

■ **Type B intercalated cells** are HCO_3^--secreting, H^+-reabsorbing, K^+-secreting cells, just the opposite actions of the Type A intercalated cells. In contrast to Type A cells, the active H^+ ATPase pumps and H^+–K^+ ATPase pumps are located at the basolateral membrane and the Cl^-–HCO_3^- antiporters are located at the luminal membrane. In this case, when H^+ and HCO_3^- are generated from the hydration of CO_2 under the influence of carbonic anhydrase, HCO_3^- moves into the tubular lumen (is secreted) in exchange for Cl^-, and H^+ is reabsorbed into the plasma in exchange for K^+ across the basolateral membrane (Figure 15-10). Even though the Type B intercalated cells actively secrete K^+, the principal cells under the control of aldosterone actively secrete quantitatively much more K^+.

Type A intercalated cells are more active than Type B intercalated cells under normal circumstances, and their activity increases even more during acidosis. Type B intercalated cells become more active during alkalosis.

The kidneys conserve or excrete HCO_3^- depending on the plasma $[H^+]$.

Before being eliminated by the kidneys, H^+ generated from noncarbonic acids is buffered to a large extent by plasma

HCO_3^-. Appropriately, therefore, renal handling of acid–base balance also involves adjustment of HCO_3^- excretion, depending on the H^+ load in the plasma.

The kidneys regulate plasma $[HCO_3^-]$ by three interrelated mechanisms: (1) variable reabsorption of filtered HCO_3^- back into the plasma in conjunction with H^+ secretion, (2) variable addition of new HCO_3^- to the plasma in conjunction with H^+
Figure 15-10 **Bicarbonate secretion coupled with hydrogen ion reabsorption in a Type B intercalated cell.** The HCO_3^--secreting antiporters are located at the luminal membrane, and the H^+-reabsorbing pumps are located at the basolateral membrane.

FIGURE FOCUS: *Comparing this figure with Figure 15-9, explain why H^+ is secreted by Type A intercalated cells, whereas H^+ is reabsorbed by Type B intercalated cells when identical chemical reactions that produce H^+ and HCO_3^- take place in both cells.*

Fluid and Acid–Base Balance | **555**

secretion, and (3) variable secretion of HCO_3^- in conjunction with H^+ reabsorption. The first two mechanisms of renal handling of HCO_3^- are inextricably linked with H^+ secretion, primarily by proximal tubular cells and to a lesser extent by Type A intercalated cells. Every time a H^+ is secreted into the tubular fluid, a HCO_3^- is simultaneously transferred into the peritubular capillary plasma. Whether a filtered HCO_3^- is reabsorbed or a new HCO_3^- is added to the plasma in accompaniment with H^+ secretion depends on whether filtered HCO_3^- is present in the tubular fluid to react with the secreted H^+.

Coupling of HCO_3^- Reabsorption with H^+ Secretion

Bicarbonate is freely filtered, but because the luminal membranes of tubular cells are impermeable to filtered HCO_3^-, it cannot diffuse into these cells. Therefore, reabsorption of HCO_3^- must occur indirectly. We will use the Type A intercalated cell as an example (see ❙Figure 15-9). H^+ secreted into the tubular fluid combines with filtered HCO_3^- to form H_2CO_3. Under the influence of a form of carbonic anhydrase that is located on the surface of the luminal membrane, H_2CO_3 decomposes into CO_2 and H_2O within the filtrate. Unlike HCO_3^-, CO_2 and H_2O can easily penetrate tubular cell membranes. Within the cells, CO_2 and H_2O, under the influence of intracellular carbonic anhydrase, form H^+ and HCO_3^-. Because HCO_3^- can permeate these tubular cells' basolateral membrane by means of the Cl^-–HCO_3^- antiporter, it diffuses out of the cells and into the peritubular capillary plasma. Meanwhile, the generated H^+ is actively secreted. Because the disappearance of a HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma, a HCO_3^- has, in effect, been "reabsorbed." Even though the HCO_3^- entering the plasma is not the same HCO_3^- that was filtered, the net result is the same as if HCO_3^- were directly reabsorbed.

The same steps are involved in HCO_3^- reabsorption in the proximal tubular cells, except in addition to having basolateral Cl^-–HCO_3^- antiporters, these cells also have more abundant basolateral Na^+–HCO_3^- symporters that simultaneously reabsorb Na^+ and HCO_3^-.

Normally, slightly more H^+ is secreted into the tubular fluid than HCO_3^- is filtered. Accordingly, all the filtered HCO_3^- is usually reabsorbed because secreted H^+ is available in the tubular fluid to combine with it to form highly reabsorbable CO_2 and H_2O. By far the largest part of the secreted H^+ combines with HCO_3^- and is not excreted because it is "used up" in HCO_3^- reabsorption. However, the slight excess of secreted H^+ that is not matched by filtered HCO_3^- is excreted in the urine. This normal H^+ excretion rate keeps pace with the normal rate of noncarbonic acid H^+ production.

To emphasize what you just learned, secreted H^+ that is coupled with

HCO_3^- reabsorption is *not excreted.* Instead of being excreted, the secreted H^+ combines with filtered HCO_3^- and ultimately becomes incorporated into reabsorbable H_2O molecules (see ❙Figure 15-9). By contrast, secreted H^+ that is *excreted* is coupled with the *addition of new HCO_3^-* to the plasma. When all the filtered HCO_3^- has been reabsorbed and additional secreted H^+ is generated by dissociation of H_2CO_3, the HCO_3^- produced by this reaction diffuses into the plasma as a "new" HCO_3^-. It is termed "new" because its appearance in plasma is not associated with reabsorption of filtered HCO_3^- (❙Figure 15-11). Meanwhile, the secreted H^+ combines with urinary buffers, especially basic phosphate (HPO_4^{2-}) and is excreted.

Renal Handling of H^+ During Acidosis and Alkalosis

The kidneys are able to exert a fine degree of control over body pH. Renal handling of H^+ and HCO_3^- depends primarily on a direct effect of the plasma's acid–base status on the kidney's tubular cells. Under normal circumstances, the proximal tubular cells and Type A intercalated cells are predominantly active, promoting net H^+ secretion and HCO_3^- reabsorption. This pattern of activity is adjusted when pH deviates from the set point.

Let us look first at the influence of acidosis and alkalosis on H^+ secretion (❙Figure 15-12):

■ When the $[H^+]$ of the plasma passing through the peritubular capillaries is elevated above normal, the proximal tubular cells and Type A intercalated cells respond by secreting greater-than-usual amounts of H^+ from the plasma into the tubular fluid to be excreted in the urine.

■ Conversely, when plasma $[H^+]$ is lower than normal, the kidneys conserve H^+ by reducing its secretion by proximal cells and Type A intercalated cells. Also, Type B intercalated
❙Figure 15-11 **Hydrogen ion secretion and excretion coupled with the addition of new HCO_3^- to the plasma.** Secreted H^+ does not combine with filtered HPO_4^{2-} and is not subsequently excreted until all the filtered HCO_3^- has been "reabsorbed," as depicted in Figure 15-9. Once all the filtered HCO_3^- has combined with secreted H^+, further secreted H^+ is excreted in the urine, primarily in association with urinary buffers such as basic phosphate. Excretion of H^+ is coupled with the appearance of new HCO_3^- in the plasma. The "new" HCO_3^- represents a net gain rather than merely a replacement for filtered HCO_3^-.

I Figure 15-12 Control of the rate of tubular H^+ secretion and HCO_3^- reabsorption.

eliminated from the body, making the urine more acidic than normal. Second, because excretion of H^+ is linked with the addition of new HCO_3^- to the plasma, more HCO_3^- than usual enters the plasma passing through the kidneys. This additional HCO_3^- is available to buffer excess H^+ present in the body.

In the opposite situation of alkalosis, the rate of H^+ secretion diminishes, whereas the rate of HCO_3^- filtration increases compared to normal. When plasma $[H^+]$ is below normal, a smaller proportion of the HCO_3^- pool than usual is tied up buffering H^+, so plasma $[HCO_3^-]$ is elevated above normal. As a result, the rate of HCO_3^- filtration correspondingly increases. Not all the filtered HCO_3^- is reabsorbed because bicarbonate ions are in excess of secreted hydrogen ions in the tubular fluid and HCO_3^- cannot be reabsorbed without first reacting with H^+. Excess HCO_3^- is left in the tubular fluid to be excreted in the urine, thus reducing plasma $[HCO_3^-]$ while making the urine alkaline. Furthermore, Type B intercalated cells come into play during alkalosis, further decreasing the excess HCO_3^- load in the body by secreting HCO_3^- into the urine.

In short, when plasma $[H^+]$ increases above normal during acidosis, renal compensation includes the following (I Table 15-8):

1. Increased secretion and subsequent increased excretion of H^+ in the urine, thereby eliminating the excess H^+ and decreasing plasma $[H^+]$

2. Reabsorption of all filtered HCO_3^-, plus addition of new HCO_3^- to the plasma, resulting in increased plasma $[HCO_3^-]$

When plasma $[H^+]$ falls below normal during alkalosis, renal responses include the following:

1. Decreased secretion and subsequent reduced excretion of H^+ in the urine, conserving H^+ and increasing plasma $[H^+]$

2. Incomplete reabsorption of filtered HCO_3^- coupled with secretion of HCO_3^-, leading to increased excretion of HCO_3^- and reduced plasma $[HCO_3^-]$

Note that to compensate for acidosis, the kidneys acidify urine (by getting rid of extra H^+) and alkalinize plasma (by conserving HCO_3^-) to bring plasma pH to normal. In the

cells become more active to compensate for alkalosis by increasing H^+ reabsorption. Together these actions decrease H^+ excretion in the urine.

Because chemical reactions for H^+ secretion begin with CO_2, the rate at which they proceed is also influenced by $[CO_2]$.

■ When plasma $[CO_2]$ increases, the rate of H^+ secretion speeds up (I Figure 15-12).
■ Conversely, the rate of H^+ secretion slows when plasma $[CO_2]$ falls below normal.

These responses are especially important in renal compensations for acid–base abnormalities involving a change in H_2CO_3 caused by respiratory dysfunction. Thus, the kidneys can adjust H^+ excretion to compensate for changes in both carbonic and noncarbonic acids.

Renal Handling of HCO_3^- During Acidosis and Alkalosis When plasma $[H^+]$ is elevated during acidosis, more H^+ is secreted than normal. At the same time, less HCO_3^- is filtered than normal because more of the plasma HCO_3^- is used up in buffering the excess H^+ in the ECF. This greater-than-usual inequity between filtered HCO_3^- and secreted H^+ has two consequences. First, more of the secreted H^+ is excreted in the urine because more hydrogen ions are entering the tubular fluid at a time when fewer are needed to reabsorb the reduced quantities of filtered HCO_3^-. In this way, extra H^+ is

I TABLE 15-8 Renal Responses to Acidosis and Alkalosis

Acid–Base Abnormality	H^+ Secretion	H^+ Excretion	HCO_3^- Reabsorption and Addition of New HCO_3^- to Plasma	HCO_3^- Excretion	pH of Urine	Compensatory Change in Plasma pH
Acidosis	↑	↑	↑	Normal (zero; all filtered is reabsorbed)	Acidic	Alkalinization toward normal
Alkalosis	↓	↓	↓	↑	Alkaline	Acidification toward normal

opposite case—alkalosis—the kidneys make urine alkaline (by eliminating excess HCO_3^-) while acidifying plasma (by conserving H^+).

The kidneys secrete ammonia during acidosis to buffer secreted H^+.

The energy-dependent H^+ carriers in the tubular cells can secrete H^+ against a concentration gradient until the tubular fluid (urine) becomes 800 times more acidic than the plasma. At this point, further H^+ secretion stops because the gradient becomes too great for the secretory process to continue. The kidneys cannot acidify urine beyond a gradient-limited urinary pH of 4.5. If left unbuffered as free H^+, only about 1% of the excess H^+ typically excreted daily would produce a urinary pH of this magnitude at normal urine flow rates, and elimination of the other 99% of the usually secreted H^+ load would be prevented—a situation that would be intolerable. For H^+ secretion to proceed, most secreted H^+ must be buffered in the tubular fluid so that it does not exist as free H^+ and, accordingly, does not contribute to tubular acidity.

Bicarbonate cannot buffer urinary H^+ as it does H^+ in the ECF because HCO_3^- is not excreted in the urine simultaneously with H^+. (Whichever of these substances is in excess in the plasma is excreted in the urine.) There are, however, two important urinary buffers: (1) filtered phosphate buffers and (2) secreted ammonia.

Filtered Phosphate as a Urinary Buffer Normally, secreted H^+ is first buffered by the phosphate buffer system, which is in the tubular fluid because excess ingested phosphate has been filtered but not reabsorbed. The basic member of the phosphate buffer pair binds with secreted H^+. When H^+ secretion is high, the buffering capacity of urinary phosphates is exceeded. The kidneys can only control the quantity of phosphate reabsorbed (under the influence of parathyroid hormone; see pp. 512 and 707). They can do nothing about the quantity of phosphate filtered and available for reabsorption; that depends on how much phosphate has been consumed. As soon as all basic phosphate ions that are coincidentally excreted (because of dietary excess) have soaked up H^+, the acidity of the tubular fluid quickly rises as more H^+ ions are secreted. Without additional buffering capacity from another source, H^+ secretion would soon halt abruptly as the free $[H^+]$ in the tubular fluid quickly rose to the critical limiting level.

Secreted NH_3 as a Urinary Buffer When acidosis exists, the tubular cells secrete **ammonia (NH_3)** into the tubular fluid once the normal urinary phosphate buffers are saturated. This NH_3 enables the kidneys to continue secreting additional H^+ ions because NH_3 combines with free H^+ in the tubular fluid to form **ammonium ion (NH_4^+)** as follows:

$$NH_3 + H^+ \rightleftharpoons NH_4^+$$
The tubular membranes are not very permeable to NH_4^+, so the ammonium ions remain in the tubular fluid and are lost in the urine, each one taking a H^+ with it. Thus, NH_3 secreted during acidosis buffers excess H^+ in the tubular fluid so that

large amounts of H^+ can be secreted into the urine before the pH falls to the limiting value of 4.5. Were it not for NH_3 secretion, the extent of H^+ secretion would be limited to whatever phosphate-buffering capacity coincidentally happened to be present as a result of more phosphate being consumed than was needed.

In contrast to the phosphate buffers, which are in the tubular fluid because they have been filtered but not reabsorbed, NH_3 is deliberately synthesized from the amino acid glutamine within the tubular cells. Once synthesized, NH_3 readily diffuses passively down its concentration gradient into the tubular fluid—that is, it is secreted into the urine. The rate of NH_3 secretion is controlled by a direct effect on the tubular cells of the amount of excess H^+ to be transported in the urine. When someone has been acidotic for more than two or three days, the rate of NH_3 production increases substantially. This extra NH_3 provides additional buffering capacity to allow H^+ secretion to continue after the normal phosphate-buffering capacity is overwhelmed during renal compensation for acidosis.

The kidneys are a powerful third line of defense against changes in $[H^+]$.

The kidneys require hours to days to compensate for changes in body-fluid pH, compared to the immediate responses of the buffer systems and the few minutes of delay before the respiratory system responds. Therefore, they are the *third line of defense* against $[H^+]$ changes in body fluids. Although not responding as quickly as the other means of pH control, the kidneys are the most potent acid–base regulatory mechanism; they not only can variably remove H^+ from any source, but they also can variably conserve or eliminate HCO_3^- depending on the acid–base status of the body. By simultaneously removing acid (H^+) from and adding base (HCO_3^-) to body fluids, the kidneys are able to restore the pH toward normal more effectively than the lungs, which can adjust only the amount of H^+-forming CO_2 in the body.

Also contributing to the kidneys' acid–base regulatory potency is their ability to return pH almost exactly to normal. By comparison to the respiratory system's inability to fully compensate for a pH abnormality, the kidneys can continue to respond to a change in pH until compensation is essentially complete.

Acid–base imbalances can arise from either respiratory or metabolic disturbances.

Clinical Note Deviations from normal acid–base status are divided into four categories, depending on the source and direction of the abnormal change in $[H^+]$. These categories are *respiratory acidosis, respiratory alkalosis, metabolic acidosis,* and *metabolic alkalosis.*

Because of the relationship between $[H^+]$ and concentrations of the members of a buffer pair, changes in $[H^+]$ are reflected by changes in the ratio of $[HCO_3^-]$ to $[CO_2]$. Recall that the normal ratio is 20/1. Using the Henderson–Hasselbalch equation and with pK being 6.1 and the log of 20 being 1.3, normal pH = 6.1 + 1.3 = 7.4. Determinations of $[HCO_3^-]$ and $[CO_2]$ provide more meaningful information about the underlying factors responsible

for a particular acid–base status than do direct measurements of $[H^+]$ alone. The following rules of thumb apply when examining acid–base imbalances before any compensations take place:

1. A change in pH that has a *respiratory* cause is associated with an *abnormal $[CO_2]$*, giving rise to a change in $H_2CO_3^-$-generated H^+. In contrast, a pH deviation of *metabolic* origin is associated with an *abnormal $[HCO_3^-]$* resulting from an inequality between the amount of HCO_3^- available and the amount of H^+ generated from noncarbonic acids that the HCO_3^- must buffer.

2. Anytime the $[HCO_3^-]/[CO_2]$ ratio falls *below 20/1,* an *acidosis* exists. The log of any number lower than 20 is less than 1.3 and, when added to the pK of 6.1, yields an acidotic pH below 7.4. Anytime the ratio *exceeds 20/1,* an *alkalosis* exists. The log of any number greater than 20 is more than 1.3 and, when added to the pK of 6.1, yields an alkalotic pH above 7.4.

Let us put these two points together:

- Respiratory acidosis has a ratio of less than 20/1 arising from an increase in $[CO_2]$.
- Respiratory alkalosis has a ratio greater than 20/1 because of a decrease in $[CO_2]$.
- Metabolic acidosis has a ratio of less than 20/1 associated with a fall in $[HCO_3^-]$.
- Metabolic alkalosis has a ratio greater than 20/1 arising from an elevation in $[HCO_3^-]$.

We will examine each of these categories separately in more detail. For comparison, Figure 15-13 presents each of these categories by two means—the Henderson–Hasselbalch equation and the "balance beam" or "seesaw" concept—to help you better visualize the contributions of the lungs and kidneys to the causes of and compensations for various acid–base disorders. The normal situation is represented in ❚ Figure 15-13a.

Respiratory acidosis arises from an increase in $[CO_2]$.

Respiratory acidosis is the result of abnormal CO_2 retention arising from *hypoventilation* (see p. 478). As less-than-normal amounts of CO_2 are lost through the lungs, the resulting increase in CO_2 generates more H^+ from this source.

Causes of Respiratory Acidosis Possible causes include lung disease, depression of the respiratory center by drugs or disease, nerve or muscle disorders that reduce respiratory muscle ability, or (transiently) even the simple act of holding one's breath.

In uncompensated respiratory acidosis (❚ Figure 15-13b, left), $[CO_2]$ is elevated (in our example, it is doubled), whereas $[HCO_3^-]$ is normal, so the ratio is 20/2 (10/1) and pH is reduced. Let us clarify a potentially confusing point. You might wonder why when $[CO_2]$ is elevated and drives the reaction $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$ to the right, we say that $[H^+]$ becomes elevated but $[HCO_3^-]$ remains normal, although the same quantities of H^+ and HCO_3^- are produced

by this reaction. The answer lies in the fact that normally $[HCO_3^-]$ is 600,000 times $[H^+]$. For every one hydrogen ion and 600,000 bicarbonate ions present in the ECF, the generation of one additional H^+ and one HCO_3^- doubles $[H^+]$ (a 100% increase) but only increases $[HCO_3^-]$ 0.00017% (from 600,000 to 600,001 ions). Therefore, an elevation in $[CO_2]$ brings about a pronounced increase in $[H^+]$, but $[HCO_3^-]$ remains essentially normal.

Compensations for Respiratory Acidosis Compensatory measures act to restore pH to normal.

1. The chemical buffers immediately take up additional H^+.

2. The respiratory mechanism usually cannot respond with compensatory increased ventilation because impaired respiration is the problem in the first place.

3. Thus, the kidneys are most important in compensating for respiratory acidosis. They conserve all the filtered HCO_3^- and add new HCO_3^- to the plasma while simultaneously secreting and, accordingly, excreting more H^+.

As a result, HCO_3^- stores in the body become elevated. In our example (❚ Figure 15-13b, right), the plasma $[HCO_3^-]$ is doubled, so the $[HCO_3^-]/[CO_2]$ ratio is 40/2 rather than 20/2 as it was in the uncompensated state. A ratio of 40/2 is equivalent to a normal 20/1 ratio, so pH is once again the normal 7.4. Enhanced renal conservation of HCO_3^- has fully compensated for CO_2 accumulation, thus restoring pH to normal, although both $[CO_2]$ and $[HCO_3^-]$ are now distorted. Note that maintaining a normal pH depends on preserving a normal ratio between $[HCO_3^-]$ and $[CO_2]$, no matter what the absolute values of each of these buffer components are. (Bear in mind that the values used are only representative. Deviations in pH actually occur over a range, and the degree to which compensation can be accomplished varies.)

Respiratory alkalosis arises from a decrease in $[CO_2]$.

Respiratory alkalosis occurs when excessive CO_2 is lost from the body as a result of *hyperventilation* (see p. 478). When pulmonary ventilation increases out of proportion to the rate of CO_2 production, too much CO_2 is blown off. Consequently, less $[H^+]$ is formed from this source.

Causes of Respiratory Alkalosis Possible causes of respiratory alkalosis include fever, anxiety, and aspirin poisoning, all of which excessively stimulate ventilation without regard to the status of O_2, CO_2, or H^+ in the body fluids. Respiratory alkalosis also occurs as a result of physiological mechanisms at high altitude. When the low concentration of O_2 in arterial blood reflexly stimulates ventilation to obtain more O_2, too much CO_2 is blown off, inadvertently leading to an alkalotic state (see p. 480).

If we look at the biochemical abnormalities in uncompensated respiratory alkalosis (❚ Figure 15-13c, left), the increase in pH reflects a reduction in $[CO_2]$ (half the normal value in our example), whereas $[HCO_3^-]$ remains normal. This yields an alkalotic ratio of 20/0.5, which is comparable to 40/1.
Figure 15-13 Relationship of [HCO$_3^-$] and [CO$_2$] to pH in various acid–base statuses. Each of the different acid–base statuses are shown mathematically as a solution to the Henderson–Hasselbalch equation and visually as a balance beam or seesaw, where the beam tips down when the relative concentration of one member of the seesaw pair increases (or gets "heavier") and tips up when the relative concentration of a member of the pair decreases (gets "lighter"). (Note that the lengths of the arms of the balance beam analogy are not drawn to scale. The [CO$_2$] arm should be 20 times longer than the [HCO$_3^-$] arm, because, when the beam is in balance, force 1 × distance 1 from the pivot point = force 2 × distance 2 from the pivot point.)

FIGURE FOCUS: *Alkalosis is always present when [HCO$_3^-$] is elevated. (True or false?)*

(a) Normal acid–base balance

$$pH = pK + \log \frac{[HCO_3^-](20)}{[CO_2]\ (1)}$$

$$= 6.1 + 1.3 = 7.4$$

Uncompensated acid–base disorders **Compensated acid–base disorders**
$$pH = 6.1 + \log \frac{20}{2}\left(\frac{10}{1}\right)$$
$$= 6.1 + 1.0 = 7.1$$

$$pH = 6.1 + \log \frac{40}{2}\left(\frac{20}{1}\right)$$
$$= 6.1 + 1.3 = 7.4$$

(b) Respiratory acidosis

$$pH = 6.1 + \log \frac{20}{0.5}\left(\frac{40}{1}\right)$$
$$= 6.1 + 1.6 = 7.7$$

$$pH = 6.1 + \log \frac{10}{0.5}\left(\frac{20}{1}\right)$$
$$= 6.1 + 1.3 = 7.4$$

(c) Respiratory alkalosis

$$pH = 6.1 + \log \frac{10}{1}$$
$$= 6.1 + 1.0 = 7.1$$

$$pH = 6.1 + \log \frac{15}{0.75}\left(\frac{20}{1}\right)$$
$$= 6.1 + 1.3 = 7.4$$

(d) Metabolic acidosis

$$pH = 6.1 + \log \frac{40}{1}$$
$$= 6.1 + 1.6 = 7.7$$

$$pH = 6.1 + \log \frac{25}{1.25}\left(\frac{20}{1}\right)$$
$$= 6.1 + 1.3 = 7.4$$
(e) Metabolic alkalosis

Compensations for Respiratory Alkalosis Compensatory measures act to shift pH back toward normal.

■ The chemical buffer systems liberate H^+ to diminish the severity of the alkalosis.

■ As plasma $[CO_2]$ and $[H^+]$ fall below normal because of excessive ventilation, two of the normally potent stimuli for driving ventilation are removed. This effect tends to "put brakes" on the extent to which some nonrespiratory factors such as fever or anxiety can overdrive ventilation. Therefore, hyperventilation does not continue completely unabated.

■ If the situation continues for a few days, the kidneys compensate by conserving H^+ and excreting more HCO_3^-. If, as in our example (❙Figure 15-13c, right), HCO_3^- stores are reduced by half by loss of HCO_3^- in the urine, the $[HCO_3^-]/[CO_2]$ ratio becomes 10/0.5, equivalent to the normal 20/1. Therefore, the pH is restored to normal by reducing the HCO_3^- load to compensate for the CO_2 loss.

Metabolic acidosis is associated with a fall in $[HCO_3^-]$.

Metabolic acidosis (also known as **nonrespiratory acidosis)** encompasses all types of acidosis besides that caused by excess CO_2 in body fluids. In the uncompensated state (❙Figure 15-13d, left), metabolic acidosis is always characterized by a reduction in plasma $[HCO_3^-]$ (in our example it is halved), whereas $[CO_2]$ remains normal, producing an acidotic ratio of 10/1. The problem may arise from excessive loss of HCO_3^--rich fluids from the body or from an accumulation of noncarbonic acids. In the latter case, plasma HCO_3^- is used up in buffering the additional H^+.

Causes of Metabolic Acidosis Metabolic acidosis is the type of acid–base disorder most frequently encountered. Here are its most common causes:

1. *Severe diarrhea.* During digestion, a HCO_3^--rich digestive juice is normally secreted into the digestive tract by the pancreas and is later reabsorbed back into the plasma when digestion is completed. During diarrhea, this HCO_3^- is lost from the body rather than reabsorbed. Because of the loss of HCO_3^-, less HCO_3^- is available to buffer H^+, leading to more free H^+ in the body fluids. Looking at the situation differently, loss of HCO_3^- shifts the $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$ reaction to the right to compensate for the HCO_3^- deficit, increasing $[H^+]$ above normal.

2. *Diabetes mellitus.* Abnormal fat metabolism resulting from the inability of cells to preferentially use glucose because of inadequate insulin action leads to formation of excess keto acids whose dissociation increases plasma $[H^+]$.

3. *Strenuous exercise.* When muscles resort to anaerobic glycolysis during strenuous exercise, excess lactic acid (lactate) is produced, raising plasma $[H^+]$.

4. *Uremic acidosis.* In severe renal failure (uremia), the kidneys cannot rid the body of even the normal amounts of H^+ generated from noncarbonic acids formed by ongoing metabolic processes, so H^+ starts to accumulate in the body fluids.

Also, the kidneys cannot conserve an adequate amount of HCO_3^- for buffering the normal acid load.

Compensations for Metabolic Acidosis Except in uremic acidosis, metabolic acidosis is compensated for by both respiratory and renal mechanisms as well as by chemical buffers.

■ The buffers take up extra H^+.

■ The lungs blow off additional H^+-generating CO_2.

■ The kidneys excrete more H^+ and conserve more HCO_3^-.

In our example (❙Figure 15-13d, right), these compensatory measures restore the ratio to normal by reducing $[CO_2]$ to 75% of normal and by raising $[HCO_3^-]$ halfway back toward normal (up from 50% to 75% of the normal value). This brings the ratio to 15/0.75 (equivalent to 20/1).

Note that in compensating for metabolic acidosis, the lungs deliberately displace $[CO_2]$ from normal in an attempt to restore $[H^+]$ toward normal. Whereas in respiratory-induced acid–base disorders an abnormal $[CO_2]$ is the *cause* of the $[H^+]$ imbalance, in metabolic acid–base disorders $[CO_2]$ is intentionally shifted from normal as an important *compensation* for the $[H^+]$ imbalance.

When kidney disease causes metabolic acidosis, complete compensation is not possible because the renal mechanism is not available for pH regulation. Recall that the respiratory system can compensate only up to 75% of the way toward normal. Uremic acidosis is very serious because the kidneys cannot help restore pH all the way to normal.

Metabolic alkalosis is associated with an elevation in $[HCO_3^-]$.

Metabolic (or **nonrespiratory) alkalosis** is a reduction in plasma $[H^+]$ caused by a relative deficiency of noncarbonic acids. This acid–base disturbance is associated with an increase in $[HCO_3^-]$, which, in the uncompensated state, is not accompanied by a change in $[CO_2]$. In our example (❙Figure 15-13e, left), $[HCO_3^-]$ is doubled, producing an alkalotic ratio of 40/1.

Causes of Metabolic Alkalosis This condition arises most commonly from the following:

1. *Vomiting* causes abnormal loss of H^+ from the body as a result of lost acidic gastric (stomach) juices. HCl is secreted into the stomach lumen during digestion. In the course of gastric HCl secretion, HCO_3^- is added to the plasma. This HCO_3^- is neutralized by H^+ as the gastric secretions are eventually reabsorbed back into the plasma, so normally there is no net addition of HCO_3^- to the plasma from this source. However, when the secreted acid is lost from the body during vomiting instead of being reabsorbed, not only is plasma $[H^+]$ decreased, but also reabsorbed H^+ is no longer available to neutralize the extra HCO_3^- added to the plasma during gastric HCl secretion. Thus, loss of HCl in effect increases plasma $[HCO_3^-]$. (In contrast, with "deeper" vomiting, HCO_3^- in the digestive juices secreted into the upper intestine may be lost in the vomit, resulting in acidosis instead of alkalosis.)

2. *Ingestion of alkaline drugs* can produce alkalosis, such as when baking soda ($NaHCO_3$, which dissociates in solution into Na^+ and HCO_3^-) is used as a self-administered remedy for treating gastric hyperacidity. By neutralizing excess acid in the stomach, HCO_3^- relieves the symptoms of stomach irritation and heartburn; but when more HCO_3^- than needed is ingested, the extra HCO_3^- is absorbed from the digestive tract and increases plasma $[HCO_3^-]$. The extra HCO_3^- binds with some of the free H^+ normally present in plasma from noncarbonic acid sources, reducing free $[H^+]$. (In contrast, commercial alkaline products for treating gastric hyperacidity are not absorbed from the digestive tract to any extent and therefore do not alter the body's acid–base status.)

Compensations for Metabolic Alkalosis

■ In metabolic alkalosis, chemical buffer systems immediately liberate H^+.

■ Ventilation is reduced so that extra H^+-generating CO_2 is retained in the body fluids.

■ If the condition persists for several days, the kidneys conserve H^+ and excrete the excess HCO_3^- in the urine.

The resultant compensatory increase in $[CO_2]$ (up 25% in our example— ❙Figure 15-13e, right) and the partial reduction in $[HCO_3^-]$ (75% of the way back down toward normal in our example) together restore the $[HCO_3^-]/[CO_2]$ ratio back to the equivalent of 20/1 at 25/1.25.

Overview of Compensated Acid–Base Disorders An individual's acid–base status cannot be assessed on the basis of pH alone. Uncompensated acid–base abnormalities can readily be distinguished on the basis of deviations of either $[CO_2]$ or

$[HCO_3^-]$ from normal (❙Table 15-9). However, when compensation has been accomplished and pH is essentially normal, determinations of $[CO_2]$ and $[HCO_3^-]$ can reveal an acid–base disorder, but the type of disorder cannot be distinguished. For example, in both compensated respiratory acidosis and compensated metabolic alkalosis, $[CO_2]$ and $[HCO_3^-]$ are both above normal. With respiratory acidosis, the original problem is an abnormal increase in $[CO_2]$, and a compensatory increase in $[HCO_3^-]$ restores the $[HCO_3^-]/[CO_2]$ ratio to 20/1. Metabolic alkalosis, by contrast, is characterized by an abnormal increase in $[HCO_3^-]$ in the first place; then a compensatory rise in $[CO_2]$ restores the ratio to normal. Similarly, compensated respiratory alkalosis and compensated metabolic acidosis share similar patterns of $[CO_2]$ and $[HCO_3^-]$. Respiratory alkalosis starts out with reduced $[CO_2]$, which is compensated by a reduction in $[HCO_3^-]$. With metabolic acidosis, $[HCO_3^-]$ falls below normal, followed by a compensatory decrease in $[CO_2]$. Thus, in compensated acid–base disorders, the original problem must be determined by clinical signs and symptoms other than deviations in $[CO_2]$ and $[HCO_3^-]$ from normal.

Check Your Understanding 15.3

1. Explain why only a narrow pH range is compatible with life.

2. Discuss in what ways H^+ is continuously added to the body fluids.

3. State the Henderson−Hasselbalch equation and use it to explain why the pH of the plasma can be shifted up or down by both kidney and respiratory influences.

4. If a person has severe diarrhea, tell what type of acid–base abnormality will likely result and describe the compensatory responses of the three lines of defense against this change in $[H^+]$.

❙TABLE 15-9 Summary of $[CO_2]$, $[HCO_3^-]$, and pH in Uncompensated and Compensated Acid–Base Abnormalities

Acid–Base Status	pH	$[CO_2]$ (Compared to Normal)	$[HCO_3^-]$ (Compared to Normal)	$[HCO_3^-]/[CO_2]$
Normal	Normal	Normal	Normal	20/1
Uncompensated respiratory acidosis	Decreased	Increased	Normal	20/2 (10/1)
Compensated respiratory acidosis	Normal	Increased	Increased	40/2 (20/1)
Uncompensated respiratory alkalosis	Increased	Decreased	Normal	20/0.5 (40/1)
Compensated respiratory alkalosis	Normal	Decreased	Decreased	10/0.5 (20/1)
Uncompensated metabolic acidosis	Decreased	Normal	Decreased	10/1
Compensated metabolic acidosis	Normal	Decreased	Decreased	15/0.75 (20/1)
Uncompensated metabolic alkalosis	Increased	Normal	Increased	40/1
Compensated metabolic alkalosis	Normal	Increased	Increased	25/1.25 (20/1)

Homeostasis: Chapter in Perspective

Homeostasis depends on maintaining a balance between the input and the output of all constituents in the internal fluid environment. Regulation of fluid balance involves two separate components: control of salt balance and control of H_2O balance. Control of salt balance is important in the long-term regulation of arterial blood pressure because the body's salt load osmotically holds H_2O, thereby determining the ECF volume, of which plasma volume is a part. An increased salt load in the ECF leads to an expansion in ECF volume, including plasma volume, which in turn causes a rise in blood pressure. Conversely, a reduction in the ECF salt load brings about a fall in blood pressure. Salt balance is maintained by constantly adjusting salt output in the urine to match unregulated, variable salt intake.

Control of H_2O balance is important in preventing changes in ECF osmolarity, which would induce detrimental osmotic shifts of H_2O between the cells and the ECF. Such shifts of H_2O into or out of the cells would cause the cells to swell or shrink, respectively. Cells, especially brain neurons, do not function normally when swollen or shrunken. Water balance is largely maintained by controlling the volume of free H_2O (H_2O not accompanied by solute) lost in the urine to compensate for uncontrolled losses of variable volumes of H_2O from other avenues, such as through sweating or diarrhea, and for poorly regulated H_2O intake. Even though a thirst mechanism exists to control H_2O intake based on need, the amount a person drinks is often influenced by social custom and habit instead of thirst alone.

A balance between input and output of H^+ is critical to maintaining the body's acid–base balance within the narrow limits compatible with life. Deviations in the internal fluid environment's pH lead to altered neuromuscular excitability, to changes in enzymatically controlled metabolic activity, and to K^+ imbalances, which can cause cardiac arrhythmias. These effects are fatal if the pH falls outside the range of 6.8 to 8.0.

Hydrogen ions are uncontrollably and continuously added to the body fluids as a result of ongoing metabolic activities, yet the ECF pH must be kept constant at a slightly alkaline level of 7.4 for optimal body function. Like salt and H_2O balance, control of H^+ output by the kidneys is the main regulatory factor in achieving H^+ balance. The lungs, which can adjust their rate of excretion of H^+-generating CO_2, also help eliminate H^+ from the body. Furthermore, chemical buffer systems can take up or liberate H^+, transiently keeping its concentration constant within the body until its output can be brought into line with its input. Such a mechanism is not available for salt or H_2O balance.

Review Exercises Answers begin on p. A-43

Reviewing Terms and Facts

1. The only avenue by which materials can be exchanged between the cells and the external environment is the ECF. *(True or false?)*

2. Water is driven into the cells when the ECF volume is expanded by an isotonic fluid gain. *(True or false?)*

3. Salt balance in humans is poorly regulated because of our hedonistic salt appetite. *(True or false?)*

4. An unintentional increase in CO_2 is a cause of respiratory acidosis, but a deliberate increase in CO_2 compensates for metabolic alkalosis. *(True or false?)*

5. Secreted H^+ that is coupled with HCO_3^- reabsorption is not excreted, whereas secreted H^+ that is excreted is linked with the addition of new HCO_3^- to plasma. *(True or false?)*

6. The largest body-fluid compartment is the _____.

7. Of the two members of the H_2CO_3:HCO_3^- buffer system, _____ is regulated by the lungs and _____ is regulated by the kidneys.

8. Which of the following factors does *not* increase vasopressin secretion?
   a. ECF hypertonicity
   b. alcohol
   c. stressful situations
   d. an ECF volume deficit
   e. angiotensin II

9. Indicate all correct answers: pH
   a. equals log $1/[H^+]$
   b. equals pK + log $[CO_2]/[HCO_3^-]$
   c. is high in acidosis
   d. falls lower as $[H^+]$ increases
   e. is normal when the $[HCO_3^-]/[CO_2]$ ratio is 20/1

10. Indicate all correct answers: Acidosis
   a. causes overexcitability of the nervous system
   b. exists when the plasma pH falls below 7.35
   c. occurs when the $[HCO_3^-]/[CO_2]$ ratio exceeds 20/1
   d. occurs when CO_2 is blown off more rapidly than it is being produced by metabolic activities
   e. occurs when excessive HCO_3^- is lost from the body, as in diarrhea

11. Indicate all correct answers: The kidney tubular cells secrete NH_3
   a. when the urinary pH becomes too high
   b. when the body is in a state of alkalosis
   c. to enable further renal secretion of H^+ to occur
   d. to buffer excess filtered HCO_3^-
   e. when there is excess NH_3 in the body fluids

12. Complete the following chart:

$\dfrac{[HCO_3^-]}{[CO_2]}$	Uncompensated Abnormality	Possible Cause	pH
10/1	1. _____	2. _____	3. _____
20/0.5	4. _____	5. _____	6. _____
20/2	7. _____	8. _____	9. _____
40/1	10. _____	11. _____	12. _____

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Explain the balance concept.
2. Outline the distribution of body H_2O.
3. Define *transcellular fluid*, and identify its components. Does the transcellular compartment as a whole reflect changes in the body's fluid balance?
4. Compare the ionic composition of plasma, interstitial fluid, and intracellular fluid.
5. What factors are regulated to maintain the body's fluid balance?
6. Why is regulation of ECF volume important? How is it regulated?
7. Why is regulation of ECF osmolarity important? How is it regulated? What are the causes and consequences of ECF hypertonicity and ECF hypotonicity?
8. Outline the sources of input and output in a daily salt balance and a daily H_2O balance. Which are subject to control to maintain the body's fluid balance?
9. Distinguish between an acid and a base.
10. What is the relationship between $[H^+]$ and pH?
11. What is the normal pH of body fluids? How does this compare to the pH of H_2O? Define *acidosis* and *alkalosis*.
12. What are the consequences of fluctuations in $[H^+]$?
13. What are the body's sources of H^+?
14. Describe the three lines of defense against changes in $[H^+]$ in terms of their mechanisms and speed of action.
15. List and indicate the functions of each of the body's chemical buffer systems.
16. Compare the means by which H^+ and HCO_3^- are handled in the proximal tubules and in the Type A and Type B intercalated cells of the distal and collecting tubules.

17. What are the causes of the four categories of acid–base imbalances?
18. Why is uremic acidosis so serious?

Solving Quantitative Exercises

1. Given that plasma pH = 7.4, arterial P_{CO_2} = 40 mm Hg, and each mm Hg partial pressure of CO_2 is equivalent to a plasma $[CO_2]$ of 0.03 mM, what is the value of plasma $[HCO_3^-]$?
2. Death occurs if the plasma pH falls outside the range of 6.8 to 8.0 for an extended time. What is the concentration range of H^+ represented by this pH range?
3. A person drinks 1 liter of distilled water. Use the data in ▌Table 15-1, p. 537, to calculate the resulting percent increase in total body water (TBW), ICF, ECF, plasma, and interstitial fluid. Repeat the calculations for ingestion of 1 liter of isotonic NaCl. Which solution would be better at expanding plasma volume in a patient who has just hemorrhaged?

Applying Clinical Reasoning

Marilyn Y. has had pronounced diarrhea for more than a week as a result of having acquired salmonellosis, a bacterial intestinal infection, from improperly handled food. What effect has this prolonged diarrhea had on her fluid balance and acid–base balance? In what ways has Marilyn's body been trying to compensate for these imbalances?

Thinking at a Higher Level

1. Alcoholic beverages inhibit vasopressin secretion. Given this fact, predict the effect of alcohol on the rate of urine formation. Predict the actions of alcohol on ECF osmolarity. Explain why a person still feels thirsty after excessive consumption of alcoholic beverages.
2. If a person loses 1500 mL of salt-rich sweat and drinks 1000 mL of water during the same time period, what will happen to vasopressin secretion? Why is it important to replace both the water and the salt?
3. If a solute that can penetrate the plasma membrane, such as dextrose (a type of sugar), is dissolved in sterile water at a concentration equal to that of normal body fluids and then is injected intravenously to provide nourishment, what is the effect on the body's fluid balance?
4. Explain why it is safer to treat gastric hyperacidity with antacids that are poorly absorbed from the digestive tract than with baking soda, which is a good buffer for acid but is readily absorbed.
5. Which of the following reactions would buffer the acidosis accompanying severe pneumonia?
   a. $H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$
   b. $CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$
   c. $H^+ + Hb \rightarrow HHb$
   d. $HHb \rightarrow H^+ + Hb$
   e. $NaH_2PO_4 + Na^+ \rightarrow Na_2HPO_4 + H^+$

The Digestive System
Biophoto Associates/Science Source

A transmission electron micrograph of small-intestine villus cells. Shown here is a section of a villus, one of myriad fingerlike projections from the small-intestine lining. Even smaller hairlike projections, the microvilli (*blue*) arise from the surface of the elongated epithelial cells (*yellow with purple nuclei*) that form the villus surface. The villi and microvilli greatly increase the surface area available for processing and absorbing nutrients. Also seen is a mucous cell (*red*), which secretes protective mucus.

CHAPTER AT A GLANCE

Homeostasis Highlights

To maintain homeostasis, nutrient molecules used for energy production must continually be replaced by new, energy-rich nutrients. Also, nutrient molecules, especially proteins, are needed for ongoing synthesis of new cells and cell parts in the course of growth and tissue turnover. Similarly, water and electrolytes constantly lost in urine and sweat and through other avenues must be replenished regularly. The **digestive system** contributes to homeostasis by transferring nutrients, water, and electrolytes from the external environment to the internal environment. The digestive system does not directly regulate the concentration of any of these constituents in the internal environment. It does not vary nutrient, water, or electrolyte uptake based on body needs (with few exceptions); rather, it optimizes conditions for digesting and absorbing what is ingested.

16.1 General Aspects of Digestion

The primary function of the **digestive** (**gastrointestinal** or **GI**) **system** (*gastro* means "stomach") is to transfer nutrients, water, and electrolytes from the food we eat into the body's internal environment. Ingested food is essential as an energy source, or fuel, from which the cells can generate adenosine triphosphate (ATP) to carry out their particular energy-dependent activities, such as active transport, contraction, synthesis, and secretion. Food is also a source of building supplies for the renewal and addition of body tissues.

The act of eating does not automatically make the preformed organic molecules in food available to body cells. Food first must be digested, or chemically broken down, into small, simple molecules that can be absorbed from the digestive tract into the circulatory system for distribution to the cells. Normally, about 95% of the ingested food is made available for the body's use.

We provide an overview of the digestive system, examining the common features of the various components of the system, before we begin a detailed tour of the tract from beginning to end.

The digestive system performs four basic digestive processes.

There are four basic digestive processes: *motility, secretion, digestion,* and *absorption.*

Motility The term **motility** refers to the muscular contractions that mix and move forward the contents within the tract. Although the smooth muscle in the walls of the digestive tract is phasic smooth muscle that displays action potential–induced bursts of contraction (see p. 289), it also maintains a constant low level of contraction known as **tone**. Tone is important in maintaining a steady pressure on the contents of the digestive tract and in preventing its walls from remaining permanently stretched following distension.

Two basic types of phasic digestive motility are superimposed on this ongoing tonic activity: propulsive movements and mixing movements. *Propulsive movements* propel or push the contents forward through the digestive tract. *Mixing movements* have a twofold function. First, by mixing food with the digestive juices, these movements promote digestion of the food. Second, they facilitate absorption by exposing all parts of the intestinal contents to the absorbing surfaces of the digestive tract.

Smooth muscle contraction within the walls of the digestive organs accomplishes movement of material through most of the digestive tract. The exceptions are at the ends of the tract: the mouth through the early part of the esophagus at the beginning and the external anal sphincter at the end. In these regions, motility involves skeletal muscle rather than smooth muscle activity. Accordingly, the acts of chewing, swallowing, and defecation have voluntary components because skeletal muscle is under voluntary control. By contrast, motility accomplished by smooth muscle throughout the rest of the tract is controlled by complex involuntary mechanisms.

Secretion The digestive system produces both exocrine and endocrine secretions. Digestive exocrine gland cells are specialized epithelial cells found in the lining of the digestive tract and in accessory digestive organs like the exocrine pancreas that secrete digestive juices into the digestive tract lumen on appropriate neural or hormonal stimulation. Each **digestive secretion** consists of water, electrolytes, and specific organic constituents important in the digestive process, such as enzymes, bile salts, or mucus. The secretory cells extract from the plasma large volumes of water and the raw materials necessary to produce their particular secretion. Secretion of all digestive juices requires energy, both for active transport of some of the raw materials into the cell (others diffuse in passively) and for synthesis of secretory products. Normally, the digestive secretions are reabsorbed in one form or another back into the blood after their participation in digestion. Failure to do so (because of vomiting or diarrhea, for example) results in loss of this fluid that has been "borrowed" from the plasma.

The digestive system is considered the largest endocrine organ in the body. Whereas peripheral endocrine tissues typically are organized into distinct glands, the endocrine tissue of the gastrointestinal tract is organized as single, individual cells scattered throughout the length of the tract. These specialized epithelial cells produce a range of signal proteins, which are classified as either **GI hormones** or **GI peptides**, that enter the blood and are carried to targets within the tract and outside of the tract. Regardless of their classification, these endocrine secretions regulate digestive function.

Digestion Humans consume three primary categories of energy-rich foodstuffs: *carbohydrates, proteins,* and *fats* (❙Figure 16-1). These large molecules cannot cross plasma membranes intact to be absorbed from the lumen of the digestive tract into the blood or lymph. Therefore, the purpose of **digestion** is to chemically break down the structurally complex foodstuffs of the diet into smaller, absorbable units as follows:

1. The simplest **carbohydrates** are the simple sugars or **monosaccharides** ("one-sugar" molecules), such as **glucose**, **fructose**, and **galactose**, very few of which are normally found in the diet (❙Figure 16-1a; also see pp. A-9–A-10). Most ingested carbohydrate is in the form of **polysaccharides** ("many-sugar" molecules), which consist of chains of interconnected glucose molecules. The most common polysaccharide consumed is **starch**, consisting of the polysaccharides **amylose** (unbranched chain of glucose) and **amylopectin** (branched chain of glucose) derived from plant sources. In addition, meat contains **glycogen**, the more highly branched polysaccharide storage form of glucose in muscle. Indigestible dietary polysaccharides found in plant walls include **insoluble fiber** such as *cellulose* and **soluble fiber** such as *pectin,* which cannot be digested into their constituent monosaccharides by digestive juices humans secrete; thus, indigestible fiber represents the "bulk" of our diets.

Monosaccharides

Glucose Fructose Galactose
Besides polysaccharides, a lesser source of dietary carbohydrate is in the form of **disaccharides** ("two-sugar" molecules), including **sucrose** (table sugar, which consists of one glucose and one fructose molecule) and **lactose** (milk sugar made up of one glucose and one galactose molecule). Through the process of digestion, starch, glycogen, and disaccharides are converted into their constituent monosaccharides, principally glucose with small amounts of fructose and galactose, which are the absorbable units for carbohydrates.

Digestive Organ	Motility
Mouth and salivary glands	Chewing
Pharynx and esophagus	Swallowing
Stomach	Receptive relaxation; peristalsis
Exocrine pancreas	Not applicable
Liver	Not applicable
Small intestine	Segmentation; migrating motility complex
Large intestine	Haustral contractions, mass movements

Secretion	Digestion	Absorption
Saliva ■ Amylase ■ Mucus ■ Lysozyme	Carbohydrate digestion begins	No foodstuffs; a few medications—for example, nitroglycerin
Mucus	None	None
Gastric juice ■ HCl ■ Pepsin ■ Mucus ■ Intrinsic factor	Carbohydrate digestion continues in body of stomach; protein digestion begins in antrum of stomach	No foodstuffs; a few lipid-soluble substances, such as alcohol and aspirin
Pancreatic digestive enzymes ■ Trypsin, chymotrypsin, carboxypeptidase ■ Amylase ■ Lipase Pancreatic aqueous NaHCO₃ secretion	These pancreatic enzymes accomplish digestion in duodenal lumen	Not applicable
Bile ■ Bile salts ■ Alkaline secretion ■ Bilirubin	Bile does not digest anything, but bile salts facilitate fat digestion and absorption in duodenal lumen	Not applicable
Succus entericus ■ Mucus ■ Salt (Small intestine enzymes—disaccharidases and aminopeptidases—are not secreted but function within the brush-border membrane)	In lumen, under influence of pancreatic enzymes and bile, carbohydrate and protein digestion continues and fat digestion is completely accomplished; in brush border, carbohydrate and protein digestion completed	All nutrients, most electrolytes, and water
Mucus	None by human enzymes; bacterial enzymes digest some fiber	Salt and water, converting contents to feces; small amount of nutrients made available by microbial activity

2. Dietary **proteins** consist of various combinations of **amino acids** held together by peptide bonds (❙ Figure 16-1c; also see pp. A-11–A-12). Through the process of digestion, proteins are degraded primarily into their constituent amino acids and a few **small polypeptides** (several amino acids linked by peptide bonds), both of which are the absorbable units for protein.

3. Most dietary **fats** are in the form of **triglycerides**, which are neutral fats, each consisting of a glycerol (an alcohol) with three **fatty acid** molecules attached (*tri* means "three") (❙ Figure 16-1d; also see pp. A-10–A-11). Enzymatic digestion of neutral fats splits two of the fatty acid molecules from the triglyceride, leaving a **monoglyceride**, a glycerol molecule with one fatty acid molecule attached (*mono* means "one"). Thus, the end products of fat digestion are monoglycerides and free fatty acids, which are the absorbable units of fat.

Digestion of all dietary foodstuffs is accomplished by enzymatic **hydrolysis** ("breakdown by water"; see p. A-14). By adding H_2O at the bond site, enzymes in the digestive secretions break down the bonds that hold the small molecular subunits within the nutrient molecules together, thus setting the small molecules free (❙ Figure 16-1b). The removal of H_2O at the bond sites originally joined these small subunits to form nutrient molecules. Hydrolysis replaces the H_2O and frees the small absorbable units. Digestive enzymes are specific in the bonds they can hydrolyze. As food moves through the digestive tract, it is subjected to various enzymes, each of which breaks down the food molecules even further. In this way, large food molecules are converted to simple absorbable units in a progressive, stepwise fashion, like an assembly line in reverse, as the digestive tract contents are propelled forward.

Absorption In the small intestine, digestion is completed and most absorption occurs. Through the process of **absorption**, the small absorbable units that result from digestion, along with water, vitamins, and electrolytes, are transferred from the digestive tract lumen into the blood or lymph.

As we examine the digestive tract from beginning to end, we discuss the four processes of motility, secretion, digestion, and absorption as they take place within each digestive organ (❙ Table 16-1).

The digestive tract and accessory digestive organs make up the digestive system.

The digestive system consists of the digestive tract plus the accessory digestive organs. The **accessory digestive organs** include the *salivary glands,* the *exocrine pancreas,* and the *biliary system,* which is composed of the *liver* and *gallbladder.* These exocrine organs lie outside the digestive tract and empty their secretions through ducts into the digestive tract lumen.

The **digestive tract** is essentially a tube about 4.5 m (15 feet) in length in its normal contractile state.[1] Running through the

---

[1]Because the uncontracted digestive tract in a cadaver is about twice as long as the contracted tract in a living person, anatomy texts indicate that the digestive tract is 30 feet long compared to the length of 15 feet indicated in physiology texts.

middle of the body, the digestive tract includes the following organs (❙Table 16-1): *mouth, pharynx* (throat), *esophagus, stomach, small intestine* (consisting of the *duodenum, jejunum,* and *ileum), large intestine* (the *cecum, appendix, colon,* and *rectum),* and *anus.* Although these organs are continuous with one another, they are considered as separate entities because of their regional modifications, which allow them to specialize in particular digestive activities.

Because the digestive tract is continuous from the mouth to the anus, the lumen of this tube, like the lumen of a straw, is continuous with the external environment. As a result, the contents within the lumen of the digestive tract are technically outside the body, just as the soda you suck through a straw is not a part of the straw. A substance is considered within the body only after it moves from the lumen into the absorptive epithelial cells lining the intestine. This is important because conditions essential to the digestive process can be tolerated in the digestive tract lumen that could not be tolerated in the body proper. Consider the following examples:

■ The pH of the stomach contents falls as low as 2 as a result of gastric secretion of hydrochloric acid (HCl), yet in the body fluids the range of pH compatible with life is 6.8 to 8.0.

■ The digestive enzymes that hydrolyze the protein in food could also destroy the body tissues that produce them. (Protein is the main structural component of cells.) Therefore, once these enzymes are synthesized in inactive form, they are not activated until they reach the lumen, where they actually attack the food outside the body (that is, within the lumen), thereby protecting the body tissues against self-digestion.

■ In the lower part of the intestine exist quadrillions of living microorganisms that are normally harmless and even beneficial, yet if these same microorganisms enter the body proper (as may happen with a ruptured appendix), they may be extremely harmful or even lethal.

■ Foodstuffs are complex foreign particles that would be attacked by the immune system if they were in contact with the body proper. However, the foodstuffs are digested within the lumen into absorbable units such as glucose, amino acids, and fatty acids that are indistinguishable from these simple energy-rich molecules already present in the body.

The digestive tract wall has four layers.

The digestive tract wall has the same general structure throughout most of its length from the esophagus to the anus, with some local variations characteristic for each region. A cross section of the digestive tube reveals four major tissue layers (❙Figure 16-2). From the innermost layer outward, they are the *mucosa,* the *submucosa,* the *muscularis externa,* and the *serosa.*

Mucosa The **mucosa** lines the luminal surface of the digestive tract. It is divided into three layers:

■ The primary component of the mucosa is a **mucous membrane**, an inner epithelial layer that serves as a protective surface. It is also modified in particular areas for secretion and

absorption. The mucous membrane contains *exocrine gland cells* for secretion of digestive juices, *endocrine gland cells* for secretion of blood-borne GI hormones, and *epithelial cells* specialized for absorbing digested nutrients.

■ The **lamina propria** is a thin middle layer of connective tissue on which the epithelium rests. It houses the **gut-associated lymphoid tissue (GALT)**, which is important in defense against disease-causing intestinal bacteria (see p. 405).

■ The **muscularis mucosa** is a sparse outermost mucosal layer of smooth muscle.

In some parts of the tract, such as the small intestine (the main site of digestion and absorption), the mucosal surface is highly folded, with many ridges and valleys that greatly increase the surface area available to maximize nutrient, water, and electrolyte absorption. In contrast, the esophagus exhibits little mucosal folding because it functions primarily as a transit tube. The pattern of surface folding can be modified by contraction of the muscularis mucosa. This is important in exposing different areas of the absorptive surface to the luminal contents.

Submucosa The **submucosa** ("under the mucosa") is a thick layer of connective tissue that provides the digestive tract with its distensibility and elasticity. It contains the larger blood and lymph vessels, both of which send branches inward to the mucosal layer and outward to the surrounding thick muscle layer. Also, a nerve network known as the **submucosal plexus** lies within the submucosa (*plexus* means "network").

Muscularis Externa The **muscularis externa**, the major smooth muscle coat of the digestive tube, surrounds the submucosa. In most parts of the tract, the muscularis externa consists of two layers: an *inner circular layer* and an *outer longitudinal layer.* The fibers of the inner smooth muscle layer (adjacent to the submucosa) run circularly around the tube. Contraction of these circular fibers decreases the diameter of the lumen, constricting the tube at the point of contraction. Contraction of the fibers in the outer layer, which run longitudinally along the length of the tube, shortens the tube. Together, contractile activity of these smooth muscle layers produces the propulsive and mixing movements. Another nerve network, the **myenteric plexus**, lies between the two muscle layers (*myo* means "muscle"; *enteric* means "intestine"). Together the submucosal and myenteric plexuses, along with GI hormones and local chemical mediators, help regulate local gut activity.

Serosa The outer connective tissue covering of the digestive tract is the **serosa**, which secretes a watery, slippery fluid **(serous fluid)** that lubricates and prevents friction between the digestive organs and the surrounding viscera. Throughout much of the tract, the serosa is continuous with the **mesentery**, which suspends the digestive organs from the inner wall of the abdominal cavity like a sling (❙Figure 16-2). This attachment provides relative fixation, supporting the digestive organs in proper position, while still allowing them freedom for mixing and propulsive movements.
Figure 16-2 Layers of the digestive tract wall. The digestive tract wall consists of four major layers: from the innermost out, they are the mucosa, submucosa, muscularis externa, and serosa.

Regulation of digestive function is complex and synergistic.

Digestive motility and secretion are carefully regulated to maximize digestion and absorption of ingested food. Four factors are involved in regulating digestive system function: (1) autonomous smooth muscle function, (2) intrinsic nerve plexuses, (3) extrinsic nerves, and (4) GI hormones.

Autonomous Smooth Muscle Function Smooth muscle of the digestive tract undergoes spontaneous, rhythmic cycles of depolarization and repolarization. The prominent type of self-induced electrical activity in digestive smooth muscle is **slow-wave potentials** (see p. 291), alternatively referred to as the digestive tract's **basic electrical rhythm (BER)**. Located throughout the layers of the muscularis externa are pacemaker cells known as the **interstitial cells of Cajal**. These pacemakers generate the slow-wave potentials that propagate via gap junctions (see p. 62) to adjacent smooth muscle cells. Slow waves are not action potentials and do not directly induce muscle contraction; they are rhythmic, wavelike fluctuations in membrane potential that cyclically bring the membrane closer to or farther from threshold potential. If these waves reach threshold at the peaks of depolarization, a volley of action potentials is triggered

at each peak, resulting in rhythmic cycles of muscle contraction (see Figure 8-32b, p. 291).

Slow waves propagate quickly from cell-to-cell throughout a sheet of digestive smooth muscle by gap junctions through which charge-carrying ions can flow, similar to pacemaker potentials propagating through cardiac muscle. Thus, the whole muscle sheet behaves like a functional syncytium, becoming excited and contracting as a unit when threshold is reached (see p. 291). If threshold is not achieved, the oscillating slow-wave electrical activity continues to sweep across the muscle sheet without being accompanied by contractile activity.

Whether threshold is reached depends on the effect of various mechanical, neural, and hormonal factors that influence the starting point around which the slow-wave rhythm oscillates. If the starting point is nearer the threshold level, as it is when food is present in the digestive tract, the depolarizing slow-wave peak reaches threshold, so action potential frequency and its accompanying contractile activity increase. Conversely, if the starting point is farther from threshold, as when no food is present, threshold will less likely be reached, so action potential frequency and contractile activity are reduced.

The *rate* (frequency) of self-induced rhythmic digestive contractile activities depends on the inherent rate established by the involved pacemaker cells. (Specific details about these

rhythmic contractions will be discussed when we examine the organs involved.) The *intensity* (strength) of these contractions depends on the number of action potentials that occur when the slow-wave potential reaches threshold, which in turn depends on how long threshold is sustained. At threshold, voltage-gated Ca^{2+} channels are activated (see p. 89), resulting in Ca^{2+} influx into the smooth muscle cell. The resultant Ca^{2+} entry has two effects: (1) It is responsible for the rising phase of an action potential, with the falling phase being brought about as usual by K^+ efflux; and (2) it triggers a contractile response (see p. 290). The greater the number of action potentials, the higher the cytosolic Ca^{2+} concentration, the greater the cross-bridge activity, and the stronger the contraction. Other factors that influence contractile activity also do so by altering the cytosolic Ca^{2+} concentration. Thus, the level of contractility can range from low-level tone to vigorous mixing and propulsive movements by varying the cytosolic Ca^{2+} concentration.

Intrinsic Nerve Plexuses The **intrinsic nerve plexuses** are the two major nerve fiber networks—the *submucosal plexus* and the *myenteric plexus*—that lie entirely within the digestive tract wall and run its entire length. Thus, unlike any other body system, the digestive tract has its own intramural ("within-wall") nervous system, which contains as many neurons as the spinal cord (about 100 million neurons) and endows the tract with a considerable degree of self-regulation. Together, these two plexuses are termed the **enteric nervous system** (see p. 135).

The intrinsic plexuses influence all facets of digestive tract activity. Various types of neurons are present in the intrinsic plexuses. Sensory neurons called **intrinsic primary afferent neurons** respond to specific local stimuli in the digestive tract. **Intrinsic efferent neurons** innervate and control smooth muscle and exocrine and endocrine cells of the digestive tract. Similar to the connections within the central nervous system, interneurons receive synaptic input from intrinsic primary afferent neurons and modulate output of the intrinsic efferent neurons.

The intrinsic efferent neurons can directly affect digestive tract motility, secretion of digestive juices, and secretion of GI hormones through excitatory or inhibitory interactions. For example, neurons that release *acetylcholine (ACh)* as a neurotransmitter promote contraction of digestive tract smooth muscle, whereas the neurotransmitters *nitric oxide* and *vasoactive intestinal peptide* act in concert to cause its relaxation. These intrinsic nerve networks primarily coordinate local activity within the digestive tract. To illustrate, if a large piece of food gets stuck in the esophagus, the intrinsic plexuses coordinate local responses to push the food forward. Adding to the complexity of control and accomplishing extensive coordination throughout the digestive tract, intrinsic nerve activity can be influenced by a vast array of endocrine, paracrine, and extrinsic nerve signals.

Extrinsic Nerves The **extrinsic nerves** are the nerve fibers from both branches of the autonomic nervous system that originate outside the digestive tract and regulate digestive tract function. The autonomic nerves influence digestive tract motility and secretion either by modifying ongoing activity in the intrinsic plexuses, altering the level of GI hormone secretion, or acting directly on the smooth muscle and glands.

Recall that, in general, the sympathetic and parasympathetic nerves supplying any given tissue exert opposing actions on that tissue. The sympathetic system, which dominates in "fight-or-flight" situations, tends to inhibit or slow down digestive tract contraction and secretion. This action is appropriate, considering that digestive processes are not of highest priority when the body faces an emergency. The parasympathetic nervous system, by contrast, dominates in quiet, "rest-and-digest" situations, when general maintenance types of activities such as digestion can proceed optimally. Accordingly, the parasympathetic nerve fibers supplying the digestive tract, which arrive primarily by way of the vagus nerve, tend to increase smooth muscle motility and promote secretion of digestive enzymes and hormones. Unique to the parasympathetic nerve supply to the digestive tract, the postganglionic parasympathetic nerve fibers are actually a part of the intrinsic nerve plexuses. They are the ACh-secreting output neurons within the plexuses. Thus, ACh is released in response to local reflexes coordinated entirely by the intrinsic plexuses as well as to vagal stimulation, which acts through the intrinsic plexuses.

In addition to being called into play during generalized sympathetic or parasympathetic discharge, the autonomic nerves, especially the vagus nerve, can be discretely activated to modify only digestive activity. One of the major purposes of specific activation of extrinsic innervation is to coordinate activity among different regions of the digestive system. For example, the act of chewing food reflexly increases not only salivary secretion but also stomach, pancreatic, and liver secretion via vagal reflexes in anticipation of the arrival of food.

GI Hormones The GI hormones produced by specialized endocrine cells tucked within the mucosa of certain regions of the digestive tract exert either excitatory or inhibitory influences on digestive smooth muscle and exocrine gland cells.

Of note, many of these same hormones are released from neurons in the brain, where they act as neurotransmitters and neuromodulators. During embryonic development, certain cells of the developing neural tissue migrate to the digestive system, where they become endocrine cells.

Receptor activation alters digestive activity through neural and hormonal pathways.

The digestive tract wall contains three types of sensory receptors that respond to local changes in the digestive tract: (1) *chemoreceptors* sensitive to chemical components within the lumen, (2) *mechanoreceptors* (pressure receptors) sensitive to stretch or tension within the wall, and (3) *osmoreceptors* sensitive to the osmolarity of the luminal contents.

Stimulation of these receptors elicits neural reflexes or secretion of hormones, both of which alter the activity level in the digestive system's effector cells. These effector cells include smooth muscle cells (for modifying motility), exocrine gland

cells (for controlling secretion of digestive juices), and endocrine gland cells (for varying secretion of GI hormones; ❙Figure 16-3). Receptor activation may bring about two types of neural reflexes—short reflexes and long reflexes. A **short reflex** takes place when all elements of the reflex are located within the wall of the digestive tract itself—that is, when the intrinsic nerve networks influence local motility or secretion in response to specific local stimulation. Extrinsic autonomic nervous activity can be superimposed on the local controls to modify smooth muscle and glandular responses, either to correlate activity between different regions of the digestive system or to modify digestive system activity in response to external influences. Because the autonomic reflexes involve long pathways between the central nervous system and digestive system, they are known as **long reflexes**.

In addition to the sensory receptors within the digestive tract wall that monitor luminal content and wall tension, the plasma membranes of the digestive system's effector cells have receptor proteins that bind with and respond to GI hormones, neurotransmitters, and local chemical mediators.

From this overview, you can see that regulation of GI function is complex, being influenced by many synergistic, interrelated pathways designed to ensure that the appropriate responses occur to digest and absorb the ingested food. Nowhere else in the body experiences so much overlapping control.

We are now going to take a "tour" of the digestive tract, beginning with the mouth and ending with the anus. We examine the four basic digestive processes of motility, secretion, digestion, and absorption at each digestive organ along the way. ❙Table 16-1 summarizes these activities and serves as a useful reference throughout the rest of the chapter.

❙Figure 16-3 **Summary of pathways controlling digestive system activities.**
FIGURE FOCUS: *Describe the means by which the extrinsic autonomic nerves that supply the digestive system are activated and the means by which these nerves control digestive activity.*

Check Your Understanding 16.1

1. List the three categories of energy-rich foodstuffs and the absorbable units of each.
2. Draw a cross section of the digestive tract and label the following: mucosa, submucosa, muscularis externa, serosa, submucosal plexus, and myenteric plexus.
3. Describe how pacemaker activity affects smooth muscle function.

16.2 Mouth

The oral cavity is the entrance to the digestive tract.

Entry to the digestive tract is through the **mouth**, or **oral cavity**. The opening is formed by the muscular **lips**, which help procure, guide, and contain the food in the mouth. The lips also have nondigestive functions; they are important in speech (articulation of many sounds depends on a particular lip formation) and as a sensory receptor in interpersonal relationships (for example, as in kissing). The lips are endowed with especially well-developed tactile (touch) sensation.

The **palate**, which forms the arched roof of the oral cavity, separates the mouth from the nasal passages. Its presence allows breathing and chewing or sucking to take place simultaneously. Hanging from the palate in the rear of the throat is a dangling projection, the **uvula**, which plays an important role in sealing off the nasal passages during swallowing. (The uvula is the structure you elevate when you say "ahhh" so that your health-care provider can better see your throat.)
Figure 16-4 Salivary glands and control of salivary secretion.

FIGURE FOCUS: *Compare the pathways by which eating food and smelling food increase salivary secretion.*

The **tongue**, which forms the floor of the oral cavity, is composed of voluntarily controlled skeletal muscle. The tongue guides food within the mouth during chewing and swallowing and also plays an important role in speech. Furthermore, the major **taste buds** are located on the tongue (see p. 224).

The teeth mechanically break down food.

The first step in the digestive process is **mastication**, or **chewing**, the mouth motility that involves the slicing, tearing, grinding, and mixing of ingested food by the **teeth**. The teeth are firmly embedded in and protrude from the jawbones. The teeth can exert forces much greater than those necessary to eat ordinary food. For example, an adult man can exert a crushing force of up to 200 pounds with his molars, which is sufficient to crack a hard nut, but ordinarily these powerful forces are not used. The degree of **occlusion** (how well the upper and lower teeth fit together when the jaw is closed) is more important than the force of the bite in determining the efficiency of chewing.

Clinical Note When the upper and lower teeth do not make proper contact with one another, they cannot accomplish their normal cutting and grinding action adequately. Such **malocclusion** is usually caused either by overcrowding of teeth too large for the available jaw space or by one jaw being displaced in relation to the other. Malocclusions can often be corrected by applying braces, which exert prolonged gentle pressure against the teeth to move them gradually to the desired position.

The exposed part of a tooth is covered by **enamel**, the hardest structure of the body. Enamel forms before the tooth's eruption by special cells that are lost as the tooth erupts.

Clinical Note Because enamel cannot be regenerated after the tooth has erupted, any defects (**dental caries**, or "cavities") that develop in the enamel must be patched by artificial fillings, or else the surface continues to erode into the underlying living pulp.

The act of chewing can be voluntary, but most chewing during a meal is a rhythmic reflexlike activity accomplished without conscious effort (see p. 277). The functions of chewing are (1) to mechanically break food into smaller pieces to facilitate swallowing and to increase the food surface area on which salivary enzymes can act, (2) to mix food with saliva, and (3) to expose food to the taste buds. Taste bud stimulation not only gives rise to the pleasurable sensation of taste, but also, in feedforward fashion, reflexly increases salivary, gastric, pancreatic, and bile secretion to prepare for the arrival of food.

Saliva begins carbohydrate digestion and helps swallowing, speech, taste, and oral health.

Saliva, the secretion associated with the mouth, is produced largely by three major pairs of salivary glands that lie outside the oral cavity and discharge saliva through short ducts into the mouth (Figure 16-4).

Saliva is about 99.5% H_2O and 0.5% electrolytes and protein. The salivary salt (NaCl) concentration is only one seventh of that in the plasma, which is important in perceiving salty tastes. Similarly, discrimination of sweet tastes is enhanced by the absence of glucose in the saliva. The most important salivary proteins are *amylase, mucus,* and *lysozyme.* They contribute to the functions of saliva, which are as follows:

1. Saliva begins digestion of dietary starches through action of the enzyme **salivary amylase**. The products of digestion include **maltose**, a disaccharide consisting of two glucose molecules (see Figure 16-1b), and **α-limit dextrins**, a branched polysaccharide resulting from amylopectin digestion.

2. Saliva facilitates swallowing by moistening food particles, thereby holding them together, and by providing lubrication through the presence of **mucus**, which is thick and slippery.

3. Saliva exerts some antibacterial action by a fourfold effect—first, by **lysozyme**, a salivary enzyme that lyses, or destroys, certain bacteria by breaking down their cell walls; second, by salivary *IgA antibodies* (see p. 417); third, by salivary *lactoferrin,* which tightly binds to iron that bacteria need to

multiply (see p. 411); and fourth, by rinsing away material that may be a food source for bacteria.

4. Saliva serves as a solvent for molecules that stimulate the taste buds. Only molecules in solution can react with taste bud receptors. The flow of saliva also flushes away the food particles on taste buds so that you can taste the next bite of food.

5. Saliva aids speech by facilitating movements of the lips and tongue. It is difficult to talk when your mouth feels dry.

6. Saliva plays an important role in oral hygiene by helping keep the mouth and teeth clean. The constant flow of saliva helps flush away food residues, foreign particles, and old epithelial cells that have shed from the oral mucosa. Saliva's contribution in this regard is apparent when you have a foul taste in your mouth when salivation is suppressed for a while, such as during a fever or when you are experiencing prolonged anxiety.

7. Saliva is rich in bicarbonate buffers, which neutralize acids in food and acids produced by bacteria in the mouth, thereby helping prevent dental caries.

Despite these many functions, saliva is not essential for digesting and absorbing foods because enzymes produced by the pancreas and small intestine can complete food digestion even in the absence of salivary and gastric secretion. *Clinical Note* The main problems associated with diminished salivary secretion, or **xerostomia**, are difficulty in chewing and swallowing, inarticulate speech unless frequent sips of water are taken when talking, and a rampant increase in dental caries unless special precautions are taken.

Salivary secretion is continuous and can be reflexly increased.

On average, about 1 to 2 liters of saliva are secreted per day, ranging from a continuous spontaneous basal rate of 0.5 mL/min to a maximum flow rate of about 5 mL/min in response to a potent stimulus such as sucking on a lemon. In the absence of food-related stimuli, low-level parasympathetic stimulation induces production of basal salivary secretion. This basal secretion is important in keeping the mouth and throat moist at all times. In addition to this continuous, low-level secretion, salivary secretion may be increased by two types of salivary reflexes, simple and conditioned (❙ Figure 16-4).

Simple and Conditioned Salivary Reflexes The **simple salivary reflex** occurs when chemoreceptors and pressure receptors within the oral cavity respond to the presence of food. On activation, these receptors initiate impulses in afferent nerve fibers that carry the information to the **salivary center**, which is located in the medulla of the brain stem, as are all the brain centers that control digestive activities. The salivary center, in turn, sends impulses via the extrinsic autonomic nerves to the salivary glands to promote increased salivation. Dental procedures, by activating pressure receptors in the mouth, promote salivary secretion in the absence of food.

With the **conditioned**, or **acquired**, **salivary reflex**, salivation occurs without oral stimulation. Just thinking about, seeing, smelling, or hearing the preparation of pleasant food initiates salivation through this reflex. All of us have experienced

such "mouth watering" in anticipation of something delicious to eat. This reflex is a learned response based on previous experience. The cerebral cortex stimulates the medullary salivary center when it receives inputs that arise outside the mouth and are mentally associated with the pleasure of eating.

Autonomic Influence on Salivary Secretion The salivary center controls the degree of salivary output by means of the autonomic nerves that supply the salivary glands. Unlike the autonomic nervous system elsewhere in the body, sympathetic and parasympathetic responses in the salivary glands are not antagonistic. Both sympathetic and parasympathetic stimulation increase salivary secretion, but the quantity and characteristics differ. Parasympathetic stimulation, which exerts the dominant role in salivary secretion, produces a prompt and abundant flow of watery saliva that is rich in enzymes. Sympathetic stimulation, by contrast, produces a smaller volume of thick saliva that is rich in mucus. Because sympathetic stimulation elicits a smaller volume of saliva, the mouth feels drier than usual when the sympathetic system is dominant, such as in stressful situations. For example, people often experience a dry feeling in the mouth when they are nervous about giving a speech.

Salivary secretion is the only digestive secretion entirely under neural control. All other digestive secretions are regulated by both nervous system reflexes and hormones.

Digestion in the mouth is minimal; no absorption of nutrients occurs.

Digestion in the mouth involves the hydrolysis of polysaccharides by amylase. However, most digestion by this enzyme is accomplished in the body of the stomach after the food mass and saliva have been swallowed. Acid inactivates amylase, but in the center of the food mass, where stomach acid has not yet reached, this salivary enzyme continues to function for several more hours.

No absorption of foodstuff occurs from the mouth. Importantly, some drugs can be absorbed by the oral mucosa, a prime example being *nitroglycerin,* a vasodilator drug sometimes used by cardiac patients to relieve angina attacks (see p. 330) associated with myocardial ischemia (see p. 314).

Check Your Understanding 16.2

1. State the functions of salivary mucus, amylase, and lysozyme.
2. Distinguish between simple and conditioned salivary reflexes.
3. Compare the effects of parasympathetic versus sympathetic stimulation of the salivary glands.

16.3 Pharynx and Esophagus

The **pharynx** is the cavity at the rear of the throat. It acts as a common passageway for both the digestive system (by serving as the link between the mouth and esophagus, for food) and the respiratory system (by providing access between the nasal pas-

sages and trachea, for air). This arrangement necessitates mechanisms (to be described shortly) to guide food and air into the proper passageways beyond the pharynx. Housed within the side walls of the pharynx are the **tonsils**, lymphoid tissues that are part of the body's defense team.

The motility associated with the pharynx and esophagus is swallowing. Most of us think of swallowing as the limited act of moving food out of the mouth into the esophagus. However, **swallowing** is the entire process of moving food from the mouth through the esophagus into the stomach.

Swallowing is a sequentially programmed all-or-none reflex.

Swallowing is initiated when a **bolus**, or ball of chewed or liquid food, is voluntarily forced by the tongue to the rear of the mouth and into the pharynx (❙Figure 16-5, step **1**). The pressure of the bolus stimulates pharyngeal pressure receptors, which send afferent impulses to the **swallowing center** located in the medulla of the brain stem. The swallowing center then reflexly activates in the appropriate sequence the muscles involved in swallowing. Swallowing is the most complex reflex in the body, with multiple highly coordinated responses being triggered in a specific all-or-none pattern over a period of time. Swallowing is initiated voluntarily, but once begun it cannot be stopped. Perhaps you have experienced this when a large piece of hard candy inadvertently slipped to the rear of your throat, triggering an unintentional swallow.

Next we describe the two stages of swallowing: the *oropharyngeal stage* and the *esophageal stage.*

During swallowing, food is prevented from entering the wrong passageways.

The **oropharyngeal stage** consists of moving the bolus from the mouth through the pharynx and into the esophagus. When the tongue propels the bolus into the pharynx (❙Figure 16-5, step **2**), the following coordinated activities prevent the bolus from entering the respiratory passageways and direct it into the esophagus:

■ The swallowing center temporarily inhibits the respiratory center (step **3**); thus the person does not attempt futile respiratory efforts while the airways are briefly sealed off.

■ The uvula is elevated and lodges against the back of the throat, sealing off the nasal passage from the pharynx so that food does not enter the nose (step **4**).

■ The tongue's position against the hard palate keeps food from reentering the mouth during swallowing (step **5**).

■ Food is prevented from entering the trachea primarily by elevation of the larynx and tight closure of the vocal folds across the laryngeal opening, or **glottis** (step **6**). The first part of the trachea is the *larynx,* or *voice box,* across which the *vocal folds* are stretched. During swallowing, the vocal folds serve a purpose unrelated to speech. Contraction of laryngeal muscles aligns the vocal folds in tight apposition to each other, thus sealing the glottis entrance (see ❙Figure 13-3, p. 448). Last, the **epiglottis** (*epi* means "upon"), a flap of cartilaginous tissue an-

terior to the glottis, folds backward down over the closed glottis as further protection from food entering the respiratory airways (step **7**).

■ With the glottis closed, pharyngeal muscles contract to force the bolus into the esophagus (step **8**).

The pharyngoesophageal sphincter prevents air from entering the digestive tract.

The **esophagus** is a fairly straight muscular tube that extends between the pharynx and the stomach (see ❙Table 16-1, p. 568). Lying mostly in the thoracic cavity, it penetrates the diaphragm and joins the stomach in the abdominal cavity a few centimeters below the diaphragm.

The esophagus is guarded at both ends by sphincters. A sphincter is a ringlike muscular structure that, when closed, prevents passage through the tube it guards. The upper esophageal sphincter is the *pharyngoesophageal sphincter,* and the lower esophageal sphincter is the *gastroesophageal sphincter.* We first discuss the role of the pharyngoesophageal sphincter, then the process of esophageal transit of food, and finally the importance of the gastroesophageal sphincter.

Because the esophagus is exposed to subatmospheric intrapleural pressure as a result of respiratory activity (see p. 450), a pressure gradient exists between the atmosphere and the esophagus. Except during a swallow, the **pharyngoesophageal sphincter** remains closed as a result of neurally induced contraction of the sphincter's circular skeletal muscle. Tonic contraction of this upper esophageal sphincter prevents large volumes of air from entering the esophagus and stomach during breathing, thus averting excessive *eructation* (burping). Instead, air is directed only into the respiratory airways. During swallowing, this sphincter opens and allows the bolus to pass into the esophagus (❙Figure 16-5, step **8**). Once the bolus has entered the esophagus, the pharyngoesophageal sphincter closes, the respiratory airways are opened, and breathing resumes (step **9**). The oropharyngeal stage is complete, and about 1 second has passed since the swallow was initiated.

Peristaltic waves push food through the esophagus.

The **esophageal stage** of the swallow now begins. The swallowing center triggers a **primary peristaltic wave** that sweeps from the beginning to the end of the esophagus, forcing the bolus ahead of it toward the stomach. The term **peristalsis** refers to ringlike contractions of the circular smooth muscle that move progressively forward, pushing the bolus into a relaxed area ahead of the contraction (❙Figure 16-5, step **10**). The peristaltic wave takes about 5 to 9 seconds to reach the lower end of the esophagus. Progression of the wave is controlled by the swallowing center, with innervation by means of the vagus.

If a large or sticky swallowed bolus, such as a bite of peanut butter sandwich, fails to be carried along to the stomach by the primary peristaltic wave, the lodged bolus distends the esophagus, stimulating stretch receptors within its walls. In response to the stimulus, the intrinsic nerve plexus at the point of distension

initiates additional peristaltic waves to clear the lodged bolus. These **secondary peristaltic waves** do not involve the swallowing center, nor is the person aware of their occurrence. Distension of the esophagus also reflexly increases salivary secretion. The trapped bolus is eventually dislodged and moved forward through the combined effects of lubrication by the extra swallowed saliva and the forceful secondary peristaltic waves. Esophageal peristalsis is so effective you could eat an entire meal while you were upside down and it would all promptly be pushed to the stomach.

The gastroesophageal sphincter prevents reflux of gastric contents.

Except during swallowing, the **gastroesophageal sphincter**, which is smooth muscle in contrast to the upper esophageal sphincter, stays tonically contracted by means of myogenic activity (see p. 291). Contraction also increases during inspiration, reducing the chance of reflux of acidic gastric contents into the esophagus during the time when the subatmosphteric intrapleural pressure would favor backward movement of gastric contents. If gastric contents do flow backward despite the sphincter, the acidity of these contents irritates the esophagus, causing the esophageal discomfort known as **heartburn**. (The heart itself is not involved.)

As the peristaltic wave sweeps down the esophagus, the gastroesophageal sphincter relaxes so that the bolus can pass into the stomach (❙Figure 16-5, step **11**). After the bolus has entered the stomach, the swallow is complete and this lower esophageal sphincter again contracts.

Esophageal secretion is entirely protective.

Esophageal secretion is entirely mucus, which lubricates passage of food, thereby lessening the likelihood of esophageal damage by any sharp edges on food. Also, mucus helps protect the esophagus from damage by acid and enzymes in gastric juice should gastric reflux occur. (In fact, protective mucus is secreted throughout the length of the digestive tract.)

The entire transit time in the pharynx and esophagus averages a mere 6 to 10 seconds, too short a time for any digestion or absorption in this region. We now move on to our next stop, the stomach.

Check Your Understanding 16.3

1. Describe how the pharynx prevents food entry into the trachea during a swallow.

2. State the functions of the pharyngoesophageal and the gastroesophageal sphincters.

16.4 Stomach

The **stomach** is a J-shaped saclike chamber lying between the esophagus and the small intestine. It is divided into three sections based on structural and functional distinctions (❙Figure 16-6). The **fundus** is the part of the stomach that lies above the esophageal opening. The middle or main part of the stomach is

the **body**. The smooth muscle layers in the fundus and body are relatively thin, but the lower part of the stomach, the **antrum**, has heavier musculature. This difference in muscle thickness plays an important role in gastric motility in these two regions, as you will see shortly. There are also glandular differences in the mucosa of these regions, as described later. The terminal portion of the stomach is the **pyloric sphincter**, which acts as a barrier between the stomach and the upper part of the small intestine, the duodenum.

The stomach stores food and begins protein digestion.

The stomach performs three main functions:

1. The stomach's most important function is to store ingested food until it can be emptied into the small intestine at a rate appropriate for optimal digestion and absorption. It takes hours to digest and absorb a meal that was consumed in only a matter of minutes. Because the small intestine is the primary site for this digestion and absorption, it is important that the stomach store the food and meter it into the duodenum at a rate that does not exceed the small intestine's capacities.

2. The stomach secretes hydrochloric acid (HCl) and enzymes that begin protein digestion.

3. Through the stomach's mixing movements, the ingested food is pulverized and mixed with gastric secretions to produce a thick liquid mixture known as **chyme**. The stomach contents must be converted to chyme before they can be emptied into the duodenum.

Next we discuss how the stomach accomplishes these functions as we examine the four basic digestive processes as they relate
❙Figure 16-6 **Anatomy of the stomach.** The stomach is divided into three sections based on structural and functional distinctions—the fundus, body, and antrum. The mucosal lining of the stomach is divided into the oxyntic mucosa and the pyloric gland area based on differences in glandular secretion.

Unless otherwise noted, all content on this page is © Cengage Learning.

to the stomach, starting with motility. Gastric motility is complex and subject to multiple regulatory inputs. The four aspects of gastric motility are (1) filling, (2) storage, (3) mixing, and (4) emptying.

Gastric filling involves receptive relaxation.

When empty, the stomach has a volume of about 50 mL, but it can expand up to 20-fold to a capacity of about 1 liter (1000 mL) during a meal. Here's how. The interior of the stomach is thrown into deep folds. During a meal, the folds get smaller and nearly flatten out as the stomach relaxes slightly with each mouthful, much like the gradual expansion of a collapsed ice bag as it is being filled. This vagally mediated response, called **receptive relaxation**, allows the stomach to accommodate the meal with little change in intragastric pressure. If more than a liter of food is consumed, however, the stomach becomes overdistended, intragastric pressure rises, and the person experiences discomfort.

Gastric storage takes place in the body of the stomach.

A group of pacemaker cells (interstitial cells of Cajal) located in the upper fundus region of the stomach generate slow-wave potentials that sweep down the length of the stomach toward the pyloric sphincter at a rate of three per minute. This rhythmic pattern of spontaneous depolarizations—the basic electrical rhythm, or BER, of the stomach—occurs continuously and may or may not be accompanied by contraction of the stomach's circular smooth muscle layer. Depending on the level of excitability in the smooth muscle, it may be brought to threshold by this flow of current and undergo action potentials, which in turn initiate peristaltic waves that sweep over the stomach in pace with the BER at a rate of three per minute.

Once initiated, a peristaltic wave spreads over the fundus and body to the antrum and pyloric sphincter. Because the muscle layers are thin in the fundus and body, the peristaltic contractions in this region are weak. When the waves reach the antrum, they become stronger and more vigorous because the muscle there is thicker.

Because only feeble mixing movements occur in the body and fundus, food delivered to the stomach from the esophagus is stored in the relatively quiet body without being mixed. The fundus usually does not store food but contains only a pocket of gas. Food is gradually fed from the body into the antrum, where mixing does take place.

Gastric mixing takes place in the antrum of the stomach.

The strong antral peristaltic contractions mix the food with gastric secretions to produce chyme. Each antral peristaltic wave propels chyme distally toward the pyloric sphincter. Tonic contraction of the pyloric sphincter normally keeps it almost, but not completely, closed. The opening is large enough for water and other fluids to pass through with ease, although particles larger than 2 mm in diameter typically do not leave. As the peristaltic wave reaches the pyloric sphincter and closes it

tightly, the large particles are forced backward toward the body of the stomach (❙ Figure 16-7). The bulk of the antral chyme that is forced backward is again propelled forward and then tumbled back as the next peristaltic wave advances. This churning action is called **retropulsion**, which thoroughly shears and grinds the chyme until the particles are small enough for emptying, mixing the contents in the process.

Gastric emptying is largely controlled by factors in the duodenum.

In addition to mixing gastric contents, the antral peristaltic contractions are the driving force for gastric emptying (❙ Figure 16-7). The amount of chyme that escapes into the duodenum with each peristaltic wave before the pyloric sphincter tightly closes depends largely on the strength of antral peristalsis. The intensity of antral peristalsis and thus the rate of gastric emptying can vary markedly under the influence of various signals from both the stomach and duodenum (❙ Table 16-2). These factors influence the stomach's excitability by slightly depolarizing or hyperpolarizing the gastric smooth muscle. The greater the excitability is, the more frequently the BER generates action potentials, the greater the strength of antral peristalsis, and the faster the rate of gastric emptying.

Factors in the Stomach that Influence the Rate of Gastric Emptying The main gastric factor that influences the strength of contraction is the amount of chyme in the stomach. Other things being equal, the stomach empties at a rate proportional to the volume of chyme in it at any given time. Stomach distension triggers increased gastric motility through a direct effect of stretch on the smooth muscle and through involvement of the intrinsic plexuses, the vagus nerve, and the stomach hormone *gastrin*. (The source, control, and other functions of this hormone will be described later.)

Furthermore, the degree of fluidity of the chyme influences gastric emptying. The stomach contents must be converted into a finely divided, thick liquid form before emptying. The sooner the appropriate degree of fluidity can be achieved, the more rapidly the contents are ready to be evacuated.

Factors in the Duodenum that Influence the Rate of Gastric Emptying Despite these gastric influences, factors in the duodenum are of primary importance in controlling the rate of gastric emptying. The duodenum must be ready to receive the chyme and can delay gastric emptying by reducing the strength of antral peristalsis until the duodenum is ready to accommodate more chyme. The four most important duodenal factors that influence gastric emptying are *fat, acid, hypertonicity,* and *distension.* The presence of one or more of these stimuli in the duodenum activates appropriate duodenal receptors, triggering neural and hormonal responses that put brakes on antral peristaltic activity, thereby slowing the rate of gastric emptying:

■ The *neural response* is mediated through both the intrinsic plexuses (short reflex) and the autonomic nerves (long reflex). Together these constitute the **enterogastric reflex**.

Gastric emptying
1 A peristaltic contraction originates in the upper fundus and sweeps down toward the pyloric sphincter.

2 The contraction becomes more vigorous as it reaches the thick-muscled antrum.

3 The strong antral peristaltic contraction propels the chyme forward.

4 A small portion of chyme is pushed through the partially open sphincter into the duodenum. The stronger the antral contraction, the more chyme is emptied with each contractile wave.

Gastric mixing

5 When the peristaltic contraction reaches the pyloric sphincter, the sphincter is tightly closed and no further emptying takes place.

6 When chyme that was being propelled forward hits the closed sphincter, it is tossed back into the antrum. Mixing of chyme is accomplished as chyme is propelled forward and tossed back into the antrum with each peristaltic contraction, a process called retropulsion.

IFigure 16-7 **Gastric emptying and mixing as a result of antral peristaltic contractions.**

■ The *hormonal response* involves the release from the small-intestine mucosa into the blood of several hormones collectively known as **enterogastrones**. The blood carries these hormones to the stomach, where they inhibit antral contractions to reduce gastric emptying. The two most important enterogastrones are **secretin** and **cholecystokinin (CCK)**. Secretin was the first hormone discovered (in 1902). Because it was a secretory product that entered the blood, it was termed *secretin*. The name *cholecystokinin* derives from this same hormone also causing contraction of the bile-containing gallbladder (*chole* means "bile";

ITABLE 16-2 Factors Regulating Gastric Motility and Emptying

Factors	Mode of Regulation	Effects on Gastric Motility and Emptying
Within the Stomach		
Volume of chyme	Distension has a direct effect on gastric smooth muscle excitability, as well as acting through the intrinsic plexuses, the vagus nerve, and gastrin	Increased volume stimulates motility and emptying
Degree of fluidity	Direct effect; contents must be in a fluid form to be evacuated	Increased fluidity allows more rapid emptying
Within the Duodenum		
Presence of fat, acid, hypertonicity, or distension	Initiates the enterogastric reflex or triggers the release of enterogastrones (secretin, cholecysto-kinin)	These factors in the duodenum inhibit further gastric motility and emptying until the duodenum has coped with factors already present
Outside the Digestive System		
Emotion	Alters autonomic balance	Stimulates or inhibits motility and emptying
Intense pain	Increases sympathetic activity	Inhibits motility and emptying

Pregame Meal: What's In and What's Out?

MANY COACHES AND ATHLETES BELIEVE intensely in special food rituals before a competitive event. For example, a football team may always eat steak before a game. Another may always include bananas in their pregame meal. Do these rituals work?

Many studies have been done to determine the effect of the pregame meal on athletic performance. Although laboratory studies have shown that substances such as caffeine improve endurance, no food substance that greatly enhances performance has been identified. The athlete's prior training is the most important determinant of performance. Even though no particular food confers a special benefit before an athletic contest, some food choices can actually hinder the competitors. For example, a meal of steak is high in fat and could take so long to digest that it might impair the football team's performance and thus should be avoided. However, food rituals that do not impair performance, such as eating bananas, but give the athletes a morale boost or extra confidence, are harmless and should be respected. People may attach special meanings to eating certain foods, and their faith in these practices can make the difference between winning and losing a game.

The greatest benefit of the pregame meal is to prevent hunger during competition. Because the stomach can take from 1 to 4 hours to empty, an athlete should eat at least 3 to 4 hours before competition begins. Excessive quantities of food should not be consumed before competition. Food that remains in the stomach during competition may cause nausea and possibly vomiting. This condition can be aggravated by nervousness, which slows digestion and delays gastric emptying by means of the sympathetic nervous system.

The best choices are foods that are high in carbohydrate and low in fat and protein. The goal is to maintain blood glucose levels and carbohydrate stores in the body and to not have much undigested food in the stomach during the event. High-carbohydrate foods are recommended because they are emptied from the stomach more quickly than fat or protein is. Carbohydrates do not inhibit gastric emptying by means of enterogastrone release, whereas fats and proteins do. Fats in particular delay gastric emptying and are slowly digested. Metabolic processing of proteins yields nitrogenous wastes such as urea whose osmotic activity draws water from the body and increases urine volume, both of which are undesirable during an athletic event. Good choices for a pregame meal include breads, pasta, rice, potatoes, gelatins, and fruit juices. Not only are these complex carbohydrates emptied from the stomach if consumed 1 to 4 hours before a competitive event, but they also help maintain the blood glucose level during the event.

Although it might seem logical to consume something sugary immediately before a competitive event to provide an "energy boost," beverages and foods high in sugar should be avoided because they trigger insulin release. Insulin is the hormone that enhances glucose entry into most body cells. Once the person begins exercising, insulin sensitivity increases (see p. 72), which lowers blood glucose level. A lowered blood glucose level induces feelings of fatigue and an increased use of muscle glycogen stores, which can limit performance in endurance events such as a marathon. Therefore, sugar consumption just before a competition can actually impair performance instead of giving the sought-after energy boost.

Within an hour of competition, it is best for athletes to drink only plain water, to ensure adequate hydration.

---

cysto means "bladder"; and *kinin* means "contraction"). Secretin and CCK are major GI hormones that perform other important functions in addition to serving as enterogastrones.

Let us examine why it is important that each of these stimuli in the duodenum (fat, acid, hypertonicity, and distension) delays gastric emptying:

■ *Fat.* Among the different nutrients that we consume, fat is most effective in delaying gastric emptying. This effect is important because fat digestion and absorption take more time than for the other nutrients and take place only in the small-intestine lumen. Triglycerides strongly stimulate duodenal release of CCK. This hormone inhibits antral contractions and also induces contraction of the pyloric sphincter, which both slow gastric emptying. This delay in emptying ensures that the small intestine has enough time to digest and absorb the fat already there before more fat enters from the stomach. That fat is the most potent inhibitor of gastric emptying is evident

when you compare the rate of emptying of a high-fat meal (after 6 hours, some of a bacon-and-eggs meal may still be in the stomach) with that of a protein and carbohydrate meal (a meal of lean meat and potatoes may empty in 3 hours). (For a discussion of the pregame meal before participation in an athletic event, see the accompanying boxed feature, ▮A Closer Look at Exercise Physiology.)

■ *Acid.* Because the stomach secretes HCl, highly acidic chyme empties into the duodenum, where it is neutralized by sodium bicarbonate ($NaHCO_3$) secreted into the duodenum primarily from the pancreas. Unneutralized acid may damage the duodenal mucosa and inactivate the pancreatic digestive enzymes secreted into the duodenum. Appropriately, unneutralized acid in the duodenum induces the release of secretin, a hormone that slows emptying of acidic gastric contents until complete neutralization can be accomplished.

■ *Hypertonicity.* As molecules of protein and starch are digested in the duodenum, large numbers of amino acid and glucose

molecules are released. If absorption of these amino acid and glucose molecules does not keep pace with the rate at which protein and carbohydrate digestion proceeds, these large numbers of molecules remain in the chyme and increase the osmolarity of the duodenal contents. Osmolarity depends on the number of molecules present, not on their size, and one protein molecule may be split into several hundred amino acid molecules, each of which has the same osmotic activity as the original protein molecule. The same holds true for one large starch molecule, which yields many smaller but equally osmotically active glucose molecules. Because water is freely diffusible across the duodenal wall, it enters the duodenal lumen from the plasma as the duodenal osmolarity rises. Large volumes of water entering the intestine from the plasma lead to intestinal distension, and, more important, circulatory disturbances result because of the reduction in plasma volume. To prevent these effects, gastric emptying is reflexly inhibited when the osmolarity of the duodenal contents starts to rise. Thus, the amount of food entering the duodenum for further digestion into a multitude of additional osmotically active particles is reduced until absorption processes have had an opportunity to catch up.

■ *Distension.* Too much chyme in the duodenum inhibits the emptying of even more gastric contents, giving the distended duodenum time to cope with the excess volume of chyme it already contains before it gets any more.

Emotions can influence gastric motility.

Other factors unrelated to digestion, such as emotions, can alter gastric motility by acting through the autonomic nerves to influence the degree of gastric smooth muscle excitability. Even though the effect of emotions on gastric motility varies among people and is not always predictable, sadness and fear generally tend to decrease motility, whereas anger and aggression tend to increase it. In addition to emotional influences, intense pain from any part of the body tends to inhibit motility throughout the digestive tract. This response is brought about by increased sympathetic activity.

The stomach does not actively participate in vomiting.

Clinical Note **Vomiting**, or **emesis**, the forceful expulsion of gastric contents out through the mouth, is not accomplished by reverse peristalsis in the stomach, as might be predicted. Actually, the stomach itself does not actively participate in vomiting. The stomach, the esophagus, and associated sphincters are all relaxed during vomiting. The major force for expulsion comes, surprisingly, from contraction of the respiratory muscles—namely, the diaphragm (the major inspiratory muscle) and the abdominal muscles (the muscles of active expiration) (see ❙Figure 13-11, p. 454).

The complex act of vomiting is coordinated by a **vomiting center** in the medulla of the brain stem. Vomiting is usually preceded by profuse salivation, sweating, rapid heart rate, and sensation of nausea. Vomiting begins with a deep inspiration and closure of the glottis. The contracting diaphragm descends downward on the stomach while simultaneous contraction of the abdominal muscles compresses the abdominal cavity, increasing

the intra-abdominal pressure and forcing the abdominal viscera upward. As the flaccid stomach is squeezed between the diaphragm from above and the compressed abdominal cavity from below, the gastric contents are forced upward through the relaxed sphincters and esophagus and out through the mouth. The glottis is closed, so vomited material does not enter the trachea. Also, the uvula is raised to close off the nasal cavity. The vomiting cycle may be repeated several times until the stomach is emptied.

Causes of Vomiting Vomiting can be initiated by afferent input to the vomiting center from various receptors throughout the body, including the following:

■ Tactile (touch) stimulation of the back of the throat, which is one of the most potent stimuli. For example, sticking a finger in the back of the throat or even the presence of a tongue depressor or dental instrument in the back of the mouth can trigger gagging and even vomiting in some people.

■ Irritation or distension of the stomach and duodenum.

■ Elevated intracranial pressure, such as that caused by cerebral hemorrhage. Thus, vomiting after a head injury is considered a bad sign; it suggests swelling or bleeding within the cranial cavity.

■ Rotation or acceleration of the head producing dizziness, such as in motion sickness.

■ Chemical agents, including drugs or noxious substances that initiate vomiting (that is, **emetics**) either by acting in the upper parts of the GI tract or by stimulating chemoreceptors in a specialized **chemoreceptor trigger zone** next to the vomiting center in the brain. For example, chemotherapeutic agents used in treating cancer often cause vomiting by acting on the chemoreceptor trigger zone.

■ Psychogenic vomiting induced by emotional factors, including those accompanying nauseating sights and odors and anxiety, as before taking an examination.

Effects of Vomiting With excessive vomiting, the body experiences large losses of secreted fluids and acids that normally would be reabsorbed. The resulting reduction in plasma volume can lead to dehydration and circulatory problems, and the loss of acid from the stomach can lead to metabolic alkalosis (see p. 561).

We have completed our discussion of gastric motility and now shift to gastric secretion.

Gastric digestive juice is secreted by glands located at the base of gastric pits.

Each day, the stomach secretes about 2 liters of gastric juice. The cells that secrete gastric juice are located in the gastric mucosa, which is divided into two distinct areas: (1) the **oxyntic mucosa**, which lines the body and fundus, and (2) the **pyloric gland area (PGA)**, which lines the antrum. The luminal surface of the stomach is pitted with deep pockets formed by infoldings of the gastric mucosa. The first parts of these invaginations are called **gastric pits**, at the base of which lie the **gastric glands**. A variety of secretory cells line these invaginations, some exocrine and some endocrine or paracrine (❙Table 16-3). Let us look at the gastric exocrine secretory cells first.

■TABLE 16-3 The Stomach Mucosa and the Gastric Glands			
Type of Secretory Cell	Product Secreted	Stimuli for Secretion	Function(s) of Secretory Product
Exocrine Cells			
Mucous cells	Alkaline mucus	Mechanical stimulation by contents	Protects mucosa against mechanical, pepsin, and acid injury
Chief cells	Pepsinogen	ACh, gastrin	When activated, begins protein digestion
Parietal cells	Hydrochloric acid	ACh, gastrin, histamine	Activates pepsinogen, breaks down connective tissue, denatures proteins, kills microorganisms
	Intrinsic factor		Facilitates absorption of vitamin B_{12}
Endocrine/Paracrine Cells			
Enterochromaffin-like (ECL) cells	Histamine	ACh, gastrin	Stimulates parietal cells
G cells	Gastrin	Protein products, ACh	Stimulates parietal, chief, and ECL cells
D cells	Somatostatin	Acid	Inhibits parietal, G, and ECL cells

Three types of gastric exocrine secretory cells are found in the walls of the pits and glands in the oxyntic mucosa:

- **Mucous cells** line the gastric pits and the entrance of the glands. They secrete a thin, watery *mucus.* (*Mucous* is the adjective; *mucus* is the noun.)

- The deeper parts of the gastric glands are lined by chief and parietal cells. The more numerous **chief cells** secrete the enzyme precursor *pepsinogen.*

- The **parietal** (or **oxyntic**) **cells** secrete *HCl* and *intrinsic factor* (*oxyntic* means "sharp," a reference to these cells' potent HCl secretory product).

These exocrine secretions are all released into the gastric lumen. Collectively, they make up the gastric digestive juice.

In contrast to the oxyntic mucosa, the gastric glands of the PGA primarily secrete mucus and a small amount of pepsinogen; no acid is secreted in this area.

Between the gastric pits, the gastric mucosa is covered by **surface epithelial cells**, which secrete a sticky, alkaline mucus that forms a visible layer several millimeters thick over the surface of the mucosa.

A few **stem cells** are also found in the gastric pits. These cells rapidly divide and are the parent cells of all new cells of the gastric mucosa. The daughter cells that result from cell division either migrate out of the pit to become surface epithelial cells or migrate deeper to the gastric glands where they differentiate into chief or parietal cells. Through this activity, the entire stomach mucosa is replaced about every 3 days. This frequent turnover is important because the harsh acidic stomach contents expose the mucosal cells to lots of wear and tear.

Let us consider these exocrine products and their roles in digestion in further detail.

Hydrochloric acid is secreted by parietal cells and activates pepsinogen.

Parietal cells are scattered among the chief cells in the epithelial lining of the gastric glands. When stimulated, parietal cells form deep invaginations called **canaliculi** (singular *canaliculus*) along the luminal (or apical) membrane, which increase the membrane surface area bearing transport proteins that actively secrete HCl into the lumen of the gastric pits. Each pit drains acid into the lumen of the stomach, which can cause the luminal pH to fall as low as 2.

Hydrogen ion (H^+) and chloride ion (Cl^-) are actively secreted by separate pumps. H^+ is actively transported against a tremendous concentration gradient, with the H^+ concentration being as much as 3 million times greater in the lumen than in the blood. Cl^- is secreted by a secondary active-transport mechanism against a much smaller concentration gradient of only 1.5 times.

Mechanism of H^+ and Cl^- Secretion The secreted H^+ is not transported from the plasma but is derived from the breakdown of H_2O molecules into H^+ and OH^- (hydroxyl ions) within the parietal cells (❙Figure

16-8). This H^+ is secreted into the lumen by a H^+–K^+ATPase pump in the parietal cell's luminal membrane. This primary active-transport carrier also pumps K^+ into the cell from the lumen (see p. 73). The transported K^+ then passively leaks back into the lumen through luminal K^+ channels, thus leaving K^+ levels unchanged by the process of H^+ secretion.

The parietal cells contain an abundance of the enzyme carbonic anhydrase (ca) (see pp. 477 and 550). In the presence of ca, the OH^- generated by the breakdown of H_2O readily combines with CO_2 (which either has been produced within the parietal cell by metabolic processes or has diffused in from the blood) to form HCO_3^-. The generated HCO_3^- is moved into the plasma by a Cl^-–HCO_3^- antiporter in the basolateral membrane of the parietal cells (see p. 74). Driven by the HCO_3^- gradient, this carrier moves HCO_3^- out of the cell into the plasma down its electrochemical gradient and simultaneously transports Cl^- from the plasma into the parietal cell against its electrochemical gradient. By building up the concentration of Cl^- inside the parietal cell, the Cl^-–HCO_3^- antiporter establishes a Cl^- concentration gradient between the parietal cell and gastric lumen. Because of this concentration gradient and because the cell interior is negative compared to the luminal contents, the negatively charged Cl^- pumped into the cell by the basolateral antiporter diffuses out of the cell down its elec-

❙Figure 16-8 **Mechanism of HCl secretion.** The stomach's parietal cells actively secrete H^+ and Cl^- by the actions of two separate pumps. H^+ is secreted into the lumen by a primary H^+–K^+ ATPase active-transport pump at the parietal cell's luminal border. The H^+ that is secreted, as well as HCO_3^-, is formed within the parietal cell from H_2O and CO_2 in a reaction catalyzed by carbonic anhydrase. Cl^- is secreted by secondary active transport. Driven by the HCO_3^- concentration gradient, a Cl^-–HCO_3^- antiporter in the basolateral membrane transports HCO_3^- down its concentration gradient into the plasma and simultaneously transports Cl^- into the parietal cell against its concentration gradient. Cl^- secretion is completed as the Cl^- that entered from the plasma diffuses out of the cell down its electrochemical gradient through a luminal Cl^- channel into the lumen.

FIGURE FOCUS: *What effect does a drug that blocks the parietal cells' H^+–K^+ ATPase pump have on gastric HCl secretion and on the pH of the venous blood leaving the stomach?*

trochemical gradient through Cl^- channels in the luminal membrane into the gastric lumen, completing the Cl^- secretory process. In the meantime, the blood leaving the stomach is alkaline because HCO_3^- has been added to it.

Functions of HCl Although HCl does not actually digest anything (that is, it does not break apart nutrient chemical bonds), it performs these specific functions that aid digestion:

1. HCl activates the enzyme precursor pepsinogen to an active enzyme, *pepsin,* and provides an acid environment optimal for pepsin action.
2. It aids in the breakdown of connective tissue and muscle fibers, reducing large food particles into smaller particles.
3. It denatures protein—that is, it uncoils proteins from their highly folded final form, thus exposing more of the peptide bonds for enzymatic attack (see p. A-14).
4. Along with salivary lysozyme, HCl kills most of the microorganisms ingested with food, although some escape and then grow and multiply in the large intestine.

Pepsinogen is activated to pepsin, which begins protein digestion.

The major digestive constituent of gastric secretion is **pepsinogen**, an inactive enzymatic molecule produced by the chief cells. Pepsinogen, once activated to the enzyme **pepsin**, begins protein digestion. Pepsinogen is stored in the chief cells' cytoplasm within secretory vesicles known as **zymogen granules**, from which it is released by exocytosis on appropriate stimulation (see p. 29). When pepsinogen is secreted into the gastric lumen, HCl cleaves off a small fragment of the molecule, converting it to the active form of pepsin. Once formed, pepsin acts on other pepsinogen molecules to produce more pepsin, a mechanism called an **autocatalytic process** (*autocatalytic* means "self-activating").

Pepsin initiates protein digestion by splitting certain amino acid linkages in proteins to yield peptide fragments (small amino acid chains); it works most effectively in the acid environment provided by HCl. Because pepsin can digest protein, it must be stored and secreted in an inactive form so that it does not digest the proteins of the cells in which it is formed. Therefore, pepsin is maintained in the inactive form of pepsinogen until it reaches the gastric lumen, where it is activated by HCl secreted into the lumen by a different cell type.

Mucus is protective.

The surface of the gastric mucosa is covered by a layer of mucus derived from the surface epithelial cells and mucous cells. This mucus is a protective barrier against several forms of potential injury to the gastric mucosa:

■ Through its lubricating properties, mucus protects the gastric mucosa against mechanical injury.
■ It helps protect the stomach wall from self-digestion because pepsin is inhibited when it comes in contact with the layer of mucus coating the stomach lining. (However, mucus does not affect pepsin activity in the lumen, where digestion of dietary protein proceeds without interference.)

■ Being alkaline, mucus helps protect against acid injury by neutralizing HCl in the vicinity of the gastric lining, but it does not interfere with the function of HCl in the lumen. Whereas the pH in the lumen may be as low as 2, the pH in the layer of mucus adjacent to the mucosal cell surface is about 7.

Intrinsic factor is essential for absorption of vitamin B$_{12}$.

Intrinsic factor, another secretory product of the parietal cells in addition to HCl, is necessary for absorption of vitamin B$_{12}$. Binding of intrinsic factor with vitamin B$_{12}$ triggers receptor-mediated endocytosis of this complex in the terminal ileum, the last part of the small intestine (see p. 31). Vitamin B$_{12}$ is essential for normal formation of red blood cells.

Clinical Note In the absence of intrinsic factor, vitamin B$_{12}$ is not absorbed, so erythrocyte production is defective and *pernicious anemia* results (see p. 386). Pernicious anemia is typically caused by an autoimmune attack against the parietal cells (see p. 432).

Multiple regulatory pathways influence the parietal and chief cells.

In addition to the gastric exocrine secretory cells, other secretory cells in the gastric glands release endocrine and paracrine regulatory factors instead of products involved in the digestion of nutrients in the gastric lumen (see p. 114). These other secretory cells are also shown in ▌Table 16-3:

■ Endocrine cells known as **G cells**, found in the gastric pits only in the PGA, secrete the hormone *gastrin* into the blood.
■ **Enterochromaffin-like (ECL) cells**, dispersed among the parietal and chief cells in the gastric glands of the oxyntic mucosa, secrete the paracrine *histamine.*
■ **D cells**, which are scattered in gastric glands near the pylorus but are more numerous in the duodenum, secrete the paracrine *somatostatin.*

These three regulatory factors from the gastric pits, along with the neurotransmitter *ACh,* primarily control secretion of gastric digestive juices. Parietal cells have separate receptors for each of these chemical messengers. Three of them—ACh, gastrin, and histamine—stimulate HCl secretion. The fourth regulatory agent—somatostatin—inhibits HCl secretion. ACh and gastrin also increase pepsinogen secretion through their stimulatory effect on the chief cells. We now consider each of these chemical messengers in further detail (▌Table 16-3).

■ **ACh** is a neurotransmitter released from the intrinsic nerve plexuses in response to both short local reflexes and vagal stimulation. ACh stimulates not only the parietal and chief cells but also the G cells and ECL cells.
■ The G cells secrete the hormone **gastrin** into the blood in response to protein products in the stomach lumen and in response to ACh. Like secretin and CCK, gastrin is a major GI hormone. After being carried by the blood back to the stomach mucosa, gastrin stimulates the parietal and chief cells, promoting secretion of a highly acidic gastric juice. In addition to

directly stimulating the parietal cells, gastrin indirectly promotes HCl secretion by stimulating the ECL cells to release histamine, which also stimulates the parietal cells. Gastrin is the main factor that brings about increased HCl secretion during meal digestion. Gastrin is also *trophic* (growth promoting) to the mucosa of the stomach and small intestine, thereby maintaining their secretory capabilities.

■ **Histamine**, a paracrine, is released from the ECL cells in response to ACh and gastrin. Histamine acts locally on nearby parietal cells to speed up HCl secretion and potentiates (makes stronger) the actions of ACh and gastrin.

ACh and gastrin both operate through IP_3/Ca^{2+} second-messenger pathways; histamine activates a cAMP second-messenger pathway to bring about its effects (see p. 123). These messengers all bring about increased secretion of HCl by promoting the insertion of additional $H^+–K^+$ ATPases into the parietal cells' plasma membrane. A pool of these pumps is stored within the parietal cell in intracellular vesicles, which fuse with the luminal membrane via exocytosis, forming the deep inward folding canaliculi as the surface membrane expands in the process of adding more of these active carriers to the membrane as needed to increase HCl secretion.

■ **Somatostatin** is released from the D cells in response to acid. It acts locally as a paracrine in negative-feedback fashion to inhibit secretion by the parietal cells, G cells, and ECL cells, thus turning off the HCl-secreting cells and their most potent stimulatory pathway.

From this list, it is obvious not only that multiple chemical messengers influence the parietal and chief cells but also that these chemicals influence one another. As we examine the phases of gastric secretion, you will see under what circumstances each of these regulatory agents is released.

Control of gastric secretion involves three phases.

The rate of gastric secretion can be influenced by (1) factors arising before food reaches the stomach, (2) factors resulting from food in the stomach, and (3) factors in the duodenum after food has left the stomach. Accordingly, gastric secretion is divided into three phases: cephalic, gastric, and intestinal.

Cephalic Phase The cephalic phase of gastric secretion refers to increased secretion of HCl and pepsinogen that occurs in feedforward fashion in response to stimuli acting in the head even before food reaches the stomach (*cephalic* means "head"). Thinking about, seeing, smelling, tasting, chewing, and swallowing food increases gastric secretion via vagal stimulation in two ways. First, vagal stimulation of the intrinsic plexuses promotes increased secretion of ACh, which leads to increased secretion of HCl and pepsinogen by the secretory cells. Second, direct vagal stimulation of the G cells induces gastrin release, which in turn further enhances secretion of HCl and pepsinogen, with the effect on HCl being potentiated by gastrin promoting the release of histamine (❚ Table 16-4).

Gastric Phase The gastric phase of gastric secretion begins when food reaches the stomach. Stimuli acting on the stomach—namely *protein, distension, caffeine,* and *alcohol*—increase gastric secretion by overlapping efferent pathways. For example, the most potent stimulus, protein (especially short peptide fragments) in the stomach lumen, stimulates chemoreceptors that activate intrinsic-plexus pathways that induce gastric secretion. Furthermore, protein brings about activation of the extrinsic vagal fibers to the stomach. Vagal activity further enhances intrinsic nerve stimulation of the secretory cells and triggers the release of gastrin. Last, protein also directly stimulates the release of gastrin. Gastrin, in turn, is a powerful stimulus for further HCl and pepsinogen secretion. Through these synergistic and overlapping pathways, protein induces secretion of a highly acidic, pepsin-rich gastric juice, which continues digestion of the protein that first initiated the process (❚ Table 16-4).

When the stomach is distended with protein-rich food that needs to be digested, these secretory responses are appropriate. Caffeine and, to a lesser extent, alcohol also stimulate secretion of a highly acidic gastric juice, even when no food is present. This unnecessary acid can irritate the linings of the stomach and duodenum. For this reason, people with ulcers or gastric hyperacidity should avoid caffeinated and alcoholic beverages.

❚ **TABLE 16-4** Stimulation of Gastric Secretion

Phase	Stimuli	Excitatory Mechanism for Enhancing Gastric Secretion
Cephalic phase of gastric secretion	Stimuli in the head— seeing, smelling, tasting, chewing, swallowing food	
Gastric phase of gastric secretion	Stimuli in the stomach— protein, (peptide fragments), distension, caffeine, alcohol	

Intestinal Phase The intestinal phase of gastric secretion encompasses the factors originating in the small intestine that influence gastric secretion. Whereas the other phases are excitatory, this phase is inhibitory. The intestinal phase is important in helping shut off the flow of gastric juices as chyme begins to be emptied into the small intestine, a topic to which we now turn.

Gastric secretion gradually decreases as food empties from the stomach into the intestine.

You now know what factors turn on gastric secretion before and during a meal, but how is the flow of gastric juices shut off when they are no longer needed? Gastric secretion is gradually reduced in three ways as the stomach empties (Table 16-5):

1. As the meal gradually empties into the duodenum, the major stimulus for enhanced gastric secretion—protein in the stomach—is withdrawn.

2. After foods leave the stomach, gastric juices accumulate to such an extent that gastric pH falls very low. This fall in pH within the stomach lumen comes about largely because food proteins that had been buffering HCl are no longer present in the lumen as the stomach empties. (Recall that proteins serve as excellent buffers; see p. 552.) Somatostatin is released in response to this high gastric acidity (pH less than 3). As a result of somatostatin's inhibitory effects, gastric secretion declines.

3. The same stimuli that inhibit gastric motility (fat, acid, hypertonicity, or distension in the duodenum brought about by emptying of stomach contents into the duodenum) inhibit gastric secretion also. The enterogastric reflex and the enterogastrones suppress the gastric secretory cells while they simultaneously reduce the strength of antral peristalsis. This inhibitory response is the intestinal phase of gastric secretion.

The gastric mucosal barrier protects the stomach lining from gastric secretions.

How can the stomach contain strong acid contents and proteolytic enzymes without destroying itself? In addition to mucus providing a protective physical coating, the surface mucous cells secrete HCO_3^- that is trapped in the mucus and neutralizes acid in the vicinity.

Other barriers to mucosal acid damage are provided by the mucosal lining itself. First, the luminal membranes of the gastric mucosal cells are essentially impermeable to H^+, so acid cannot penetrate into the cells and damage them. Second, the lateral edges of these cells are joined near their luminal borders by tight junctions, so acid cannot diffuse between the cells from the lumen into the underlying submucosa (see p. 61). The properties of the gastric mucosa that enable the stomach to contain acid without injuring itself constitute the **gastric mucosal barrier** (Figure 16-9). These protective mechanisms are further enhanced by replacement of the entire stomach lining every 3 days. Because of rapid mucosal turnover, cells are usually replaced before they are exposed to the wear and tear of harsh gastric conditions long enough to suffer damage.

Clinical Note Despite the protection provided by mucus, by the gastric mucosal barrier, and by frequent turnover of cells, the barrier occasionally is broken and the gastric wall is injured by its acidic and enzymatic contents, producing an erosion, or **peptic ulcer**, of the stomach wall. Excessive gastric reflux into the esophagus and dumping of excessive acidic gastric contents into the duodenum can lead to peptic ulcers in these locations also. (For a further discussion of ulcers, see the boxed feature on p. 589, Concepts, Challenges, and Controversies.)

We now turn to the remaining two digestive processes in the stomach: gastric digestion and absorption.

TABLE 16-5 Inhibition of Gastric Secretion

Region	Stimuli	Inhibitory Mechanism for Gastric Secretion
Body and antrum	Removal of protein and distension as the stomach empties	— → Intrinsic nerves — → Vagus — → G cells → ↓Gastrin → ↓Histamine → ↓Gastric secretion

KEY

= Passage prevented

The components of the gastric mucosal barrier enable the stomach to contain acid without injuring itself:

1 The luminal membranes of the gastric mucosal cells are impermeable to H⁺ so that HCl cannot penetrate into the cells.

2 The cells are joined by tight junctions that prevent HCl from penetrating between them.

3 A mucus coating over the gastric mucosa serves as a physical barrier to acid penetration.

4 The HCO₃⁻-rich mucus also serves as a chemical barrier that neutralizes acid in the vicinity of the mucosa. Even when luminal pH is 2, the mucus pH is 7.

Carbohydrate digestion continues in the body of the stomach; protein digestion begins in the antrum.

Two separate digestive processes take place within the stomach. In the body of the stomach, food remains in a semisolid mass because peristaltic contractions in this region are too weak for mixing to occur. Because food is not mixed with gastric secretions, little protein digestion occurs here. In the interior of the mass, however, carbohydrate digestion continues under the influence of salivary amylase. Even though acid inactivates salivary amylase, the unmixed interior of the food mass is free of acid.

Chemical digestion by the gastric juice itself occurs in the antrum of the stomach, where the food is thoroughly mixed with pepsin and HCl via retropulsion.

The stomach absorbs alcohol and aspirin but no food.

No food or water is absorbed into the blood through the stomach mucosa. However, two noteworthy nonnutrient substances are absorbed directly by the stomach—*ethyl alcohol* and *aspirin.* Alcohol is somewhat lipid soluble, so it can diffuse through the lipid membranes of the epithelial cells that line the stomach and can enter the blood through the submucosal capillaries. However, it can be absorbed even more rapidly by the small-intestine mucosa because of the greater surface area of the small-intestine mucosa. Thus, alcohol absorption occurs more slowly if gastric emptying is delayed so that the alcohol remains in the more slowly absorbing stomach longer. Because fat is the most potent duodenal stimulus for inhibiting gastric motility, consuming fat-rich foods (for example, whole milk, pizza, or nuts) before or during alcohol ingestion delays gastric emptying and prevents the alcohol from producing its effects as rapidly.

Clinical Note Another category of substances absorbed by the gastric mucosa includes weak acids, most notably *acetylsalicylic acid* (aspirin). In the highly acidic environment of the stomach lumen, weak acids are almost totally undissociated—that is, the H⁺ and associated anion of the acid are bound together. In an undissociated, or intact, form, these weak acids are lipid soluble, so they can be absorbed quickly by crossing the plasma membranes of the epithelial cells that line the stomach. Most other drugs are not absorbed until they reach the small intestine, so they do not begin to take effect as quickly.

Having completed our coverage of the stomach, we move to the next part of the digestive tract, the small intestine and the accessory digestive organs that release their secretions into the small-intestine lumen.

Check Your Understanding 16.4

1. Describe the process of retropulsion and explain what it accomplishes.

2. Name the secretions of these gastric cells: mucous cells, chief cells, parietal cells, ECL cells, G cells, and D cells.

3. Discuss how food-related stimuli induce gastric secretions during the cephalic phase of gastric secretion.

4. Describe the mechanisms that protect the gastric mucosa from acid damage.

16.5 Pancreatic and Biliary Secretions

When gastric contents empty into the duodenum, they are mixed not only with juice secreted by the small-intestine mucosa, but also with the secretions of the exocrine pancreas

Ulcers: When Bugs Break the Barrier

PEPTIC ULCERS ARE EROSIONS THAT typically begin in the mucosal lining of the stomach and may penetrate into the deeper layers of the stomach wall. They occur when the gastric mucosal barrier is disrupted, and thus pepsin and HCl act on the stomach wall as well as on food in the lumen. Frequent backflow of acidic gastric juices into the esophagus or excess unneutralized acid from the stomach in the duodenum can lead to peptic ulcers in these sites also.

In a surprising discovery in the early 1990s, the bacterium *Helicobacter pylori* was pinpointed as the cause of more than 80% of all peptic ulcers. Thirty percent of the population in the United States harbor *H. pylori.* Those who have this slow bacterium have a 3 to 12 times greater risk of developing an ulcer within 10 to 20 years of acquiring the infection than those without the bacterium. They are also at increased risk of developing stomach cancer.

For years, scientists had overlooked the possibility that ulcers could be triggered by an infectious agent because bacteria typically cannot survive in a strongly acidic environment such as the stomach lumen. An exception, *H. pylori* exploits several strategies to survive in this hostile environment. First, these organisms are motile, being equipped with four to six flagella (whiplike appendages; see the accompanying figure), which enable them to tunnel through and take up residence under the stomach's thick layer of alkaline mucus. Here they are protected from the highly acidic gastric contents. Furthermore, *H. pylori* preferentially settles in the antrum, which has no acid-producing parietal cells, although HCl from the upper parts of the stomach does reach the antrum. Also, these bacteria produce *urease,* an enzyme that breaks down urea, an end product of protein metabolism, into ammonia (NH_3) and CO_2. Ammonia serves as a buffer (see p. 558) that neutralizes stomach acid locally in the vicinity of the *H. pylori.*

H. pylori contributes to ulcer formation in part by secreting toxins that cause a persistent inflammation, or *chronic superficial gastritis,* at the site it colonizes. *H. pylori* further weakens the gastric mucosal barrier by disrupting the tight junctions between the gastric epithelial cells, thereby making the gastric mucosa leakier than normal.

Alone or in conjunction with this infectious culprit, other factors are known to contribute to ulcer formation. Frequent exposure to some chemicals can break the gastric mucosal barrier; the most important
Helicobacter pylori. *Helicobacter pylori,* the bacterium responsible for most cases of peptic ulcers, has flagella that enable it to tunnel beneath the protective layer of mucus that coats the stomach lining.

of these are ethyl alcohol and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, ibuprofen, or more potent medications for the treatment of arthritis or other chronic inflammatory processes. The barrier frequently breaks in patients with preexisting debilitating conditions, such as severe injuries or infections. Persistent stressful situations are frequently associated with ulcer formation, presumably because emotional response to stress can stimulate excessive gastric secretion.

When the gastric mucosal barrier is broken, acid and pepsin diffuse into the mucosa and underlying submucosa, with serious pathophysiologic consequences. The surface erosion, or ulcer, progressively enlarges as increasing levels of acid and pepsin continue to damage the stomach wall. Two of the most serious consequences of ulcers are (1) hemorrhage resulting from damage to submucosal capillaries and (2) perforation, or complete erosion through the stomach wall, resulting in the escape of potent gastric contents into the abdominal cavity.

Treatment of ulcers includes antibiotics, H-2 histamine receptor blockers, and proton pump inhibitors. With the discovery of the infectious component of most ulcers, antibiotics are now a treatment of choice. The other drugs are also used alone or in combination with antibiotics.

Two decades before the discovery of *H. pylori,* researchers discovered an antihistamine (*cimetidine*) that specifically blocks H-2 receptors, the type of receptors that bind histamine released from the stomach. These receptors differ from H-1 receptors, which bind the histamine involved in allergic respiratory disorders. Accordingly, traditional antihistamines used for respiratory allergies (such as hay fever and asthma) are not effective against ulcers, nor is cimetidine useful for respiratory problems. Because histamine potentiates the acid-promoting actions of ACh and gastrin, treatment with H-2 histamine blockers significantly suppresses acid secretion despite the fact that they do not directly interfere with the actions of these other two stimulatory messengers.

Another newer class of drugs used in treating ulcers inhibits acid secretion by directly blocking the pump that transports H^+ into the stomach lumen. These so-called *proton-pump inhibitors* (H^+ is a naked proton without its electron), for example *Prilosec,* help reduce the corrosive effect of HCl on the exposed tissue.

and liver that are released into the duodenum. We discuss the roles of each of these accessory digestive organs before we examine the contributions of the small intestine itself.

The pancreas is a mixture of exocrine and endocrine tissue.

The **pancreas** is an elongated gland that lies behind and below the stomach, above the first loop of the duodenum (❙Figure 16-10). This mixed gland contains both exocrine and endocrine tissue. The predominant exocrine part consists of grape-like clusters of secretory cells that form sacs known as **acini**, which connect to ducts that eventually empty into the duodenum. The smaller endocrine part consists of isolated islands of endocrine tissue, the **islets of Langerhans**, which are dispersed throughout the pancreas. The most important hormones secreted by the islet cells are insulin and glucagon (Chapter 19). The exocrine and endocrine tissues of the pancreas are derived from different tissues during embryonic development and share only their location in common. Although both are involved with the metabolism of nutrient molecules, they have different functions under the control of different regulatory mechanisms.

The exocrine pancreas secretes digestive enzymes and an alkaline fluid.

The **exocrine pancreas** secretes a pancreatic juice consisting of two components: (1) *pancreatic enzymes* actively secreted by the *acinar cells* that form the acini and (2) an *aqueous alkaline solution* actively secreted by the *duct cells* that line the pancreatic ducts. The aqueous (watery) alkaline component is rich in sodium bicarbonate ($NaHCO_3$).

Like pepsinogen, pancreatic enzymes are stored within zymogen granules (secretory vesicles) after being produced and then are released by exocytosis as needed. The acinar cells secrete three types of pancreatic enzymes capable of digesting all three categories of foodstuffs: (1) *proteolytic enzymes* for protein digestion, (2) *pancreatic amylase* for carbohydrate digestion, and (3) *pancreatic lipase* for fat digestion. Pancreatic enzymes can almost completely digest food in the absence of all other digestive secretions.

Pancreatic Proteolytic Enzymes The three major pancreatic **proteolytic enzymes** are *trypsinogen, chymotrypsinogen,* and *procarboxypeptidase,* each of which is secreted in an inactive form. When **trypsinogen** is secreted into the duodenal lumen, it is activated to its active enzyme form, **trypsin**, by **enteropeptidase** (formerly known as **enterokinase**), an enzyme embedded in the luminal membrane of the cells that line the duodenal mucosa. Like pepsinogen, trypsinogen must remain inactive within the pancreas to prevent this proteolytic enzyme from digesting the proteins of the cells in which it is formed. Trypsinogen remains inactive, therefore, until it reaches the duodenal lumen, where enteropeptidase triggers the activation process. Trypsin then autocatalytically activates more trypsinogen. As further protection, the pancreas also produces a chemical known as **trypsin inhibitor**, which blocks trypsin's actions if spontaneous activation of trypsinogen inadvertently occurs within the pancreas.
❙Figure 16-10 **Exocrine and endocrine portions of the pancreas.** The exocrine pancreas secretes into the duodenal lumen a digestive juice composed of digestive enzymes secreted by the acinar cells and an aqueous $NaHCO_3$ solution secreted by the duct cells. The endocrine pancreas secretes the hormones insulin and glucagon into the blood.

Chymotrypsinogen and procarboxypeptidase are converted by trypsin to their active forms, chymotrypsin and carboxypeptidase, respectively, within the duodenal lumen. Thus, once enteropeptidase has activated some of the trypsin, trypsin carries out the rest of the activation process.

Each of these proteolytic enzymes attacks different peptide linkages. The end products that result from this action are a mixture of small peptide chains and amino acids. Mucus secreted by the intestinal cells protects against digestion of the small-intestine wall by the activated proteolytic enzymes.

Pancreatic Amylase Like salivary amylase, **pancreatic amylase** contributes to carbohydrate digestion by converting dietary starches (amylose and amylopectin) into the disaccharide maltose and the branched polysaccharide α-limit dextrins. Amylase is secreted in the pancreatic juice in an active form because active amylase does not endanger the secretory cells. These cells do not contain any polysaccharides.

Pancreatic Lipase **Pancreatic lipase** is extremely important because it is the only enzyme secreted throughout the entire digestive system that can digest fat. (In humans, insignificant amounts of lipase are secreted in the saliva and gastric juice—*lingual lipase* and *gastric lipase*.) Pancreatic lipase hydrolyzes dietary triglycerides into monoglycerides and free fatty acids, which are the absorbable units of fat (see ▮Figure 16-1d, p. 567). Like amylase, lipase is secreted in its active form because there is no risk of pancreatic self-digestion by lipase. Triglycerides are not a structural component of pancreatic cells.

Clinical Note **Pancreatic Insufficiency** When pancreatic enzymes are deficient, digestion of food is incomplete. Because the pancreas is the only significant source of lipase, pancreatic enzyme deficiency results in serious maldigestion and malabsorption of dietary fat. The main clinical manifestation of pancreatic exocrine insufficiency is **steatorrhea**, or excessive undigested fat in the feces. Up to 60% to 70% of the ingested fat may be excreted in the feces. Digestion of protein and carbohydrates is impaired to a lesser degree because salivary, gastric, and small-intestinal enzymes contribute to the digestion of these two foodstuffs.

Pancreatic Aqueous Alkaline Secretion Pancreatic enzymes function best in a neutral or slightly alkaline environment, yet the highly acidic gastric contents empty into the duodenum in the vicinity of pancreatic enzyme entry into the duodenum. This acidic chyme must be neu-

tralized quickly in the duodenal lumen, not only to allow optimal functioning of the pancreatic enzymes but also to prevent acid damage to the duodenal mucosa. The alkaline ($NaHCO_3$-rich) fluid secreted by the pancreatic duct cells into the duodenum serves the important function of neutralizing the acidic chyme that empties into the duodenum from the stomach. This aqueous $NaHCO_3$ secretion is by far the largest component of pancreatic secretion. The volume of pancreatic secretion ranges between 1 and 2 liters per day, depending on the type and degree of stimulation.

Following is the current model of pancreatic $NaHCO_3$ secretion based on recent evidence (▮Figure 16-11). The HCO_3^- that is secreted into the duct lumen comes from two sources: (1) Some of the secreted HCO_3^- is derived within the pancreatic duct cell from CO_2 that has either diffused in from the plasma or been produced by cellular metabolism. Under the influence of carbonic anhydrase, CO_2 in the duct cell combines with OH^- generated from H_2O to produce HCO_3^-, just as in the gastric parietal cell. The H^+ simultaneously generated from H_2O enters the plasma across the basolateral border by a Na^+–H^+ antiporter, thus acidifying the venous blood that leaves the pancreas. (2) However, most of

KEY

ATP ⇄ = Active transport	**CFTR** = Cystic fibrosis transmembrane conductance regulator protein
⬤→ = Secondary active transport	——→ = Passive diffusion
ca = Carbonic anhydrase	——→ = Chemical reaction
▮**Figure 16-11 Mechanism of NaHCO₃ secretion.** Most of the to-be-secreted HCO_3^- enters the pancreatic duct cell by means of a Na^+–HCO_3^- symporter in the basolateral membrane, but some is generated within the duct cell through carbonic-anydrase catalyzed formation of HCO_3^- and H^+ from H_2O and CO_2. HCO_3^- is secreted from the pancreatic duct cell into the pancreatic duct lumen by two avenues: via a HCO_3^-–Cl^- antiporter and through a CFTR channel, both in the luminal membrane. Na^+ diffuses down its electrochemical gradient through "leaky" tight junctions between the pancreatic duct cells to complete $NaHCO_3$ secretion.

the secreted HCO_3^- is not generated within the pancreatic duct cell. Instead the bulk of the HCO_3^- that exits across the luminal membrane enters the cell from the plasma via a Na^+–HCO_3^- symporter at the basolateral membrane. This is the active step in $NaHCO_3$ secretion. The basolateral Na^+–K^+ pump provides the driving energy for the secondary active transport mechanisms.

HCO_3^- is secreted (that is, exits the pancreatic duct cell across the luminal membrane to enter the duct lumen) by two means: (1) Cl^-–HCO_3^- antiporters in the luminal membrane move HCO_3^- into the lumen in exchange for Cl^-, and (2) HCO_3^- also enters the lumen by diffusing through a cystic fibrosis transmembrane conductance regulator (CFTR) channel. This is the same channel that serves as a Cl^- channel and is absent in the lungs and pancreas in cystic fibrosis (see p. 59). Na^+ does not exit the pancreatic duct cells to be secreted. Instead, Na^+ diffuses down an electrochemical gradient via paracellular transport through the "leaky" tight junctions between the duct cells into the lumen (see p. 62). Together these actions accomplish $NaHCO_3$ secretion.

Pancreatic exocrine secretion is regulated by secretin and CCK.

A small amount of parasympathetically induced pancreatic exocrine secretion occurs during the cephalic phase of digestion, with a further token increase occurring during the gastric phase in response to gastrin. However, the predominant stimulation of pancreatic secretion occurs during the intestinal phase of digestion when chyme is in the small intestine. The release of the two major enterogastrones, secretin and CCK, in response to chyme in the duodenum plays the central role in controlling pancreatic exocrine secretion (❙Figure 16-12).

Role of Secretin in Pancreatic Secretion Of the factors that stimulate enterogastrone secretion (fat, acid, hypertonicity, and distension), the primary stimulus specifically for secretin release into the blood from the duodenal mucosa is acid in the duodenal lumen. The blood carries secretin to the pancreas, where it stimulates the duct cells to markedly increase their secretion of a $NaHCO_3$-rich aqueous fluid into the duodenum. It is appropriate that the most potent stimulus for secretin release is acid in the small intestine lumen because the resulting alkaline pancreatic secretion neutralizes the acid. The amount of secretin released is proportional to the amount of acid that

enters the duodenum, so the amount of $NaHCO_3$ secreted parallels duodenal acidity.

Role of CCK in Pancreatic Secretion CCK is important in regulating pancreatic digestive enzyme secretion. The main stimulus for CCK release into the blood from the duodenal mucosa is the presence of fat and, to a lesser extent, products of protein digestion in the lumen. The blood transports CCK to the pancreas where it stimulates the pancreatic acinar cells to increase digestive enzyme secretion. Among these enzymes are pancreatic lipase and the proteolytic enzymes, which appropriately further digest the fat and protein that initiated the response. In contrast to fat and protein, carbohydrate does not directly influence pancreatic digestive enzyme secretion.

All three types of pancreatic digestive enzymes are packaged together in the zymogen granules, so all the pancreatic enzymes are released together during exocytosis. Therefore, even though the *total amount* of enzymes released varies depending on the type of meal consumed (the most being secreted in response to fat), the *proportion* of enzymes released does not vary on a meal-to-meal basis. That is, a high-protein meal does not cause the release of a greater proportion of proteolytic enzymes.

Just as gastrin is trophic to the stomach and small intestine, CCK and secretin exert trophic effects on the exocrine pancreas to maintain its integrity.

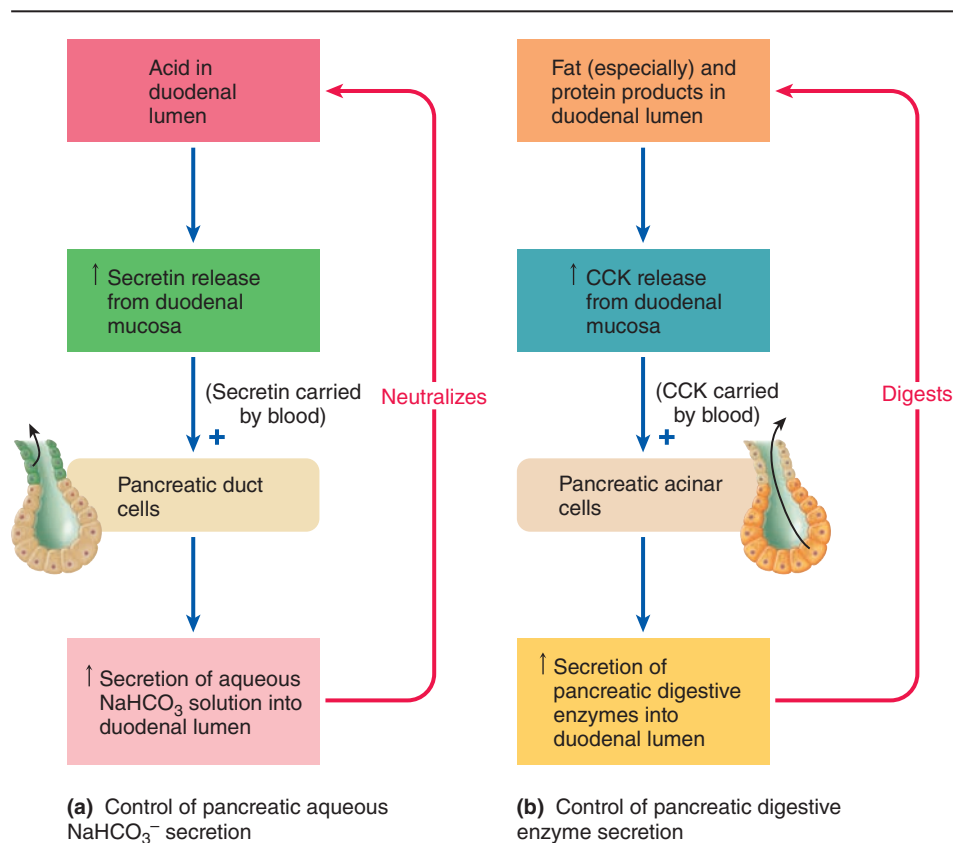
(b) Control of pancreatic digestive enzyme secretion


❙Figure 16-12 **Hormonal control of pancreatic exocrine secretion.**
FIGURE FOCUS: *If a person has bacon, eggs, toast, and orange juice for breakfast, discuss which GI hormones are released from the duodenal mucosa as a result of each component of the meal.*

We now look at the contributions of the remaining accessory digestive unit, the liver and gallbladder.

The liver performs various important functions, including bile production.

Besides pancreatic juice, the other secretory product emptied into the duodenal lumen is **bile**. The **biliary system** includes the *liver,* the *gallbladder,* and associated ducts.

Liver Functions The **liver** is the largest and most important metabolic organ in the body; it can be viewed as the body's major biochemical factory. Its functions include the following:

1. Secretion of *bile salts,* which aid fat digestion and absorption. This is the only liver function directly related to digestion.

2. Metabolic processing of the major categories of nutrients (carbohydrates, proteins, and lipids) after their absorption from the digestive tract (see p. 609)

3. Detoxifying or degrading body wastes and hormones, as well as drugs and other foreign compounds (see p. 27)

4. Synthesizing plasma proteins, including those needed for blood clotting (see p. 397), those that transport steroid and thyroid hormones and cholesterol in the blood (see pp. 122 and 328), and angiotensinogen important in the salt-conserving renin–angiotensin–aldosterone system (see p. 508)

5. Storing glycogen, fats, iron, copper, and many vitamins (see p. 44)

6. Activating vitamin D, which the liver does in conjunction with the kidneys (see p. 709)

7. Secreting the hormones thrombopoietin (stimulates platelet production; see p. 395), hepcidin (inhibits iron uptake from the intestine; see p. 603), and insulin-like growth factor-I (stimulates growth; see p. 654)

8. Producing acute phase proteins important in inflammation (see p. 411)

9. Excreting cholesterol (see p. 329) and bilirubin, the latter being a breakdown product derived from the destruction of worn-out red blood cells (see p. 597)

10. Removing bacteria and worn-out red blood cells, thanks to its resident macrophages.

Given this range of complex functions, there is amazingly little specialization among cells within the liver. Each liver cell, or **hepatocyte**, performs the same wide variety of metabolic and secretory tasks (*hepato* means "liver"; *cyte* means "cell"). The specialization comes from the highly developed organelles within each hepatocyte. The only liver function not accomplished by hepatocytes is the phagocytic activity carried out by the resident macrophages, which are known as **Kupffer cells**.

Liver Blood Flow To carry out these wide-ranging tasks, the anatomic organization of the liver permits each hepatocyte to be in direct contact with blood from two sources: arterial blood coming from the heart and venous blood coming directly from the digestive tract. Like other cells, the hepatocytes receive fresh arterial blood via the hepatic artery, which supplies their oxygen and delivers blood-borne metabolites for hepatic process-

ing. Venous blood also enters the liver by the **hepatic portal system**, a unique and complex vascular connection between the digestive tract and the liver (❙Figure 16-13). The veins draining the digestive tract do not directly join the inferior vena cava, the large vein that returns blood to the heart. Instead, the veins
The liver receives blood from two sources:

1a Arterial blood, which provides the liver's O_2 supply and carries blood-borne metabolites for hepatic processing, is delivered by the **hepatic artery**.

1b Venous blood draining the digestive tract is carried by the **hepatic portal vein** to the liver for processing and storage of newly absorbed nutrients.

2 Blood leaves the liver via the **hepatic vein**.

❙Figure 16-13 **Schematic representation of liver blood flow.**
FIGURE FOCUS: *State the vessel through which (1) O_2 enters the liver, (2) just absorbed glucose enters the liver, and (3) ingested alcohol that has been detoxified by the liver enters the systemic circulation.*

from the stomach and intestine enter the *hepatic portal vein,* which carries the products absorbed from the digestive tract directly to the liver for processing, storage, or detoxification before they gain access to the general circulation. Within the liver, the portal vein again breaks up into a capillary network (the liver *sinusoids)* to permit exchange between the blood and the hepatocytes before draining into the hepatic vein, which joins the inferior vena cava.

Liver Organization The liver is organized into functional units known as **lobules**, which are hexagonal columns of tissue surrounding a central vein and delineated by vascular and bile channels (❚Figure 16-14a and b). At each of the six outer corners of a lobule are three vessels: a branch of the hepatic artery, a branch of the hepatic portal vein, and a bile duct. Blood from the branches of both the hepatic artery and the portal vein flows from the periphery of the lobule into large, expanded capillary

spaces called **sinusoids** (see p. 354), which run between rows of liver cells to the central vein like spokes on a bicycle wheel (❚Figure 16-14b). The Kupffer cells line the sinusoids and engulf and destroy old red blood cells and bacteria that pass through in the blood. The hepatocytes are arranged between the sinusoids in plates that are two cell layers thick so that each lateral edge faces a sinusoidal pool of blood. The central veins of all the liver lobules converge to form the hepatic vein, which carries blood away from the liver. The thin bile-carrying channel, a **bile canaliculus**, runs between the cells within each hepatic plate (❚Figure 16-14c). Hepatocytes continuously secrete bile into these thin channels, which carry the bile to a bile duct at the periphery of the lobule. The bile ducts from the various lobules converge to eventually form the **common bile duct**, which transports the bile from the liver to the duodenum. Each hepatocyte is in contact with a sinusoid on one side and a bile canaliculus on the other side.

❚Figure 16-14 **Anatomy of the liver.** The photomicrograph is of a transverse section of a lobule in a pig liver, often used in teaching because the lobules are more clearly demarcated by connective tissue in pigs than in humans so that the hexagonal arrangement of the lobule is readily apparent.

Bile is continuously secreted by the liver and is diverted to the gallbladder between meals.

The liver continuously secretes bile, even between meals. The opening of the bile duct into the duodenum is guarded by the **sphincter of Oddi**, which prevents bile from entering the duodenum except during digestion of meals (❙ Figure 16-15). When this sphincter is closed, bile secreted by the liver hits the closed sphincter and is diverted back up into the **gallbladder**, a small, saclike structure tucked beneath but not directly connected to the liver. Thus, bile is not transported directly from the liver to the gallbladder. Bile is subsequently stored and concentrated in the gallbladder between meals. Active transport of salt out of the gallbladder, with water following osmotically, results in a 5 to 10 times greater concentration of the organic constituents.

After a meal, bile enters the duodenum as a result of the combined effects of relaxation of the sphincter of Oddi, gallbladder contraction, and increased bile secretion by the liver. The amount of bile secreted per day ranges from 250 mL to 1 liter, depending on the degree of stimulation.

Clinical Note Because the gallbladder stores concentrated bile, it is the primary site for precipitation of concentrated bile constituents into **gallstones**. Fortunately, the gallbladder does not play an essential digestive role, so its removal as a treatment for gallstones presents no particular problem. After gallbladder removal, the bile secreted between meals is stored instead in the common bile duct, which becomes dilated.

Bile salts are recycled through the enterohepatic circulation.

Bile contains several organic constituents, namely, *bile salts, cholesterol, lecithin* (a phospholipid), and *bilirubin* (all derived from hepatocyte activity) in an *aqueous alkaline fluid* (added by the duct cells). Even though bile does not contain any digestive enzymes, it is important for the digestion and absorption of fats, primarily through the activity of bile salts.

Bile salts are derivatives of cholesterol. They are actively secreted into the bile and eventually enter the duodenum, along with the other biliary constituents. Following their participation in fat digestion and absorption, most bile salts are reabsorbed into the blood by special active-transport mechanisms located only in the terminal ileum. From here, bile salts are returned by the hepatic portal system to the liver, which resecretes them into the bile. This recycling of bile salts (and some of the other biliary constituents) between the small intestine and the liver is called the **enterohepatic circulation** (*entero* means "intestine"; *hepatic* means "liver") (❙ Figure 16-15).

The total amount of bile salts in the body averages about 3 to 4 g, yet 3 to 15 g of bile salts may be emptied into the duode-

❶ Secreted bile salts consist of 95% old, recycled bile salts and 5% newly synthesized bile salts.

❙ **Figure 16-15 Enterohepatic circulation of bile salts.** Most bile salts are recycled between the liver and small intestine through the enterohepatic circulation (*blue arrows*). After participating in fat digestion and absorption, most bile salts are reabsorbed by active transport in the terminal ileum and returned through the hepatic portal vein to the liver, which resecretes them in the bile.

num in a single meal. On average, bile salts cycle between the liver and the small intestine twice during the digestion of a typical meal. Usually, only about 5% of the secreted bile escapes into the feces daily. These lost bile salts are replaced by new bile salts synthesized by the liver; thus, the size of the pool of bile salts is kept constant.

Bile salts aid fat digestion and absorption.

Bile salts aid fat digestion through their detergent action (emulsification) and facilitate fat absorption by participating in the formation of micelles. Both functions are related to the structure of bile salts. Let us see how.

Detergent Action of Bile Salts The term **detergent action** refers to bile salts' ability to convert large fat globules into a **lipid emulsion** consisting of many small fat droplets suspended in the aqueous chyme. Breaking up the large fat globule into small, stabilized droplets increases the surface area available for

The Digestive System | **595**

attack by pancreatic lipase. To digest fat, lipase must come into direct contact with the triglyceride molecule. Because triglycerides are not soluble in water, they tend to aggregate into large droplets in the watery environment of the small-intestine lumen. If bile salts did not emulsify these large droplets, lipase could act on the triglyceride molecules only at the surface of the large droplets, and fat digestion would be greatly prolonged.

Bile salts emulsify fats similar to the detergent you use to break up grease when you wash dishes. A bile salt molecule contains a lipid-soluble part (a steroid derived from cholesterol) plus a negatively charged, water-soluble part. Bile salts *adsorb* on the surface of a fat droplet—that is, the lipid-soluble part of the bile salt dissolves in the fat droplet, leaving the charged water-soluble part projecting from the surface of the droplet (❙ Figure 16-16a). Intestinal mixing movements break up large fat droplets into smaller ones. These small droplets would quickly recoalesce were it not for bile salts adsorbing on their surface and creating a shell of water-soluble negative charges on the surface of each little droplet. Because like charges repel, these negatively charged groups on the droplet surfaces cause the small fat droplets to repel one another (❙ Figure 16-16b) and prevent them from recoalescing into large droplets. The small emulsified fat droplets range in diameter from 200 to 5000 nm, with an average of about 1000 nm (1 μm).

Although bile salts increase the surface area available for attack by pancreatic lipase, lipase alone cannot penetrate the layer of bile salts adsorbed on the surface of the small emulsified fat droplets. To solve this dilemma, the pancreas secretes the polypeptide **colipase** along with lipase. Like bile salts, colipase has both a lipid-soluble part and a water-soluble part. Colipase displaces some bile salts and lodges at the surface of the fat droplets, where it binds to lipase, thus anchoring this enzyme to its site of action amid the bile-salt coating.

Formation of Micelles Bile salts—along with cholesterol and lecithin, which are also constituents of bile—play an important role in facilitating fat absorption through formation of micelles. Like bile salts, lecithin (a phospholipid similar to the ones in the lipid bilayer of the plasma mem-

brane) has both a lipid-soluble and a water-soluble part, whereas cholesterol is almost totally insoluble in water. In a **micelle**, the bile salts and lecithin aggregate in small clusters with their fat-soluble parts huddled together in the middle to form a hydrophobic ("water-fearing") core, while their water-soluble parts form an outer hydrophilic ("water-loving") shell (❙ Figure 16-17). A micelle is 3 to 10 nm in diameter, compared to an average diameter of 1000 nm for an emulsified lipid droplet. Micelles are water soluble because of their hydrophilic shells, but they can dissolve water-insoluble (and hence lipid-soluble)
(a) Structure of bile salts and their adsorption on the surface of a small lipid droplet
(b) Formation of a lipid emulsion through the action of bile salts

❙ **Figure 16-16 Schematic structure and function of bile salts.** (a) A bile salt consists of a lipid-soluble part that dissolves in the fat droplet and a negatively charged, water-soluble part that projects from the surface of the droplet. (b) When a large fat droplet is broken up into smaller fat droplets by intestinal contractions, bile salts adsorb on the surface of the small droplets, creating shells of negatively charged, water-soluble bile salt components that cause the fat droplets to repel one another. This emulsifying action holds the fat droplets apart and prevents them from recoalescing, increasing the surface area of exposed fat available for digestion by pancreatic lipase.

substances in their lipid-soluble cores. Micelles thus provide a handy vehicle for carrying water-insoluble substances through the watery luminal contents. The most important lipid-soluble substances carried within micelles are the products of fat digestion (monoglycerides and free fatty acids), and fat-soluble vitamins, which are all transported to their sites of absorption by this means. If they did not hitch a ride in the water-soluble micelles, these nutrients would float on the surface of the aqueous chyme (just as oil floats on top of water), never reaching the absorptive surfaces of the small intestine. In addition, cholesterol, a highly water-insoluble substance, dissolves in the micelle's hydrophobic core.

Bile salts stimulate bile secretion; CCK promotes gallbladder emptying.

Any substance that increases bile secretion is called a **choleretic**. The most potent choleretic is bile salts themselves. Between meals bile is stored in the gallbladder, but during a meal bile is emptied into the duodenum as the gallbladder contracts. After bile salts participate in fat digestion and absorption, they are reabsorbed and returned by the enterohepatic circulation to the liver, where they act as potent choleretics to stimulate further bile secretion. Therefore, during a meal, when bile salts are needed and being used, bile secretion by the liver is enhanced.

Vagal stimulation of the liver plays a minor role in bile secretion during the cephalic phase of digestion, promoting an increase in liver bile flow before food ever reaches the intestine.

Hydrophobic core

Hydrophilic shell

KEY

All lipid-soluble	Water-soluble portion / Lipid-soluble portion	Water-soluble portion / Lipid-soluble portion
Cholesterol	**Bile salt**	**Lecithin**
❙ **Figure 16-17** **A micelle.** Bile constituents (bile salts, lecithin, and cholesterol) aggregate to form micelles that consist of a hydrophilic (water-soluble) shell and a hydrophobic (lipid-soluble) core. Because the outer shell of a micelle is water soluble, the products of fat digestion, which are not water soluble, can be carried through the watery luminal contents to the absorptive surface of the small intestine by dissolving in the micelle's lipid-soluble core. This figure is not drawn to scale compared to the lipid emulsion droplets in ❙ Figure 16-16b. An emulsified fat droplet ranges in diameter from 200 to 5000 nm (average 1000 nm) compared to a micelle, which is 3 to 10 nm in diameter.

When chyme reaches the small intestine, the presence especially of fat products in the duodenal lumen triggers release of CCK. This hormone stimulates contraction of the gallbladder and relaxation of the sphincter of Oddi, so bile is discharged into the duodenum, where it appropriately aids in the digestion and absorption of the fat that initiated CCK release.

Bilirubin is a waste product excreted in the bile.

Bilirubin, the other major constituent of bile, does not play a role in digestion but instead is a waste product excreted in the bile. Bilirubin is the primary bile pigment derived from the breakdown of worn-out red blood cells, which are removed from the blood by the macrophages that line the liver sinusoids and reside in other areas in the body. Bilirubin is the end product from degradation of the heme (iron-containing) part of the hemoglobin contained within these old red blood cells (see p. 383). Hepatocytes take up bilirubin from the plasma, slightly modify the pigment to increase its solubility, then actively excrete it into the bile.

Bilirubin is a yellow pigment that gives bile its color. Within the intestinal tract, this pigment is modified by bacterial enzymes, giving rise to the characteristic brown color of feces. When bile secretion does not occur, as when the bile duct is completely obstructed by a gallstone, the feces are grayish white. A small amount of bilirubin is normally reabsorbed by the intestine back into the blood, and when it is eventually excreted in the urine, it is largely responsible for the urine's yellow color. The kidneys cannot excrete bilirubin until after it has been modified during its passage through the liver and intestine.

Clinical Note If bilirubin is formed more rapidly than it can be excreted, it accumulates in the body and causes **jaundice**. Patients with this condition appear yellowish, with this color being seen most easily in the whites of their eyes. Jaundice can be brought about in three ways:

1. *Prehepatic* (the problem occurs "before the liver"), or *hemolytic, jaundice* arises from excessive breakdown (hemolysis) of red blood cells, which results in the liver being presented with more bilirubin than it is capable of excreting.

2. *Hepatic* (the problem is the "liver") *jaundice* occurs when the liver is diseased and cannot deal with even the normal load of bilirubin.

3. *Posthepatic* (the problem occurs "after the liver"), or *obstructive, jaundice* occurs when the bile duct is obstructed, such as by a gallstone, so that bilirubin cannot be eliminated in the feces.

Hepatitis and cirrhosis are the most common liver disorders.

Clinical Note **Hepatitis** is an inflammatory disease of the liver that results from a variety of causes, including viral infection, obesity (*fatty liver disease*), or most commonly exposure to toxic agents, including alcohol, carbon tetrachloride, and certain tranquilizers. Hepatitis ranges in severity from mild, reversible symptoms to acute massive liver dam-

age, with possible imminent death resulting from acute hepatic failure.

Repeated or prolonged hepatic inflammation, usually in association with chronic alcoholism, can lead to **cirrhosis**, a condition in which damaged hepatocytes are permanently replaced by connective tissue. Liver tissue has the ability to regenerate, normally undergoing a gradual turnover of cells. If part of the hepatic tissue is destroyed, the lost tissue can be replaced by an increase in the rate of cell division. There is a limit, however, to how rapidly hepatocytes can be replaced. In addition to hepatocytes, a small number of fibroblasts (connective tissue cells) are dispersed between the hepatic plates and form a supporting framework for the liver. Chronic or high exposure to alcohol impairs hepatocyte replacement such that the sturdier fibroblasts take advantage of the situation and overproduce. This extra connective tissue leaves little space for the hepatocytes' regrowth. Thus, as cirrhosis develops slowly over time, active liver tissue is gradually reduced, leading eventually to chronic liver failure.

Having looked at the accessory digestive organs that empty their exocrine products into the small-intestine lumen, we now examine the contributions of the small intestine itself.

Check Your Understanding 16.5

1. State the functions of the pancreatic enzymes.
2. Explain the significance of some pancreatic enzymes being stored as precursors in zymogen granules.
3. Describe how bile salts contribute to dietary fat digestion.

16.6 Small Intestine

The **small intestine** is the site where most digestion and absorption takes place. The small intestine lies coiled within the abdominal cavity, extending between the stomach and the large intestine. It is arbitrarily divided into three segments—the **duodenum**, the **jejunum**, and the **ileum**.

As usual, we examine motility, secretion, digestion, and absorption in the small intestine in that order. Small-intestine motility includes *segmentation* and the *migrating motility complex*.

Segmentation contractions mix and slowly propel the chyme.

Segmentation, the small intestine's primary motility during digestion of a meal, both mixes and slowly propels the chyme. Segmentation consists of oscillating, ringlike contractions of the circular smooth muscle along the small intestine's length; between the contracted segments are relaxed areas containing a small bolus of chyme. The contractile rings occur every few centimeters, dividing the small intestine into segments like a chain of sausages. These contractile rings do not sweep along the length of the intestine as peristaltic waves do. Rather, after a brief period, the contracted segments relax, and ringlike contractions appear in the previously relaxed areas (❙Figure 16-18).

The new contraction forces the chyme in a previously relaxed segment to move in both directions into the now relaxed adjacent segments. A newly relaxed segment therefore receives chyme from both the contracting segment immediately ahead of it and the one immediately behind it. Shortly thereafter, the areas of contraction and relaxation alternate again. In this way, the chyme is chopped, churned, and thoroughly mixed. These contractions can be compared to squeezing a pastry tube with your hands to mix the contents.

Initiation and Control of Segmentation Segmentation contractions are initiated by a BER produced by small intestine's pacemaker cells. If the small-intestine BER brings the circular smooth muscle layer to threshold, segmentation contractions are induced, with the frequency of segmentation following the frequency of the BER.

The circular smooth muscle's degree of responsiveness and thus the intensity of segmentation contractions can be influenced by distension of the intestine, by the hormone gastrin, and by extrinsic nerve activity. All these factors influence the excitability of the small-intestine smooth muscle cells by moving the starting potential around which the BER oscillates closer to or farther from threshold. Segmentation is slight or absent between meals but becomes vigorous immediately after a meal. Both the duodenum and the ileum start to segment simultaneously when the meal first enters the small intestine. The duodenum starts to segment primarily in response to local distension caused by the presence of chyme. Segmentation of the empty ileum, in contrast, is brought about by gastrin secreted in response to the presence of chyme in the stomach, a mechanism known as the **gastroileal reflex**. Extrinsic nerves can modify the strength of these contractions. Parasympathetic stimulation enhances segmentation, whereas sympathetic stimulation depresses segmental activity.
❙Figure 16-18 **Segmentation.** Segmentation consists of ringlike contractions along the length of the small intestine. Within a matter of seconds, the contracted segments relax and the previously relaxed areas contract. These oscillating contractions thoroughly mix the chyme within the small-intestine lumen.

Functions of Segmentation The mixing accomplished by segmentation serves the dual functions of (1) mixing the chyme with the digestive juices secreted into the small-intestine lumen and (2) exposing all the chyme to the absorptive surfaces of the small-intestine mucosa.

Segmentation not only accomplishes mixing but also slowly moves chyme through the small intestine. How can this be, when each segmental contraction propels chyme both forward and backward? The chyme slowly progresses forward because the frequency of segmentation declines along the length of the small intestine. The pacemaker cells in the duodenum spontaneously depolarize faster than those farther down the tract, with segmentation contractions occurring in the duodenum at a rate of 12 per minute, compared to only 9 per minute in the terminal ileum. Because segmentation occurs with greater frequency in the upper part of the small intestine than in the lower part, more chyme, on average, is pushed forward than is pushed backward. As a result, chyme is moved slowly from the upper to the lower part of the small intestine, being shuffled back and forth to accomplish thorough mixing and absorption in the process. This slow propulsive mechanism is advantageous because it allows ample time for the digestive and absorptive processes to take place. The contents usually take 3 to 5 hours to move through the small intestine.

The migrating motility complex sweeps the intestine clean between meals.

During periods of short fasting, when most of the meal has been absorbed, the stomach and small intestine exhibit a unique motor activity. Intestinal segmentation contractions cease and are replaced by the **migrating motility complex (MMC)**, or **"intestinal housekeeper"** activity. The MMC cycles through the following phases in a repetitive pattern about every 1.5 hours as long as a person is fasting:

1. Phase I: A long period lasting about 40 to 60 minutes of relative quiet with very few contractions

2. Phase II: A 20- to 30-minute period with some peristaltic contractions, with the time varying between contractions

3. Phase III: The shortest phase, where intense peristaltic contractions begin in the upper stomach and propagate (migrate) through to the end of the small intestine. The contractions rhythmically repeat for 5 to 10 minutes. During this period, the pyloric sphincter relaxes and opens completely.

The motor activity of the MMC is thought to sweep any remnants of the preceding meal plus mucosal debris and bacteria forward toward the colon, just like a good "intestinal housekeeper." If a person continues to fast, the MMC motor activity repeats itself, beginning again at Phase I. While fasting, some individuals become acutely aware of the MMC because Phase III contractions cause gurgling noises that are often thought of as the stomach "growling." The MMC is regulated between meals by the hormone *motilin,* which is secreted during the unfed state by endocrine cells of the small-intestine mucosa. When the next meal arrives, the MMC ceases and the motor activity associated with a meal takes over. Motilin release is inhibited by feeding.

The ileocecal juncture prevents contamination of the small intestine by colonic bacteria.

At the juncture between the small and the large intestines, the last part of the ileum empties into the cecum. Two factors contribute to this region's ability to act as a barrier between the small and the large intestines. First, the anatomic arrangement is such that valvelike folds of tissue protrude from the ileum into the lumen of the cecum. When the ileal contents are pushed forward, this **ileocecal valve** is easily pushed open, but the folds of tissue are forcibly closed when the cecal contents attempt to move backward. Second, the smooth muscle within the last several centimeters of the ileal wall is thickened, forming a sphincter that is under neural and hormonal control. Most of the time, this **ileocecal sphincter** remains at least mildly constricted. Pressure on the cecal side of the sphincter causes it to contract more forcibly; distension of the ileal side causes the sphincter to relax, a reaction mediated by the intrinsic plexuses in the area. In this way, the ileocecal juncture prevents the bacteria-laden contents of the large intestine from contaminating the small intestine yet lets the ileal contents pass into the colon. If the colonic bacteria gained access to the nutrient-rich small intestine, they would multiply rapidly. Relaxation of the sphincter is enhanced by release of gastrin at the onset of a meal, when increased gastric activity is taking place. This relaxation allows the undigested fibers and unabsorbed solutes from the preceding meal to be moved forward as the new meal enters the tract.

Small-intestine secretions do not contain any digestive enzymes.

Each day, the exocrine gland cells in the small-intestine mucosa secrete into the lumen about 1.5 liters of an aqueous salt and mucus solution called **succus entericus** ("juice of intestine"). Secretion increases after a meal in response to local stimulation of the small-intestine mucosa by the presence of chyme.

The mucus in the secretion provides protection and lubrication. Furthermore, this aqueous secretion provides plenty of H_2O to participate in the enzymatic digestion of food. Recall that digestion involves hydrolysis—bond breakage by reaction with H_2O—which proceeds most efficiently when all the reactants are in solution.

No digestive enzymes are secreted into this intestinal juice. The small intestine does synthesize digestive enzymes, but they act intracellularly within the brush-border membrane of the epithelial cells that line the lumen instead of being secreted directly into the lumen.

The small-intestine enzymes complete digestion within the brush-border membrane.

Pancreatic enzymes are responsible for most of the digestion within the small-intestine lumen, with fat digestion being enhanced by bile secretion. As a result of pancreatic enzymatic activity, fats are completely reduced to their absorbable units of monoglycerides and free fatty acids, proteins are broken down into small peptide fragments and some amino acids, and carbohydrates are reduced to disaccharides, α-limit dextrins, and

some monosaccharides. Thus, fat digestion is completed within the small-intestine lumen, but carbohydrate and protein digestion have not been brought to completion.

Special hairlike projections on the luminal surface of the small-intestine epithelial cells, the **microvilli**, form the **brush border** (see ❚Figure 2-26, p. 51 and chapter opener photo, p. 565). The brush-border plasma membrane contains three categories of membrane-spanning proteins that function as membrane-bound enzymes:

1. **Enteropeptidase**, which activates the pancreatic proteolytic enzyme trypsinogen

2. The **disaccharidases (maltase, sucrase-isomaltase**, and **lactase)**, which target maltose, α-limit dextrins, and dietary disaccharides. Maltose (which is a product of salivary and pancreatic amylase) is broken down to glucose by maltase or sucrase-isomaltase activity. However, the other product of starch digestion, the α-limit dextrins is only broken down by sucrase-isomaltase. The end digestion of the dietary disaccharides sucrose and lactose is completed by sucrase-isomaltase and lactase, respectively.

3. The **aminopeptidases**, which hydrolyze most of the small peptide fragments into their amino acid components, thereby completing protein digestion

Thus, carbohydrate and protein digestion are completed within the confines of the brush border. (❚Table 16-6 provides a summary of the digestive processes for the three major categories of nutrients.)

Clinical Note A fairly common disorder, **lactose intolerance**, involves a deficiency of lactase, the disaccharidase specific for the digestion of lactose, or milk sugar. Most children younger than 4 years of age have adequate lactase, but this may be gradually lost so that, in many adults, lactase activity is diminished or absent. When lactose-rich milk or dairy products are consumed by a person with lactase deficiency, the undigested lactose remains in the lumen and has several related consequences. First, accumulation of undigested lactose creates an osmotic gradient that draws H_2O into the intestinal lumen. Second, bacteria living in the large intestine have lactose-splitting ability, so they eagerly attack the lactose as an energy source, producing large quantities of CO_2 and methane gas in the process. Distension of the intestine by both fluid and gas produces pain (cramping) and diarrhea. Infants with lactose intolerance may also suffer from malnutrition.

Finally, we are ready to discuss absorption of nutrients. Up to this point, no food, water, or electrolytes have been absorbed.

The small intestine is remarkably well adapted for its primary role in absorption.

All products of carbohydrate, protein, and fat digestion, and most of the ingested electrolytes, vitamins, and water, are normally absorbed by the small intestine indiscriminately. Usually, only the absorption of calcium and iron is adjusted to the body's

❚**TABLE 16-6** Digestive Processes for the Three Major Categories of Nutrients

Nutrients	Enzymes for Digesting Nutrient	Source of Enzymes	Site of Action of Enzymes	Action of Enzymes	Absorbable Units of Nutrients
Carbohydrate	Amylase	Salivary glands	Mouth and (mostly) body of stomach	Hydrolyzes polysaccharides to disaccharides and α-limit dextrins	
		Exocrine pancreas	Small-intestine lumen		
	Disaccharidases (maltase, sucrase-isomaltase, lactase)	Small-intestine epithelial cells	Small-intestine brush border	Hydrolyze disaccharides to monosaccharides	Monosaccharides, especially glucose
Protein	Pepsin	Stomach chief cells	Stomach antrum	Hydrolyzes protein to peptide fragments	
	Trypsin, chymotrypsin carboxypeptidase	Exocrine pancreas	Small-intestine lumen	Attack different peptide fragments	
	Aminopeptidases	Small-intestine epithelial cells	Small-intestine brush border	Hydrolyze peptide fragments to amino acids	Amino acids and a few small peptides
Fat	Lipase	Exocrine pancreas	Small-intestine lumen	Hydrolyzes triglycerides to fatty acids and monoglyerides	Fatty acids and monoglycerides
	Bile salts (not an enzyme)	Liver	Small-intestine lumen	Emulsify large fat globules for attack by pancreatic lipase	

needs. Thus, the more food consumed, the more that is digested and absorbed, as people who are trying to control their weight are all too painfully aware.

Most absorption occurs in the duodenum and jejunum; very little occurs in the ileum, not because the ileum does not have absorptive capacity but because most absorption has already been accomplished before the intestinal contents reach the ileum. The small intestine has an abundant reserve absorptive capacity. About 50% of the small intestine can be removed with little interference to absorption—with one exception. If the terminal ileum is removed, vitamin B_{12} and bile salts are not properly absorbed because the specialized transport mechanisms for these two substances are located only in this region. All other substances can be absorbed throughout the small intestine's length.

The mucous lining of the small intestine is remarkably well adapted for its special absorptive function for two reasons: (1) it has a large surface area, and (2) the epithelial cells in this lining have a variety of specialized transport mechanisms.

Adaptations that Increase the Small Intestine's Surface Area The following special modifications of the small-intestine mucosa greatly increase the surface area available for absorption (❙Figure 16-19):

▪ The inner surface of the small intestine is thrown into permanent **circular folds** that are visible to the naked eye and increase the surface area threefold.

▪ Extending from this folded surface are microscopic, fingerlike projections known as **villi**, which give the lining a velvety appearance and increase the surface area another 10 times (❙Figure 16-20). The surface of each villus is covered by epithelial cells interspersed occasionally with mucous cells.

▪ Even smaller hairlike projections, the *microvilli* or *brush border,* arise from the luminal surface of these epithelial cells, increasing the surface area another 20-fold. Each epithelial cell has as many as 3000 to 6000 of these microvilli, which are visible only with an electron microscope (see chapter opener photo). The small-intestine enzymes perform their functions within the membrane of this brush border.

Altogether, the folds, villi, and microvilli provide the small intestine with a luminal surface area 600 times greater than if it were a tube of the same length and diameter lined by a flat surface. If the surface area of the small intestine were spread out flat, it would cover an entire tennis court.

Clinical Note **Malabsorption** (impairment of absorption) may be caused by damage to or reduction of the surface area of the small intestine. One of the most common causes is **gluten enteropathy**, also known as **celiac disease**. In this condition, the person's small intestine is abnormally sensitive to *gluten,* a protein constituent of wheat, barley, and rye. These grain products are widely prevalent in processed foods. This condition is a complex immunological disorder in which exposure to gluten erroneously activates a T-cell response (see p. 423) that damages the intestinal villi: The normally luxuriant array of villi is reduced, the mucosa becomes flattened, and the brush border becomes short and stubby (❙Figure 16-21). Because this loss of villi and microvilli decreases the surface

area available for absorption, absorption of all nutrients is impaired. The condition is treated by not eating gluten.

Structure of a Villus Absorption across the digestive tract wall involves transepithelial transport similar to movement of material across the kidney tubules (see p. 505). Each villus has the following major components (see Figures 16-19c and 16-20):

- *Epithelial cells that cover the surface of the villus.* The epithelial cells are joined at their lateral borders by tight junctions, which limit passage of luminal contents between the cells, although the tight junctions in the small intestine are leakier than those in the stomach. Within their luminal brush borders, these epithelial cells have carriers for absorption of specific nutrients and electrolytes from the lumen, and the membrane-bound digestive enzymes that complete carbohydrate and protein digestion.
- *A connective tissue core.* This core is formed by the lamina propria.
- *A capillary network.* Each villus is supplied by an arteriole that breaks up into a capillary network within the villus core. The capillaries rejoin to form a venule that drains away from the villus.
- *A terminal lymphatic vessel.* Each villus is supplied by a single blind-ended lymphatic vessel known as the **central lacteal**, which occupies the center of the villus core.

During the process of absorption, digested substances enter the capillary network or the central lacteal. To be absorbed, a substance must pass completely through the epithelial cell, diffuse through the interstitial fluid within the connective tissue core of the villus, and then cross the wall of a capillary or lymph vessel. Like renal transport, intestinal absorption may be active or pas-

sive, with active absorption involving energy expenditure during at least one of the transepithelial transport steps.

The mucosal lining experiences rapid turnover.

Dipping down into the mucosal surface between the villi are shallow invaginations known as the **crypts of Lieberkühn** (see Figure 16-19c). Unlike the gastric pits, these intestinal crypts do not secrete digestive enzymes, but they do secrete water and salt, which, along with the mucus secreted by the cells on the villus surface, constitute the succus entericus.

Furthermore, the crypts function as nurseries. The epithelial cells lining the small intestine slough off and are replaced at a rapid rate as a result of high mitotic activity of *stem cells* in the crypts. New cells that are continually being produced in the crypts migrate up the villi and, in the process, push off the older cells at the tips of the villi into the lumen. In this manner, more than 100 million intestinal cells are shed per minute. The entire trip from crypt to tip averages about 3 days, so the mucosal epithelium is replaced approximately every 3 days. Because of this high rate of cell division, the crypt stem cells are very sensitive to damage by radiation and anticancer drugs, both of which may inhibit cell division.

The new cells undergo several changes as they migrate up the villus. The concentration of brush-border enzymes increases and the capacity for absorption improves, so the cells at the tip of the villus have the greatest digestive and absorptive capability. Just at their peak, these cells are pushed off by the newly migrating cells. Thus, the luminal contents are constantly exposed to cells that are optimally equipped to complete the digestive and absorptive functions efficiently. Furthermore, just as in the stomach, the rapid turnover of cells in the small intestine is essential because of the harsh luminal conditions. Cells exposed to the abrasive and corrosive luminal contents are easily damaged and cannot live for long, so they must be continually replaced by a fresh supply of newborn cells.

The old cells sloughed off into the lumen are not entirely lost to the body. These cells are digested, with the cell constituents being absorbed into the blood and reclaimed for synthesis of new cells, among other things.

In addition to stem cells, defensive **Paneth cells** are found in the crypts. Paneth cells produce two chemicals that thwart bacteria: (1) *lysozyme,* the bacteria-lysing enzyme also found in saliva; and (2) *defensins,* small proteins with antimicrobial powers (see p. 438).

We now turn attention to the ways in which the epithelial lining of the small intestine is specialized to accomplish absorption of luminal contents and the mechanisms through which the specific dietary constituents are normally absorbed.

Energy-dependent Na^+ absorption drives passive H_2O absorption.

Na^+ may be absorbed both passively and actively. When the electrochemical gradient favors movement of Na^+ from the lumen to the blood, passive diffusion of Na^+ can occur by paracellular transport *between* the intestinal epithelial cells through the "leaky" tight junctions into the interstitial fluid within the villus. Movement of Na^+ *through* the cells is energy dependent and involves different carriers or channels at the luminal and basolateral membranes, similar to the process of Na^+ reabsorption across the kidney tubules (see pp. 506 and 510). Na^+ enters the epithelial cells across the luminal border either by itself passively through Na^+ channels or in the company of another ion or a nutrient molecule by secondary active transport via three different carriers: Na^+–Cl^- symporter, Na^+–H^+ antiporter, or Na^+–glucose (or amino acid) symporter. Na^+ is actively pumped out of the cell by the Na^+–K^+ pump at the basolateral membrane into the interstitial fluid in the lateral spaces between the cells where they are not joined by tight junctions. From the interstitial fluid, Na^+ diffuses into the capillaries.

As with the renal tubules in the early part of the nephron, the absorption of Cl^-, H_2O, glucose, and amino acids from the small intestine is linked to this energy-dependent Na^+ absorption. Cl^- passively follows down the electrical gradient created by Na^+ absorption and also can be absorbed by secondary active transport if needed. Most H_2O absorption in the digestive tract depends on the active carrier that pumps Na^+ into the lateral spaces, resulting in a concentrated area of high osmotic pressure in that localized region between the cells, similar to the situation in the kidneys (see p. 512). This localized high osmotic

pressure induces H_2O to move from the lumen through the cell (and possibly from the lumen through the leaky tight junction) into the lateral space. Water entering the space reduces the osmotic pressure but raises the hydrostatic (fluid) pressure. The elevated hydrostatic pressure flushes H_2O out of the lateral space into the interior of the villus, where it is picked up by the capillary network. Meanwhile, more Na^+ is pumped into the lateral space to encourage more H_2O absorption.

Digested carbohydrates and proteins are both absorbed by secondary active transport and enter the blood.

Absorption of the digestion end products of both carbohydrates and proteins is accomplished by Na^+-dependent symport, and both categories of end products are absorbed into the blood.

Carbohydrate Absorption Dietary carbohydrates are presented to the small intestine for absorption mainly in the forms of the disaccharides maltose, sucrose, and lactose (and to a lesser extent in the form of the short polysaccharide a-limit dextrins) (❙Figure 16-22a). The disaccharidases located in the brush-border membrane of the small intestine cells further reduce these disaccharides and polysaccharides into the absorbable monosaccharide units of glucose (mostly), galactose, and fructose.

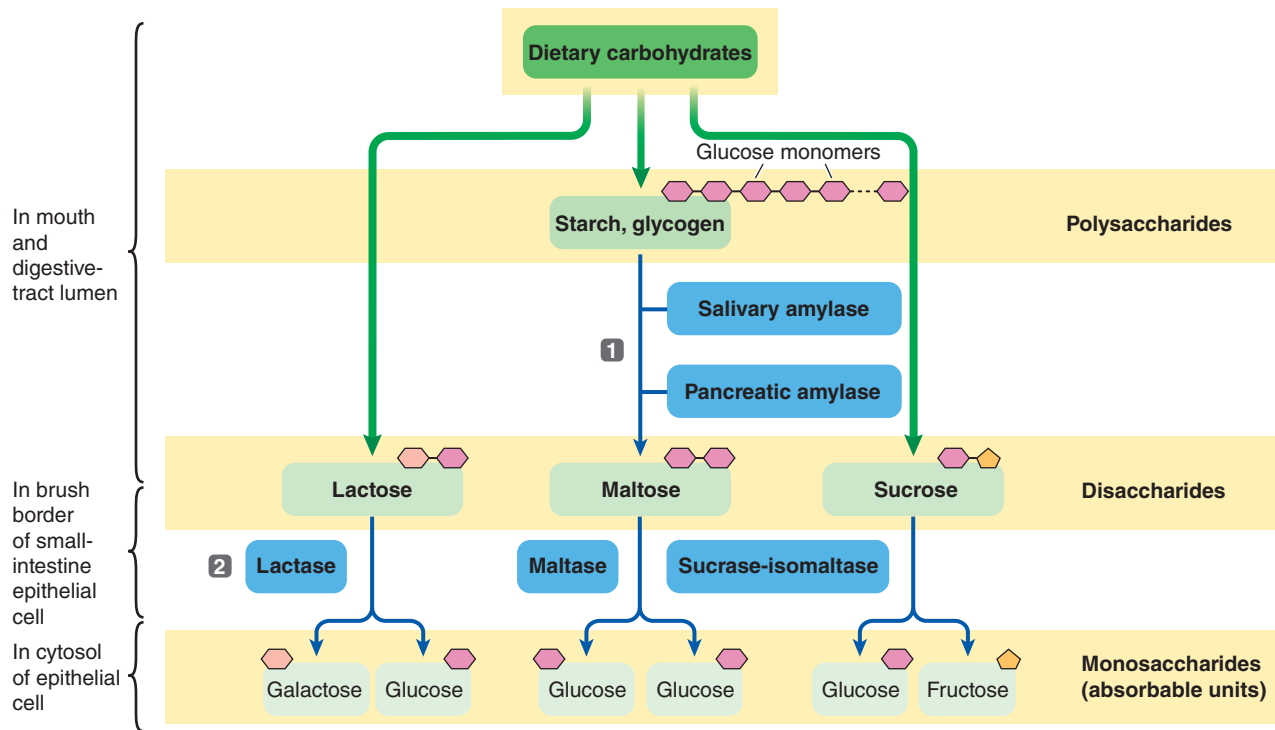
Glucose and galactose are both absorbed by secondary active transport, in which symport carriers, such as the *sodium and glucose cotransporter* (SGLT; see Figure 3-18, p. 76) on the luminal membrane transport both the monosaccharide and Na^+ from the lumen into the interior of the intestinal cell (❙Figure 16-22b). The operation of these symporters, which do not directly use energy themselves, depends on the Na^+ concentration gradient established by the energy-consuming basolateral Na^+–K^+ pump (see p. 73). Glucose (or galactose), having been concentrated in the cell by these symporters, leaves the cell down its concentration gradient by facilitated diffusion (passive carrier-mediated transport; see p. 72) via the *glucose transporter GLUT-2* in the basal border to enter the blood within the villus. In addition to glucose being absorbed through the cells by means of the symporter, recent evidence suggests that a significant amount of glucose crosses the epithelial barrier through the leaky tight junctions between the epithelial cells.

Fructose enters the epithelial cells from the lumen via *GLUT-5* using facilitated diffusion. This process involves the higher concentration of luminal fructose driving the monosaccharide into the cell. Like the other monosaccharides, fructose exits via GLUT-2 and enters the blood (❙Figure 16-22b).

Protein Absorption Both ingested proteins and endogenous (within the body) proteins that have entered the digestive tract lumen from the following sources are digested and absorbed:

1. Digestive enzymes, all of which are proteins, that have been secreted into the lumen

2. Proteins within the cells that are pushed off from the villi into the lumen during the process of mucosal turnover

3. Small amounts of plasma proteins that normally leak from the capillaries into the digestive tract lumen


(a) Carbohydrate digestion

(b) Carbohydrate absorption
❚Figure 16-22 Carbohydrate digestion and absorption.

1 The dietary polysaccharides starch and glycogen are converted into the disaccharide maltose through the action of salivary and pancreatic amylase.

2 Maltose and the dietary disaccharides lactose and sucrose are converted to their respective monosaccharides by the disaccharidases (maltase, lactase, and sucrase-isomaltase) located in the brush borders of the small-intestine epithelial cells.

3 The monosaccharides glucose and galactose are absorbed into the epithelial cells by Na^+- and energy-dependent secondary active transport (via the symporter SGLT) located at the luminal membrane.

4 The monosaccharide fructose enters the cell by passive facilitated diffusion via GLUT-5.

5 Glucose, galactose, and fructose exit the cell at the basal membrane by passive facilitated diffusion via GLUT-2.

6 These monosaccharides enter the blood by simple diffusion.

→	= Simple diffusion

About 20 to 40 g of endogenous proteins enter the lumen each day from these three sources. This quantity can amount to more than the quantity of proteins in ingested food. All endogenous proteins must be digested and absorbed, along with the dietary proteins, to prevent depletion of the body's protein stores. The amino acids absorbed from both food and endogenous proteins are used primarily to synthesize new proteins in the body.

The proteins presented to the small intestine for absorption are in the form of amino acids and a few small peptide fragments (❚Figure 16-23a). Amino acids are absorbed into the intestinal cells by symporters, similar to glucose and galactose absorption (❚Figure 16-23b). The sugar symporters are distinct from the amino-acid symporters, and the amino-acid symporters are selective for different amino acids. Small peptides gain entry by means of yet another Na^+-dependent carrier in a process known as **tertiary active transport** (*tertiary* meaning "third," in reference to a third linked step ultimately being driven by energy used in the first step). In this case, the symporter simultaneously transports both H^+ and the peptide from the lumen into the cell, driven by H^+ moving down its concentration gradient and the peptide moving against its concentration gradient (❚Figure 16-23b). The H^+ gradient is established by an antiporter in the luminal membrane that is driven by Na^+ moving into the cell down its concentration gradient and H^+ moving out of the cell against its concentration gradient. The Na^+ concentration gradient that drives the antiporter in turn is established by the energy-dependent Na^+–K^+ pump at the basolateral membrane. Thus, glucose, galactose, amino acids, and small peptides all get a "free ride" in on the energy expended for Na^+ transport. The small peptides are broken down into their constituent amino acids by the aminopeptidases in the brush-border membrane or by intracellular peptidases (❚Figure 16-23a). Like monosaccharides, amino acids leave the intestinal cells by facilitated diffusion and enter the capillary network within the villus.

Digested fat is absorbed passively and enters the lymph.

Fat absorption is different from carbohydrate and protein absorption because the insolubility of fat in water presents a special problem. Fat must be transferred from the watery chyme through the watery body fluids, even though fat is not water soluble. Therefore, fat must undergo a series of physical and chemical transformations to circumvent this problem during its digestion and absorption (❚Figure 16-24).

A Review of Fat Emulsification and Digestion When the stomach contents are emptied into the duodenum, the ingested fat is aggregated into large, oily triglyceride droplets that float in the chyme. Recall that through the bile salts' detergent action in the small-intestine lumen, the large droplets are dispersed into a lipid emulsification of small droplets, exposing a greater surface area of fat for digestion by pancreatic lipase (❚Figure 16-24, step ❶). The products of lipase digestion (monoglycerides and free fatty acids; step ❷) are also not very water soluble, so little of these end products of fat digestion can diffuse through the aqueous chyme to reach the absorptive lining.

However, biliary components facilitate absorption of these fatty end products by forming micelles.

Fat Absorption Remember that micelles are water-soluble particles that can carry the end products of fat digestion within their lipid-soluble interiors (❚Figure 16-24, step ❸). Once these micelles reach the luminal membranes of the epithelial cells, the monoglycerides and free fatty acids passively diffuse from the micelles through the lipid component of the epithelial cell membranes to enter the interior of these cells (step ❹).

Bile salts continuously repeat their fat-solubilizing function down the length of the small intestine until all fat is absorbed. Then the bile salts themselves are reabsorbed in the terminal ileum by special active transport. This is an efficient process because relatively small amounts of bile salts can facilitate digestion and absorption of large amounts of fat, with each bile salt performing its ferrying function repeatedly before it is reabsorbed.

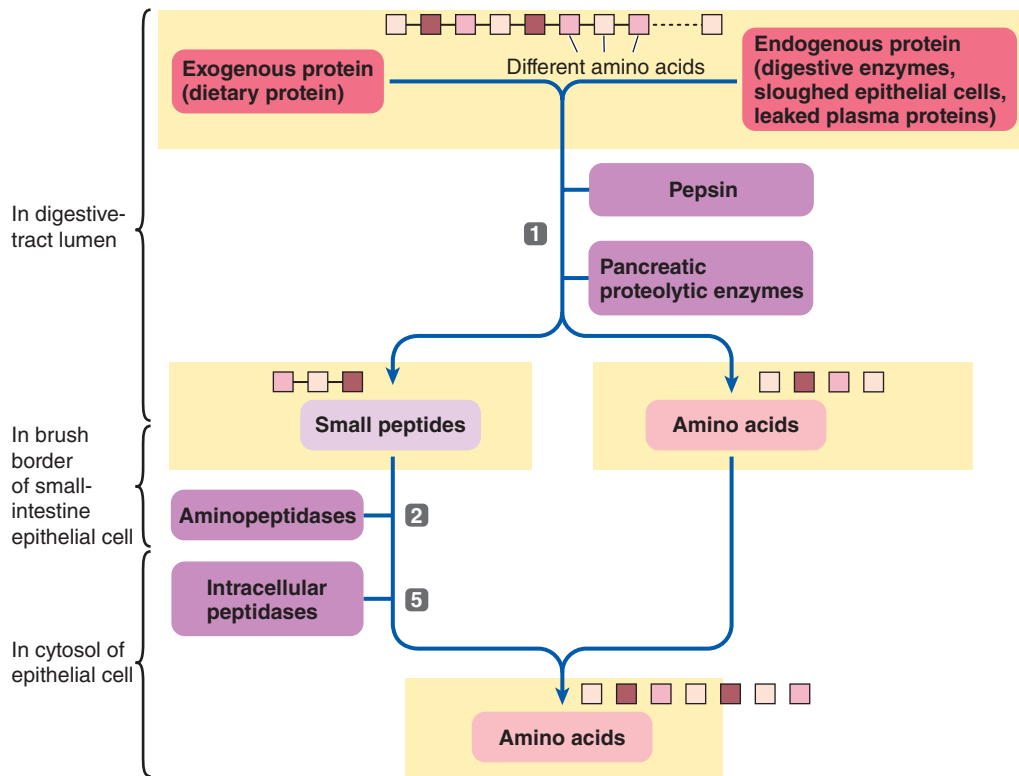
Once within the interior of the epithelial cells, the monoglycerides and free fatty acids are resynthesized into triglycerides (step ❺). These triglycerides conglomerate into droplets and are coated with a layer of lipoprotein (synthesized by the endoplasmic reticulum of the epithelial cell), which makes the fat droplets water soluble (step ❻). The large, coated fat droplets, known as **chylomicrons**, are extruded by exocytosis from the epithelial cells into the interstitial fluid within the villus (step ❼). Chylomicrons are 75 to 500 nm in diameter, compared to micelles, which are 3 to 10 nm in diameter. The chylomicrons subsequently enter the central lacteals rather than the capillaries because of the structural differences between these two vessels (step ❽). Capillaries have a basement membrane (an outer layer of polysaccharides) (see p. 352) that prevents the chylomicrons from entering, but the lymph vessels do not have this barrier. Thus, fat can be absorbed into the lymphatics but not directly into the blood.

The actual absorption of monoglycerides and free fatty acids from the chyme across the luminal membrane of the small-intestine epithelial cells is traditionally considered a passive process because the lipid-soluble fatty end products merely dissolve in and pass through the lipid part of the membrane. However, the overall sequence of events needed for fat absorption requires energy. For example, bile salts are actively secreted by the liver, the resynthesis of triglycerides and formation of chylomicrons within the epithelial cells are active processes, and the exocytosis of chylomicrons requires energy.

Vitamin absorption is largely passive.

Water-soluble vitamins are primarily absorbed passively with water, whereas fat-soluble vitamins are carried in the micelles and absorbed passively with the end products of fat digestion. Some of the vitamins can also be absorbed by carriers, if necessary. Vitamin B_{12} is unique in that it must be in combination with gastric intrinsic factor for absorption by receptor-mediated endocytosis in the terminal ileum.

Iron and calcium absorption is regulated.

In contrast to the almost complete, unregulated absorption of other ingested electrolytes, dietary iron and calcium may not be absorbed completely because their absorption is subject to


(a) Protein digestion

1 Dietary and endogenous proteins are hydrolyzed into their constituent amino acids and a few small peptide fragments by gastric pepsin and the pancreatic proteolytic enzymes.

2 Many small peptides are converted into their respective amino acids by the aminopeptidases located in the brush borders of the small-intestine epithelial cells.

3 Amino acids are absorbed into the epithelial cells by means of Na^+- and energy-dependent secondary active transport via a symporter. Various amino acids are transported by carriers specific for them.

4 Some small peptides are absorbed by a different type of symporter driven by H^+, Na^+-, and energy-dependent tertiary active transport.

5 Most absorbed small peptides are broken down into their amino acids by intracellular peptidases.

6 Amino acids exit the cell at the basal membrane via various passive carriers.

7 Amino acids enter the blood by simple diffusion. (A small percentage of di- and tripeptides also enter the blood intact.)

(b) Protein absorption
▐Figure 16-23 **Protein digestion and absorption**.
FIGURE FOCUS: *Which monosaccharide is absorbed passively and which require energy to be absorbed?*
❙Figure 16-24 Fat digestion and absorption. Because fat is not soluble in water, it must undergo a series of transformations to be digested and absorbed.

1 Dietary fat in the form of large fat globules composed of triglycerides is emulsified by the detergent action of bile salts into a suspension of smaller fat droplets. This lipid emulsion prevents the fat droplets from coalescing and thereby increases the surface area available for attack by pancreatic lipase.

2 Lipase hydrolyzes the triglycerides into monoglycerides and free fatty acids.

3 These water-insoluble products are carried to the luminal surface of the small-intestine epithelial cells within water-soluble micelles, which are formed by bile salts and other bile constituents.

4 When a micelle approaches the absorptive epithelial surface, the monoglycerides and fatty acids leave the micelle and passively diffuse through the lipid bilayer of the luminal membranes.
5 The monoglycerides and free fatty acids are resynthesized into triglycerides inside the epithelial cells.

6 These triglycerides aggregate and are coated with a layer of lipoprotein from the endoplasmic reticulum to form water-soluble chylomicrons.

7 Chylomicrons are extruded through the basal membrane of the cells by exocytosis.

8 Chylomicrons are unable to cross the basement membrane of capillaries, so instead they enter the lymphatic vessels, the central lacteals.

regulation, depending on the body's needs for these electrolytes. Normally, only enough iron and calcium are actively absorbed into the blood to maintain the homeostasis of these electrolytes, with excess ingested quantities being lost in the feces.

Iron Absorption Iron is essential for hemoglobin production. The normal iron intake is typically 15 to 20 mg/day, yet a man usu-

ally absorbs about 0.5 to 1 mg/day into the blood, and a woman takes up slightly more, at 1.0 to 1.5 mg/day. (Women need more iron because they periodically lose iron in menstrual blood flow.)

Two main steps are involved in absorption of iron into the blood: (1) absorption of iron from the lumen into the small-intestine epithelial cells and (2) absorption of iron from the epithelial cells into the blood (❙Figure 16-25).

The Digestive System   **607**
IFigure 16-25 Iron absorption.

1 Only a portion of ingested iron is in a form that can be absorbed, either heme iron or ferrous iron (Fe^{2+}).

2 Iron is absorbed across the luminal membrane of small-intestine epithelial cells by different energy-dependent carriers for heme and Fe^{2+}.

3 Dietary iron that is absorbed into the small-intestine epithelial cells and is immediately needed for red blood cell production is transferred into the blood by the membrane iron transporter ferroportin.

4 In the blood, the absorbed iron is carried to the bone marrow bound to transferrin, a plasma protein carrier.

5 Absorbed dietary iron that is not immediately needed is stored in the epithelial cells as ferritin, which cannot be transferred into the blood.

6 This unused iron is lost in the feces as the ferritin-containing epithelial cells are sloughed.

7 Dietary iron that was not absorbed is also lost in the feces.

Iron is actively transported from the lumen into the epithelial cells, with women having about four times more active-transport sites for iron than men. The extent to which ingested iron is taken up by the epithelial cells depends on the type of iron consumed. Dietary iron exists in two forms: *heme iron,* in which iron is bound as part of a heme group found in hemoglobin (see p. 383) and is present in meat, and *inorganic iron,* which is present in plants. Dietary heme is absorbed more efficiently than inorganic iron is. Dietary inorganic iron exists primarily in the oxidized ferric iron (Fe^{3+}) form, but the reduced ferrous iron (Fe^{2+}) form is absorbed more easily. Dietary Fe^{3+} is reduced to Fe^{2+} by a membrane-bound enzyme at the luminal membrane before absorption. The presence of other substances in the lumen can either promote or reduce iron absorption. For example, vitamin C increases iron absorption, primarily by reducing Fe^{3+} to Fe^{2+}. Phosphate and oxalate, in contrast, combine with ingested iron to form insoluble iron salts that cannot be absorbed.

Heme iron and Fe^{2+} are transported across the luminal membrane by separate energy-dependent carriers in the brush border: Heme iron enters the intestinal cell by *heme carrier protein 1* and Fe^{2+} is carried in via *divalent metal transporter 1,* which also transports other metals that have a valence of +2. An enzyme within the cell frees iron from the heme complex.

After absorption into the small-intestine epithelial cells, iron has two possible fates:

1. Iron needed immediately for production of red blood cells is absorbed into the blood for delivery to the bone marrow, the site of red blood cell production. Iron exits the small-intestine epithelial cell via a membrane iron transporter known as **ferroportin**. Iron absorption is largely controlled by a recently discovered hormone, **hepcidin**, which is released from the liver when iron levels in the body become too high. Hepcidin prevents further iron export from the small-intestine epithelial cell into the blood by binding with ferroportin and promoting its internalization into the cell by endocytosis and its subsequent degradation by lysosomes. Thus, hepcidin is the primary regulator of iron homeostasis. A deficiency of hepcidin leads to tissue iron overload because ferroportin continues to transfer iron into the body without control.

Iron that exits the small-intestine epithelial cell is transported in the blood by a plasma protein carrier known as **transferrin**. The absorbed iron is then used in the synthesis of hemoglobin for the newly produced red blood cells.

2. Iron not immediately needed is irreversibly stored within the small-intestine epithelial cells in a granular form called **ferritin**, which cannot be absorbed into the blood. Iron stored as ferritin is lost in the feces within three days as the epithelial cells containing these granules are sloughed off during mucosal regeneration. Large amounts of iron in the feces give them a dark, almost black color.

Calcium Absorption The amount of calcium (Ca^{2+}) absorbed is also regulated. Calcium enters the luminal membrane of the small-intestine epithelial cells down its electrochemical gradient through a specialized Ca^{2+} channel; is ferried within the cell by a Ca^{2+}-binding protein, **calbindin**; and exits the basolateral membrane by two energy-dependent mecha-

nisms: a primary active transport Ca^{2+} ATPase pump and a secondary active transport Na^+–Ca^{2+} antiporter. Vitamin D greatly enhances all of these steps in Ca^{2+} absorption. Vitamin D can exert this effect only after it has been activated in the liver and kidneys, a process that is enhanced by parathyroid hormone. Appropriately, secretion of parathyroid hormone increases in response to a fall in Ca^{2+} concentration in the blood. Normally, of the average 1000 mg of Ca^{2+} taken in daily, only about two thirds is absorbed in the small intestine, with the rest passing out in the feces.

Most absorbed nutrients immediately pass through the liver for processing.

The venules that leave the small-intestine villi, along with those from the rest of the digestive tract, empty into the hepatic portal vein, which carries the blood to the liver. Consequently, anything absorbed into the digestive capillaries first must pass through the hepatic biochemical factory before entering the general circulation. Thus, the products of carbohydrate and protein digestion are channeled into the liver, where many of these energy-rich products are subjected to immediate metabolic processing. Furthermore, harmful substances that may have been absorbed are detoxified by the liver before gaining access to the general circulation. After passing through the portal circulation, the venous blood from the digestive system empties into the vena cava and returns to the heart to be distributed throughout the body, carrying glucose and amino acids for use by the tissues.

Fat, which cannot penetrate the intestinal capillaries, is picked up by the central lacteal and enters the lymphatic system instead, bypassing the hepatic portal system. Contractions of the villi, accomplished by the muscularis mucosa, periodically compress the central lacteal and "milk" the lymph out of this vessel. The smaller lymph vessels converge and eventually form the *thoracic duct,* a large lymph vessel that empties into the venous system within the chest. In this way, fat ultimately gains access to the blood. The absorbed fat is carried by the systemic circulation to the liver and to other tissues of the body. Therefore, the liver does have a chance to act on the digested fat, but not until the fat has been diluted by the blood in the general circulatory system. This dilution of fat protects the liver from being inundated with more fat than it can handle at one time.

Extensive absorption by the small intestine keeps pace with secretion.

The small intestine normally absorbs about 9 liters of fluid per day in the form of H_2O and solutes, including the absorbable units of nutrients, vitamins, and electrolytes. How can that be, when humans normally ingest only about 1250 mL of fluid and consume 1250 g of solid food (80% of which is H_2O) per day (see p. 544)? ▮Table 16-7 illustrates the tremendous daily absorption performed by the small intestine. Each day, about 9500 mL of H_2O and solutes enter the small intestine. Note that of this 9500 mL, only 2500 mL are ingested from the external environment. The remaining 7000 mL (7 liters) of fluid are digestive juices derived from the plasma. Recall that plasma is

▮**TABLE 16-7** Volumes Absorbed by the Small and Large Intestine per Day

Volume entering the small intestine per day

Sources	Ingested	Food eaten	1250 g*
		Fluid drunk	1250 mL
	Secreted from the plasma	Saliva	1500 mL
		Gastric juice	2000 mL
		Pancreatic juice	1500 mL
		Bile	500 mL
		Intestinal juice	1500 mL

	9500 mL
Volume absorbed by the small intestine per day	9000 mL
Volume entering the colon from the small intestine per day	500 mL
Volume absorbed by the colon per day	350 mL
Volume of feces eliminated from the colon per day	150 g*

*Because 1 mL of H_2O weighs 1 g, and a high percentage of food and feces is H_2O, we can roughly equate grams with milliliters of fluid.

the ultimate source of digestive secretions because the secretory cells extract from the plasma the necessary raw materials for their secretory product. Considering that the entire plasma volume is only about 2.75 liters, absorption must closely parallel secretion to keep the plasma volume from falling sharply.

Of the 9500 mL of fluid entering the small-intestine lumen per day, about 95%, or 9000 mL of fluid, is normally absorbed by the small intestine back into the plasma, with only 500 mL of the small-intestine contents passing on into the colon. Thus, the body normally does not lose the digestive juices. After the constituents of the juices are secreted into the digestive tract lumen and perform their function, they are returned to the plasma. The only secretory product that escapes from the body is bilirubin, a waste product that must be eliminated.

Biochemical balance among the stomach, pancreas, and small intestine is normally maintained.

Production of gastric and pancreatic digestive secretions typically does not alter the acid–base status of the body because the amount of H^+ secreted by the gastric parietal cells is usually matched by the amount of HCO_3^- secreted by the pancreatic duct cells. Also, the by-products generated during these secretory processes—HCO_3^- by the parietal cells and H^+ by the pancreatic duct cells—are normally transported back into the plasma in equal amounts.

Furthermore, the acid–base balance is not altered as the secreted juices are absorbed back into the plasma. Within the small-intestine lumen, the HCl secreted by the parietal cells of the stomach is neutralized by the $NaHCO_3$ secreted by the pancreatic duct cells:

$$HCl + NaHCO_3 \rightarrow NaCl + H_2CO_3$$
The resultant H_2CO_3 decomposes into $CO_2 + H_2O$:

$$H_2CO_3 \rightarrow CO_2 + H_2O$$
The end products of these reactions—NaCl (ionized as Na^+ and Cl^-), CO_2, and H_2O—are all absorbed by the small intestine into the blood. Thus, through these interactions, the body normally does not experience a net gain or loss of acid or base during digestion.

Diarrhea results in loss of fluid and electrolytes.

Clinical Note When secretion and absorption do not parallel each other, however, acid–base abnormalities can result because these normal neutralization processes cannot take place. We have already described vomiting and the subsequent loss of acidic gastric contents leading to metabolic alkalosis. The other common digestive tract disturbance that can lead to a loss of fluid and an acid–base imbalance is **diarrhea**. This condition is characterized by passage of a highly fluid fecal matter, often with increased frequency of defecation. Not only are some of the ingested materials lost but some of the secreted materials that normally would have been reabsorbed are lost also. Excessive loss of intestinal contents causes dehydration, loss of nutrient material, and metabolic acidosis resulting from loss of HCO_3^- (see p. 561). The abnormal fluidity of the feces usually occurs because the small intestine is unable to absorb fluid as extensively as normal. This extra unabsorbed fluid passes out in the feces.

The causes of diarrhea are as follows:

1. The most common cause of diarrhea is excessive small-intestinal motility, which arises either from local irritation of the gut wall by bacterial or viral infection of the small intestine or from emotional stress. Rapid transit of the small-intestine contents does not allow enough time for adequate absorption of fluid to occur.

2. Diarrhea also occurs when excess osmotically active particles, such as those found in lactase deficiency, are present in the digestive tract lumen. These particles cause excessive fluid to enter and be retained in the lumen, thus increasing the fluidity of the feces.

3. Toxins of the bacterium *Vibrio cholera* (the causative agent of cholera) and certain other microorganisms promote the secretion of excessive amounts of fluid by the small-intestine mucosa, resulting in profuse diarrhea. Diarrhea produced in response to toxins from infectious agents is the leading cause of death of small children in developing nations. Fortunately, a low-cost, effective *oral rehydration therapy* that takes advantage of the intestine's glucose symport carrier is saving the lives of millions of children. (For details about oral rehydration therapy, see the accompanying boxed feature, ▌Concepts, Challenges, and Controversies.)

Check Your Understanding 16.6

1. Explain how segmentation accomplishes both mixing and propulsion.

2. Describe the structural features that increase the surface area of the small intestine and explain the significance of increasing the surface area.

3. Discuss how the Na^+–K^+ pump of mucosal epithelial cells facilitates nutrient absorption.

16.7 Large Intestine

The **large intestine** consists of the colon, cecum, appendix, and rectum (▌Figure 16-26). The **cecum** forms a blind-ended pouch below the junction of the small and large intestines at the ileocecal valve. The small, fingerlike projection at the bottom of the cecum is the **appendix**, a lymphoid tissue that houses lymphocytes (see p. 405). The **colon**, which makes up most of the large intestine, is not coiled like the small intestine but consists of three relatively straight parts—the *ascending colon,* the *transverse colon,* and the *descending colon.* The end part of the descending colon becomes S shaped, forming the *sigmoid colon* (*sigmoid* means "S shaped"), and then straightens out to form the rectum (meaning "straight").

The large intestine is primarily a drying and storage organ.

The colon normally receives about 500 mL of chyme from the small intestine each day. Because most digestion and absorption have been accomplished in the small intestine, the contents delivered to the colon consist of indigestible food residues (such as cellulose), unabsorbed biliary components, and the remaining fluid. The colon extracts more H_2O and salt, drying and compacting the contents to form a firm mass known as **feces** for elimination from the body. The primary function of the large intestine is to store feces before defecation. Cellulose and other
▌Figure 16-26 **Anatomy of the large intestine.**

Oral Rehydration Therapy: Sipping a Simple Solution Saves Lives

DIARRHEA-INDUCING MICROORGANISMS SUCH AS *Vibrio cholera,* which causes cholera, are the leading cause of death in children younger than age 5 worldwide. The problem is especially pronounced in developing countries, refugee camps, and elsewhere where poor sanitary conditions encourage the spread of the microorganisms, and medical supplies and health-care personnel are scarce. Fortunately, a low-cost, easily obtainable, uncomplicated remedy—**oral rehydration therapy (ORT)**—has been developed to combat potentially fatal diarrhea. This treatment exploits the symporters located at the luminal border of the villus epithelial cells.

Let us examine the pathophysiology of life-threatening diarrhea and then see how simple ORT can save lives. During digestion of a meal, the crypt cells of the small intestine normally secrete succus entericus, a salt and mucus solution, into the lumen. These cells actively transport Cl^- into the lumen, promoting the parallel passive transport of Na^+ and H_2O from the blood into the lumen. The fluid provides the watery environment needed for enzymatic breakdown of ingested nutrients into absorbable units. Glucose and amino acids, the absorbable units of dietary carbohydrates and proteins, respectively, are absorbed by secondary active transport. This absorption mechanism uses the Na^+–glucose (or amino acid) cotransport carriers (SGLT) located at the luminal membrane of the villus epithelial cells (see p. 75). In addition, separate active Na^+ carriers not linked with nutrient absorption transfer Na^+, passively accompanied by Cl^- and H_2O, from the lumen into the blood.

The net result of these various carrier activities is absorption of the secreted salt and H_2O along with the digested nutrients. Normally, absorption of salt and H_2O exceeds their secretion, so not only are the secreted fluids salvaged, but also additional ingested salt and H_2O are absorbed.

Cholera and most diarrhea-inducing microbes cause diarrhea by stimulating the secretion of Cl^- or impairing the absorption of Na^+. As a result, more fluid is secreted from the blood into the lumen than is subsequently transferred back into the blood. The excess fluid is lost in the feces, producing the watery stool characteristic of diarrhea. More important, the loss of fluids and electrolytes that came from the blood leads to dehydration. The subsequent reduction in effective circulating plasma volume can cause death in a matter of days or even hours, depending on the severity of the fluid loss.

In the middle of the past century, physicians learned that replacing the lost fluids and electrolytes intravenously saves the lives of most patients with diarrhea. In many parts of the world, however, adequate facilities, equipment, and personnel are not available to administer intravenous rehydration therapy. Consequently, millions of children still succumbed to diarrhea annually.

In 1966 researchers learned that SGLT is not affected by diarrhea-causing microbes. This discovery led to the development of ORT. When both Na^+ and glucose are present in the lumen, this symporter transports them both from the lumen into the villus epithelial cells, from which they enter the blood. Because H_2O osmotically follows the absorbed Na^+, ingestion of a glucose and salt solution promotes the uptake of fluid into the blood from the intestinal tract without the need for intravenous replacement of fluids.

The first proof of ORT's life-saving ability in the field came in 1971 when several million refugees poured into India from war-ravaged Bangladesh. Of the thousands of refugees who fell victim to cholera and other diarrheal diseases, more than 30% died because of the scarcity of sterile fluids and needles for intravenous therapy. In one refugee camp, however, under the supervision of a group of scientists who had been experimenting with ORT, families were taught to administer ORT to people with diarrhea, most of whom were small children. The scarce intravenous solutions were reserved for those unable to drink. Death from diarrhea was reduced to 3% in this camp, compared with a 10-fold higher mortality among refugees elsewhere.

Based on this evidence, the World Health Organization (WHO) started aggressively promoting ORT. Packets of dry ingredients for ORT are now manufactured locally in more than 60 countries. The WHO estimates that about 30% of the world's children who contract diarrhea are treated with the prepackaged mixture or home-prepared versions. In the United States, commercially prepared oral solutions are widely available at pharmacies and supermarkets. An estimated 1 million children worldwide are saved annually as a result of ORT.

---

indigestible substances in the diet provide bulk and help maintain regular bowel movements by contributing to the volume of the colonic contents.

Haustral contractions slowly shuffle the colonic contents back and forth.

The outer longitudinal smooth muscle layer does not completely surround the large intestine. Instead, it consists only of three separate, conspicuous, longitudinal bands of muscle, the **taeniae coli**, which run the length of the large intestine. These taeniae coli are shorter than the underlying circular smooth muscle and mucosal layers would be if these layers were stretched out flat. Because of this, the underlying layers are gathered into pouches or sacs called **haustra**, much as the material of a full skirt is gathered at the narrower waistband. The haustra are not merely passive permanent gathers, however; they actively change location as a result of contraction of the circular smooth muscle layer.

Most of the time, movements of the large intestine are slow and nonpropulsive, as is appropriate for its absorptive and storage functions. The colon's main motility is **haustral contrac-**

tions initiated by the BER of colonic smooth muscle cells. These contractions, which throw the large intestine into haustra, are oscillating ringlike contractions similar to small-intestine segmentations but occur less frequently. Thirty minutes may elapse between haustral contractions, whereas segmentation contractions in the small intestine occur at rates of between 9 and 12 per minute. The location of the haustral sacs gradually changes as a relaxed segment that has formed a sac slowly contracts while a previously contracted area simultaneously relaxes to form a new sac. These movements are nonpropulsive; they slowly shuffle the contents in a back-and-forth mixing movement that exposes the colonic contents to the absorptive mucosa. Haustral contractions are largely controlled by locally mediated reflexes involving the intrinsic plexuses.

Mass movements propel feces long distances.

Three to four times a day, generally after meals, a marked increase in motility takes place during which large segments of the ascending and transverse colon contract simultaneously, driving the feces one third to three fourths of the length of the colon in a few seconds. These massive contractions, appropriately called **mass movements**, drive the colonic contents into the distal part of the large intestine, where material is stored until defecation occurs.

When food enters the stomach, mass movements are triggered in the colon primarily by the **gastrocolic reflex**, which is mediated from the stomach to the colon by gastrin and by parasympathetic innervation. In many people, this reflex is most evident after the first meal of the day and is often followed by the urge to defecate. Thus, when a new meal enters the digestive tract, reflexes are initiated to move the existing contents farther along the tract to make way for the incoming food. The gastroileal reflex moves the remaining small-intestine contents into the large intestine, and the gastrocolic reflex pushes the colonic contents into the rectum, triggering the defecation reflex.

Feces are eliminated by the defecation reflex.

When mass movements move feces into the rectum, the resultant distension of the rectum stimulates stretch receptors in the rectal wall, initiating the **defecation reflex**. This reflex causes the **internal anal sphincter** (which is smooth muscle) to relax and the rectum and sigmoid colon to contract more vigorously. If the **external anal sphincter** (which is skeletal muscle) is also relaxed, defecation occurs. Being skeletal muscle, the external anal sphincter is under voluntary control. The initial rectal distension is accompanied by the conscious urge to defecate. If circumstances are unfavorable for defecation, voluntary tightening of the external anal sphincter can prevent defecation despite the defecation reflex. If defecation is delayed, the distended rectal wall gradually relaxes, and the urge to defecate subsides until the next mass movement propels more feces into the rectum, again distending the rectum and triggering the defecation reflex. During periods of inactivity, both anal sphincters remain contracted to ensure fecal continence.

When defecation does occur, it is usually assisted by voluntary straining movements that involve simultaneous contraction of the abdominal muscles and a forcible expiration against a closed glottis. This maneuver greatly increases intra-abdominal pressure, which helps expel the feces.

Constipation occurs when the feces become too dry.

If defecation is delayed too long, **constipation** may result. When colonic contents are retained for longer periods than normal, more than the usual amount of H_2O is absorbed from the feces, so they become hard and dry. Normal variations in frequency of defecation among individuals range from after every meal to up to once a week. When the frequency is delayed beyond what is normal for a particular person, constipation and its attendant symptoms may occur. These symptoms include abdominal discomfort, dull headache, loss of appetite sometimes accompanied by nausea, and mental depression. Contrary to popular belief, these symptoms are not caused by toxins absorbed from the retained fecal material. Although bacterial metabolism produces some potentially toxic substances in the colon, these substances normally pass through the portal system and are removed by the liver before they can reach the systemic circulation. Instead, the symptoms associated with constipation are caused by prolonged distension of the large intestine, particularly the rectum; the symptoms promptly disappear after relief from distension.

Possible causes for delayed defecation that might lead to constipation include (1) ignoring the urge to defecate; (2) decreased colon motility accompanying aging, emotion, or a low-bulk diet; (3) obstruction of fecal movement in the large bowel caused by a local tumor or colonic spasm; and (4) impairment of the defecation reflex, such as through injury of the nerve pathways involved. *Clinical Note* If hardened fecal material becomes lodged in the appendix, it may obstruct normal circulation and mucus secretion in this narrow, blind-ended appendage. This blockage leads to **appendicitis**. The inflamed appendix often becomes swollen and filled with pus, and the tissue may die as a result of local circulatory interference. If not surgically removed, the diseased appendix may rupture, spewing its infectious contents into the abdominal cavity.

Intestinal gases are absorbed or expelled.

Occasionally, instead of feces passing from the anus, intestinal gas, or **flatus**, passes out. This gas is derived from two sources: (1) swallowed air (as much as 500 mL of air may be swallowed during a meal) and (2) gas produced by bacterial fermentation in the colon. The presence of gas percolating through the luminal contents gives rise to gurgling sounds. Burping removes most of the swallowed air from the stomach, but some passes on into the intestine. Usually, very little gas is present in the small intestine because the gas is either quickly absorbed or passes on into the colon. Most gas in the colon is the result of bacterial activity, with the quantity and nature of the gas depending on the type of food eaten and the characteristics of the colonic bacteria. Much of the gas is absorbed through the intestinal mucosa. The rest is expelled through the anus.

To selectively expel gas when feces are also present in the rectum, the person voluntarily contracts the abdominal mus-

cles and external anal sphincter at the same time. When abdominal contraction raises the pressure against the contracted anal sphincter sufficiently, the pressure gradient forces air out at a high velocity through a slitlike anal opening that is too narrow for solid feces to escape through. This passage of air at high velocity causes the edges of the anal opening to vibrate, giving rise to the characteristic low-pitched sound accompanying passage of gas.

Large-intestine secretion is entirely protective.

Colonic secretion consists of an alkaline ($NaHCO_3$) mucus solution, whose function is to protect the large-intestine mucosa from mechanical and chemical injury. The mucus provides lubrication to facilitate passage of feces, whereas the $NaHCO_3$ neutralizes irritating acids produced by local bacterial fermentation. Secretion increases in response to mechanical and chemical stimulation of the colonic mucosa mediated by short reflexes and parasympathetic innervation.

The large intestine does not secrete any digestive enzymes. Digestion of food constituents that humans have the ability to digest is completed within the small intestine. Of the ingested energy-rich nutrients, only indigestible fiber reaches the colon. However, the colon contains an abundance of bacteria that break down undigested fiber for their own and our use.

The colon contains myriad beneficial bacteria.

Because of slow colonic movement, bacteria have time to grow and accumulate in the large intestine. Not all ingested bacteria are destroyed by antimicrobial agents earlier in the digestive tract; the surviving bacteria continue to thrive in the large intestine. About 10 times more bacteria live in the human colon than the human body has cells. About 2000 species of bacteria have been identified in the human large intestine. Although bacteria are by far the most numerous microscopic colonic residents, fungi and viruses of various sorts also live in the large intestine. The gut microbes weigh up to 4 pounds in total.

Microbes also inhabit other parts of our bodies in contact with the external environment, such as the skin, nose, mouth, pharynx, and vagina. Collectively, the community of microbes that coexist peacefully and usefully with their human host is called the **microbiota**, and the aggregate collection of genomes of our microbiota is known as the **microbiome**. Researchers have identified 8 million nonredundant microbial genes in the microbiome, a number 400 times greater than the 20,000 genes in our human genome (see p. 24). Each person has a unique microbiota. We normally harbor no microbes in the sterile uterus but are seeded with bacteria from our mother's birth canal during birth and acquire further resident microorganisms through variable exposure to people, animals, and objects in our environment after birth. The composition of our gut microbiota is further shaped by our behaviors, such as what we eat (different dietary habits support different populations of microorganisms) and the type and extent of antibiotics we use (antibiotics inadvertently destroy intestinal microbes).

We do not just provide a home for the microbiota. In a mutually beneficial relationship, the diverse mix of microbes that reside with us plays important roles in our well-being, as will be described shortly. Because we and our microbiota co-develop and are interdependent, some scientists boldly propose that we should broaden the concept of "self" to start thinking about our resident microbial community as part of us—that is, to view a person as a superorganism consisting of an assembly of human cells and many symbiotic microbial species with a vast combined inventory of genes.

The indigenous colonic microbes:

1. *Promote colonic motility.*

2. *Help maintain colonic mucosal integrity.*

3. *Aid immune function.* In interplay fashion, the immune system helps shape the composition of the colon microbiota, and these microorganisms in turn promote the normal development and activities of the immune system. Some bacteria also help rein in localized intestinal inflammation and help calm immune system overreactivity.

4. *Compete with potentially pathogenic microbes for nutrients and space* (see p. 441). By crowding out infectious microbes, the normal resident microbiota make it hard for these disease-causing microorganisms to establish themselves in the intestine. Taking an oral antibiotic for an infection elsewhere in the body can sometimes lead to an intestinal infection by disrupting the normal protective gut microbial community.

5. *Help digest food and make nutritional contributions.* Gut microbes increase digestive efficiency by producing enzymes that break down dietary fiber that human digestive enzymes cannot hydrolyze. Colonic bacteria ferment fiber primarily to short-chain fatty acids, with gases being produced as a by-product. This metabolic processing not only nourishes the microbes but also provides their host with an additional source of nutrition that is otherwise lost in the feces. Being fat soluble, some of the fatty acids are absorbed by simple diffusion by the colonic mucosa, accounting on average for 5% to 10% of daily caloric intake. Gut microbes make other nutritional contributions in addition to digesting fiber. For example, bacteria synthesize vitamin K, vitamin B_{12}, and folate, which can be absorbed by the colon and serve as endogenous sources of these vitamins. Furthermore, the microbiota releases products that raise colonic acidity, thereby promoting the absorption of calcium, magnesium, and zinc.

6. *Influence the brain and behavior.* A new "bowel-to-brain" concept is emerging from recent studies. Products encoded by the gut microbiome and released into the digestive tract lumen can enter the blood and have a far-reaching effect on the brain and elsewhere. Furthermore, bacterial products in the digestive tract lumen can stimulate the vagus nerve, which has an important role in signaling the brain from the digestive tract. For instance, gut bacteria have been shown to mediate behavior and mood in animal studies, and other investigations have hinted that an altered distribution of specific bacterial species in the colon might be linked with autism in humans.

Although a good balance of colonic microbes can confer health benefits, sometimes the landscape of the microbiota can contribute to health disorders, an example being obesity. When food is scarce, the gut microbes' supplemental caloric contribu-

tion by gleaning energy from fiber is valuable. On the other hand, when food is plentiful, extra energy obtained from bacterial processing of indigestible food may contribute to the development of obesity. Making matters worse, obese individuals compared to their leaner counterparts host a greater proportion of bacteria that are highly efficient at extracting energy from food.

Less than ideal balance in the gut microbiota has been implicated in a variety of other diseases, including diabetes, asthma, irritable bowel disease, colon cancer, atherosclerosis, and rheumatoid arthritis.

Scientists are still only at the beginning stages of studying the microbiome and its implications for human health and disease susceptibility. In 2007 the National Institutes of Health launched an ambitious **Human Microbiome Project (HMP)** to catalog all of the bacterial genes that make up the microbiome. By sampling bacteria that live in multiple body sites and comparing the differences among healthy and unhealthy people, the investigators hope to use their findings to ultimately manipulate the microbial inhabitants to improve health and to fight a variety of diseases. Unlike the human genome, which is essentially permanent in a given individual, the person's microbiome can readily be changed, a feature that holds promise for favorable intervention. For example, the composition of the gut microbiota can be altered through consumption of **probiotics** (foods or dietary supplements that contain live bacteria that confer a health benefit on the host) or **prebiotics** (nondigestible dietary supplements that stimulate growth and activity of beneficial resident colonic bacteria) or by instilling a desired mix of bacteria directly into the colon (such as by fecal transplant). Furthermore, a change in the types of foods a person predominantly eats (for example, shifting from an abundance of meat to an abundance of plant foods) can quickly shift the composition and activity of microbes in the gut. Through further studies in this hot area of science, dietary recommendations will continue to be forthcoming to improve the microbiome for the host's benefit.

The large intestine absorbs salt and water, converting the luminal contents into feces.

Some absorption takes place within the colon but not to the same extent as in the small intestine. Because the luminal surface of the colon is fairly smooth, it has considerably less absorptive surface area than the small intestine. Furthermore, the colon is not equipped with extensive specialized transport mechanisms like the small intestine. When excessive small-intestine motility delivers the contents to the colon before absorption of nutrients has been completed, the colon cannot absorb most of these materials and they are lost in diarrhea.

The colon normally absorbs salt and H_2O. Na^+ is actively absorbed, Cl^- follows passively down the electrical gradient, and H_2O follows osmotically. The colon absorbs token amounts of other electrolytes, as well as the short-chain fatty acids and vitamins produced by colonic bacteria.

Through absorption of salt and H_2O, a firm fecal mass is formed. Of the 500 mL of material entering the colon per day from the small intestine, the colon normally absorbs about 350 mL, leaving 150 g of feces to be eliminated from the body each day (see ▌Table 16-7, p. 609). This fecal material normally consists of 100 g of H_2O and 50 g of solid, including undigested cellulose, bilirubin, bacteria, and small amounts of salt. Thus, contrary to popular thinking, the digestive tract is not a major excretory passageway for eliminating wastes from the body. The main waste product excreted in the feces is bilirubin. The other fecal constituents are unabsorbed food residues and bacteria, which were never actually a part of the body. Bacteria account for nearly one third of the dry weight of feces.

16.8 Overview of the GI Hormones

Throughout our discussion of digestion, we have repeatedly mentioned different functions of the three major GI hormones: gastrin, secretin, and CCK. We now fit all of these functions together so that you can appreciate the overall adaptive importance of these interactions. Furthermore, we introduce a more recently identified GI hormone, *glucose-dependent insulinotropic peptide* (*GIP*). All of these hormones are small peptides that perform their functions by binding to G-protein-coupled receptors on the plasma membrane of their target cells, thereby activating second-messenger pathways that bring about the desired responses (see p. 117).

Gastrin Protein in the stomach stimulates the release of gastrin, which performs the following functions:

1. It acts in multiple ways to increase secretion of HCl and pepsinogen, two substances of primary importance in initiating digestion of the protein that promoted their secretion.

2. It enhances gastric motility, stimulates ileal motility, relaxes the ileocecal sphincter, and induces mass movements in the colon—all functions aimed at keeping the contents moving through the tract on arrival of a new meal.

3. It also is trophic to both the stomach mucosa and the small-intestine mucosa, helping maintain a well-developed, functionally viable digestive tract lining.

Predictably, gastrin secretion is inhibited by an accumulation of acid in the stomach and by the presence in the duodenal lumen of acid and other constituents that necessitate a delay in gastric secretion.

Secretin As the stomach empties into the duodenum, the presence of acid in the duodenum stimulates the release of secretin, which performs the following interrelated functions:

1. It inhibits gastric emptying to prevent further acid from entering the duodenum until the acid already present is neutralized.

2. It inhibits gastric secretion to reduce the amount of acid being produced.

3. It stimulates the pancreatic duct cells to produce a large volume of aqueous $NaHCO_3$ secretion, which is emptied into the duodenum to neutralize the acid. Neutralization of the acidic chyme in the duodenum helps prevent damage to the duodenal walls and provides a suitable environment for optimal functioning of the pancreatic digestive enzymes, which are inhibited by acid.

4. Secretin and CCK are both trophic to the exocrine pancreas.

CCK As chyme empties from the stomach, fat and other nutrients enter the duodenum. These nutrients—especially fat and, to a lesser extent, protein products—cause the release of CCK, which performs the following interrelated functions:

1. It inhibits gastric motility and secretion, thereby allowing adequate time for the nutrients already in the duodenum to be digested and absorbed.

2. It stimulates the pancreatic acinar cells to increase secretion of pancreatic enzymes, which continue the digestion of these nutrients in the duodenal lumen (this action is especially important for fat digestion because pancreatic lipase is the only enzyme that digests fat).

3. It causes contraction of the gallbladder and relaxation of the sphincter of Oddi so that bile is emptied into the duodenum to aid fat digestion and absorption. Bile salts' detergent action is particularly important in enabling pancreatic lipase to perform its digestive task. Again, the multiple effects of CCK are remarkably well adapted to dealing with the fat whose presence in the duodenum triggered this hormone's release.

4. Besides facilitating digestion of ingested nutrients, CCK is an important regulator of food intake. It plays a key role in satiety, the sensation of having had enough to eat (see p. 623).

GIP A more recently recognized hormone released by the duodenum, GIP, helps promote metabolic processing of the nutrients once they are absorbed. This hormone was originally named *gastric inhibitory peptide (GIP)* for its presumed role as an enterogastrone. It was believed to inhibit gastric motility and secretion, similar to secretin and CCK. Its contribution in this regard is now considered minimal. Instead, this hormone stimulates insulin release by the pancreas, so it is now called **glucose-dependent insulinotropic peptide** (again, **GIP**). This action is remarkably adaptive. As soon as the meal is absorbed, the body has to shift its metabolic gears to use and store the newly arriving nutrients. The metabolic activities of this absorptive phase are largely under the control of insulin (see pp. 688 and 690–692). Stimulated by the presence of a meal, especially glucose, in the digestive tract, GIP initiates the release of insulin in anticipation of absorption of the meal, in a feedforward fashion. Insulin is especially important in promoting the uptake and storage of glucose.

This overview of the multiple, integrated, adaptive functions of the GI hormones provides an excellent example of the remarkable efficiency of the human body.

Homeostasis: Chapter in Perspective

To maintain constancy in the internal environment, materials that are used up in the body (such as energy-rich nutrients and O_2) or uncontrollably lost from the body (such as evaporative H_2O loss from the airways or salt loss in sweat) must constantly be replaced by new supplies of these materials from the external environment. All these replacement supplies except O_2 are acquired through the digestive system. Fresh supplies of O_2 are transferred to the internal environment by the respiratory system, but all the nutrients, H_2O, and various electrolytes needed to maintain homeostasis are acquired through the digestive system. The large, complex food that is ingested is broken down by the digestive system into small absorbable units. These small, energy-rich nutrient molecules are transferred across the small-intestine epithelium into the blood for delivery to the cells to replace the nutrients constantly used for ATP production and for repair and growth of body tissues. Likewise, ingested H_2O, salt, and other electrolytes are absorbed by the intestine into the blood.

Unlike regulation in most body systems, regulation of digestive system activities is not aimed at maintaining homeostasis. The quantity of nutrients and H_2O ingested is subject to control, but the quantity of ingested materials absorbed by the digestive tract is not subject to control, with few exceptions. The hunger mechanism governs food intake to help maintain energy balance (see Chapter 17), and the thirst mechanism controls H_2O intake to help maintain H_2O balance (see Chapter 15). However, we often do not heed these control mechanisms, eating and drinking even when we are not hungry or thirsty. Once these materials are in the digestive tract, the digestive system does not vary its rate of nutrient, H_2O, or electrolyte uptake according to body needs (with the exception of iron and calcium); rather, it optimizes conditions for digesting and absorbing what is ingested. Truly, what you eat is what you get. The digestive system is subject to many regulatory processes, but these are not influenced by the nutritional or hydration state of the body. Instead, these control mechanisms are governed by the composition and volume of digestive tract contents so that the rate of motility and secretion of digestive juices are optimal for digestion and absorption of the ingested food.

If excess energy-rich nutrients are ingested and absorbed, the extra nutrients are placed in storage, such as in adipose tissue (fat), so that the blood level of nutrient molecules is kept at a constant level. Excess ingested H_2O and electrolytes are eliminated in the urine to homeostatically maintain the blood levels of these constituents.

Review Exercises Answers begin on p. A-46

Reviewing Terms and Facts

1. The extent of nutrient uptake from the digestive tract depends on the body's needs. *(True or false?)*

2. The stomach is relaxed during vomiting. *(True or false?)*

3. Acid cannot normally penetrate into or between the cells lining the stomach, which enables the stomach to contain acid without injuring itself. *(True or false?)*

4. Protein is continually lost from the body through digestive secretions and sloughed epithelial cells, which pass out in the feces. *(True or false?)*

5. Digested foodstuffs not absorbed by the small intestine are absorbed by the large intestine. *(True or false?)*

6. The endocrine pancreas secretes secretin and CCK. *(True or false?)*

7. A digestive reflex involving the autonomic nerves is known as a _____ reflex, whereas a reflex in which all elements of the reflex arc are located within the gut wall is known as a _____ reflex.

8. The salivary center, swallowing center, and vomiting center are all located in the _____.

9. When food is mechanically broken down and mixed with gastric secretions, the resultant thick, liquid mixture is known as _____.

10. The entire lining of the small intestine is replaced approximately every _____ days.

11. The two substances absorbed by specialized transport mechanisms located only in the terminal ileum are _____ and _____.

12. The most potent choleretic is _____.

13. Match the following:

1. prevents reentry of food into the mouth during swallowing	(a) closure of the pharyngo-esophageal sphincter
2. triggers the swallowing reflex	(b) elevation of the uvula
3. seals off the nasal passages during swallowing	(c) position of the tongue against the hard palate
4. prevents air from entering the esophagus during breathing	(d) closure of the gastro-esophageal sphincter
5. closes off the respiratory airways during swallowing	(e) bolus pushed to the rear of the mouth by the tongue
6. prevents gastric contents from backing up into the esophagus	(f) tight apposition of the vocal folds

14. Which of the following is *not* a function of saliva?

a. begins digestion of carbohydrate

b. facilitates absorption of glucose across the oral mucosa

c. facilitates speech

d. exerts an antibacterial effect

e. plays an important role in oral hygiene

15. Use the answer code on the right to identify the characteristics of the listed substances:

1. activates pepsinogen	(a) pepsin
2. inhibits amylase	(b) mucus
3. is essential for vitamin B_{12} absorption	(c) HCl
4. can act autocatalytically	(d) intrinsic factor
5. is a potent stimulant for acid secretion	(e) histamine
6. denatures protein	
7. begins protein digestion	
8. serves as a lubricant	
9. kills ingested bacteria	
10. is alkaline	
11. is deficient in pernicious anemia	
12. coats the gastric mucosa	

Understanding Concepts
(Answers at www.cengagebrain.com)

1. Describe the four basic digestive processes.

2. List the components of the digestive system. Describe the cross-sectional anatomy of the digestive tract.

3. What four general factors are involved in regulating digestive system function? What is the role of each?

4. Describe the types of motility in each component of the digestive tract. What factors control each type of motility?

5. State the composition of the digestive juice secreted by each component of the digestive system. Describe the factors that control each digestive secretion.

6. List the enzymes involved in digesting each category of foodstuff. Indicate the source and control of secretion of each of the enzymes.

7. Why are some digestive enzymes secreted in inactive form? How are they activated?

8. What absorption processes take place within each component of the digestive tract? What special adaptations of the small intestine enhance its absorptive capacity?

9. Describe the absorptive mechanisms for salt, water, carbohydrate, protein, and fat.

10. What are the contributions of the accessory digestive organs? What are the nondigestive functions of the liver?

11. Summarize the functions of each of the three major GI hormones.

12. What waste product is excreted in the feces?

13. How is vomiting accomplished? What are the causes and consequences of vomiting, diarrhea, and constipation?

14. Describe the process of mucosal turnover in the stomach and small intestine.

Solving Quantitative Exercises

1. Suppose a lipid droplet in the gut is essentially a sphere with a diameter of 1 cm.

  a. What is the surface area–to–volume ratio of the droplet? (*Hint:* The area of a sphere is $4\pi r^2$, and the volume is $4/3\pi r^3$.)

  b. Now, suppose that this sphere were emulsified into 100 essentially equal-sized droplets. What is the average surface area–to–volume ratio of each droplet?

  c. How much greater is the total surface area of these 100 droplets compared to the original single droplet?

  d. How much did the total volume change as a result of emulsification?

Applying Clinical Reasoning

Thomas W. experiences a sharp pain in his upper right abdomen after eating a high-fat meal. Also, he has noted that his feces are grayish-white instead of brown. What is the most likely cause of his symptoms? Explain why each of these symptoms occurs with this condition.

Thinking at a Higher Level

1. Why do patients who have had a large part of their stomachs removed for treatment of stomach cancer or severe peptic ulcer disease have to eat small quantities of food frequently instead of consuming three meals a day?

2. The number of immune cells in the *gut-associated lymphoid tissue (GALT)* housed in the mucosa is estimated to be equal to the total number of these defense cells in the rest of the body. Speculate on the adaptive significance of this extensive defense capability of the digestive system.

3. How would defecation be accomplished in a patient paralyzed from the waist down by a lower spinal-cord injury?

4. After bilirubin is extracted from the blood by the liver, it is conjugated (combined) with glucuronic acid by the enzyme *glucuronyl transferase* within the liver. Only when conjugated can bilirubin be actively excreted into the bile. For the first few days of life, the liver does not make adequate quantities of glucuronyl transferase. Explain how this transient enzyme deficiency leads to the common condition of jaundice in newborns.

5. Explain why removal of either the stomach or the terminal ileum leads to pernicious anemia.

17

Energy Balance and Temperature Regulation

Examples of energy in and energy out. To maintain energy balance and body weight, energy input (food intake) must equal energy output, which encompasses external work (such as cycling) and internal work (such as pumping blood). The hypothalamus governs food intake to maintain energy balance. The young adults shown here are enjoying El Capitan State Beach in California.

Homeostasis Highlights

Food intake is essential to power cell activities. For body weight to remain constant, the caloric value of food (energy input) must equal total energy needs (energy output or expenditure). **Energy balance** and thus body weight are maintained primarily by controlling food intake.

Energy expenditure generates heat, which is important in **temperature regulation**. Humans, usually in environments cooler than their bodies, must constantly generate heat to maintain their body temperatures. Also, they must have mechanisms to cool the body if it gains too much heat from heat-generating skeletal muscle activity or from a hot external environment. Body temperature must be regulated because the rate of cellular chemical reactions depends on temperature and because overheating damages cell proteins.

The hypothalamus is the major integrating center for maintaining both energy balance and body temperature.

17.1 Energy Balance

Each cell in the body needs energy to perform the functions essential for the cell's survival (such as active transport and cellular repair) and to carry out its specialized contributions toward maintaining homeostasis (such as gland secretion or muscle contraction). All energy used by cells is ultimately provided by food intake.

Most food energy is ultimately converted into heat in the body.

According to the **first law of thermodynamics**, energy can be neither created nor destroyed. Therefore, energy is subject to the same kind of input–output balance as are the chemical components of the body, such as water and salt (see p. 536).

Energy Input and Output The energy in ingested food constitutes *energy input* to the body. Chemical energy locked in the bonds that hold the atoms together in nutrient molecules is released when these molecules are broken down in the body. Cells capture a portion of this nutrient energy in the high-energy phosphate bonds of adenosine triphosphate (ATP; see pp. 34 and A-15). Energy harvested from biochemical processing of ingested nutrients is either used immediately to perform biological work or stored in the body for later use as needed during periods when food is not being digested and absorbed.

Energy output or *expenditure* by the body falls into two categories: **external work** and **internal work** (❚ Figure 17-1). **External work** is the energy expended when skeletal muscles contract to move external objects or to move the body in relation to the environment. **Internal work** constitutes all other forms of biological energy expenditure that do not accomplish mechanical work outside the body. Internal work encompasses two types of energy-dependent activities: (1) skeletal muscle activity used for purposes other than external work, such as the contractions associated with postural maintenance and shivering, and (2) all energy-expending activities that must go on all the time just to sustain life. The latter include the work of pumping blood and breathing, the energy required for active transport of critical materials across plasma membranes, and the energy used during synthetic reactions essential for the maintenance, repair, and growth of cellular structures—in short, the "metabolic cost of living."

Conversion of Nutrient Energy to Heat Not all energy in nutrient molecules can be harnessed to perform biological work. Energy cannot be created or destroyed, but it can be converted from one form to another. The energy in nutrient molecules not used to energize work is transformed into **thermal energy**, or **heat**. During biochemical processing, only about 50% of the energy in nutrient molecules is transferred to ATP; the other 50% of nutrient energy is immediately lost as heat. When the cells expend ATP, another 25% of the energy derived from ingested food becomes heat. Because the body is not a heat engine, it cannot convert heat into work. Therefore, not more than 25% of nutrient energy is available for work, either external or internal. The remaining 75% is lost as heat.

Furthermore, of the energy actually captured for use by the body, almost all expended energy eventually becomes heat. To exemplify, energy expended by the heart to pump blood is gradually changed into heat by friction as blood flows through the vessels. Likewise, energy used in synthesizing structural protein eventually appears as heat when that protein is degraded during the normal course of turnover of bodily constituents. Even in performing external work, skeletal muscles convert chemical energy into mechanical energy inefficiently; as much as 75% of the expended energy is lost as heat. Thus, all energy liberated from ingested food that is not directly used for moving external objects or stored in fat (adipose tissue) deposits (or, in the case of growth, as protein) eventually becomes body heat. This heat is not entirely wasted energy, however, because much of it is used to maintain body temperature.

The metabolic rate is the rate of energy use.

The rate at which energy is expended by the body during both external and internal work is known as the **metabolic rate**:

$$\text{Metabolic rate} = \text{energy expenditure/unit of time}$$

Because most of the body's energy expenditure eventually appears as heat, the metabolic rate is normally expressed in terms of the rate of heat production in kilocalories per hour. The basic unit of heat energy is the **calorie,** which is the amount of heat required to raise the temperature of 1 g of H_2O by 1°C. This unit is too small to be convenient when discussing the human body because of the magnitude of heat involved, so the **kilocalorie** or **Calorie,** which is equivalent to 1000 calories, is used. When nutritionists speak of "calories" in quantifying the energy content of various foods, they are actually referring to kilocalories or Calories. Four kilocalories of heat energy are released when 1 g of glucose is oxidized or "burned," whether the oxidation takes place inside or outside the body.

❚ Figure 17-1 **Energy input and output.**

Conditions for Measuring the Basal Metabolic Rate

The metabolic rate and, consequently, the rate of heat production vary depending on several factors, such as exercise, anxiety, shivering, and food intake. Increased skeletal muscle activity is the factor that can increase metabolic rate to the greatest extent. Even slight increases in muscle tone notably elevate the metabolic rate, and various levels of physical activity markedly alter energy expenditure and heat production (▌Table 17-1). For this reason, a person's metabolic rate is determined under standardized basal conditions established to control as many variables that can alter metabolic rate as possible. In this way, the metabolic activity necessary to maintain the basic body functions at rest can be determined. The **basal metabolic rate (BMR)** is a reflection of the body's "idling speed," or the minimal waking rate of internal energy expenditure. The BMR is measured under the following specified conditions:

1. The person should be at physical rest, having refrained from exercise for at least 30 minutes to eliminate any contribution of muscular exertion to heat production.

2. The person should be at mental rest to minimize skeletal muscle tone (people "tense up" when they are nervous) and to prevent a rise in epinephrine, a hormone secreted in response to stress that increases metabolic rate.

3. The measurement should be performed at a comfortable room temperature so that the person does not shiver. Shivering can markedly increase heat production.

▌**TABLE 17-1** Rate of Energy Expenditure for a 70-kg (154-Pound) Person During Different Activities

Energy	Expenditure Activity (kcal/hr)
Sleeping	65
Awake, lying still	77
Sitting at rest	100
Standing relaxed	105
Getting dressed	118
Typing	140
Walking slowly on level ground (2.6 mi/hr)	200
Carpentry or painting a house	240
Sexual intercourse	280
Bicycling on level ground (5.5 mi/hr)	304
Shoveling snow or sawing wood	480
Swimming	500
Jogging (5.3 mi/hr)	570
Rowing (20 strokes/min)	828
Walking up stairs	1100

4. The subject should not have eaten any food within 12 hours before the BMR determination to avoid **diet-induced thermogenesis** (*thermo* means "heat"; *genesis* means "production"), or the obligatory, short-lived (less than 12-hour) rise in metabolic rate that occurs as a result of the increased metabolic activity associated with processing and storing ingested nutrients.

Methods of Measuring the Basal Metabolic Rate The rate of heat production in BMR determinations can be measured directly or indirectly. To directly measure heat production, the person sits in an insulated chamber with water circulating through the walls. The difference in the temperature of the water entering and leaving the chamber reflects the amount of heat liberated by the person and picked up by the water as it passes through the chamber. A more convenient method of indirectly determining the rate of heat production requires only measuring the person's O_2 uptake per unit of time, which is a simple task using minimal equipment. Recall that

$$\text{Food} + O_2 \rightarrow CO_2 + H_2O + \text{energy (mostly transformed into heat)}$$
Accordingly, a direct relationship exists between the volume of O_2 used and the quantity of heat produced. This relationship also depends on the type of food being oxidized. Although carbohydrates, proteins, and fats require different amounts of O_2 for their oxidation and yield different amounts of kilocalories when oxidized, an average estimate can be made of the quantity of heat produced per liter of O_2 consumed on a typical mixed American diet. This approximate value, known as the **energy equivalent of O_2**, is 4.8 kcal of energy liberated per liter of O_2 consumed. Using this method, the metabolic rate of a person consuming 15 liters/hour of O_2 can be estimated as follows:

$$
\begin{aligned}
15 \text{ liters/hr} &= O_2 \text{ consumption} \\
\times\ 4.8 \text{ kilocalories/liter} &= \text{energy equivalent of } O_2 \\
\hline
72 \text{ kilocalories/hr} &= \text{estimated metabolic rate}
\end{aligned}
$$

Once the rate of heat production is determined under the prescribed basal conditions, it must be compared with normal values for people of the same sex, age, height, and weight because these factors all affect the basal rate of energy expenditure. For example, a large man has a higher rate of heat production than a smaller man, but expressed in terms of total surface area (which is a reflection of height and weight), the output in kilocalories per hour per square meter of surface area is normally about the same.

Factors Influencing the Basal Metabolic Rate Thyroid hormone is the primary but not sole determinant of the rate of basal metabolism. As thyroid hormone increases, the BMR increases correspondingly. As mentioned, epinephrine also increases the BMR.

Contrary to what might be expected, the BMR is not the body's lowest metabolic rate. The rate of energy expenditure during sleep is 10% to 15% lower than the BMR, presumably because of the more complete muscle relaxation that occurs during the paradoxical stage of sleep (see p. 169).

Energy input must equal energy output to maintain a neutral energy balance.

Because energy cannot be created or destroyed, energy input must equal energy output, as follows:

$$\text{Energy input} = \text{energy output}$$

$$\begin{matrix} \text{Energy in food} = & \text{external} & + & \text{internal heat} & \pm & \text{stored} \\ \text{consumed} & \text{work} & & \text{production} & & \text{energy} \end{matrix}$$

There are three possible states of energy balance:

- *Neutral energy balance.* If the amount of energy in food intake exactly equals the amount of energy expended in performing external work plus the basal internal energy expenditure that eventually appears as body heat, then energy input and output are exactly in balance, and body weight remains constant.

- *Positive energy balance.* If the amount of energy in food intake is greater than the amount of energy expended, the extra energy taken in but not used is stored in the body, primarily as adipose tissue, so body weight increases.

- *Negative energy balance.* If the energy derived from food intake is less than the body's immediate energy requirements, the body must use stored energy to supply energy needs, and body weight decreases accordingly.

For a person to maintain a constant body weight (with the exception of minor fluctuations caused by changes in H_2O content), energy acquired through food intake must equal energy expenditure by the body. Because the average adult maintains a fairly constant weight over long periods, this implies that precise homeostatic mechanisms exist to maintain a long-term balance between energy intake and energy expenditure. Theoretically, total body energy content could be maintained at a constant level by regulating the magnitude of food intake, physical activity, or internal work and heat production. Control of food intake to match changing metabolic expenditures is the major means of maintaining a neutral energy balance. The level of physical activity is principally under voluntary control, and mechanisms that alter the degree of internal work and heat production are aimed primarily at regulating body temperature rather than total energy balance.

However, after several weeks of eating less or more than desired, small counteracting changes in metabolism may occur. For example, a compensatory increase in the body's efficiency of energy use in response to underfeeding partially explains why some dieters become stuck at a plateau after having lost the first 10 or so pounds of weight fairly easily. Similarly, a compensatory reduction in the efficiency of energy use in response to overfeeding accounts in part for the difficulty experienced by very thin people who are deliberately trying to gain weight. Despite these modest compensatory changes in metabolism, regulation of food intake is the most important factor in long-term maintenance of energy balance and body weight.

Food intake is controlled primarily by the hypothalamus.

Even though food intake is adjusted to balance changing energy expenditures over time, there are no calorie receptors per se to monitor energy input, energy output, or total body energy con-tent. Instead, various blood-borne chemical factors that signal the body's nutritional state, such as how much fat is stored or the feeding status, are important in regulating food intake. Control of food intake does not depend on changes in a single signal but is determined by the integration of many inputs that provide information about the body's energy status, both the levels of stored and circulating nutrients. Multiple molecular signals together ensure that feeding behavior is synchronized with the body's immediate and long-term energy needs. Some information is used for short-term control of meal size and frequency. Even so, over a 24-hour period the energy in ingested food rarely matches energy expenditure for that day. The correlation between total caloric intake and total energy output is excellent, however, over long periods. As a result, the total energy content of the body—and, consequently, body weight—remains relatively constant long term.

Role of the Arcuate Nucleus: NPY and Melanocortins

The **arcuate nucleus** of the hypothalamus plays a central role in both long-term control of energy balance and body weight and short-term control of food intake from meal to meal. The arcuate nucleus is an arc-shaped collection of neurons located adjacent to the floor of the third ventricle. Multiple, highly integrated, redundant pathways crisscross into and out of the arcuate nucleus, indicative of the complex systems involved in feeding and satiety. **Feeding**, or **appetite**, **signals** give rise to the sensation of **hunger**, driving us to eat. By contrast, **satiety** is the feeling of being full. **Satiety signals** tell us when we have had enough and suppress the desire to eat.

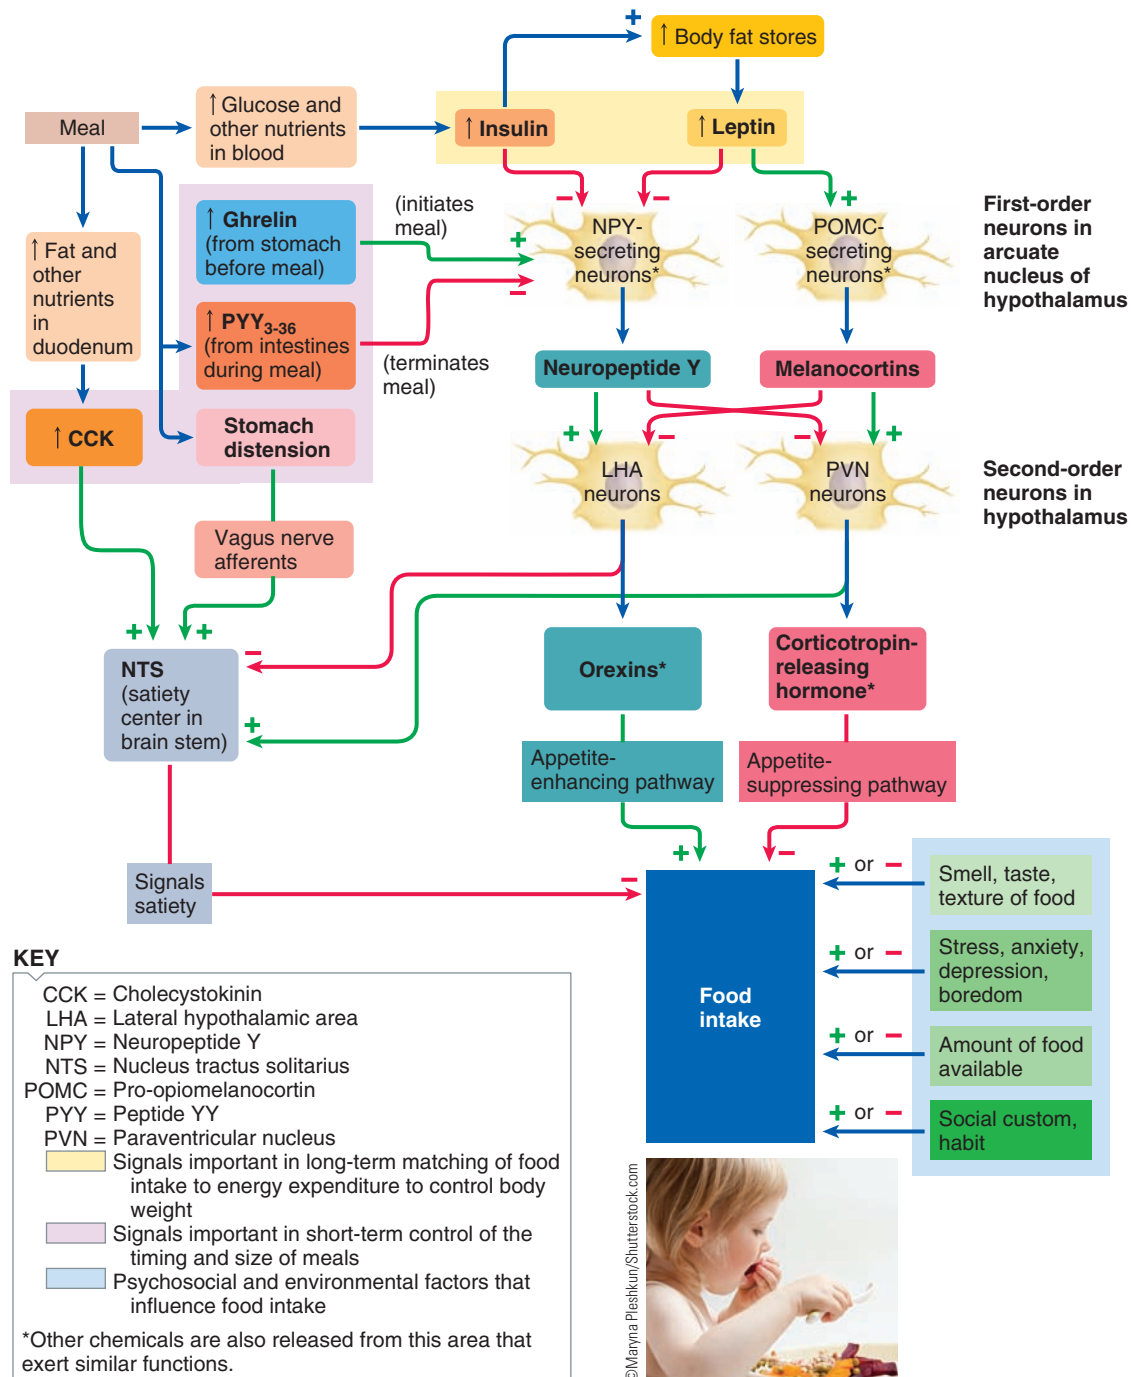
The arcuate nucleus has two subsets of neurons that function in an opposing manner. One subset releases *neuropeptide Y,* and the other releases *melanocortins* derived from proopiomelanocortin (POMC), a precursor molecule that can be cleaved in different ways to produce several hormone products (see p. 648).[1] **Neuropeptide Y (NPY),** one of the most potent appetite stimulators ever found, leads to increased food intake, thus promoting weight gain. **Melanocortins,** a group of hormones traditionally known to be important in varying the skin color for the purpose of camouflage in some species, have been shown to exert an unexpected role in energy homeostasis in humans. Melanocortins, most notably *α-melanocyte-stimulating hormone (α-MSH)* from the hypothalamus, suppress appetite, thus leading to reduced food intake and weight loss. Melanocortins do not play a role in determining inherited skin coloration in humans, but α-MSH produced in the skin in response to ultraviolet light from the sun acts locally on melanin (pigment)-producing cells to cause tanning (see p. 441). Melanocortins' major importance in our species, however, is the role of hypothalamic α-MSH in toning down appetite.

NPY and melanocortins are not the final effectors in appetite control. These arcuate-nucleus chemical messengers influence the release of neuropeptides in other parts of the brain that exert more direct control over food intake. Scientists are trying

---

[1]The two subsets of neurons in the arcuate nucleus are the **NPY/AgRP** population and the **POMC/CART** population. *Agouti-related protein (AgRP),* like NPY, stimulates appetite, and *cocaine- and amphetamine-related transcript (CART),* like melanocortins, suppresses appetite. For simplicity's sake, we discuss only the roles of NPY and melanocortins as representative examples.

to unravel the other factors that act upstream and downstream from NPY and melanocortins to regulate appetite. Based on current evidence, the following regulatory inputs to the arcuate nucleus and beyond are important in the long-term maintenance of energy balance and the short-term control of food intake at meals (❚ Figure 17-2).

Regulatory Inputs to the Arcuate Nucleus in Long-Term Maintenance of Energy Balance: Leptin and Insulin Scientists' notion of fat cells (**adipocytes**) in adipose tissue as merely storage space for triglyceride fat underwent a dramatic change late in the past century with the discovery of their active role in energy homeostasis. Adipose tissue secretes several hormones, collectively termed **adipokines,** that play important roles in energy balance and metabolism. Thus, adipose tissue is now considered an endocrine gland and is the largest hormone-secreting organ in the body. Some adipokines are released only from adipocytes, an example being *leptin,* which plays an important role in energy balance. Some, like *tumor necrosis factor (TNF)* and *interleukin 6 (IL-6),* are released


❚ Figure 17-2 **Factors that influence food intake.**

FIGURE FOCUS: *Follow the pathways by which increased body fat stores lead to decreased food intake.*

from adipocytes and from immune cells such as macrophages (large stationary phagocytes; see p. 411) that reside in abundance in excessive adipose tissue. These inflammation-causing adipokines contribute to inflammation in obese fat stores and to chronic low-grade systemic inflammation that alters glucose metabolism, among other detrimental metabolic effects. This newly identified link between obesity-induced inflammation and its metabolic consequences is termed **metaflammation**. Some adipokines, like *visfatin,* are released only from **visceral fat,** the deep, "bad" fat that surrounds the abdominal organs. Visceral fat is more likely to be chronically inflamed and is associated with increased heart disease and other disorders, in contrast to the more superficial and less harmful **subcutaneous fat** that is deposited under the skin. (Subcutaneous fat is the fat you can pinch.) Some, like *adiponectin,* are "good" adipokines. Adiponectin increases sensitivity to insulin (which helps protect against Type 2, or adult-onset, diabetes mellitus; see p. 696); decreases body weight; exerts anti-inflammatory actions; and promotes cell survival via its anti-apoptosis effects. Unfortunately, obesity suppresses adiponectin secretion. By contrast, some, like *resistin,* are "bad" adipokines. Resistin, which is released primarily in obesity, leads to insulin resistance (thus increasing the risk of developing Type 2 diabetes).

One of the most important adipokines is **leptin,** a hormone essential for normal body-weight regulation (*leptin* means "thin"). The amount of leptin in the blood is an excellent indicator of the total amount of triglyceride fat stored in adipose tissue: The larger the fat stores, the more leptin released into the blood. This blood-borne signal, discovered in the mid-1990s, was the first molecular satiety signal identified. This finding touched off a flurry of research responsible for greatly expanding our knowledge in recent years of the complex interplay of chemical signals that regulate food intake and body size.

The arcuate nucleus is the major site for leptin action. Acting in negative-feedback fashion, increased leptin from burgeoning fat stores serves as a "trim-down" signal. Leptin suppresses appetite, thus decreasing food consumption and promoting weight loss, by inhibiting hypothalamic output of appetite-stimulating NPY and stimulating output of appetite-suppressing melanocortins. Conversely, a decrease in fat stores and the resultant decline in leptin secretion bring about an increase in appetite, leading to weight gain. The leptin signal is generally considered the dominant factor responsible for the long-term matching of food intake to energy expenditure so that total body energy content remains balanced and body weight remains constant.

Another blood-borne signal besides leptin that plays an important role in long-term control of body weight is **insulin**. Insulin, a hormone secreted by the pancreas in response to a rise in the concentration of glucose and other nutrients in the blood following a meal, stimulates cellular uptake, use, and storage of these nutrients (see p. 690). Thus, the increase in insulin secretion that accompanies nutrient abundance, use, and storage appropriately inhibits the NPY-secreting cells of the arcuate nucleus, thus suppressing further food intake.

Beyond the Arcuate Nucleus: Orexins and Others
Two hypothalamic areas are richly supplied by axons from the NPY- and melanocortin-secreting neurons of the arcuate nucleus. These second-order neuronal areas involved in energy balance and food intake are the **lateral hypothalamic area (LHA)** and **paraventricular nucleus (PVN)**. The LHA and PVN release chemical messengers in response to input from the arcuate nucleus neurons. These messengers act downstream from the NPY and melanocortin signals to regulate appetite. The LHA produces **orexins** (ore-EKS-ins), which are potent stimulators of food intake (*orexis* means "appetite"). NPY stimulates and melanocortins inhibit the release of appetite-enhancing orexins. By contrast, the PVN releases chemical messengers, for example, **corticotropin-releasing hormone**, that decrease appetite and food intake. (As its name implies, corticotropin-releasing hormone is better known for its role as a hormone; see p. 675.) Melanocortins stimulate and NPY inhibits the release of these appetite-suppressing chemicals.

In addition to the importance of leptin, insulin, and perhaps other so-called **adiposity signals** (signals related to the size of fat stores in adipose tissue) and their downstream mediators in the long-term control of body weight, other factors play a role in controlling the timing and size of meals.

Short-Term Eating Behavior: Ghrelin and PYY$_{3-36}$ Secretion
Two blood-borne peptides secreted by the digestive tract that are important in regulating how often and how much we eat in a given day are *ghrelin* and *peptide YY$_{3-36}$* (*PYY$_{3-36}$*), which signify hunger and fullness, respectively. **Ghrelin** (GRELL-in), the so-called hunger hormone, is a potent appetite stimulator produced by the stomach and regulated by the feeding status (*ghrelin* is the Hindu word for "growth"). Secretion of this mealtime stimulator peaks before meals and makes people feel like eating, and then it falls once food is eaten. Ghrelin stimulates appetite by activating the hypothalamic NPY-secreting neurons.

PYY$_{3-36}$ is a counterpart of ghrelin. The secretion of PYY$_{3-36}$, which is produced by the small and large intestines, is at its lowest level before a meal but rises during meals and signals satiety. This peptide acts by inhibiting the appetite-stimulating NPY-secreting neurons in the arcuate nucleus. By thwarting appetite, PYY$_{3-36}$ is an important mealtime terminator.

The following other factors are also involved in signaling where the body is on the hunger–satiety scale.

Satiety Center
In addition to the key role the hypothalamus plays in maintaining energy balance, a **satiety center** in the brain stem known as the **nucleus tractus solitarius (NTS)** processes signals important in the feeling of being full and thus contributes to short-term control of meals. Not only does the NTS receive input from the higher hypothalamic neurons involved in energy homeostasis, but it also receives afferent inputs from the digestive tract (for example, afferent input indicating the extent of stomach distension) and elsewhere that signal satiety. We now turn to cholecystokinin, one of the most important of these satiety signals.

Cholecystokinin as a Satiety Signal
Cholecystokinin (CCK), one of the gastrointestinal hormones released from the duodenal mucosa during digestion of a meal, is an important

satiety signal for regulating meal size. CCK is secreted in response to the presence of nutrients in the small intestine. Through multiple effects on the digestive system, CCK facilitates digestion and absorption of these nutrients (see p. 615). It is appropriate that this blood-borne signal, whose rate of secretion is correlated with the amount of nutrients ingested, contributes to the sense of being filled after a meal has been consumed but before it has been digested and absorbed. We feel satisfied when adequate food to replenish the stores is in the digestive tract even though the body's energy stores are still low. This explains why we stop eating before the ingested food is made available to meet the body's energy needs. Other related, more recently discovered gut peptides released in response to a meal that serve as satiety signals include **glucagon-like peptide 1 (GLP-1)** and **oxyntomodulin.**

❙Table 17-2 summarizes the effect of involuntary regulatory signals on appetite.

Psychosocial and Environmental Influences Thus far, we have described involuntary signals that automatically occur to control food intake. However, as with water intake, people's eating habits are also shaped by psychological, social, and environmental factors. Often our decision to eat or stop eating is not determined merely by whether we are hungry or full, respectively. Frequently, we eat out of habit (eating three meals a day on schedule no matter what our status on the hunger–satiety continuum) or because of social custom (food often plays a prime role in entertainment, leisure, and business activities).

❙**TABLE 17-2** Effects of Involuntary Regulatory Signals on Appetite

Regulatory Signal	Source of Signal	Effect of Signal on Appetite
Neuropeptide Y	Arcuate nucleus of hypothalamus	↑
Melanocortins	Arcuate nucleus of hypothalamus	↓
Leptin	Adipose tissue	↓
Insulin	Endocrine pancreas	↓
Orexins	Lateral hypothalamus	↑
Corticotropin-releasing hormone	Paraventricular nucleus of hypothalamus	↓
Ghrelin	Stomach	↑
Peptide YY$_{3-36}$	Small and large intestines	↓
Stomach distension	Stomach	↓
Cholecystokinin	Small intestine	↓

Even well-intentioned family pressure—"Clean your plate before you leave the table"—can affect the amount consumed.

Furthermore, the amount of pleasure derived from eating can reinforce feeding behavior. Eating foods with an enjoyable taste, smell, and texture can increase appetite and food intake. Stress, anxiety, depression, and boredom have also been shown to alter feeding behavior in ways unrelated to energy needs. People often eat to satisfy psychological needs rather than to satisfy hunger. Furthermore, environmental influences, such as the amount of food available, play an important role in determining the extent of food intake. Thus, any comprehensive explanation of how food intake is controlled must take into account these voluntary eating acts that can reinforce or override the internal signals governing feeding behavior.

Obesity occurs when more kilocalories are consumed than are burned.

Clinical Note Experts categorize body weight-for-height into four groups: underweight, healthy, overweight, and obese. The arbitrary boundary for being **overweight** is having a **body mass index** (**BMI**) (a mathematical means of assessing the proportion of body fat) of between 25 and 29.9, and for being **obese** as having a BMI of 30 or greater. (See the accompanying boxed feature, ❙A Closer Look at Exercise Physiology, to see how to calculate the BMI.) Having excessive fat content in adipose tissue stores may have an adverse effect on health. More than two thirds of the adults in the United States weigh too much, with one third being clinically obese, and nearly one third of children are overweight or obese. To make matters worse, obesity is on the rise. The weight gain started in the 1970s and is continuing a sharp upward trend. The number of obese adults in the United States is nearly 2.5 times higher now than it was in the early 1970s, up from 14% to 34% of adults, and the incidence of childhood obesity is increasing even more rapidly. Researchers project that by 2030, if the rising rate is not curtailed, 50% of adults in the United States will be obese. Much of the world is following the same trend, leading the World Health Organization (WHO) to coin the word _globesity_ to describe the worldwide situation. Obesity is now recognized as a disease state with multiple pathophysiological consequences by the WHO, the National Institutes of Health, the Food and Drug Administration, and the American Medical Association.

Obesity occurs when, over time, more kilocalories are ingested in food than are used to support the body's energy needs, with the excessive energy being stored as triglycerides in adipose tissue. Early in the development of obesity, existing fat cells get larger. An average adult has between 40 billion and 50 billion adipocytes. Each fat cell can store the maximum of about 1.2 mg of triglycerides. Once existing fat cells are full, if people continue to consume more calories than they expend, they make more adipocytes.

The causes of obesity are many, and some remain obscure. Both genetic and environmental factors, including but not limited to the following, may contribute to the development of obesity:

■ _Hereditary tendencies._ Often, differences in the regulatory pathways for energy balance—either those governing food in-

Unless otherwise noted, all content on this page is © Cengage Learning.

BODY COMPOSITION IS THE PERCENTAGE of body weight that is composed of lean tissue and adipose tissue. Assessing body composition is an important step in evaluating a person's health status. One crude means of assessing body composition is by calculating the **body mass index (BMI)** using the following formula:

$$\text{BMI} = \frac{(\text{weight in pounds}) \times 700}{(\text{height in inches})^2}$$

A BMI of less than 25 is considered healthy, whereas a BMI of 30 or higher (being obese) places the person at increased risk for various diseases and premature death. BMIs between this range (being overweight but not obese) are considered borderline.

BMI determinations and the age–height–weight tables used by insurance companies can be misleading for determining healthy body weight. By these charts, many athletes, for example, would be considered overweight. A football player may be 6 feet 5 inches tall and weigh 300 pounds but have only 12% body fat. This player's extra weight is muscle, not fat, and therefore is not a detriment to his health. A sedentary person, in contrast, may be normal on the height–weight charts but have 30% body fat. This person should maintain body weight while increasing muscle mass and decreasing fat. Ideally, men should have 15% fat or less and women should have 20% fat or less.

The most accurate method for assessing body composition is underwater weighing. This technique is based on the fact that lean tissue is denser than water and fat tissue is less dense than water. (You can readily demonstrate this for yourself by dropping a piece of lean meat and a piece of fat into a glass of water; the lean meat sinks and the fat floats.) The results are used to determine body density using equations that take into consideration the difference between the person's weight in air and underwater. Because of the difference in density between lean and fat tissue, people who have more fat have a lower density and weigh relatively less underwater than in air compared to their lean counterparts. Body composition is then determined by means of an equation that correlates percentage fat with body density.

A more convenient and more commonly used but less accurate way to assess body composition is skinfold thickness. Because approximately half of the body's total fat content is located just beneath the skin, total body fat can be estimated from measurements of skinfold thickness taken at various sites on the body. Skinfold thickness is determined by pinching up a fold of skin at one of the designated sites and measuring its thickness by means of a caliper, a hinged instrument that fits over the fold and is calibrated to measure thickness. Mathematical equations specific for the person's age and sex can be used to predict the percentage of fat from the skinfold thickness scores. A major criticism of skinfold assessment is that accuracy depends on the investigator's skill.

There are different ways to be fat, and one way is more dangerous than the other. Obese patients can be classified into two categories—*android,* a male-type of adipose tissue distribution, and *gynoid,* a female-type distribution—based on the anatomic distribution of adipose tissue measured as the ratio of waist circumference to hip circumference. **Android obesity** is characterized by abdominal fat distribution (people shaped like "apples"), whereas **gynoid obesity** is characterized by fat distribution in the hips and thighs (people shaped like "pears"). Both sexes can display either android or gynoid obesity.

Android obesity is associated with a number of disorders, including insulin resistance, Type 2 (adult-onset) diabetes mellitus, excess blood lipid levels, high blood pressure, coronary heart disease, stroke, cancer, and dementia. "Apple" people have a greater proportion of visceral fat, which is more worrisome than accumulation of subcutaneous fat because visceral fat releases more of the bad adipokines that promote insulin resistance and boost the low-level inflammation that underlies the development of atherosclerosis (see p. 327). Gynoid obesity is not associated with the high risk of these diseases.

Research on the success of weight-reduction programs indicates that it is very difficult for people to lose weight, but when weight loss occurs, it is from the areas of increased stores. Because very-low-calorie diets are difficult to maintain, an alternative to severely cutting caloric intake to lose weight is to increase energy expenditure through physical exercise. Exercise physiologists often assess body composition as an aid in prescribing and evaluating exercise programs. Exercise generally reduces the percentage of body fat and, by increasing muscle mass, increases the percentage of lean tissue. An aerobic exercise program further helps reduce the risk of the disorders associated with android obesity.

take or those influencing energy expenditure—arise from genetic variations. Scientists have identified variations in more than 20 genes that predispose people to gaining excess weight easily. Take for example the *FTO* gene (the polite acronym now used instead of the less flattering original name "fatso gene"). There are two versions of the FTO gene: the "normal" T variant and the "faulty" A variant. Individuals who have one A version and one T version are 30% more likely to be obese than those who have two T copies of the gene. For people who have two A copies of FTO, the risk of becoming obese jumps to 70%. Recent evidence suggests ghrelin, the hunger hormone, is not properly suppressed by eating in those with A versions of the gene.

■ *Disturbances in the leptin-signaling pathway.* Some cases of obesity have been linked to leptin resistance. Some investigators suggest that the hypothalamic centers involved in maintaining energy homeostasis are "set at a higher level" in obese people. For example, the problem may lie with faulty leptin receptors in the brain that do not respond appropriately to the high levels of circulating leptin from abundant adipose stores.

Thus, the brain does not detect leptin as a signal to turn down appetite until a higher set point (and accordingly greater fat storage) is achieved. This could explain why overweight people tend to maintain their weight but at a heavier-than-normal level. Instead of faulty leptin receptors, other disturbances in the leptin pathway may be at fault, such as defective transport of leptin across the blood–brain barrier or a deficiency of one of the chemical messengers in the leptin pathway.

■ *An abundance of convenient, highly palatable, energy-dense, relatively inexpensive foods.* The current availability and convenience of food compared to most of human history make overeating easier than ever. Making matters worse, bad-for-you fast food and junk food are heavily marketed via powerful, widespread food advertising using modern mass media as a vehicle.

■ *Differences in extracting energy from food.* Another reason lean people and obese people may have dramatically different body weights despite consuming the same number of kilocalories may lie in the efficiency with which energy is extracted from food. Studies suggest that leaner individuals tend to derive less energy from the food they consume because they convert more of the food's energy into heat than into energy for immediate use or for storage. For example, slimmer individuals have more *uncoupling proteins,* which allow their cells to convert more of the nutrient calories into heat instead of fat. These are the people who can eat a lot without gaining weight. By contrast, obese people may have more efficient metabolic systems for extracting energy from food—a useful trait in times of food shortage but a hardship when trying to maintain a desirable weight when food is plentiful.

■ *Composition of colonic bacterial communities.* Studies demonstrate that obese people have a greater proportion of a type of bacteria in their colon that breaks down indigestible fiber more efficiently for absorption from the digestive tract compared to the bacterial communities in lean people (see p. 614). By making more absorbable units available for uptake from the digestive tract, the fat-promoting bacteria help their human host obtain more energy from the same number of kilocalories consumed than leaner people who have a preponderance of less energy-efficient colonic bacteria.

■ *Lack of exercise.* Numerous studies have shown that, on average, fat people do not eat more than thin people. One possible explanation is that overweight people do not overeat but underexercise—the "couch potato" syndrome. Low levels of physical activity typically are not accompanied by comparable reductions in food intake. For this reason, modern technology is partly to blame for the current obesity epidemic. Our ancestors had to exert physical effort to eke out subsistence. By comparison, we now have machines to replace much manual labor, automobiles that we use to get to locations within walking distance, remote controls to operate our machines with minimal effort, and computers that encourage long hours of sitting. We have to make a conscious effort to exercise.

■ *Differences in the "fidget factor."* **Nonexercise activity thermogenesis (NEAT),** or the "fidget factor," might explain some variation in fat storage among people. NEAT refers to energy expended by physical activities other than planned exercise. Those who engage in toe tapping or other types of repetitive, spontaneous physical activity expend a substantial number of kilocalories throughout the day without conscious effort.

■ *Certain endocrine disorders such as hypothyroidism* (see p. 669). Hypothyroidism involves a deficiency of thyroid hormone, the main factor that bumps up the BMR so that the body burns more calories in its idling state.

■ *Emotional disturbances in which overeating replaces other gratifications.*

■ *Stress.* Evidence suggests that chronic stress leads to increased release of NPY from sympathetic nerves, in turn causing increased deposition of visceral fat.

■ *Eating out of sync with normal biological rhythms set by the "master clock"* (see p. 660). The body's daily rhythms such as the cyclic rise and fall in secretion of particular hormones, the regular fluctuations in body temperature, the sleep/wake cycle, and metabolic patterns are guided by a "master biologic clock" in the brain that operates in tune with environmental patterns of light and darkness. Consuming food at night when the body naturally shifts to a metabolic mode in anticipation of a sleeping and fasting phase may contribute to weight gain.

■ *Too little sleep.* Some studies suggest that decreased time sleeping may be a contributing factor in the recent rise of obesity. On average, people in the United States are sleeping 1 to 2 hours less per night now than they did 40 years ago. Researchers found that those who typically sleep 6 hours a night are 23% more likely to be obese, those who average 5 hours of sleep are 50% more likely to be obese, and those who sleep 4 hours nightly are 75% more likely to be obese than "traditional" sleepers who sleep for 7 to 8 hours. Studies have shown that levels of leptin (a signal to stop eating) are lower and levels of ghrelin (a signal to start eating) are higher in people who sleep less compared with those who sleep the traditional 8 hours.

■ *A possible virus link.* One intriguing proposal links a relatively common cold virus to a propensity to become overweight and may account for a portion of the current obesity epidemic. One study showed that the cold virus *adenovirus-36* might lead to obesity by transforming adult tissue-specific stem cells into fat-storing adipocytes.

■ *Heating and air conditioning.* Climate control has reduced the need for calorie-consuming activities such as shivering and sweating that the body uses to maintain body temperature.

■ *Development of an excessive number of fat cells as a result of overfeeding.* One of the problems in fighting obesity is that once fat cells are created they do not disappear with dieting and weight loss. Even if a dieter loses a large portion of the triglyceride fat stored in these cells, the depleted cells remain, ready to refill. Therefore, rebound weight gain after losing weight is difficult to avoid and discouraging for the dieter.

Despite this rather lengthy list, our knowledge about the causes and control of obesity is still rather limited, as evidenced by the number of people who are constantly trying to stabilize their weight at a more desirable level. Losing excess pounds is important from more than an aesthetic viewpoint. It is known that obesity, especially of the android type, can predispose an

individual to illness and premature death from a multitude of diseases. (To learn about the differences between android and gynoid obesity, see the boxed feature on p. 625, ▌A Closer Look at Exercise Physiology.) The burden of obesity-related problems on the U.S health care system is $147 billion annually. Scientists are working on multiple fronts to find ways to help curb the obesity epidemic.

People suffering from anorexia nervosa have a pathological fear of gaining weight.

Clinical Note The converse of obesity is generalized nutritional deficiency. The obvious causes for reduction of food intake below energy needs are lack of availability of food, interference with swallowing or digestion, and impairment of appetite.

One poorly understood disorder in which lack of appetite is a prominent feature is **anorexia nervosa,** a condition that affects 0.6% of the adult population in the United States. Patients with this disorder, most commonly adolescent girls and young women, have a morbid fear of becoming fat. They have a distorted body image, tending to visualize themselves as being heavier than they actually are. Because they have an aversion to food, they eat little and consequently lose considerable weight, perhaps even starving themselves to death. Among females 15 to 24 years old, the death rate associated with anorexia is 12 times higher than the death rate from all other causes. Other characteristics of the condition include altered secretion of many hormones, absence of menstrual periods, and low body temperature. It is unclear whether these symptoms occur secondarily as a result of general malnutrition or arise independently of the eating disturbance as a part of a primary brain malfunction. The underlying mechanisms responsible for anorexia nervosa are presently unknown, although researchers are scrambling to find answers in hopes of developing better therapies. Researchers cannot even agree on whether the causal problem is biological or psychological.

Check Your Understanding 17.1

1. Define *external work, internal work, metabolic rate, appetite signals, satiety signals, adiposity signals, adipokines, visceral fat,* and *subcutaneous fat.*

2. Explain how the basal metabolic rate can be determined indirectly.

3. Make a chart listing the involuntary regulatory signals on appetite and indicate the source and effect of each (that is, whether it increases or decreases appetite).

17.2 Temperature Regulation

Humans are usually in environments cooler than their bodies, but they constantly generate heat internally, which helps maintain body temperature. Heat production ultimately depends on oxidation of metabolic fuel derived from food.

Changes in body temperature in either direction alter cell activity—an increase in temperature speeds up cellular chemical reactions, whereas a decrease in temperature slows down these reactions. Because cell function is sensitive to fluctuations in internal temperature, humans homeostatically maintain body temperature at a level optimal for stable cellular metabolism. Overheating is more serious than cooling. Even moderate elevations of body temperature begin to cause nerve malfunction and irreversible protein denaturation. Most people suffer convulsions when the internal body temperature reaches about 106°F (41°C); 110°F (43.3°C) is considered the upper limit compatible with life.

Clinical Note By contrast, most of the body's tissues can transiently withstand substantial cooling. This characteristic is useful during cardiac surgery when the heart must be stopped. For such surgery, the patient's body temperature is deliberately lowered; the cooled tissues need less nourishment than they do at normal body temperature because of their reduced metabolic activity. However, a pronounced, prolonged fall in body temperature slows metabolism to a fatal level.

Internal core temperature is homeostatically maintained at 100°F (37.8°C).

Normal body temperature taken orally (by mouth) has traditionally been considered 98.6°F (37°C). However, more recent studies indicate that normal body temperature varies among individuals and varies throughout the day, ranging from 96.0°F (35.5°C) in the morning to 99.9°F (37.7°C) in the evening, with an overall average of 98.2°F (36.7°C).

Furthermore, there is no one body temperature because the temperature varies from organ to organ. From a thermoregulatory viewpoint, the body may conveniently be viewed as a *central core* surrounded by an *outer shell*. The temperature within the central core, which consists of the abdominal and thoracic organs, the central nervous system, and the skeletal muscles, generally remains fairly constant. This internal **core temperature** is subject to precise regulation to maintain its homeostatic constancy. The core tissues function best at a relatively constant temperature of around 100°F (37.8°C).

The skin and subcutaneous fat constitute the outer shell. In contrast to the constant high temperature in the core, the temperature within the shell is generally cooler and may vary substantially. For example, skin temperature may fluctuate between 68°F and 104°F (20°C and 40°C) without damage. As you will see, the temperature of the skin is deliberately varied as a control measure to help maintain the core's thermal constancy.

Sites for Monitoring Body Temperature Several easily accessible sites are used for monitoring body temperature. The oral and axillary (under the armpit) temperatures are comparable, whereas rectal temperature averages about 1°F (0.56°C) higher. Also available is a temperature-monitoring instrument that scans the heat generated by the eardrum and converts this temperature into an oral equivalent. A more recent device is the temporal scanner, a computerized instrument that is gently stroked across the forehead to measure the temperature of the blood in the temporal artery, which lies less than 2 mm below

the skin surface in this region. Temporal temperature is the best determinant of core temperature because it is nearly identical to the temperature of the blood exiting the heart. However, none of these measurements is an absolute indication of the internal core temperature, which is a bit higher, at 100°F, than the monitored sites.

Normal Variations in Core Temperature Even though the core temperature is held relatively constant, several factors cause it to vary slightly:

1. Most people's core temperature normally varies about 1.8°F (1°C) during the day, with the lowest level early in the morning before rising (6 to 7 A.M.) and the highest point in late afternoon (5 to 7 P.M.). This variation is the result of an innate rhythm driven by the master biologic clock.

2. Women also experience a monthly rhythm in core temperature in connection with their menstrual cycle. For an undetermined reason, the "set point" is elevated (the body thermostat is turned up) so that core temperature averages 0.9°F (0.5°C) higher during the last half of the cycle from the time of ovulation to menstruation.

3. The core temperature increases during exercise because of the tremendous increase in heat production by the contracting muscles. During hard exercise, the core temperature may increase to as much as 104°F (40°C). In a resting person, this temperature would be considered a fever, but it is normal during strenuous exercise.

4. Older is colder. The elderly naturally have lower temperatures, with a midday average of 97.7°F (36.4°C).

5. Because the temperature-regulating mechanisms are not 100% effective, the core temperature may vary slightly with exposure to extremes of temperature. For example, the core temperature may fall several degrees in cold weather or rise a degree or so in hot weather.

Thus, the core temperature can vary at the extremes between about 96° and 104°F but usually deviates less than a few degrees. This relative constancy is made possible by multiple thermoregulatory mechanisms coordinated by the hypothalamus.

Heat input must balance heat output to maintain a stable core temperature.

The core temperature is a reflection of the body's total heat content. Heat input to the body must balance heat output to maintain a constant total heat content and thus a stable core temperature (▮Figure 17-3). *Heat input* occurs by way of heat gain from the external environment and internal heat production, the latter being the most important source of heat for the body. Usually, more heat is generated than required to maintain normal body temperature, so the excess heat must be eliminated. *Heat output* occurs by way of heat loss from exposed body surfaces to the external environment.

Balance between heat input and heat output is frequently disturbed by (1) changes in internal heat production for purposes unrelated to regulation of body temperature—most notably by exercise, which markedly increases heat production—and
▮Figure 17-3 **Heat input and output.**

(2) changes in the external environmental temperature that influence the degree of heat gain or heat loss that occurs between the body and its surroundings. Compensatory adjustments must take place in heat-loss and heat-gain mechanisms to maintain body temperature within narrow limits, despite changes in metabolic heat production and changes in environmental temperature. We now elaborate on how these adjustments are made.

Heat exchange takes place by radiation, conduction, convection, and evaporation.

All heat loss or heat gain between the body and the external environment must take place between the body surface and its surroundings. The same physical laws of nature that govern heat transfer between inanimate objects control the transfer of heat between the body surface and the environment. The temperature of an object is a measure of the concentration of heat within the object. Heat always moves down its concentration gradient—that is, down a **thermal gradient** from a warmer to a cooler region. The body uses four mechanisms of heat transfer: *radiation, conduction, convection,* and *evaporation.*

Radiation **Radiation** is the emission of heat energy from the surface of a warm body in the form of **electromagnetic waves,** or **heat waves,** which travel through space (▮Figure 17-4a). When radiant energy strikes an object and is absorbed, the energy of the wave motion is transformed into heat within the object. The human body both emits (source of heat loss) and absorbs (source of heat gain) radiant energy. Whether the body loses or gains heat by radiation depends on the difference in temperature between the skin surface and the surfaces of other objects in the body's environment. Because net transfer of heat by radiation is always from warmer objects to cooler ones, the body gains heat by radiation from objects warmer than the skin surface, such as the sun, burning logs, or a radiant heat system. By contrast, the body loses heat by radiation to objects in its environment whose surfaces are cooler than the surface of the skin, such as building walls, furniture, or trees. On average, humans lose close to half of their heat energy through radiation.

Conduction **Conduction** is the transfer of heat between objects of differing temperatures that are in direct contact with
(a) **Radiation**—the transfer of heat energy from a warmer object to a cooler object in the form of electromagnetic waves ("heat waves"), which travel through space.
(b) **Conduction**—the transfer of heat from a warmer to a cooler object that is in direct contact with the warmer one. The heat is transferred through the movement of thermal energy from molecule to adjacent molecule.

Convection current
(c) **Convection**—the transfer of heat energy by air currents. Cool air warmed by the body through conduction rises and is replaced by more cool air. This process is enhanced by the forced movement of air across the body surface.

Liquid converted to gaseous vapor
(d) **Evaporation**—conversion of a liquid such as sweat into a gaseous vapor, a process that requires heat (the heat of vaporization), which is absorbed from the skin.

❙Figure 17-4 **Mechanisms of heat transfer.** The direction of the arrows depicts the direction of heat transfer.
FIGURE FOCUS: *Describe the heat transfer mechanisms taking place when a person is jogging on a warm, sunny afternoon.*

each other, with heat moving down its thermal gradient from the warmer to the cooler object.

The rate of heat transfer by conduction depends on the *temperature difference* between the touching objects and the *thermal conductivity* of the substances involved (that is, how easily heat is conducted by the substances). Heat can be lost or gained by conduction when the skin is in contact with a good conductor (❙Figure 17-4b). When you hold a snowball, for example, your hand becomes cold because heat moves by conduction from your hand to the snowball. Conversely, when you apply a heating pad to a body part, the part is warmed up as heat is transferred directly from the pad to the body.

Similarly, you either lose or gain heat by conduction to the layer of air in direct contact with your body. The direction of heat transfer depends on whether the air is cooler or warmer, respectively, than your skin. Only a small percentage of total heat exchange between the skin and the environment takes place by conduction alone, however, because air is not a good conductor of heat. (For this reason, swimming pool water at 80°F [26.7°C] feels cooler than air at the same temperature; heat

is conducted more rapidly from the body surface into the water, which is a good conductor, than into the air, which is a poor conductor.)

Convection The term **convection** refers to the transfer of heat energy by *air* (or *water*) *currents*. As the body loses heat by conduction to the surrounding cooler air, the air in immediate contact with the skin is warmed. Because warm air is lighter (less dense) than cool air, the warmed air rises while cooler air moves in next to the skin to replace the vacating warm air. The process is then repeated (❙Figure 17-4c). These air movements, known as *convection currents,* help carry heat away from the body. Without convection currents, no further heat could be dissipated from the skin by conduction once the temperature of the layer of air immediately around the body equilibrated with skin temperature.

The combined conduction–convection process of dissipating heat from the body is enhanced by forced movement of air across the body surface, either by external air movements, such as those caused by the wind or a fan, or by movement of the

Energy Balance and Temperature Regulation | **629**

body through the air, as during bicycle riding. Because forced air movement sweeps away the air warmed by conduction and replaces it with cooler air more rapidly, a greater total amount of heat can be carried away from the body over a given period. Thus, wind makes us feel cooler on hot days, and windy days in the winter are more chilling than calm days at the same cold temperature. For this reason, weather forecasters have developed the concept of *wind chill factor* (how cold it feels).

Evaporation During **evaporation** from the skin surface, the heat required to transform water from a liquid to a gaseous state is absorbed from the skin, thereby cooling the body (❙ Figure 17-4d). Evaporative heat loss makes you feel cooler when your bathing suit is wet than when it is dry. Evaporative heat loss occurs continually from the linings of the respiratory airways and from the surface of the skin. Heat is continuously lost in expired air as a result of the air being humidified (gaining water vapor) during its passage through the respiratory system (see p. 447). Similarly, because the skin is not completely waterproof, water molecules constantly diffuse through the skin and evaporate. This ongoing evaporation from the skin is unrelated to the sweat glands. These passive evaporative heat-loss processes are not subject to physiological control and go on even in very cold weather, when the problem is one of conserving body heat.

Sweating is a regulated evaporative heat-loss process.

Sweating is an active evaporative heat-loss process under sympathetic nervous control. The rate of evaporative heat loss can be deliberately adjusted by varying the extent of sweating, which is an important homeostatic mechanism to eliminate excess heat as needed. In fact, when the environmental temperature exceeds the skin temperature, sweating is the only avenue for heat loss because the body is gaining heat by radiation and conduction under these circumstances. At normal temperature, an average of 100 mL of sweat is produced per day; this value increases to 1.5 liters during hot weather and climbs to 4 liters during heavy exercise.

Most **sweat** is an odorless, dilute salt solution actively extruded to the surface of the skin by **eccrine sweat glands** dispersed all over the body. This clear, salty sweat is the kind important in cooling the body. Eccrine sweat glands also produce **dermcidin**, a newly discovered antimicrobial peptide, a natural antibiotic in sweat that helps defend against potential skin infections. **Apocrine sweat glands,** which are located primarily in the armpits and genital area, produce a thick, milky sweat that is rich in organic constituents, like proteins and lipids. Apocrine sweat is initially odorless, but body odor is generated when bacteria in the vicinity break down these organic compounds into substances that have an unpleasant scent. Apocrine sweat glands are remnants of sexual scent glands found in other species. Apocrine sweat is most abundant during emotional stress and sexual excitement. Both eccrine and apocrine sweat glands are stimulated by sympathetic innervation, but the postganglionic sympathetic fibers supplying eccrine glands are unusual in that they release acetylcholine instead of norepinephrine. ACh binds with muscarinic receptors on the eccrine glands, whereas apocrine glands have the usual adrenergic receptors that bind with catecholamines (see p. 239).

Eccrine sweat must be evaporated from the skin for heat loss to occur. If sweat merely drips from the surface of skin or is wiped away, no heat loss is accomplished. The most important factor determining the extent of evaporation of sweat is the *relative humidity* of the surrounding air (the percentage of H_2O vapor actually present in the air compared to the greatest amount that the air can possibly hold at that temperature; for example, a relative humidity of 70% means that the air contains 70% of the H_2O vapor it is capable of holding). When the relative humidity is high, the air is already almost fully saturated with H_2O, so it has limited ability to take up additional moisture from the skin. Thus, little evaporative heat loss can occur on hot, humid days. The sweat glands continue to secrete, but the sweat simply remains on the skin or drips off instead of evaporating and producing a cooling effect. As a measure of the discomfort associated with combined heat and high humidity, meteorologists have devised the *temperature–humidity index,* or *heat index* (how hot it feels).

The hypothalamus integrates a multitude of thermosensory inputs.

The hypothalamus is the body's thermostat. The home thermostat keeps track of the temperature in a room and triggers a heating mechanism (the furnace) or a cooling mechanism (the air conditioner) as necessary to maintain room temperature at the indicated setting. Similarly, the hypothalamus, as the body's thermoregulatory integrating center, receives afferent information about the temperature in various regions of the body and initiates extremely complex, coordinated adjustments in heat-gain and heat-loss mechanisms as necessary to correct any deviations in core temperature from normal. The hypothalamus is far more sensitive than your home thermostat. It can respond to changes in blood temperature as small as 0.01°C.

To appropriately adjust the delicate balance between the heat-loss mechanisms and the opposing heat-producing and heat-conserving mechanisms, the hypothalamus must be apprised continuously of both the core and the skin temperature by specialized temperature-sensitive receptors called **thermoreceptors**. The core temperature is monitored by *central thermoreceptors,* which are located in the hypothalamus itself, and in the abdominal organs and elsewhere. *Peripheral thermoreceptors* monitor skin temperature throughout the body.

Two centers for temperature regulation are in the hypothalamus. The *posterior region,* activated by cold, triggers reflexes that mediate heat production and heat conservation. The *anterior region,* activated by warmth, initiates reflexes that mediate heat loss. Let us examine the means by which the hypothalamus fulfills its thermoregulatory functions (❙ Figure 17-5).

Shivering is the primary involuntary means of increasing heat production.

The body can gain heat as a result of internal heat production generated by metabolic activity or from the external environment if the latter is warmer than body temperature. Because

FIGURE FOCUS: *Drugs that block the action of acetylcholine at muscarinic receptors (for example, oxybutynin used to treat overactive bladder) can increase a person's risk of heat exhaustion or heat stroke. Explain how.*

body temperature usually is higher than environmental temperature, metabolic heat production is the primary source of body heat. In a resting person, most body heat is produced by the thoracic and abdominal organs as a result of ongoing, cost-of-living metabolic activities. Beyond this basal level, the rate of metabolic heat production can be variably increased primarily by changes in skeletal muscle activity or, to a lesser extent, by certain chemical activity. Thus, changes in skeletal muscle activity constitute the major way heat gain is controlled for temperature regulation.

Adjustments in Heat Production by Skeletal Muscles

In response to a fall in core temperature caused by exposure to cold, the hypothalamus takes advantage of increased skeletal muscle activity generating more heat. Acting through descending pathways that terminate on the motor neurons controlling the skeletal muscles, the hypothalamus first gradually increases

skeletal muscle tone. (Muscle tone is the constant level of tension within the muscles.) Soon shivering begins. **Shivering** consists of rhythmic, oscillating skeletal muscle contractions that occur at a rapid rate of 10 to 20 per second. This mechanism is efficient and effective in increasing heat production; all energy liberated during these muscle tremors is converted to heat because no external work is accomplished. Within seconds to minutes, internal heat production may increase two- to fivefold as a result of shivering.

Frequently, these reflex changes in skeletal muscle activity are augmented by increased voluntary, heat-producing actions such as bouncing up and down or hand clapping. The hypothalamus influences these behavioral responses as well as the involuntary physiological responses. As part of the limbic system, the hypothalamus is extensively involved with controlling motivated behavior (see p. 155).

In the opposite situation—a rise in core temperature caused by heat exposure—two mechanisms reduce heat-producing skeletal muscle activity: Muscle tone is reflexly decreased, and voluntary movement is curtailed. When the air becomes very warm, people often complain it is "too hot even to move."

Nonshivering Thermogenesis by Brown Fat Although reflex and voluntary changes in muscle activity are the major means of increasing the rate of heat production, **nonshivering (chemical) thermogenesis** also plays a role in thermoregulation. In most mammals, chronic cold exposure brings about an increase in metabolic heat production independent of muscle contraction by changes in heat-generating chemical activity. Nonshivering thermogenesis is mediated on cold exposure by the sympathetic nervous system, which increases heat production by stimulating **brown adipose tissue**, or **brown fat**, a special type of adipose tissue that is especially capable of converting chemical energy from food into heat. In humans nonshivering thermogenesis is most important in newborns, who have prominent deposits of brown fat. Unlike the ordinary **white adipose tissue** that stores energy in the form of triglyceride deposits, brown adipose tissue acts like a furnace that burns energy to generate heat. Newborns use brown fat to keep warm because they cannot shiver. Brown fat is brown in color because it has an abundance of mitochondria that contain iron, which causes the tissue to appear reddish brown. The mitochondria of brown fat contain a unique **uncoupling protein** called **thermogenin** ("heat producer") that uncouples the electron transport system from the process of generating ATP (see p. 37) during oxidation of glucose and fatty acids. Instead of some of the energy released by the electron transport system being harnessed in ATP by chemiosmosis, all of the energy is dissipated as heat.

Brown fat deposits regress beyond infancy and were thought to disappear by 2 years of age. However, new radiologic imaging techniques such as PET scans (see p. 145) have revealed small, persistent brown fat reserves in adults. Brown fat is more abundant in lean people and decreases with advancing age. As expected, adult brown fat becomes more active on cold exposure. Brown fat not only is a heat-producing, but also a calorie-consuming tissue because all of the calories in nutrients burned by brown fat are turned into heat. Thus, researchers are searching for ways to fight obesity by boosting the amount or activity of adult brown fat stores or by coaxing white fat cells to behave more like brown fat cells. Fifty grams of brown fat burns 500 calories per day without the person expending any energy, as much as burned by 1 hour of aerobic exercise.

Recent studies suggest that exercise may promote "browning" of white adipose tissue. Exercising muscles release **irisin** into the blood. This hormone appears to promote synthesis of uncoupling proteins in mitochondria of white fat cells, making these cells act more like brown fat cells.

Having examined the mechanisms for adjusting heat production, we now turn to the other side of the equation: adjustments in heat loss.

The magnitude of heat loss can be adjusted by varying the flow of blood through the skin.

Heat-loss mechanisms are subject to control, again largely by the hypothalamus. When we are hot, we need to increase heat loss to the environment; when we are cold, we need to decrease heat loss. The amount of heat lost to the environment by radiation and the conduction–convection process is largely determined by the temperature gradient between the skin and the external environment. To maintain a constant core temperature, the insulative capacity and temperature of the skin can be adjusted to vary the temperature gradient between the skin and the external environment, thereby influencing the extent of heat loss.

The insulative capacity of the skin can be varied by controlling the amount of blood flowing through. Skin blood flow serves two functions. First, it provides a nutritive blood supply to the skin. Second, most skin blood flow is for the function of temperature regulation; at normal room temperature, 20 to 30 times more blood flows through the skin than is needed for skin nutrition. In the process of thermoregulation, skin blood flow can vary tremendously, from 400 to 2500 mL/min. The more blood that reaches the skin from the warm core, the closer the skin's temperature is to the core temperature. The skin's blood vessels diminish the effectiveness of the skin as an insulator by carrying heat to the surface, where it can be lost from the body by radiation and the conduction–convection process. Accordingly, vasodilation of skin arterioles increases heat loss by permitting increased flow of heated blood through the skin. Conversely, skin arteriolar vasoconstriction, which reduces skin blood flow, decreases heat loss by keeping the warm blood in the central core, where it is insulated from the external environment. This response conserves heat that otherwise would have been lost.

These skin vasomotor responses are coordinated by the hypothalamus by means of sympathetic nervous system output.

Increased sympathetic activity to the skin arterioles produces heat-conserving vasoconstriction in response to cold exposure, whereas decreased sympathetic activity produces heat-losing vasodilation of these vessels in response to heat exposure.

Recall that the cardiovascular control center in the medulla also exerts control over the skin arterioles (and arterioles throughout the body) by means of adjusting sympathetic activity to these vessels for the purpose of blood pressure regulation (see pp. 349 nd 350). Hypothalamic control over the skin arterioles for the purpose of temperature regulation takes precedence over the cardiovascular control center's control of these same vessels (see p. 369). Thus, changes in blood pressure can result from pronounced thermoregulatory skin vasomotor responses. For example, blood pressure can fall on exposure to a very hot environment because the skin vasodilator response set in motion by the hypothalamic thermoregulatory center overrides the skin vasoconstrictor response called forth by the medullary cardiovascular control center.

The hypothalamus simultaneously coordinates heat-production and heat-loss mechanisms.

Let us now pull together the coordinated adjustments in heat production and heat loss in response to exposure to either a cold or a hot environment (❙Table 17-3). (For a discussion of the effects of extreme cold or heat exposure, see the boxed feature on p. 634, ❙Concepts, Challenges, and Controversies.)

Coordinated Responses to Cold Exposure In response to cold exposure, the posterior region of the hypothalamus directs increased heat production, such as by shivering, while simultaneously decreasing heat loss (that is, conserving heat) by skin vasoconstriction and other measures.

Because there is a limit to the body's ability to reduce skin temperature through vasoconstriction, even maximum vasoconstriction is not sufficient to prevent excessive heat loss when the external temperature falls too low. Accordingly, other measures must be instituted to further reduce heat loss. In animals with dense fur or feathers, the hypothalamus, acting through the sympathetic nervous system, brings about contraction of the tiny muscles at the base of the hair or feather shafts to lift the hair or feathers off the skin surface. This puffing up traps a layer of poorly conductive air between the skin surface and the environment, thus increasing the insulating barrier between the core and the cold air and reducing heat loss. Even though the hair-shaft muscles contract in humans in response to cold exposure, this heat-retention mechanism is ineffective because of the low density and fine texture of most human body hair. The result instead is useless *goose bumps*.

After maximum skin vasoconstriction has been achieved, further heat dissipation in humans can be prevented only by behavioral adaptations, such as postural changes that reduce as much as possible the exposed surface area from which heat can escape. These heat-conserving maneuvers include hunching over or clasping the arms in front of the chest. Putting on warmer clothing further insulates the body from too much heat loss. Clothing entraps layers of poorly conductive air between the skin surface and the environment, thereby diminishing loss

IN RESPONSE TO COLD EXPOSURE (COORDINATED BY THE POSTERIOR HYPOTHALAMUS)		IN RESPONSE TO HEAT EXPOSURE (COORDINATED BY THE ANTERIOR HYPOTHALAMUS)	
Increased Heat Production	Decreased Heat Loss (Heat Conservation)	Decreased Heat Production	Increased Heat Loss

Shivering	Postural changes to reduce exposed surface area (hunching shoulders, etc.)*	Decreased voluntary exercise*	Sweating
Increased voluntary exercise*	Warm clothing*		Cool clothing*
Nonshivering thermogenesis			

*Behavioral adaptations

of heat by conduction from the skin to the cold external air and curtailing the flow of convection currents.

Coordinated Responses to Heat Exposure During heat exposure, the anterior part of the hypothalamus reduces heat production by decreasing skeletal muscle activity and promotes increased heat loss by inducing skin vasodilation. When even maximal skin vasodilation is inadequate to rid the body of excess heat, sweating is brought into play to accomplish further heat loss through evaporation. If the air temperature rises above the temperature of maximally vasodilated skin, the temperature gradient reverses itself so that heat is gained from the environment. Sweating is the only means of heat loss under these conditions.

Humans also employ voluntary measures, such as using fans, wetting the body, drinking cold beverages, and wearing cool clothing, to further enhance heat loss. Contrary to popular belief, wearing light-colored, loose clothing is cooler than being nude. Naked skin absorbs almost all radiant energy that strikes it, whereas light-colored clothing reflects almost all radiant energy that falls on it. Thus, if light-colored clothing is loose and thin enough to permit convection currents and evaporative heat loss to occur, wearing it is actually cooler than going without any clothes.

Thermoneutral Zone Skin vasomotor activity is highly effective in controlling heat loss in environmental temperatures between the upper 60s and mid-80s. This range, within which core temperature can be kept constant by vasomotor responses without calling supplementary heat-production mechanisms (shivering) or heat-loss mechanisms (sweating) into play, is called the **thermoneutral zone.**

During a fever, the hypothalamic thermostat is "reset" at an elevated temperature.

Clinical Note The term **fever** refers to an elevation in body temperature as a result of infection or inflammation. In response to microbial invasion, macrophages release **endogenous pyrogen,** which acts on the hypothalamic thermoregula-

tory center to raise the thermostat setting (▮Figure 17-6; also see p. 411). The hypothalamus now maintains the temperature at the new set level instead of maintaining normal body temperature. If, for example, endogenous pyrogen raises the set point to 102°F (38.9°C), the hypothalamus senses that the normal pre-fever temperature is too cold, so it initiates cold-response mechanisms to raise the temperature to 102°F. It promotes skin vasoconstriction to rapidly reduce heat loss and initiates shivering to rapidly increase heat production, both of which drive the temperature upward. These events account for the sudden cold chills often experienced at the onset of a fever. Feeling cold, the person may voluntarily pile on more blankets to help raise body temperature by conserving body heat. Once the new temperature is achieved, body temperature is regulated as normal in response to cold and heat—but at a higher setting. Thus, fever production in response to an infection is a deliberate outcome and is not caused by a breakdown of thermoregulation. Although the physiological significance of a fever is still unclear, many medical experts believe that a rise in body temperature has a beneficial role in fighting infection. A fever augments the inflammatory response and may interfere with bacterial multiplication.

During fever production, endogenous pyrogen raises the set point of the hypothalamic thermostat by triggering the local release of *prostaglandins,* which are local chemical mediators that act directly on the hypothalamus (see p. 119). Aspirin reduces a fever by inhibiting synthesis of prostaglandins. Aspirin does not lower the temperature in a nonfebrile person because in the absence of endogenous pyrogen, prostaglandins are not present in the hypothalamus in appreciable quantities.

The exact molecular cause of a fever "breaking" naturally is unknown, although it presumably results from reduced pyrogen release or decreased prostaglandin synthesis. When the hypothalamic set point is restored to normal, the temperature at 102°F (in this example) is too high. Heat-response mechanisms are instituted to cool the body. Skin vasodilation occurs, and sweating commences. The person feels hot and throws off extra covers. The gearing up of these heat-loss mechanisms by the hypothalamus reduces the temperature to normal.

The Extremes of Heat and Cold Can Be Fatal

PROLONGED EXPOSURE TO TEMPERATURE EXTREMES in either direction can overtax the body's thermoregulatory mechanisms, leading to disorders and even death.

Cold-Related Disorders

The body can be harmed by cold exposure in two ways: frostbite and generalized hypothermia. **Frostbite** involves excessive cooling of a particular part of the body to the point where tissue in that area is damaged. If exposed tissues actually freeze, tissue damage results from disruption of the cells by formation of ice crystals or by lack of liquid water.

Hypothermia, a fall in body temperature, occurs when generalized cooling of the body exceeds the ability of the normal heat-producing and heat-conserving regulatory mechanisms to match the excessive heat loss. As hypothermia sets in, the rate of all metabolic processes slows because of the declining temperature. Higher cerebral functions are the first affected by body cooling, leading to loss of judgment, apathy, disorientation, and tiredness, all of which diminish the cold victim's ability to initiate voluntary mechanisms to reverse the falling body temperature. As body temperature continues to plummet, depression of the respiratory center occurs, reducing the ventilatory drive so that breathing becomes slow and weak. Activity of the cardiovascular system also is gradually reduced. The heart is slowed and cardiac output decreased. Cardiac rhythm is disturbed, eventually leading to ventricular fibrillation and death.

Heat-Related Disorders

At the other extreme, two disorders related to excessive heat exposure are heat exhaustion and heat stroke. **Heat exhaustion** is a state of collapse, usually manifested by fainting, that is caused by reduced blood pressure brought about as a result of overtaxing the heat-loss mechanisms. Extensive sweating reduces cardiac output by depleting the plasma volume, and pronounced skin vasodilation causes a drop in total peripheral resistance. Because blood pressure is determined by cardiac output times total peripheral resistance, blood pressure falls, an insufficient amount of blood is delivered to the brain, and fainting takes place. Thus, heat exhaustion is a consequence of over-activity of the heat-loss mechanisms rather than a breakdown of these mechanisms. Because the heat-loss mechanisms have been very active, body temperature is only mildly elevated in heat exhaustion. By forcing cessation of activity when the heat-loss mechanisms are no longer able to cope with heat gain through exercise or a hot environment, heat exhaustion serves as a safety valve to help prevent the more serious consequences of heat stroke.

Heat stroke is an extremely dangerous situation that arises from the complete breakdown of the hypothalamic thermoregulatory systems. Heat exhaustion may progress into heat stroke if the heat-loss mechanisms continue to be overtaxed. Heat stroke is more likely to occur on overexertion during a prolonged exposure to a hot, humid environment. The elderly, in whom thermoregulatory responses are generally slower and less efficient, are particularly vulnerable to heat stroke during prolonged, stifling heat waves. So too are individuals who are taking certain drugs that can hinder the body's ability to cool off, for example by hampering sweating (anticholinergics), by preventing increased blood flow to the skin (sympathomimetics), or by interfering with the hypothalamic thermoregulatory centers' neurotransmitter activity (some tranquilizers).

The most striking feature of heat stroke is a lack of compensatory heat-loss measures, such as sweating, in the face of a rapidly rising body temperature **(hyperthermia)**. No sweating occurs, despite a markedly elevated body temperature, because the hypothalamic thermoregulatory control centers are not functioning properly and cannot initiate heat-loss mechanisms. During the development of heat stroke, body temperature starts to climb as the heat-loss mechanisms are eventually overwhelmed by prolonged, excessive heat gain. Once the core temperature reaches the point at which the hypothalamic temperature-control centers are damaged by the heat, the body temperature rapidly rises even higher because of the complete shutdown of heat-loss mechanisms. Furthermore, as the body temperature increases, the rate of metabolism increases correspondingly because higher temperatures speed up the rate of all chemical reactions; the result is even greater heat production. This positive-feedback state sends the temperature spiraling upward. Heat stroke is a very dangerous situation that is rapidly fatal if untreated. Even with treatment to halt and reverse the rampant rise in body temperature, the mortality rate is still high. The rate of permanent disability in survivors is also high because of irreversible protein denaturation caused by the high internal heat.

Hyperthermia can occur unrelated to infection.

Hyperthermia denotes any elevation in body temperature above the normally accepted range. The term *fever* is usually reserved for an elevation in temperature caused by endogenous pyrogen resetting the hypothalamic set point during infection or inflammation; *hyperthermia* refers to all other imbalances between heat gain and heat loss that increase body temperature. Hyperthermia has a variety of causes, some of which are normal and harmless, others pathologic and fatal.

Exercise-Induced Hyperthermia The most common cause of hyperthermia is sustained exercise. As a physical consequence of the tremendous heat load generated by exercising muscles, body temperature rises during the initial stage of exer-
Figure 17-6 Fever production.

1 At the onset of exercise, the rate of heat production initially exceeds the rate of heat loss so the core temperature rises.

2 When heat loss mechanisms are reflexly increased sufficiently to equalize the elevated heat production, the core temperature stabilizes slightly above the resting point for the duration of the exercise.

Figure 17-7 Hyperthermia in sustained exercise.

cise because heat gain exceeds heat loss (Figure 17-7). The elevation in core temperature reflexly triggers heat-loss mechanisms (skin vasodilation and sweating), which eliminate the discrepancy between heat production and heat loss. As soon as the heat-loss mechanisms are stepped up sufficiently to counterbalance the increased heat production, the core temperature stabilizes at a level slightly above the set point despite continued heat-producing exercise. Thus, during sustained exercise, body temperature initially rises, then is maintained at the higher level as long as the exercise continues.

Clinical Note **Pathological Hyperthermia** Hyperthermia can also be brought about in a completely different way: excessive heat production in connection with abnormally high circulating levels of thyroid hormone or epinephrine that result from dysfunctions of the thyroid gland or adrenal medulla, respectively. Both these hormones elevate the core temperature by increasing the overall rate of metabolic activity and heat production.

Hyperthermia can also result from malfunction of the hypothalamic control centers. Certain brain lesions, for example, destroy the normal regulatory capacity of the hypothalamic thermostat. When the thermoregulatory mechanisms are not functional, lethal hyperthermia may occur very rapidly. Normal metabolism produces enough heat to kill a per-

son in less than 5 hours if the heat-loss mechanisms are completely shut down. Exposure to severe, prolonged heat stress can also break down the function of hypothalamic thermoregulation (see the accompanying boxed feature, Concepts, Challenges, and Controversies.)

1. Describe the mechanisms of heat transfer.

2. Make a chart comparing the responses initiated by the posterior hypothalamus and the anterior hypothalamus to maintain core body temperature when the environmental temperature becomes cold or hot.

3. Define *thermoneutral zone.*

Homeostasis: Chapter in Perspective

Because energy can be neither created nor destroyed, for body weight and body temperature to remain constant, input must equal output in the case of, respectively, the body's total energy balance and its heat energy balance. If total energy input exceeds total energy output, the extra energy is stored in the body and body weight increases. Similarly, if the input of heat energy exceeds its output, body temperature increases. Conversely, if output exceeds input, body weight decreases or body temperature falls. The hypothalamus is the major integrating center for maintaining both a constant total energy balance (and thus a constant body weight) and a constant heat energy balance (and thus a constant body temperature).

Body temperature, which is one of the homeostatically regulated factors of the internal environment, must be maintained within narrow limits because the structure and reactivity of the chemicals that compose the body are temperature

sensitive. Deviations in body temperature outside a limited range result in protein denaturation and death of the individual if the temperature rises too high or metabolic slowing and death if the temperature falls too low.

Body weight, in contrast, varies widely among individuals. Only the extremes of imbalances between total energy input and total energy output become incompatible with life. For example, in the face of insufficient energy input in the form of ingested food during prolonged starvation, the body resorts to breaking down muscle protein to meet its needs for energy expenditure once the adipose stores are depleted. Body weight dwindles because of this self-cannibalistic mechanism until death finally occurs as a result of loss of heart muscle, among other things. At the other extreme, when the food energy consumed greatly exceeds the energy expended, the extra energy input is stored as adipose tissue and body weight increases. The resultant gross obesity can also lead to heart failure. Not only must the heart work harder to pump blood to the excess adipose tissue, but obesity also predisposes the person to atherosclerosis and heart attacks (see p. 327).

Review Exercises Answers begin on p. A-47

Reviewing Terms and Facts

1. If more food energy is consumed than is expended, the excess energy is lost as heat. *(True or false?)*

2. All energy within nutrient molecules can be harnessed to perform biological work. *(True or false?)*

3. Each liter of O_2 contains 4.8 kcal of heat energy. *(True or false?)*

4. A body temperature greater than 98.2°F is always indicative of a fever. *(True or false?)*

5. Core temperature is relatively constant, but skin temperature can vary markedly. *(True or false?)*

6. Sweat that drips off the body has no cooling effect. *(True or false?)*

7. Production of "goose bumps" has no value in regulating body temperature. *(True or false?)*

8. The posterior region of the hypothalamus triggers shivering and skin vasoconstriction. *(True or false?)*

9. The hypothalamus is not effective in regulating body temperature during a fever. *(True or false?)*

10. The _____ of the hypothalamus contains two populations of neurons, one that secretes appetite-enhancing NPY and another that secretes appetite-suppressing melanocortins.

11. The primary means of involuntarily increasing heat production is _____.

12. Increased heat production independent of muscle contraction is known as _____.

13. The only means of heat loss when the environmental temperature exceeds the core temperature is _____.

14. Which of the following statements concerning heat exchange between the body and the external environment is *incorrect?*

   a. Heat gain is primarily by means of internal heat production.

   b. Radiation serves as a means of heat gain but not of heat loss.

   c. Heat energy always moves down its concentration gradient from warmer to cooler objects.

   d. The temperature gradient between the skin and the external air is subject to control.

   e. Little body heat is lost by conduction alone.

15. Using the answer code on the right, indicate which mechanism of heat transfer is being described:

   1. sitting on a cold metal chair   (a) radiation
   2. sunbathing on the beach   (b) conduction
   3. being in a gentle breeze   (c) convection
   4. sitting in front of a fireplace   (d) evaporation
   5. sweating
   6. riding in a car with the windows open
   7. lying under an electric blanket
   8. sitting in a wet bathing suit
   9. fanning yourself
   10. immersing yourself in cold water

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Differentiate between external work and internal work.

2. Define *metabolic rate* and *basal metabolic rate*.

3. Describe the three states of energy balance.

4. By what means is energy balance primarily maintained?

5. Describe the source and role of the following in long-term regulation of energy balance and short-term control of the timing and size of meals: neuropeptide Y, melanocortins, leptin, insulin, orexins, corticotropin-releasing hormone, ghrelin, peptide YY_{3-36}, cholecystokinin, and stomach distension.

6. List the sources of heat input and heat output for the body.

7. Discuss the compensatory measures that occur in response to a fall in core temperature as a result of cold exposure and in response to a rise in core temperature as a result of heat exposure.

8. Describe the sequence of events in fever production.

Solving Quantitative Exercises

1. The basal metabolic rate (BMR) is a measure of how much energy the body consumes to maintain its "idling speed." Normal BMR = about 72 kcal/hr. Most of this energy is converted to heat. Our thermoregulatory systems function to eliminate this heat to keep body temperature constant. If our bodies were not able to lose this heat, our temperature would rise until we boiled (of course, a person would die before reaching that temperature). It is relatively easy to calculate how long it would take to reach the hypothetical boiling point. If an amount of energy ΔU is put into a liquid of mass m, the temperature change ΔT (in °C) is given by the following formula:

$$\Delta T = \Delta U/m \times C$$

In this equation, C is the specific heat of the liquid. For water, $C = 1.0$ kcal/kg-°C. Calculate how long it would take for the heat from the BMR to boil your body fluids (assume 42 liters of water in your body and a starting point of normal body temperature at 37°C). When exercising maximally, a person consumes about 1000 kcal/hr. How long would it take to boil in this case?

Applying Clinical Reasoning

Michael F., a near-drowning victim, was pulled from the icy water by rescuers 15 minutes after he fell through thin ice when skating. Michael is now alert and recuperating in the hospital. How can you explain his "miraculous" survival even though he was submerged without breathing air for 15 minutes, yet irreversible brain damage, soon followed by death, normally occurs if the brain is deprived of O_2 for more than 4 or 5 minutes?

Thinking at a Higher Level

1. Explain how drugs that selectively inhibit cholecystokinin increase feeding behavior in experimental animals.

2. What advice would you give an overweight friend who asks for your help in designing a safe, sensible, inexpensive program for losing weight?

3. Why is it dangerous to engage in heavy exercise on a hot, humid day?

4. Describe the avenues for heat loss in a person soaking in a hot bath.

5. Consider the difference between you and a fish in a local pond with regard to control of body temperature. Humans are *thermoregulators*; they can maintain a remarkably constant, rather high internal body temperature despite the body's exposure to a range of environmental temperatures. To maintain thermal homeostasis, humans physiologically manipulate mechanisms within their bodies to adjust heat production, conservation, and loss. In contrast, fish are *thermoconformers*; their body temperatures conform to the temperature of their surroundings. Thus, their body temperatures vary capriciously with changes in the environmental temperature. Even though fish produce heat, they cannot physiologically regulate internal heat production, nor can they control heat exchange with their environment to maintain a constant body temperature when the temperature in their surroundings rises or falls. Knowing this, do you think fish run a fever when they have a systemic infection? Why or why not?

18 Principles of Endocrinology; The Central Endocrine Glands
A transmission electron micrograph of a growth hormone–producing cell in the anterior pituitary. Growth hormone, synthesized by the extensive endoplasmic reticulum (*thin, light blue, curved sacs*), is stored in numerous secretory vesicles (*blue-green circles*) until it is released by exocytosis into the blood on appropriate stimulation.

Biophoto Associates/Science Source

Homeostasis Highlights

The endocrine system regulates activities that require duration rather than speed. Endocrine glands release hormones, blood-borne chemical messengers that act on target cells located a long distance from the endocrine gland. Most target-cell activities under hormonal control are directed toward maintaining homeostasis. The **central endocrine glands**, which are in or closely associated with the brain, include the hypothalamus, the pituitary gland, and the pineal gland. The **hypothalamus** and **posterior pituitary gland** act as a unit to release hormones essential for maintaining water balance, for giving birth, and for breast-feeding. The hypothalamus also secretes regulatory hormones that control the hormonal output of the **anterior pituitary gland**, which secretes six hormones that, in turn, largely control the hormonal output of several peripheral endocrine glands. One anterior pituitary hormone, growth hormone, promotes growth and influences nutrient homeostasis. The **pineal gland** secretes a hormone important in establishing the body's biological rhythms.

18.1 General Principles of Endocrinology

The endocrine system consists of the ductless endocrine glands (see p. 6) scattered throughout the body (I Figure 18-1). Even though the endocrine glands for the most part are not connected anatomically, they constitute a system in a functional sense. They all accomplish their functions by secreting hormones into the blood, and many functional interactions take place among various endocrine glands. Once secreted, a hormone travels in the blood to its distant target cells, where it regulates a particular function (see p. 113). **Endocrinology** is the study of the homeostatic chemical adjustments and other activities that hormones accomplish.

Even though the blood distributes hormones throughout the body, only specific target cells can respond to each hormone

because only the target cells have receptors for binding with the particular hormone. Binding of a hormone with its specific target-cell receptors initiates a chain of events within the target cells to bring about the hormone's final effect.

Recall that the means by which a hormone brings about its ultimate physiologic effect depends on whether the hormone is hydrophilic (peptide hormones, catecholamines, and indoleamines) or lipophilic (steroid hormones and thyroid hormone). *Peptide hormones,* the most abundant chemical category of hormone, are chains of amino acids of varying length. *Catecholamines,* produced by the adrenal medulla, are derived from the amino acid tyrosine. *Indoleamines* are produced by the pineal gland and are derived from the amino acid tryptophan. *Steroid hormones,* produced by the adrenal cortex and reproductive endocrine glands, are neutral lipids derived from cholesterol. *Thyroid hormone,* produced by the thyroid gland, is an iodinated tyrosine derivative. To review, hydrophilic

hormones on binding with surface membrane receptors primarily act through second-messenger systems to alter the activity of preexisting proteins, such as enzymes, within the target cell to produce their physiologic response. Lipophilic steroid hormones and thyroid hormone, by contrast, activate genes on binding with receptors inside the cell, thus bringing about formation of new proteins in the target cell that carry out the desired response. Hydrophilic hormones circulate in the blood largely dissolved in the plasma, whereas lipophilic hormones are largely bound to plasma proteins. (See pp. 120–127 for further detail.)

Hormones exert a variety of regulatory effects throughout the body.

The endocrine system is one of the body's two major regulatory systems, the other being the nervous system, with which you are already familiar (Chapters 4 through 7). In general, the nervous system coordinates rapid, precise responses and is especially important in mediating the body's interactions with the external environment. The endocrine system primarily controls processes that require duration rather than speed, most of which are aimed at maintaining homeostasis, such as regulating nutrient metabolism and water and electrolyte balance; promoting growth; and facilitating reproductive capacity. Furthermore, the endocrine system works along with the autonomic nervous system to control and integrate activities of both the circulatory and the digestive systems.

Tropic Hormones Some hormones regulate the production and secretion of another hormone. A hormone that has as its primary function the regulation of hormone secretion by another endocrine gland is classified functionally as a **tropic hormone** (*tropic* means "nourishing" and is pronounced "trō-pik"). Tropic hormones not only stimulate but also maintain the structure of their endocrine target tissues. A tropic hormone's actions aimed at maintaining the structural integrity of its target gland are specifically known as *trophic* (growth promoting) actions, similar to the effects of the GI hormones in maintaining functionally viable digestive organs (see pp. 586 and 592), but for convenience we link these terms together under the common umbrella term *tropic*. For example, thyroid-stimulating hormone (TSH), a tropic hormone from the anterior pituitary, stimulates thyroid hormone secretion by the thyroid gland and maintains the structural integrity of this gland. In the absence of TSH, the thyroid gland atrophies (shrinks) and produces very low levels of its hormones.

Complexity of Endocrine Function The following factors add to the complexity of the endocrine system:

■ A single endocrine gland may produce multiple hormones. The anterior pituitary, for example, secretes six different hormones, each under a different control mechanism and having distinct functions.

■ A single hormone may be secreted by more than one endocrine gland. For example, both the hypothalamus and pancreas

secrete the hormone somatostatin, and somatostatin acts as a paracrine in the stomach.

■ Frequently, a single hormone has more than one type of target cell and therefore can induce more than one type of effect, typically by binding with different subtypes of receptors. For example, vasopressin promotes H_2O reabsorption by the kidney tubules by binding with V_2 (vasopressin 2) receptors on the distal and collecting tubular cells and causes vasoconstriction of arterioles throughout the body by binding with V_1 receptors on arteriolar smooth muscle. Sometimes hormones that have multiple target-cell types can coordinate and integrate the activities of various tissues toward a common end. For example, the effects of insulin on muscle, liver, and fat all act in concert to store nutrients after absorption of a meal.

■ The rate of secretion of some hormones varies considerably over the course of time in a cyclic pattern. Therefore, endocrine systems also provide temporal (time) coordination of function. This is particularly apparent in endocrine control of reproductive cycles, such as the menstrual cycle, in which normal function requires highly specific patterns of change in the secretion of various hormones.

■ A single target cell may be influenced by more than one hormone. Some cells contain an array of receptors for responding in different ways to different hormones. To illustrate, insulin promotes the conversion of glucose into glycogen within liver cells by stimulating one particular hepatic enzyme, whereas another hormone, glucagon, by activating yet another hepatic enzyme, enhances the degradation of glycogen into glucose within liver cells.

■ The same chemical messenger may be either a hormone or a neurotransmitter, depending on its source and mode of delivery to the target cell. Norepinephrine, which is secreted as a hormone by the adrenal medulla and released as a neurotransmitter from sympathetic postganglionic nerve fibers, is a prime example.

■ Some organs are solely endocrine in function (they specialize in hormone secretion alone, the anterior pituitary being an example), whereas other organs of the endocrine system perform nonendocrine functions, in addition to secreting hormones. For example, the testes produce sperm and secrete the male sex hormone testosterone.

The effective plasma concentration of a hormone is influenced by the hormone's secretion, peripheral conversion, transport, inactivation, and excretion.

The primary function of most hormones is regulation of various homeostatic activities. Because hormones' effects are proportional to their concentrations in the plasma, these concentrations are subject to control according to homeostatic need. Furthermore, the magnitude of the hormonal response depends on the availability and sensitivity of the target cells' receptors for the hormone. We examine the factors that influence the plasma concentration of hormones before turning to the target cells' responsiveness to hormones.

The **effective plasma concentration** of the free, biologically active form of a hormone—and thus the hormone's availability to its receptors—depends on several factors:

- *The hormone's rate of secretion into the blood by the endocrine gland.* The rate of secretion, a factor that increases the plasma concentration of the hormone, is subject to control to maintain the hormone concentration at a desired set point.

- *For a few hormones, its rate of metabolic activation or conversion.* After being secreted into the blood by the endocrine gland, lipophilic hormones in particular are often modified in other organs. Sometimes this peripheral (away from the endocrine gland) modification results in a more active form of the hormone. For example, the most abundant form of thyroid hormone secreted by the thyroid gland is thyroxine (which contains four iodines), but the most powerful form of thyroid hormone in the blood is tri-iodothyronine (which contains three iodines). Once secreted, thyroxine is converted to the more active form as a result of one of its iodines being stripped peripherally, primarily by the liver and kidneys. Usually the rate of such hormone activation is itself under hormonal control. Sometimes peripheral action actually converts one hormone into a functionally different hormone. For example, a small proportion of testosterone, a potent male sex hormone, is converted peripherally by action of the enzyme *aromatase* in adipose tissue and elsewhere into estrogen, a potent female sex hormone.

- *For lipophilic hormones, its extent of binding to plasma proteins.* Because lipophilic hormones are poorly soluble in water, they circulate in the plasma bound to specific plasma proteins. Only the small, unbound portion of the hormone is free to interact with its target cells. The magnitude of this free pool rather than the total pool of hormone is monitored and adjusted to maintain normal endocrine function.

- *Its rate of removal from the blood by metabolic inactivation and excretion in the urine.* All hormones are eventually inactivated by enzymes in the liver, kidneys, blood, or target cells. The amount of time after a hormone is secreted before it is inactivated, and the means by which this takes place, differ for different classes of hormones. Hydrophilic peptides most commonly are inactivated by hydrolysis of peptide bonds (see p. 569). In the case of some peptide hormones, such as insulin, the target cell actually engulfs the bound hormone by receptor-mediated endocytosis and degrades it intracellularly (see p. 31). Catecholamines are enzymatically converted to related biologically inactive molecules. Lipophilic steroid hormones and thyroid hormone are inactivated by alteration of the active portion of the molecule by various biochemical means. After lipophilic hormones are inactivated, the liver typically adds charged groups to make them more water soluble so that they are freed from their plasma protein carriers and eliminated in the urine.

In general, the hydrophilic peptides and catecholamines are easy targets for blood and tissue enzymes, so they remain in the blood only briefly (a few minutes to a few hours) before being enzymatically inactivated. In contrast, binding of lipophilic hormones to plasma proteins makes them less vulnerable to metabolic inactivation and keeps them from escaping into the urine. Therefore, lipophilic hormones are removed from plasma more slowly: They may persist in the blood for hours (steroids) or up to a week (thyroid hormone).

Hormones and their metabolites are typically eliminated from the plasma by urinary excretion. In contrast to the tight controls on hormone secretion, hormone inactivation and excretion are not regulated.

The effective plasma concentration of a hormone is normally regulated by changes in the rate of its secretion.

Normally, the effective plasma concentration of a hormone is regulated by appropriate adjustments in the rate of its secretion. Endocrine glands do not secrete their hormones at a constant rate; the secretion rates of all hormones vary, subject to control often by a combination of several complex mechanisms. The regulatory system for each hormone is considered in detail in later sections. For now, we address these general mechanisms of controlling secretion that are common to many different hormones: negative-feedback control, neuroendocrine reflexes, and diurnal (circadian) rhythms.

Negative-Feedback Control Negative feedback is a prominent feature of hormonal control systems. Stated simply, *negative feedback exists when the output of a system counteracts a change in input,* maintaining a controlled variable within a narrow range around a desired level, or set point (see p. 16). Negative feedback maintains the plasma concentration of a hormone at a given level, like a home heating system maintains the room temperature at a given set point. For example, when the plasma concentration of free circulating thyroid hormone falls below a given set point, the anterior pituitary secretes thyroid-stimulating hormone (TSH), which stimulates the thyroid to increase its secretion of thyroid hormone. Thyroid hormone, in turn, inhibits further secretion of TSH by the anterior pituitary. Negative feedback ensures that once thyroid gland secretion has been "turned on" by TSH, it will not continue unabated but will be "turned off" when the appropriate level of free circulating thyroid hormone has been achieved. Thus, the effect of a particular hormone's actions can inhibit its own secretion. The feedback loops often become quite complex.

Neuroendocrine Reflexes Many endocrine control systems involve **neuroendocrine reflexes**, which include neural as well as hormonal components. The purpose of such reflexes is to produce a sudden increase in hormone secretion (that is, "turn up the thermostat setting") in response to a specific stimulus, frequently a stimulus external to the body. In some instances, neural input to the endocrine gland is the only factor regulating secretion of the hormone. For example, secretion of epinephrine by the adrenal medulla is solely controlled by the sympathetic nervous system. Some endocrine control systems, in contrast, include both feedback control (which maintains a constant basal level of the hormone) and neuroendocrine reflexes (which cause sudden bursts in secretion in response to a sudden increased need for the hormone). An example is the increased secretion of

cortisol, the "stress hormone," by the adrenal cortex during a stress response (see ▌Figure 19-9, p. 675).

Diurnal (Circadian) Rhythms The secretion rates of many hormones rhythmically fluctuate up and down as a function of time. The most common endocrine rhythm is the **diurnal** ("day–night"), or **circadian** ("around a day") **rhythm**, which is characterized by repetitive oscillations in hormone levels that are very regular and cycle once every 24 hours. This rhythmicity is caused by endogenous oscillators whose activity level autonomously rises and falls, similar to the self-paced respiratory neurons in the brain stem that control the rhythmic motions of breathing, except the timekeeping oscillators cycle on a much longer time scale. Furthermore, unlike the rhythmicity of breathing, endocrine rhythms are locked on, or **entrained**, to external cues such as the light–dark cycle. That is, the inherent 24-hour cycles of peak and ebb of hormone secretion are set to "march in step" with cycles of light and dark. For example, cortisol secretion rises during the night, reaches its peak secretion in the morning before a person gets up, then falls throughout the day to its lowest level at bedtime (▌Figure 18-2). Inherent hormonal rhythmicity and entrainment are not accomplished by the endocrine glands themselves but result from the central nervous system changing the set point of these glands. We discuss the master biological clock further in a later section. Negative-feedback control mechanisms operate to maintain whatever set point is established for that time of day. Some endocrine cycles operate on time scales other than a circadian rhythm, a well-known example being the monthly menstrual cycle.

Endocrine disorders result from hormone excess or deficiency or decreased target-cell responsiveness.

Clinical Note Abnormalities in a hormone's effective plasma concentration can arise from a variety of factors (▌Table 18-1). Endocrine disorders most commonly result from abnormal plasma concentrations of a hormone caused by inappropriate rates of secretion—that is, too little hormone secreted (**hyposecretion**) or too much hormone secreted (**hypersecretion**). Occasionally, endocrine dysfunction arises because target-cell respon-
▌Figure 18-2 **Diurnal rhythm of cortisol secretion.**

▌TABLE 18-1 Means by Which Endocrine Disorders Can Arise	
Too Little Hormone Activity	**Too Much Hormone Activity**
Too little hormone secreted by the endocrine gland (hyposecretion)*	Too much hormone secreted by the endocrine gland (hypersecretion)*
Increased removal of the hormone from the blood	Reduced plasma protein binding of the hormone (too much free, biologically active hormone)
Abnormal tissue responsiveness to the hormone	Decreased removal of the hormone from the blood
Lack of target-cell receptors	Decreased inactivation
Lack of an enzyme essential to the target-cell response	Decreased excretion

*Most common causes of endocrine dysfunction.

siveness to the hormone is abnormally low, even though plasma concentration of the hormone is normal.

Hyposecretion *Primary hyposecretion* occurs when an endocrine gland is secreting too little of its hormone because of an abnormality within that gland. *Secondary hyposecretion* takes place when an endocrine gland is normal but is secreting too little hormone because of a deficiency of its tropic hormone.

The following are among the many different factors (each listed with an example) that may cause primary hyposecretion: (1) genetic (inborn absence of an enzyme that catalyzes synthesis of the hormone, such as the inability to synthesize cortisol because of the lack of a specific enzyme in the adrenal cortex); (2) dietary (lack of iodine, which is needed for synthesis of thyroid hormone); (3) chemical or toxic (certain insecticide residues may destroy the adrenal cortex); (4) immunologic (autoimmune antibodies sometimes destroy thyroid tissue); (5) other disease processes (cancer or tuberculosis may coincidentally destroy endocrine glands); (6) *iatrogenic* (physician induced, such as surgical removal of a cancerous thyroid gland); and (7) *idiopathic* (meaning the cause is not known).

Hypersecretion Like hyposecretion, hypersecretion by a particular endocrine gland is designated as primary or secondary depending on whether the defect lies in that gland or results from excessive stimulation from the outside, respectively. Hypersecretion may be caused by (1) tumors that ignore the normal regulatory input and continuously secrete excess hormone and (2) immunologic factors, such as excessive stimulation of the thyroid gland by an abnormal antibody that mimics the action of TSH. Excessive levels of a particular hormone may also arise from substance abuse, such as the outlawed practice among athletes of using certain steroids that increase muscle mass by promoting protein synthesis in muscle cells (see p. 276).

Abnormal Target-Cell Responsiveness Endocrine dysfunction can also occur because target cells do not respond

adequately to the hormone, even though the effective plasma concentration of a hormone is normal. This unresponsiveness may be caused, for example, by an inborn lack of receptors for the hormone, as in **testicular feminization syndrome**. In this condition, receptors for testosterone, a masculinizing hormone produced by the male testes, are not produced because of a specific genetic defect. Although adequate testosterone is available, masculinization does not take place, just as if no testosterone were present.

The responsiveness of a target cell can be varied by regulating the number of hormone-specific receptors.

In contrast to endocrine dysfunction caused by *unintentional* receptor abnormalities, the target-cell receptors for a particular hormone can be *deliberately altered* as a result of physiologic control mechanisms. A target cell's response to a hormone is correlated with the number of the cell's receptors occupied by molecules of that hormone, which in turn depends not only on the plasma concentration of the hormone but also on the number of receptors in the target cell for that hormone. Thus, the response of a target cell to a given plasma concentration can be fine-tuned up or down by varying the number of receptors available for hormone binding.

Down Regulation As an illustration of this fine-tuning, when the plasma concentration of insulin is chronically elevated, the total number of target-cell receptors for insulin is gradually reduced as a direct result of the effect a sustained elevation of insulin has on the insulin receptors. This phenomenon, known as **down regulation**, constitutes an important locally acting negative-feedback mechanism that prevents the target cells from overreacting to a prolonged high concentration of insulin—that is, the target cells are *desensitized* to insulin, helping blunt the effect of insulin hypersecretion.

Down regulation of insulin is accomplished by the following mechanism. The binding of insulin to its surface receptors first triggers the dictated cellular response, then induces receptor-mediated endocytosis of the hormone receptor complex, which is subsequently attacked by intracellular lysosomal enzymes (see p. 30). This internalization serves a twofold purpose: It provides a pathway for degrading the hormone after it has exerted its effect and helps regulate the number of receptors available for binding on the target cell's surface. At high plasma insulin concentrations, the number of surface receptors for insulin is gradually reduced by the accelerated rate of receptor internalization and degradation brought about by increased hormonal binding. The rate of synthesis of new receptors within the endoplasmic reticulum and their insertion in the plasma membrane do not keep pace with their rate of destruction. Over time, this self-induced loss of target-cell receptors for insulin reduces the target cell's sensitivity to the elevated hormone concentration.

Permissiveness, Synergism, and Antagonism A given hormone's effects are influenced not only by the concentration of the hormone itself but also by the concentra-

tions of other hormones that interact with it. Because hormones are widely distributed through the blood, target cells may be exposed simultaneously to many different hormones, giving rise to numerous hormonal interactions on target cells. Hormones frequently alter the receptors for other kinds of hormones as part of their normal activity. A hormone can influence the activity of another hormone at a given target cell in one of three ways: permissiveness, synergism, and antagonism.

With **permissiveness**, one hormone must be present in adequate amounts to "permit" another hormone to exert its full effect. The first hormone enhances a target cell's responsiveness to the second hormone by increasing the number of receptors for the second hormone. For example, thyroid hormone increases the number of receptors for epinephrine in epinephrine's target cells, increasing the effectiveness of epinephrine. In the absence of thyroid hormone, epinephrine is only marginally effective.

Synergism occurs when the actions of several hormones are complementary and their combined effect is greater than the sum of their separate effects. An example is the synergistic action of follicle-stimulating hormone and testosterone, both of which are needed to maintain the normal rate of sperm production. Synergism results from each hormone's influence on the number or affinity (attraction) of receptors for the other hormone.

Antagonism occurs when one hormone causes the loss of another hormone's receptors, reducing the effectiveness of the second hormone. To illustrate, progesterone (a hormone secreted during pregnancy that decreases contractions of the uterus) inhibits uterine responsiveness to estrogen (another hormone secreted during pregnancy that increases uterine contractions). By causing loss of estrogen receptors on uterine smooth muscle, progesterone prevents estrogen from exerting its excitatory effects during pregnancy and thus keeps the uterus as a quiet (noncontracting) environment suitable for the developing fetus.

This has been a brief overview of the general features of the endocrine system. ▌Table 18-2 on pp. 644–645 summarizes the most important specific functions of the major hormones. As extensive as the table appears, it leaves out a variety of "candidate" hormones whose hormonal status has not yet been conclusively documented. Furthermore, new hormones are likely to be discovered, and additional functions may be found for known hormones. As an example, vasopressin's role in conserving H_2O during urine formation was determined first, followed later by the discovery of its constrictor effect on arterioles. More recently, vasopressin has also been found to play roles in fever, learning, memory, and behavior.

Some of the hormones listed in the table have been introduced elsewhere and are not discussed further; these are the renal hormones (erythropoietin in Chapter 11 and renin in Chapter 14), the hepatic hormones (thrombopoietin in Chapter 11 and hepcidin in Chapter 16), thymosin from the thymus (Chapter 12), atrial and brain natriuretic peptides from the heart (Chapter 14), the gastrointestinal (GI) hormones (Chapter 16), leptin and other adipokines from adipose tissue (Chapter 17), and hunger and satiety signals from the diges-

Endocrine Gland	Hormones	Target Cells	Major Functions of Hormones
Hypothalamus	Releasing and inhibiting hormones (TRH, CRH, GnRH, GHRH, somatostatin, PrRP, dopamine)	Anterior pituitary	Control release of anterior pituitary hormones
Posterior pituitary (hormones stored in)	Vasopressin (antidiuretic hormone, ADH)	Kidney tubules	Increases H_2O reabsorption
		Arterioles	Produces vasoconstriction
	Oxytocin	Uterus	Increases contractility
		Mammary glands (breasts)	Causes milk ejection
Anterior pituitary	Thyroid-stimulating hormone (TSH)	Thyroid follicular cells	Stimulates T_3 and T_4 secretion
	Adrenocorticotropic hormone (ACTH)	Zona fasciculata and zona reticularis of the adrenal cortex	Stimulates cortisol secretion
	Growth hormone (GH)	Bone and soft tissues	Is essential but not solely responsible for growth and exerts metabolic effects. By means of IGF-I, indirectly stimulates growth of bones and soft tissues; directly stimulates protein synthesis, mobilizes fat, and conserves glucose
		Liver	Stimulates IGF-I secretion
	Follicle-stimulating hormone (FSH)	Females: Ovarian follicles	Promotes follicular growth and development; stimulates estrogen secretion
		Males: Seminiferous tubules in testes	Stimulates sperm production
	Luteinizing hormone (LH)	Females: Ovarian follicle and corpus luteum	Stimulates ovulation, corpus luteum development, and estrogen and progesterone secretion
		Males: Interstitial cells of Leydig in testes	Stimulates testosterone secretion
	Prolactin (PRL)	Females: Mammary glands	Promotes breast development; stimulates milk secretion
		Males	Uncertain
Pineal gland	Melatonin	Brain, anterior pituitary, reproductive organs, and possibly others	Entrains body's biological rhythm with external cues; inhibits gonadotropins; its reduction likely initiates puberty; acts as an antioxidant
Thyroid gland follicular cells	Tetraiodothyronine (T_4, thyroxine); tri-iodothyronine (T_3)	Most cells	Increases metabolic rate; is essential for normal growth and nerve development
Thyroid gland C cells	Calcitonin	Bone	Decreases plasma Ca^{2+} concentration
Adrenal cortex			
Zona glomerulosa	Aldosterone (mineralocorticoid)	Kidney tubules	Increases Na^+ reabsorption and K^+ secretion
Zona fasciculata and zona reticularis	Cortisol (glucocorticoid)	Most cells	Increases blood glucose at the expense of protein and fat stores; contributes to stress adaptation
	Androgens (dehydroepiandrosterone)	Females: Hair follicles and brain	Promotes axillary and pubic hair growth and sex drive
Adrenal medulla	Epinephrine and norepinephrine	Sympathetic receptor sites throughout the body	Reinforce sympathetic nervous system; contribute to stress adaptation and blood pressure regulation

Endocrine Gland	Hormones	Target Cells	Major Functions of Hormones
Endocrine pancreas (islets of Langerhans)	Insulin (β cells)	Most cells	Promotes cellular uptake, use, and storage of absorbed nutrients
	Glucagon (α cells)	Most cells	Is important for maintaining nutrient levels in blood during the postabsorptive state
	Somatostatin (D cells)	Digestive system	Inhibits digestion and absorption of nutrients
Parathyroid gland	Parathyroid hormone (PTH)	Bone, kidneys, and intestine	Increases plasma Ca^{2+} and decreases plasma PO_4^{3-} concentrations; stimulates vitamin D activation
Female gonads: Ovaries	Estrogen (estradiol)	Female sex organs and body as a whole	Promotes follicular development; governs development of female secondary sexual characteristics; stimulates uterine and breast growth
		Bone	Enhances pubertal growth spurt; promotes closure of the epiphyseal plate
	Progesterone	Uterus	Prepares for pregnancy
Male gonads: Testes	Testosterone	Male sex organs and body as a whole	Stimulates sperm production; governs development of male secondary sexual characteristics; promotes sex drive
		Bone	Enhances pubertal growth spurt; promotes closure of the epiphyseal plate
Testes and ovaries	Inhibin	Anterior pituitary	Inhibits secretion of FSH
Placenta	Estrogen (estriol) and progesterone	Female sex organs	Help maintain pregnancy; prepare breasts for lactation
	Human chorionic gonadotropin (hCG)	Ovarian corpus luteum	Maintains corpus luteum of pregnancy
Kidneys	Renin (by activating angiotensin)	Zona glomerulosa of adrenal cortex (acted on by angiotensin, which is activated by renin)	Stimulates aldosterone secretion; angiotensin II is also a potent vasoconstrictor and stimulates thirst
	Erythropoietin	Bone marrow	Stimulates erythrocyte production
Stomach	Ghrelin	Hypothalamus	Signals hunger; stimulates appetite
	Gastrin	Digestive tract exocrine glands and smooth muscles; pancreas; liver; gallbladder	Control motility and secretion to facilitate digestive and absorptive processes
Small intestine	Secretin and cholecystokinin (CCK)		
	Glucose-dependent insulinotropic peptide (GIP)	Endocrine pancreas	Stimulates insulin secretion
	Peptide YY_{3-36}	Hypothalamus	Signals satiety; suppresses appetite
Liver	Insulin-like growth factor I (IGF-I)	Bone and soft tissues	Promotes growth
	Thrombopoietin	Bone marrow	Stimulates platelet production
	Hepcidin	Intestine	Inhibits iron absorption into blood
Skin	Vitamin D	Intestine	Increases absorption of ingested Ca^{2+} and PO_4^{3-}
Thymus	Thymosin	T lymphocytes	Enhances T lymphocyte proliferation and function
Heart	Atrial and brain natriuretic peptides (ANP; BNP)	Kidney tubules	Inhibit Na^+ reabsorption
Adipose tissue	Leptin	Hypothalamus	Suppresses appetite; is important in long-term control of body weight
	Other adipokines	Multiple sites	Play a role in metabolism and inflammation

tive tract (Chapter 17). The remainder of the hormones are described in greater detail in this and the next two chapters. We start in this chapter with the central endocrine glands—those in the brain or in close association with the brain—namely, the hypothalamus, the pituitary gland, and the pineal gland. The peripheral endocrine glands are discussed in the following chapters.

Check Your Understanding 18.1

1. Def ne *tropic hormone*.
2. Describe the three general mechanisms of controlling hormone secretion that are common to many different hormones.
3. Explain down regulation, permissiveness, synergism, and antagonism.

18.2 Hypothalamus and Pituitary

The **pituitary gland**, or **hypophysis**, is a small endocrine gland located in a bony cavity at the base of the brain just below the hypothalamus (❙Figure 18-3). The pituitary is connected to the hypothalamus by a thin connecting stalk. If you point one finger between your eyes and another finger toward one of your ears, the imaginary point where these lines would intersect is about where your pituitary is located.

The pituitary gland consists of anterior and posterior lobes.

The pituitary has two anatomically and functionally distinct lobes, the **posterior pituitary** and the **anterior pituitary** (❙Figure 18-3). The posterior pituitary is composed of nervous tissue and thus is also termed the **neurohypophysis**. The anterior pituitary consists of glandular epithelial tissue and accordingly is also called the **adenohypophysis** (*adeno* means "glandular"). The posterior and anterior pituitary lobes have only their location in common. They arise from different tissues embryonically, serve different functions, and are subject to different control mechanisms.

The release of hormones from both the posterior and the anterior pituitary is directly controlled by the hypothalamus, but the natures of these relationships are entirely different. The posterior pituitary connects to the hypothalamus by a neural pathway, whereas the anterior pituitary connects to the hypothalamus by a unique vascular link. We look first at the posterior pituitary.

The hypothalamus and posterior pituitary act as a unit to secrete vasopressin and oxytocin.

The hypothalamus and posterior pituitary form a neuroendocrine system that consists of a population of neurosecretory neurons whose cell bodies lie in two well-defined clusters in the hypothalamus, the **supraoptic nucleus** and the **paraventricular nucleus**. The axons of these neurons pass down through the connecting stalk to terminate on capillaries in the posterior pituitary (❙Figure 18-4). The posterior pituitary consists of these neuronal terminals plus glial-like supporting cells known as **pituicytes**. Functionally and anatomically, the posterior pituitary is simply an extension of the hypothalamus.

The posterior pituitary does not actually produce any hormones. It simply stores and, on appropriate stimulation, releases into the blood two small peptide hormones, *vasopressin* and *oxytocin*, which are synthesized by the neuronal cell bodies in the hypothalamus. These hydrophilic peptides are made in both the supraoptic and paraventricular nuclei, but a single neuron can produce only one of these hormones. The synthesized hormones are packaged in secretory granules (secretory vesicles) that are transported by motor proteins down the cytoplasm of the axon (see p. 48) and stored in the neuronal terminals within the posterior pituitary. Each terminal stores either vasopressin or oxytocin. Thus, these hormones can be released independently as needed. On stimulatory input to the hypothalamus, either vasopressin or oxytocin is released into the systemic blood from the posterior pituitary by exocytosis of the appropriate secretory granules. This hormonal release is triggered in

Nephrons in kidneys	Arterioles throughout body	Uterus	Mammary glands

Increases permeability of distal and collecting tubules to H_2O	Causes vasoconstriction	Stimulates uterine contractions	Stimulates milk ejection during breast-feeding

1 The paraventricular and supraoptic nuclei both contain neurons that produce vasopressin and oxytocin. The hormone, either vasopressin or oxytocin depending on the neuron, is synthesized in the neuronal cell body in the hypothalamus.

2 The hormone travels down the axon to be stored in the neuronal terminals within the posterior pituitary.

3 When the neuron is excited, the stored hormone is released from the terminals into the systemic blood for distribution throughout the body.

❙Figure 18-4 Relationship of the hypothalamus and posterior pituitary.

response to action potentials that originate in the hypothalamic cell body and sweep down the axon to the neuronal terminal in the posterior pituitary. As in any other neuron, action potentials are generated in these neurosecretory neurons in response to synaptic input to their cell bodies.

The actions of vasopressin and oxytocin are briefly summarized here to make our endocrine story complete. They are described more thoroughly elsewhere—vasopressin in Chapters 14 and 15 and oxytocin in Chapter 20.

Vasopressin Vasopressin (antidiuretic hormone, ADH) has two major effects that correspond to its two names: (1) it conserves H_2O during urine formation by the kidney nephrons (an antidiuretic effect) and (2) it causes contraction of arteriolar smooth muscle (a vessel pressor effect). The first effect has more physiologic importance. Under normal conditions, vasopressin is the primary endocrine factor that regulates urinary H_2O loss and overall H_2O balance. In contrast, typical levels of vasopressin play only a minor role in regulating blood pressure by means of promoting arteriolar vasoconstriction.

The major control for hypothalamic-induced release of vasopressin from the posterior pituitary is input from hypothalamic osmoreceptors, which increase vasopressin secretion in response to a rise in plasma osmolarity. A less powerful input from the left atrial volume receptors increases vasopressin secretion in response to a fall in ECF volume and arterial blood pressure (see p. 545). (For further information on the importance of vasopressin secretion when exercising in the heat, see the boxed feature on p. 648, ❙A Closer Look at Exercise Physiology.)

Oxytocin Oxytocin stimulates contraction of uterine smooth muscle to help expel the infant during childbirth, and it promotes ejection of milk from the mammary glands (breasts) during breast-feeding. Appropriately, oxytocin secretion is increased by reflexes that originate within the birth canal during childbirth and by reflexes that are triggered when the infant suckles the breast.

In addition to these two major physiologic effects, oxytocin influences a variety of behaviors, especially maternal behaviors. For example, this hormone fittingly facilitates bonding, or attachment, between a mother and her infant. For this reason, oxytocin is sometimes nicknamed the "love hormone" or "cuddle chemical." Recent studies suggest that oxytocin may play a role in other types of close human attachment, such as helping bond couples to one another.

Most anterior pituitary hormones are tropic.

Unlike the posterior pituitary, which releases hormones synthesized by the hypothalamus, the anterior pituitary synthesizes the hormones it releases into the blood. Five different cell populations within the anterior pituitary secrete six major peptide hormones. The actions of each of these hormones are described in detail in later sections. For now, this brief statement of their source and primary effects provides a rationale for their names (❙Figure 18-5):

1. The anterior pituitary cells known as **somatotropes** secrete **growth hormone (GH, somatotropin)**, the primary hormone responsible for regulating overall body growth (*somato* means "body"). GH also exerts important metabolic actions.

2. **Thyrotropes** secrete **thyroid-stimulating hormone (TSH, thyrotropin)**, which stimulates secretion of thyroid hormone and growth of the thyroid gland.

The Endocrine Response to the Challenge of Combined Heat and Marching Feet

WHEN ONE EXERCISES IN A hot environment, maintaining plasma volume becomes a critical homeostatic concern. Exercise in the heat results in losing large amounts of fluid through sweating. Simultaneously, blood is needed for shunting to the skin for cooling and for increased blood flow to nourish the working muscles. To maintain cardiac output, venous return must also be adequate. The hypothalamus–posterior pituitary neurosecretory system responds to these multiple, conflicting needs for fluid by releasing water-conserving vasopressin, reducing urinary fluid loss to preserve plasma volume.

Studies have generally shown that exercise in heat stimulates vasopressin release, which results in decreased urinary fluid loss. In one study conducted during an 18-mile road march in heat, the partici-

pants' average urine output dropped to 134 mL (normal urine output during the same time period would be about 2 ½ times that much), whereas sweat loss averaged 4 liters. Overhydration before exercise appears to decrease the intensity of this response, suggesting that increased vasopressin release is related to plasma osmolarity. If lost fluid is not adequately replaced, plasma osmolarity increases. When the hypothalamic osmoreceptors detect this hypertonic condition, they promote increased secretion of vasopressin from the posterior pituitary. Some investigators believe, however, that increased vasopressin release results from other factors, such as changes in blood pressure or renal blood flow. Regardless of the mechanism, vasopressin release is an important physiologic response to exercise in heat.

3. **Corticotropes** produce and release **adrenocorticotropic hormone (ACTH, adrenocorticotropin)**, the hormone that stimulates cortisol secretion by and promotes growth of the adrenal cortex.

ACTH is synthesized as part of a large precursor molecule known as **pro-opiomelanocortin (POMC)**. POMC can be cleaved into three active products: *ACTH, melanocyte-stimulating hormone (MSH)*, and *endorphin*. Several diverse cell types produce POMC and slice it in unique ways, depending on the processing enzymes they possess, to yield different active products, along with peptide "scraps" that have no known function. For example, as their major active product from this same precursor molecule, corticotropes produce ACTH; in response to UV light from the sun, keratinocytes in the skin produce α-MSH, which promotes dispersal from nearby melanocytes of the pigment melanin to cause tanning (see p. 441); appetite-suppressing neurons in the hypothalamus secrete α-MSH to control food intake (see p. 621); and other neurons in the CNS produce endorphin, an endogenous opioid that suppresses pain (see p. 192).

4. **Gonadotropes** secrete two hormones that act on the gonads (reproductive organs, namely, the ovaries and testes)—follicle-stimulating hormone and luteinizing hormone. **Follicle-stimulating hormone (FSH)** helps regulate gamete (reproductive cells, namely, ova and sperm) production in both sexes. In females, it stimulates growth and development of ovarian follicles, within which the ova, or eggs, develop. It also promotes secretion of the hormone estrogen by the ovaries. In males, FSH is required for sperm production.

5. **Luteinizing hormone (LH)**, also secreted by gonadotropes, helps control sex hormone secretion in both sexes, among other important actions in females. LH regulates ovarian secretion of the female sex hormones, estrogen and progesterone. In males, the same hormone stimulates the testes to

secrete the male sex hormone, testosterone. In females, LH is also responsible for ovulation (egg release) and luteinization (formation of a hormone-secreting corpus luteum in the ovary following ovulation). Note that both FSH and LH are named for their functions in females.

6. **Lactotropes** secrete **prolactin (PRL)**, which enhances breast development and lactation (milk production) in females. Its reproductive function in males is uncertain. Evidence suggests other functions of prolactin unrelated to the reproductive system, such as enhancing the immune system in both sexes.

GH, TSH, ACTH, FSH, and LH are all tropic hormones because they each regulate secretion of another specific endocrine gland. FSH and LH are collectively referred to as **gonadotropins** because they control secretion of the sex hormones by the gonads. Among the anterior pituitary hormones, PRL is the only one that does not stimulate secretion of another hormone. It acts directly on nonendocrine tissue to exert its effects. Of the tropic hormones, FSH, LH, and GH exert effects on nonendocrine target cells in addition to stimulating secretion of other hormones.

TSH, ACTH, FSH, and LH all act at their target organs by binding with G-protein-coupled receptors that activate the cyclic adenosine monophosphate (cAMP) second-messenger system (see p. 123). GH and PRL both exert their effects via the JAK/STAT pathway (see p. 116).

Hypothalamic releasing and inhibiting hormones help regulate anterior pituitary hormone secretion.

None of the anterior pituitary hormones are secreted at a constant rate. Even though each of these hormones has a unique control system, they have some common regulatory patterns. The two most important factors that regulate anterior pituitary

hormone secretion are hypothalamic hormones and feedback by target-gland hormones.

Release of each anterior pituitary hormone is largely controlled by still other hormones produced by the hypothalamus. The secretion of these regulatory neurohormones, in turn, is controlled by a variety of neural and hormonal inputs to the hypothalamic neurosecretory cells.

Role of the Hypothalamic Releasing and Inhibiting Hormones The secretion of each anterior pituitary hormone
Figure 18-5 **Functions of the anterior pituitary hormones.** Five different endocrine cell types produce the six anterior pituitary hormones—TSH, ACTH, growth hormone, LH and FSH (produced by the same cell type), and prolactin—which exert a wide range of effects throughout the body.
FIGURE FOCUS: *Use this figure to identify which anterior pituitary hormones are tropic.*

is stimulated or inhibited by one or more of seven hypothalamic **hypophysiotropic hormones** (*hypophysis* means "pituitary"; *tropic* means "nourishing"). These small peptide hormones are listed in ▌Table 18-3. Depending on their actions, these hormones are called **releasing hormones** or **inhibiting hormones**. In each case, the primary action of the hormone is apparent from its name. For example, **thyrotropin-releasing hormone (TRH)** stimulates release of TSH (alias thyrotropin) from the anterior pituitary, whereas **prolactin-inhibiting hormone (PIH)**, which is **dopamine** (the same as the neurotransmitter in the basal nuclei and in the "pleasure" pathways in the brain; see pp. 154 and 156), inhibits release of PRL from the anterior pituitary. Note that hypophysiotropic hormones in most cases are involved in a three-hormone hierarchic chain of command (▌Figure 18-6): The hypothalamic hypophysiotropic hormone *(hormone 1)* controls the output of an anterior-pituitary tropic hormone *(hormone 2)*. This tropic hormone, in turn, regulates secretion of the target endocrine gland's hormone *(hormone 3)*, which exerts the final physiologic effect. This three-hormone sequence is called an **endocrine axis**, as in the hypothalamus–pituitary–thyroid axis.

Although endocrinologists originally speculated that there was one hypophysiotropic hormone for each anterior pituitary hormone, some hypothalamic hormones have more than one effect, so their names indicate only the function first identified. Moreover, a single anterior pituitary hormone may be regulated by two or more hypophysiotropic hormones, which may even exert opposing effects. For example, **growth hormone–releasing hormone (GHRH)** stimulates growth hormone secretion, whereas **growth hormone–inhibiting hormone (GHIH)**, also known as **somatostatin**, inhibits it. The output of

the anterior-pituitary somatotropes (that is, the rate of growth hormone secretion) in response to two such opposing inputs depends on the relative concentrations of these hypothalamic hormones and on the intensity of other regulatory inputs.

Chemical messengers identical in structure to the hypothalamic releasing and inhibiting hormones and to vasopressin are produced in many areas of the brain outside the hypothalamus. Instead of being released into the blood, these messengers act locally as neurotransmitters or neuromodulators in these other sites, an example being that PIH is identical to the neurotransmitter dopamine. Others modulate a variety of functions that range from motor activity (TRH) to libido (GnRH) to learning (vasopressin). These examples further illustrate the multiplicity of ways chemical messengers function.

Role of the Hypothalamic–Hypophyseal Portal System

The hypothalamic regulatory hormones reach the anterior pituitary by means of a unique vascular link. In contrast to the direct neural connection between the hypothalamus and the posterior pituitary, the anatomic and functional link between the hypothalamus and the anterior pituitary is an unusual capillary-to-capillary connection, the **hypothalamic–hypophyseal portal system**. (A portal system is a vascular arrangement in which venous blood flows directly from one capillary bed through a connecting vessel to another capillary bed, as in the hepatic portal system; see p. 593.) The hypothalamic–hypophyseal portal system provides a critical link between the brain and much of the endocrine system. It begins in the base of the hypothalamus with a group of capillaries that recombine into small portal vessels, which pass down through the connecting stalk into the anterior pituitary. Here, the portal vessels branch to form most of the anterior pituitary capillaries, which in turn drain into the systemic venous system (▌Figure 18-7).

As a result, almost all blood supplied to the anterior pituitary must first pass through the hypothalamus. Because materials can be exchanged between blood and surrounding tissue only at the capillary level, the hypothalamic–hypophyseal portal system provides a "private" route through which releasing and inhibiting hormones can be picked up at the hypothalamus and delivered immediately and directly to the anterior pituitary at relatively high concentrations, bypassing the general circulation. If the portal system did not exist, once the hypophysiotropic hormones were picked up in the hypothalamus, they would be returned to the heart through the systemic veins, pumped through the pulmonary circulation, then returned to the heart and finally be pumped into the systemic arteries for delivery throughout the body, including the anterior pituitary. Not only would this process take much longer, but the hypophysiotropic hormones would be considerably diluted before arriving at the anterior pituitary.

The axons of the neurosecretory neurons that produce the hypothalamic regulatory hormones terminate on the capillaries at the origin of the portal system. These hypothalamic neurons secrete their hormones in the same way as the hypothalamic neurons that produce vasopressin and oxytocin. The hormone is synthesized in the cell body and then transported in vesicles by motor proteins to the axon terminal. It is stored there until its release by exocytosis into an adjacent capillary on appropri-

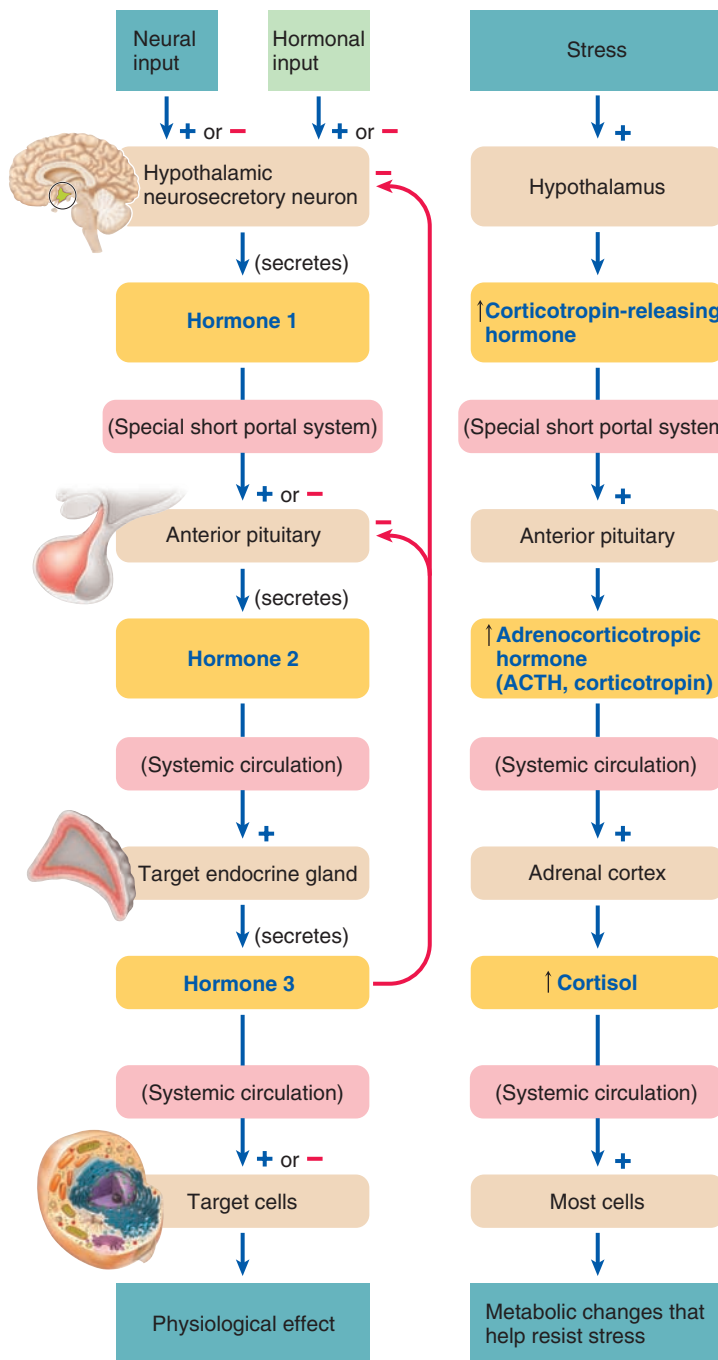
Hormone	Effect on the Anterior Pituitary
Thyrotropin-releasing hormone (TRH)	Stimulates release of TSH (thyrotropin) and prolactin
Corticotropin-releasing hormone (CRH)	Stimulates release of ACTH (corticotropin)
Gonadotropin-releasing hormone (GnRH)	Stimulates release of FSH and LH (gonadotropins)
Growth hormone–releasing hormone (GHRH)	Stimulates release of GH
Somatostatin (growth hormone–inhibiting hormone; GHIH)	Inhibits release of GH and TSH
Prolactin-releasing peptide (PrRP)	Stimulates release of PRL
Dopamine (prolactin-inhibiting hormone; PIH)	Inhibits release of PRL


Figure 18-6 Hierarchic chain of command and negative feedback in endocrine control. The general pathway involved in the hierarchic chain of command in the hypothalamus–anterior pituitary–peripheral target endocrine-gland axis is depicted on the left. The pathway on the right leading to cortisol secretion provides a specific example of this endocrine chain of command. The hormone ultimately secreted by the target endocrine gland, such as cortisol, acts in negative-feedback fashion to reduce secretion of the regulatory hormones higher in the chain of command.

Control of Hypothalamic Releasing and Inhibiting Hormones What regulates secretion of these hypophysiotropic hormones? Like other neurons, the neurons secreting these regulatory hormones receive abundant input of information (both neural and hormonal and both excitatory and inhibitory) that they must integrate. Studies are still in progress to unravel the complex neural input from many diverse areas of the brain to the hypophysiotropic secretory neurons. Some of these inputs carry information about a variety of environmental conditions. One example is the marked increase in secretion of corticotropin-releasing hormone (CRH) in response to stress (see ❙Figure 18-6). Numerous neural connections also exist between the hypothalamus and the portions of the brain concerned with emotions (the limbic system; see p. 155). Thus, emotions greatly influence secretion of hypophysiotropic hormones. The menstrual irregularities sometimes experienced by women who are emotionally upset are a common manifestation of this relationship.

In addition to being regulated by different regions of the brain, the hypophysiotropic neurons are controlled by various chemical inputs that reach the hypothalamus through the blood. Unlike other regions of the brain, portions of the hypothalamus are not guarded by the blood–brain barrier, so the hypothalamus can easily monitor chemical changes in the blood. The most common blood-borne factors that influence hypothalamic neurosecretion are the negative-feedback effects of target-gland hormones, to which we now turn.

Target-gland hormones inhibit hypothalamic and anterior pituitary hormone secretion via negative feedback.

In most cases, hypophysiotropic hormones initiate a three-hormone sequence: hypophysiotropic hormone, anterior-pituitary tropic hormone, and hormone from the peripheral target endocrine gland. Typically, in addition to producing its physiologic effects, the target-gland hormone suppresses secretion of the tropic hormone that is driving it. This negative feedback is accomplished by the target-gland hormone acting directly on the pituitary and on the release of hypothalamic hormones, which in turn regulate anterior pituitary function (see ❙Figure 18-6). As an example, consider the CRH–ACTH–cortisol system. Hypothalamic CRH (corticotropin-releasing hormone) stimulates the anterior pituitary to secrete ACTH (alias corticotropin), which in turn stimulates the adrenal cortex to secrete cortisol. The final hormone in the system, cortisol, inhibits the hypothalamus to reduce CRH secretion and acts directly on the corticotropes in the anterior pituitary to reduce ACTH secretion. Through this double-barreled approach, cortisol exerts negative-feedback control to stabilize its plasma concentration. If plasma cortisol levels start to rise above a prescribed level, cortisol suppresses its

ate stimulation. The major difference is that the hypophysiotropic hormones are released into the portal vessels, which deliver them to the anterior pituitary, where they control release of anterior pituitary hormones into the general circulation. In contrast, the hypothalamic hormones stored in the posterior pituitary are themselves released into the general circulation.

- Anterior pituitary

KEY
- ● ● = Hypophysiotropic hormones
- ● = Anterior pituitary hormone

1. Hypophysiotropic hormones (releasing hormones and inhibiting hormones) produced by neurosecretory neurons in the hypothalamus enter the hypothalamic capillaries.

2. These hypothalamic capillaries rejoin to form the hypothalamic–hypophyseal portal system, a vascular link to the anterior pituitary.

3. The portal system branches into the capillaries of the anterior pituitary.

4. The hypophysiotropic hormones, which leave the blood across the anterior pituitary capillaries, control the release of anterior pituitary hormones.

5. When stimulated by the appropriate hypothalamic releasing hormone, the anterior pituitary secretes a given hormone into these capillaries.

6. The anterior pituitary capillaries rejoin to form a vein, through which the anterior pituitary hormones leave for ultimate distribution throughout the body by the systemic circulation.

own secretion by its inhibitory actions at the hypothalamus and anterior pituitary. This mechanism ensures that once a hormonal system is activated its secretion does not continue unabated. If plasma cortisol levels fall below the desired set point, cortisol's inhibitory actions at the hypothalamus and anterior pituitary are reduced, so the driving forces for cortisol secretion (CRH–ACTH) increase accordingly. The other target-gland hormones act by similar negative-feedback loops to maintain their plasma levels relatively constant at the set point.

Diurnal rhythms are superimposed on this type of stabilizing negative-feedback regulation—that is, the set point changes as a function of the time of day. Furthermore, other controlling inputs may break through the negative-feedback control to alter hormone secretion (that is, change the set level) at times of special need, such as stress raising the set point for cortisol secretion.

The detailed functions and control of all the anterior pituitary hormones except growth hormone are discussed elsewhere in conjunction with the target tissues that they influence; for example, thyroid-stimulating hormone is covered in the next chapter with the discussion of the thyroid gland. Accordingly, growth hormone is the only anterior pituitary hormone we elaborate on at this time.

Check Your Understanding 18.2

1. Draw a flow diagram showing the hierarchic chain of command and negative feedback in the hypothalamic–anterior pituitary–peripheral target endocrine-gland axis.

2. List the posterior pituitary hormones, the anterior pituitary hormones, and the hypophysiotropic hormones.

3. Compare the means by which the hypothalamus controls hormonal output from the posterior pituitary and from the anterior pituitary.

18.3 Endocrine Control of Growth

In growing children, continuous net protein synthesis occurs under the influence of growth hormone (GH) as the body steadily gets larger. Weight gain alone is not synonymous with growth because weight gain may occur from retaining excess water or storing fat without true structural growth of tissues. Growth requires net synthesis of proteins and includes lengthening of the long bones (the bones of the extremities) and increases in the size and number of cells in the soft tissues.

Growth depends on GH but is influenced by other factors.

Although, as the name implies, growth hormone is essential for growth, it is not wholly responsible for determining the rate and final magnitude of growth in a given individual. The following factors affect growth:

■ *Genetic determination* of an individual's maximum growth capacity. Attaining this full growth potential further depends on the other factors listed here.

■ *Adequate diet,* including enough total protein and ample essential amino acids to accomplish the protein synthesis neces-

sary for growth. Malnourished children never achieve their full growth potential. By contrast, a person cannot exceed his or her genetically determined maximum by eating a more-than-adequate diet. The excess food intake produces obesity instead of growth.

■ *Freedom from chronic disease and stressful conditions.* Stunted growth under adverse circumstances is largely a result of the prolonged stress-induced secretion of cortisol from the adrenal cortex. Cortisol exerts several potent antigrowth effects, such as promoting protein breakdown, inhibiting growth in the long bones, and blocking secretion of GH.

■ *Normal levels of growth-influencing hormones.* In addition to the essential GH, other hormones including thyroid hormone, insulin, and the sex hormones play secondary roles in promoting growth.

The rate of growth is not continuous, nor are the factors responsible for promoting growth the same throughout the growth period. *Fetal growth* is promoted largely by certain hormones from the placenta (the hormone-secreting organ of exchange between the fetal and maternal circulatory systems; see p. 757), with the size at birth being determined principally by genetic and environmental factors. GH plays no role in fetal development. After birth, GH and other nonplacental hormonal factors begin to play an important role in regulating growth. Genetic and nutritional factors also strongly affect growth during this period.

Children display two periods of rapid growth—a *postnatal* ("after birth") *growth spurt* during their first 2 years of life and a *pubertal growth spurt* during adolescence (❙Figure 18-8). From age 2 until puberty, the *rate* of linear growth progressively declines, even though the child is still growing. Before puberty, there is little sexual difference in height or weight by age. During puberty, a marked acceleration in linear growth takes place because the long bones lengthen. Puberty begins at about age 11 in girls and 13 in boys and lasts for several years in both sexes. Both genetic and hormonal factors are involved in the pubertal growth spurt. GH secretion is elevated during puberty and contributes to growth acceleration during this time. Furthermore, the sex hormones, whose secretion increases dramatically at puberty, also directly contribute to the pubertal growth spurt and stimulate further secretion of GH. Ultimately, however, estrogen in females and testosterone-turned-estrogen (by action of aromatase) in males act on bone to halt its further growth so that full adult height is attained by the end of adolescence.

GH is essential for growth, but it also directly exerts metabolic effects not related to growth.

GH is the most abundant hormone produced by the anterior pituitary, even in adults in whom growth has already ceased, although GH secretion typically starts to decline after middle age. The continued high secretion of GH beyond the growing period implies that this hormone has important influences beyond its influence on growth, such as metabolic effects. We briefly describe GH's metabolic effects before turning to its growth-promoting actions.
❙Figure 18-8 **Normal growth curve.**

To exert its metabolic effects, GH binds directly with its target organs, namely, adipose tissue, skeletal muscles, and liver. GH increases fatty acid levels in the blood by enhancing the breakdown of triglyceride fat stored in adipose tissue, and it increases blood glucose levels by decreasing glucose uptake by muscles and increasing glucose output by the liver. Muscles use the mobilized fatty acids instead of glucose as a metabolic fuel. Thus, the overall metabolic effect of GH is to mobilize fat stores as a major energy source while sparing glucose for glucose-dependent tissues such as the brain. The brain can use only glucose as its metabolic fuel, yet nervous tissue cannot store glycogen (stored glucose) to any extent. This metabolic pattern induced by GH is suitable for maintaining the body during prolonged fasting or other situations when the body's energy needs exceed available glucose stores.

GH also stimulates amino acid uptake and protein synthesis and inhibits protein degradation throughout the body, especially in protein-rich muscle, decreasing blood amino acids in the process. GH directly contributes to growth via these metabolic effects. However, GH acts indirectly by means of insulin-like growth factors to accomplish its other growth-related actions.

GH mostly exerts its growth-promoting effects indirectly by stimulating insulin-like growth factors.

GH's growth-producing actions include protein synthesis, increased cell division, and bone growth. Except for directly increasing protein synthesis, GH indirectly brings about its other growth-promoting actions by stimulating production of **insulin-like growth factors (IGFs)**, which directly act on the target cells to cause growth of both soft tissues and bones. IGFs are produced in many tissues and have endocrine, paracrine, and autocrine actions (see p. 114). Originally called **somatomedins**, these peptide mediators are now preferentially called insulin-like growth factors because they are structurally and functionally similar to insulin. Like insulin, IGFs exert their effects largely by binding with receptor-enzymes that activate designated effector proteins within the target cell by phosphor-

ylating the tyrosines (a type of amino acid) in the protein (the tyrosine kinase pathway; see p. 116). There are two IGFs—**IGF-I** and **IGF-II**.

IGF-I IGF-I synthesis is stimulated by GH and mediates most of this hormone's growth-promoting actions. (As an interesting aside, variations in the IGF-I gene are one reason that Great Danes grow so much larger than Chihuahuas.) The major source of circulating IGF-I is the liver, which releases this peptide product into the blood in response to GH stimulation. IGF-I is also produced by most other tissues, although they do not release it into the blood to any extent. Researchers propose that IGF-I produced locally in target tissues may act through paracrine means. Such a mechanism could explain why blood levels of GH are no higher, and indeed circulating IGF-I levels are lower, during the first several years of life compared to adult values, even though growth is quite rapid during the postnatal period. Local production of IGF-I in target tissues may be more important than delivery of blood-borne IGF-I or GH during this time.

Production of IGF-I is controlled by a number of factors other than GH, including nutritional status, age, and tissue-specific factors as follows:

▪ IGF-I production depends on adequate nutrition. Inadequate food intake reduces IGF-I production. As a result, changes in circulating IGF-I levels do not always coincide with changes in GH secretion. For example, fasting decreases IGF-I levels even though it increases GH secretion.

▪ Age-related factors influence IGF-I production. A dramatic increase in circulating IGF-I levels accompanies the moderate increase in GH at puberty, which is important for the pubertal growth spurt.

▪ Finally, various tissue-specific stimulatory factors can increase IGF-I production in particular tissues. To illustrate, the gonadotropins and sex hormones stimulate IGF-I production within reproductive organs such as the testes in males and the ovaries and uterus in females.

Thus, control of IGF-I production is complex and subject to a variety of systemic and local factors.

IGF-II In contrast to IGF-I, GH does not influence IGF-II production. IGF-II is primarily important during fetal development. Although IGF-II continues to be produced during adulthood, its role in adults remains unclear.

We now describe GH's growth-promoting effects, mostly mediated by IGF-I.

GH, through IGF-I, promotes growth of soft tissues by stimulating hypertrophy and hyperplasia.

When tissues are responsive to its growth-promoting effects, GH stimulates growth of both the soft tissues and the skeleton. GH promotes growth of soft tissues by (1) increasing the size of cells (**hypertrophy**) and (2) increasing the number of cells (**hyperplasia**). GH increases the size of cells by favoring synthesis of proteins, the main structural component of cells. GH and IGF-I both directly stimulate almost all aspects of protein synthesis while simultaneously inhibiting protein degradation. GH (via IGF-I) increases the number of cells by stimulating cell division and by preventing apoptosis (programmed cell death; see p. 40).

Growth of the long bones resulting in increased height is the most dramatic effect of GH. Before you can understand the means by which GH stimulates bone growth, you must become familiar with bone structure and how growth of bone is accomplished.

Bone grows in thickness and in length by different mechanisms, both stimulated by GH.

Bone is a living tissue. Being a form of connective tissue, it consists of cells and an extracellular organic matrix known as **osteoid** produced by the cells. The bone cells that produce the organic matrix are known as **osteoblasts** (*osteo* means "bone"; *blasts* means "formers"). Osteoid is composed of collagen fibers (see p. 60) in a semisolid gel. This organic matrix has a rubbery consistency and is responsible for bone's tensile strength (the resilience of bone to breakage when tension is applied). Bone is made hard by precipitation of *calcium phosphate crystals* within the osteoid. These inorganic crystals provide the bone with compressional strength (the ability of bone to hold its shape when squeezed or compressed). If bones consisted entirely of inorganic crystals, they would be brittle, like pieces of chalk. Bones have structural strength approaching that of reinforced concrete, yet they are not brittle and weigh much less because they have the structural blending of an organic scaffolding hardened by inorganic crystals. **Cartilage** is similar to bone, except that living cartilage is not calcified.

A long bone basically consists of a fairly uniform cylindrical shaft, the **diaphysis**, with a flared articulating knob at either end, an **epiphysis**. In a growing bone, the diaphysis is separated at each end from the epiphysis by a layer of cartilage known as the **epiphyseal plate** (❙Figure 18-9a). The central cavity of the bone is filled with bone marrow, the site of blood cell production (see p. 385).

Mechanisms of Bone Growth Growth in *thickness* of bone is achieved by adding new bone on top of the outer surface of existing bone. This growth is produced by osteoblasts within the **periosteum**, a connective tissue sheath that covers the outer bone. As osteoblast activity deposits new bone on the external surface, other cells within the bone, the **osteoclasts** ("bone breakers"), dissolve the bony tissue on the inner surface next to the marrow cavity. In this way, the marrow cavity enlarges to keep pace with the increased circumference of the bone shaft.

Growth in *length* of long bones is accomplished by a different mechanism. Bones lengthen as a result of activity of the cartilage cells, or **chondrocytes**, in the epiphyseal plates (❙Figure 18-9b). During growth, cartilage cells on the outer edge of the plate next to the epiphysis divide and multiply. As new chondrocytes are formed on the epiphyseal border, the older cartilage cells toward the diaphyseal border are enlarging. This combination of proliferation of new cartilage cells and hypertrophy of maturing chondrocytes temporarily wid-

ens the epiphyseal plate. This thickening of the intervening cartilaginous plate pushes the bony epiphysis farther away from the diaphysis. Soon the matrix surrounding the oldest hypertrophied cartilage becomes calcified. Because cartilage lacks its own capillary network, the survival of cartilage cells depends on diffusion of nutrients and O_2 through the matrix, a process prevented by the deposition of calcium salts. As a result, the old nutrient-deprived cartilage cells on the diaphyseal border die. As osteoclasts clear away dead chondrocytes and the calcified matrix that imprisoned them, the area is invaded by osteoblasts, which swarm upward from the diaphysis, trailing their capillary supply with them. These new tenants lay down bone around the persisting remnants of disin-

tegrating cartilage until bone entirely replaces the inner region of cartilage on the diaphyseal side of the plate. When this **ossification** ("bone formation") is complete, the bone on the diaphyseal side has lengthened and the epiphyseal plate has returned to its original thickness. The cartilage that bone has replaced on the diaphyseal end of the plate is as thick as the new cartilage on the epiphyseal end of the plate. Thus, bone growth is made possible by the growth and death of cartilage, which acts like a "spacer" to push the epiphysis farther out while it provides a framework for future bone formation on the end of the diaphysis.

Mature, Nongrowing Bone As the extracellular organic matrix produced by an osteoblast calcifies, the osteoblast becomes entombed by the matrix it has deposited around itself. Unlike chondrocytes, however, osteoblasts trapped within a calcified matrix do not die because they are supplied by nutrients transported to them through small canals that the osteoblasts form by sending out cytoplasmic extensions around which the bony matrix is deposited. Thus, within the final bony product, a network of permeating tunnels radiates from each

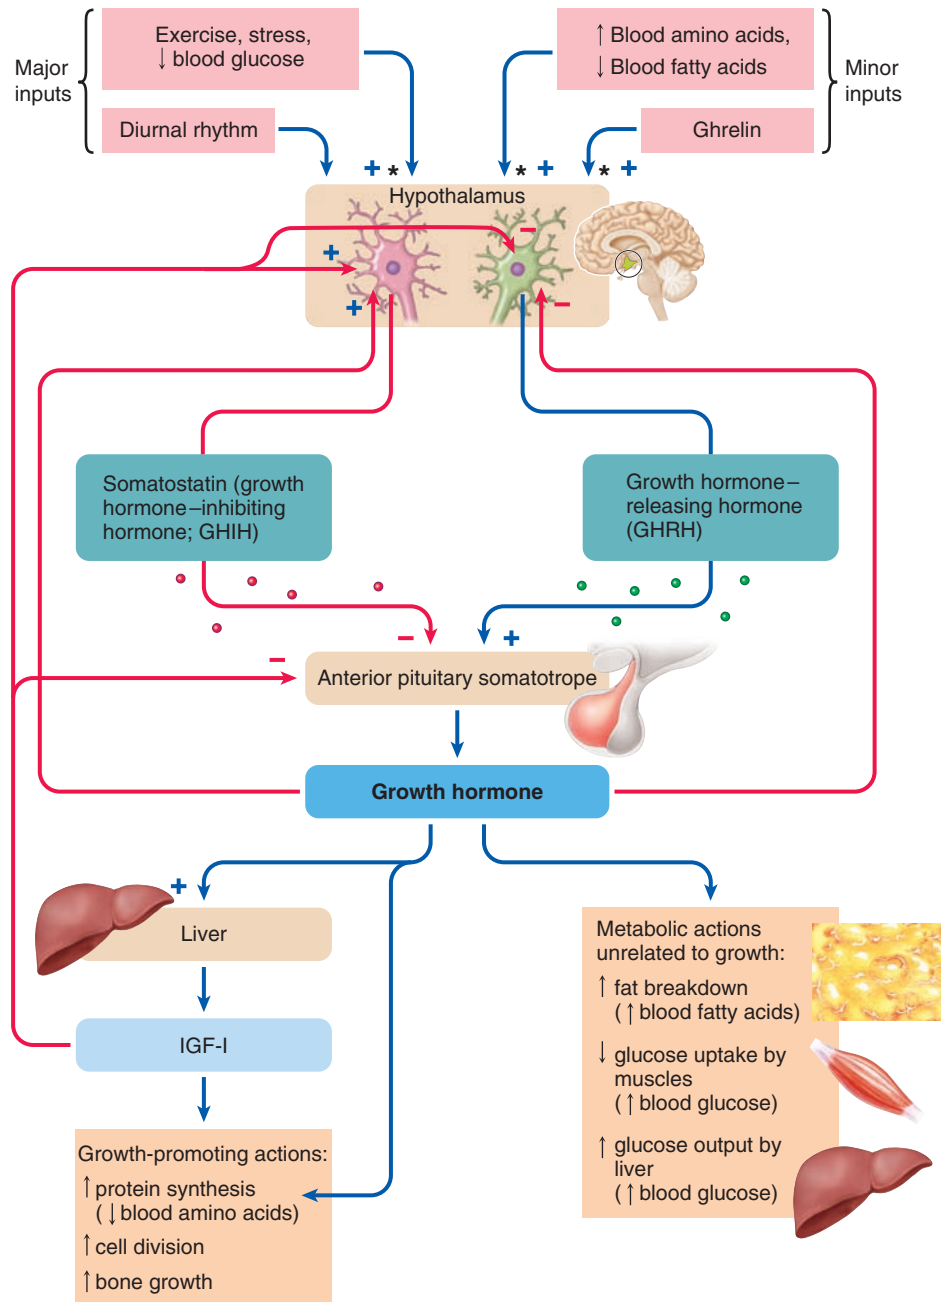
entrapped osteoblast, serving as a lifeline system for nutrient delivery and waste removal. The entrapped osteoblasts, now called **osteocytes**, retire from active bone-forming duty because their imprisonment prevents them from laying down new bone. However, they are involved in the hormonally regulated exchange of calcium between bone and blood. This exchange is under the control of parathyroid hormone (discussed in the next chapter), not GH.

GH Control of Bone Growth GH causes bones to grow both in length and in thickness via IGF-I, which has profound effects on cartilage and bone. IGF-I stimulates proliferation of epiphyseal cartilage, thereby making space for more bone formation, and stimulates osteoblast activity. GH/IGF-I can promote lengthening of long bones as long as the epiphyseal plate remains cartilaginous, or is "open." At the end of adolescence, sex steroids completely ossify, or "close" the epiphyseal plates so that the bones cannot lengthen any further despite the presence of GH and IGF-I. Thus, after the plates are closed, the individual does not grow any taller.

GH secretion is regulated by two hypophysiotropic hormones.

The control of GH secretion is complex, with two hypothalamic hypophysiotropic hormones playing a key role.

Growth Hormone–Releasing Hormone and Growth Hormone–Inhibiting Hormone Two antagonistic regulatory hormones from the hypothalamus are involved in controlling GH secretion: growth hormone–releasing hormone (GHRH), which is stimulatory and the dominant influence, and growth hormone–inhibiting hormone (GHIH, or somatostatin), which is inhibitory (Figure 18-10). (Note the distinctions among *somatotropin,* alias growth hormone; *somatomedin,* a liver hormone (alias IGF-I) that directly mediates the effects of GH; and *somatostatin,* which inhibits GH secretion.) Both GHRH and somatostatin act on the anterior pituitary somatotropes by binding with G-protein-coupled receptors linked to the cAMP second-messenger pathway, with GHRH increasing cAMP and somatostatin decreasing cAMP.


*These factors all increase growth hormone secretion, but it is unclear whether they do so by stimulating GHRH or inhibiting somatostatin (GHIH), or both.

Figure 18-10 Control of growth hormone secretion.
FIGURE FOCUS: *Describe the negative-feedback loops involved in control of growth hormone secretion.*

As with control of other anterior pituitary hormones, negative-feedback loops participate in controlling GH secretion. Complicating the feedback loops for the hypothalamus–pituitary–liver axis is direct regulation of GH secretion by both stimulatory and inhibitory factors. Therefore, negative-feedback loops involve both inhibition of stimulatory factors and stimulation of inhibitory factors. GH stimulates IGF-I secretion by the liver, and IGF-I in turn is the primary inhibitor of GH secretion by the anterior pituitary. IGF-I inhibits the somatotropes in the pituitary directly and further decreases GH

secretion by inhibiting GHRH-secreting cells and stimulating the somatostatin-secreting cells in the hypothalamus, thus decreasing hypothalamic stimulation of the somatotropes. Furthermore, GH itself inhibits hypothalamic GHRH secretion and stimulates somatostatin release.

Factors that Influence GH Secretion A number of factors influence GH secretion by acting on the hypothalamus. GH secretion displays a well-characterized diurnal rhythm. Through most of the day, GH levels tend to be low and fairly constant. About an hour after onset of deep sleep, however, GH secretion markedly increases up to five times the low daytime value.

Superimposed on this diurnal fluctuation in GH secretion are further bursts in secretion that occur in response to exercise, stress, and low blood glucose, the major stimuli for increased secretion. The benefits of increased GH secretion during these situations when energy demands outstrip the body's glucose reserves are presumably that glucose is conserved for the brain and fatty acids are provided as an alternative energy source for muscle.

Because GH uses up fat stores and promotes synthesis of body proteins, it encourages a change in body composition away from adipose deposition toward an increase in muscle protein. Accordingly, the increase in GH secretion that accompanies exercise may at least in part mediate the effects of exercise in reducing the percentage of body fat while increasing lean body mass.

Several minor inputs also influence GH secretion. A rise in blood amino acids after a high-protein meal enhances GH secretion. In turn, GH promotes the use of these amino acids for protein synthesis. GH is also stimulated by a decline in blood fatty acids. Because GH mobilizes fat, such regulation helps maintain fairly constant blood fatty acid levels.

Finally, ghrelin, a potent appetite stimulator released from the stomach, also stimulates GH secretion (see p. 623). This "hunger hormone" may play a role in coordinating growth with nutrient acquisition.

Note that the known regulatory inputs for GH secretion are aimed at adjusting the levels of glucose, amino acids, and fatty acids in the blood. No known growth-related signals influence GH secretion. The whole issue of what really controls growth is complicated by GH levels during early childhood, a period of quite rapid growth in height, being similar to those in normal adults. As mentioned earlier, the poorly understood control of local IGF-I activity may be important in this regard. Another related question is, Why aren't adult tissues still responsive to GH's growth-promoting effects? We know we do not grow any taller after adolescence because the epiphyseal plates have closed, but why do soft tissues not continue to grow through hypertrophy and hyperplasia under the influence of GH? One speculation is that levels of GH may only be high enough to produce its growth-promoting effects during the secretion bursts that occur in deep sleep. Time spent in deep sleep is greatest in infancy and gradually declines with age. Still, even as we age, we spend some time in deep sleep, yet we do not gradually get larger. Further research is needed to unravel these mysteries.

Abnormal GH secretion results in aberrant growth patterns.

Clinical Note Diseases related to both deficiencies and excesses of GH can occur. The effects on the pattern of growth are more pronounced than the metabolic consequences.

GH Deficiency GH deficiency may be caused by a pituitary defect (lack of GH) or may occur secondary to hypothalamic dysfunctions (lack of GHRH). Hyposecretion of GH in a child is one cause of **dwarfism**. The predominant feature is short stature caused by retarded skeletal growth (❚Figure 18-11). Less obvious characteristics include poorly developed muscles (reduced muscle protein synthesis) and excess subcutaneous fat (less fat mobilization).

In addition, growth may be thwarted because the tissues fail to respond normally to GH. An example is *Laron dwarfism,* which is characterized by abnormal GH receptors that are unresponsive to the hormone. The symptoms of this condition resemble those of severe GH deficiency even though blood levels of GH are actually high. In some instances, GH levels are adequate and target-cell responsiveness is normal, but IGF-I is lacking, as is the case with *African pygmies.*

❚Figure 18-11 **Examples of the effect of abnormalities in growth hormone secretion on growth.** The man at the left displays pituitary dwarfism resulting from underproduction of growth hormone in childhood. The man at the center has gigantism caused by excessive growth hormone secretion in childhood. The woman at the right is of average height.

Growth and Youth in a Bottle?

AFTER HUMAN GH BECAME AVAILABLE through genetic engineering, a new problem for the medical community was to determine under which circumstances synthetic GH treatment is appropriate. Until recently, the FDA had approved treatment only for the following uses: (1) for children with GH deficiency, (2) for adults with a pituitary tumor or other disease that causes severe GH deficiency, and (3) for patients with AIDS who have severe muscle wasting. Although not approved by the FDA for this use, GH therapy is also widely used to promote faster healing of skin in patients who have been severely burned. In 2003, amid emotionally charged debates, the FDA approved GH shots for another group, the shortest 1.2% of children who are unusually short for no apparent reason. This therapy involves multiple GH injections per week for a number of years under careful supervision of pediatric endocrinologists for an average gain in height of 1 to 3 inches. Children with GH deficiency experience more dramatic gains of about 6 to 8 inches on GH therapy.

Another group who may benefit from replacement GH therapy is the elderly. GH secretion typically peaks during a person's 20s, then in many people may start to dwindle after age 40. This decline may contribute to some of the characteristic signs of aging:

- Decreased muscle mass (GH promotes synthesis of proteins, including muscle protein)

- Increased fat deposition (GH promotes leanness by mobilizing fat stores for use as an energy source)
- Reduced bone density (GH stimulates bone-forming cells)
- Thinner, sagging skin (GH promotes proliferation of skin cells)

(However, inactivity is also believed to play a major role in age-associated reductions in muscle mass, bone density, and strength.)

Several studies in the early 1990s suggested that some of these consequences of aging may be counteracted through the use of synthetic GH in people older than age 60. Elderly men treated with supplemental GH showed increased muscle mass, reduced fatty tissue, and thickened skin. In similar studies in elderly women, supplemental GH therapy did not increase muscle mass significantly but did reduce fat mass and protect against bone loss.

Even though these early results were exciting, further studies were more discouraging. Despite increased lean body mass, many treated people surprisingly do not have increased muscle strength or exercise capabilities. Also, when GH is supplemented for an extended time or in large doses, harmful side effects include an increased likelihood of diabetes, kidney stones, high blood pressure, headaches, joint pain, and carpal tunnel syndrome (thickening and narrowing of the tunnel in the wrist through which the nerve supply to the hand muscles passes; *carpal* means "wrist"). Furthermore, synthetic GH is

---

The onset of GH deficiency in adulthood after growth is already complete produces relatively few symptoms. Adults who are GH deficient tend to have reduced skeletal muscle mass and strength (less muscle protein), and decreased bone density (less osteoblast activity during ongoing bone remodeling). Furthermore, because GH is essential for maintaining cardiac muscle mass and performance in adulthood, GH-deficient adults may be at increased risk of developing heart failure. (For a discussion of GH therapy, see the accompanying boxed feature, ▌Concepts, Challenges, and Controversies.)

GH Excess Hypersecretion of GH is most often caused by a tumor of the GH-producing cells of the anterior pituitary. The symptoms depend on the age of the individual when the abnormal secretion begins. If overproduction of GH begins in childhood before the epiphyseal plates close, the principal manifestation is a rapid growth in height without distortion of body proportions. Appropriately, this condition is known as **gigantism** (▌Figure 18-11). If not treated by removal of the tumor or by drugs that block the effect of GH, the person may reach a height of 8 feet or more. All the soft tissues grow correspondingly, so the body is still well proportioned.

If GH hypersecretion occurs after adolescence when the epiphyseal plates have already closed, further growth in height

is prevented. Under the influence of excess GH, however, the bones become thicker and the soft tissues, especially connective tissue and skin, proliferate. This disproportionate growth pattern produces a disfiguring condition known as **acromegaly** (*acro* means "extremity"; *megaly* means "large"). Bone thickening is most obvious in the extremities and face. A marked coarsening of the features to an almost apelike appearance gradually develops as the jaws and cheekbones become more prominent because of thickening of the facial bones and the skin (▌Figure 18-12). The hands and feet enlarge, and the fingers and toes become greatly thickened.

Other hormones besides growth hormone are essential for normal growth.

Several other hormones in addition to GH contribute in special ways to overall growth:

- *Thyroid hormone* is essential for growth but is not itself directly responsible for promoting growth. It plays a permissive role in skeletal growth; the actions of GH fully manifest only when enough thyroid hormone is present. As a result, growth is severely stunted in hypothyroid children, but hypersecretion of thyroid hormone does not cause excessive growth.

costly ($15,000 to $20,000 annually) and must be injected regularly. Also, some scientists worry that sustained administration of synthetic GH may raise the risk of developing cancer by promoting uncontrolled cell proliferation. For these reasons, most investigators no longer view synthetic GH as a potential "fountain of youth." Instead, they hope it can be used in a more limited way to strengthen muscle and bone suffciently in the many elderly who have GH defcits, to help reduce the incidence of bone-breaking falls that often lead to disability. The National Institute of Aging is currently sponsoring a nationwide series of studies involving GH therapy in the elderly to help sort out potentially legitimate roles of this supplemental hormone.

An ethical dilemma is whether the drug should be used by others who have normal GH levels but want the product's growth-promoting actions for cosmetic or athletic reasons, such as normally growing teenagers who wish to attain even greater height. The drug is already being used illegally by some athletes and bodybuilders. Furthermore, a recent study found that only 4 out of 10 children who are legitimately receiving GH therapy under medical supervision are actually GH defcient or in the bottom 1.2% of height. The others are receiving the treatment because parents, physicians, and the children are being swayed by perceived cultural pressures that favor height rather than by medical factors.

Using the drug in children with normal GH levels may be problematic because synthetic GH is a double-edged product. Although it promotes growth and muscle mass, it also has negative effects, such as potentially troubling side effects. Furthermore, one study revealed that supplemental GH therapy in children who do not lack the hormone redistributes the body's fat and protein. The investigators compared two groups of otherwise-healthy 6- to 8-year-old children who were among the shortest for their age. One group consisted of children who were receiving GH and the other consisted of children who were not. At the end of 6 months, the children taking the synthetic hormone had outpaced the untreated group in growth by more than 1.5 inches per year. However, the untreated children added both muscle and fat as they grew, whereas the treated children became unusually muscular and lost up to 76% of their body fat. The loss of fat became especially obvious in their faces and limbs, giving them a rawboned, gangly appearance. It is unclear what long-term effects—either deleterious or desirable—these dramatic changes in body composition might have. Scientists also express concern that these readily observable physical changes may be accompanied by more subtle abnormalities in organs and cells. Thus, the debate about whether to use GH in normal but short children is likely to continue.

■ *Insulin* is an important growth promoter. Insulin deficiency often blocks growth, and hyperinsulinism frequently spurs excessive growth. Because insulin promotes protein synthesis, its growth-promoting effects should not be surprising. However, these effects may also arise from a mechanism other than insulin's direct effect on protein synthesis. Insulin structurally resembles the IGFs and may interact with the IGF-I receptor, which is very similar to the insulin receptor.

■ *Sex steroids* are potent growth stimulators and contribute to the pubertal growth spurt, but they ultimately stop further growth by closing the epiphyseal plates. Sex steroids include *androgens* (masculinizing hormones, such as testosterone in

males) and *estrogen* (feminizing hormone in females). Androgens but not estrogen also powerfully stimulates protein synthesis, thereby increasing muscle mass. This action is responsible for men developing heavier musculature than women do.

Several factors contribute to the average height differences between men and women. First, because puberty occurs about 2 years earlier in girls than in boys, on the average boys have 2 more years of prepubertal growth than girls do. As a result, boys are usually several inches taller than girls at the start of their respective growth spurts. Second, boys experience a greater steroid-hormone induced growth spurt than girls before their respective gonadal steroids seal their long bones from further growth; this results in greater heights in men than in women on average. Third, evidence suggests that androgens "imprint" the brains of males during development, giving rise to a "masculine" secretory pattern of GH characterized by higher cyclic peaks, which are speculated to contribute to the greater height of males.

In addition to these hormones that exert overall effects on body growth, a number of poorly understood peptide *growth factors* have been identified that stimulate mitotic activity of specific tissues (for example, epidermal growth factor).

We now shift attention to the other endocrine gland in the brain—the pineal gland.

Check Your Understanding 18.3

1. Describe GH's metabolic effects.
2. Explain the relationship between GH and IGF-I in promoting growth.
3. Compare the means by which bone grows in thickness and in length.

18.4 Pineal Gland and Circadian Rhythms

The **pineal gland**, (PIN-ē-ul) a tiny, pinecone-shaped structure located in the center of the brain (see ❙Figure 5-7b, p. 143, ❙Figure 5-15, p. 154, and ❙Figure 18-1, p. 639), secretes the hormone **melatonin**, an indoleamine hormone. (Do not confuse melatonin with the skin-darkening pigment, *melanin*.) Although melatonin was discovered in 1959, investigators have only recently begun to unravel its many functions. One of melatonin's most widely accepted roles is helping keep the body's inherent circadian rhythms in synchrony with the light–dark cycle. We examine circadian rhythms in general before looking at the role of melatonin in this regard and considering other functions of this hormone.

The suprachiasmatic nucleus is the master biological clock.

Hormone secretion rates are not the only factor in the body that fluctuates cyclically over a 24-hour period. Humans have similar biological clocks for many other bodily functions, ranging from gene expression, to physiological processes such as temperature regulation (see p. 628), to feeding and metabolic patterns (see p. 626), to behavior. The master biological clock that serves as the pacemaker for the body's circadian rhythms is the **suprachiasmatic nucleus (SCN)**. It consists of two clusters of nerve cell bodies (one on each side of the brain) in the hypothalamus above the optic chiasm, the point at which part of the nerve fibers from each eye cross to the opposite half of the brain (*supra* means "above"; *chiasm* means "cross") (see p. 207; ❙Figure 5-7b, p. 143 and Figure 18-3, p. 646). Only 20,000 neurons populate the SCN, yet the self-induced rhythmic firing of this meager number of SCN neurons plays a major role in synchronizing all the body's inherent daily rhythms. This is analogous to the residents of a small town setting the schedule for all the residents of the world. Many tissues have independent clocks, but the SCN serves as the central timekeeper to keep these peripheral clocks in sync.

Role of Clock Proteins The underlying molecular mechanism responsible for the SCN's circadian oscillations involves autoregulatory feedback loops leading to alternating cycles of activation and repression of genes within the nuclei of SCN neurons that code for oscillator **clock proteins**. Self-starting transcription factors known as **CLOCK** and **BMAL-1**[1] in the nucleus of an SCN neuron form a complex that activates transcription of DNA's genetic code for the clock proteins **PER** and **CRY**[1], setting in motion a series of events leading to synthesis of these clock proteins in the cytosol surrounding the nucleus (❙Figure 18-13). As the day wears on, these clock proteins continue to accumulate, finally reaching a critical mass, at which time they are transported into the nucleus. Here, PER and CRY inhibit CLOCK and BMAL-1, thereby repressing the genetic process responsible for these clock proteins' production. After the clock proteins block synthesis of more clock proteins, the level of clock proteins gradually dwindles as they degrade within the nucleus, thus removing their inhibitory influence from the clock-protein genetic machinery. No longer being blocked, these genes again rev up the production of more clock proteins as the cycle repeats itself. Each cycle takes about a day. The fluctuating levels of clock proteins bring about cyclic changes in neural output from the SCN that, in turn, lead to cyclic changes in effector organs throughout the day. An example is the diurnal variation in cortisol secretion (see ❙Figure 18-2, p. 642). In this way, internal timekeeping (circadian rhythms) is a self-sustaining mechanism built into the genetic makeup of the SCN neurons. The SCN provides "standard time" by which all peripheral tissue clocks are set.

Synchronization of the Biological Clock with Environmental Cues On its own, this biological clock generally cycles a bit slower than the 24-hour environmental cycle. Without any external cues, the SCN sets up cycles that average about 25 hours. The cycles are consistent for a given individual

---

[1]*CLOCK* is the acronym for "circadian rhythms of locomotor activity kaput." *BMAL-1* stands for "brain and muscle Arnt-like-1." *PER* refers to proteins known as "period." *CRY* is short for "cryptochrome" proteins.

Tinkering with Our Biological Clocks

RESEARCH SHOWS THAT THE HECTIC pace of modern life, stress, noise, and the irregular schedules many workers follow can upset internal rhythms, illustrating how a healthy external environment affects our own internal environment—and our health.

The greatest disrupter of our natural circadian rhythms is the variable work schedule common in industrialized countries. Today one out of every four working men and one out of every six working women has a variable work schedule—shifting frequently between day and night work. To spread the burden, many companies that maintain shifts round the clock alter their workers' schedules. One week, employees work the day shift. The next week, they move to the "graveyard shift" from midnight to 8 a.m. The next week, they work the night shift from 4 P.M. to midnight. Many shift workers feel tired most of the time and have trouble staying awake at the job. Work performance suffers because of the workers' fatigue. When workers arrive home for bed, they're exhausted but cannot sleep because they are trying to doze off when the body is trying to wake them up. Unfortunately, the weekly changes in schedule never permit workers' internal alarm clocks to fully adjust. Most people require 4 to 14 days to adjust to a new schedule.

People whose lifestyle operates against their circadian clock for any reason suffer more ulcers, insomnia, irritability, depression, tension, cardiovascular disease, cancer, and metabolic disorders like Type 2 diabetes mellitus and obesity than those whose daily schedule is in sync with their biological rhythms. To make matters worse, tired, irritable workers whose judgment is impaired by fatigue pose a threat to society. Consider these infamous industrial accidents that resulted from judgment errors and occurred during the night shift: in 1979, the worst nuclear accident in United States history at the Three Mile Island nuclear reactor in Pennsylvania; in 1986, the world's largest and most costly nuclear accident in Chernobyl, Ukraine; and in 1989, accidental grounding of the oil tanker *Exxon Valdez* and subsequent oil spill in Alaska. These disasters may have been the result of workers operating at a time unsuitable for clear thinking. One has to wonder how many plane crashes, auto accidents, and acts of medical malpractice can be traced to compromised vigilance and judgment resulting from working against inherent body rhythms.

Thanks to studies of biological rhythms, researchers are finding ways to reset biological clocks when warranted. For instance, one simple measure is to put shift workers on 3-week cycles to give their clocks time to adjust. Bright lights can also be used to reset the biological clock. Furthermore, use of supplemental melatonin, the hormone that sets the internal clock to march in step with environmental cycles, may prove useful in resetting the body's clock when that clock is out of sync with external cues.

---

but vary somewhat among different people. If this master clock were not continually adjusted to keep pace with the world outside, the body's circadian rhythms would become progressively out of sync with the cycles of light (periods of activity) and dark (periods of rest). Thus, the SCN must be reset daily by external cues so that biological rhythms are synchronized with the activity levels driven by the surrounding environment. For example, during the day people are typically awake and active and their metabolic activity is high, while at night they sleep and their metabolism is low. The effect of not keeping the internal clock synchronized with the environment is well known by people who experience **jet lag** when their inherent rhythm is out of step with external cues. (For a discussion of problems associated with being out of sync with environmental cues, see the accompanying boxed feature, ▮Concepts, Challenges, and Controversies.)

The SCN works with the pineal gland and its hormonal product melatonin to synchronize the various circadian rhythms with the 24-hour day–night cycle.

Melatonin helps keep the body's circadian rhythms in time with the light–dark cycle.

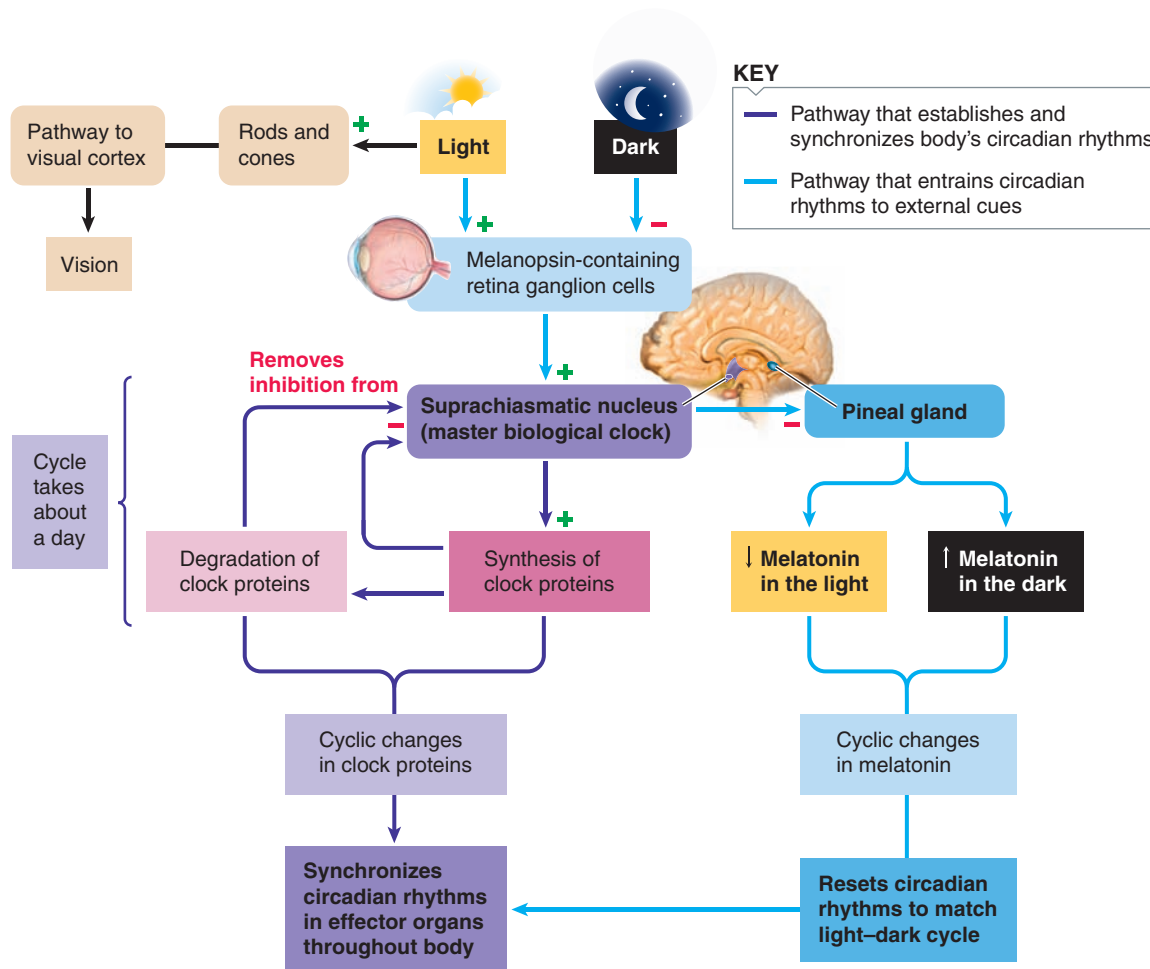
Daily changes in light intensity are the major environmental cue used to adjust the SCN master clock. Special photoreceptors in the retina pick up light signals and transmit them directly to the SCN. These photoreceptors are distinct from the rods and cones used to see light (see p. 200). **Melanopsin**, a protein found in a special type of retinal ganglion cell (see p. 199), is the receptor molecule for light that keeps the body in tune with external time (▮Figure 18-13). Most retinal ganglion cells receive input from the rod and cone photoreceptors. The axons of these ganglion cells form the *optic nerve*, which carries information for final processing by the visual cortex in the occipital lobe (see pp. 148 and 207). Intermingled among the visually oriented retinal ganglion cells, about 1% to 2% of the retinal ganglion cells instead form an entirely independent light-detection system that responds to levels of illumination, like a light meter on a camera, rather than the contrasts, colors, and contours detected by the image-forming visual system. The melanopsin-containing, light-detecting retinal ganglion cells cue the pineal gland about the presence or absence of light by sending their signals along the **retino-hypothalamic tract** to the SCN. This pathway is distinct from the neural systems that result in vision perception. The SCN relays the message regarding light status to the pineal gland. This is the major way the internal clock is coordinated to a 24-hour day. Melatonin is the hormone of darkness. Melatonin secretion increases up to 10-fold during the darkness of night and then falls to low levels during the light of day. Fluctuations


Figure 18-13 Synchronization and entrainment of circadian rhythms.

in melatonin secretion, in turn, help entrain the body's biological rhythms with the external light–dark cues.

Studies suggest the following additional roles of melatonin, besides its clock-related function:

■ Taken exogenously (in a pill), melatonin induces a natural sleep without the side effects that accompany hypnotic sedatives, so it may play a normal role in promoting sleep.

■ Melatonin inhibits the hormones that stimulate reproductive activity. Puberty may be initiated by a reduction in melatonin secretion.

■ In a related role, in some species, seasonal fluctuations in melatonin secretion associated with changes in the number of daylight hours are important triggers for seasonal breeding, migration, and hibernation.

■ Melatonin is an effective *antioxidant,* a defense tool against biologically damaging free radicals. *Free radicals* are very unstable electron-deficient particles that are highly reactive and destructive. Free radicals have been implicated in several chronic diseases, such as coronary artery disease (see p. 327) and cancer, and are believed to contribute to the aging process.

■ Melatonin may slow the aging process, perhaps by removing free radicals or by other means.

■ Melatonin enhances immunity, reduces inflammation, and has been shown to reverse some of the age-related shrinkage of the thymus, the source of T lymphocytes (see p. 416).

■ Melatonin has positive effects on the brain, such as protecting against neurodegeneration, participating in neurogenesis (production of new neurons), and combating depression.

■ Melatonin also facilitates learning, memory, and cognition.

Clinical Note Because of melatonin's many proposed roles, use of supplemental melatonin for a variety of conditions is promising. However, most experts are cautious about recommending supplemental melatonin until its effectiveness as a drug is further substantiated. Meanwhile, many people are turning to melatonin as a health food supplement; as such, it is not regulated by the Food and Drug Administration (FDA) for safety and effectiveness. The two biggest self-prescribed uses of melatonin are as a prevention for jet lag and as a sleep aid.

1. Discuss the means by which the suprachiasmatic nucleus serves as the master biological clock.

2. Distinguish between *melanopsin* and *melatonin*.

3. Compare the type of information carried by the optic nerve pathway and by the retino-hypothalamic tract.

Homeostasis: Chapter in Perspective
The endocrine system is one of the body's two major regulatory systems; the other is the nervous system. Through its relatively slowly acting hormone messengers, the endocrine system generally regulates activities that require duration rather than speed. Most of these activities are directed toward maintaining homeostasis. The specif c contributions of the central endocrine organs to homeostasis are as follows:

■ The hypothalamus–posterior pituitary unit secretes vasopressin, which acts on the kidneys during urine formation to help maintain H_2O balance. Control of H_2O balance, in turn, is essential for maintaining ECF osmolarity and proper cell volume.

■ For the most part, the hormones secreted by the anterior pituitary do not directly contribute to homeostasis. Instead, most are tropic—that is, they stimulate the secretion of other hormones.

■ However, growth hormone from the anterior pituitary, in addition to its growth-promoting actions, also exerts metabolic effects that help maintain the plasma concentration of glucose, fatty acids, and amino acids.

■ The pineal gland secretes melatonin, which helps entrain the body's circadian rhythm to the environmental cycle of light (period of activity) and dark (period of inactivity).

The peripheral endocrine glands further help maintain homeostasis in the following ways:

■ Hormones help maintain the proper concentration of nutrients in the internal environment by directing chemical reactions involved in the cellular uptake, storage, and release of these molecules. Furthermore, the rate at which these nutrients are metabolized is controlled in large part by the endocrine system.

■ Salt balance, which is important in maintaining the proper ECF volume and arterial blood pressure, is achieved by hormonally controlled adjustments in salt reabsorption by the kidneys during urine formation.

■ Likewise, hormones act on various target cells to maintain the plasma concentration of calcium and other electrolytes. These electrolytes, in turn, play key roles in homeostatic activities. For example, maintenance of calcium levels within narrow limits is critical for neuromuscular excitability and blood clotting, among other life-supporting actions.

■ The endocrine system orchestrates a wide range of adjustments that help the body maintain homeostasis in response to stressful situations.

■ The endocrine and nervous systems work in concert to control the circulatory and digestive systems, which in turn carry out important homeostatic activities.

Unrelated to homeostasis, hormones direct the growing process and control most aspects of the reproductive system.

Review Exercises Answers begin on p. A-48

Reviewing Terms and Facts

1. One endocrine gland may secrete more than one hormone. *(True or false?)*

2. One hormone may influence more than one type of target cell. *(True or false?)*

3. All endocrine glands are exclusively endocrine in function. *(True or false?)*

4. A single target cell may be influenced by more than one hormone. *(True or false?)*

5. Hyposecretion or hypersecretion of a specific hormone can occur even though its endocrine gland is perfectly normal. *(True or false?)*

6. Growth hormone levels in the blood are no higher during the early childhood growing years than during adulthood. *(True or false?)*

7. A hormone that has as its primary function the regulation of another endocrine gland is classified functionally as a _____ hormone.

8. Self-induced reduction in the number of receptors for a specific hormone is known as _____.

9. Activity within the cartilaginous layer of bone known as the _____ is responsible for lengthening of long bones.

10. The _____ in the hypothalamus is the body's master biological clock.

11. Indicate the relationships among the hormones in the hypothalamus–anterior pituitary–adrenal cortex axis by using the following answer code to identify which hormone belongs in each blank:

(a) cortisol   (b) ACTH   (c) CRH

(1) _____ from the hypothalamus stimulates the secretion of (2) _____ from the anterior pituitary. (3) _____, in turn, stimulates the secretion of (4) _____ from the adrenal cortex. In negative-feedback fashion, (5) _____ inhibits secretion of the releasing hormone (6) _____ and furthermore inhibits secretion of the tropic hormone (7) _____.

Understanding Concepts

(Answers at www.cengagebrain.com)

1. Discuss the general functions of the endocrine system.

2. How is the plasma concentration of a hormone normally regulated?

3. List and briefly state the source and functions of the posterior pituitary hormones.

4. List and briefly state the source and functions of the anterior pituitary hormones.

5. Compare the relationship between the hypothalamus and posterior pituitary with the relationship between the hypothalamus and anterior pituitary. Describe the role of the hypothalamic–hypophyseal portal system and the hypothalamic releasing and inhibiting hormones.

6. Describe the actions of growth hormone that are unrelated to growth. What are growth hormone's growth-promoting actions? What is the role of IGFs?

7. Discuss the control of growth hormone secretion.

8. Describe the role of clock proteins.

9. What are the source, functions, and stimulus for secretion of melatonin?

Applying Clinical Reasoning

At 18 years of age and 8 feet tall, Anthony O. was diagnosed with gigantism caused by a pituitary tumor. The condition was treated by surgically removing his pituitary gland. What hormonal replacement therapy would Anthony need?

Thinking at a Higher Level

1. Would you expect the concentration of hypothalamic releasing and inhibiting hormones in a systemic venous blood sample to be higher, lower, or the same as the concentration of these hormones in a sample of hypothalamic–hypophyseal portal blood?

2. Thinking about the feedback control loop among TRH, TSH, and thyroid hormone, would you expect the concentration of TSH to be normal, above normal, or below normal in a person whose diet is deficient in iodine?

3. A patient displays symptoms of excess cortisol secretion. What factors could be measured in a blood sample to determine whether the condition is caused by a defect at the hypothalamus–anterior pituitary level or the adrenal cortex level?

4. Why would males with testicular feminization syndrome be unusually tall?

5. A black market for growth hormone abuse exists among weight lifters and other athletes. What actions of growth hormone would induce a full-grown athlete to take supplemental doses of this hormone? What are the potential detrimental side effects?

The Peripheral Endocrine Glands
A scintiscan of a normal thyroid gland. In this diagnostic technique, the activity of the thyroid gland is detected by a gamma camera that shows how much of an injected radioactive chemical tracer is taken up, with *red* being the most active and *blue* being the least active areas. Note that the two lobes of this endocrine gland give it a bow tie or butterfly shape. The thyroid gland secretes hormones that control the body's basal metabolic rate (idling speed).

CHAPTER AT A GLANCE

Homeostasis Highlights

The endocrine system, by means of the blood-borne hormones it secretes, generally regulates activities that require duration rather than speed. Most target-cell activities under hormonal control are directed toward maintaining homeostasis. The peripheral endocrine glands include the **thyroid gland**, which controls the body's basal metabolic rate; the **adrenal glands**, which secrete hormones important in maintaining salt balance, in metabolizing nutrient molecules, and in adapting to stress; the **endocrine pancreas**, which secretes hormones important in metabolizing nutrient molecules; and the **parathyroid glands**, which secrete a hormone important in Ca^{2+} metabolism.

19.1 Thyroid Gland

The **thyroid gland** consists of two lobes of endocrine tissue joined in the middle by a narrow portion of the gland, the *isthmus,* giving it a bow-tie shape (alternatively described as a butterfly shape) (❚Figure 19-1a and chapter opener photo). The gland is even located in the appropriate place for a bow tie, lying in the neck over the trachea just below the larynx.

The major cells that secrete thyroid hormone are organized into colloid-filled follicles.

The major thyroid secretory cells, known as **follicular cells,** are arranged into hollow spheres, each of which forms a functional unit called a **follicle.** On microscopic section (❚Figure 19-1b), the follicles appear as rings consisting of a single layer of follicular cells enclosing an inner lumen filled with **colloid,** a substance that serves as an extracellular storage site for thyroid hormone. Note that the colloid within the follicular lumen is extracellular (that is, outside the thyroid cells), even though it is located within the interior of the follicle. Colloid is not in direct contact with the extracellular fluid (ECF) that surrounds the follicle, similar to an inland lake that is not in direct contact with the oceans that surround a continent.

The chief constituent of colloid is a large glycoprotein molecule known as **thyroglobulin (Tg),** within which are incorporated the thyroid hormones in their various stages of synthesis. The follicular cells produce two iodine-containing hormones derived from the amino acid tyrosine: **tetraiodothyronine (T$_4$, or thyroxine)** and **tri-iodothyronine (T$_3$).** The prefixes *tetra* and *tri* and the subscripts *4* and *3* denote the number of iodine atoms incorporated into each of these hormones. These two hormones, collectively referred to as **thyroid hormone,** are important regulators of overall basal metabolic rate.

Interspersed in the interstitial spaces between the follicles is another secretory cell type, the **C cells,** which secrete the peptide hormone **calcitonin.** Calcitonin plays a role in calcium (Ca^{2+}) metabolism and is not related to T$_4$ and T$_3$. We discuss T$_4$ and T$_3$ here and talk about calcitonin later in a section dealing with endocrine control of Ca^{2+} balance.

Thyroid hormone is synthesized and stored on the thyroglobulin molecule.

The basic ingredients for thyroid hormone synthesis are tyrosine and iodine, both of which must be taken up from the blood by the follicular cells. Tyrosine, an amino acid, is synthesized in sufficient amounts by the body, so it is not essential to the diet. By contrast, the iodine needed for thyroid hormone synthesis must be obtained from dietary intake. Dietary *iodine (I)* is reduced to *iodide (I$^-$)* before absorption by the small intestine.

Most steps of thyroid hormone synthesis take place on the thyroglobulin molecules within the colloid. Thyroglobulin itself is produced by the endoplasmic reticulum–Golgi complex of the thyroid follicular cells. The amino acid tyrosine becomes incorporated in the much larger thyroglobulin molecules as the latter are being produced. Once produced, tyrosine-containing
(a) Gross anatomy of thyroid gland
(b) Light-microscopic appearance of thyroid gland

❚**Figure 19-1 Anatomy of the thyroid gland.** (a) Gross anatomy of the thyroid gland, anterior view. The thyroid gland lies over the trachea just below the larynx and consists of two lobes connected by a thin strip called the isthmus. (b) Light-microscopic appearance of the thyroid gland. The thyroid gland is composed primarily of colloid-filled spheres enclosed by a single layer of follicular cells.

thyroglobulin is exported in vesicles from the follicular cells into the colloid by exocytosis (❚Figure 19-2, step **1**). The thyroid captures I$^-$ from the blood and transfers it into the follicular cell by an iodide pump referred to as the **iodide trap**—the powerful, energy-requiring carrier protein in the outer membrane of a follicular cell (step **2**). The iodide trap is a symporter driven by the Na$^+$ concentration gradient established by the
KEY

ATP symbol →	= Primary active transport

Tg = Thyroglobulin
I⁻ = Iodide
TPO = Thyroperoxidase
MIT = Monoiodotyrosine

DIT = Di-iodotyrosine
T_3 = Tri-iodothyronine
T_4 = Tetraiodothyronine (thyroxine)

1 Tyrosine-containing Tg produced within the thyroid follicular cells by the endoplasmic reticulum–Golgi complex is transported by exocytosis into the colloid.

2 Iodide is carried by secondary active transport from the blood into the colloid by symporters in the basolateral membrane of the follicular cells.

3 In the follicular cell, the iodide is oxidized to active form by TPO at the luminal membrane.

4 The active iodide exits the cell through a luminal channel to enter the colloid.

5a Catalyzed by TPO, attachment of one iodide to tyrosine within the Tg molecule yields MIT.

5b Attachment of two iodides to tyrosine yields DIT.

6a Coupling of one MIT and one DIT yields T_3.

6b Coupling of two DITs yields T_4.

7 On appropriate stimulation, the thyroid follicular cells engulf a portion of Tg-containing colloid by phagocytosis.

8 Lysosomes attack the engulfed vesicle and split the iodinated products from Tg.

9a T_3 and T_4 diffuse into the blood (secretion).

9b MIT and DIT are deiodinated, and the freed iodide is recycled for synthesizing more hormone.

Figure 19-2 Synthesis, storage, and secretion of thyroid hormone. Note that the organelles are not drawn to scale. The endoplasmic reticulum–Golgi complex are proportionally too small.

FIGURE FOCUS: *If you were trying to develop a drug to reduce synthesis of T_3 and T_4 as a treatment for hyperthyroidism (too much thyroid hormone), which steps in this biosynthetic pathway are unique to the thyroid gland and thus would be good targets to block?*

Na^+–K^+ pump at the basolateral membrane (the membrane in contact with the interstitial fluid). The iodide trap transports Na^+ into the follicular cell down its concentration gradient and I^- into the cell against its concentration gradient. Almost all I^- in the body is moved against its concentration gradient to become trapped in the thyroid for thyroid hormone synthesis. Iodide is usually about 30 times more concentrated in the thyroid follicular cells than in the blood. Iodide serves no other function in the body.

Inside the follicular cell, iodide is oxidized to "active" iodide by a membrane-bound enzyme, **thyroperoxidase (TPO)**, located at the luminal membrane (the membrane in contact with the colloid) (step **3**). This active I^- exits through a channel in the luminal membrane to enter the colloid (step **4**).

Within the colloid, TPO, still membrane-bound, quickly attaches I^- to a tyrosine within the thyroglobulin molecule. Attachment of one iodide to tyrosine yields **monoiodotyrosine (MIT)** (step **5a**). Attachment of two iodides to tyrosine yields

di-iodotyrosine (DIT) (step **5b**). After MIT and DIT are formed, a coupling process occurs within the thyroglobulin molecule between the iodinated tyrosine molecules to form the thyroid hormones. Coupling of one MIT (with one iodide) and one DIT (with two iodides) yields **tri-iodothyronine**, or T_3 (with three iodides) (step **6a**). Coupling of two DITs (each bearing two iodides) yields **tetraiodothyronine (T_4, or thyroxine),** the four-iodide form of thyroid hormone (step **6b**). Coupling does not occur between two MIT molecules. All these products remain attached to thyroglobulin by peptide bonds. Thyroid hormones remain stored in this form in the colloid until they are split off and secreted. Sufficient thyroid hormone is normally stored to supply the body's needs for several months.

To secrete thyroid hormone, the follicular cells phagocytize thyroglobulin-laden colloid.

Release of thyroid hormone into the systemic circulation is complex for two reasons. First, before their release, T_3 and T_4 are still bound within the thyroglobulin molecule. Second, these hormones are stored at an inland extracellular site, in the colloid in the follicular lumen, so they must be transported completely across the follicular cells to reach the capillaries that course through the interstitial spaces between the follicles.

The process of thyroid hormone secretion essentially involves the follicular cells "biting off" a piece of colloid, breaking the thyroglobulin molecule down into its component parts, and "spitting out" the freed T_3 and T_4 into the blood. On appropriate stimulation for thyroid hormone secretion, the follicular cells internalize a portion of the thyroglobulin-hormone complex by phagocytizing a piece of colloid (❚Figure 19-2, step **7**). Within the cells, the membrane-enclosed droplets of colloid coalesce with lysosomes, whose enzymes split off the biologically active thyroid hormones, T_3 and T_4, and the inactive MIT and DIT (step **8**). The thyroid hormones, being very lipophilic, pass freely through the outer membranes of the follicular cells and into the blood (step **9a**).

MIT and DIT are of no endocrine value. The follicular cells contain an iodide-removing enzyme, *deiodinase*, which swiftly removes the I^- from MIT and DIT, allowing the freed I^- to be recycled for synthesis of more hormone (step **9b**). This highly specific enzyme removes I^- only from the worthless MIT and DIT, not the valuable T_3 or T_4.

Once released into the blood, the highly lipophilic (and therefore water-insoluble) thyroid hormone molecules quickly bind with several plasma proteins. Most circulating T_4 and T_3 is transported by **thyroxine-binding globulin**, a plasma protein that selectively binds only thyroid hormone. Less than 0.1% of the T_4 and less than 1% of the T_3 remain in the unbound (free) form. This is remarkable, considering that only the free portion of the total thyroid hormone pool has access to the target-cell receptors and thus can exert an effect.

About 90% of the secretory product released from the thyroid gland is in the form of T_4, yet T_3 is about 10 times more biologically potent. However, most secreted T_4 is converted into T_3, or *activated,* by being stripped of one of its iodides outside the thyroid gland, primarily in the liver and kidneys. These organs contain a different deiodinase enzyme than the type found in the thyroid gland, one that only removes an I^- from T_4. About 80% of the circulating T_3 is derived from secreted T_4 that has been peripherally stripped. Therefore, T_3 is the major biologically active form of thyroid hormone at the cellular level, even though the thyroid gland secretes mostly T_4.

Thyroid hormone increases the basal metabolic rate and exerts other effects.

Thyroid hormone does not have any discrete target organs. It affects virtually every tissue in the body. Like all lipophilic hormones, thyroid hormone crosses the plasma membrane and binds with an intracellular receptor, in this case a nuclear receptor bound to the **thyroid-response element** of DNA. This binding alters the transcription of specific mRNAs and thus synthesis of specific new proteins, typically enzymes, which carry out the cellular response. The nuclear thyroid hormone receptor has a 10 times greater affinity for T_3 than for T_4. Because a hormone's potency depends on how strongly the hormone binds to its target-cell receptors, T_3 is more potent than T_4.

Compared to other hormones, thyroid hormone action is "sluggish." The response to an increase in thyroid hormone is detectable only after a delay of several hours, and the maximal response is not evident for several days. The duration of the response is also quite long, partially because thyroid hormone is not rapidly degraded but also because the response to an increase in secretion continues for days or even weeks after the plasma thyroid hormone concentrations have returned to normal.

All body cells are affected either directly or indirectly by thyroid hormone. The effects of T_3 and T_4 can be grouped into several overlapping categories.

Effect on Metabolic Rate and Heat Production Thyroid hormone increases the body's overall basal metabolic rate (BMR), or "idling speed" (see p. 620). It is the most important regulator of the body's rate of O_2 consumption and energy expenditure under resting conditions.

Closely related to thyroid hormone's metabolic effect is its **calorigenic effect** (*calorigenic* means "heat-producing"). Increased metabolic activity results in increased heat production.

Sympathomimetic Effect Any action similar to one produced by the sympathetic nervous system is known as a **sympathomimetic effect** (*sympathomimetic* means "sympathetic-mimicking"). Thyroid hormone increases target-cell responsiveness to catecholamines (epinephrine and norepinephrine), the chemical messengers used by the sympathetic nervous system and its hormonal reinforcements from the adrenal medulla. Thyroid hormone accomplishes this permissive action by causing a proliferation of catecholamine target-cell receptors (see p. 643). Because of this action, many of the effects observed when thyroid hormone secretion is elevated are similar to those that accompany activation of the sympathetic nervous system.

Effect on the Cardiovascular System Thyroid hormone increases heart rate and force of contraction, thus increasing cardiac output (see p. 319), via both its direct effect on the heart

and through its effect of increasing the heart's responsiveness to catecholamines.

Effect on Growth and the Nervous System Thyroid hormone is essential for normal growth because of its effects on growth hormone (GH) and IGF-I (see p. 654). Thyroid hormone not only stimulates GH secretion and increases production of IGF-I by the liver but also promotes the effects of GH and IGF-I on the synthesis of new structural proteins and on bone growth. Thyroid-deficient children have stunted growth that can be reversed by thyroid replacement therapy, but excess thyroid hormone does not produce excessive growth.

Thyroid hormone plays a crucial role in development of the nervous system, especially the CNS, an effect impeded in children who have thyroid deficiency from birth. Thyroid hormone is also essential for normal CNS activity in adults.

Thyroid hormone is regulated by the hypothalamus–pituitary–thyroid axis.

Thyroid-stimulating hormone (TSH), the thyroid tropic hormone from the anterior pituitary, is the most important regulator of thyroid hormone secretion (❚ Figure 19-3) (see p. 647). TSH acts by increasing cAMP (see p. 123) in the thyrotropes. TSH stimulates almost every step of thyroid hormone synthesis and release. In addition to enhancing thyroid hormone secretion, TSH maintains the structural integrity of the thyroid gland. In the absence of TSH, the thyroid atrophies (decreases in size) and secretes its hormones at a very low rate. Conversely, it undergoes hypertrophy (increases the size of each follicular cell) and hyperplasia (increases the number of follicular cells) in response to excess TSH stimulation.

The hypothalamic **thyrotropin-releasing hormone (TRH)**, in tropic fashion, "turns on" TSH secretion by the anterior pituitary (see p. 650), whereas thyroid hormone, in negative-feedback fashion, "turns off" TSH secretion by inhibiting the anterior pituitary and hypothalamus. TRH functions via the IP_3 and DAG second-messenger pathways (see p. 124). Like other negative-feedback loops, the one between thyroid hormone and TSH tends to maintain a stable thyroid hormone output.

Negative feedback between the thyroid and anterior pituitary accomplishes day-to-day regulation of free thyroid hormone levels, whereas the hypothalamus mediates long-range adjustments. Unlike most other hormonal systems, the hormones in the hypothalamus–pituitary–thyroid axis in an adult normally do not undergo sudden, wide swings in secretion, although they do display a modest diurnal rhythm (day–night

fluctuations in secretion; see p. 642), with peak levels taking place as morning approaches and lowest concentrations occurring in early evening.

The only known factor that increases TRH secretion (and, accordingly, TSH and thyroid hormone secretion) is exposure to cold in newborn infants, a highly adaptive mechanism. The dramatic increase in heat-producing thyroid hormone secretion helps maintain body temperature during the abrupt drop in surrounding temperature at birth as the infant passes from the mother's warm body to the cooler environmental air. A similar immediate rise in secretion of hormones in this axis in response to cold exposure does not occur in adults, although it would make sense physiologically and does occur in many animals. Evidence suggests that on a longer-term basis during acclimatization to a cold environment, the concentration of hormones in this axis does increase as a means to increase the BMR and heat production.

Various types of stress, including physical stress, starvation, and infection, inhibit TSH and thyroid hormone secretion, presumably through neural influences on the hypothalamus, although the adaptive importance of this inhibition is unclear.

Abnormalities of thyroid function include both hypothyroidism and hyperthyroidism.

Clinical Note Abnormalities of thyroid function are among the most common endocrine disorders. They fall into two major categories—**hypothyroidism** and **hyperthyroidism**—reflecting deficient and excess thyroid hormone secretion, respectively. A number of causes can give rise to each of these conditions (❚ Table 19-1). Whatever the cause, the consequences of too little or too much thyroid hormone are largely predictable, based on knowing this hormone's functions.

Hypothyroidism Hypothyroidism can result (1) from primary failure of the thyroid gland; (2) secondary to a deficiency of TRH, TSH, or both; or (3) from inadequate dietary iodine.

Most symptoms of hypothyroidism are caused by a reduction in overall metabolic activity: A patient with hypothyroidism

Types of Thyroid Dysfunctions

Thyroid Dysfunction	Cause	Plasma Concentrations of Relevant Hormones	Goiter Present?
Hypothyroidism	Primary failure of the thyroid gland	↓ T_3 and T_4, ↑ TSH	Yes
	Secondary to hypothalamic or anterior pituitary failure	↓ T_3 and T_4, ↓ TRH and/or ↓ TSH	No
	Lack of dietary iodine	↓ T_3 and T_4, ↑ TSH	Yes
Hyperthyroidism	Abnormal presence of thyroid-stimulating immunoglobulin (TSI) (Graves' disease)	↑ T_3 and T_4, ↓ TSH	Yes
	Secondary to excess hypothalamic or anterior pituitary secretion	↑ T_3 and T_4, ↑ TRH and/or ↑ TSH	Yes
	Hypersecreting thyroid tumor	↑ T_3 and T_4, ↓ TSH	No

has a reduced BMR (less energy expenditure at rest); displays poor tolerance of cold (lack of the calorigenic effect); has a tendency to gain excessive weight (not burning fuels at a normal rate); and is easily fatigued (lower energy production). Another symptom is a slow, weak pulse (caused by a reduction in the rate and strength of cardiac contraction resulting from the diminished direct and sympathomimetic effects of thyroid hormone on the heart). A hypothyroid patient also exhibits slow reflexes and slow mental responsiveness (because of this hormone's effect on the nervous system). The mental effects are characterized by diminished alertness, slow speech, and poor memory.

Another notable characteristic is an edematous condition caused by infiltration of the skin with complex, water-retaining carbohydrate molecules *(glycosaminoglycans)*, the production of which by connective tissue cells is normally suppressed by thyroid hormone. The resultant puffy appearance, primarily of the face, hands, and feet, is known as **myxedema.** If a person has hypothyroidism from birth, a condition known as **cretinism** develops. Because adequate levels of thyroid hormone are essential for normal growth and CNS development, cretinism is characterized by dwarfism and mental retardation, in addition to general symptoms of thyroid deficiency. The mental retardation is preventable if replacement therapy is started promptly, but it is not reversible once it has developed for a few months after birth, even with later treatment with thyroid hormone.

Hypothyroidism is treated by taking replacement thyroid hormone pills, except in hypothyroidism caused by iodine deficiency, in which case the remedy is adequate dietary iodine.

Hyperthyroidism The most common cause of hyperthyroidism is **Graves' disease.** This is an autoimmune disease in which the body erroneously produces **thyroid-stimulating immunoglobulin (TSI)**, also known as **long-acting thyroid stimulator (LATS)**, an antibody whose target is the TSH receptors on the thyroid cells. (An *autoimmune disease* is one in which the immune system produces antibodies for one of the body's tissues.) TSI stimulates both secretion and growth of the thyroid in a manner similar to TSH. Unlike TSH, however, TSI is not subject to negative-feedback inhibition by thyroid hormone, so thyroid secretion and growth continue unchecked (❙Figure

19-4). Less frequently, hyperthyroidism occurs secondary to excess TRH or TSH or in association with a hypersecreting thyroid tumor.

As expected, the hyperthyroid patient has an elevated BMR. The resultant increase in heat production leads to excessive perspiration and poor tolerance of heat. Body weight typically falls because the body is burning fuel at an abnormally rapid rate. Net degradation of carbohydrate, fat, and protein stores occurs. The resultant loss of skeletal muscle protein results in weakness. Various cardiovascular abnormalities are associated with hyperthyroidism, caused both by the direct effects of thyroid hormone and by its interactions with catecholamines. Heart rate and strength of contraction may increase so much that the individual has palpitations (an unpleasant awareness of the heart's activity). The effects on the CNS are characterized by an excessive degree of mental alertness to the point where the patient is irritable, tense, anxious, and excessively emotional.
❙Figure 19-4 **Role of thyroid-stimulating immunoglobulin in Graves' disease.** Thyroid-stimulating immunoglobulin (TSI), an antibody erroneously produced in the autoimmune condition of Graves' disease, binds with the TSH receptors on the thyroid gland and continuously stimulates thyroid hormone secretion outside the normal negative-feedback control system.
❙Figure 19-5 **Woman with Graves' disease displaying exophthalmos.**

❙Figure 19-6 **Woman with a goiter.**

A prominent feature of Graves' disease but not of the other types of hyperthyroidism is **exophthalmos** (bulging eyes) (❙Figure 19-5). Inflammation and swelling of the eye muscles and fat behind the eyes within the orbits (eye sockets in the skull) push the eyeballs forward so that they bulge from these bony cavities.

Three general methods of treatment can suppress excess thyroid hormone secretion: use of anti-thyroid drugs that specifically interfere with thyroid hormone synthesis (for example, drugs that block symporter uptake of I^- or drugs that inhibit thyroperoxidase); surgical removal of a portion of the oversecreting thyroid gland; or administration of radioactive iodine, which, after being concentrated in the thyroid gland by the iodide trap, selectively destroys thyroid glandular tissue.

A goiter develops when the thyroid gland is overstimulated.

Clinical Note A **goiter** is an enlarged thyroid gland. Because the thyroid lies over the trachea, a goiter is readily palpable and usually highly visible (❙Figure 19-6). A goiter occurs whenever either TSH or TSI excessively stimulates the thyroid gland. Note from ❙Table 19-1 that a goiter may accompany hypothyroidism or hyperthyroidism, but it need not be present in either condition. Knowing the hypothalamus–pituitary–thyroid axis and feedback control, we can predict which types of thyroid dysfunction will produce a goiter. Let us consider hypothyroidism first:

■ Hypothyroidism secondary to hypothalamic or anterior pituitary failure is not accompanied by a goiter because the thyroid gland is not being adequately stimulated, let alone excessively stimulated.

■ With hypothyroidism caused by thyroid gland failure or lack of iodine, a goiter develops because the circulating level of thyroid hormone is so low that little negative-feedback inhibition takes place on the anterior pituitary and hypothalamus; TSH secretion is therefore elevated. TSH acts on the thyroid to increase the size and number of follicular cells and to increase their rate of secretion. If the thyroid cells cannot secrete hormone because of a lack of a critical enzyme or lack of iodine, no amount of TSH will be able to induce these cells to secrete T_3 and T_4. However, TSH can still promote hypertrophy and hyperplasia of the thyroid, with a consequent paradoxical enlargement of the gland (that is, a goiter), even though the gland is still underproducing.

Similarly, a goiter may or may not accompany hyperthyroidism:

■ Excess TSH secretion resulting from a hypothalamic or anterior pituitary defect would be accompanied by a goiter and excess T_3 and T_4 secretion because of overstimulation of thyroid growth.

■ In Graves' disease, a hypersecreting goiter occurs because TSI promotes growth of the thyroid, as well as enhancing secretion of thyroid hormone. Because the high levels of circulating T_3 and T_4 inhibit the anterior pituitary, TSH secretion itself is low.

■ Hyperthyroidism resulting from overactivity of the thyroid in the absence of overstimulation, such as caused by an uncontrolled thyroid tumor, is not accompanied by a goiter. The spontaneous secretion of excessive amounts of T_3 and T_4 inhibits TSH, so there is no stimulatory input to promote growth of the thyroid. (Even though a goiter does not develop, a tumor may cause enlargement of the thyroid, depending on the nature or size of the tumor.)

Check Your Understanding 19.1

1. Define *thyroid follicle, colloid, thyroglobulin, MIT, DIT, T_3,* and *T_4.*

2. Describe the action of the iodide trap.

3. Draw a flow diagram showing the effects and regulation of thyroid hormone secretion.

19.2 Adrenal Glands

There are two **adrenal glands,** one embedded above each kidney in a capsule of fat (*ad* means "next to"; *renal* means "kidney") (❚Figure 19-7a).

Each adrenal gland consists of a steroid-secreting cortex and a catecholamine-secreting medulla.

Each adrenal is composed of two endocrine glands, one surrounding the other. The outer layers composing the **adrenal cortex** secrete a variety of steroid hormones; the inner portion, the **adrenal medulla,** secretes catecholamines. Thus, the adrenal cortex and medulla secrete hormones belonging to different

chemical categories, whose functions, mechanisms of action, and regulation are entirely different. We examine the adrenal cortex before turning to the adrenal medulla.

The adrenal cortex secretes mineralocorticoids, glucocorticoids, and sex hormones.

The adrenal cortex consists of three layers, or zones: the **zona glomerulosa,** the outermost layer; the **zona fasciculata,** the middle and largest portion; and the **zona reticularis,** the innermost zone (❚Figure 19-7b). The adrenal cortex produces a number of different **adrenocortical hormones,** all of which are steroids derived from the common precursor molecule, cholesterol. All steroidogenic ("steroid-producing") tissues first convert

cholesterol to *pregnenolone,* then modify this common core molecule by stepwise enzymatic reactions to produce active steroid hormones. Each steroidogenic tissue has a complement of enzymes to produce one or several but not all steroid hormones (❙Figure 19-8). The adrenal cortex produces a greater variety of hormones than any other steroidogenic tissue. Slight variations in structure confer different functional capabilities on the various adrenocortical hormones, which can be divided into three categories based on their primary actions:

1. **Mineralocorticoids,** mainly *aldosterone,* influence mineral (electrolyte) balance, specifically Na^+ and K^+ balance.

2. **Glucocorticoids,** primarily *cortisol,* play a major role in glucose metabolism, as well as in protein and lipid metabolism and in adaptation to stress.

3. **Sex hormones** are identical or similar to those produced by the gonads (testes in males, ovaries in females). The most abundant and physiologically important of the adrenocortical sex hormones is *dehydroepiandrosterone,* an androgen, or "male" sex hormone.

The three categories of adrenal steroids are produced in anatomically distinct portions of the adrenal cortex as a result of differential distribution of the enzymes required to catalyze the different biosynthetic pathways leading to the formation of each of these steroids. Of the two major adrenocortical hormones, aldosterone is produced exclusively in the zona glo-merulosa, whereas cortisol synthesis is limited to the two inner layers of the cortex, with the zona fasciculata being the major source of this glucocorticoid (see ❙Figure 19-7b). No other steroidogenic tissues have the capability of producing either mineralocorticoids or glucocorticoids. In contrast, the adrenal sex hormones, also produced by the two inner cortical zones, are produced in far greater abundance in the gonads.

Because the adrenocortical hormones are all lipophilic and immediately diffuse through the plasma membrane of the steroidogenic cell into the blood after being synthesized, controlling the rate of synthesis regulates the rate of secretion.

Being lipophilic, the adrenocortical hormones are all carried in the blood extensively bound to plasma proteins. Cortisol is bound mostly to a plasma protein specific for it called **corticosteroid-binding globulin (transcortin)**, whereas aldosterone and dehydroepiandrosterone are largely bound to albumin, which nonspecifically binds a variety of lipophilic hormones.

Each of the adrenocortical steroid hormones binds with a receptor specific for it within the cytoplasm of the hormone's target cells: Mineralocorticoids bind to the **mineralocorticoid receptor (MR)**, glucocorticoids to the **glucocorticoid receptor (GR)**, and dehydroepiandrosterone to the **androgen receptor (AR)**. As is true of all steroid hormones, each hormone-receptor complex moves to the nucleus and binds with a complementary hormone-response element in DNA, namely the **mineralocorticoid response element**, **glucocorticoid response**
❙Figure 19-8 **Steroidogenic pathways for the major steroid hormones.** All steroid hormones are produced through a series of enzymatic reactions that modify cholesterol molecules, such as by varying the side groups attached to them. Each steroidogenic organ can produce only those steroid hormones for which it has a complete set of the enzymes needed to appropriately modify cholesterol, after first converting it to pregnenolone. The active hormones produced in the steroidogenic pathways are highlighted by screens. The intermediates that are not biologically active in humans are not screened.

FIGURE FOCUS: *"Male" sex hormones are produced in both males and females by the adrenal cortex. (True or false?)*

element, and **androgen response element**. This binding initiates specific gene transcription leading to synthesis of new proteins that carry out the effects of the hormone.

The major effects of mineralocorticoids are on Na$^+$ and K$^+$ balance and blood pressure homeostasis.

The actions and regulation of the primary adrenocortical mineralocorticoid, **aldosterone,** are described thoroughly elsewhere (Chapters 14 and 15). The principal site of aldosterone action is on the distal and collecting tubules of the kidney, where it promotes Na$^+$ retention and enhances K$^+$ elimination during the formation of urine. The promotion of Na$^+$ retention by aldosterone secondarily induces osmotic retention of H$_2$O, expanding the ECF volume (including the plasma volume), which is important in the long-term regulation of blood pressure.

Mineralocorticoids are *essential for life.* Without aldosterone, a person rapidly dies from circulatory shock because of the marked fall in plasma volume caused by excessive losses of H$_2$O-holding Na$^+$. With most other hormonal deficiencies, death is not imminent, even though a chronic hormonal deficiency may eventually lead to a premature death.

Aldosterone secretion is increased (1) via the complex renin–angiotensin–aldosterone system (RAAS) in response to a reduction in Na$^+$ and a fall in blood pressure (see ❚Figure 14-16, p. 508), and (2) via direct stimulation of the adrenal cortex by a rise in plasma K$^+$ concentration (see ❚Figure 14-22, p. 516). In tropic fashion, in addition to its effect on aldosterone secretion, angiotensin promotes growth of the zona glomerulosa. **Adrenocorticotropic hormone (ACTH)** from the anterior pituitary promotes secretion of cortisol, not aldosterone. Thus, regulation of aldosterone secretion is independent of anterior pituitary control.

Glucocorticoids exert metabolic effects and play a key role in adaptation to stress.

Cortisol, the primary glucocorticoid, plays an important role in carbohydrate, protein, and fat metabolism; executes significant permissive actions for other hormonal activities; and helps people resist stress.

Metabolic Effects The overall effect of cortisol's metabolic actions is to increase the concentration of blood glucose at the expense of protein and fat stores. Specifically, cortisol performs the following functions:

- It stimulates hepatic (liver) **gluconeogenesis,** the conversion of noncarbohydrate sources (namely, amino acids) into carbohydrate (*gluco* means "glucose"; *neo* means "new"; *genesis* means "production"). Between meals or during periods of fasting, when no new nutrients are being absorbed into the blood for use and storage, the glycogen (stored glucose) in the liver tends to become depleted as it is broken down to release glucose into the blood. Gluconeogenesis is an important factor in replenishing hepatic glycogen stores and thus in maintaining normal blood glucose levels between meals. This is essential

because the brain can use only glucose as its metabolic fuel, yet nervous tissue cannot store glycogen to any extent. The concentration of glucose in the blood must therefore be maintained at an appropriate level to adequately supply the glucose-dependent brain with nutrients.

- Cortisol inhibits glucose uptake and use by many tissues, but not the brain, thus sparing glucose for use by the brain, which requires it as a metabolic fuel. This action, like gluconeogenesis, increases blood glucose.
- It stimulates protein degradation in many tissues, especially muscle. By breaking down a portion of muscle proteins into their constituent amino acids, cortisol increases the blood amino acid concentration. These mobilized amino acids are available for use in gluconeogenesis or wherever else they are needed, such as for repair of damaged tissue or synthesis of new cellular structures.
- Cortisol facilitates **lipolysis,** the breakdown of lipid (fat) stores in adipose tissue, thus releasing free fatty acids into the blood (*lysis* means "breakdown"). The mobilized fatty acids are available as an alternative metabolic fuel for tissues that can use this energy source in lieu of glucose, thereby conserving glucose for the brain.

Permissive Actions Cortisol is extremely important for its permissiveness. For example, cortisol must be present in adequate amounts to permit the catecholamines to induce vasoconstriction (blood vessel narrowing). A person lacking cortisol, if untreated, may go into circulatory shock in a stressful situation that demands immediate widespread vasoconstriction.

Role in Adaptation to Stress Cortisol plays a key role in adaptation to stress. Stress of any kind is the major stimulus for increased cortisol secretion. Although cortisol's precise role in adapting to stress is not known, a speculative but plausible explanation might be as follows: A primitive human or an animal wounded or faced with a life-threatening situation must forgo eating. A cortisol-induced shift away from protein and fat stores in favor of expanded carbohydrate stores and increased availability of blood glucose would help protect the brain from malnutrition during the imposed fasting period. Also, the amino acids liberated by protein degradation would provide a supply of building blocks for tissue repair if physical injury occurred. Thus, cortisol increases the pool of glucose, amino acids, and fatty acids for use as needed.

Anti-Inflammatory and Immunosuppressive Effects When stress is accompanied by tissue injury, inflammatory and immune responses accompany the stress response. Cortisol exerts *anti-inflammatory* and *immunosuppressive* effects to help hold these immune system responses in a check-and-balance fashion. An exaggerated inflammatory response has the potential of causing harm. Cortisol interferes with almost every step of inflammation, such as by suppressing migration of neutrophils to the injured site and interfering with their phagocytic activity (see p. 410) and by suppressing production of inflammatory cytokines (see p. 411). Cortisol inhibits immune responses by interfering with antibody production by lymphocytes.

Blurring the line between endocrine and immune control, lymphocytes have been shown to secrete ACTH, and some of the cytokines released from immune cells can stimulate the hypothalamus–pituitary–adrenal axis. In feedback fashion, cortisol in turn has a profound dampening (turning-down) impact on the immune system. These interactions between the immune system and cortisol secretion help maintain immune homeostasis, an area only beginning to be explored.

Clinical Note Synthetic glucocorticoids (drugs) have been developed that maximize the anti-inflammatory and immunosuppressive effects of these steroids while minimizing the metabolic effects (see p. 412). When these drugs are administered therapeutically at pharmacologic levels (that is, at higher-than-physiologic concentrations), they are effective in treating conditions in which the inflammatory response itself has become destructive, such as *rheumatoid arthritis.* Glucocorticoids used in this manner do not affect the underlying disease process; they merely suppress the body's response to the disease. Because glucocorticoids also exert multiple inhibitory effects on the overall immune process, these agents have proved useful in managing various allergic disorders (inappropriate immune attacks) and in preventing organ transplant rejections (immune attack against foreign cells).

However, these steroids should be used only when warranted, and then only sparingly, for several important reasons. First, because these drugs suppress the normal inflammatory and immune responses that form the backbone of the body's defense system, a glucocorticoid-treated person has limited ability to resist infections. Second, troublesome side effects may occur with prolonged exposure to higher-than-normal concentrations of glucocorticoids. These effects include development of gastric ulcers, high blood pressure, atherosclerosis, menstrual irregularities, and bone thinning. Third, high levels of exogenous glucocorticoids act in negative-feedback fashion to suppress the hypothalamus–pituitary–adrenal axis that drives normal glucocorticoid secretion and maintains the integrity of the adrenal cortex. Prolonged suppression of this axis can lead to irreversible atrophy (shrinkage) of the cortisol-secreting cells of the adrenal gland and thus to permanent inability of the body to produce its own cortisol. That is why *nonsteroidal anti-inflammatory drugs (NSAIDs),* such as aspirin and ibuprofen, are used as alternative anti-inflammatory therapy.

Cortisol secretion is regulated by the hypothalamus–pituitary–adrenal cortex axis.

Cortisol secretion by the adrenal cortex is regulated by a negative-feedback system involving the hypothalamus and anterior pituitary (Figure 19-9). ACTH from the anterior pituitary corticotropes, acting through the cAMP pathway, stimulates the adrenal cortex to secrete cortisol. Being tropic to the zona fasciculata and zona reticularis, ACTH stimulates both the growth and the secretory output of these two inner layers of the cortex. In the absence of adequate amounts of ACTH, these layers shrink considerably and cortisol secretion is drastically reduced. Recall that angiotensin, not ACTH, maintains the size of the zona glomerulosa. ACTH enhances many steps in the synthesis of cortisol. ACTH-producing cells, in turn, secrete only at the

command of **corticotropin-releasing hormone (CRH)** from the hypothalamus. CRH stimulates the corticotropes via the cAMP pathway. The feedback control loop is completed by cortisol's inhibitory actions on CRH and ACTH secretion by the hypothalamus and anterior pituitary, respectively.

The negative-feedback system for cortisol maintains the level of cortisol secretion relatively constant around the set point. Superimposed on the basic negative-feedback control system are two additional factors that influence plasma cortisol concentrations by changing the set point: *diurnal rhythm* and *stress,* both of which act on the hypothalamus to vary the secretion rate of CRH.

Recall that plasma cortisol concentration displays a characteristic diurnal rhythm, with the highest level occurring in the morning and the lowest level at night (see Figure 18-2, p. 642).

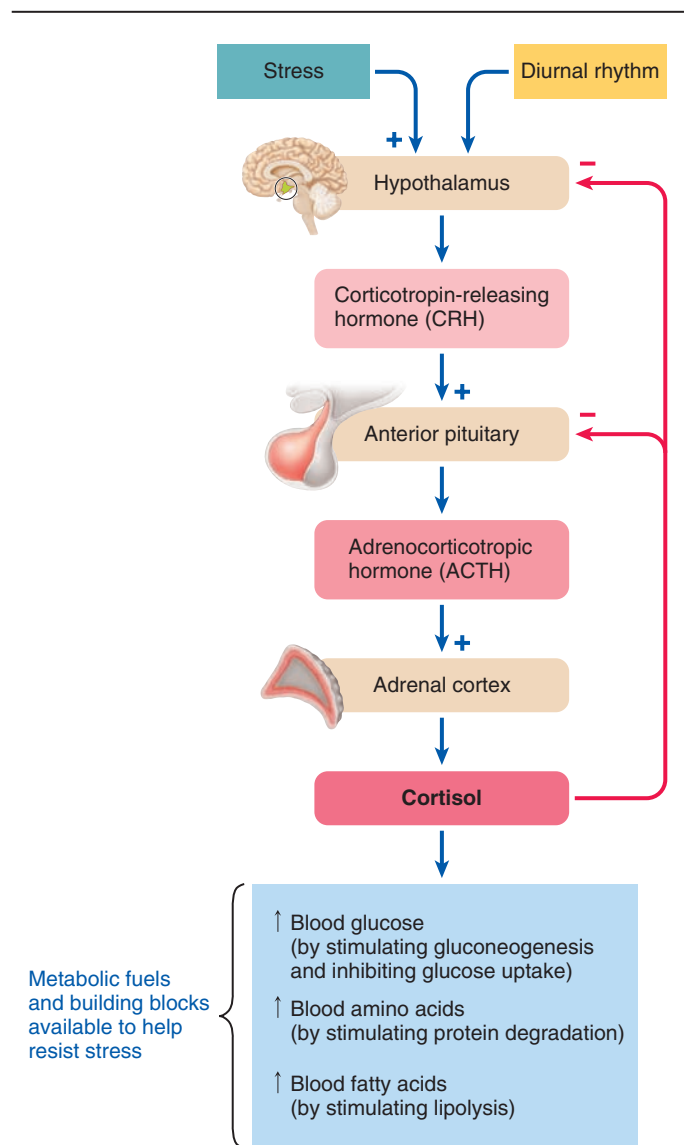
The other major factor that is independent of, and can override, the stabilizing negative-feedback control of cortisol is stress. Dramatic increases in cortisol secretion, mediated by the CNS through enhanced activity of the CRH–ACTH–cortisol


Figure 19-9 Control of cortisol secretion.

system, occur in response to all kinds of stressful situations. The magnitude of the increase in plasma cortisol concentration is generally proportional to the intensity of the stressful stimulation: A greater increase in cortisol levels takes place in response to severe stress than to mild stress.

The adrenal cortex secretes both male and female sex hormones in both sexes.

In both sexes, the adrenal cortex produces both *androgens,* or "male" sex hormones, and *estrogens,* or "female" sex hormones. The main site of production for the sex hormones is the gonads: the testes for androgens and the ovaries for estrogens. Accordingly, males have a preponderance of circulating androgens, whereas in females estrogens predominate. However, no hormones are unique to either males or females (except those from the placenta during pregnancy) because the adrenal cortex in both sexes produces small amounts of the sex hormone of the opposite sex. Additional small amounts of sex hormone of the opposite sex come from nonadrenal sources. Some testosterone in males is converted into estrogen by the enzyme *aromatase,* found especially in adipose tissue (see p. 726). In females, the ovaries produce androgen as an intermediate step in estrogen production (see ▎Figure 19-8). A little of this androgen is released into the blood instead of being converted into estrogen.

Under normal circumstances, the adrenal androgens and estrogens are not sufficiently abundant or powerful to induce masculinizing or feminizing effects, respectively. The only adrenal sex hormone that has any biological importance is the androgen **dehydroepiandrosterone (DHEA)**. The testes' primary androgen product is the potent testosterone, but the most abundant adrenal androgen is the weaker DHEA. (Testosterone exerts about 100 times greater "androgenicity" than DHEA.) Adrenal DHEA is overpowered by testicular testosterone in males but is of physiologic significance in females, who otherwise have little androgens. DHEA governs androgen-dependent processes in the female such as growth of pubic and axillary (armpit) hair, enhancement of the pubertal growth spurt, and development and maintenance of the female sex drive.

In addition to controlling cortisol secretion, ACTH (not the pituitary gonadotropic hormones) controls adrenal androgen secretion. In general, cortisol and DHEA output by the adrenal cortex parallel each other. However, adrenal androgens feed back outside the hypothalamus–pituitary–adrenal axis. Instead of inhibiting CRH, DHEA inhibits gonadotropin-releasing hormone, just as testicular androgens do. Furthermore, sometimes adrenal androgen and cortisol output diverge from each other— for example, at the time of puberty adrenal androgen secretion undergoes a marked surge, but cortisol secretion does not change. This enhanced secretion initiates the development of androgen-dependent processes in females. In males the same thing is accomplished primarily by testicular androgen secretion, which is also aroused at puberty. The nature of the pubertal inputs to the adrenals and gonads is still unresolved.

A surge in DHEA secretion begins at puberty and peaks between the ages of 25 and 30. DHEA is the most abundant circulating steroid in young adults. After 30, DHEA secretion slowly tapers off until, by the age of 60, the plasma DHEA concentration is less than 15% of its peak level.

Some scientists suspect that the age-related decline of DHEA and other hormones such as GH (see p. 658) plays a role in some problems of aging. (See the accompanying boxed feature, ▎Concepts, Challenges, and Controversies, for a discussion of theories of aging and anti-aging strategies under investigation.) DHEA supplementation as an anti-aging therapy is not recommended because of lack of evidence for its effectiveness and because of possible harmful side effects, such as raising the odds of acquiring ovarian or breast cancer in women and prostate cancer in men. Ironically, although the Food and Drug Administration (FDA) banned sales of DHEA as an over-the-counter drug in 1985 because of concerns about very real risks coupled with little proof of benefits, the product is widely available today as an unregulated food supplement. DHEA can be marketed as a dietary supplement without approval by the FDA as long as the product label makes no specific medical claims.

The adrenal cortex may secrete too much or too little of any of its hormones.

Clinical Note Although uncommon, there are a number of different disorders of adrenocortical function. Excessive secretion may occur with any of the three categories of adrenocortical hormones: aldosterone hypersecretion, cortisol hypersecretion, and adrenal androgen hypersecretion.

Aldosterone Hypersecretion Excess aldosterone secretion may be caused by (1) a hypersecreting adrenal tumor made up of aldosterone-secreting cells (**primary hyperaldosteronism**, or **Conn's syndrome)** or (2) inappropriately high activity of RAAS (**secondary hyperaldosteronism**). The latter may be produced by any number of conditions that cause a chronic reduction in arterial blood flow to the kidneys, thereby excessively activating RAAS. An example is atherosclerotic narrowing of the renal arteries.

Symptoms are related to the exaggerated effects of aldosterone—namely, excessive Na^+ retention *(hypernatremia)* and K^+ depletion *(hypokalemia)*. Also, high blood pressure (hypertension) is generally present, at least partially because of excessive Na^+ and fluid retention.

Cortisol Hypersecretion Excessive cortisol secretion (**Cushing's syndrome**) can be caused by (1) overstimulation of the adrenal cortex by excessive amounts of CRH, ACTH, or both, or (2) adrenal tumors that uncontrollably secrete cortisol independent of ACTH, or (3) ACTH-secreting tumors located in places other than the pituitary, most commonly in the lung.

The prominent symptoms of this syndrome are related to the exaggerated effects of glucocorticoid, specifically those caused by excessive gluconeogenesis. When too many amino acids are converted into glucose, the body suffers from combined glucose excess (high blood glucose) and protein shortage. Because the resultant hyperglycemia and glucosuria (glucose in the urine) mimic diabetes mellitus, the condition is sometimes referred to as *adrenal diabetes.* For unclear reasons, some of the extra glucose is deposited as body fat in locations characteristic for this

disease, typically in the abdomen, above the shoulder blades, and in the face. The abnormal fat distributions in the latter two locations are descriptively called a "buffalo hump" and a "moon face," respectively (❙Figure 19-10).

Besides the effects attributable to excessive glucose production, other effects arise from the widespread mobilization of amino acids from body proteins for use as glucose precursors. The appendages are thin because of muscle breakdown, in contrast to the abnormal fat deposits elsewhere. Loss of muscle protein leads to muscle weakness and fatigue. The protein-poor, thin skin of the abdomen becomes overstretched by the excessive underlying fat deposits, forming irregular, reddish purple linear streaks. Loss of structural protein within the walls of the small blood vessels leads to easy bruisability. Wounds heal poorly because formation of collagen, a major structural protein found in scar tissue, is depressed. Furthermore, loss of the collagen framework of bone weakens the skeleton, so fractures may result from little or no apparent injury.

(a) Young boy prior to onset of the condition

(b) Only four months later, the same boy displaying a "moon face" characteristic of Cushing's syndrome

❙Figure 19-10 **Patient with Cushing's syndrome**.

Adrenal Androgen Hypersecretion Excess adrenal androgen secretion, a masculinizing condition, is more common than the extremely rare feminizing condition of excess adrenal estrogen secretion. Either condition is referred to as **adrenogenital syndrome,** emphasizing the pronounced effects that excessive adrenal sex hormones have on the genitalia and associated sexual characteristics.

The symptoms that result from excess androgen secretion depend on the sex of the individual and the age at which the hyperactivity first begins.

■ *In adult females.* Because androgens exert masculinizing effects, a woman with this disease develops a male pattern of body hair, a condition referred to as **hirsutism.** She also acquires other male secondary sexual characteristics, such as deepening of the voice and more muscular arms and legs. The breasts become smaller, and menstruation may cease as a result of androgen suppression of the woman's hypothalamus and pituitary so that her ovaries are not stimulated to secrete the female sex hormones responsible for the menstrual cycle.

■ *In newborn females.* Female infants born with adrenogenital syndrome manifest male-type external genitalia because excessive androgen secretion occurs early enough during fetal life to induce development of their genitalia along male lines, similar to the development of males under the influence of testicular androgen (see p. 721). The clitoris, which is the female homologue of the male penis, enlarges under androgen influence and takes on a penile appearance, so in some cases it is difficult at first to determine the child's sex. This hormonal abnormality is one of the major causes of female **pseudoher-**

maphroditism, a condition in which female gonads (ovaries) are present but the external genitalia resemble those of a male. (A true hermaphrodite has the gonads of both sexes.)

■ *In prepubertal males.* Excessive adrenal androgen secretion in prepubertal boys causes them to prematurely develop male secondary sexual characteristics—for example, deep voice, beard, enlarged penis, and sex drive. This condition is referred to as **precocious pseudopuberty** to differentiate it from true puberty, which occurs as a result of increased testicular activity. In precocious pseudopuberty, the androgen secretion from the adrenal cortex is not accompanied by sperm production or any other gonadal activity because the testes are still in their nonfunctional prepubertal state.

■ *In adult males.* Overactivity of adrenal androgens in adult males has no apparent effect because any masculinizing effect induced by the weak DHEA, even when in excess, is unnoticeable in the face of the powerful masculinizing effects of the much more abundant and potent testosterone from the testes.

The adrenogenital syndrome is most commonly caused by an inherited enzymatic defect in the cortisol steroidogenic pathway. The pathway for synthesis of androgens branches from the normal biosynthetic pathway for cortisol (see ❙Figure 19-8). When an enzyme specifically essential for synthesis of cortisol is deficient, the result is decreased secretion of cortisol. The decline in cortisol secretion removes the negative-feedback effect on the hypothalamus and anterior pituitary so that levels of CRH and ACTH increase considerably (❙Figure 19-11). The defective adrenal cortex is incapable of responding to this increased ACTH secretion with cortisol output and instead shunts more of its cholesterol precursor into the androgen pathway. The result is excess DHEA production. This excess androgen does not inhibit ACTH but rather inhibits the gonadotropins. Because gamete production is not stimulated in the absence of gonadotropins,

Still a Big Question: Why Do We Age?

WE ALL RECOGNIZE OUTWARD SIGNS of aging when we see it (wrinkled faces, gray hair, slower movement). We are also aware of the increased incidence of cardiovascular disease, Alzheimer's disease, arthritis, and cataracts, to name a few, among the elderly. **Aging** is the progressive impairment of cellular, organ, and system functions characterized by loss of skin elasticity, hair color, and muscle strength; decreased immunity; metabolic dysfunction; decline in memory and other cognitive abilities; increased incidence of age-related diseases; and ultimately death. However, despite years of intensive research, no one knows for sure why and how aging happens. Many theories, some interrelated, and each with some supportive evidence, have been set forth. However, none of the theories alone can account for the inevitable progress toward senescence. Many of these theories are not mutually exclusive. Undoubtedly multiple factors contribute to the aging process.

Theories of aging can be grouped into three broad categories: (1) *programmed aging theories*, which propose that aging and lifespan are predetermined by a built-in timing mechanism; (2) *damage or error accumulation theories*, which suggest that aging occurs as a result of accumulated structural damage and functional errors arising from chance environmental insults that lead to progressive failure of cells and organs; and (3) *evolutionary theories*, which maintain that aging is an inadvertent by-product of natural selection for reproductive fitness. Following are the major theories in each category.

Programmed Aging Theories

■ The *age program theory*: We are genetically programmed to age and die. That is, aging follows an intrinsic biological timeline that is predestined, in the same way that an infant inevitably grows and matures into an adult.

■ The *limit theory*: Body cells can only divide an estimated 50 times on average after birth. Then they stop dividing, after which organs progressively fail, as cells that die are no longer replaced. Related is the *telomere shortening theory*: Telomeres, the end caps of chromosomes, get shorter with each successive cell division; when they get too short, further cell division is blocked.

■ The *endocrine theory*: Hormones control the pace of aging, much as they control growth, puberty, and reproductive capacity. For example, the natural decline of growth hormone and dehydroepiandrosterone contribute to the aging process.

■ The *immunological theory*: A programmed decline in immune function with advancing age leaves the elderly more susceptible to aging-associated diseases, including infectious diseases (for example, pneumonia) and cancer. Dysregulated immune responses are also implicated in cardiovascular disease and Alzheimer's disease, among other detrimental outcomes that lead to progressive loss of health and eventual death.

Damage or Error Accumulation Theories of Aging

■ The *free radical and oxidative stress theory*: Toxic by-products of living lead to aging and death. To sustain life, the mitochondrial electron transport chain uses O$_2$ to generate ATP from energy derived from nutrient molecules (see p. 37). Resultant side reactions constantly produce toxic by-products, namely *reactive oxygen species (ROS)* that can form destructive *free radicals*, highly reactive particles that damage DNA, proteins, and other biomolecules; see p. 142). Natural antioxidants in the body help curb the dangerous buildup of free radicals. *Oxidative stress* occurs when the body's ability to detoxify oxidizing agents is overwhelmed by a high ROS load. Environmental sources of oxidizing activity such as exposure to ionizing radiation or toxins in tobacco smoke can add to the body's total oxidative stress burden. The cumulative damage resulting from the inability of our antioxidant defenses to cope with generated reactive oxidative products over time gradually increases the risk of late-onset diseases. In a vicious cycle, oxidative stress promotes systemic inflammation, and inflammation intensifies oxidative stress.

■ The *accumulative waste theory*: Buildup of cellular garbage interferes with cellular functions. Molecules damaged by free radicals and other means can accumulate within a cell with advancing age to the point of interfering with cell signaling, with metabolic pathways, and with intracellular transport, causing cells to malfunction and deteriorate.

■ The *somatic DNA damage theory*: The genes that code for body proteins get messed up with time. Damage to DNA occurs continuously as a result of oxidative stress, copying errors during DNA replication, and external factors. Most DNA damage can be repaired, but some persist. The resulting defects in our body cells' genetic integrity accumulate with advancing age, leading to the progressive cellular and organ malfunctions associated with senescence.

■ The *wear and tear theory*: We are not built to last. The body gradually wears out as forces that damage the body (such as diseases, accidents, oxidative stress, and so on) outpace the body's ability to prevent, repair, overcome, or cope with these insults. Cumulative damage to irreplaceable molecules and cells eventually leads to progressive organ failure with increasing age.

■ The *cross-linkage theory*: Protein molecules literally stick together to the detriment of body function. Excess sugar in the blood can haphazardly attach to proteins, which causes cross links to form between and within proteins. Progressive formation of cross links among proteins such as collagen in the skin, tendons, and blood vessels causes these structures to lose their elasticity. Similar cross linking of other proteins, including enzymes, likewise gradually impairs cellular and organ function elsewhere.

Evolutionary Theories of Aging

■ The *mutation accumulation theory*: A deleterious gene mutation that kills the young will not be passed on to the next generation (that is, the mutation is strongly selected against), whereas a harmful gene mutation present within eggs and sperm as well as other body cells that does not manifest itself until people are past their reproductive years and have already passed the gene on to their offspring is not selected against. Over successive generations, late-acting lethal mutations accumulate, leading to an increase in mortality rates in older individuals.

■ The *antagonistic pleitropy theory*: This theory is based on a benefit-while-you're-young, pay-the-price-later principle. Some genes have multiple effects (this is what *pleitropy* means). An example is the gene that codes for the *mTOR* protein, a two-faced enzyme that is beneficial early in life for cell growth and development but is harmful after maturity as a key driver of aging. That is, the gene has antagonistic actions, depending on age. This gene would have been naturally selected because it favors reproductive fitness, despite its negative effect beyond the reproductive years. In this roundabout way, therefore, senescence has inadvertently been selected during evolution.

mTOR stands for *m*ammalian *t*arget *o*f *r*apamycin. Rapamycin is a drug that extends life in yeast and experimental animals by inhibiting their versions of TOR. Rapamycin itself has too many side effects for widespread use in humans, but scientists are searching for an anti-aging alternative. Severe calorie restriction (nutritionally adequate, near-starvation diet) suppresses mTOR activity and reduces oxidative stress, among other beneficial effects. As a result, the time of youthful vigor is increased and lifespan is extended up to 50% in experimental animals. Investigators are seeking milder ways to mimic these longevity effects. The hope is to buy us quality time by delaying or preventing the diseases of aging, not just to extend our years of senility. (Even now, healthy lifestyle choices are recommended to add some quality years to your life.)

Scientists are searching for other clues about what causes aging and possible ways to intercede by studying what goes wrong when children are on an incorrect aging timetable—either aging ahead of or behind schedule.

Progeria: Aging Ahead of Schedule

Progeria is a rare disorder (about 100 confirmed cases worldwide) where children manifest signs of aging and aging-related diseases (wrinkled skin, atherosclerosis, and stiff joints) along with other characteristics of the condition, including limited growth and a distinctive appearance (relatively large head, narrow face, no hair) (see the accompanying figure) (*pro* means "in favor of"; *geras* means "aging"). Mental and motor development is usually normal. Children with progeria age at a rate 8 to 10 times faster than normal and typically die in their early teens from heart attacks or strokes.

Progeria is a genetic condition that arises as a result of a new (not inherited) mutation. The most common mutation leads to production of a recently discovered, shortened form of a normal protein. This mutant form, dubbed *progerin*, causes significant disfigurement of the nuclear membrane and leads to cell dysfunction. Progerin has been associated not only with abnormal aging in progeria but also with normal aging. Progerin is produced in skin on exposure to ultraviolet light from the sun and tanning beds and is speculated to accelerate photoaging of skin, and a new finding suggests that during normal aging cells produce progerin when their telomeres become short.

Perpetual Childhood: Aging Behind Schedule

Even rarer, a handful of cases of "perpetual childhood" have been identified around the world. These individuals are moving along the

Seven-year-old girl with progeria. Seen here with her mother.

aging timeline at an incredibly slow pace, each apparently from a different underlying cause. One, a girl from Montana, at 8 years of age weighs only 11 pounds and still has the skin, dependency, and appearance of a baby, except that her hair, nails, and teeth are growing normally (see the accompanying figure). An aging specialist studying her case has identified some specific DNA flaws in her fully sequenced genes, but many questions remain. Might further analysis lead to a better understanding not only of this child's condition but of the aging process in general?

Eight-year-old "baby" girl. Seen here with her mother.
KEY

----→ = Normal pathways that do not occur	
ACTH = Adrenocorticotropic hormone	FSH = Follicle-stimulating hormone
GnRH = Gonadotropin-releasing hormone	LH = Luteinizing hormone
	CRH = Corticotropin-releasing hormone

I Figure 19-11 Hormonal interrelationships in adrenogenital syndrome. The adrenocortical cells that are supposed to produce cortisol produce androgens instead because of a deficiency of a specific enzyme essential for cortisol synthesis. Because no cortisol is secreted to act in negative-feedback fashion, CRH and ACTH levels are elevated. The adrenal cortex responds to increased ACTH by further increasing androgen secretion. The excess androgen produces virilization and inhibits the gonadotropin pathway, with the result that the gonads stop producing sex hormones and gametes.

people with adrenogenital syndrome are sterile. Of course, they also exhibit symptoms of cortisol deficiency.

The symptoms of adrenal virilization (having physical characteristics befitting a man in a person other than an adult male), sterility, and cortisol deficiency are all reversed by glucocorticoid therapy. Administration of exogenous glucocorticoid replaces the cortisol deficit and, more dramatically, inhibits the hypothalamus and pituitary so that ACTH secretion is suppressed. Once ACTH secretion is reduced, the profound stimulation of the adrenal cortex ceases and androgen secretion declines markedly. Removing the large quantities of adrenal androgens from circulation allows masculinizing characteristics to gradually recede and normal gonadotropin secretion to resume. Without understanding how these hormonal systems are related, it would be very difficult to comprehend how glucocorticoid administration could dramatically reverse symptoms of masculinization and sterility.

Adrenocortical Insufficiency If one adrenal gland is nonfunctional or removed, the other healthy organ can take over the function of both through hypertrophy and hyperplasia. Therefore, both glands must be affected before adrenocortical insufficiency occurs.

In **primary adrenocortical insufficiency (Addison's disease)**, all layers of the adrenal cortex are undersecreting. This condition is most commonly caused by autoimmune destruction of the cortex by erroneous production of adrenal cortex–attacking antibodies, in which case both aldosterone and cortisol are deficient. **Secondary adrenocortical insufficiency** may occur because of a pituitary or hypothalamic abnormality, resulting in insufficient ACTH secretion. In this case, only cortisol is deficient because aldosterone secretion does not depend on ACTH stimulation.

The symptoms associated with aldosterone deficiency in Addison's disease are the most threatening. If severe enough, the condition is fatal because aldosterone is essential for life. However, the loss of adrenal function may develop slowly and insidiously so that aldosterone secretion may be subnormal but not totally lacking. Patients with aldosterone deficiency display K^+ retention *(hyperkalemia)*, caused by reduced K^+ loss in the urine, and Na^+ depletion *(hyponatremia)*, caused by excessive urinary loss of Na^+. The former disturbs cardiac rhythm. The latter reduces ECF volume, including circulating blood volume, which in turn lowers blood pressure (hypotension).

Symptoms of cortisol deficiency are as would be expected: poor response to stress, hypoglycemia (low blood glucose) caused by reduced gluconeogenic activity, and lack of permissive action for many metabolic activities. The primary form of the disease also produces hyperpigmentation (darkening of the skin) resulting from excessive secretion of ACTH. Because the pituitary is normal, the decline in cortisol secretion brings about an uninhibited elevation in ACTH output (resulting from reduced negative feedback). Recall that ACTH and α melanocyte-stimulating hormone (α-MSH, a skin-darkening hormone that promotes dispersion of the pigment melanin) can both be cleaved from the same pro-opiomelanocortin precursor molecule (but not at the same time nor in the same organ; see p. 648). However, being closely related, at high levels ACTH can also bind with α-MSH's receptors in the skin and cause darkening of the skin.

Having completed discussion of the adrenal cortex, we now shift attention to the adrenal medulla.

The adrenal medulla consists of modified sympathetic postganglionic neurons.

The adrenal medulla is actually a modified part of the sympathetic nervous system. A sympathetic pathway consists of two neurons in sequence. A preganglionic neuron originating in the CNS has an axonal fiber that terminates on a second peripherally located postganglionic neuron, which in turn terminates on the effector organ (see p. 234). The neurotransmitter released by sympathetic postganglionic fibers is norepinephrine, which interacts locally with the innervated organ by binding with specific target receptors known as adrenergic receptors.

The adrenal medulla consists of modified postganglionic sympathetic neurons called **chromaffin cells** because of their staining preference for chromium ions. Unlike ordinary postganglionic sympathetic neurons, chromaffin cells do not have axonal fibers that terminate on effector organs. Instead, on stimulation by the preganglionic fiber the chromaffin cells release their chemical transmitter directly into the blood (see ▌Figure 7-2, p. 235). In this case, the transmitter qualifies as a hormone instead of a neurotransmitter. Like sympathetic fibers, the adrenal medulla does release norepinephrine, but its most abundant secretory output is a similar chemical messenger known as **epinephrine**. Both epinephrine and norepinephrine are catecholamines that possess the same structure except for epinephrine having a methyl group.

Epinephrine and norepinephrine are synthesized almost entirely within the cytosol of the adrenomedullary secretory cells. Once produced, these catecholamines are stored in **chromaffin granules**, which are similar to the transmitter storage vesicles found in sympathetic nerve endings. Segregation of catecholamines in chromaffin granules protects them from being destroyed by cytosolic enzymes during storage.

Secretion of Catecholamines from the Adrenal Medulla
Catecholamines are secreted into the blood by exocytosis of chromaffin granules. Their release is analogous to the release of stored peptide hormones from secretory vesicles or the release of norepinephrine at sympathetic postganglionic terminals.

Of the total adrenomedullary catecholamine output, epinephrine accounts for 80% and norepinephrine for 20%. Epinephrine is produced exclusively by the adrenal medulla, but the bulk of norepinephrine is produced by sympathetic postganglionic fibers. Adrenomedullary norepinephrine is secreted in quantities too small to exert significant effects on target cells. Therefore, for practical purposes we can assume that norepinephrine effects are predominantly mediated directly by the sympathetic nervous system and that epinephrine effects are brought about exclusively by the adrenal medulla.

Epinephrine and norepinephrine vary in their affinities for different receptor types.

Epinephrine and norepinephrine have differing affinities for four distinctive receptor types: α_1, α_2, β_1, and β_2 adrenergic receptors (see p. 240). (See ▌Table 7-1, p. 238 and ▌Table 7-2, p. 240 to review the distribution of these receptor types among target organs.)

Norepinephrine binds predominantly with α and β_1 receptors located near postganglionic sympathetic-fiber terminals. Hormonal epinephrine, which can reach all α and β_1 receptors via its circulatory distribution, interacts with these same receptors. Norepinephrine has a little greater affinity than epinephrine for the α receptors, and the two hormones have approximately the same potency at the β_1 receptors. Thus, epinephrine and norepinephrine exert similar effects in many tissues, with epinephrine generally reinforcing sympathetic nervous activity. In addition, epinephrine activates β_2 receptors, over which the sympathetic nervous system exerts no influence. Many of the epinephrine-exclusive β_2 receptors are located at tissues not even supplied by the sympathetic nervous system but reached by epinephrine through the blood. Examples include skeletal muscle, where epinephrine exerts metabolic effects such as promoting the breakdown of stored glycogen, and bronchiolar smooth muscle, where it causes bronchodilation.

Sometimes epinephrine, through its exclusive β_2-receptor activation, brings about a different action from that elicited by norepinephrine and epinephrine action through their mutual activation of other adrenergic receptors. As an example, norepinephrine and epinephrine bring about a generalized vasoconstrictor effect mediated by α_1-receptor stimulation. By contrast, epinephrine promotes vasodilation of the blood vessels that supply skeletal muscles and the heart through β_2-receptor activation (see p. 350).

Realize, however, that epinephrine functions only at the bidding of the sympathetic nervous system, which is solely responsible for stimulating its secretion from the adrenal medulla. Epinephrine secretion always accompanies a generalized sympathetic nervous system discharge, so sympathetic activity indirectly controls actions of epinephrine. By having the more versatile circulating epinephrine at its call, the sympathetic nervous system has a means of reinforcing its own neurotransmitter effects plus a way of executing additional actions on tissues that it does not directly innervate.

Catecholamines exert their effects via second-messenger pathways. Effects arising from binding to β receptor types are mediated via increased cAMP, to the α_2 receptors via decreased cAMP, and to the α_1 receptors via increased IP_3 and DAG.

Epinephrine reinforces the sympathetic nervous system and exerts metabolic effects.

Adrenomedullary hormones are not essential for life, but virtually all organs in the body are affected by these catecholamines. They play important roles in mounting stress responses, regulating arterial blood pressure, and controlling fuel metabolism. The following sections discuss epinephrine's major effects, which it achieves either in collaboration with the sympathetic transmitter norepinephrine or alone to complement direct sympathetic response.

Effects on Organ Systems
Together, the sympathetic nervous system and adrenomedullary epinephrine mobilize the body's resources to support peak physical exertion in emergency or stressful situations. The sympathetic and epinephrine

actions constitute a fight-or-flight response that prepares the person to combat an enemy or flee from danger (see p. 238). Specifically, the sympathetic system and epinephrine increase cardiac output by increasing the rate and strength of cardiac contraction, and their generalized vasoconstrictor effects increase total peripheral resistance. Together, these effects raise arterial blood pressure, thus ensuring an appropriate driving pressure to force blood to the organs most vital for meeting the emergency. Meanwhile, vasodilation of coronary and skeletal muscle blood vessels induced by epinephrine and local metabolic factors shifts blood to the heart and skeletal muscles from other vasoconstricted regions of the body, thus shunting blood to the areas of most immediate need. Because of their profound influence on the heart and blood vessels, the sympathetic system and epinephrine also play an important role in ongoing maintenance of arterial blood pressure, even in the absence of an emergency.

Epinephrine (but not norepinephrine) dilates the respiratory airways to reduce the resistance encountered in moving air in and out of the lungs. Epinephrine and norepinephrine also reduce digestive activity and inhibit bladder emptying, both activities that can be "put on hold" during a fight-or-flight situation.

Metabolic Effects Epinephrine exerts some important metabolic effects. In general, it prompts the mobilization of stored carbohydrate and fat so that extra energy is available for use as needed to fuel muscular work. Specifically, epinephrine increases blood glucose by several different mechanisms. First, it stimulates both hepatic gluconeogenesis and **glycogenolysis**, the latter being the breakdown of stored glycogen into glucose, which is released into the blood. Epinephrine also stimulates glycogenolysis in skeletal muscles. Because of the difference in enzyme content between liver and muscle, however, muscle glycogen cannot be converted directly to glucose. Instead, the breakdown of muscle glycogen releases lactate into the blood. The liver removes lactate from the blood and converts it into glucose, so epinephrine's actions on skeletal muscle indirectly help raise blood glucose levels. Epinephrine and the sympathetic system further add to this hyperglycemic effect by inhibiting secretion of insulin, the pancreatic hormone primarily responsible for removing glucose from the blood, and by stimulating glucagon, another pancreatic hormone that promotes hepatic glycogenolysis and gluconeogenesis. In addition to increasing blood glucose levels, epinephrine also increases the level of blood fatty acids by promoting lipolysis.

Epinephrine's metabolic effects are appropriate for fight-or-flight situations. The elevated levels of glucose and fatty acids provide additional fuel to power the muscular movement required by the situation and also assure adequate nourishment for the brain during the crisis when no new nutrients are being consumed. Muscles can use fatty acids for energy production, but the brain cannot.

Because of its other widespread actions, epinephrine also increases the overall metabolic rate. Under the influence of epinephrine, many tissues metabolize faster. For example, the work of the heart and respiratory muscles increases, and the pace of liver metabolism steps up. Thus, epinephrine and thyroid hormone both increase the metabolic rate.

Other Effects Epinephrine acts on the CNS to promote a state of arousal and increased alertness. This permits "quick thinking" to help cope with the impending emergency. Many drugs used as stimulants or sedatives exert their effects by altering catecholamine levels in the CNS.

Both epinephrine and norepinephrine cause sweating, which helps the body rid itself of extra heat generated by increased muscular activity. Also, epinephrine acts on smooth muscles within the eyes to dilate the pupil and flatten the lens. These actions adjust the eyes for more encompassing vision so that the whole threatening scene can be quickly viewed.

Epinephrine is released only on sympathetic stimulation of the adrenal medulla.

Catecholamine secretion by the adrenal medulla is controlled entirely by sympathetic input to the gland. When the sympathetic system is activated under conditions of fear or stress, it simultaneously triggers a surge of adrenomedullary catecholamine release. The concentration of epinephrine in the blood may increase up to 300 times normal, with the amount of epinephrine released depending on the type and intensity of the stressful stimulus.

Because both parts of the adrenal gland are important in responding to stress, this is an appropriate place to pull together the major factors involved in the stress response, the topic of the next section.

Check Your Understanding 19.2

1. List the three categories of adrenocortical hormones, name the primary hormone in each category, and state the functions of each of these hormones.

2. Discuss the effect of ACTH on the adrenal cortex.

3. Name the two catecholamines secreted by the adrenal medulla and describe how they are stored and released.

19.3 Integrated Stress Response

Stress is the generalized, nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis. Contrary to popular usage, the agent inducing the response is correctly called a *stressor,* whereas *stress* refers to the state induced by the stressor. The following types of noxious stimuli illustrate the range of factors that can induce a stress response: *physical* (trauma, surgery, intense heat or cold); *chemical* (reduced O_2 supply, acid–base imbalance); *physiologic* (heavy exercise, hemorrhagic shock, pain); infectious (bacterial invasion); *psychological* or *emotional* (anxiety, fear, sorrow); and *social* (personal conflicts, change in lifestyle).

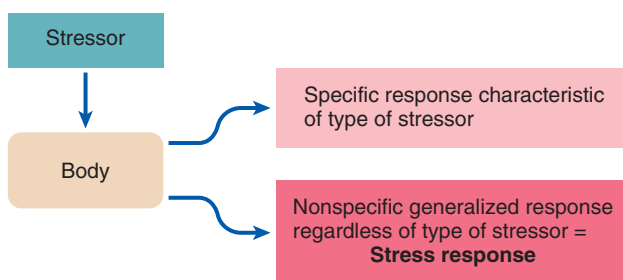
The stress response is a generalized pattern of reactions to any situation that threatens homeostasis.

Different stressors may produce some specific responses characteristic of that stressor; for example, the body's specific response to cold exposure is shivering and skin vasoconstriction, whereas the specific response to bacterial invasion includes increased phagocytic activity and antibody production. In addition to their specific response, however, all stressors produce a similar nonspecific, generalized response (▮Figure 19-12). This set of responses common to all noxious stimuli is called the **general adaptation syndrome.** When a stressor is recognized, both nervous and hormonal responses bring about defensive measures to cope with the emergency. The result is a state of intense readiness and mobilization of biochemical resources.

To appreciate the value of the multifaceted stress response, imagine a primitive cave dweller who has just seen a large wild beast lurking in the shadows. We consider both the neural and the hormonal responses that would take place in this scenario. The body responds in the same way to modern-day stressors. We cover all these responses in further detail elsewhere. At this time, we just examine how they work together.

Roles of the Sympathetic Nervous System and Epinephrine in Stress The major neural response to such a stressful stimulus is generalized activation of the sympathetic nervous system, which prepares the body for a fight-or-flight response. Simultaneously, the sympathetic system calls forth a massive outpouring of epinephrine from the adrenal medulla. Epinephrine strengthens sympathetic responses and mobilizes carbohydrate and fat stores.

Roles of the CRH–ACTH–Cortisol System In Stress Besides epinephrine, a number of other hormones are involved in the overall stress response. The predominant hormonal response is activation of the CRH–ACTH–cortisol system. Recall that cortisol's role in helping the body cope with stress is presumed to be related to its metabolic effects, namely increasing the pool of glucose, amino acids, and fatty acids in the blood for use as needed, such as to sustain nourishment to the brain and provide building blocks for repair of damaged tissues.

In addition to the effects of cortisol in the hypothalamus–pituitary–adrenal cortex axis, ACTH may also play a role in


resisting stress. ACTH is one of several peptides that facilitate learning and behavior. Thus, an increase in ACTH during psychosocial stress may help the body cope more readily with similar stressors in the future by facilitating the learning of appropriate behavioral responses.

Role of Other Hormonal Responses in Stress Besides the CRH–ACTH–cortisol system, other hormonal systems play key roles in the stress response, as follows:

■ *Elevation of blood glucose and fatty acids through decreased insulin and increased glucagon.* The sympathetic nervous system and the epinephrine secreted at its bidding both inhibit insulin and stimulate glucagon. These hormonal changes act in concert to elevate blood glucose and blood fatty acids. Epinephrine and glucagon, both of which are increased during stress, promote hepatic glycogenolysis and (along with cortisol) hepatic gluconeogenesis. However, insulin, whose secretion is suppressed during stress, opposes the breakdown of liver glycogen stores. All these effects help increase blood glucose. The primary stimulus for insulin secretion is a rise in blood glucose; in turn, a primary effect of insulin is to lower blood glucose. If it were not for the deliberate inhibition of insulin during the stress response, the hyperglycemia caused by stress would stimulate secretion of glucose-lowering insulin. As a result, the elevation in blood glucose could not be sustained. Stress-related hormonal responses also promote release of fatty acids from fat stores because lipolysis is favored by epinephrine, glucagon, and cortisol but opposed by insulin.

■ *Maintenance of blood volume and blood pressure through increased renin–angiotensin–aldosterone and vasopressin activity.* In addition to the hormonal changes that mobilize energy stores during stress, other hormones are simultaneously called into play to sustain plasma volume and blood pressure during the emergency. The sympathetic system and epinephrine play major roles in acting directly on the heart and blood vessels to improve circulatory function. In addition, RAAS is activated as a consequence of increased sympathetic activity to the kidneys (see p. 507). Vasopressin secretion is also increased during stressful situations (see p. 543). Collectively, these hormones expand the plasma volume by promoting retention of salt and H_2O. Presumably, the enlarged plasma volume is a protective measure to help sustain blood pressure should acute loss of plasma fluid occur through hemorrhage or heavy sweating during the impending period of danger. Vasopressin and angiotensin also have direct vasopressor effects, which would be of benefit in maintaining an adequate blood pressure in the event of acute blood loss (see p. 350). Vasopressin is further believed to facilitate learning, which has implications for future adaptation to stress.

The multifaceted stress response is coordinated by the hypothalamus.

All the individual responses to stress just described are either directly or indirectly influenced by the hypothalamus (▮Figure 19-13). The hypothalamus receives input concerning physical

▮Figure 19-12 Action of a stressor on the body.
Figure 19-13 Integration of the stress response by the hypothalamus.
FIGURE FOCUS: *(1) Trace all of the pathways that lead to mobilization of energy stores and metabolic building blocks during the stress response. (2) Likewise, trace all of the pathways that lead to salt and water conservation.*

and emotional stressors from virtually all areas of the brain and from many receptors throughout the body. In response, the hypothalamus directly activates the sympathetic nervous system, secretes CRH to stimulate ACTH and cortisol release, and triggers vasopressin release. Sympathetic stimulation, in turn, brings about secretion of epinephrine, with which it has a conjoined effect on the pancreatic secretion of insulin and glucagon. Furthermore, vasoconstriction of the renal afferent arterioles by the catecholamines indirectly triggers secretion of renin by reducing blood flow through the kidneys (a stimulus for renin secretion). Renin, in turn, sets in motion RAAS. Thus, the hypothalamus integrates the responses of both the sympathetic nervous system and the endocrine system during stress.

Activation of the stress response by chronic psychosocial stressors may be harmful.

Acceleration of cardiovascular and respiratory activity, retention of salt and H_2O, and mobilization of metabolic fuels and building blocks can be of benefit in response to a physical stressor, such as an athletic competition. Most of the stressors in our everyday lives are psychosocial in nature; however, they induce these same

magnified responses. Stressors such as anxiety about an exam, conflicts with loved ones, or impatience while sitting in a traffic jam can elicit a stress response. Although the rapid mobilization of body resources is appropriate in the face of real or threatened physical injury, it is generally inappropriate in response to nonphysical stress. If no extra energy is demanded, no tissue is damaged, and no blood lost, body stores are being broken down and fluid retained needlessly, probably to the detriment of the emotionally stressed individual. In fact, strong circumstantial evidence suggests a link between chronic exposure to psychosocial stressors and development of pathological conditions such as high blood pressure, although no definitive cause-and-effect relationship has been ascertained. As a result of "unused" stress responses, could hypertension result from too much sympathetic vasoconstriction? From too much salt and H_2O retention? From too much vasopressin and angiotensin pressor activity? A combination of these? Other factors? Recall that hypertension can develop with prolonged exposure to pharmacological levels of glucocorticoids. Could long-standing lesser elevations of cortisol, such as might occur in the face of continual psychosocial stressors, do the same thing, only more slowly? Considerable work remains to be done to evaluate the contributions that the stressors in our everyday lives make toward disease production.

19.4 Endocrine Pancreas and Control of Fuel Metabolism

We have just discussed the metabolic changes elicited during the stress response. Now we concentrate on the metabolic patterns that occur in the absence of stress, including the hormonal factors that govern this normal metabolism.

Fuel metabolism includes anabolism, catabolism, and interconversions among energy-rich organic molecules.

The term **metabolism** refers to all the chemical reactions that occur within body cells. Those reactions involving the degradation, synthesis, and transformation of the three classes of energy-rich organic molecules—protein, carbohydrate, and fat—are collectively known as **intermediary metabolism,** or **fuel metabolism** (❙Table 19-2).

During the process of digestion, large nutrient molecules (**macromolecules**) are broken down into their smaller absorbable subunits as follows: Proteins are converted into amino acids, complex carbohydrates into monosaccharides (mainly glucose), and triglycerides (dietary fats) into monoglycerides and free fatty acids. These absorbable units are transferred from the digestive tract lumen into the blood, either directly or by way of the lymph (Chapter 16).

Anabolism and Catabolism Once absorbed, the organic subunits are constantly exchanged between the blood and the body cells. The chemical reactions in which these small organic molecules participate within the cells are categorized into two metabolic processes: anabolism and catabolism (❙Figure 19-14). **Anabolism** is the buildup or synthesis of larger organic macromolecules from small organic molecular subunits. Anabolic reactions generally require energy input in the form of adenosine triphosphate (ATP). These reactions result in either (1) the manufacture of materials needed by the cell, such as cellular structural proteins or secretory products, or (2) the storage of excess ingested nutrients not immediately needed for energy production or as cellular building blocks. Storage is in the form of glycogen (the storage form of glucose) or fat reservoirs. **Catabolism** is the breakdown, or degradation, of large, energy-rich organic molecules within cells. Catabolism encompasses two levels of breakdown: (1) hydrolysis (see pp. 31 and A-14) of large cellular organic macromolecules into their smaller subunits, similar to the process of digestion except that the reactions take place within the body cells instead of within the digestive tract lumen (for example, release of glucose by the catabolism of stored glycogen), and (2) oxidation of the smaller subunits, such as glucose, to yield energy for ATP production (see p. 37).

❙**TABLE 19-2** Summary of Reactions in Fuel Metabolism

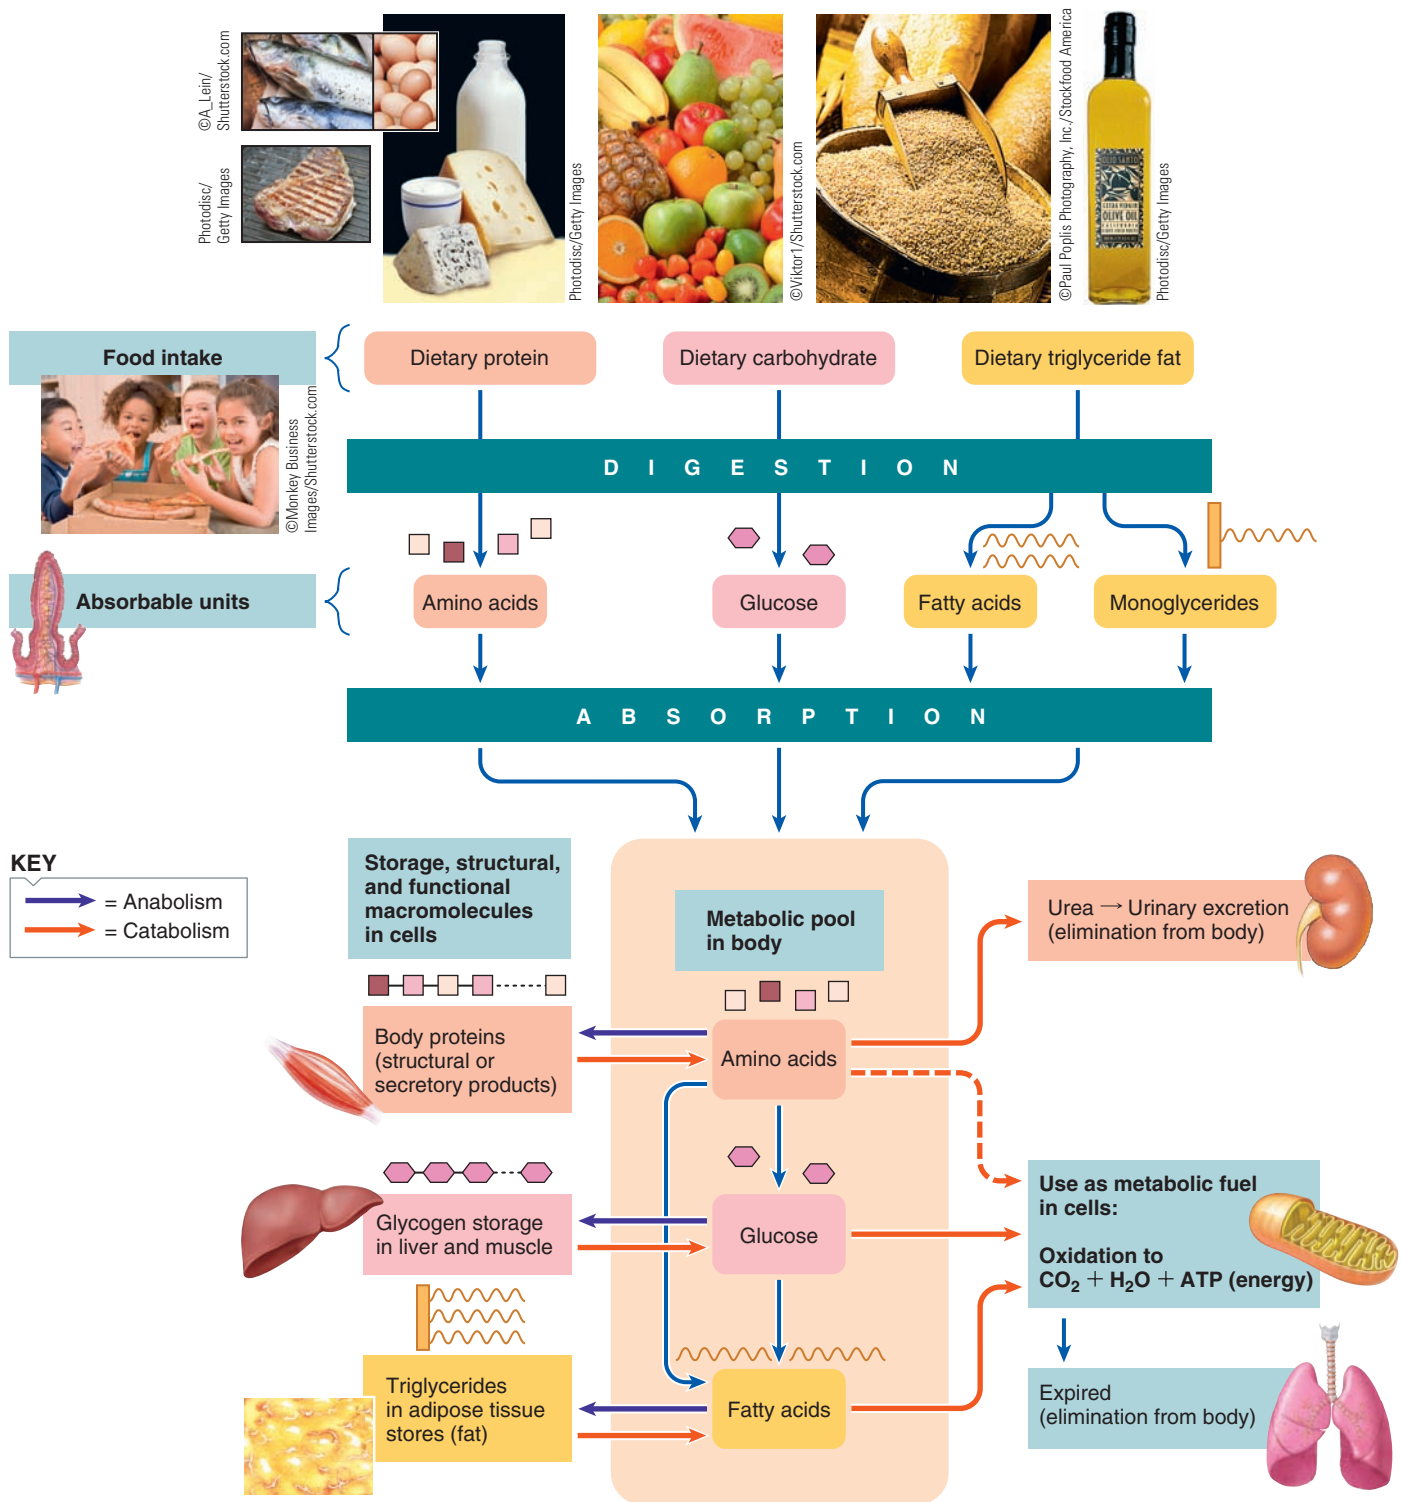
Metabolic Process	Reaction	Consequence
Glycogenesis	Glucose → glycogen	↓ Blood glucose
Glycogenolysis	Glycogen → glucose	↑ Blood glucose
Gluconeogenesis	Amino acids → glucose	↑ Blood glucose
Protein synthesis	Amino acids → protein	↓ Blood amino acids
Protein degradation	Protein → amino acids	↑ Blood amino acids
Fat synthesis (lipogenesis or triglyceride synthesis)	Fatty acids and glycerol → triglycerides	↓ Blood fatty acids
Fat breakdown (lipolysis or triglyceride degradation)	Triglycerides → fatty acids and glycerol	↑ Blood fatty acids


Figure 19-14 Summary of the major pathways involving organic nutrient molecules.

As an alternative to energy production, the smaller, multi-potential organic subunits derived from intracellular hydrolysis may be released into the blood. These mobilized glucose, fatty acid, and amino acid molecules can then be used as needed for energy production or cellular synthesis elsewhere in the body.

In an adult, the rates of anabolism and catabolism are generally in balance, so the adult body remains in a dynamic steady state and appears unchanged even though the organic molecules that determine its structure and function are continuously being turned over. During growth, anabolism exceeds catabolism.

Interconversions Among Organic Molecules In addition to being able to resynthesize catabolized organic molecules back into the same type of molecules, many cells of the body, especially liver cells, can convert most types of small organic molecules into other types—as in, for example, transforming

Metabolic Fuel	Circulating Form	Storage Form	Major Storage Site	Percentage of Total Body Energy Content (and Calories*)	Reservoir Capacity	Role
Carbohydrate	Glucose	Glycogen	Liver, muscle	1% (1500 calories)	Less than a day's worth of energy	First energy source; essential for the brain
Fat	Free fatty acids	Triglycerides	Adipose tissue	77% (143,000 calories)	About two months' worth of energy	Primary energy reservoir; energy source during a fast
Protein	Amino acids	Body proteins	Muscle	22% (41,000 calories)	Death results long before capacity is fully used because of structural and functional impairment	Source of glucose for the brain during a fast; last resort to meet other energy needs

*Actually refers to kilocalories; see p. 619.

amino acids into glucose or fatty acids. Because of these inter-conversions, adequate nourishment can be provided by a range of molecules present in different types of foods. There are limits, however. **Essential nutrients,** such as the essential amino acids and vitamins, cannot be formed in the body by conversion from another type of organic molecule.

The major fate of ingested carbohydrates and fats is catabolism to yield energy. Amino acids are predominantly used for protein synthesis but can be used to supply energy after being converted to carbohydrate or fat. Thus, all three categories of foodstuff can be used as fuel, and excesses of any foodstuff can be deposited as stored fuel, as you will see shortly.

At a superficial level, fuel metabolism appears relatively simple: The amount of nutrients in the diet must be sufficient to meet the body's needs for energy production and cellular synthesis. This apparently simple relationship is complicated, however, by two important considerations: (1) nutrients taken in at meals must be stored and then released between meals, and (2) the brain must be continuously supplied with glucose. Let us examine the implications of each.

Because food intake is intermittent, nutrients must be stored for use between meals.

Dietary fuel intake is intermittent, not continuous. As a result, excess energy must be absorbed during meals and stored for use during fasting periods between meals, when dietary sources of metabolic fuel are not available. Despite intermittent energy intake, the body cells' demand for energy is ever-present and fluctuating. That is, energy must constantly be available for cells to use as needed no matter what the status of food intake is. Stored energy fills in the gaps between meals. Energy storage takes three forms (ǀTable 19-3):

■ *Excess circulating glucose* is stored in the liver and muscle as *glycogen,* a large molecule consisting of interconnected glucose molecules (see ǀFigures 2-18, p. 44, and 16-1, p. 567). About

twice as much glycogen is stored in the skeletal muscles collectively as in the liver. Because glycogen is a relatively small energy reservoir, less than a day's energy needs can be stored in this form. Once the liver and muscle glycogen stores are "filled up," additional glucose is transformed into fatty acids and glycerol, which are used to synthesize *triglycerides* (glycerol with three fatty acids attached), primarily in adipose tissue (fat).

■ *Excess circulating fatty acids* derived from dietary intake also become incorporated into triglycerides.

■ *Excess circulating amino acids* not needed for protein synthesis are not stored as extra protein but are converted to glucose and fatty acids, which ultimately end up being stored as triglycerides.

Thus, the major site of energy storage for excess nutrients of all three classes is adipose tissue. Normally, enough triglyceride is stored to provide energy for about 2 months, with more stored in an overweight person. Consequently, during any prolonged period of fasting, the fatty acids released from triglyceride catabolism are the primary source of energy for most tissues. Catabolism of stored triglycerides yields 90% fatty acids and 10% glycerol by weight. Glycerol (but not fatty acids) can be converted to glucose by the liver and contributes in a small way to maintaining blood glucose during a fast.

As a third energy reservoir, a substantial amount of energy is stored as *structural protein,* primarily in muscle, the most abundant protein mass in the body. Protein is not the first choice to tap as an energy source, however, because it serves other essential functions; in contrast, the glycogen and triglyceride reservoirs are solely energy depots.

The brain must be continuously supplied with glucose.

The second factor complicating fuel metabolism (besides intermittent nutrient intake and the resultant necessity of storing nutrients) is that the brain normally depends on

delivery of adequate blood glucose as its sole source of energy. Consequently, the blood glucose concentration must be maintained above a critical level. The blood glucose concentration is typically 100 mg of glucose for every 100 mL of plasma and is normally kept within the narrow limits of 70 to 110 mg per 100 mL.[1] Liver glycogen is an important reservoir for maintaining blood glucose levels during a short fast. However, liver glycogen is depleted relatively rapidly, so during a longer fast other mechanisms must meet the energy requirements of the glucose-dependent brain. First, when no new dietary glucose is entering the blood, tissues not obligated to use glucose shift their metabolic gears to burn fatty acids instead, sparing glucose for the brain. Fatty acids are made available by catabolism of triglyceride stores as an alternative energy source for tissues that are not glucose dependent. Second, amino acids can be converted to glucose by gluconeogenesis, whereas fatty acids cannot. Thus, once glycogen stores are depleted despite glucose sparing, new glucose supplies for the brain are provided by the catabolism of body proteins and conversion of the freed amino acids into glucose.

Metabolic fuels are stored during the absorptive state and mobilized during the postabsorptive state.

The preceding discussion should make clear that how the body deals with organic molecules depends on the body's metabolic state. The two functional metabolic states—the *absorptive state* and the *postabsorptive state*—are related to eating and fasting cycles, respectively (▮Table 19-4).

Absorptive State After a meal, ingested nutrients are being absorbed and entering the blood during the **absorptive**, or **fed**, **state**. During this time, glucose is plentiful and is the major energy source. Very little absorbed fat and amino acids are used

for energy during the absorptive state because most cells preferentially use glucose when it is available. Extra nutrients not immediately used for energy or structural repairs are channeled into storage as glycogen or triglycerides.

Postabsorptive State The average meal is completely absorbed in about 4 hours. Therefore, on a typical three-meals-a-day diet, no nutrients are being absorbed from the digestive tract during late morning and late afternoon and throughout the night. These times constitute the **postabsorptive**, or **fasting**, **state.** During this state, endogenous energy stores are mobilized to provide energy, whereas gluconeogenesis and glucose sparing maintain the blood glucose at an adequate level to nourish the brain. Synthesis of protein and fat is curtailed. Instead, stores of these organic molecules are catabolized for glucose formation and energy production, respectively. Carbohydrate synthesis does occur through gluconeogenesis, but the use of glucose for energy is greatly reduced.

Note that the blood concentration of nutrients does not fluctuate markedly between the absorptive and postabsorptive states. During the absorptive state, the glut of absorbed nutrients is swiftly removed from the blood and placed into storage; during the postabsorptive state, these stores are catabolized to maintain the blood concentrations at levels necessary to fill tissue energy demands.

Roles of Key Tissues in Metabolic States During these alternating metabolic states, various tissues play different roles, as summarized here:

■ The *liver* plays the primary role in maintaining normal blood glucose levels. It stores glycogen when excess glucose is available, releases glucose into the blood when needed, and is the principal site for metabolic interconversions such as gluconeogenesis.

■ *Adipose tissue* serves as the primary energy storage site and is important in regulating fatty acid levels in the blood.

■ *Muscle* is the primary site of amino acid storage and is the major energy user.

---

[1]Blood glucose concentration is sometimes given in terms of molarity, with normal blood glucose concentration hovering around 5 mM (see p. A-7).

▮**TABLE 19-4** Comparison of Absorptive and Postabsorptive States

Metabolic Fuel	Absorptive State	Postabsorptive State
Carbohydrate	Glucose providing major energy source	Glycogen degradation and depletion
	Glycogen synthesis and storage	Glucose sparing to conserve glucose for the brain
	Excess converted and stored as triglyceride fat	Production of new glucose through gluconeogenesis
Fat	Triglyceride synthesis and storage	Triglyceride catabolism
		Fatty acids providing major energy source for non-glucose–dependent tissues
Protein	Protein synthesis	Protein catabolism
	Excess converted and stored as triglyceride fat	Amino acids used for gluconeogenesis

- The *brain* normally can use only glucose as an energy source, yet it does not store glycogen, making it mandatory that adequate blood glucose levels be maintained.

Lesser energy sources are tapped as needed.

Several other organic intermediates play a lesser role as energy sources—namely, glycerol, lactate, and ketone bodies.

- As mentioned earlier, glycerol derived from triglyceride hydrolysis can be converted to glucose by the liver.
- Similarly, lactate, which is produced by the incomplete catabolism of glucose via glycolysis in muscle (see p. 272), can also be converted to glucose in the liver.
- **Ketone bodies** (namely *acetone, acetoacidic acid,* and β-*hydroxybutyric acid*) are a group of compounds produced by the liver during glucose sparing. Unlike other tissues, when the liver uses fatty acids as an energy source, it oxidizes them only to acetyl coenzyme A (acetyl CoA), which it is unable to process through the citric acid cycle for further energy extraction (see p. 35). Thus, the liver does not degrade fatty acids all the way to CO_2 and H_2O for maximum energy release. Instead, it partially extracts the available energy and converts the remaining energy-bearing acetyl CoA molecules into ketone bodies, which it releases into the blood. Ketone bodies serve as an alternative energy source for tissues capable of oxidizing them further by means of the citric acid cycle.

During long-term starvation, the brain starts using ketones instead of glucose as a major energy source. Because death resulting from starvation is usually the result of protein wasting rather than hypoglycemia (low blood glucose), prolonged survival without any caloric intake requires that gluconeogenesis be kept to a minimum as long as the energy needs of the brain are not compromised. A sizable portion of cell protein can be catabolized without serious cellular malfunction, but a point is finally reached at which a cannibalized cell can no longer function adequately. To ward off the fatal point of failure as long as possible during prolonged starvation, the brain starts using ketones as a major energy source, correspondingly decreasing its use of glucose. Use by the brain of this fatty acid "table scrap" left over from the liver's "meal" limits the necessity of mobilizing body proteins for glucose production to nourish the brain. Both the major metabolic adaptations to prolonged starvation—a decrease in protein catabolism and use of ketones by the brain—are attributable to the high levels of ketones in the blood at the time. The brain uses ketones only when blood ketone level is high. The high blood levels of ketones also directly inhibit protein degradation in muscle. Thus, ketones spare body proteins while satisfying the brain's energy needs.

The pancreatic hormones, insulin and glucagon, are most important in regulating fuel metabolism.

How does the body "know" when to shift its metabolic gears from a system of net anabolism and nutrient storage to one of net catabolism and glucose sparing? The flow of organic nutri-

ents along metabolic pathways is influenced by a variety of hormones, including insulin, glucagon, epinephrine, cortisol, and GH. Under most circumstances, the pancreatic hormones, insulin and glucagon, are the dominant hormonal regulators that shift the metabolic pathways from net anabolism to net catabolism and glucose sparing, or vice versa, depending on whether the body is feasting or fasting, respectively.

Islets of Langerhans The **pancreas** is an organ composed of both exocrine and endocrine tissues. The exocrine portion secretes a watery, alkaline solution and digestive enzymes through the pancreatic duct into the digestive tract lumen (see p. 590). Scattered throughout the pancreas between the exocrine cells are about a million clusters, or "islands," of endocrine cells known as the **islets of Langerhans** (❚ Figure 19-15a). The islets make up about 1% to 2% of the total pancreatic mass. The pancreatic endocrine cell types, in decreasing order of abundance, are:

- **β (beta) cells** (constituting about 60% of islet cells), which simultaneously secrete *insulin*, the most important pancreatic hormone, and *amylin*, the newest discovered pancreatic hormone. β cells secrete 100 times more insulin than amylin.
- **α (alpha) cells** (about 25% of islet cells), which produce the hormone *glucagon*
- **delta, or D, cells** (about 10% of islet cells), the pancreatic site of *somatostatin* synthesis
- **gamma**, or **F**, **cells** (about 4% of islet cells), which secrete *pancreatic polypeptide,* a hormone that plays a possible role in reducing appetite and food intake, is poorly understood, and will not be discussed any further.
- **epsilon cells** (<1% of islet cells), which are newly found cells that release *ghrelin*, the "hunger hormone." Most ghrelin is secreted by the stomach before meals (see p. 623).

The β cells are concentrated centrally in the islets, with the other cells clustered around the periphery (❚ Figure 19-15b). We briefly highlight somatostatin now, and then we focus on insulin (and accompanying amylin) and glucagon, the most important hormones in the regulation of fuel metabolism.

Somatostatin Acting as a hormone, pancreatic **somatostatin** inhibits the digestive system in a variety of ways, the overall effects of which are to inhibit digestion of nutrients and to decrease nutrient absorption. Somatostatin is released from the pancreatic D cells in direct response to an increase in blood glucose and blood amino acids during absorption of a meal. By exerting its inhibitory effects, pancreatic somatostatin acts in negative-feedback fashion to put the brakes on the rate at which the meal is being digested and absorbed, thereby preventing excessive plasma levels of nutrients. Pancreatic somatostatin also acts as a paracrine in regulating pancreatic hormone secretion. The local presence of somatostatin decreases the secretion of insulin, glucagon, and somatostatin itself, but the physiologic importance of such paracrine function has not been determined.

Cells lining the digestive tract also produce somatostatin, where it acts locally as a paracrine to inhibit most digestive processes (see p. 585). Furthermore, somatostatin (alias GHIH)

is produced by the hypothalamus, where it inhibits secretion of GH and TSH (see p. 650).

We next consider insulin and then glucagon, followed by a discussion of how insulin and glucagon function as an endocrine unit to shift metabolic gears between the absorptive and the postabsorptive states.

Insulin lowers blood glucose, fatty acid, and amino acid levels and promotes their storage.

Insulin has important effects on carbohydrate, fat, and protein metabolism. It lowers the blood levels of glucose, fatty acids, and amino acids and promotes their storage. As these nutrient molecules enter the blood during the absorptive state, insulin promotes their cellular uptake and conversion into glycogen, triglycerides, and protein, respectively. Insulin exerts its many effects by altering either transport of specific blood-borne nutrients into cells or activity of the enzymes involved in specific metabolic pathways. To accomplish its effects, in some instances insulin increases the activity of an enzyme, for example *glycogen synthase,* the enzyme that synthesizes glycogen from glucose molecules. In other cases, however, insulin decreases the activity of an enzyme, for example by inhibiting *hormone-sensitive lipase,* the enzyme that catalyzes the breakdown of stored triglycerides back to free fatty acids and glycerol.

Actions on Carbohydrates Maintaining blood glucose homeostasis is a particularly important function of the pancreas. The balance among the following processes determines circulating glucose concentrations (IFigure 19-16): glucose absorption from the digestive tract, transport of glucose into cells, hepatic glucose production, and (abnormally) urinary excretion of glucose. Among these factors, only glucose transport into cells and hepatic glucose production are subject to control.

Insulin exerts four effects that lower blood glucose levels and promote carbohydrate storage:

1. Insulin facilitates glucose transport into most cells. (The mechanism of this increased glucose uptake is explained after insulin's other blood-glucose lowering effects are listed.)

2. Insulin stimulates **glycogenesis,** the production of glycogen from glucose, in both skeletal muscle and the liver.

3. Insulin inhibits glycogenolysis, the breakdown of glycogen into glucose.

4. Insulin inhibits gluconeogenesis, the conversion of amino acids into glucose in the liver. Insulin does so by decreasing the amount of amino acids in the blood available to the liver for gluconeogenesis and by inhibiting the hepatic enzymes required for converting amino acids into glucose.

Factors that increase blood glucose

Glucose absorption from digestive tract

Hepatic glucose production:
—Through glycogenolysis of stored glycogen
—Through gluconeogenesis

Blood glucose

Factors that decrease blood glucose

Transport of glucose into cells:
—For utilization for energy production
—For storage
• as glycogen through glycogenesis
• as triglycerides

Urinary excretion of glucose (occurs only abnormally, when blood glucose level becomes so high it exceeds the reabsorptive capacity of kidney tubules during urine formation)

KEY

= Factors subject to hormonal control to maintain blood glucose level

IFigure 19-16 Factors affecting blood glucose concentration.
FIGURE FOCUS*: Name the two factors that are subject to hormonal control to maintain blood glucose.*

Thus, insulin decreases the concentration of blood glucose by promoting the cells' uptake of glucose from the blood for use and storage while simultaneously blocking the two mechanisms by which the liver releases glucose into the blood (glycogenolysis and gluconeogenesis). Insulin is the only hormone capable of lowering blood glucose.

Insulin promotes uptake of glucose from the blood by most cells through recruitment of glucose transporters. A **glucose transporter (GLUT)** is a plasma membrane carrier that accomplishes passive facilitated diffusion of glucose across the plasma membrane (see p. 72). Once GLUT facilitates entry of glucose into a cell down this nutrient's concentration gradient, an enzyme within the cell immediately phosphorylates glucose to **glucose-6-phosphate**. Glucose-6-phosphate has no means out of the cell, unlike "plain" glucose, which could exit through the bidirectional glucose transporter. Phosphorylation of glucose as it enters the cell not only "traps" the glucose inside the cell but also keeps the intracellular concentration of plain glucose low so that a gradient favoring the facilitated diffusion of glucose into the cell is maintained.

Fourteen forms of glucose transporters have been identified, named in the order they were discovered—GLUT-1, GLUT-2, and so on. Each member of the GLUT family performs slightly different functions. For example, *GLUT-1* transports glucose across the blood–brain barrier, *GLUT-2* transfers into the adjacent bloodstream the glucose that has entered the kidney and intestinal cells by means of the sodium and glucose cotransporter (SGLT; see p. 75), and *GLUT-3* is the main transporter of glucose into neurons. The transporter responsible for glucose uptake by most body cells is *GLUT-4,* which operates only at the bidding of insulin. Glucose molecules cannot readily penetrate most cell membranes in the absence of insulin, making most tissues highly dependent on insulin for uptake of glucose from the blood and for its subsequent use. GLUT-4 is

especially abundant in the tissues that account for the bulk of glucose uptake from the blood during the absorptive state, namely, resting skeletal muscle and adipose tissue cells.

GLUT-4 is the only type of transporter that responds to insulin. Unlike the other types of GLUT molecules, which are always present in the plasma membranes at the sites where they perform their functions, GLUT-4 is not present in the plasma membrane in the absence of insulin. Insulin promotes glucose uptake by **transporter recruitment.** Insulin-dependent cells maintain a pool of intracellular vesicles containing GLUT-4. When insulin binds with its receptor (a receptor that acts as a tyrosine kinase enzyme; see p. 116) on the surface membrane of the target cell, the subsequent signaling pathway induces these vesicles to move to the plasma membrane and fuse with it, thus inserting GLUT-4 molecules into the plasma membrane. In this way, increased insulin secretion promotes a rapid 10- to 30-fold increase in glucose uptake by insulin-dependent cells. When insulin secretion decreases, these GLUTs are retrieved from the membrane by endocytosis and returned to the intracellular pool.

Several tissues do not depend on insulin for their glucose uptake—namely, the brain, working muscles, and liver. The brain, which requires a constant supply of glucose for its minute-to-minute energy needs, is freely permeable to glucose at all times by means of GLUT-1 and GLUT-3 molecules. Skeletal muscle cells do not depend on insulin for their glucose uptake during exercise, even though they are dependent at rest. Muscle contraction triggers insertion of GLUT-4 into the plasma membranes of exercising muscle cells in the absence of insulin. This fact is important in managing diabetes mellitus (insulin deficiency), as described later. The liver also does not depend on insulin for glucose uptake because it does not use GLUT-4. However, insulin does enhance the metabolism of glucose by the liver by stimulating the first step in glucose metabolism, the phosphorylation of glucose to form glucose-6-phosphate.

The Peripheral Endocrine Glands | **691**

Actions on Fat Insulin exerts multiple effects to lower blood fatty acids and promote triglyceride storage:

1. It enhances entry of fatty acids from the blood into adipose tissue cells.

2. It increases transport of glucose into adipose tissue cells by means of GLUT-4 recruitment. Glucose serves as a precursor for formation of fatty acids and glycerol, which are the raw materials for triglyceride synthesis.

3. It promotes chemical reactions that ultimately use fatty acids and glucose derivatives for triglyceride synthesis.

4. It inhibits lipolysis, reducing the release of fatty acids from adipose tissue into the blood.

Collectively, these actions favor removal of fatty acids and glucose from the blood and promote their storage as triglycerides.

Actions on Protein Insulin lowers blood amino acid levels and enhances protein synthesis through several effects:

1. It promotes active transport of amino acids from the blood into muscles and other tissues. This effect decreases the blood amino acid level and provides the building blocks for protein synthesis within the cells.

2. It increases the rate of amino acid incorporation into protein by stimulating the cells' protein-synthesizing machinery.

3. It inhibits protein degradation.

The collective result of these actions is a protein anabolic effect. For this reason, insulin is essential for normal growth.

Summary of Insulin's Actions In short, insulin primarily exerts its effects by acting on the liver, adipose tissue, and non-working skeletal muscle. It stimulates biosynthetic pathways that lead to increased glucose use, increased carbohydrate and fat storage, and increased protein synthesis. In so doing, this hormone lowers the blood glucose, fatty acid, and amino acid levels. This metabolic pattern is characteristic of the absorptive state. Indeed, insulin secretion rises during this state and shifts metabolic pathways to net anabolism.

When insulin secretion is low, the opposite effects occur. The rate of glucose entry into cells is reduced, and net catabolism occurs rather than net synthesis of glycogen, triglycerides, and protein. This pattern is reminiscent of the postabsorptive state; indeed, insulin secretion is reduced during the postabsorptive state. However, the other major pancreatic hormone, glucagon, also plays an important role in shifting from absorptive to postabsorptive metabolic patterns, as described later.

Role of Amylin Amylin is cosecreted with insulin from pancreatic β cells at a ratio of 1:100. Unlike insulin, amylin does not act on peripheral tissues but instead acts in the central nervous system to enhance satiety (feeling of being full), delay gastric emptying (thereby slowing digestion of food), and suppress secretion of glucagon (a hormone that raises blood glucose). Thus amylin acts as a partner hormone to insulin to lower blood glucose. In complementary fashion, amylin reduces glucose influx into the blood from the digestive tract after a meal

while insulin removes glucose from the blood and promotes its use and storage after a meal.

The primary stimulus for increased insulin secretion is an increase in blood glucose.

The primary control of insulin secretion is a direct negative-feedback system between the pancreatic β cells and the concentration of glucose in the blood flowing to them. Elevated blood glucose, such as during absorption of a meal, directly stimulates the β cells to secrete insulin. Increased insulin, in turn, reduces blood glucose to normal and promotes use and storage of this nutrient. Conversely, a fall in blood glucose below normal, such as during fasting, directly inhibits insulin secretion. Lowering the rate of insulin secretion shifts metabolism from the absorptive to the postabsorptive pattern. Thus, this simple negative-feedback system can maintain a relatively constant supply of glucose to the tissues without requiring the participation of nerves or other hormones.

Glucose stimulates insulin secretion by means of an **excitation–secretion coupling** process. That is, glucose initiates a chain of events that changes the β cell's membrane potential, leading to secretion of insulin. This is one of the few known examples where cells other than nerve or muscle cells undergo functionally related changes in membrane potential. Specifically, glucose enters the β cell by means of GLUT-2 (❙ Figure 19-17, step ❶). Once inside, glucose is immediately phosphorylated to glucose-6-phosphate (step ❷), which is oxidized by the β cell to yield ATP (step ❸). A β cell has two types of channels: an **ATP-sensitive K⁺ channel,** which is a leak channel that remains open unless ATP binds to it, and a **voltage-gated Ca²⁺ channel,** which is closed at resting potential. The ATP-sensitive K⁺ channel closes when ATP generated from glucose-6-phosphate binds to it (step ❹). The resultant decrease in K⁺ permeability leads to depolarization of the β cell (because of less outward movement of positively charged K⁺) (step ❺). This depolarization causes the voltage-gated Ca²⁺ channels to open (step ❻). The subsequent Ca²⁺ entry (step ❼) triggers exocytosis of secretory vesicles containing insulin (step ❽), resulting in insulin secretion (step ❾).

In addition to blood glucose concentration, which is the major controlling factor, other inputs are involved in regulating insulin secretion, as follows (❙ Figure 19-18):

■ An elevated blood amino acid level, such as after a high-protein meal, directly stimulates the β cells to increase insulin secretion. In negative-feedback fashion, increased insulin enhances the entry of these amino acids into the cells, lowering the blood amino acid level while promoting protein synthesis. Amino acids increase insulin secretion in the same way as glucose does, by generating ATP that leads to excitation–secretion coupling.

■ Gastrointestinal hormones secreted by the digestive tract in response to the presence of food, especially *glucose-dependent insulinotropic peptide (GIP)* (see p. 615) and *glucagon-like peptide 1 (GLP-1)* (see p. 624), stimulate pancreatic insulin secretion, in addition to having direct regulatory effects on the digestive system. Through this control, insulin secretion is

Figure 19-17 Stimulation of insulin secretion by glucose via excitation–secretion coupling. **FIGURE FOCUS:** *How is the β cell depolarized? How does this depolarization lead to insulin secretion?*
1. Glucose enters β cell by facilitated diffusion via GLUT-2.

2. Glucose is phosphorylated to glucose-6-phosphate.

3. Oxidation of glucose-6-phosphate generates ATP.

4. ATP acts on ATP-sensitive K^+ channel, closing it.

5. Reduced exit of K^+ depolarizes membrane.

6. Depolarization opens voltage-gated Ca^{2+} channels.

7. Ca^{2+} enters β cell.

8. Ca^{2+} triggers exocytosis of insulin vesicles.

9. Insulin is secreted.

increased in "feedforward," or anticipatory, fashion even before nutrient absorption increases the blood concentration of glucose and amino acids. Hormones released from the digestive tract that "notify" the pancreatic β cell of the impending rise in blood nutrients (primarily blood glucose) are termed **incretins**. Incretins increase insulin secretion by increasing cAMP, which enhances Ca^{2+}-induced release of insulin.

■ The autonomic nervous system also directly influences insulin secretion. The islets are richly innervated by both parasympathetic (vagal) and sympathetic nerve fibers. The increase in parasympathetic activity that occurs in response to food in the digestive tract stimulates insulin release, with the parasympathetic neurotransmitter acetylcholine acting through the IP_3–Ca^{2+} pathway. This, too, is a feedforward response in anticipation of nutrient absorption. In contrast, sympathetic stimulation and the concurrent increase in epinephrine both inhibit insulin secretion by decreasing

cAMP. The fall in insulin level allows the blood glucose level to rise, an appropriate response to the circumstances under which generalized sympathetic activation occurs—namely, stress (fight-or-flight) and exercise. In both situations, extra fuel is needed for increased muscle activity.

The symptoms of diabetes mellitus are characteristic of an exaggerated postabsorptive state.

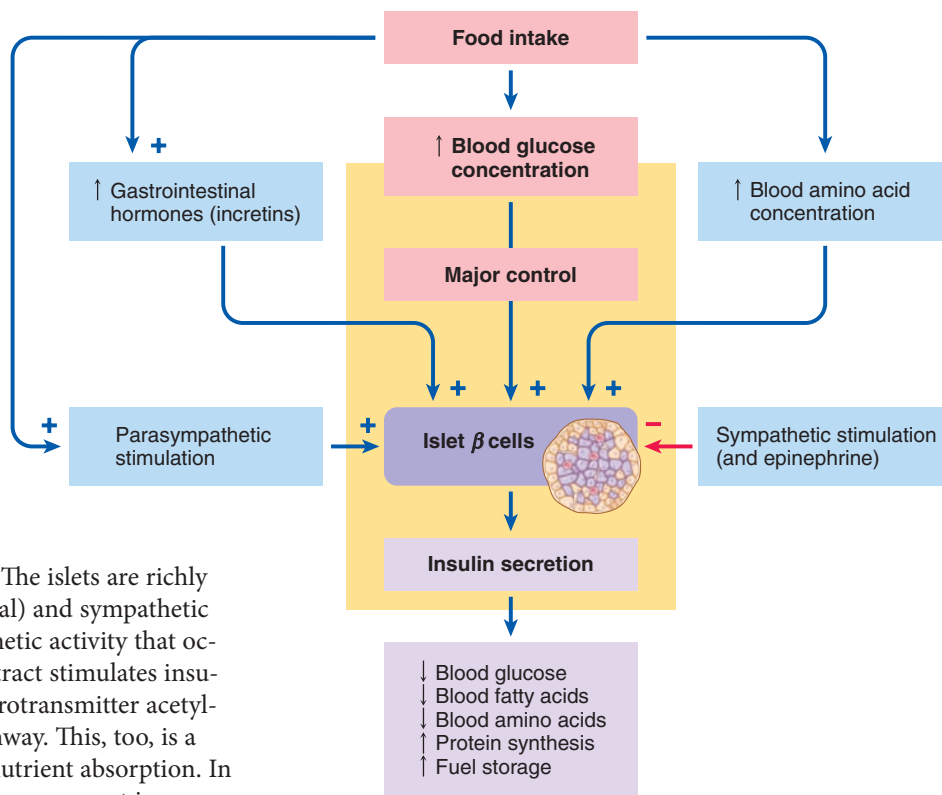
Clinical Note **Diabetes mellitus** is by far the most common of all endocrine disorders. The acute symptoms of diabetes mellitus are attributable to inadequate insulin action. Because insulin is the only hormone capable of lowering blood glucose levels, one of the most prominent features of diabetes mellitus is elevated blood glucose levels, or *hyperglycemia*. *Diabetes* literally means "siphon" or "running through," a reference to the large urine volume accompanying this condition. A large urine volume occurs in both diabetes mellitus (a result of insulin insufficiency) and diabetes insipidus (a result of vasopressin deficiency; see p. 541). *Mellitus* means "sweet"; *insipidus* means "tasteless." The urine of patients with diabetes mellitus acquires


Figure 19-18 Factors controlling insulin secretion.

its sweetness from excess blood glucose that spills into the urine, whereas the urine of patients with diabetes insipidus contains no sugar, so it is tasteless. (Aren't you glad you were not a health professional at the time when these two conditions were distinguished on the basis of the taste of the urine?)

Diabetes mellitus has two major variants, differing in the capacity for pancreatic insulin secretion: *Type 1 diabetes*, characterized by a lack of insulin secretion, and *Type 2 diabetes,* characterized by normal or even increased insulin secretion but reduced sensitivity of insulin's target cells to this hormone. (For a further discussion of the distinguishing features of these two types of diabetes mellitus, see the boxed feature on pp. 696–697, Concepts, Challenges, and Controversies.)

The acute consequences of diabetes mellitus can be grouped according to the effects of inadequate insulin action on carbohydrate, fat, and protein metabolism (Figure 19-19). The figure may look overwhelming, but the numbers, which correspond to the numbers in the following discussion, help you work your way through this complex disease step by step.

Consequences Related to Effects on Carbohydrate Metabolism Because the postabsorptive metabolic pattern is induced by low insulin activity, the changes that occur in diabetes mellitus are an exaggeration of this state, with the exception of hyperglycemia. In the usual fasting state, the blood glucose level is slightly below normal. Hyperglycemia, the hallmark of diabetes mellitus, arises from reduced glucose uptake by cells, coupled with increased output of glucose from the liver (Figure 19-19, step **1**). As the glucose-yielding processes of glycogenolysis and gluconeogenesis proceed unchecked in the absence of insulin, hepatic output of glucose increases. Because many of the body's cells cannot use glucose without the help of insulin, an ironic extracellular glucose excess occurs coincident with an intracellular glucose deficiency—"starvation in the midst of plenty." Even though the non–insulin-dependent brain is adequately nourished during diabetes mellitus, further consequences of the disease lead to brain dysfunction, as you will see shortly.

When blood glucose rises to the level where the amount of glucose filtered by the kidney nephrons during urine formation exceeds the tubular cells' capacity for reabsorption (that is, when the T_m for glucose is exceeded; see p. 511), glucose appears in the urine (*glucosuria*) (step **2**). Glucose in the urine exerts an osmotic effect that draws H_2O with it, producing an osmotic diuresis characterized by *polyuria* (frequent urination) (step **3**). The excess fluid lost from the body leads to dehydration (step **4**), which in turn can lead to peripheral circulatory failure because of the marked reduction in blood volume (step **5**). Circulatory failure, if uncorrected, can lead to death because of low cerebral blood flow (step **6**) or secondary renal failure resulting from inadequate filtration pressure (step **7**). Furthermore, as the body becomes dehydrated, cells lose water by an osmotic shift of water from the cells into the hypertonic (too concentrated) extracellular fluid (step **8**). Brain cells are especially sensitive to shrinking, so nervous system malfunction ensues (step **9**) (see p. 542). Another characteristic symptom of diabetes mellitus is *polydipsia* (excessive thirst) (step **10**), which is actually a compensatory mechanism to counteract the dehydration.

The story is not complete. In intracellular glucose deficiency, appetite is stimulated, leading to *polyphagia* (excessive food intake) (step **11**). Despite increased food intake, however, progressive weight loss occurs from the effects of insulin deficiency on fat and protein metabolism.

Consequences Related to Effects on Fat Metabolism Triglyceride synthesis decreases while lipolysis increases, resulting in large-scale mobilization of fatty acids from triglyceride stores (step **12**). The cells largely use the increased blood fatty acids as an alternative energy source. Increased liver use of fatty acids results in the release of excessive ketone bodies into the blood, causing *ketosis* (step **13**). Ketone bodies include several different acids, such as acetoacetic acid, that result from incomplete breakdown of fat during hepatic energy production. Therefore, this developing ketosis leads to progressive metabolic acidosis (step **14**). Acidosis depresses the brain and, if severe enough, can lead to diabetic coma and death (step **15**).

A compensatory measure for metabolic acidosis is increased ventilation to blow off extra, acid-forming CO_2 (step **16**). Exhalation of one of the ketone bodies, acetone, causes a "fruity" breath odor that smells like a combination of Juicy Fruit gum and nail polish remover. Sometimes because of this odor, passersby unfortunately mistake a patient collapsed in a diabetic coma for a "wino" passed out in a state of drunkenness. (This situation illustrates the merits of medical alert identification tags.) People with Type 1 diabetes are more prone to develop ketosis than are Type 2 diabetics.

Consequences Related to Effects on Protein Metabolism The effects of a lack of insulin on protein metabolism result in a net shift toward protein catabolism. The net breakdown of muscle proteins leads to muscle wasting and weakness, as well as weight loss (step **17**) and, in child diabetics, a reduction in overall growth. Reduced amino acid uptake coupled with increased protein degradation results in excess amino acids in the blood (step **18**). The increased circulating amino acids can be used for additional gluconeogenesis, which further aggravates the hyperglycemia (step **19**).

As you can readily appreciate from this overview, diabetes mellitus is a complicated disease that can disturb not only carbohydrate, fat, and protein metabolism but also fluid and acid–base balance. Moreover it can have repercussions on the circulatory system, kidneys, respiratory system, and nervous system.

Long-Term Complications In addition to these potential acute consequences of untreated diabetes, which can be explained on the basis of insulin's short-term metabolic effects, numerous long-range complications of this disease frequently occur after 15 to 20 years despite treatment to prevent the short-term effects. These chronic complications, which account for the shorter life expectancy of diabetics, primarily involve degenerative disorders of the blood vessels and nervous system. Cardiovascular lesions are the most common cause of premature death in diabetics. Heart disease and strokes occur with greater incidence than in nondiabetics. Because vascular lesions often develop in the kidneys and retinas of the eyes, diabetes is the leading cause of both kidney failure and blindness in the
Figure 19-19 Acute effects of diabetes mellitus. The acute consequences of diabetes mellitus can be grouped according to the effects of inadequate insulin action on carbohydrate, fat, and protein metabolism. These effects ultimately cause death through a variety of pathways. See p. 694 for an explanation of the numbers.

United States. Impaired delivery of blood to the extremities may cause these tissues to become gangrenous, and toes or even whole limbs may have to be amputated. In addition to circulatory problems, degenerative lesions in nerves lead to multiple neuropathies that result in dysfunction of the brain, spinal cord, and peripheral nerves. The latter is most often characterized by pain, numbness, and tingling, especially in the extremities.

Regular exposure of tissues to excess blood glucose over a prolonged time leads to tissue alterations responsible for the development of these long-range vascular and neural degenerative complications. Thus, the best management for diabetes mellitus is to continuously keep blood glucose levels within normal limits to diminish the incidence of these chronic abnormalities. However, the blood glucose levels of diabetic patients on traditional therapy typically fluctuate over a broader range than normal, exposing their tissues to a moderately elevated blood glucose level during a portion of each day. Fortunately, recent advances in understanding and learning how to

Diabetics and Insulin: Some Have It and Some Don't

THERE ARE TWO DISTINCT TYPES of diabetes mellitus. **Type 1 (insulin-dependent**, or **juvenile-onset) diabetes mellitus (T1DM)** is characterized by a lack of insulin. Because their pancreatic β cells do not secrete insulin, Type 1 diabetics require exogenous insulin for survival. In **Type 2 (non–insulin-dependent**, or **maturity-onset) diabetes mellitus (T2DM)**, insulin secretion may be normal or even increased, but insulin's target cells are less sensitive than normal to this hormone. That is, Type 2 diabetics are *insulin resistant*. Ninety percent of diabetics have the Type 2 form. Although either type can first be manifested at any age, T1DM occurs more in children, whereas T2DM more generally arises in adulthood, hence the age-related designations. Diabetes of both types currently affects more than 25 million people in the United States, costing this country an estimated $245 billion annually in health-care expenses and accounting for 10% of the health-care dollars spent. The U.S. diabetes-related death rate has increased by 30% since 1980, largely because the incidence of the disease has been rising.

Underlying Defect in Type 1 Diabetes

Type 1 diabetes mellitus is an autoimmune process involving the erroneous, selective destruction of pancreatic β cells by inappropriately activated T lymphocytes (see p. 432). The precise cause of this self-attack is unclear. Some have a genetic susceptibility to acquiring T1DM. Environmental triggers also appear to play a role, but investigators have not been able to definitively pin down any culprits.

Underlying Defect in Type 2 Diabetes

Various genetic and lifestyle factors appear important in the development of T2DM. Obesity is the biggest risk factor; 90% of Type 2 diabetics are obese.

Many Type 2 diabetics have *metabolic syndrome* as a forerunner of diabetes. **Metabolic syndrome** encompasses a cluster of features that predispose the person to developing T2DM and atherosclerosis (see p. 327). These features include obesity, large waist circumference ("apple" shapes; see p. 625), high trigylceride levels, low HDL (the "good" cholesterol; see p. 328), high blood glucose, and high blood pressure. An estimated 20% of the U.S. population has metabolic syndrome (up to 45% for those older than age 50).

The ultimate cause of T2DM remains elusive despite intense investigation, but researchers have identified a number of possible links between obesity and reduced insulin sensitivity. Circulating adipokines (hormones secreted by adipose cells) modulate the responsiveness of skeletal muscle and liver to insulin. For example, adipose tissue, especially the troublesome, inflamed visceral fat (see p. 623), secretes the hormone *resistin,* which promotes insulin resistance by interfering with insulin action. Resistin production increases in obesity. By contrast, the adipokine *adiponectin* increases insulin sensitivity by enhancing insulin's effects, but its production is decreased in obesity. Compounding the problem, the abundant macrophages attracted to inflamed fat secrete inflammatory signals that amplify the inflammation. Furthermore, excess free fatty acids released from overloaded adipose tissue can abnormally accumulate in muscle and interfere with insulin action in muscle. Excess free fatty acids deposited in the liver can contribute to hyperglycemia by stimulating inappropriate hepatic glucose production. Also, excess free fatty acids can indirectly trigger apoptosis of β cells. High levels of glucose and free fatty acids can also promote inflammation and progressive failure of β cells in pancreatic islets by triggering local production of IL-1β. And this is only part of the tangled web of mechanisms involved in T2DM that investigators are trying to unravel.

Early in the development of the disease, the resulting decrease in sensitivity to insulin is overcome by secretion of additional insulin. However, the sustained overtaxing of the genetically weak β cells eventually exceeds their reserve secretory capacity. Even though insulin secretion may be normal or even elevated, symptoms of insulin insufficiency develop because the amount of insulin is still inadequate to prevent hyperglycemia.

Treatment of Diabetes

The treatment for T1DM is a controlled balance of regular insulin injections timed around meals, management of the amounts and types of food consumed, and exercise. Insulin is injected because if it were swallowed, protein-digesting enzymes in the stomach and small intestine would digest this peptide hormone. Exercise is useful in managing both types of diabetes because working muscles are not insulin dependent. Exercising muscles take up some of the excess glucose in the blood, reducing the overall need for insulin.

Whereas Type 1 diabetics are permanently insulin dependent, dietary control and weight reduction may be all that is necessary to completely reverse the symptoms in Type 2 diabetics. Seven classes of blood-glucose lowering oral medications are currently available for use if needed for treating T2DM in conjunction with a dietary and exercise regime. These pills help the patient's body use its own insulin more effectively, each by a different mechanism, as follows:

1. By suppressing liver output of glucose (*metformin*; for example, Glucophage). The American Diabetes Association recommends metformin as the firstline therapy.

2. By stimulating the β cells to secrete more insulin than they do on their own (*sulfonylureas*; for example, Glucotrol)

3. By blocking enzymes that digest complex carbohydrates, thus slowing glucose absorption into the blood from the digestive tract and blunting the surge of glucose immediately after a meal (*alpha-glycosidase inhibitors*; for example, Precose)

4. By making muscle and fat cells more receptive to insulin (*thiazolidinediones*; for example, Avandia)

5. By mimicking naturally occurring incretins, which are hormones released by the gut in response to food that act in feedforward fashion on the endocrine pancreas to reduce the anticipated rise in blood glucose (*incretin mimetics*; for example, Byetta, which mimics the gut-released hormone glucagon-like peptide 1 [GLP-1; see p. 624]). Like GLP-1, Byetta, which must be injected, stimulates insulin secretion when blood glucose is high but not when glucose is in the normal range. Drugs that mimic the action of amylin, which is produced by β cells rather than intestinal cells, act in a manner similar to incretin mimetics (injectable *amylin analogs*, such as Symlin).

6. By increasing endogenous GLP-1 levels (*dipeptidyl peptidase-4,* or *DPP-4, inhibitors*; for example, Januvia). This class of drugs increases endogenous GLP-1 levels by blocking DPP-4, an enzyme that breaks down GLP-1, thus prolonging action of this incretin. Prolonged activity of GLP-1 boosts insulin secretion until glucose levels return to normal. Januvia also suppresses release of glucose by the liver and slows digestion.

7. By blocking a sodium and glucose cotransporter (SGLT2) found almost exclusively in the kidney that is responsible for 90% of glucose reabsorption during urine formation (*SGLT2 inhibitors,* such as Invokana). This newest class of approved diabetic drugs suppresses reabsorption of glucose by the renal tubules, thereby reducing blood glucose by increasing urinary excretion of the surplus glucose. It also promotes weight loss because the glucose lost in the urine is no longer available as an energy source for the body.

Nearly 400 new drugs for diabetes, mostly for the Type 2 form of the disease, are under development.

In the future a surgical approach might also be used to treat T2DM. Obese individuals with Type 2 diabetes who undergo *bariatric (weight loss) surgery* frequently experience a lessening or disappearance of their diabetes symptoms even before they begin to shed pounds. The mechanism responsible for the improved glucose metabolism is still being researched, but apparently gastric bypass surgery precludes the stomach from releasing food-induced blood-borne chemicals that affect blood glucose levels.

New Approaches to Managing Insulin-Dependent Diabetes

Because none of the available oral diabetic drugs deliver new insulin to the body, they cannot replace insulin therapy for people with T1DM. Furthermore, sometimes the weakened β cells in T2DM eventually burn out and can no longer produce insulin, in which case the previously non–insulin-dependent patient must be placed on insulin therapy.

Several newer approaches are currently available for insulin-dependent diabetics that preclude the need for the one or more insulin injections daily.

■ *Implanted insulin pumps* can deliver a prescribed amount of insulin on a regular basis, but the recipient must time meals with care to match the automatic insulin delivery.

■ *Pancreas transplants* are also being performed more widely now, with increasing success. On the downside, transplant recipients must take immunosuppressive drugs for life to prevent rejection of their donated organs. Also, donor organs are in short supply.

The following new treatments for T1DM are on the horizon:

■ Some new delivery methods circumvent the need for daily insulin injections by using alternative routes of administration that bypass the destructive digestive tract enzymes. Examples include, using inhaled powdered insulin (*Afrezza*, recently approved but not yet being manufactured) or using an oral insulin spray product that can be absorbed in the mouth. A related approach is to protect swallowed insulin from destruction by the digestive tract, for example, by attaching oral insulin to vitamin B_{12}, which protects the insulin from digestive enzymes until the vitamin–insulin complex is absorbed by intrinsic factor-induced endocytosis in the terminal ileum (see p. 585).

■ A new vaccine that selectively removes only the T cells responsible for the autoimmunity that destroys β cells (leaving the other useful T cells intact to do their job) is in late-stage clinical trials.

■ Another hope is pancreatic islet transplants. Scientists have developed several types of devices that isolate donor islet cells from the recipient's immune system. Such immunoisolation of islet cells permits use of grafts from other animals, circumventing the shortage of human donor cells. Pig islet cells are an especially good source because pig insulin is nearly identical to human insulin.

■ Some researchers have coaxed stem cells to develop into insulin-secreting cells that hopefully can be implanted.

■ In a related approach, others are turning to genetic engineering to develop surrogates for pancreatic β cells. An example is the potential reprogramming of the small-intestine endocrine cells that produce the GI hormone GIP (see p. 615). The goal is to cause these non-β cells to cosecrete both insulin and GIP in response to a meal.

■ Another approach under development is an implanted, glucose-detecting, insulin-releasing "artificial pancreas" that would continuously monitor the patient's blood glucose level and deliver insulin in response to need.

■ One of the latest leads is the discovery of a gene in the liver and fat tissue that codes for a newly identified hormone, *betatrophin*, which can prompt production of more pancreatic β cells.

manipulate underlying molecular defects in diabetes offer hope that more effective therapies will soon be developed to better manage or even cure existing cases and perhaps to prevent new cases of this devastating disease. (See the boxed feature on diabetes on pp. 696–697 for current and potential future treatment strategies for this disorder.)

Insulin excess causes brain-starving hypoglycemia.

Clinical Note Let us now look at the opposite of diabetes mellitus, insulin excess, which is characterized by *hypoglycemia* (low blood glucose) and can arise in two ways. First, insulin excess can occur in a diabetic patient when too much insulin has been injected for the person's caloric intake and exercise level, resulting in **insulin shock.** Second, blood insulin level may rise abnormally high in a nondiabetic individual whose β cells are overresponsive to glucose, a condition called **reactive hypoglycemia.** Such β cells "overshoot" and secrete more insulin than necessary in response to elevated blood glucose after a high-carbohydrate meal. The excess insulin drives too much glucose into the cells, resulting in hypoglycemia.

The consequences of insulin excess are primarily manifestations of the effects of hypoglycemia on the brain. Recall that the brain relies on a continuous supply of blood glucose for its nourishment and that glucose uptake by the brain does not depend on insulin. With insulin excess, more glucose than necessary is driven into the other insulin-dependent cells. The result is a lowering of the blood glucose level so that not enough glucose is left in the blood to be delivered to the brain. In hypoglycemia, the brain literally starves. The symptoms, therefore, are primarily referable to depressed brain function, which, if severe enough, may rapidly progress to unconsciousness and death. People with overresponsive β cells do not become sufficiently hypoglycemic to manifest these more serious consequences, but they do show milder symptoms of depressed CNS activity.

The true incidence of reactive hypoglycemia is a subject of intense controversy because it is difficult to diagnose without confirming the presence of low blood glucose during the time of symptoms. Mild symptoms of depressed CNS function, such as tremor, fatigue, sleepiness, and inability to concentrate, are nonspecific and could also be attributable to emotional problems or other factors. Therefore, a definitive diagnosis based on symptoms alone is impossible to make.

The treatment of hypoglycemia depends on the cause. At the first indication of a hypoglycemic attack with insulin overdose, the diabetic person should eat or drink something sugary. Prompt treatment of severe hypoglycemia is imperative to prevent brain damage. Note that a diabetic can lose consciousness and die from either diabetic ketoacidotic coma caused by prolonged insulin deficiency or acute hypoglycemia caused by insulin shock. Fortunately, the other accompanying signs and symptoms differ sufficiently between the conditions to enable medical caretakers to administer appropriate therapy, either insulin or glucose. For example, ketoacidotic coma is accompanied by deep, labored breathing (in compensation for the metabolic acidosis) and fruity breath (from exhaled ketone bodies), whereas insulin shock is not.

Ironically, even though reactive hypoglycemia is characterized by low blood glucose, people with this disorder are treated by limiting their intake of sugar and other glucose yielding carbohydrates to prevent their β cells from overresponding to a high glucose intake. Giving a symptomatic individual with reactive hypoglycemia something sugary temporarily alleviates the symptoms. The blood glucose level is transiently restored to normal so that the brain's energy needs are again satisfied. However, as soon as the extra glucose triggers further insulin release, the situation is merely aggravated.

Glucagon in general opposes the actions of insulin.

Even though insulin plays a central role in controlling metabolic adjustments between the absorptive and the postabsorptive states, the secretory product of the pancreatic islet α cells, **glucagon,** is also important. Many physiologists view the insulin-secreting β cells and the glucagon-secreting α cells as a coupled endocrine system whose combined secretory output is a major factor in regulating fuel metabolism.

Glucagon affects many of the same metabolic processes that insulin influences, but in most cases glucagon's actions are opposite to those of insulin. The major site of action of glucagon is the liver, where it exerts a variety of effects on carbohydrate, fat, and protein metabolism. Glucagon acts by increasing cAMP.

Actions on Carbohydrate The overall effects of glucagon on carbohydrate metabolism result in an increase in hepatic glucose production and release and thus in an increase in blood glucose. Glucagon exerts its hyperglycemic effects by decreasing glycogenesis, promoting glycogenolysis, and stimulating gluconeogenesis.

Actions on Fat Glucagon also antagonizes the actions of insulin with regard to fat metabolism by promoting lipolysis and inhibiting triglyceride synthesis, thus increasing blood levels of fatty acids. Glucagon enhances hepatic ketone production (ketogenesis) by promoting conversion of fatty acids to ketone bodies.

Actions on Protein Glucagon inhibits hepatic protein synthesis and promotes degradation of hepatic protein. Stimulation of gluconeogenesis further contributes to glucagon's catabolic effect on hepatic protein metabolism. Glucagon promotes protein catabolism in the liver, but it does not have any significant effect on blood amino acid levels because it does not affect muscle protein, the major protein store in the body.

Glucagon secretion is increased during the postabsorptive state.

Glucagon secretion increases during the postabsorptive state and decreases during the absorptive state, just the opposite of insulin secretion. In fact, insulin is sometimes referred to as a "hormone of feasting" and glucagon as a "hormone of fasting." Insulin tends to put nutrients in storage when their blood levels are high, such as after a meal, whereas glucagon promotes catabolism of nutrient

stores between meals to keep up the blood nutrient levels, especially blood glucose.

As in insulin secretion, the major factor regulating glucagon secretion is a direct effect of the blood glucose concentration on the endocrine pancreas. In this case, the pancreatic α cells increase glucagon secretion in response to a fall in blood glucose. Glucagon's hyperglycemic actions tend to raise blood glucose back to normal. Conversely, an increase in blood glucose concentration, such as after a meal, inhibits glucagon secretion, which tends to drop blood glucose back to normal.

Insulin and glucagon work as a team to maintain blood glucose and fatty acid levels.

Thus, a direct negative-feedback relationship exists between blood glucose concentration and both β cells' and α cells' rates of secretion, but in opposite directions. An elevated blood glucose stimulates insulin secretion but inhibits glucagon secretion, whereas a fall in blood glucose leads to decreased insulin secretion and increased glucagon secretion (❙Figure 19-20). Because insulin lowers and glucagon raises blood glucose, the changes in secretion of these pancreatic hormones in response to deviations in blood glucose work together homeostatically to restore blood glucose to normal.

Similarly, a fall in blood fatty acid concentration directly inhibits insulin output and stimulates glucagon output by the pancreas, both of which are negative-feedback control mechanisms to restore the blood fatty acid level to normal.

The opposite effects exerted by blood concentrations of glucose and fatty acids on the pancreatic α and β cells are appropriate for regulating the circulating levels of these nutrient molecules because the actions of insulin and glucagon on carbohydrate and fat metabolism oppose one another. The effect of blood amino acid concentration on the secretion of these two hormones is a different story. A rise in blood amino acid concentration stimulates both insulin and glucagon secretion. Why this seeming paradox because glucagon does not exert any effect on blood amino acid concentration? The identical effect of high blood amino acid levels on both insulin and glucagon secretion makes sense if you consider the concomitant effects these two hormones have on blood glucose levels. If, during absorption of a protein-rich meal, the rise in blood amino acids stimulated only insulin secretion, hypoglycemia might result. Because little carbohydrate is available for absorption following consumption of a high-protein meal, the amino acid–induced increase in insulin secretion would drive too much glucose into the cells, causing a sudden, inappropriate drop in blood glucose. However, the simultaneous increase in glucagon secretion elicited by elevated blood amino acid levels increases hepatic glucose production. Because the hyperglycemic effects of glucagon counteract the hypoglycemic actions of insulin, the net result is maintenance of normal blood glucose levels (and pre-

vention of hypoglycemic starvation of the brain) during absorption of a meal that is high in protein but low in carbohydrates.
Glucagon excess can aggravate the hyperglycemia of diabetes mellitus.

Clinical Note No known clinical abnormalities are caused by glucagon deficiency or excess per se. However, diabetes mellitus is frequently accompanied by excess glucagon secretion because insulin is required for glucose to gain entry into the α cells, where it can exert control over glucagon secretion. As a result, diabetics frequently have a high rate of glucagon secretion concurrent with their insulin insufficiency because the elevated blood glucose cannot inhibit glucagon secretion as it normally would. Because glucagon is a hormone that raises blood glucose, its excess intensifies the hyperglycemia of diabetes mellitus. For this reason, some insulin-dependent diabetics respond best to a combination of insulin and somatostatin therapy. By inhibiting glucagon secretion, somatostatin indirectly helps achieve better reduction of the elevated blood glucose than can be accomplished by insulin therapy alone.

Epinephrine, cortisol, and growth hormone also exert direct metabolic effects.

The pancreatic hormones are the most important regulators of normal fuel metabolism. However, several other hormones exert direct metabolic effects, even though control of their secretion is keyed to factors other than transitions in metabolism between feasting and fasting states (❙Table 19-5).

The stress hormones, epinephrine and cortisol, both increase blood glucose and blood fatty acids through a variety of metabolic effects. In addition, cortisol mobilizes amino acids by promoting protein catabolism. Neither hormone plays an important role in regulating fuel metabolism under resting

	MAJOR METABOLIC EFFECTS				CONTROL OF SECRETION	
Hormone	Effect on Blood Glucose	Effect on Blood Fatty Acids	Effect on Blood Amino Acids	Effect on Muscle Protein	Major Stimuli for Secretion	Primary Role in Metabolism
Insulin	↓ +Glucose uptake +Glycogenesis – Glycogenolysis – Gluconeogenesis	↓ +Triglyceride synthesis – Lipolysis	↓ +Amino acid uptake	↑ +Protein synthesis – Protein degradation	↑Blood glucose ↑Blood amino acids	Primary regulator of absorptive and postabsorptive cycles
Glucagon	↑ +Glycogenolysis +Gluconeogenesis – Glycogenesis	↑ +Lipolysis – Triglyceride synthesis	No effect	No effect	↓Blood glucose ↑Blood amino acids	Regulation of absorptive and postabsorptive cycles in concert with insulin; protection against hypoglycemia
Epinephrine	↑ +Glycogenolysis +Gluconeogenesis – Insulin secretion +Glucagon secretion	↑ +Lipolysis	No effect	No effect	Sympathetic stimulation during stress and exercise	Provision of energy for emergencies and exercise
Cortisol	↑ +Gluconeogenesis – Glucose uptake by tissues other than brain; glucose sparing	↑ +Lipolysis	↑ +Protein degradation	↓ +Protein degradation	Stress	Mobilization of metabolic fuels and building blocks during adaptation to stress
Growth Hormone	↑ – Glucose uptake by muscles; glucose sparing	↑ +Lipolysis	↓ +Amino acid uptake	↑ +Protein synthesis – Protein degradation +Synthesis of DNA and RNA	Deep sleep Stress Exercise Hypoglycemia	Promotion of growth; normally little role in metabolism; mobilization of fuels plus glucose sparing in extenuating circumstances

conditions, but both are critical for the metabolic responses to stress.

GH (itself and acting through IGF-I) has protein anabolic effects in muscle. In fact, this is one of its growth-promoting features. Although GH can elevate the blood levels of glucose and fatty acids, it is normally of little importance to the overall regulation of fuel metabolism. Deep sleep (responsible for the marked nighttime diurnal increase in GH), exercise, stress, and severe hypoglycemia stimulate GH secretion, possibly to provide fatty acids as an energy source and spare glucose for the brain under these circumstances.

Although thyroid hormone increases the overall metabolic rate and has both anabolic and catabolic actions, changes in thyroid hormone secretion are usually not important for fuel homeostasis, for two reasons. First, control of thyroid hormone secretion is not directed toward maintaining nutrient levels in the blood. Second, the onset of thyroid hormone action is too slow to have any significant effect on the rapid adjustments required to maintain normal blood levels of nutrients.

Note that, with the exception of the anabolic effects of GH on protein metabolism, all the metabolic actions of these other hormones are opposite to those of insulin. Insulin alone can reduce blood glucose and blood fatty acid levels, whereas glucagon, epinephrine, cortisol, and GH all increase blood levels of these nutrients. These other hormones are therefore considered **insulin antagonists**. The main reason diabetes mellitus has

such devastating metabolic consequences is that no other control mechanism is available to pick up the slack to promote anabolism when insulin activity is insufficient, so the catabolic reactions promoted by other hormones proceed unchecked. The only exception is protein anabolism stimulated by GH.

The hypothalamus plays a role in controlling glucose homeostasis.

In addition to the hormones that play key roles in peripherally regulating blood glucose, recent evidence indicates that the CNS, in particular the hypothalamus, directly senses blood-borne nutrients (glucose and fatty acids) and hormones associated with nutrient management (insulin, leptin, and GLP-1) and uses this information to directly or indirectly influence the three main regulators of glucose homeostasis—pancreatic insulin and glucagon secretion, hepatic glucose output, and glucose uptake by skeletal muscles—to help maintain stable blood glucose levels in response to ingestion of food. A recent surge in research related to the role of the CNS in maintaining glucose homeostasis suggests that the pathways involved overlap considerably with the CNS circuits that maintain energy balance and body weight. For example, the arcuate nucleus in the hypothalamus is involved in both sensing glucose (after it has been converted to pyruvate) and in regulating hepatic glucose production, in addition to housing the appetite-stimulating NPY neurons and appetite-suppressing POMC neurons (see p. 621). Unraveling these pathways could lead to new therapies for combating obesity-related factors in the development of Type 2 diabetes.

Check Your Understanding 19.4

1. Define *glycogenesis, glycogenolysis,* and *gluconeogenesis.*
2. Describe the metabolic effects of insulin and glucagon.
3. Compare the effect of increased blood glucose on pancreatic β cells and α cells.
4. Distinguish between Type 1 and Type 2 diabetes mellitus.

19.5 Parathyroid Glands and Control of Calcium Metabolism

Besides regulating the concentration of organic nutrient molecules in the blood by manipulating anabolic and catabolic pathways, the endocrine system regulates the plasma concentration of a number of inorganic electrolytes. As you already know, aldosterone controls Na^+ and K^+ concentrations in the ECF. Three other hormones—*parathyroid hormone, calcitonin,* and *vitamin D*—control calcium (Ca^{2+}) and phosphate (PO_4^{3-}) metabolism. These hormonal agents concern themselves with regulating plasma Ca^{2+}; in the process, plasma PO_4^{3-} is maintained. Plasma Ca^{2+} concentration is one of the most tightly controlled variables in the body. The need for the precise regulation of plasma Ca^{2+} stems from its critical influence on so many body activities.

Plasma Ca^{2+} must be closely regulated to prevent changes in neuromuscular excitability.

About 99% of the Ca^{2+} in the body (about 1000 g) is in crystalline form within the skeleton and teeth. Of the remaining Ca^{2+}, about 0.9% (9 g) is found intracellularly within the soft tissues; less than 0.1% (1 g) is present in the ECF. Approximately half of the ECF Ca^{2+} is bound to plasma proteins and therefore restricted to the plasma or is complexed with PO_4^{3-} and not free to participate in chemical reactions. The other half of the ECF Ca^{2+} is freely diffusible and can readily pass from the plasma into the interstitial fluid and interact with the cells. Only this free ECF Ca^{2+} is biologically active and subject to regulation; it constitutes less than one thousandth of the total Ca^{2+} in the body.

This small, free fraction of ECF Ca^{2+} plays a vital role in a number of essential activities, including the following:

1. *Neuromuscular excitability.* Even minor variations in the concentration of free ECF Ca^{2+} can have a profound and immediate effect on the sensitivity of excitable tissues. A fall in free Ca^{2+} results in overexcitability of nerves and muscles; conversely, a rise in free Ca^{2+} depresses neuromuscular excitability. These effects result from the influence of Ca^{2+} on membrane permeability to Na^+. A decrease in free Ca^{2+} increases Na^+ permeability, with the resultant influx of Na^+ moving the resting potential closer to threshold. Consequently, in the presence of *hypocalcemia* (low blood Ca^{2+}), excitable tissues may be brought to threshold by normally ineffective physiologic stimuli so that skeletal muscles discharge and contract (go into spasm) "spontaneously" (in the absence of normal stimulation). If severe enough, spastic contraction of the respiratory muscles results in death by asphyxiation. *Hypercalcemia* (elevated blood Ca^{2+}) is also life threatening because it causes cardiac arrhythmias and generalized depression of neuromuscular excitability.

2. *Excitation–contraction coupling in cardiac and smooth muscle.* Entry of ECF Ca^{2+} into cardiac and phasic smooth muscle cells, resulting from increased Ca^{2+} permeability in response to an action potential, triggers the contractile mechanism. Calcium is also necessary for excitation–contraction coupling in skeletal muscle fibers, but in this case the Ca^{2+} is released from intracellular Ca^{2+} stores in response to an action potential. A significant part of the increase in cytosolic Ca^{2+} in cardiac muscle cells also derives from internal stores.

Note that a rise in *cytosolic Ca^{2+}* within a muscle cell causes contraction, whereas an increase in *free ECF Ca^{2+}* decreases neuromuscular excitability and reduces the likelihood of contraction. Unless one keeps this point in mind, it is difficult to understand why low plasma Ca^{2+} levels bring about muscle hyperactivity when Ca^{2+} is necessary to switch on the contractile apparatus. We are talking about two different Ca^{2+} pools, which exert different effects.

3. *Stimulus–secretion coupling.* The entry of Ca^{2+} into secretory cells, which results from increased permeability to Ca^{2+} in response to appropriate stimulation, triggers the release of the secretory product by exocytosis. This process is important

for the secretion of neurotransmitters by nerve cells and for secretion of hydrophilic hormones by endocrine cells.

4. *Excitation–secretion coupling.* In pancreatic β cells, Ca^{2+} entry from the ECF in response to membrane depolarization leads to insulin secretion.

5. *Maintenance of tight junctions between cells.* Calcium forms part of the intercellular cement that holds particular cells tightly together.

6. *Clotting of blood.* Calcium serves as a cofactor in several steps of the cascade of reactions that leads to clot formation.

In addition to these functions of free ECF Ca^{2+}, intracellular Ca^{2+} serves as a second messenger in many cells and is involved in cell motility and cilia action. Finally, the Ca^{2+} in bone and teeth is essential for the structural and functional integrity of these tissues.

Because of the profound effects of deviations in free ECF Ca^{2+}, especially on neuromuscular excitability, the plasma concentration of this electrolyte is regulated with extraordinary precision. Let us see how.

Control of Ca^{2+} metabolism includes regulation of both Ca^{2+} homeostasis and Ca^{2+} balance.

Maintaining the proper plasma concentration of free Ca^{2+} differs from the regulation of Na^+ and K^+ in two important ways: (1) Na^+ and K^+ homeostasis is maintained primarily by regulating the urinary excretion of these electrolytes so that controlled output matches uncontrolled input. Although urinary excretion of Ca^{2+} is hormonally controlled, in contrast to Na^+ and K^+, not all ingested Ca^{2+} is absorbed from the digestive tract; instead, the extent of absorption is hormonally controlled and depends on the Ca^{2+} status of the body. (2) Bone serves as a large Ca^{2+} reservoir that can be drawn on to maintain the free plasma Ca^{2+} concentration within the narrow limits compatible with life should dietary intake become too low. Exchange of Ca^{2+} between the ECF and bone is also subject to hormonal control. Similar in-house stores are not available for Na^+ and K^+.

Regulation of Ca^{2+} metabolism depends on hormonal control of exchanges between the ECF and three other compartments: *bone, kidneys,* and *intestine.* Control of Ca^{2+} metabolism encompasses two aspects:

■ Regulation of **calcium homeostasis** involves the immediate adjustments required to maintain a constant free plasma Ca^{2+} concentration on a minute-to-minute basis. This is largely accomplished by rapid exchanges between bone and ECF and to a lesser extent by modifications in urinary excretion of Ca^{2+}.

■ Regulation of **calcium balance** involves the more slowly responding adjustments required to maintain a constant total amount of Ca^{2+} in the body. Control of Ca^{2+} balance ensures that Ca^{2+} intake is equivalent to Ca^{2+} excretion over the long term (weeks to months). Calcium balance is maintained by adjusting the extent of intestinal Ca^{2+} absorption and urinary Ca^{2+} excretion.

Parathyroid hormone, the principal regulator of Ca^{2+} metabolism, acts directly or indirectly on all three of these

effector sites. It is the primary hormone responsible for maintaining Ca^{2+} homeostasis and is essential for maintaining Ca^{2+} balance, although vitamin D also contributes in important ways to Ca^{2+} balance. The third Ca^{2+}-influencing hormone, calcitonin, is not essential for maintaining either Ca^{2+} homeostasis or balance. It serves a backup function during the rare times of extreme hypercalcemia. We now examine the specific effects of each of these hormonal systems in more detail.

Parathyroid hormone raises free plasma Ca^{2+}, a life-saving effect.

Parathyroid hormone (PTH) is a peptide hormone secreted by the **parathyroid glands**, four rice grain–sized glands located on the back surface of the thyroid gland, one in each corner (Figure 19-21). Like aldosterone, PTH *is essential for life.* The overall effect of PTH is to increase the Ca^{2+} concentration of plasma (and, accordingly, of the entire ECF), thereby preventing hypocalcemia. In the complete absence of PTH, death ensues within a few days, usually because of asphyxiation caused by hypocalcemic spasm of respiratory muscles. By its actions on bone, kidneys, and intestine, PTH raises plasma Ca^{2+} concentration when it starts to fall, so hypocalcemia and its effects are normally avoided. This hormone also lowers plasma PO_4^{3-} concentration. We consider each of these mechanisms, beginning with an overview of bone remodeling and the actions of PTH on bone.
 Figure 19-21 **Anatomy of parathyroid glands.**

Bone continuously undergoes remodeling.

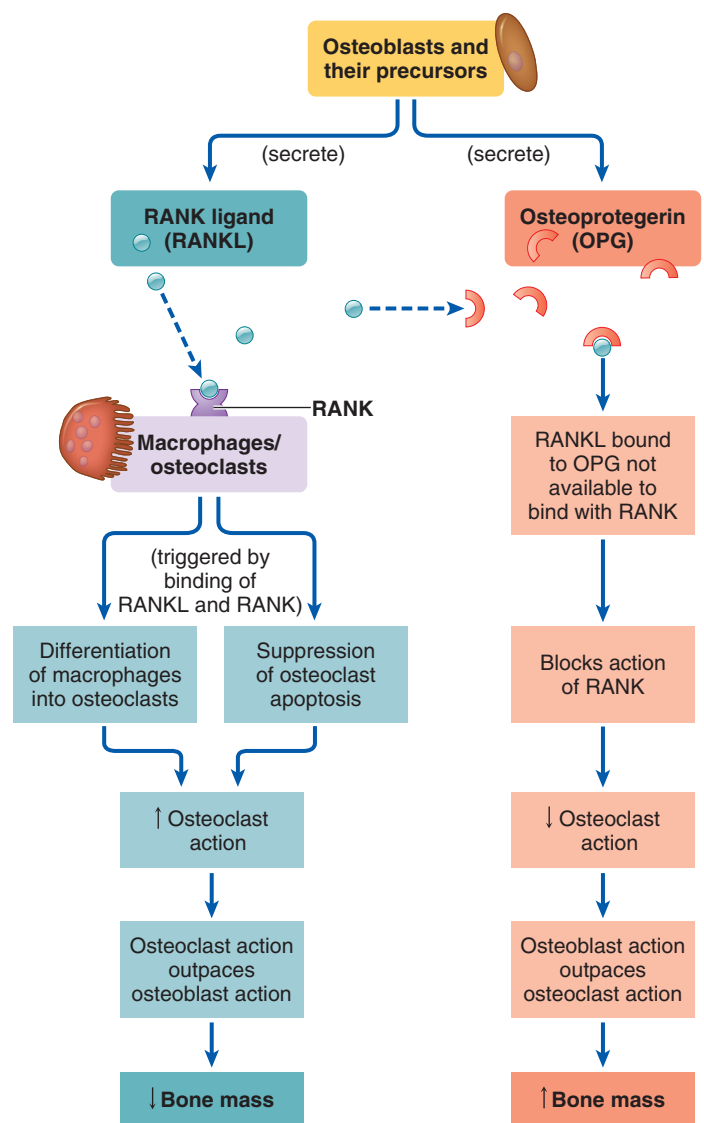
Because 99% of the body's Ca^{2+} is in bone, the skeleton serves as a storage depot for Ca^{2+}. Bone is a living tissue composed of an organic extracellular matrix or *osteoid* (see p. 654) made hard by **hydroxyapatite crystals** consisting primarily of precipitated calcium phosphate salts $(Ca_3(PO_4)_2)$. Normally, $Ca_3(PO_4)_2$ salts are in solution in the ECF, but conditions within bone are suitable for these salts to precipitate (crystallize) around the collagen fibers in the matrix. By mobilizing some of these Ca^{2+} stores in bone, PTH raises plasma Ca^{2+} concentration when it starts to fall.

Bone Remodeling Despite the apparent inanimate nature of bone, its constituents are continually being turned over. **Bone deposition** (formation) and **bone resorption** (removal) normally go on concurrently so that bone is constantly being remodeled, much as people remodel buildings by tearing down walls and replacing them. Through remodeling, the adult human skeleton is completely regenerated an estimated every 10 years. Bone remodeling serves two purposes: (1) it keeps the skeleton appropriately "engineered" for maximum effectiveness in its mechanical uses, and (2) it helps maintain the plasma Ca^{2+} level. Let us examine in more detail the underlying mechanisms and controlling factors for each of these purposes.

Recall that three types of bone cells are present in bone (see pp. 654 and 656). The *osteoblasts* secrete the extracellular organic matrix within which the $Ca_3(PO_4)_2$ crystals precipitate. The *osteocytes* are the retired osteoblasts imprisoned within the bony wall they have deposited around themselves. The *osteoclasts* resorb bone in their vicinity. The large, multinucleated osteoclasts attach to the organic matrix and form a "ruffled membrane" that increases its surface area in contact with the bone. Thus attached, the osteoclast actively secretes hydrochloric acid that dissolves the $Ca_3(PO_4)_2$ crystals and enzymes that break down the organic matrix. After it has created a cavity, an osteoclast moves on to an adjacent site to burrow another hole. Osteoblasts move into the vacated cavity and secrete osteoid to fill in the hole. Subsequent mineralization of this organic matrix results in new bone to replace the bone dissolved by the osteoclast. Thus, a constant cellular tug-of-war goes on in bone, with bone-forming osteoblasts countering the efforts of the bone-destroying osteoclasts. These construction and demolition crews, working side by side, continuously remodel bone. At any given time, about a million microscopic sites throughout the skeleton are undergoing resorption or deposition. Throughout most of adult life, the rates of bone formation and bone resorption are about equal, so total bone mass remains fairly constant during this period.

Osteocytes, despite their boney confinement, influence ongoing bone formation by secreting **sclerostin**, a paracrine that inhibits osteoblast activity in a check-and-balance way to prevent excessive bone growth that might end up clamping off nearby nerves or fusing the spinal column. Parathyroid hormone and mechanical stress, both of which favor bone formation, inhibit sclerostin, whereas calcitonin, which favors bone resorption, stimulates sclerostin.

Osteoblasts and osteoclasts both trace their origins to the bone marrow. Osteoblasts are derived from a type of connective tissue cell in the bone marrow, whereas osteoclasts differentiate from macrophages, which are tissue-bound derivatives of monocytes, a type of white blood cell that originates in the bone marrow (see p. 393). In a unique communication system, osteoblasts and their immature precursors produce two chemical signals that govern osteoclast development and activity in opposite ways—*RANK ligand* and *osteoprotegerin*—as follows (❙Figure 19-22):

■ **RANK ligand (RANKL)** revs up osteoclast action. (A ligand is a small molecule that binds with a larger protein molecule; an example is an extracellular chemical messenger binding with a plasma membrane receptor.) As its name implies, RANK ligand binds to **RANK** (for *receptor activator of NF-κB*), a protein receptor on the membrane surface of nearby macrophages. This binding induces the macrophages to differentiate into osteoclasts and helps them live longer by suppressing apoptosis. As a result, bone resorption is stepped up and bone mass decreases.


❙Figure 19-22 **Role of osteoblasts in governing osteoclast development and activity.**

- Alternatively, neighboring osteoblasts can secrete **osteoprotegerin (OPG)**, which by contrast suppresses osteoclast activity. OPG secreted into the matrix serves as a freestanding decoy receptor that binds with RANKL. By taking RANKL out of action so that it cannot bind with its intended RANK receptors, OPG prevents RANKL from revving up osteoclasts' bone-resorbing activity. As a result, the matrix-making osteoblasts are able to outpace the matrix-removing osteoclasts, so bone mass increases. The balance between RANKL and OPG thus is an important determinant of bone density. If osteoblasts produce more RANKL, the more osteoclast action, the lower the bone mass. If osteoblasts produce more OPG, the less osteoclast action, the greater the bone mass. Scientists are currently unraveling the influence of various factors on this balance. For example, the female sex hormone estrogen stimulates activity of the OPG-producing gene in osteoblasts and also promotes apoptosis of osteoclasts, both mechanisms by which this hormone preserves bone mass.

Mechanical stress favors bone deposition.

As a child grows, the bone builders keep ahead of the bone destroyers under the influence of GH and IGF-I (see pp. 654–656).

Mechanical stress also tips the balance in favor of bone deposition, causing bone mass to increase and the bones to strengthen. Mechanical factors adjust the strength of bone in response to the demands placed on it. The greater the physical stress and compression to which a bone is subjected, the greater the rate of bone deposition. For example, the bones of athletes are stronger and more massive than those of sedentary people.

By contrast, bone mass diminishes and the bones weaken when bone resorption gains a competitive edge over bone deposition in response to removal of mechanical stress. For example, bone mass decreases in people who undergo prolonged bed confinement or those in spaceflight. Early astronauts lost up to 20% of their bone mass during their time in orbit. Therapeutic exercise can limit or prevent such loss of bone.

Clinical Note Bone mass also decreases as a person ages. Bone density peaks when a person is in the 30s and then starts to decline after age 40. By 50 to 60 years of age, bone resorption often exceeds bone formation. The result is a reduction in bone mass known as **osteoporosis** (meaning "porous bones"). This bone-thinning condition is characterized by a diminished laying down of organic matrix as a result of reduced osteoblast activity, increased osteoclast activity, or both, rather than abnormal bone calcification. The underlying cause of osteoporosis is uncertain. Plasma Ca^{2+} and PO_4^{3-} levels are normal, as is PTH. Osteoporosis occurs with greatest frequency in postmenopausal women because of the associated withdrawal of bone-preserving estrogen. (For more details on osteoporosis, see the boxed feature on pp. 706–707, ❙A Closer Look at Exercise Physiology.)

PTH raises plasma Ca^{2+} by withdrawing Ca^{2+} from the bone bank.

In addition to the factors geared toward controlling the mechanical effectiveness of bone, throughout life PTH uses bone as a "bank" from which it withdraws Ca^{2+} as needed to maintain plasma Ca^{2+} level. PTH has two major effects on bone that raise plasma Ca^{2+} concentration. First, it induces a fast Ca^{2+} efflux into the plasma from the small *labile pool* of Ca^{2+} in the bone fluid. Second, by stimulating bone dissolution, it promotes a slow transfer into the plasma of both Ca^{2+} and PO_4^{3-} from the *stable pool* of bone minerals in bone itself. Let us examine more thoroughly PTH's actions in mobilizing Ca^{2+} from its labile and stable pools in bone.

PTH's immediate effect is to promote transfer of Ca^{2+} from bone fluid into plasma.

Compact bone forms the dense outer portion of a bone. Interconnecting spicules of **trabecular bone** make up the more lacy-appearing inner core of a bone (❙Figure 19-23a). The inner honeycomb network allows bones to be sturdy without being too heavy. Compact bone is organized into **osteon** units, each of which consists of a **central canal** surrounded by concentrically arranged **lamellae** (❙Figure 19-23b). Lamellae are layers of osteocytes entombed within the bone they have deposited around themselves (❙Figure 19-23b and c). The osteons typically run parallel to the long axis of the bone. Blood vessels penetrate the bone from either the outer surface or the marrow cavity and run through the central canals. Osteoblasts are present along the outer surface of the bone and along the inner surfaces lining the central canals. Osteoclasts are also located on bone surfaces undergoing resorption. The surface osteoblasts and entombed osteocytes are connected by an extensive network of small, fluid-containing canals, the **canaliculi**, which permit exchange of substances between the trapped osteocytes and the circulation. These small canals also contain long, filmy cytoplasmic extensions, or "arms," of osteocytes and osteoblasts that are connected to one another, much as if these cells were "holding hands." The "hands" of adjacent cells are connected by gap junctions, which permit communication and exchange of materials among these bone cells. The interconnecting cell network, which is called the **osteocytic–osteoblastic bone membrane**, separates the mineralized bone itself from the blood vessels within the central canals (❙Figure 19-24a, p. 708). The small, labile pool of Ca^{2+} is in the **bone fluid** that lies between this bone membrane and the adjacent bone, both within the canaliculi and along the surface of the central canal.

PTH exerts its effects via cAMP. The earliest effect of PTH is to activate membrane-bound Ca^{2+} pumps located in the plasma membranes of the cytoplasmic extensions of osteocytes and osteoblasts. These pumps promote movement of Ca^{2+}, without the accompaniment of PO_4^{3-}, from the bone fluid into these cells, which in turn transfer the Ca^{2+} into the plasma within the central canal. Thus, PTH stimulates the transfer of Ca^{2+} from the bone fluid across the osteocytic–osteoblastic bone membrane into the plasma. Movement of Ca^{2+} out of the labile pool across the bone membrane accounts for the fast exchange between bone and plasma (❙Figure 19-24b). Because of the large surface area of the bone membrane, small movements of Ca^{2+} across individual cells are amplified into large Ca^{2+} fluxes between the bone fluid and plasma.

After Ca^{2+} is pumped out, the bone fluid is replenished with Ca^{2+} from partially mineralized bone along the adjacent bone
IFigure 19-23 Organization of compact bone into osteons. (a) Structure of a long bone showing location of compact bone and trabecular bone. (b) An osteon, the structural unit of compact bone, consists of concentric lamellae (layers of osteocytes entombed by the bone they have deposited around themselves) surrounding a central canal containing a small blood vessel branch. The light micrograph is of compact bone in a human femur (thigh bone). (c) A magnification of lamellae.

surface. Thus, the fast exchange of Ca^{2+} does not involve resorption of completely mineralized bone, and bone mass is not decreased. Through this means, PTH draws Ca^{2+} out of the "quick-cash branch" of the bone bank and rapidly increases plasma Ca^{2+} without actually entering the bank (that is, without breaking down mineralized bone itself). Under normal conditions, this exchange is sufficient for maintaining plasma Ca^{2+} concentration.

PTH's chronic effect is to promote localized dissolution of bone to release Ca^{2+} into plasma.

Under conditions of chronic hypocalcemia, such as may occur with dietary Ca^{2+} deficiency, PTH stimulates localized dissolution of bone, promoting a slower transfer into the plasma of both Ca^{2+} and PO_4^{3-} from the minerals within the bone itself. Osteoblasts have PTH receptors, but osteoclasts do not. PTH promotes localized bone dissolution by acting on osteoblasts, causing them to secrete RANKL, thereby indirectly stimulating osteoclasts to gobble up bone. PTH also transiently inhibits the bone-forming activity of the osteoblasts. Bone contains so much Ca^{2+} compared to the plasma (more than 1000 times as much) that even when PTH tips the balance in favor of increased bone resorption, no immediate effects on the skeleton are discernible because such a tiny amount of bone is affected. Yet the negligible amount of Ca^{2+} "borrowed" from the bone bank can be lifesaving in terms of restoring the free plasma Ca^{2+} level to normal. The borrowed Ca^{2+} is then redeposited in the bone at another time when Ca^{2+} supplies are more abundant. Meanwhile, the plasma Ca^{2+} level has been maintained without sacrificing bone integrity. However, prolonged excess

Osteoporosis: The Bane of Brittle Bones

OSTEOPOROSIS, A DECREASE IN BONE density resulting from reduced deposition of the bone's organic matrix (see the accompanying figure), is a major health problem affecting 200 million people worldwide. In the United States, 8 million women and 2 million men already have osteoporosis, with another 34 million having a low bone mass that makes them at high risk for developing this disorder. The condition is especially prevalent among women following menopause (permanent cessation of menstruation), owing to the marked drop in bone-preserving estrogen. Thirty percent of postmenopausal women have osteoporosis. Following menopause, women start losing 1% or more bone density each year. Skeletons of elderly women are typically only 50% to 80% as dense as at their peak at about age 35, whereas elderly men's skeletons retain 80% to 90% of their youthful density. Similar to estrogen, testosterone also helps preserve bone density, but unlike women's programmed withdrawal of estrogen at menopause, men do not experience a similar built-in loss of testosterone secretion.

Osteoporosis is responsible for the greater incidence of bone fractures among women older than age 50 years than among the population at large. One in three women with osteoporosis ends up with a fractured bone, most commonly of the hip or spine, which may lead to permanent disability or even death. Because bone mass is reduced, osteoporotic bones are more brittle and more susceptible to fracture in response to a fall, blow, or lifting action that normally would not strain stronger bones. For every 10% loss of bone mass, the risk of fracture doubles. In the United States, osteoporosis is the underlying cause of approximately 1.5 million fractures each year, and the attendant medical and rehabilitation cost is $17 billion per year. The cost in pain, suffering, and loss of independence is not measurable. Half of all American women have spinal pain and deformity by age 75.

Drug Therapy for Osteoporosis

Ca^{2+} and vitamin D supplementation and a regular weight-bearing exercise program are long-standing therapeutic approaches used to prevent or treat osteoporosis. Additionally, the following drugs can minimize or reverse bone loss:

■ *Estrogen replacement therapy* was used to treat osteoporosis in the past. Estrogen slows bone loss by promoting apoptosis (cell suicide) of osteoclasts and by enhancing activity of osteoblasts. However, the Food and Drug Administration (FDA) no longer approves es-

trogen therapy for treating osteoporosis because this drug has been linked to an increased risk of breast cancer and cardiovascular disease. However, the following newer classes of drugs are already approved by the FDA or are under investigation.

■ *Alendronate* (Fosamax), a bisphosphonate, was the first nonhormonal osteoporosis drug. It works by blocking osteoclasts' bone-destroying actions. Alendronate pills have to be taken daily, or a newer version can be taken weekly. Even newer bisphosphonates can be taken at longer intervals, such as *ibondronate* (Boniva) (once-a-month pill) and *zoledronic acid* (Reclast) (once-a-year intravenous infusion).

■ *Calcitonin* (Miacalcin), the thyroid C-cell hormone that slows osteoclast activity, is used to treat advanced osteoporosis, but traditionally it had to be injected daily, a deterrent to patient compliance. Now calcitonin is available in a more patient-friendly nasal spray (Fortical).

■ *Raloxifene* (Evista) belongs to a new class of drugs known as *selective estrogen receptor modulators (SERMs).* Raloxifene does not

PTH secretion over months or years eventually leads to the formation of holes throughout the skeleton, which are filled with very large, overstuffed osteoclasts.

When PTH promotes dissolution of $Ca_3(PO_4)_2$ crystals in bone to harvest their Ca^{2+} content, both Ca^{2+} and PO_4^{3-} are released into the plasma. An elevated plasma PO_4^{3-} is undesirable, but PTH deals with this dilemma by its actions on the kidneys.

PTH acts on the kidneys to conserve Ca^{2+} and eliminate PO_4^{3-}.

PTH promotes Ca^{2+} conservation and PO_4^{3-} elimination by the kidneys during urine formation. Under the influence of PTH, the kidneys can reabsorb more of the filtered Ca^{2+}, so less Ca^{2+} escapes into the urine. This effect increases plasma Ca^{2+} and decreases urinary Ca^{2+} losses. (It would be counterproduc-

bind with estrogen receptors in reproductive organs, but it does bind with estrogen receptors outside the reproductive system, such as in bone. Through this selective receptor binding, raloxifene mimics estrogen's beneficial effects on bone to provide protection against osteoporosis by keeping osteoclasts in check while avoiding estrogen's potentially harmful effects on reproductive organs, such as increased risk of breast cancer.

■ *Teriparatide* (Forteo) was the first approved treatment that stimulates bone formation instead of acting to prevent bone loss, as the other drugs do. Teriparatide, which must be injected, is an active fragment of parathyroid hormone (PTH). Even though continuous exposure to PTH, as with hyperparathyroidism, increases osteoclast activity and thereby promotes the breakdown of bone, evidence suggests that, by contrast, intermittent administration of PTH (or its active teriparatide fragment) increases osteoblast formation and prolongs survival of these bone builders by blocking osteoblast apoptosis.

• *Denosumab* (Prolia) is the newest drug for treatment of osteoporosis. This injectable drug reduces destruction of bone by binding to and inhibiting RANKL, the protein that promotes maturation, function, and survival of bone-resorbing osteoclasts. Denosumab mimics the natural action of osteoprotegerin (see p. 704).

■ The *statins* (for example, Lipitor) are another group of drugs with some promise for treating osteoporosis. The statins are already commonly used as cholesterol-lowering agents. They also stimulate osteoblast activity, promoting bone formation and reducing the fracture rate, which are side benefits to their favorable cholesterol actions. They still have not been approved specifically for use in preventing bone loss.

■ *ANGELS (activators of nongenomic estrogen-like signaling)* is a new class of osteoporosis drug under development. Most of estrogen's effects are brought about by estrogen binding with its receptors in the target cell's nucleus, thereby turning on specific genes, just as all steroids do (see p. 126). However, scientists recently discovered that estrogen blocks apoptosis among osteoblasts by using a different pathway. In this alternative cytoplasmic-signaling pathway, estrogen binds with a cytoplasmic receptor instead of binding with its nuclear receptor to bring about its effect. ANGELS drugs trigger estrogen's cytoplasmic signaling pathway to block osteoblast

apoptosis. The term ANGELS refers to activation of this nongene pathway, in contrast to SERMs, which trigger estrogen's traditional nuclear gene pathway in bone.

■ *Romosozumab* is the latest class of investigational osteoporosis drug. It is an antibody developed to bind to and block the action of sclerostin, the osteocyte-derived protein that naturally inhibits bone-forming osteoblasts (see p. 703). By this means, romosozumab favors bone rebuilding by allowing osteoblasts to proceed uninterrupted.

Benefits of Exercise on Bone

Despite advances in osteoporosis therapy, treatment is still often less than satisfactory, and all the current therapeutic agents are associated with some undesirable side effects. Therefore, prevention is by far the best approach to managing this disease. Development of strong bones to begin with before menopause through a good, Ca^{2+}-rich diet and adequate exercise appears to be the best preventive measure. A large reservoir of bone at midlife may delay the clinical manifestations of osteoporosis in later life. Continued physical activity throughout life appears to retard or prevent bone loss, even in the elderly.

It is well documented that osteoporosis can result from disuse— that is, from reduced mechanical loading of the skeleton. Space travel has clearly shown that lack of gravity results in a decrease in bone density. Studies of athletes, by contrast, demonstrate that weight-bearing physical activity increases bone density. Within groups of athletes, bone density correlates directly with the load the bone must bear. If one looks at athletes' femurs (thigh bones), the greatest bone density is found in weight lifters, followed in order by throwers, runners, soccer players, and finally swimmers. In fact, the bone density of swimmers does not differ from that of nonathletic controls. Swimming does not place any strain on bones. The bone density in the playing arm of male tennis players has been found to be as much as 35% greater than in their other arm; female tennis players have been found to have 28% greater density in their playing arm than in their other arm. One study found that very mild activity in nursing-home patients, whose average age was 82 years, not only slowed bone loss but even resulted in bone buildup over a 36-month period. Thus, exercise is a good defense against osteoporosis.

tive to dissolve bone to obtain more Ca^{2+} only to lose it in urine.) By contrast, PTH decreases PO_4^{3-} reabsorption, thus increasing urinary PO_4^{3-} excretion. As a result, PTH reduces plasma PO_4^{3-} at the same time it increases plasma Ca^{2+}.

This PTH-induced urinary removal of extra PO_4^{3-} from the body fluids is essential for preventing reprecipitation of the Ca^{2+} freed from bone. Both Ca^{2+} and PO_4^{3-} are released from bone when PTH promotes bone dissolution. Because PTH is

secreted only when plasma Ca^{2+} falls below normal, the released Ca^{2+} is needed to restore plasma Ca^{2+} to normal, yet the released PO_4^{3-} tends to raise plasma PO_4^{3-} above normal. Because of the solubility characteristics of $Ca_3(PO_4)_2$ salt, the product of the plasma concentration of Ca^{2+} times the plasma concentration of plasma PO_4^{3-} must remain roughly constant. Therefore, an inverse relationship exists between the plasma concentrations of Ca^{2+} and PO_4^{3-}. If plasma PO_4^{3-} levels were

(a) Osteocytic–osteoblastic bone membrane

KEY

= Membrane-bound Ca^{2+} pump

1. In a fast exchange, Ca^{2+} is moved from the labile pool in the bone fluid into the plasma by PTH-activated Ca^{2+} pumps located in the osteocytic–osteoblastic bone membrane.

2. In a slow exchange, Ca^{2+} is moved from the stable pool in the mineralized bone into the plasma through PTH-induced dissolution of the bone by osteoclasts.
(b) Fast and slow exchange of Ca^{2+} between bone and plasma

❙Figure 19-24 Fast and slow exchanges of Ca^{2+} between bone and plasma. (a) Entombed osteocytes and surface osteoblasts are interconnected by long cytoplasmic processes that extend from these cells and connect to one another within the canaliculi. This interconnecting cell network, the osteocytic–osteoblastic bone membrane, separates the mineralized bone from the plasma in the central canal. Bone fluid lies between the membrane and the mineralized bone. (b) Fast exchange of Ca^{2+} between the bone and plasma is accomplished by Ca^{2+} pumps in the osteocytic–osteoblastic bone membrane that transport Ca^{2+} from the bone fluid into these bone cells, which transfer the Ca^{2+} into the plasma. Slow exchange of Ca^{2+} between the bone and plasma is accomplished by osteoclast dissolution of bone.

FIGURE FOCUS: *Use one of these terms to fill in each blank in the following statements regarding PTH action: (a) labile, (b) stable, (c) osteoclasts, (d) bone-membrane Ca^{2+} pumps. In a fast exchange, PTH moves Ca^{2+} from the ____ Ca^{2+} pool in bone by stimulating ____. In a slow exchange, PTH moves Ca^{2+} from the ____ Ca^{2+} pool in bone by increasing activity of ____.*

though extra PO_4^{3-} is being released from bone into the plasma.

The third important action of PTH on the kidneys (besides increasing Ca^{2+} reabsorption and decreasing PO_4^{3-} reabsorption) is to enhance activation of vitamin D by the kidneys.

PTH indirectly promotes absorption of Ca^{2+} and PO_4^{3-} by the intestine.

Although PTH has no direct effect on the intestine, it indirectly increases both Ca^{2+} and PO_4^{3-} absorption from the small intestine by helping activate vitamin D. This vitamin, in turn, directly increases intestinal absorption of Ca^{2+} and PO_4^{3-}, a topic we discuss more thoroughly shortly.

The primary regulator of PTH secretion is plasma concentration of free Ca^{2+}.

All the effects of PTH raise plasma Ca^{2+} levels. Appropriately, PTH secretion increases when plasma Ca^{2+} falls and decreases when plasma Ca^{2+} rises. The secretory cells of the parathyroid glands are directly and exquisitely sensitive to changes in free plasma Ca^{2+}. Because PTH regulates plasma Ca^{2+} concentration, this relationship forms a simple negative-feedback loop for controlling PTH secretion without involving any nervous or other hormonal intervention (❙Figure 19-25).

Calcitonin lowers plasma Ca^{2+} concentration but is not important in the normal control of Ca^{2+} metabolism.

Calcitonin, the hormone produced by the C cells of the thyroid gland (see ❙Figure 19-1b, p. 666), also exerts an influence on plasma Ca^{2+} levels. Like PTH, calcitonin has two effects on bone, but in this case both effects *decrease* plasma Ca^{2+} levels: Short term, calcitonin decreases Ca^{2+} movement from the bone fluid into the plasma. Long term, calcitonin decreases bone resorption by inhibiting the activity of osteoclasts via the cAMP pathway. The suppression of bone resorption reduces plasma Ca^{2+} concentration and lowers plasma PO_4^{3-} levels. Calcitonin also inhibits Ca^{2+} and PO_4^{3-} reabsorption from the kidney tubules during urine formation, further reinforcing its hypocalcemic and hypophos-

allowed to rise above normal, some of the released Ca^{2+} would be forced along with the PO_4^{3-} back into bone through hydroxyapatite crystal formation to keep the calcium phosphate product constant. This self-defeating redeposition of Ca^{2+} would lower plasma Ca^{2+}, just the opposite of the needed effect. Therefore, PTH acts on the kidneys to decrease the reabsorption of PO_4^{3-} by the renal tubules. This action increases urinary excretion of PO_4^{3-} and lowers its plasma concentration, even

Figure 19-25 Negative-feedback loops controlling parathyroid hormone (PTH) and calcitonin secretion.

phatemic effects. Calcitonin has no effect on the intestine or on vitamin D.

As with PTH, the primary regulator of calcitonin release is free plasma Ca^{2+} concentration, but unlike with PTH, an increase in plasma Ca^{2+} stimulates calcitonin secretion and a fall in plasma Ca^{2+} inhibits calcitonin secretion (Figure 19-25). Because calcitonin reduces plasma Ca^{2+} levels, this system constitutes a second simple negative-feedback control over plasma Ca^{2+} concentration, one opposed to the PTH system.

However, calcitonin plays little or no role in the normal control of Ca^{2+} or PO_4^{3-} metabolism. Although calcitonin protects against hypercalcemia, this condition rarely occurs under normal circumstances. Moreover, neither thyroid removal nor calcitonin-secreting tumors alter circulating levels of Ca^{2+} or PO_4^{3-}, implying that this hormone is not normally essential for maintaining Ca^{2+} or PO_4^{3-} homeostasis. Calcitonin may, however, play a role in protecting skeletal integrity when there is a large Ca^{2+} demand, such as during pregnancy or breast-feeding. Furthermore, some experts speculate that calcitonin may hasten the storage of newly absorbed Ca^{2+} following a meal.

Vitamin D is actually a hormone that increases Ca^{2+} absorption in the intestine.

The final factor involved in regulating Ca^{2+} metabolism is **cholecalciferol,** or **vitamin D,** a steroidlike compound essential for Ca^{2+} absorption in the intestine. Strictly speaking, vitamin D should be considered a hormone because the skin (specifically, the keratinocytes; see p. 441) can produce it from a precursor related to cholesterol (7-dehydrocholesterol) on exposure to sunlight. Skin-produced vitamin D is subsequently released into the blood to act at a distant target site, the intestine. The skin, therefore, is actually an endocrine gland and vitamin D is a hormone. Traditionally, however, this chemical messenger has been considered a vitamin for two reasons. First, it was originally discovered and isolated from a dietary source and tagged as a vitamin. Second, even though the skin would be an adequate source of vitamin D if it were exposed to sufficient sun-

light, indoor dwelling and clothing in response to cold weather and social customs preclude significant exposure of the skin to sunlight in the United States and many other parts of the world most of the time. At least part of the essential vitamin D must therefore be derived from dietary sources.

Activation of Vitamin D Regardless of its source, vitamin D is biologically inactive when it first enters the blood from either the skin or the digestive tract. It must be activated by two sequential biochemical alterations that involve the addition of two hydroxyl (—OH) groups (Figure 19-26). The first of these reactions occurs in the liver, and the second takes place in the kidneys. The end result is production of the active form of vitamin D, *1,25-(OH)₂-vitamin D₃*, also known as *calcitriol.* PTH stimulates the kidney enzymes involved in the second step of vitamin D activation in response to a fall in plasma Ca^{2+}. To a lesser extent, a fall in plasma PO_4^{3-} also enhances the activation process. Vitamin D in its various forms circulates in the blood primarily bound to **vitamin D–binding protein**.

Function of Vitamin D The most dramatic effect of activated vitamin D is to increase Ca^{2+} absorption by the intestine. Unlike most dietary constituents, dietary Ca^{2+} is not indiscriminately absorbed by the digestive system. In fact, the majority of ingested Ca^{2+} is typically not absorbed but is lost in the feces. When needed, more dietary Ca^{2+} is absorbed into the plasma under the influence of vitamin D. Independently of its effects on Ca^{2+} absorption, the active form of vitamin D increases intestinal PO_4^{3-} absorption. Furthermore, vitamin D increases responsiveness of bone to PTH. Thus, vitamin D and PTH are closely interdependent. Like steroid hormones, vitamin D exerts its effects by binding with a nuclear **vitamin D receptor (VDR)**, with this complex regulating gene transcription in the target cells by binding with the **vitamin D–response element** in DNA. (Because vitamin D is the last major hormone to be introduced, for your convenience we summarize in Table 19-6 the signal transduction pathways used by the major hormones. Review these pathways on pp. 116–117, 123–124, and 126–127.)

PTH is principally responsible for controlling Ca^{2+} homeostasis because the actions of vitamin D are too sluggish for it to contribute substantially to the minute-to-minute regulation of plasma Ca^{2+} concentration. However, both PTH and vitamin D are essential to Ca^{2+} balance, the process ensuring that, over the long term, dietary Ca^{2+} input into the body is equivalent to Ca^{2+} output in the urine. When dietary Ca^{2+} intake is reduced, the resultant transient fall in plasma Ca^{2+} level stimulates PTH secretion. The increased PTH has two effects important for maintaining Ca^{2+} balance: (1) It stimulates Ca^{2+} reabsorption by the kidneys, thereby decreasing Ca^{2+} output; and (2) it activates vitamin D, which increases the efficiency of uptake of ingested Ca^{2+}. Because PTH also promotes bone resorption, a substantial loss of bone minerals occurs if Ca^{2+} intake is reduced for a prolonged period, even though bone is not directly involved in maintaining Ca^{2+} input and output in balance.

A torrent of studies in recent decades indicates that vitamin D's functions are more far reaching than its effects on uptake of

Promotes intestinal absorption
of Ca^{2+} and PO_4^{3-}
blood cells responsible for cell-mediated immunity that targets virally invaded cells and cancer cells (see p. 423). It also promotes production of antioxidants that combat free radicals, naturally occurring highly reactive, unstable, cell-damaging molecules (see p. 142). Studies further suggest that vitamin D helps thwart development of diabetes mellitus, counter autoimmune diseases like multiple sclerosis, and lower the risk of high blood pressure, heart attacks, and strokes. Vitamin D may help clear beta amyloid from the brain plaques associated with Alzheimer's disease (see p. 164). Researchers continue to seek the underlying mechanisms by which vitamin D exerts these protective effects.

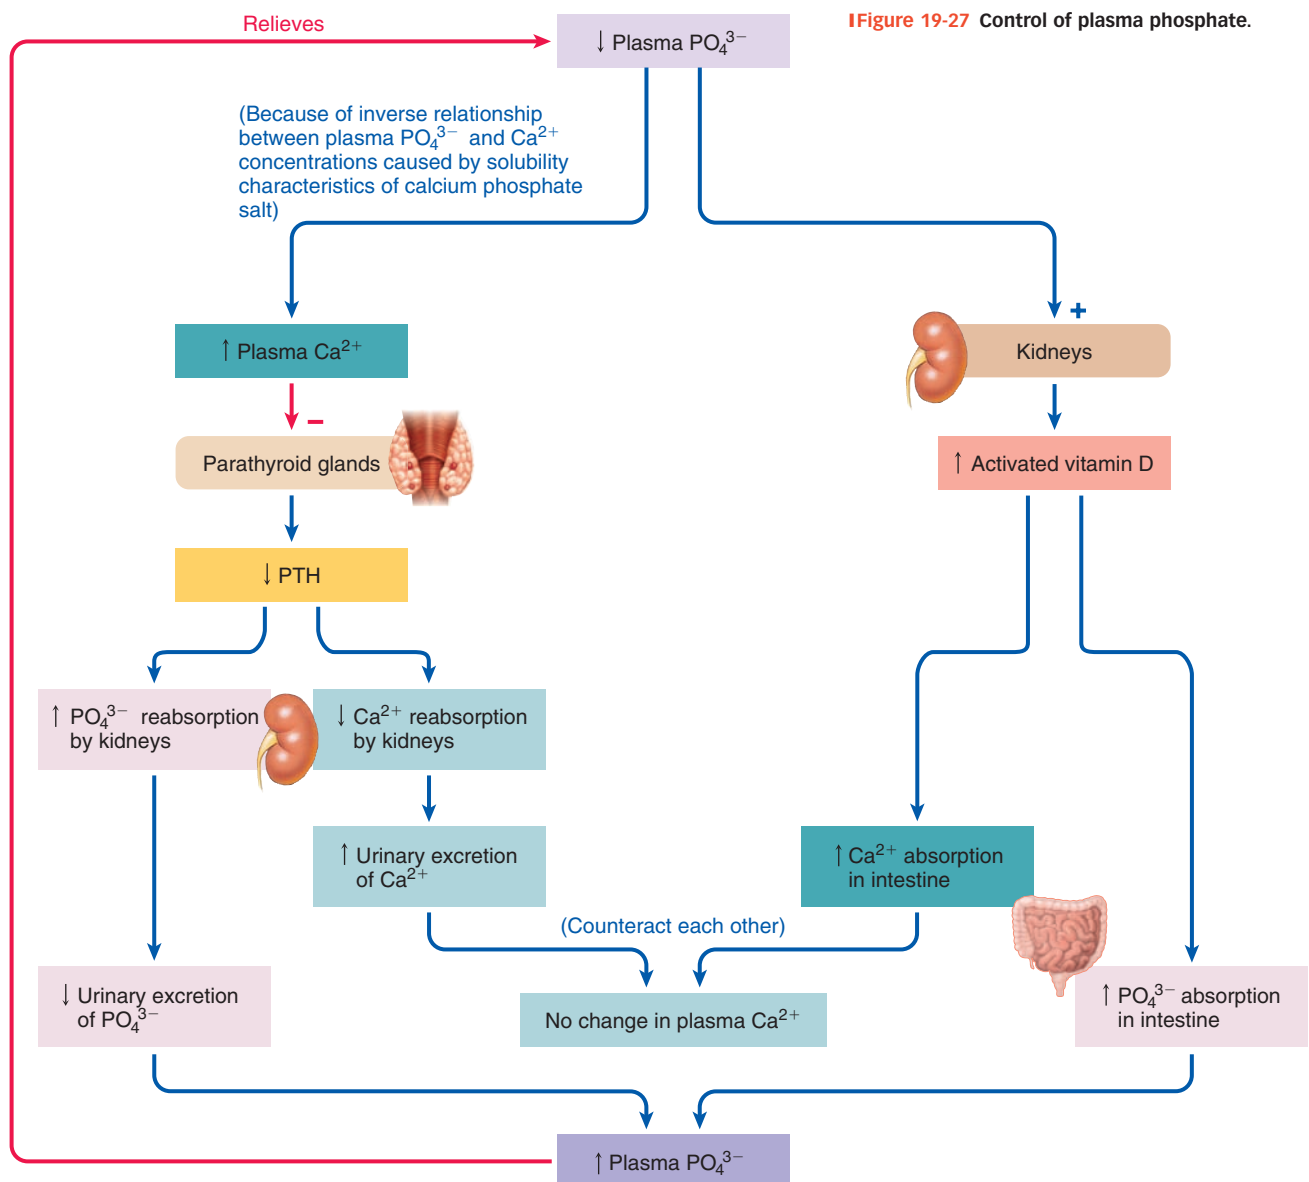
Phosphate metabolism is controlled by the same mechanisms that regulate Ca^{2+} metabolism.

Intracellular PO_4^{3-} is important in the high-energy phosphate bonds of ATP, plays a key regulatory role in phosphorylating designated proteins in second-messenger pathways, and helps form the backbone of DNA molecules. Excreted PO_4^{3-} is an important urinary buffer. In the ECF, plasma PO_4^{3-} concentration is not as tightly controlled as plasma Ca^{2+} concentration. Phosphate is regulated directly by vitamin D and indirectly by the plasma Ca^{2+}–PTH feedback loop. To illustrate, a fall in plasma PO_4^{3-} concentration exerts a twofold effect to help raise the circulating PO_4^{3-} level back to normal (Figure 19-27). First, because of the inverse relationship between the plasma concentrations of PO_4^{3-} and Ca^{2+}, a fall in plasma PO_4^{3-} increases plasma Ca^{2+}, which directly suppresses PTH secretion. In the presence of reduced PTH, PO_4^{3-} reabsorption by the kidneys increases, returning plasma PO_4^{3-} concentration toward normal. Second, a fall in plasma PO_4^{3-} also increases activation of vitamin D, which then promotes PO_4^{3-} absorption in

ingested Ca^{2+} and PO_4^{3-}. Vitamin D's broad effect results from its activation of VDRs that have been found in many organs throughout the body. Vitamin D, at higher blood concentrations than those sufficient to protect bone, appears to bolster muscle strength and thereby help prevent falls by improving leg strength. It also seems to be an important force in energy metabolism and immune health. Vitamin D reduces inflammation and must be present for activation of T cells, the white

the intestine. This further helps alleviate the initial hypophosphatemia. Note that these changes do not compromise Ca^{2+} balance. Although the increase in activated vitamin D stimulates Ca^{2+} absorption from the intestine, the concurrent fall in PTH produces a compensatory increase in urinary Ca^{2+} excretion because less of the filtered Ca^{2+} is reabsorbed. Therefore, plasma Ca^{2+} remains unchanged while plasma PO_4^{3-} increases to normal.

Signal Transduction Pathway	Hormones That Use This Pathway
↑ **Cyclic AMP/PKA**	TSH, ACTH, FSH, LH, CRH, GHRH, somatostatin, vasopressin, epinephrine (for β adrenergic receptor induced actions), secretin, glucagon, PTH, calcitonin
↓ **Cyclic AMP/PKA**	Dopamine, melatonin, epinephrine (for α_2 adrenergic receptor induced actions), $PPY_{3\text{-}36}$
IP_3/Ca^{2+} **and DAG/PKC**	TRH, GnRH, oxytocin, ghrelin, gastrin, cholecystokinin, epinephrine (for α_1 adrenergic receptor induced actions)
Tyrosine kinase	Insulin, IGF-I, and IGF-II
JAK/STAT	Growth hormone, prolactin, erythropoietin, leptin
Hormone-response elements on DNA	All lipophilic hormones: thyroid hormone, cortisol, aldosterone, testosterone, estrogen, progesterone, vitamin D

IFigure 19-27 Control of plasma phosphate.


Disorders in Ca²⁺ metabolism may arise from abnormal levels of PTH or vitamin D.

Clinical Note The primary disorders that affect Ca²⁺ metabolism are too much or too little PTH or a deficiency of vitamin D.

PTH Hypersecretion Excess PTH secretion, or **hyperparathyroidism,** which is usually caused by a hypersecreting tumor in one of the parathyroid glands, is characterized by *hypercalcemia* and *hypophosphatemia*. The affected individual can be asymptomatic or symptoms can be severe, depending on the magnitude of the problem. The following are among the possible consequences:

■ Hypercalcemia reduces the excitability of muscle and nervous tissue, leading to muscle weakness and neurologic disorders, including decreased alertness, poor memory, and depression. Cardiac disturbances may also occur.

■ Excessive mobilization of Ca²⁺ and PO_4^{3-} from skeletal stores leads to thinning of bone, which may result in skeletal deformities and increased incidence of fractures.

■ An increased incidence of Ca²⁺-containing kidney stones occurs because the excess quantity of Ca²⁺ being filtered through the kidneys may precipitate and form stones. These stones may impair renal function. Passage of the stones through the ureters causes extreme pain. Because of these potential multiple consequences, hyperparathyroidism has been called a disease of "bones, stones, and abdominal groans."

■ To further account for the "abdominal groans," hypercalcemia can cause peptic ulcers, nausea, and constipation.

PTH Hyposecretion Because of the parathyroid glands' close anatomic relation to the thyroid, the most common cause of deficient PTH secretion, or **hypoparathyroidism,** used to be inadvertent removal of the parathyroid glands (before doctors knew about their existence) during surgical removal of the thyroid gland (to treat thyroid disease). If all the parathyroid tissue was removed, these patients died, of course, because PTH is essential for life. Physicians were puzzled why some patients died soon after thyroid removal but others did not. Now that the location and importance of the parathyroid glands are known, surgeons are careful to leave parathyroid tissue during thyroid removal. Rarely, PTH hyposecretion results from an autoimmune attack against the parathyroid glands.

Hypoparathyroidism leads to *hypocalcemia* and *hyperphosphatemia*. The symptoms are mainly caused by increased neuromuscular excitability from the reduced level of free plasma Ca²⁺. In the complete absence of PTH, death is imminent. With a relative deficiency of PTH, milder symptoms of increased neuromuscular excitability become evident. Muscle cramps and twitches occur from spontaneous activity in the motor nerves, whereas tingling and pins-and-needles sensations result from spontaneous activity in the sensory nerves. Mental changes include irritability and paranoia.

Vitamin D Deficiency The major consequence of vitamin D deficiency is impaired intestinal absorption of Ca²⁺. In the face of reduced Ca²⁺ uptake, PTH maintains the plasma Ca²⁺ level

❚Figure 19-28 **Rickets.**

at the expense of the bones. As a result, the bone matrix is not properly mineralized because Ca²⁺ salts are not available for deposition. The demineralized bones become soft and deformed, bowing under the pressures of weight bearing, especially in children. This condition is known as **rickets** in children and **osteomalacia** in adults (❚Figure 19-28).

Check Your Understanding 19.5

1. Describe the distribution of Ca²⁺ in the body and the functions of free ECF Ca²⁺.

2. Distinguish between calcium homeostasis and calcium balance.

3. Discuss the effects of PTH on bone, kidneys, and the intestine.

Homeostasis: Chapter in Perspective

A number of peripherally located endocrine glands play key roles in maintaining homeostasis, primarily by means of their regulatory influences over the rate of various metabolic reactions and over electrolyte balance. These endocrine glands all secrete hormones in response to specific stimuli. The hormones, in turn, exert effects that act in negative-feedback fashion to resist the change that induced their secretion, thus maintaining stability in the internal environment. The specific contributions of the peripheral endocrine glands to homeostasis include the following:

■ Two closely related hormones secreted by the thyroid gland, tetraiodothyronine (T_4) and tri-iodothyronine (T_3), in-

crease the overall metabolic rate. Not only does this action influence the rate at which cells use nutrient molecules and O_2 within the internal environment, but it also produces heat, which helps maintain body temperature.

■ The adrenal cortex secretes three classes of hormones. Aldosterone, the primary mineralocorticoid, is essential for Na^+ and K^+ balance. Because of Na^+'s osmotic effect, Na^+ balance is critical to maintaining the proper ECF volume and arterial blood pressure. This action is essential for life. Without aldosterone's Na^+- and H_2O-conserving effect, so much plasma volume would be lost in the urine that death would quickly ensue. Maintaining K^+ balance is essential for homeostasis because changes in extracellular K^+ profoundly affect neuromuscular excitability, jeopardizing normal heart function, among other detrimental effects.

■ Cortisol, the primary glucocorticoid secreted by the adrenal cortex, increases the plasma concentrations of glucose, fatty acids, and amino acids above normal. Although these actions destabilize the concentrations of these molecules in the internal environment, they indirectly contribute to homeostasis by making the molecules readily available as energy sources or building blocks for tissue repair to help the body adapt to stressful situations.

■ The sex hormones secreted by the adrenal cortex do not contribute to homeostasis.

■ The major hormone secreted by the adrenal medulla, epinephrine, generally reinforces activities of the sympathetic nervous system. It contributes to homeostasis directly by its role in blood pressure regulation. Epinephrine also contributes to homeostasis indirectly by helping prepare the body for peak physical responsiveness in fight-or-flight situations. This includes increasing the plasma concentrations of glucose and fatty acids above normal, which provides additional energy sources for increased physical activity.

■ The two major hormones secreted by the endocrine pancreas, insulin and glucagon, are important in shifting metabolic pathways between the absorptive and postabsorptive states, which maintains the appropriate plasma levels of nutrient molecules.

■ Parathyroid hormone from the parathyroid glands is critical to maintaining plasma concentration of Ca^{2+}. PTH is essential for life because of Ca^{2+}'s effect on neuromuscular excitability. In the absence of PTH, death rapidly occurs from asphyxiation caused by pronounced spasms of the respiratory muscles.

Review Exercises   Answers begin on p. A-50

Reviewing Terms and Facts

1. The response to thyroid hormone is detectable within a few minutes after its secretion. (*True or false?*)

2. Adrenal androgen hypersecretion is caused by a deficit of an enzyme crucial to cortisol synthesis. (*True or false?*)

3. Excess glucose and amino acids as well as fatty acids can be stored as triglycerides. (*True or false?*)

4. Insulin is the only hormone that can lower blood glucose levels. (*True or false?*)

5. The most life-threatening consequence of hypocalcemia is reduced blood clotting. (*True or false?*)

6. All ingested Ca^{2+} is indiscriminately absorbed in the intestine. (*True or false?*)

7. The $Ca_3(PO_4)_2$ bone crystals form a labile pool from which Ca^{2+} can rapidly be extracted under the influence of PTH. (*True or false?*)

8. The lumen of the thyroid follicle is filled with _____, the chief constituent of which is a large protein molecule known as _____.

9. _____ is the conversion of glucose into glycogen. _____ is the conversion of glycogen into glucose. _____ is the conversion of amino acids into glucose.

10. The three major tissues that do not depend on insulin for their glucose uptake are _____, _____, and _____.

11. The three compartments with which ECF Ca^{2+} is exchanged are _____, _____, and _____.

12. Among the bone cells, _____ are bone builders, _____ are bone dissolvers, and _____ are entombed.

13. Which of the following hormones does *not* exert a direct metabolic effect?
   a. epinephrine
   b. growth hormone
   c. aldosterone
   d. cortisol
   e. thyroid hormone

14. Which of the following are characteristic of the postabsorptive state? (Indicate all that apply.)
   a. glycogenolysis   f. triglyceride synthesis
   b. gluconeogenesis   g. protein degradation
   c. lipolysis   h. increased insulin secretion
   d. glycogenesis   i. increased glucagon secretion
   e. protein synthesis   j. glucose sparing

Understanding Concepts

1. Describe the steps of thyroid hormone synthesis.

2. What are the effects of T_3 and T_4? Which is the more potent? What is the source of most circulating T_3?

3. Describe the regulation of thyroid hormone secretion.

4. Discuss the causes and symptoms of both hypothyroidism and hyperthyroidism. For each cause, indicate whether a goiter occurs, and explain why.

5. What hormones are secreted by the adrenal cortex? What are the functions and control of each of these hormones?

6. Discuss the causes and symptoms of each type of adrenocortical dysfunction.

7. What is the relationship of the adrenal medulla to the sympathetic nervous system? What are the functions of epinephrine? How is epinephrine release controlled?

8. Define *stress*. Describe the neural and hormonal responses to a stressor.

9. Define *fuel metabolism, anabolism,* and *catabolism.*

10. Indicate the primary circulating form and storage form of each of the three classes of organic nutrients.

11. Distinguish between the absorptive and postabsorptive states with regard to the handling of nutrient molecules.

12. Name the two major cell types of the islets of Langerhans, and indicate the primary hormonal product of each.

13. Compare the functions and control of insulin secretion with those of glucagon secretion.

14. What are the consequences of diabetes mellitus?

15. Why must plasma Ca^{2+} be closely regulated?

16. Explain how osteoblasts influence osteoclast function.

17. Discuss the contributions of parathyroid hormone, calcitonin, and vitamin D to Ca^{2+} metabolism. Describe the source and control of each of these hormones.

18. Discuss the major disorders in Ca^{2+} metabolism.

Applying Clinical Reasoning

Najma G. sought medical attention after her menstrual periods ceased and she started growing excessive facial hair. Also, she had been thirstier than usual and urinated more frequently. A clinical evaluation revealed that Najma was hyperglycemic. Her physician told her that she had an endocrine disorder dubbed "diabetes of bearded ladies." What underlying defect do you think is responsible for Najma's condition?

Thinking at a Higher Level

1. Iodine is naturally present in salt water and is abundant in soil along coastal regions. Fish and shellfish living in the ocean and plants grown in coastal soil take up iodine from their environment. Fresh water does not contain iodine, and the soil becomes more iron poor the farther inland it is. Knowing this, explain why the midwestern United States was once known as an endemic goiter belt. Why is this region no longer an endemic goiter belt even though the soil is still iodine poor?

2. Why do doctors recommend that people who are allergic to bee stings and thus at risk for anaphylactic shock (see p. 438) carry a vial of epinephrine for immediate injection in case of a sting?

3. Why would an infection tend to raise the blood glucose level of a diabetic individual?

4. Tapping the facial nerve at the angle of the jaw in a patient with moderate hyposecretion of a particular hormone elicits a characteristic grimace on that side of the face. What endocrine abnormality could give rise to this so-called *Chvostek's sign*?

5. Soon after a technique to measure plasma Ca^{2+} levels was developed in the 1920s, physicians observed that hypercalcemia accompanied a broad range of cancers. Early researchers proposed that malignancy-associated hypercalcemia arose from metastatic (see p. 432) tumor cells that invaded and destroyed bone, releasing Ca^{2+} into the blood. This conceptual framework was overturned when physicians noted that hypercalcemia often appeared in the absence of bone lesions. Furthermore, cancer patients often manifested hypophosphatemia in addition to hypercalcemia. This finding led investigators to suspect that the tumors might be producing a PTHlike substance. Explain how they reached this conclusion. In 1987, this substance was identified and named *parathyroid hormone–related peptide (PTHrP),* which binds to and activates PTH receptors.

The Reproductive System
Dr. Yorgos Nikas/Science Source

CHAPTER AT A GLANCE

A scanning electron micrograph of a human sperm penetrating an egg. This image, taken in a fertility clinic, shows one spermatozoon penetrating an ovum (egg) by means of enzymes at its head end. The enzymes from many sperm are needed to break down the outer barrier before one victorious sperm penetrates into the egg cytoplasm to accomplish fertilization.

Homeostasis Highlights

Normal functioning of the reproductive system is not aimed at homeostasis and is not necessary for survival of an individual, but it is essential for survival of the species. Only through reproduction can the complex genetic blueprint of each species survive beyond the lives of individual members of the species.

20.1 Uniqueness of the Reproductive System

The central theme of this book has been the physiologic processes aimed at maintaining homeostasis to ensure survival of the individual. We are now going to leave this theme to discuss the **reproductive system**, which serves primarily the purpose of perpetuating the species.

Unique among body systems, the reproductive system does not contribute to homeostasis but plays other roles.

Even though the reproductive system does not contribute to homeostasis and is not essential for survival of an individual, it still plays an important role in a person's life. The manner in which people relate as sexual beings contributes in significant ways to psychosocial behavior and has important influences on how people view themselves and how they interact with others. Reproductive function also has a profound effect on society. The universal organization of societies into family units provides a stable environment that is conducive for perpetuating our species.

Reproductive capability depends on intricate relationships among the hypothalamus, anterior pituitary, reproductive organs, and target cells of the sex hormones. These relationships employ many of the regulatory mechanisms used by other body systems for maintaining homeostasis, such as negative-feedback control. In addition to these basic biological processes, sexual behavior and attitudes are deeply influenced by emotional factors and the sociocultural mores of the society in which the individual lives. We concentrate on the basic sexual and reproductive functions under nervous and hormonal control and do not examine the psychological and social ramifications of sexual behavior.

The reproductive system includes the gonads, reproductive tract, and accessory sex glands, all of which differ in males and females.

Reproduction depends on the union of male and female **gametes (reproductive**, or **germ**, **cells)**, each with a half set of chromosomes, to form a new individual with a full, unique set of chromosomes. Unlike other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are markedly different, befitting their different roles in the reproductive process. The **male** and **female reproductive systems** are designed to enable union of genetic material from the two sexual partners, and the female system is equipped to house and nourish the offspring to the developmental point at which it can survive independently in the external environment.

The **primary reproductive organs**, or **gonads**, consist of a pair of **testes** in the male and a pair of **ovaries** in the female. In both sexes, the mature gonads perform the dual function of (1) producing gametes (**gametogenesis**), that is, **spermatozoa (sperm)** in the male and **ova (eggs)** in the female; and

(2) secreting sex hormones, specifically, **testosterone** in males and **estrogen** and **progesterone** in females. (The term *estrogen* refers to a group of closely related compounds, namely *estradiol, estrone,* and *estriol,* of which estradiol is the principal estrogen secreted by the ovaries.)

In addition to the gonads, the reproductive system in each sex includes a **reproductive tract** encompassing a system of ducts specialized to transport or house the gametes after they are produced, plus **accessory sex glands** that empty their supportive secretions into these passageways. In females, the breasts are also considered accessory reproductive organs. The externally visible portions of the reproductive system are known as **external genitalia**.

Secondary Sexual Characteristics The **secondary sexual characteristics** are the many external characteristics not directly involved in reproduction that distinguish males and females, such as body configuration and hair distribution. In humans, for example, males have broader shoulders, whereas females have curvier hips, and males have beards, whereas females do not. Testosterone in the male and estrogen in the female govern the development and maintenance of these characteristics. Progesterone has no influence on secondary sexual characteristics.

In some species, the secondary sexual characteristics are of great importance in courting and mating behavior; for example, the rooster's comb attracts the female's attention, and the stag's antlers are useful to ward off other males. In humans, the differentiating marks between males and females do attract the opposite sex, but attraction is also strongly influenced by the complexities of human society and cultural behavior.

Overview of Male Reproductive Functions and Organs
The essential male reproductive functions are as follows:

1. Production of sperm (*spermatogenesis*)
2. Delivery of sperm to the female

The sperm-producing organs, the testes, are suspended outside the abdominal cavity in a skin-covered sac, the **scrotum**, which lies within the angle between the legs. The male reproductive system is designed to deliver sperm to the female reproductive tract in a liquid vehicle, *semen,* which is conducive to sperm viability. The major **male accessory sex glands**, whose secretions provide the bulk of the semen, are the *seminal vesicles, prostate gland,* and *bulbourethral glands* (❙ Figure 20-1). The **penis** is the organ used to deposit semen in the female. The **glans penis** (the cap at the distal end of the penis) is exquisitely sensitive erotic tissue important in sexual arousal. Sperm exit each testis through the **male reproductive tract**, consisting on each side of an *epididymis, ductus (vas) deferens,* and *ejaculatory duct.* These pairs of reproductive tubes, along with the secretions from the accessory sex glands, empty into a single *urethra,* the canal that runs the length of the penis and empties to the exterior. All of these parts are described more thoroughly when their functions are discussed.

than the male's. The essential female reproductive functions include the following:

1. Production of ova (*oogenesis*)

2. Reception of sperm

3. Transport of the sperm and ovum to a common site for union (*fertilization,* or *conception*)

4. Maintenance of the developing fetus until it can survive in the outside world (*gestation,* or *pregnancy*), including formation of the *placenta,* the organ of exchange between mother and fetus

5. Giving birth to the baby (*parturition*)

6. Nourishing the infant after birth by milk production (*lactation*)

The product of fertilization is known as an **embryo** during the first 2 months of intrauterine development, when tissue differentiation is taking place. Beyond this time, the developing living being is recognizable as human and is known as a **fetus** during the remainder of gestation. Although no further tissue differentiation takes place during fetal life, it is a time of tremendous tissue growth and maturation.

The ovaries and female reproductive tract lie within the pelvic cavity. The female reproductive tract consists of the fol-

The Reproductive System

lowing components (❙Figure 20-2a and b): Two **oviducts (uterine**, or **fallopian tubes)**, which are in close association with the two ovaries, pick up ova on ovulation (ovum release from an ovary) and serve as the site for fertilization. The thick-walled, hollow **uterus** is primarily responsible for maintaining the fetus during its development and expelling it at the end of pregnancy. The **vagina** is a muscular, expandable tube that connects the uterus to the external environment. The lowest portion of the uterus, the **cervix**, projects into the vagina and contains a single, small opening, the **cervical canal**. Sperm are deposited in the vagina by the penis during sexual intercourse. The cervical canal is a pathway for sperm through the uterus to the site of fertilization in the oviduct and, when greatly dilated during parturition, is the passageway for delivery of the baby from the uterus.

The vaginal opening is located in the **perineum** (the external region that bounds the pelvic outlet) between the urethral opening anteriorly and the anal opening posteriorly (❙Figure 20-2c). It is partially covered by a thin mucous membrane, the **hymen**, which typically is physically disrupted by the first sexual intercourse. The vaginal and urethral openings are surrounded laterally by two pairs of skin folds, the **labia minora** and **labia majora**. The smaller labia minora are located medially to the more prominent labia majora. The **clitoris** in females is derived from the same embryonic tissue as is the penis in males. Most of the clitoris is located internally, except for the externally visible **glans clitoris**, an erotic structure composed of tissue similar to that of the glans penis (❙Figure 20-2d). The glans clitoris is roughly the size and shape of a pea and lies at the anterior end of the folds of the labia minora (❙Figure 20-2c). The female external genitalia are collectively referred to as the **vulva**.

Reproductive cells each contain a half set of chromosomes.

The deoxyribonucleic acid (DNA) molecules that carry the cell's genetic code are not randomly crammed into the nucleus but, along with associated nuclear proteins, are precisely organized into **chromosomes**. Each chromosome consists of a different DNA molecule that contains a unique set of genes. Somatic (body) cells contain 46 chromosomes (the **diploid number**), which can be sorted into 23 pairs on the basis of various distinguishing features. Chromosomes composing a matched pair are termed **homologous chromosomes**, one member of each pair having been derived from the individual's mother and the other member from the father. Gametes (that is, sperm and eggs) contain only one member of each homologous pair for a total of 23 chromosomes (the **haploid number**).

Gametogenesis is accomplished by meiosis, resulting in genetically unique sperm and ova.

Most cells in the human body have the ability to reproduce themselves, a process important in growth, replacement, and repair of tissues. Cell division involves two components: division of the nucleus and division of the cytoplasm. Nuclear division in somatic cells is accomplished by **mitosis**. In mitosis, the chromosomes replicate (make duplicate copies of themselves); then, the identical chromosomes are separated so that a complete set of genetic information (that is, a diploid number of chromosomes) is distributed to each of the two new daughter cells. Nuclear division in the specialized case of gametes is accomplished by **meiosis**, in which only a half set of genetic information (that is, a haploid number of chromosomes) is distributed to each of four new daughter cells.

During meiosis, a specialized diploid germ cell undergoes one chromosome replication followed by two nuclear divisions. In the first meiotic division, the replicated chromosomes do not separate into two individual, identical chromosomes but remain joined. The doubled chromosomes sort themselves into homologous pairs, and the pairs separate so that each of two daughter cells receives a half set of doubled chromosomes. During the second meiotic division, the doubled chromosomes within each of the two daughter cells separate and are distributed into two cells, yielding four daughter cells, each containing a half set of chromosomes, a single member of each pair. During this process, the maternally and paternally derived chromosomes of each homologous pair are distributed to the daughter cells in random assortments containing one member of each chromosome pair without regard for its original derivation. That is, not all of the mother-derived chromosomes go to one daughter cell and the father-derived chromosomes to the other cell. More than 8 million (2^{23}) mixtures of the 23 paternal and maternal chromosomes are possible. This genetic mixing provides novel combinations of chromosomes. Crossing-over contributes even further to genetic diversity. *Crossing-over* refers to the physical exchange of chromosome material between the homologous pairs before their separation during the first meiotic division.

Thus, sperm and ova each have a unique haploid number of chromosomes. During fertilization, a sperm and ovum fuse to form the start of a new individual with 46 chromosomes, one member of each chromosomal pair having been inherited from the mother and the other member from the father.

The sex of an individual is determined by the combination of sex chromosomes.

Whether individuals are destined to be males or females is a genetic phenomenon determined by the sex chromosomes they possess. As the 23 chromosome pairs are separated during meiosis, each sperm or ovum receives only one member of each chromosome pair. Of the chromosome pairs, 22 are **autosomal chromosomes** that code for general human characteristics and for specific traits such as eye color. The remaining pair of chromosomes consists of the **sex chromosomes**, of which there are two genetically different types—a larger **X chromosome** and a smaller **Y chromosome** (❙Figure 20-3).

Sex determination depends on the combination of sex chromosomes: **Genetic males** have both an X and a Y sex chromosome; **genetic females** have two X sex chromosomes. Thus, the genetic difference responsible for all the anatomic and functional distinctions between males and females is the single Y chromosome. Males have it; females do not.

As a result of meiosis during gametogenesis, all chromosome pairs are separated so that each daughter cell contains

only one member of each pair, including the sex chromosome pair. When the XY sex chromosome pair separates during sperm formation, half the sperm receive an X chromosome and the other half a Y chromosome. In contrast, during oogenesis, every ovum receives an X chromosome because separation of the XX sex chromosome pair yields only X chromosomes. During fertilization, combination of an X-bearing sperm with an X-bearing ovum produces a genetic female, XX, whereas union of a Y-bearing sperm with an X-bearing ovum results in a genetic male, XY. Thus, genetic sex is determined at the time of conception and depends on which type of sex chromosome is contained within the fertilizing sperm.

Sexual differentiation along male or female lines depends on the presence or absence of masculinizing determinants.

Differences between males and females exist at three sex levels: genetic, gonadal, and phenotypic (anatomic) (❚Figure 20-3).

Genetic and Gonadal Sex **Genetic sex**, which depends on the combination of sex chromosomes at the time of conception, in turn determines **gonadal sex**, that is, whether testes or ovaries develop. The presence or absence of a Y chromosome determines gonadal differentiation. For the first month and a half of gestation, all embryos have the potential to differentiate along either male or female lines because the developing reproductive tissues of both sexes are identical and indifferent. Gonadal specificity appears during the seventh week of intrauterine life when the **gonadal ridge** (undifferentiated gonadal tissue present in both males and females) of a genetic male begins to differentiate into testes under the influence of the **sex-determining region** of the Y chromosome **(SRY)**, the gene solely responsible for sex determination. This gene triggers a chain of reactions that leads to physical development of a male. SRY "masculinizes" the gonads by coding for production of **testis-determining factor (TDF)** (also known as **SRY protein**) within primitive gonadal cells. TDF directs a series of events that leads to differentiation of the gonads into testes.

Because genetic females lack the SRY gene and consequently do not produce TDF, their gonadal cells never receive a signal for testes formation, so by default during the ninth week the undifferentiated gonadal tissue starts developing into ovaries instead, guided by female-specific gene products whose action is blocked by TDF in male embryos.

Phenotypic Sex **Phenotypic sex**, the apparent anatomic sex of an individual, is hormonally mediated and depends on the genetically determined gonadal sex. The term **sexual differentiation** refers to the embryonic development of the external genitalia and reproductive tract along either male or female lines. As with the undifferentiated gonads, embryos of both sexes have the potential to develop male or female external genitalia and reproductive tracts. Differentiation into a male-type reproductive system is induced by **androgens**, which are masculinizing hormones secreted by the developing testes. The absence of these testicular hormones in female fetuses results in the development of a female-type reproductive system. By 10 to 12 weeks of gestation, the sexes can easily be distinguished by the anatomic appearance of the external genitalia.

Sexual Differentiation of the External Genitalia Male and female external genitalia develop from the same embryonic tissue. In both sexes, the undifferentiated external genitals consist of a *genital tubercle;* paired *urethral folds* surrounding a urethral groove; and, more laterally, *genital (labioscrotal) swellings* (❚Figure 20-4). The **genital tubercle** gives rise in males to the penis and in females to the clitoris (see ❚Figures 20-1a and 20-2d). In males, the **urethral folds** fuse around the urethral groove to form the cord of erectile tissue that encircles the urethra within the penis (see ❚Figure 20-1c). The **genital swellings** similarly fuse to form the scrotum; the skin that covers the penis; and the **prepuce**, a fold of skin that extends over the end of the penis and more or less completely covers the glans penis (unless this extra skin is cut off during **circumcision**). In females, the urethral folds and genital swellings do not fuse at midline but develop instead into the labia minora and labia majora, respectively. The urethral groove remains open, providing access to the interior through both the urethral opening and the vaginal opening.

Sexual Differentiation of the Reproductive Tract Although the male and female external genitalia develop from the same multipotential undifferentiated embryonic tissue, this is not the case with the reproductive tracts. Two primitive duct systems—the Wolffian ducts and the Müllerian ducts—develop in all embryos. In males, the reproductive tract develops from the **Wolffian ducts** and the Müllerian ducts degenerate, whereas in females the **Müllerian ducts** differentiate into the reproductive tract and the Wolffian ducts regress (❚Figure 20-5). Because both duct systems are present before sexual differentiation occurs, the early embryo has the potential to develop either a male or a female reproductive tract.

Development of the reproductive tract along male or female lines is determined by the presence or absence of two hormones secreted by two different cell types in the fetal testes—*testosterone* produced by the newly developed Leydig cells and **Müllerian-inhibiting factor** (also known as **anti-Müllerian hormone**), produced by the early Sertoli cells (see ❚Figure 20-3). (You will learn shortly about the location and functions of Leydig and Sertoli cells in the adult testes.) A hormone released by the placenta, *human chorionic gonadotropin,* is the stimulus for this early testicular secretion. A portion of testosterone secreted by the testes is converted peripherally by the enzyme **5α-reductase** into **dihydrotestosterone (DHT)**, a closely related, potent androgen. Testosterone induces development of the Wolffian ducts into the male reproductive tract (epididymis, ductus deferens, ejaculatory duct, and seminal vesicles), whereas its derivative DHT promotes differentiation of the external genitalia into the penis and scrotum. Meanwhile, Müllerian-inhibiting factor causes regression of the Müllerian ducts. The other two male accessory reproductive organs, the prostate gland and the bulbourethral glands, arise from the **urogenital sinus**, an embryonic structure from which the urinary bladder and urethra are also derived.

In the absence of testosterone and Müllerian-inhibiting factor in females, the Wolffian ducts regress, the Müllerian ducts

develop into the female reproductive tract (oviducts, uterus, cervix, and upper vagina), and the external genitalia differentiate into the clitoris and labia. The lower vagina is derived from the urogenital sinus, as is the urinary bladder and urethra.

Note that the undifferentiated embryonic reproductive tissue develops into a female structure unless actively acted on by masculinizing factors that inhibit female development. In the absence of male testicular hormones, a female reproductive tract and external genitalia develop regardless of the genetic sex of the individual. For feminization of the fetal genital tissue, ovaries do not even need to be present. Such a control pattern for determining sexual differentiation is appropriate, considering that fetuses of both sexes are exposed to high concentrations of female sex hormones throughout gestation. If female sex hormones influenced the development of the reproductive tract and external genitalia, all fetuses would be feminized.

Clinical Note **Errors in Sexual Differentiation** Genetic sex and phenotypic sex are usually compatible—that is, a genetic male anatomically appears to be a male and functions as a male, and the same compatibility holds true for females. Occasionally, however, discrepancies occur between genetic and anatomic sexes because of errors in sexual differentiation, as the following examples illustrate:

■ If testes in a genetic male fail to properly differentiate and secrete hormones, the result is the development of an apparent anatomic female, who will be sterile, in a genetic male. Similarly, genetic males whose target cells lack receptors for testosterone are feminized, even though their testes secrete adequate testosterone (see p. 643, *testicular feminization syndrome*, also known as *androgen insensitivity syndrome*).

■ Because testosterone acts on the Wolffian ducts to convert them into a male reproductive tract but the testosterone deriv-

ative DHT is responsible for masculinization of the external genitalia, a genetic deficiency of the enzyme that converts testosterone into DHT results in a genetic male with testes and a male reproductive tract but with female external genitalia.

- The adrenal gland normally secretes a weak androgen, *dehydroepiandrosterone (DHEA)*, in insufficient quantities to masculinize females. However, pathologically excessive secretion of this hormone in a genetically female fetus during critical developmental stages imposes differentiation of the reproductive tract and genitalia along male lines (see p. 677, *adrenogenital syndrome*).

Sometimes these discrepancies between genetic sex and apparent anatomic sex are not recognized until puberty, when the discovery produces a psychologically traumatic gender identity crisis. For example, a masculinized genetic female with ovaries but with male-type external genitalia may be reared as a boy until puberty, when breast enlargement (caused by estrogen secretion by the awakening ovaries) and lack of beard growth (caused by lack of testosterone secretion in the absence of tes-

tes) signal an apparent problem. Therefore, it is important to diagnose any problems in sexual differentiation in infancy. Once a sex has been assigned, it can be reinforced, if necessary, with surgical and hormonal treatment so that psychosexual development can proceed as normally as possible. Less dramatic cases of inappropriate sexual differentiation often appear as sterility problems.

Check Your Understanding 20.1

1. Name the primary reproductive organs in males and in females and state the dual function of these organs in each sex.

2. Define *genetic, gonadal,* and *phenotypic sex* and discuss what factors drive the development of each of these sex levels along either male or female lines.

3. Prepare a table comparing what reproductive structures are derived during embryonic development from the gonadal ridge, genital tubercle, urethral folds, genital swellings, Wolffian ducts, Müllerian ducts, and urogenital sinus in males and in females.

(a) **Undifferentiated reproductive system**

(b) **Wolffian ducts differentiate into male reproductive tract** (shown before descent of testes into scrotum)

(c) **Müllerian ducts differentiate into female reproductive tract**

❙Figure 20-5 **Sexual differentiation of the reproductive tract**.

20.2 Male Reproductive Physiology

In the embryo, the testes develop from the gonadal ridge located in the rear of the abdominal cavity. Late in fetal life, they begin a slow descent, passing out of the abdominal cavity through the **inguinal canal** into the scrotum, one testis dropping into each pocket of the scrotal sac. Testosterone from the fetal testes induces descent of the testes into the scrotum.

After the testes descend into the scrotum, the opening in the abdominal wall through which the inguinal canal passes closes snugly around the sperm-carrying duct and blood vessels that traverse between each testis and the abdominal cavity. Incomplete closure or rupture of this opening permits abdominal viscera to slip through, resulting in an **inguinal hernia**.

Although the time varies somewhat, descent is usually complete by the seventh month of gestation. As a result, descent is complete in 98% of full-term baby boys.

Clinical Note However, in a substantial percentage of premature male infants the testes are still within the inguinal canal at birth. In most instances of retained testes, descent occurs naturally before puberty or can be encouraged with administration of testosterone. Rarely, a testis remains undescended into adulthood, a condition known as **cryptorchidism** (*crypt* means "hidden"; *orchid* means "testis").

The scrotal location of the testes provides a cooler environment for spermatogenesis.

The temperature within the scrotum averages several degrees Celsius less than normal body (core) temperature. Descent of the testes into

(d) Relationship of the Sertoli cells to the developing sperm cells.

this cooler environment is essential because spermatogenesis is temperature sensitive and cannot occur at normal body temperature. Therefore, a cryptorchid is unable to produce viable sperm.

The position of the scrotum in relation to the abdominal cavity can be varied by a spinal reflex mechanism that plays an important role in regulating testicular temperature. Reflex contraction of scrotal muscles on exposure to a cold environment raises the scrotal sac to bring the testes closer to the warmer abdomen. Conversely, relaxation of the muscles on exposure to heat permits the scrotal sac to become more pendulous, moving the testes farther from the warm core of the body.

The testicular Leydig cells secrete masculinizing testosterone.

The testes perform the dual function of producing sperm and secreting testosterone. About 80% of the testicular mass consists of highly coiled **seminiferous tubules**, within which spermatogenesis takes place (❙Figure 20-6a). The endocrine cells that produce testosterone—the **Leydig**, or **interstitial**, **cells**—lie in the connective tissue (interstitial tissue) between the seminiferous tubules (❙Figure 20-6b). Thus, the portions of the testes that produce sperm and secrete testosterone are structurally and functionally distinct.

Testosterone is a steroid hormone derived from a cholesterol precursor molecule, as are the female sex hormones, estrogen and progesterone (see ❙Figure 19-8, p. 673). Once produced, some of the testosterone is secreted into the blood, where it is transported to its target sites of action. A substantial portion of the newly synthesized testosterone goes into the lumen of the seminiferous tubules, where it plays an important role in sperm production.

To exert its effects, testosterone binds with androgen receptors in the cytoplasm of target cells. The androgen-receptor complex moves to the nucleus, where it binds with the androgen response element on DNA, leading to transcription of genes that direct synthesis of new proteins that carry out the desired cellular response.

Most of testosterone's actions ultimately function to ensure delivery of sperm to the female. The effects of testosterone can be grouped into five categories: (1) effects on the reproductive system before birth, (2) effects on sex-specific tissues after birth, (3) other reproduction-related effects, (4) effects on secondary sexual characteristics, and (5) nonreproductive actions (❙Table 20-1).

Effects on the Reproductive System Before Birth
Before birth, testosterone secretion by the Leydig cells of the fetal testes masculinizes the reproductive tract and external genitalia and promotes descent of the testes into the scrotum, as already described. After birth, testosterone secretion ceases, and the testes and remainder of the reproductive system remain small and nonfunctional until puberty.

Effects on Sex-Specific Tissues After Birth
Puberty is the period of arousal and maturation of the previously nonfunctional reproductive system, culminating in sexual maturity and the ability to reproduce. It usually begins some time between the ages of 10 and 14 in males (on average, earlier, between the ages of 9 and 13, in females). Usually lasting three to five years, puberty encompasses a complex sequence of endocrine, physical, and behavioral events. **Adolescence** is a broader concept that refers to the entire transition period between childhood and adulthood, not just to sexual maturation. In both sexes, the reproductive changes that take place during puberty are (1) enlargement and maturation of gonads, (2) development of secondary sexual characteristics, (3) achievement of fertility (gamete production), (4) growth and maturation of the reproductive tract, and (5) attainment of libido (sex drive). The pubertal growth spurt also occurs.

❙TABLE 20-1 Effects of Testosterone

Effects before Birth

Masculinizes the reproductive tract and external genitalia

Promotes descent of the testes into the scrotum

Effects on Sex-Specific Tissues after Birth

Promotes growth and maturation of the reproductive system at puberty

Is essential for spermatogenesis

Maintains the reproductive tract throughout adulthood

Other Reproduction-Related Effects

Develops the sex drive at puberty

Controls gonadotropin hormone secretion

Effects on Secondary Sexual Characteristics

Induces the male pattern of hair growth (e.g., beard)

Causes the voice to deepen because vocal folds thicken

Promotes muscle growth responsible for the male body configuration

Nonreproductive Actions

Exerts a protein anabolic effect

Promotes bone growth at puberty

Closes the epiphyseal plates after being converted to estrogen by aromatase

May induce aggressive behavior

At puberty in males, the Leydig cells start secreting testosterone once again. Testosterone is responsible for growth and maturation of the entire male reproductive system. Under the influence of the pubertal surge in testosterone secretion, the testes enlarge and start producing sperm for the first time, the accessory sex glands enlarge and become secretory, and the penis and scrotum enlarge.

Ongoing testosterone secretion is essential for spermatogenesis and for maintaining a mature male reproductive tract throughout adulthood. Once initiated at puberty, testosterone secretion and spermatogenesis occur continuously throughout the male's life, although testicular efficiency gradually declines after 45 to 50 years of age. However, men in their 70s and beyond may continue to enjoy an active sex life, and some even father a child at this late age. The gradual reduction in circulating testosterone levels and in sperm production is not caused by a decrease in stimulation of the testes but arises instead from degenerative changes associated with aging that occur in small testicular blood vessels. This age-related gradual decline is sometimes mistakenly termed "male menopause" or "andropause," but it is not comparable to female menopause, which is preprogrammed and results in complete, abrupt cessation of reproductive capability. The androgen decline in males is more aptly termed **androgen deficiency in aging males (ADAM)**.

Following **castration** (surgical removal of the testes) or testicular failure caused by disease, the other sex organs regress in size and function.

Other Reproduction-Related Effects Testosterone governs development of sexual libido at puberty and helps maintain the sex drive in the adult male. Stimulation of this behavior by testosterone is important for facilitating delivery of sperm to females. In humans, libido is also influenced by many interacting social and emotional factors.

In another reproduction-related function, testosterone participates in the normal negative-feedback control of gonadotropin hormone secretion by the anterior pituitary, a topic covered more thoroughly later.

Effects on Secondary Sexual Characteristics All male secondary sexual characteristics depend on testosterone for their development and maintenance. These nonreproductive male characteristics induced by testosterone include (1) the male pattern of hair growth (for example, beard and chest hair and, in genetically predisposed men, baldness); (2) a deep voice caused by enlargement of the larynx and thickening of the vocal folds; (3) thick skin; and (4) the male body configuration (for example, broad shoulders and heavy arm and leg musculature) as a result of protein deposition. A male castrated before puberty (a **eunuch**) does not mature sexually, nor does he develop secondary sexual characteristics.

Nonreproductive Actions Testosterone exerts several important effects not related to reproduction. It has a general protein anabolic (synthesis) effect, thus contributing to the more muscular physique of males. It also plays a role in the pubertal growth spurt. Ironically, testosterone not only stimulates bone growth, but also eventually prevents further growth by sealing the growing ends of the long bones (that is, ossifying, or "closing," the epiphyseal plates; see p. 656).

In animals, testosterone induces aggressive behavior, but its influence on human behavior other than in the area of sexual behavior is unresolved. Even though some athletes and bodybuilders who (illegally) take testosteronelike anabolic androgenic steroids to increase muscle mass display more aggressive behavior (see p. 277), to what extent general behavioral differences between the sexes are hormonally induced or result from social conditioning is unclear.

Conversion of Testosterone to Estrogen in Males Although testosterone is classically considered the male sex hormone and estrogen a female sex hormone, the distinctions are not as clear-cut as once thought. In addition to the minuscule amount of estrogen produced by the adrenal cortex (see p. 676), a small portion of testosterone secreted by the testes is converted to estrogen outside the testes by the enzyme **aromatase**, which is widely distributed but most abundant in adipose tissue. (Remember that part of the secreted testosterone is also converted to dihydrotestosterone. Unlike testosterone, DHT cannot be converted to estrogen.) It is sometimes difficult to distinguish effects of testosterone and those of testosterone-turned-estrogen. For example, closure of the epiphyseal plates in males is induced not by testosterone per se but by testosterone turned into estrogen by aromatization. Estrogen receptors have been identified in the testes, prostate, bone, and elsewhere in males. Estrogen even plays an essential role in male reproductive health; for example, it is important in spermatogenesis and, surprisingly, contributes to male heterosexuality. The depth, breadth, and mechanisms of action of estrogen in males are only beginning to be explored. (Likewise, in addition to the weak androgenic hormone DHEA produced by the adrenal cortex in both sexes, the ovaries in females secrete a small amount of testosterone, the functions of which remain unclear.)

We now shift attention from testosterone secretion to the other function of the testes—sperm production.

Spermatogenesis yields an abundance of highly specialized, mobile sperm.

About 250 m (800 ft) of sperm-producing seminiferous tubules are packed within the testes (❙Figure 20-6a, b, and c). Two functionally important cell types are present in these tubules: *germ cells,* most of which are in various stages of sperm development, and *Sertoli cells,* which provide crucial support for spermatogenesis (❙Figure 20-6b and d). **Spermatogenesis** is a complex process by which relatively undifferentiated primordial (primitive or initial) germ cells, the **spermatogonia** (each of which contains a diploid complement of 46 chromosomes), proliferate and are converted into extremely specialized, motile spermatozoa (sperm), each bearing a randomly distributed haploid set of 23 chromosomes.

Microscopic examination of a seminiferous tubule reveals layers of germ cells in a progression of sperm development, starting with the least differentiated in the outer layer and moving inward through various stages of division to the lumen, where the highly differentiated sperm are ready for exit from the testis (❙Figure 20-6b, c, and d). Spermatogenesis takes 64 days for development from a spermatogonium to a mature sperm. At any given time, different seminiferous tubules are in different stages of spermatogenesis. Up to several hundred million sperm may reach maturity daily. Spermatogenesis encompasses three major stages: *mitotic proliferation, meiosis,* and *packaging* (❙Figure 20-7).

Mitotic Proliferation Spermatogonia located in the outermost layer of the tubule continuously divide mitotically, with all new cells bearing the full complement of 46 chromosomes identical to those of the parent cell. Such proliferation provides a continual supply of new germ cells. Following mitotic division of a spermatogonium, one of the daughter cells remains at the outer edge of the tubule as an undifferentiated spermatogonium, thus maintaining the germ-cell line. The other daughter cell starts moving toward the lumen while undergoing the various steps required to form sperm, which will be released into the lumen. In humans, the sperm-forming daughter cell divides mitotically twice more to form four identical **primary spermatocytes**. After the last mitotic division, the primary spermatocytes enter a resting phase during which the chromosomes are duplicated and the doubled strands remain together in preparation for the first meiotic division.

Stages of spermatogenesis

Chromosomes in each cell

Spermatogonium	46 (diploid number; single strands)
Mitosis	

1 Mitotic proliferation

Spermatogonia — One daughter cell remains at the outer edge of the seminiferous tubule to maintain the germ cell line — One daughter cell moves toward the lumen to produce spermatozoa — 46 (diploid number; single strands)

Mitosis

Mitosis

Primary spermatocytes — 46 (diploid number; doubled strands)

First meiotic division

2 Meiosis

Secondary spermatocytes — 23 (haploid number; doubled strands)

Second meiotic division

Spermatids — 23 (haploid number; single strands)

3 Packaging (spermiogenesis)

Spermatozoa — 23 (haploid number; single strands)

IFigure 20-7 **Spermatogenesis.**
FIGURE FOCUS: *(1) How many spermatozoa are produced from a single spermatogonium? (2) Compare the chromosome composition in these two stages of gamete development.*

Meiosis During meiosis, each primary spermatocyte (with a diploid number of 46 doubled chromosomes) forms two **secondary spermatocytes** (each with a haploid number of 23 doubled chromosomes) during the first meiotic division, finally yielding four **spermatids** (each with 23 single chromosomes) as a result of the second meiotic division.

No further division takes place beyond this stage of spermatogenesis. Each spermatid is remodeled into a single spermatozoon. Because each sperm-producing spermatogonium mitotically produces four primary spermatocytes and each primary spermatocyte meiotically yields four spermatids (spermatozoa-to-be), the spermatogenic sequence in humans can theoretically produce 16 spermatozoa each time a spermatogonium initiates this process. Usually, however, some cells are lost at various stages, so the efficiency of productivity is rarely this high.

Packaging Even after meiosis, spermatids still resemble undifferentiated spermatogonia structurally, except for their half complement of chromosomes. Production of extremely specialized, mobile spermatozoa from spermatids requires extensive remodeling, or **packaging**, of cell elements, a process alternatively known as **spermiogenesis**. Sperm are essentially "stripped-down" cells in which most of the cytosol and any organelles not needed for delivering the sperm's genetic information to an ovum have been extruded. Thus, sperm travel lightly, taking with them only the bare essentials to accomplish fertilization.

(a) Scanning electron micrograph of human spermatozoa
(b) Parts of spermatozoon

❙ Figure 20-8 Anatomy of a spermatozoon. A spermatozoon has three functional parts: a head with its acrosome "cap," a midpiece, and a tail.

A **spermatozoon** has three parts (❙ Figure 20-8): a head capped with an acrosome, a midpiece, and a tail. The **head** consists primarily of the nucleus, which contains the sperm's complement of genetic information. The **acrosome**, an enzyme-filled vesicle that caps the tip of the head, is used as an "enzymatic drill" for penetrating the ovum. The acrosome, a modified lysosome (see p. 30), is formed by aggregation of vesicles produced by the endoplasmic reticulum–Golgi complex before these organelles are discarded. The acrosomal enzymes remain inactive until the sperm contacts an egg, at which time the enzymes are released. Mobility for the spermatozoon is provided by a long, whiplike **tail** (a flagellum; see p. 48), movement of which is powered by energy generated by the mitochondria concentrated within the **midpiece** of the sperm.

Until sperm maturation is complete, the developing germ cells arising from a single primary spermatocyte remain joined by cytoplasmic bridges. These connections, which result from incomplete cytoplasmic division, permit the four developing sperm to exchange cytoplasm. This linkage is important because the X chromosome, but not the Y chromosome, contains genes that code for cell products essential for sperm development. (Whereas the large X chromosome contains several thousand genes, the small Y chromosome has only a few dozen, the most important of which are the SRY gene and others that play critical roles in male fertility.) During meiosis, half the sperm receive an X and the other half a Y chromosome. Were it not for the sharing of cytoplasm so that all the haploid cells are provided with the products coded for by X chromosomes until sperm development is complete, the Y-bearing, male-producing sperm could not develop and survive.

Throughout their development, sperm remain intimately associated with Sertoli cells.

The seminiferous tubules house **Sertoli cells** in addition to the developing sperm cells. Sertoli cells, which are epithelial cells, lie side by side and form a ring around the tubule lumen, with each Sertoli cell spanning the entire distance from the outer surface of the seminiferous tubule to the fluid-filled lumen (see ❙ Figure 20-6b and d). Adjacent Sertoli cells are joined by tight junctions at a point slightly beneath the outer membrane (see p. 61). Developing sperm cells are tucked between adjacent Sertoli cells, with spermatogonia lying at the outer perimeter of the tubule, outside the tight junction (see ❙ Figure 20-6b and d). During spermatogenesis, developing sperm cells arising from spermatogonial mitotic activity pass through the tight junctions, which transiently separate to make a path for them, then migrate toward the lumen in close association with the adjacent Sertoli cells, undergoing their further divisions during this migration. The lateral edges of the Sertoli cells envelop the migrating sperm cells, which remain buried within these cavelike recesses throughout their development. Sertoli cells form tight junctions and gap junctions with the developing sperm cells. Unlike gap junctions in excitable tissues that permit passage of charge-carrying ions, gap junctions in the seminiferous tubules serve a role other than transfer of electrical activity. At all stages of spermatogenic maturation, the developing sperm and Sertoli cells exchange small molecules and communicate with one another by means of this direct cell-to-cell binding. Final release of a mature spermatozoa from the Sertoli cell, a process called **spermiation**, requires breakdown of the tight junctions and gap junctions between the Sertoli cell and spermatozoa.

Sertoli cells perform the following functions essential for spermatogenesis:

1. The tight junctions between adjacent Sertoli cells form a **blood–testes barrier** that prevents blood-borne substances from passing between the cells to gain entry to the lumen of the seminiferous tubule. Because of this barrier, only selected molecules that can pass through Sertoli cells reach the intratubular fluid. As a result, the composition of the intratubular fluid varies considerably from that of the blood. The unique composition of this fluid that bathes the germ cells is critical for later stages of sperm development. The blood–testes barrier also prevents the antibody-producing cells in the ECF from reaching the tubular sperm factory, thus preventing the formation of antibodies against the highly differentiated spermatozoa.

2. Because the secluded developing sperm cells do not have direct access to blood-borne nutrients, the "nurse" Sertoli cells provide nourishment for them. Developing sperm cells cannot efficiently use glucose. Sertoli cells take up glucose, metabolize the glucose to lactate, then transfer the lactate to the sperm cells, which can use lactate as an energy source.

3. Sertoli cells have an important phagocytic function: They engulf the cytoplasm extruded from spermatids during their
Figure 20-9 Control of testicular function.

FIGURE FOCUS: *(1) What is LH's effect on the testes? (2) By what means is LH secretion inhibited? (3) What is FSH's effect on the testes? (4) By what means is FSH secretion inhibited?*

remodeling, and they destroy defective germ cells that fail to successfully complete all stages of spermatogenesis.

4. Sertoli cells secrete into the lumen **seminiferous tubule fluid**, which "flushes" the released sperm from the tubule into the epididymis for storage and further processing.

5. An important component of this Sertoli secretion is **androgen-binding protein**. As the name implies, this protein binds androgens (predominantly testosterone), thus maintaining a very high level of this hormone within the seminiferous tubule lumen. Testosterone is 100 times more concentrated in

the seminiferous tubule fluid than in the blood. This high local concentration of testosterone is essential for sustaining sperm production. Androgen-binding protein is necessary to retain testosterone within the lumen because this steroid hormone is lipid soluble and could easily diffuse across the plasma membranes and leave the lumen. Testosterone itself stimulates production of androgen-binding protein.

6. Sertoli cells are the site of action for control of spermatogenesis by both testosterone and follicle-stimulating hormone (FSH). Sertoli cells have distinct receptors for each of these hormones: The receptors for testosterone are intracellular and the FSH receptors are on the membrane surface, as is characteristic of receptors for steroid and peptide hormones, respectively. Sertoli cells themselves release another hormone, *inhibin,* which acts in negative-feedback fashion to regulate FSH secretion.

7. During fetal development, Sertoli cells also secrete Müllerian-inhibiting factor.

LH and FSH from the anterior pituitary control testosterone secretion and spermatogenesis.

The testes are controlled by the two gonadotropic hormones secreted by the anterior pituitary, *luteinizing hormone (LH)* and *FSH*, both of which are produced by the same cell type, the gonadotrope (see p. 648). Both hormones in both sexes act on the gonads by activating cAMP.

Feedback Control of Testicular Function LH and FSH, which are named for their functions in females, act on separate components of the testes (❚ Figure 20-9). LH acts on Leydig cells to regulate testosterone secretion. FSH acts on Sertoli cells to enhance spermatogenesis. Secretion of both LH and FSH from the anterior pituitary is stimulated in turn by a single hypothalamic hormone, *gonadotropin-releasing hormone (GnRH)* (see p. 650). GnRH is released in bursts once every two to three hours, with no secretion occurring in between. The blood concentration of GnRH depends on the frequency of these bursts in secretion. This pulsatile secretion of GnRH stimulates ongoing LH and FSH secretion. However, LH and FSH are segregated to a large extent into separate secretory vesicles in the gonadotrope and are not secreted in equal amounts because other regulatory factors influence how much of each gonadotropin is secreted.

Two factors—*testosterone* and *inhibin*—differentially influence the secretory rate of LH and FSH. Testosterone, the product of LH stimulation of Leydig cells, acts in negative-feedback fashion to inhibit LH secretion in two ways. The predominant negative-feedback effect of testosterone is to decrease GnRH release by acting on the hypothalamus, thus indirectly decreasing both LH and FSH release by the anterior pituitary. In addition, testosterone acts directly on the anterior pituitary to selectively reduce LH secretion. The latter action explains why testosterone exerts a greater inhibitory effect on LH secretion than on FSH secretion.

The testicular inhibitory signal specifically directed at controlling FSH secretion is the peptide hormone **inhibin**, which is secreted by the Sertoli cells in response to FSH. Inhibin acts directly on the anterior pituitary to selectively inhibit FSH secretion. This feedback inhibition of FSH by a Sertoli cell product is appropriate because FSH stimulates spermatogenesis by acting on Sertoli cells.

Recent studies indicate that control of testicular function begins farther upstream than GnRH. **Kiss1 neurons** in the **arcuate (ARC) nucleus** of the hypothalamus (the same region involved in control of food intake and body weight; see p. 621) release **kisspeptins**, which are peptide neurotransmitters that stimulate GnRH secretion. (The researchers used the name "kiss" after the location where they made their discovery—Hershey, Pennsylvania, famous for chocolate Hershey Kisses.) GnRH-secreting neurons are also located in the ARC nucleus. Testosterone exerts its negative-feedback effects at the hypothalamus on the kiss1 neurons, not directly on the GnRH-secreting neurons. GnRH-secreting neurons do not have androgen receptors (or estrogen or progesterone receptors in females), but kiss1 neurons do have these receptors. By directly inhibiting kiss1 neurons, testosterone indirectly inhibits GnRH-secreting neurons by blocking kiss1 neurons' excitatory action on GnRH-secreting neurons. Kisspeptin signaling appears to be critical for integrating central and peripheral input to regulate GnRH (and thus FSH and LH and sex steroid hormone) output, for initiating puberty, and for maintaining normal reproductive function.

Roles of Testosterone and FSH in Spermatogenesis

Both testosterone and FSH play critical roles in controlling spermatogenesis, each exerting its effect by acting on Sertoli cells. Testosterone is essential for both mitosis and meiosis of the germ cells, whereas FSH is needed for spermatid remodeling. Only the high concentration of testicular testosterone maintained in the intratubular fluid (as a result of a substantial portion of this hormone being complexed with androgen-binding protein) is adequate to sustain sperm production.

GnRH activity increases at puberty.

Even though the fetal testes secrete testosterone, which directs masculine development of the reproductive system, after birth the testes become dormant until puberty. During the prepubertal period, LH and FSH are not secreted at adequate levels to stimulate any significant testicular activity. The prepubertal delay in the onset of reproductive capability allows time for the individual to mature physically (although not necessarily psychologically) enough to handle child rearing. (This physical maturation is especially important in the female, whose body must support the developing fetus.)

During the prepubertal period, GnRH activity is inhibited. The pubertal process is initiated by an increase in GnRH activity. Early in puberty, GnRH secretion occurs only at night, causing a brief nocturnal increase in LH secretion and, accordingly, testosterone secretion. The extent of GnRH secretion gradually increases as puberty progresses until the adult pattern of GnRH, FSH, LH, and testosterone secretion is established. Under the influence of the rising levels of testosterone during puberty, the physical changes that encompass the secondary sexual characteristics and reproductive maturation become evident.

The factors responsible for initiating puberty in humans remain unclear. The hormone *melatonin,* which is secreted by the *pineal gland* within the brain, appears to play an important role (see p. 662). Melatonin, whose secretion decreases during exposure to the light and increases during exposure to the dark, has an antigonadotropic effect in many species. Light striking the eyes inhibits the nerve pathways that stimulate melatonin secretion. In many seasonally breeding species, the overall decrease in melatonin secretion in connection with longer days and shorter nights initiates the mating season. A reduction in the overall rate of melatonin secretion coincides with the onset of puberty in humans—particularly during the night, when the peaks in GnRH secretion first occur. Furthermore, *leptin,* the hormone released from adipose (fat) stores (see p. 623), plays an important role in the onset of puberty, especially in females. In evolutionary history, this mechanism could have been a way to ensure that females had sufficient energy stored to sustain a pregnancy when food supplies were unpredictable.

Recent studies suggest that known signals for triggering puberty, such as circadian and nutritional cues, converge on the ARC nucleus kiss1 neurons, which activate the neuroendocrine reproductive axis by initiating pulsatile secretion of GnRH. Therefore, puberty might begin with a "kiss."

Having completed discussing testicular function, we now shift to the other components of the male reproductive system.

The reproductive tract stores and concentrates sperm and increases their fertility.

The remainder of the male reproductive system (besides the testes) is designed to deliver sperm to the female reproductive tract. It consists of (1) a tortuous pathway of tubes (the reproductive tract), which transports sperm from the testes to outside the body; (2) several accessory sex glands, which contribute secretions important to the viability and motility of the sperm; and (3) the penis, which is designed to penetrate and deposit sperm within the female vagina. We examine each of these parts in greater detail, beginning with the reproductive tract.

Components of the Male Reproductive Tract
A comma-shaped **epididymis** is loosely attached to the rear surface of each testis (see ❙Figures 20-1, p. 717, and 20-6a, p. 724). After sperm are produced in the seminiferous tubules, they are swept into the epididymis as a result of the pressure created by the continual secretion of tubular fluid by the Sertoli cells. The epididymal ducts from each testis converge to form a large, thick-walled, muscular duct called the **ductus (vas) deferens**. The ductus deferens from each testis passes up out of the scrotal sac and runs back through the inguinal canal into the abdominal cavity, where it eventually empties into the urethra at the neck of the bladder (see ❙Figure 20-1). The urethra carries

sperm out of the penis during ejaculation, the forceful expulsion of semen from the body.

Functions of the Epididymis and Ductus Deferens

These ducts perform several important functions. The epididymis and ductus deferens serve as the exit route for sperm from the testis. As they leave the testis, sperm are not capable of either moving or fertilizing. They gain both capabilities during their passage through the epididymis. This maturational process is stimulated by the testosterone retained within the tubular fluid bound to androgen-binding protein. The capacity of sperm to fertilize is further enhanced by exposure to secretions of the female reproductive tract. This enhancement of sperm's capacity in the male and female reproductive tracts is known as **capacitation**. The epididymis also concentrates sperm 100-fold by absorbing most of the fluid that enters from the seminiferous tubules. The maturing sperm are slowly moved through the epididymis into the ductus deferens by rhythmic contractions of the smooth muscle in the walls of these tubes.

The ductus deferens is an important site for sperm storage. Because the tightly packed sperm are relatively inactive and their metabolic needs are accordingly low, they can be stored in the ductus deferens for up to 2 months, even though they have no nutrient blood supply and are nourished only by simple sugars present in the tubular secretions.

Vasectomy In a **vasectomy**, a common sterilization procedure in males, a small segment of each ductus deferens (alias vas deferens, hence the term *vasectomy*) is surgically removed after it passes from the testis but before it enters the inguinal canal, thus blocking exit of sperm from the testes. Sperm that build up behind the tied-off testicular end of the severed ductus are removed by phagocytosis. Although this procedure blocks sperm exit, it does not interfere with testosterone activity because the Leydig cells secrete testosterone into the blood, not through the ductus deferens. Thus, vasectomy does not diminish testosterone-dependent masculinity or libido.

The accessory sex glands contribute the bulk of the semen.

Several accessory sex glands—the seminal vesicles and prostate—empty their secretions into the duct system before it joins the urethra (see ❚Figure 20-1). A pair of saclike *seminal vesicles* empties into the last portion of the two ductus deferens, one on each side. The short segment of duct that passes beyond the entry point of the seminal vesicle to join the urethra is called the *ejaculatory duct.* The *prostate* is a large, single gland that completely surrounds the ejaculatory ducts and urethra. Another pair of accessory sex glands, the *bulbourethral glands,* drains into the urethra after this canal has passed through the prostate and just before it enters the penis. Numerous mucus-secreting glands also lie along the length of the urethra. In a significant number of men, the prostate enlarges in middle to older age (a condition called **benign prostatic hypertrophy**, or **BPH**). Difficulty in urinating often occurs as the enlarging prostate impinges on the portion of the urethra that passes through the prostate.

Semen During ejaculation, the accessory sex glands contribute secretions that provide support for the continuing viability of sperm inside the female reproductive tract. These secretions constitute the bulk of the **semen**, which is a mixture of accessory sex gland secretions, sperm, and mucus. Sperm make up only a small percentage of the total ejaculated fluid.

Functions of the Male Accessory Sex Glands

Although the accessory sex gland secretions are not absolutely essential for fertilization, they do greatly facilitate the process.

■ The **seminal vesicles** (1) supply fructose, which is the primary energy source for ejaculated sperm; (2) secrete prostaglandins (see p. 119), which stimulate contractions of the smooth muscle in both the male and the female reproductive tracts, thereby helping transport sperm from their storage site in the male to the site of fertilization in the female oviduct; (3) provide about 60% of the semen volume, which helps wash the sperm into the urethra and dilutes the thick mass of sperm, enabling them to become mobile; and (4) secrete fibrinogen, a precursor of fibrin, which forms the meshwork of a clot (see p. 397).

■ The **prostate gland** (1) secretes an alkaline fluid that neutralizes the acidic vaginal secretions, an important function because sperm are more viable in a slightly alkaline environment; (2) provides clotting enzymes; and (3) releases prostate-specific antigen. The prostatic clotting enzymes act on fibrinogen from the seminal vesicles to produce fibrin, which "clots" the semen, thus helping keep the ejaculated sperm in the female reproductive tract during withdrawal of the penis. Shortly thereafter, the seminal clot is broken down by **prostate-specific antigen (PSA)**, a fibrin-degrading enzyme from the prostate, thus releasing mobile sperm within the female tract.

Because PSA is produced only in the prostate gland, measurement of PSA levels in the blood is used as one type of screening test for possible prostate cancer. Elevated levels of PSA in the blood are associated with prostate cancer, benign prostatic hypertrophy, or prostate infections.

A new study suggests another role for the prostate: releasing **prostasomes**, which are vesicles that fuse with and transfer to sperm a molecular "tool kit" that contains components needed for Ca^{2+} signal transduction. For example, prostasomes pass ryanodine receptors (Ca^{2+}-release channels; see p. 258) and an enzyme that opens these channels. These materials passed to sperm from the prostate gland let the stripped-down sperm that cannot make these components themselves use enhanced Ca^{2+} signaling needed for optimal motility and efficient fertilization.

■ During sexual arousal, the **bulbourethral glands** secrete mucus that provides lubrication for sexual intercourse. However, females provide most lubrication for sex.

❚Table 20-2 summarizes the locations and functions of the components of the male reproductive system.

Next, before considering the female in greater detail, we examine the means by which males and females come together via sexual intercourse to accomplish reproduction.

Component	Number and Location	Functions
Testis	Pair; located in the scrotum, a skin-covered sac suspended within the angle between the legs	Produce sperm
		Secrete testosterone
Epididymis and ductus deferens	Pair; one epididymis attached to the rear of each testis; one ductus deferens travels from each epididymis up out of the scrotal sac through the inguinal canal and empties into the urethra at the neck of the bladder	Serve as the sperm's exit route from the testis
		Serve as the site for maturation of the sperm for motility and fertility
		Concentrate and store the sperm
Seminal vesicle	Pair; both empty into the last portion of the ductus deferens, one on each side	Supply fructose to nourish the ejaculated sperm
		Secrete prostaglandins that stimulate motility to help transport the sperm within the male and female
		Provide the bulk of the semen
		Provide precursors for the clotting of semen
Prostate gland	Single; completely surrounds the urethra at the neck of the bladder	Secretes an alkaline fluid that neutralizes the acidic vaginal secretions
		Triggers clotting of the semen to keep the sperm in the vagina during penis withdrawal
Bulbourethral gland	Pair; both empty into the urethra, one on each side, just before the urethra enters the penis	Secrete mucus for lubrication

---

Check Your Understanding 20.2

1. List the functions of testosterone.
2. Define *seminiferous tubules, Leydig cells, Sertoli cells, spermatogenesis, spermiogenesis, spermiation, spermatogonia, primary spermatocytes, secondary spermatocytes, spermatids,* and *spermatozoa.*
3. Draw a flow diagram showing the control of testicular function.
4. State the functions of the male accessory sex glands.

20.3 Sexual Intercourse between Males and Females

Ultimately, union of male and female gametes to accomplish reproduction in humans requires delivery of sperm-laden semen into the female vagina through the **sex act**, also known as **sexual intercourse**, **coitus**, or **copulation**.

The male sex act is characterized by erection and ejaculation.

The male sex act involves two components: (1) **erection**, or hardening of the normally flaccid penis to permit its entry into the vagina, and (2) **ejaculation**, or forceful expulsion of semen into the urethra and out of the penis (▌Table 20-3). In addition to these strictly reproduction-related components, the **sexual response cycle** encompasses broader physiologic responses that can be divided into four phases:

1. The *excitement phase* includes erection and heightened sexual awareness.
2. The *plateau phase* is characterized by intensification of these responses, plus more generalized body responses, such as steadily increasing heart rate, blood pressure, respiratory rate, and muscle tension.
3. The *orgasmic phase* includes ejaculation and other responses that culminate the mounting sexual excitement and are collectively experienced as an intense physical pleasure.
4. The *resolution phase* returns the genitalia and body systems to their prearousal state.

The human sexual response is a multicomponent experience that, in addition to these physiologic phenomena, encompasses emotional, psychological, and sociological factors. We examine only the physiologic aspects of sex.

Erection is accomplished by penis vasocongestion.

Erection is accomplished by engorgement of the penis with blood. The penis consists almost entirely of **erectile tissue** made up of three columns or cords of spongelike vascular spaces extending the length of the organ (see ▌Figure 20-1a, b, and c). In the absence of sexual excitation, the erectile tissues contain little blood because the arterioles that supply these vascular chambers are constricted. As a result, the penis remains small

Components of the Male Sex Act

Components of the Male Sex Act	Definition	Accomplished by
Erection	Hardening of the normally flaccid penis to permit its entry into the vagina	Engorgement of the penis erectile tissue with blood as a result of marked parasympathetically induced vasodilation of the penile arterioles and mechanical compression of the veins
Ejaculation		
Emission phase	Emptying of sperm and accessory sex-gland secretions (semen) into the urethra	Sympathetically induced contraction of the smooth muscle in the walls of the reproductive ducts and accessory sex glands
Expulsion phase	Forceful expulsion of semen from the penis	Motor neuron–induced contraction of the skeletal muscles at the base of the penis

and flaccid. During sexual arousal, these arterioles reflexly dilate and the erectile tissue fills with blood, causing the penis to enlarge both in length and in width and to become more rigid. The veins that drain the erectile tissue are mechanically compressed by this engorgement and expansion of the vascular spaces, reducing venous outflow and thereby contributing even further to the buildup of blood, or *vasocongestion.* These local vascular responses transform the penis into a hardened, elongated organ capable of penetrating the vagina.

Erection Reflex The erection reflex is a spinal reflex triggered by stimulation of highly sensitive mechanoreceptors located in the glans penis, which caps the tip of the penis. An **erection-generating center** lies in the lower spinal cord. Tactile stimulation of the glans reflexly triggers, by means of this center, increased parasympathetic vasodilator activity and decreased sympathetic vasoconstrictor activity to the penile arterioles. The result is rapid, pronounced vasodilation of these arterioles and an ensuing erection (▌Figure 20-10). As long as this spinal reflex arc remains intact, erection is possible even in men paralyzed by a higher spinal-cord injury.

This parasympathetically induced vasodilation is the major instance of direct parasympathetic control over blood vessel diameter in the body. Parasympathetic stimulation brings about relaxation of penile arteriolar smooth muscle by *nitric oxide* (*NO*), which causes arteriolar vasodilation in response to local tissue changes elsewhere in the body (see p. 346). Only sympathetic nerves typically supply arterioles, with increased sympathetic activity producing vasoconstriction and decreased sympathetic activity resulting in vasodilation (see p. 349). Concurrent parasympathetic stimulation and sympathetic inhibition of penile arterioles accomplish vasodilation more rapidly and

in greater magnitude than is possible in other arterioles supplied only by sympathetic nerves. Through this efficient means of rapidly increasing blood flow into the penis, the penis can become completely erect in as little as 5 seconds. At the same time, parasympathetic impulses promote secretion of lubricat-
▌Figure 20-10 **Erection reflex**.

ing mucus from the bulbourethral glands and the urethral glands in preparation for coitus.

Numerous regions throughout the brain can influence the male sexual response. The erection-influencing brain sites appear extensively interconnected and function as a unified network to either facilitate or inhibit the basic spinal erection reflex, depending on the momentary circumstances. As an example of facilitation, mental stimuli, such as viewing something sexually exciting, can induce an erection in the absence of tactile stimulation of the penis. In contrast, failure to achieve an erection despite appropriate stimulation may result from inhibition of the erection reflex by higher brain centers. Let us examine erectile dysfunction in more detail.

Clinical Note **Erectile Dysfunction** A pattern of failing to achieve or maintain an erection suitable for sexual intercourse— **erectile dysfunction (ED)** or **impotence**—may be attributable to psychological or physical factors. An occasional episode of a failed erection does not constitute impotence, but a man who becomes overly anxious about his ability to perform the sex act may well be on his way to chronic failure. Anxiety can lead to ED, which fuels the man's anxiety level and thus perpetuates the problem. Impotence may also arise from physical limitations, including nerve damage, certain medications that interfere with autonomic function, and problems with blood flow through the penis.

ED is widespread. More than 50% of men between ages 40 and 70 experience some impotence, climbing to nearly 70% by age 70. No wonder, then, that more prescriptions were written for the much-publicized drug *sildenafil* (*Viagra*) during its first year on the market after its approval in 1998 for treating ED than for any other new drug in history. Sildenafil does not produce an erection, but it amplifies and prolongs an erectile response triggered by usual means of stimulation. Here is how the drug works: Nitric oxide released in response to parasympathetic stimulation activates a membrane-bound enzyme, **soluble guanylate cyclase (sGC)**, within nearby arteriolar smooth muscle cells. This enzyme activates **cyclic guanosine monophosphate (cyclic GMP** or **cGMP)**, an intracellular second messenger similar to cAMP. Cyclic GMP, in turn, leads to relaxation of the penile arteriolar smooth muscle, bringing about pronounced local vasodilation. Under normal circumstances, once cGMP is activated and brings about an erection, this second messenger is broken down by the intracellular enzyme **phosphodiesterase 5 (PDE5)**. Sildenafil inhibits PDE5. As a result, cGMP remains active longer so that penile arteriolar vasodilation continues and the erection is sustained long enough for a formerly impotent man to accomplish the sex act. Just as pushing a pedal on a piano will not cause a note to be played but will prolong a played note, sildenafil cannot cause the release of NO and subsequent activation of erection-producing cGMP, but it can prolong the triggered response. The drug has no benefit for those who do not have ED, but its success rate has been high among sufferers of the condition. Side effects have been limited because the drug concentrates in the penis, thus having more effect on this organ than elsewhere in the body.

When NO formation is severely impaired and PDE5 inhibitors are not effective, two new classes of drugs are under investigation for treatment of ED: *sGC stimulators* and *sGC activators* that act independently of NO in slightly different ways to increase cGMP formation and promote erection.

Ejaculation includes emission and expulsion.

The second component of the male sex act is ejaculation. Like erection, ejaculation is a spinal reflex. The same types of tactile and psychic stimuli that induce erection cause ejaculation when the level of excitation intensifies to a critical peak. The overall ejaculatory response occurs in two phases: *emission* and *expulsion* (see ▌Table 20-3).

Emission First, sympathetic impulses cause sequential contraction of smooth muscles in the prostate, reproductive ducts, and seminal vesicles. This contractile activity delivers prostatic fluid, then sperm, and finally seminal vesicle fluid (collectively, semen) into the urethra. This phase of the ejaculatory reflex is called **emission**. During this time, the sphincter at the neck of the bladder is tightly closed to prevent semen from entering the bladder and urine from being expelled along with the ejaculate through the urethra.

Expulsion Second, filling of the urethra with semen triggers nerve impulses that activate skeletal muscles at the base of the penis. Rhythmic contractions of these muscles occur at 0.8-second intervals and increase the pressure within the penis, forcibly expelling the semen through the urethra to the exterior. This is the **expulsion** phase of ejaculation.

Orgasm and resolution complete the sexual response cycle.

The third phase of the sexual response cycle, orgasm, accompanies the expulsion part of the ejaculatory response and is followed by the resolution phase of the cycle.

Orgasm The rhythmic contractions that occur during semen expulsion are accompanied by involuntary rhythmic throbbing of pelvic muscles and peak intensity of the overall body responses that were climbing during the earlier phases. Heavy breathing, a heart rate of up to 180 beats per minute, marked generalized skeletal muscle contraction, and heightened emotions are characteristic. These pelvic and overall systemic responses that culminate the sex act are associated with an intense pleasure characterized by a feeling of release and complete gratification, an experience known as **orgasm**.

Resolution During the resolution phase following orgasm, sympathetic vasoconstrictor impulses slow the inflow of blood into the penis, causing the erection to subside. A deep relaxation ensues, often accompanied by a feeling of fatigue. Muscle tone returns to normal, while the cardiovascular and respiratory systems return to their prearousal level of activity. Once ejaculation has occurred, a temporary refractory period of vari-

able duration ensues before sexual stimulation can trigger another erection. Males therefore cannot experience multiple orgasms within a matter of minutes, as females sometimes do.

Volume and sperm content of the ejaculate vary.

The volume and sperm content of the ejaculate depend on the length of time between ejaculations. The average volume of semen is 2.75 mL, ranging from 2 to 6 mL, the higher volumes following periods of abstinence. An average human ejaculate contains about 165 million sperm (60 million/mL), but some ejaculates contain as many as 400 million sperm.

Clinical Note Both quantity and quality of sperm are important determinants of fertility. A man is considered clinically **infertile** if his sperm concentration falls below 20 million/mL of semen. Even though only one spermatozoon actually fertilizes the ovum, large numbers of accompanying sperm are needed to provide sufficient acrosomal enzymes to break down the barriers surrounding the ovum until the victorious sperm penetrates into the ovum's cytoplasm (❙Figure 20-11). The quality of sperm also must be taken into account when assessing the fertility potential of a semen sample. The presence of substantial numbers of sperm with abnormal motility or structure, such as sperm with distorted tails, reduces the chances of fertilization. (For a discussion of how environmental estrogens may be decreasing sperm counts and negatively affecting the male and female reproductive systems in other ways, see the boxed feature on pp. 736–737, ❙Concepts, Challenges, and Controversies.)

The female sexual cycle is similar to the male cycle.

Both sexes experience the same four phases of the sexual cycle—excitement, plateau, orgasm, and resolution. Furthermore, the physiologic mechanisms responsible for orgasm are fundamentally the same in males and females.

The excitement phase in females can be initiated by either physical or psychological stimuli. Tactile stimulation of the glans clitoris and surrounding perineal area is an especially powerful sexual stimulus. These stimuli trigger spinal reflexes that bring about parasympathetically induced vasodilation of arterioles throughout the vagina and external genitalia, especially the clitoris. The resultant inflow of blood becomes evident as swelling of the labia and erection of the clitoris. The latter—like its male homolog, the penis—is composed largely of erectile tissue. Contrary to a common misconception, the clitoris is much larger than its externally visible portion. Most of the clitoris is located internally and consists mainly of large, highly vascular **vestibular bulbs** that surround the urethra and vagina (see ❙Figure 20-2d, p. 719). These bulbs engorge with blood during erection. The functional significance of this vasocongestion is unclear. Scientists speculate that it may (1) squeeze the urethra closed to prevent contamination of the urinary tract during sexual activity, (2) support the vaginal wall and squeeze the penis during sexual intercourse, and (3) increase pleasure signaling.
❙Figure 20-11 **Scanning electron micrograph of sperm amassed at the surface of an ovum**.

Vasocongestion of vaginal capillaries forces fluid out of these vessels into the vaginal lumen. This fluid, which is the first positive indication of sexual arousal, serves as the primary lubricant for intercourse. Mucus secretions from the male and mucus released during sexual arousal from glands located at the outer opening of the vagina provide additional lubrication. Also during the excitement phase in the female, the nipples become erect and the breasts enlarge as a result of vasocongestion.

During the plateau phase, the changes initiated during the excitement phase intensify, while systemic responses similar to those in the male (such as increased heart rate, blood pressure, respiratory rate, and muscle tension) occur. Further vasocongestion of the lower third of the vagina during this time (accompanied by vasocongestion of the surrounding vestibular bulbs) reduces the inner capacity of the vagina so that it tightens around the thrusting penis, heightening tactile sensation for both the female and the male. Simultaneously, the uterus raises upward, lifting the cervix and enlarging the upper two thirds of the vagina. This ballooning, or **tenting effect**, creates a space for ejaculate deposition.

If erotic stimulation continues, the sexual response culminates in orgasm as sympathetic impulses trigger rhythmic contractions of pelvic musculature at 0.8-second intervals, the same rate as in males. The contractions occur most intensely in the engorged lower third of the vaginal canal. Systemic responses identical to those of the male orgasm also occur. In fact, the orgasmic experience in females parallels that of males with two exceptions. First, there is no female counterpart to ejaculation. Second, females do not become refractory following an orgasm, so they can respond immediately to continued erotic stimulation and achieve multiple orgasms.

During resolution, pelvic vasocongestion and the systemic manifestations gradually subside. As with males, this is a time of great physical relaxation for females.

We now examine how females fulfill their part of the reproductive process.

Environmental "Estrogens": Bad News for the Reproductive System

UNKNOWINGLY, DURING THE PAST 70 years humans have been polluting our environment with synthetic endocrine-disrupting chemicals as an unintended side effect of industrialization. Known as **endocrine disrupters,** these hormonelike pollutants bind with the receptor sites normally reserved for the naturally occurring hormones. Depending on how they interact with the receptors, these disrupters can either mimic or block normal hormonal activity. Many of these environmental contaminants mimic or alter the action of estrogen, the feminizing steroid hormone produced by the female ovaries.

Estrogenic pollutants are everywhere. They contaminate our food, drinking water, and air. Proved feminizing synthetic compounds are found in (1) certain weed killers and insecticides, (2) some detergent breakdown products, (3) petroleum by-products found in car exhaust, (4) a common food preservative used to retard rancidity, (5) dental sealants, (6) cash register receipts, and (7) softeners that make plastics flexible. These plastic softeners are commonly found in food packaging and can readily leach into food with which they come in contact, especially during heating. The softeners were also found to leach from some babies' plastic teething toys into the saliva. They are in numerous medical products, such as the bags in which blood is stored. Plastic softeners are among the most plentiful industrial contaminants in our environment.

Investigators are only beginning to identify and understand the implications for reproductive health of myriad synthetic chemicals that are an integral part of modern societies. An estimated 87,000 synthetic chemicals are already in our environment. Scientists suspect that the estrogen-mimicking chemicals among these may underlie a spectrum of reproductive disorders that have been rising in the past 70 years—the same period during which large amounts of these pollutants have been introduced into our environment. Here are examples of male reproductive dysfunctions that may be circumstantially linked to exposure to environmental **estrogen disrupters:**

■ *Falling sperm counts.* The average sperm count has fallen from 113 million sperm per milliliter of semen in the 1940s to 60 million/

mL now. Making matters worse, the volume of a single ejaculate has declined from 3.40 to 2.75 mL. This means that men, on average, are now ejaculating less than half the number of sperm as men did about 70 years ago—a drop from more than 380 million sperm to about 165 million sperm per ejaculate. Furthermore, the number of motile sperm has dipped. Of note, the sperm count has not declined in the less polluted areas of the world during the same period.

■ *Increased incidence of testicular and prostate cancer.* Cases of testicular cancer have tripled since the 1940s, and the rate continues to climb. Prostate cancer has also been on the rise over the same period.

■ *Rising number of male reproductive tract abnormalities at birth.* The incidence of cryptorchidism (undescended testis) nearly doubled from the 1950s to the 1970s. The number of cases of *hypospadia,* a malformation of the penis, more than doubled between the mid-1960s and the mid-1990s. Hypospadia results when the urethral fold fails to fuse closed during development of a male fetus.

■ *Evidence of reduced masculinization in animals.* Some fish and wild animal populations severely exposed to environmental estrogens—such as those living in or near water heavily polluted with hormone-mimicking chemical wastes—display a high rate of grossly impaired reproductive systems. Examples include male fish that are hermaphrodites (having both male and female reproductive parts) and male alligators with abnormally small penises. Similar reproductive abnormalities have been identified in land mammals. Presumably, excessive estrogen exposure is emasculating these populations.

■ *Decline in male births.* Many countries are reporting a slight decline in the ratio of baby boys to baby girls being born. In the United States, 17 fewer males were born per 10,000 births in 2007 compared to 1970, and Japan has seen an overall drop of 37 males per 10,000 births during the same period. Although several other plausible explanations have been put forth (such as late-age childbearing,

---

1. List and describe the four phases of the sexual response cycle.
2. Define the components of the male sex act and explain how each is accomplished.
3. Compare orgasm in males and females.

20.4 Female Reproductive Physiology

Female reproductive physiology is more complex than male reproductive physiology.

Complex cycling characterizes female reproductive physiology.

Unlike the continuous sperm production and essentially constant testosterone secretion characteristic of the male, release of ova is intermittent, and secretion of female sex hormones displays wide cyclic swings. The tissues influenced by these sex hormones also undergo cyclic changes, the most obvious of which is the monthly menstrual cycle (*menstruus* means "monthly"). During each cycle, the female reproductive tract is prepared for the fertilization and implantation of an ovum released from the ovary at ovulation. If fertilization does not occur, the cycle repeats. If fertilization does occur, the cycles are interrupted while the female system adapts to nurture and pro-

increasing obesity, and greater use of reproductive technologies), many researchers attribute this troubling trend primarily to disruption of normal male fetal development by environmental estrogens. In one compelling piece of circumstantial evidence, people inadvertently exposed to the highest level of an endocrine-disrupting agent during an industrial accident subsequently had all daughters and no sons, whereas those least exposed had the normal ratio of girls and boys. Similarly, a 2004 study in the Russian Arctic found a remarkable ratio of 2.5 to 1 female-to-male births among women who had blood concentrations of 4 mg/L or greater of a known estrogen-mimicking pollutant.

Environmental estrogens are also implicated in the rising incidence of breast cancer in females. Breast cancer is 25% to 30% more prevalent now than in the 1940s. Many of the established risk factors for breast cancer, such as starting to menstruate earlier than usual and undergoing menopause later than usual, are associated with an elevation in the total lifetime exposure to estrogen. Because increased exposure to natural estrogen bumps up the risk for breast cancer, prolonged exposure to environmental estrogens may be contributing to the rising prevalence of this malignancy among women (and men).

In addition to the estrogen disrupters, scientists more recently identified a new class of chemical offenders—**androgen disrupters** that either mimic or suppress the action of male hormones. For example, studies suggest that bacteria in wastewater from pulp mills can convert the sterols in pine pulp into androgens. By contrast, anti-androgen compounds have been found in the fungicides commonly sprayed on vegetable and fruit crops. Yet another cause for concern comes from the androgens used by the livestock industry to enhance the production of muscle (that is, meat) in feedlot cattle. (Androgens have a protein anabolic effect.) These drugs do not end up in the meat, but they can get into drinking water and other food as hormone-laden feces contaminate rivers and streams.

Under the *Toxic Substances Control Act (TSCA)*, which became law in the United States in 1976, chemicals are presumed safe unless proven otherwise. The Environmental Protection Agency (EPA) must show that a chemical is dangerous after it is already in use. In response to the growing evidence that has emerged circumstantially linking numerous environmental pollutants to disturbing reproductive abnormalities, the U.S. Congress legally mandated the EPA in 1996 to determine which synthetic chemicals might be endocrine disrupters. In response, the EPA formed an advisory committee, which in 1998 proposed an ambitious plan to begin comprehensive testing of manufactured compounds for their potential to disrupt hormones in humans and wildlife. Although eventually all the 87,000 existing synthetic compounds will be tested, the initial screening was narrowed to evaluate the endocrine-disrupting potential of widely used chemicals. Declaring this a national health priority, the government has allocated millions of dollars for this research. Yet in this time-consuming process, only a few thousand chemicals were tested in the first 10 years of investigation as the EPA's *Toxic Release Inventory* slowly grew and other chemicals were deemed safe.

To more quickly, more efficiently, and more effectively screen chemicals for their potential toxicity, the *Toxicology in the 21st Century (Tox21) program* was established in 2008. Tox21 is a federal collaboration involving the EPA, National Institutes of Health (NIH), and Food and Drug Administration (FDA). In 2011, the Tox21 consortium introduced a high-speed, cost-effective robot screening system that is currently testing 10,000 chemicals to predict their potential for disrupting physiologic pathways that may negatively affect human health.

In the meantime, increasingly, environmental watchdogs are calling for additional measures to limit exposure to synthetic chemicals (such as switching from plastic to glass baby bottles) and better labeling from manufacturers so that consumers can make more informed decisions about products they use.

---

tect the newly conceived human until it has developed into an individual capable of living outside the maternal environment. Furthermore, the female continues her reproductive functions after birth by producing milk (lactation) for the baby's nourishment. Thus, the female reproductive system is characterized by complex cycles that are interrupted by even more complex changes should pregnancy occur.

The ovaries perform the dual function of producing ova (oogenesis) and secreting the female sex hormones, estrogen and progesterone. These hormones act together to promote fertilization of the ovum and to prepare the female reproductive system for pregnancy. Estrogen in the female governs many functions similar to those carried out by testosterone in the male, such as maturation and maintenance of the entire female reproductive system and establishment of female secondary sexual characteristics. In general, the actions of estrogen are important to preconception events. Estrogen is essential for ova maturation and release, development of physical characteristics that are sexually attractive to males, and transport of sperm from the vagina to the site of fertilization in the oviduct. Furthermore, estrogen contributes to breast development in anticipation of lactation. The other ovarian steroid, progesterone, sometimes called the "hormone of pregnancy," is important in preparing a suitable environment for nourishing a developing embryo and then fetus and for contributing to the breasts' ability to produce milk.

Being steroids, estrogen and progesterone exert their multiple effects by binding with their respective receptors in the cytoplasm of their target cells, with the hormone-receptor complex moving to the nucleus where it binds with a hormone-specific DNA hormone-response element. This binding leads to gene transcription and synthesis of designated proteins that exert the hormone's dictated response in the target cells. Estrogen has two different cytoplasmic receptors, which have a differential distribution in various tissues and permit selective actions in specific target tissues. **Selective estrogen receptor modulators (SERMs)**, like *raloxifene*, are drugs that selectively bind with a specific estrogen receptor. Raloxifene is approved to treat osteoporosis because it selectively binds with estrogen receptors in bone, where it mimics estrogen's beneficial effect on maintaining bone density, while not exerting any effect on reproductive organs, where extra estrogenlike influence could increase the risk of cancer (see pp. 704 and 706). Estrogen also binds with surface membrane receptors, where it acts via cAMP to elicit rapid, nongenomic effects (see p. 127).

As in males, reproductive capability begins at puberty in females, but unlike males, who have reproductive potential throughout life, female reproductive potential ceases during middle age at menopause.

The steps of gametogenesis are the same in both sexes, but the timing and outcome differ sharply.

Even though the identical steps of chromosome replication and division take place during gamete production in both sexes, **oogenesis** contrasts sharply with spermatogenesis in several important aspects. The undifferentiated primordial germ cells in the fetal ovaries, the **oogonia** (comparable to spermatogonia), divide mitotically to produce about 7 million oogonia by the fifth month of gestation, when mitotic proliferation ceases.

Formation of Primary Oocytes and Primordial Follicles During the last part of fetal life, the oogonia begin the early steps of the first meiotic division but do not complete it. Known now as **primary oocytes**, they contain the diploid number of 46 replicated chromosomes, which are gathered into homologous pairs but do not separate. The primary oocytes remain in this state of **meiotic arrest** for years until they are prepared for ovulation.

Before birth, each primary oocyte is surrounded by a single layer of connective tissue–derived **granulosa cells**. Together, an oocyte and surrounding granulosa cells make up a **primordial follicle**. Primary oocytes that are not incorporated into follicles self-destruct by apoptosis (cell suicide). At birth, only about 2 million primordial follicles remain, each containing a single primary oocyte capable of producing a single ovum. No new oocytes or follicles appear after birth, with the follicles already present in the ovaries at birth serving as a reservoir from which all ova throughout the reproductive life of a female arise. The follicular pool gradually dwindles away as a result of processes that "use up" the oocyte-containing follicles. Even before puberty, the pool of primordial follicles gives rise to an ongoing trickle of developing follicles, stimulated by poorly understood paracrine factors produced by both oocytes and granulosa cells. Once it starts to develop, a follicle is destined for one of two fates: It will reach maturity and ovulate, or it will degenerate to form scar tissue, a process known as **atresia**. Until puberty, all the follicles that start to develop undergo atresia in the early stages without ever ovulating. For the first few years after puberty, many of the cycles are anovulatory (that is, no ovum is released). Of the original total pool of follicles at birth, about 300,000 remain at puberty, and only about 400 will mature and release ova; 99.97% never ovulate but instead undergo atresia at some stage of development. By menopause, which occurs on average in a woman's early 50s, few primordial follicles remain, having either already ovulated or become atretic. From this point on, the woman's reproductive capacity ceases.

This limited gamete potential in females is in sharp contrast to the continual process of spermatogenesis in males, who have the potential to produce several hundred million sperm in a single day. Furthermore, considerable chromosome wastage occurs in oogenesis compared with spermatogenesis. Let us see how.

Formation of Secondary Oocytes The primary oocyte within a primordial follicle is still a diploid cell that contains 46 doubled chromosomes. From puberty until menopause, a portion of the developing follicles in the pool progress cyclically into more advanced follicles. The mechanisms determining which follicles in the pool develop during a given cycle are unknown. Further development of a follicle is characterized by growth of the primary oocyte and by expansion and differentiation of the surrounding cell layers. We focus now on oogenesis before we discuss the accompanying changes in the follicle. The oocyte enlarges about a thousandfold. This oocyte enlargement is caused by a buildup of cytoplasmic materials that are needed by the early embryo.

Just before ovulation, the primary oocyte, whose nucleus has been in meiotic arrest for years, completes its first meiotic division. This division yields two daughter cells, each receiving a haploid set of 23 doubled chromosomes, analogous to the formation of secondary spermatocytes (❚ Figure 20-12). However, almost all the cytoplasm remains with one of the daughter cells, now called the **secondary oocyte**, which is destined to become the ovum. The chromosomes of the other daughter cell, together with a small share of cytoplasm, form the **first polar body**. In this way, the ovum-to-be loses half of its chromosomes to form a haploid gamete but retains all of its nutrient-rich cytoplasm. The nutrient-poor polar body soon degenerates.

Formation of a Mature Ovum Actually, the secondary oocyte, and not the mature ovum, is ovulated and fertilized, but common usage refers to the developing female gamete as an *ovum* even in its primary and secondary oocyte stages. Sperm entry into the secondary oocyte is needed to trigger the second meiotic division. Unfertilized secondary oocytes never complete this final division. During this division, a half set of chromosomes, along with a thin layer of cytoplasm, is extruded as the **second polar body**. The other half set of 23 unpaired chromosomes remains behind in what is now the **mature ovum** (sometimes called the *ootid,* comparable to the spermatid, until

Stages of oogenesis		Chromosomes in each cell
Oogonium		**46** (diploid number; single strands)
1 Mitotic proliferation prior to birth		
Primary oocytes	(Arrested in first meiotic division)	**46** (diploid number; doubled strands)
After puberty, one primary oocyte reaches maturity and is ovulated about once a month until menopause ensues	**Enlarged primary oocyte**	**46** (diploid number; doubled strands)
2 Meiosis	(First meiotic division completed just prior to ovulation)	
First polar body	**Secondary oocyte**	**23** (haploid number; doubled strands)
	(Second meiotic division completed after fertilization)	
Second polar body	**Mature ovum**	**23** (haploid number; single strands) from ovum plus **23** (haploid number; single strands) from sperm for diploid fertilized ovum with **46** chromosomes
Polar bodies degenerate		

❙Figure 20-12 Oogenesis. Compare with Figure 20-7, p. 727, spermatogenesis.

the polar bodies disintegrate and the mature ovum alone remains). These 23 maternal chromosomes unite with the 23 paternal chromosomes of the penetrating sperm to complete fertilization. If the first polar body has not already degenerated, it too undergoes the second meiotic division at the same time the fertilized secondary oocyte is dividing its chromosomes.

Comparison of Steps in Oogenesis and Spermatogenesis The steps involved in chromosome distribution during oogenesis parallel those of spermatogenesis, except that the cytoplasmic distribution and time span for completion differ sharply (❙Figure 20-13). Just as four haploid spermatids are produced by each primary spermatocyte, four haploid daughter cells are produced by each primary oocyte (if the first polar body does not degenerate before it completes the second meiotic division). In spermatogenesis, each daughter cell develops into a highly specialized, motile spermatozoon unencumbered by unessential cytoplasm and organelles, its only destiny being to supply half of the genes for a new individual. In oogenesis,

however, of the four daughter cells, only the one destined to become the mature ovum receives cytoplasm. This uneven distribution of cytoplasm is important because the ovum, in addition to providing half the genes, provides all of the cytoplasmic components needed to support early development of the fertilized ovum. The large, relatively undifferentiated ovum contains numerous nutrients, organelles, and structural and enzymatic proteins. The three other cytoplasm-scarce daughter cells, the polar bodies, rapidly degenerate, their chromosomes being deliberately wasted.

Note also the considerable difference in time to complete spermatogenesis and oogenesis. A spermatogonium develops into fully remodeled spermatozoa in about 2 months. In contrast, development of an oogonium (present before birth) to a mature ovum takes anywhere from 11 years (beginning of ovulation at onset of puberty) to 50 years (end of ovulation at onset of menopause). The length of the active steps in meiosis is the same in both males and females, but in females the developing eggs remain in meiotic arrest for a variable number of years.

Clinical Note The older age of ova released by women in their late 30s and 40s is believed to account for the higher incidence of genetic abnormalities, such as Down syndrome, in children born to women in this age range.

The ovarian cycle consists of alternating follicular and luteal phases.

After the onset of puberty, the ovary constantly alternates between two phases: the **follicular phase**, which is dominated by the presence of *maturing follicles*; and the **luteal phase**, which is characterized by the presence of the *corpus luteum* (to be described shortly). Normally, this cycle is interrupted only if pregnancy occurs and is finally terminated by menopause. The average ovarian cycle lasts 28 days, but this varies among women and among cycles in any particular woman. The follicle operates in the first half of the cycle to produce a mature egg ready for ovulation at midcycle. The corpus luteum takes over during the last half of the cycle to prepare the female reproductive tract for pregnancy in case fertilization of the released egg occurs.

The follicular phase is characterized by development of maturing follicles.

At any given time throughout the cycle, a portion of the primordial follicles (❙Figure 20-14b, step ❶) is starting to develop under paracrine influence. However, only those that reach a certain stage of development during the follicular phase, when the gonadotropin hormone environment is right to promote their final maturation, continue beyond the earlier stages of development. The others, lacking hormonal support, undergo atresia. During follicular development, as the primary oocyte is synthesizing and storing materials for future use if fertilized, important changes take place in the cells surrounding the reactivated oocyte in preparation for the egg's release from the ovary.

Preantral Follicular Development The first stage of follicular development is conversion of selected primordial follicles into **preantral follicles** (❙Figure 20-14, step ❷, and ❙Table 20-4). A preantral follicle is a follicle that has begun to grow but has not yet formed an *antrum*, a fluid-filled cavity within the follicle's interior. When a primordial follicle begins to develop into a preantral follicle, the single layer of granulosa cells thickens and then proliferates to create several layers that surround the oocyte. The oocyte and granulosa cell secrete glycoproteins that form a thick, gel-like "rind" that covers the oocyte and separates it from the surrounding granulosa cells. This intervening membrane is known as the **zona pellucida**. Gap junctions penetrate the zona pellucida and extend between the oocyte and surrounding granulosa cells. Glucose, amino acids, and other important molecules are delivered to the oocyte from the granulosa cells through these connecting tunnels, enabling the egg to stockpile these critical nutrients. Also, signaling molecules pass through the gap junctions in both directions, helping coordinate the changes that take place in the oocyte and surrounding cells as both mature and prepare for ovulation. The nurturing relationship between granulosa cells and a develop-

ing egg is similar in many ways to the relationship between Sertoli cells and developing sperm.

At the same time as the oocyte is enlarging and granulosa cells are proliferating, specialized ovarian connective tissue cells in contact with the expanding granulosa cells proliferate and differentiate to form an outer layer of **thecal cells** in response to paracrines secreted by the granulosa cells. Thecal and granulosa cells, collectively known as **follicular cells**, have the ability to function as a unit to secrete estrogen, although they do not do so at this early stage of follicular development. Preantral follicular development takes several months to complete and occurs without gonadotropin influence.

Formation of an Antral Follicle; Estrogen Secretion The next stage of follicular development is gonadotropin-dependent and involves formation of the antrum and conversion of the preantral follicle into an **antral follicle** that secretes estrogen (❙Figure 20-14, step ❸). During this stage of follicular development, a fluid-filled cavity, or **antrum**, forms in the middle of the granulosa cells (❙Figure 20-15). The follicular fluid originates partially from transudation (passage through capillary pores) of plasma and partially from follicular cell secretions. As the follicular cells start producing estrogen, some of this hormone is secreted into the blood for distribution throughout the body. However, a portion of the estrogen collects in the hormone-rich antral fluid. Of the three physiologically important estrogens in order of potency—*estradiol, estrone,* and *estriol*—**estradiol** is the principal ovarian estrogen.

The oocyte reaches full size during early development of the antrum. The shift from a preantral follicle to an antral follicle initiates a period of rapid follicular growth. Part of the follicular growth is the result of continued proliferation of the granulosa and thecal cells, but most results from a dramatic expansion of the antrum. As the follicle grows, estrogen is produced in increasing quantities.

Early antral development depends on the presence of gonadotropins, but the fluctuating levels of these hormones that occur during the monthly reproductive cycle do not influence early antral follicles. This early antral development takes another 45 days and, like preantral development, is not part of the follicular phase of the ovarian cycle. Only antral follicles that have developed to the point of becoming extremely sensitive to FSH are "recruited" for further rapid development at the beginning of the follicular phase when FSH levels rise. Typically during each cycle, about 15 to 20 follicles are recruited (see ❙Figure 20-14, step ❹). Whereas the diameter of a preantral follicle is still less than 1 mm, that of a recruitable antral follicle is 2 to 5 mm, and that of a recruited mature follicle reaches 15 to 20 mm shortly before ovulation.

Formation of a Mature Follicle Of the follicles recruited, one, the "dominant" follicle, usually grows more rapidly than the others, developing into a **mature (preovulatory**, **tertiary**, or **Graafian) follicle** within about 14 days after being recruited (step ❺). Rapid growth of recruited follicles and development of a mature follicle is the only stage of follicular development that takes place during the follicular phase of the ovarian cycle under the influence of FSH. The dominant follicle that develops into a mature follicle generally has the most FSH receptors and

(b) Development of a follicle, ovulation, and formation and degeneration of a corpus luteum

1 In a primordial follicle, a primary oocyte is surrounded by a single layer of granulosa cells.

2 During development of a preantral follicle, under the influence of local paracrines, granulosa cells proliferate, the zona pellucida forms around the oocyte, and surrounding ovarian connective tissue cells differentiate into thecal cells.

3 During early development of an antral follicle, an estrogen-rich antrum starts to form and the follicle continues to enlarge.

4 Antral follicles that have reached a given size at the beginning of the follicular phase of

the ovarian cycle are recruited for further rapid development and antrum expansion under the influence of FSH.

5 After about 2 weeks of rapid growth under the influence of FSH, the follicle has developed into a mature follicle, which has a greatly expanded antrum; the oocyte, which by now has developed into a secondary oocyte, is displaced to one side.

6 At midcycle, in response to a burst in LH secretion, the mature follicle, bulging on the ovarian surface, ruptures and releases the oocyte, resulting in ovulation and ending the follicular phase.

7 Ushering in the luteal phase, the ruptured follicle develops into a corpus luteum under the influence of LH.

8 The corpus luteum continues to grow and secrete progesterone and estrogen that prepare the uterus for implantation of a fertilized ovum.

9 After 14 days, if a fertilized ovum does not implant in the uterus, the corpus luteum degenerates, the luteal phase ends, and a new follicular phase begins under the influence of a changing hormonal milieu.

therefore is most responsive to hormonal stimulation. The antrum occupies most of the space in a mature follicle. The oocyte, surrounded by the zona pellucida and a single layer of granulosa cells, is displaced asymmetrically at one side of the growing follicle, in a little mound that protrudes into the antrum.

Ovulation The greatly expanded mature follicle bulges on the ovarian surface, creating a thin area that ruptures to release the oocyte at ovulation (❚Figure 20-16). Rupture of the follicle is facilitated by release from the follicular cells of enzymes (triggered by a burst in LH secretion, which is described later) that digest the connective tissue in the follicular wall. The bulging wall, thus weakened, balloons out even farther to the point that it can no longer contain the rapidly expanding follicular contents.

Just before ovulation, the oocyte completes its first meiotic division. The ovum (secondary oocyte), still surrounded by its

❚ TABLE 20-4 Stages of Follicular Development

Phase	Size of Follicle (in mm)	Status of Follicle	Influence of Gonadotropins on Follicle	Hormone Production by	Status of Gamete
Resting primordial follicle	0.04	Gamete is surrounded by single layer of granulosa cells.	None	None	The primary oocyte has entered the first meiotic division and is in meiotic arrest.
Preantral follicle	0.04–1	Granulosa cells thicken and proliferate; zona pellucida forms; thecal cells develop.	None (Early growth of selected follicles occurs under paracrine influence.)	None (Follicular cells [granulosa cells and thecal cells collectively] develop capacity to secrete estrogen but do not do so.)	The primary oocyte begins to grow and stockpile nutrients.
Early developing antral follicle	1–2	The antrum starts to form, contributing to follicular growth.	The follicle is dependent on both FSH and LH for estrogen secretion but is not influenced by cyclical fluctuations in these hormones.	Estrogen production begins; part is secreted into the blood; part remains in the follicle, expanding the antrum.	The primary oocyte grows rapidly and reaches near full size.
Recruitable antral follicle	2–5	After a follicle is recruited, the antrum continues to expand and the follicle grows rapidly.	The follicle is extremely sensitive to FSH and is recruited by the increase in FSH at the onset of the follicular phase of the ovarian cycle for further rapid growth and development.	The follicle continues to produce increasing amounts of estrogen.	The primary oocyte grows slowly and remains in meiotic arrest.
Dominant, mature follicle	15–20	The antrum occupies most of the greatly expanded follicle, which bulges on the ovarian surface. The oocyte and its surrounding layers are displaced to one side.	Rapid growth of the dominant follicle is stimulated by FSH during the follicular phase of the ovarian cycle.	A marked increase in estrogen secretion takes place, which triggers the LH surge responsible for ovulation.	The oocyte completes its first meiotic division and becomes a secondary oocyte just before ovulation.

tightly adhering zona pellucida and granulosa cells (now called the **corona radiata**, meaning "radiating crown"), is swept out of the ruptured follicle into the abdominal cavity by the leaking antral fluid (see ❙Figure 20-14, step ⑥). The released ovum is quickly drawn into the oviduct, where fertilization may or may not take place.

The other developing follicles that failed to reach maturation and ovulate undergo degeneration, never to be reactivated. Occasionally, two (or perhaps more) follicles reach maturation and ovulate around the same time. If both are fertilized, **fraternal twins** result. Because fraternal twins arise from separate ova fertilized by separate sperm, they share no more in common than any other two siblings except for the same birth date. **Identical twins**, in contrast, develop from a single fertilized ovum that completely divides into two separate, genetically identical embryos at an early stage of development.

Rupture of the follicle at ovulation signals the end of the follicular phase and ushers in the luteal phase.

The luteal phase is characterized by the presence of a corpus luteum.

The ruptured follicle left behind in the ovary after release of the ovum changes rapidly as the granulosa and thecal cells remaining in the remnant follicle undergo a dramatic structural and functional transformation.

Formation of the Corpus Luteum; Estrogen and Progesterone Secretion These old follicular cells form the **corpus luteum (CL)**, a process called *luteinization* (step ⑦). The follicular-turned-luteal cells enlarge and are converted into very active steroid hormone–producing tissue. Abundant storage of cholesterol, the steroid precursor molecule, in lipid droplets within the corpus luteum gives this tissue a yellowish appearance, hence its name (*corpus* means "body"; *luteum* means "yellow").
The CL secretes into the blood abundant quantities of progesterone, along with smaller amounts of estrogen. Estrogen secretion in the follicular phase followed by progesterone secretion in the luteal phase is essential for preparing the uterus for implantation of a fertilized ovum. The CL becomes fully functional within 4 days after ovulation, but it continues to increase in size for another 4 or 5 days (step ⑧).

Degeneration of the Corpus Luteum If the released ovum is not fertilized and does not implant, the CL degenerates within about 14 days after its formation (step ⑨). The luteal cells degenerate and are phagocytized, and connective tissue rapidly fills in to form a fibrous tissue mass. The luteal phase is now over, and one ovarian cycle is complete. A new wave of development of recruited follicles, which begins when degeneration of the old CL is completed, signals the onset of a new follicular phase.

Corpus Luteum of Pregnancy If fertilization and implantation do occur, the corpus luteum continues to grow and produce increasing quantities of progesterone and estrogen instead of degenerating. Now called the *corpus luteum of pregnancy,* this ovarian structure persists until pregnancy ends. It provides the hormones essential for maintaining pregnancy until the developing placenta can take over this crucial function. You will learn more about the role of these structures later.

The ovarian cycle is regulated by complex hormonal interactions.

The ovary has two related endocrine units: (1) the estrogen-secreting follicle during the first half of the cycle and (2) the corpus luteum, which secretes both progesterone and estrogen, during the last half of the cycle. These units are sequentially triggered by complex cyclic hormonal relationships among the hypothalamus, anterior pituitary, and these two ovarian endocrine units.

As in the male, gonadal function in the female is directly controlled by the anterior pituitary gonadotropic hormones—namely, follicle-stimulating hormone and luteinizing hormone.

Figure 20-17 Correlation between hormonal levels and cyclic ovarian and uterine changes. Anterior pituitary gonadotropin hormone secretion governs the ovarian cycle and ovarian hormone secretion, which in turn drives cyclical uterine changes. Follow each horizontal strip across to see the cyclical, sequential changes that take place in the plasma concentrations of FSH and LH from the anterior pituitary, the resultant follicular and luteal changes in the ovary, the subsequent cyclical changes in the plasma concentrations of estrogen and progesterone from the ovaries, the consequential endometrial changes that occur during the uterine cycle, and the corresponding phases of the ovarian cycle that occur concurrently with and cause the phases of the uterine cycle. Follow vertically downward to see the concurrent interrelationships among these factors at any given time during the monthly female reproductive cycle. See pp. 746–750 for a detailed explanation of the numbered points.

FIGURE FOCUS: *Compare the relationship among the concentration of the gonadotropic hormones, the status of ovarian follicle/corpus luteum development, the concentration of ovarian hormones, the status of the endometrial lining, and the phases of the uterine cycle and the phases of the ovarian cycle at day 8 and day 21 of the female reproductive cycle.*

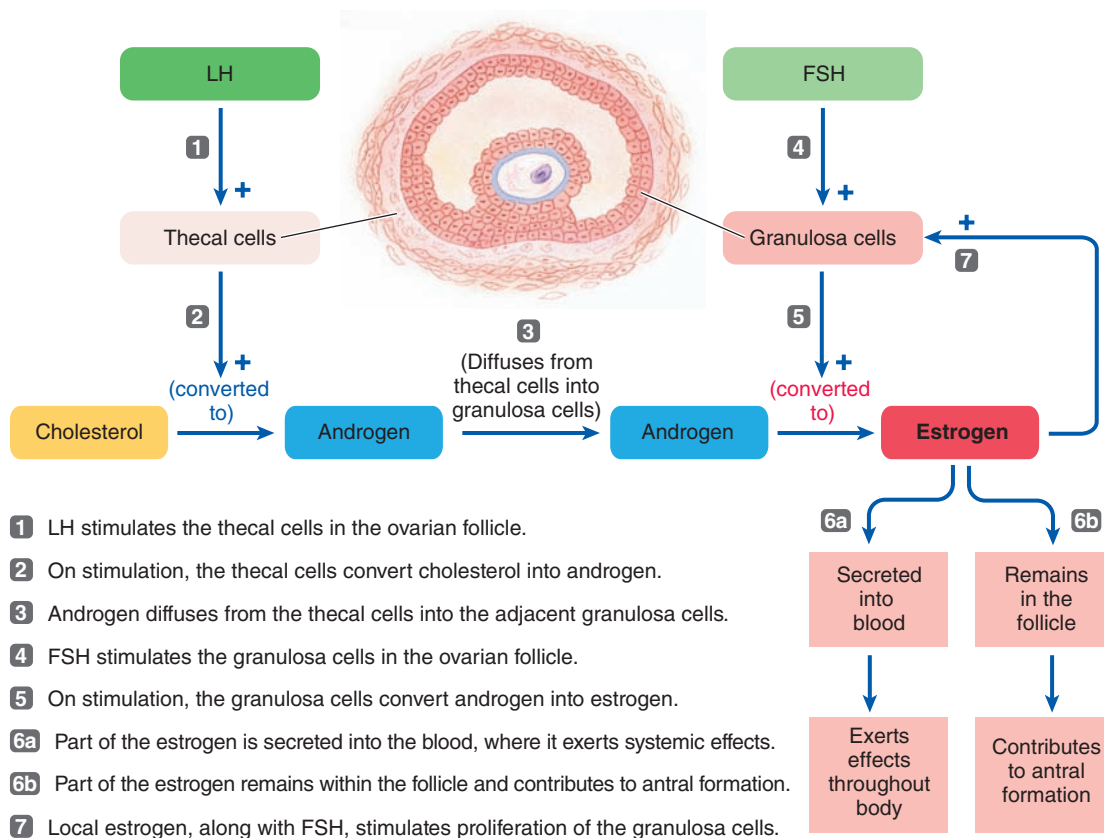
These hormones are regulated by hypothalamic gonadotropin-releasing hormone. The GnRH-secreting neurons, in turn, are stimulated by kisspeptin released by higher-level hypothalamic kiss1 neurons. Feedback actions of gonadal hormones at the anterior pituitary and hypothalamus complete the control loop. Unlike in the male, however, control of the female gonads is complicated by the cyclic nature of ovarian function. For example, the effects of FSH and LH on the ovaries depend on the stage of the ovarian cycle. Furthermore, as you will see, estrogen exerts negative-feedback effects during part of the cycle and positive-feedback effects during another part of the cycle, depending on the concentration of estrogen. Also in contrast to the male, FSH is not strictly responsible for gametogenesis, nor is LH solely responsible for gonadal hormone secretion. We consider control of follicular function, ovulation, and the corpus luteum separately, using ❙ Figure 20-17 as a means of integrating the various concurrent


Figure 20-18 Production of estrogen by an ovarian follicle.
FIGURE FOCUS: *Deduce from this figure which type of follicular cell has aromatase.*

The following steps are labeled in the figure:

1 LH stimulates the thecal cells in the ovarian follicle.

2 On stimulation, the thecal cells convert cholesterol into androgen.

3 Androgen diffuses from the thecal cells into the adjacent granulosa cells.

4 FSH stimulates the granulosa cells in the ovarian follicle.

5 On stimulation, the granulosa cells convert androgen into estrogen.

6a Part of the estrogen is secreted into the blood, where it exerts systemic effects.

6b Part of the estrogen remains within the follicle and contributes to antral formation.

7 Local estrogen, along with FSH, stimulates proliferation of the granulosa cells.

and sequential activities that take place throughout the cycle. To facilitate correlation between this rather intimidating figure and the accompanying text description of this complex cycle, the numbers in the figure correspond to the numbers in the text description.

Control of Follicular Function We begin with the follicular phase of the ovarian cycle (▮Figure 20-17, step **1**). The early stages of preantral follicular growth and oocyte maturation precede the follicular phase and do not require gonadotropic stimulation. Hormonal support is required, however, for further follicular development and antrum formation (step **2**), and for estrogen secretion (step **3**). Estrogen, FSH (step **4**), and LH (step **5**) are all needed. FSH induces antrum formation. Both FSH and estrogen stimulate proliferation of the granulosa cells. Both LH and FSH are required for synthesis and secretion of estrogen by the follicle, but these hormones act on different cells and at different steps in the estrogen production pathway (▮Figure 20-18). Both granulosa and thecal cells participate in estrogen production. The conversion of cholesterol into estrogen requires a number of sequential steps, the last of which is conversion of androgens into estrogens (see ▮Figure 19-8, p. 673). Thecal cells readily produce androgens but have limited capacity to convert them into estrogens. Granulosa cells, in contrast, contain the enzyme aromatase, so they can readily convert androgens into estrogens, but they cannot produce androgens in the first place. LH

acts on the thecal cells to stimulate androgen production, whereas FSH acts on the granulosa cells to promote conversion of thecal androgens (which diffuse into the granulosa cells from the thecal cells) into estrogens. Because low basal levels of FSH (see ▮Figure 20-17, step **6**) are sufficient to promote this final conversion to estrogen, the rate of estrogen secretion by the follicle primarily depends on the circulating level of LH, which continues to rise during the follicular phase (step **7**). Furthermore, as the follicle continues to grow, more estrogen is produced simply because more estrogen-producing follicular cells are present.

Part of the estrogen produced by the growing follicle is secreted into the blood and is responsible for the steadily increasing plasma estrogen levels during the follicular phase (step **8**). The remainder of the estrogen remains within the follicle, contributing to the antral fluid and stimulating further granulosa cell proliferation (see ▮Figure 20-18).

The secreted estrogen, in addition to acting on sex-specific tissues such as the uterus, inhibits the hypothalamus and anterior pituitary in typical negative-feedback fashion (▮Figure 20-19). The rising, moderate levels of estrogen characterizing the follicular phase act directly on the hypothalamus to inhibit the ARC nucleus kiss1 neurons, thus indirectly inhibiting GnRH secretion and thereby suppressing GnRH-prompted release of FSH and LH from the anterior pituitary. However, estrogen's primary effect is directly on the pituitary. Estrogen selectively inhibits FSH secretion by the gonadotropes.

This differential secretion of FSH and LH by the gonadotropes induced by estrogen is in part responsible for the declining plasma FSH level, unlike the rising plasma LH concentration, during the follicular phase as the estrogen level rises (see ❚Figure 20-17, step ⑥). Another contributing factor to the fall in FSH during the follicular phase is secretion of *inhibin* by the follicular cells. Inhibin preferentially inhibits FSH secretion by acting at the anterior pituitary, just as it does in the male (see ❚Figure 20-19). The decline in FSH secretion brings about atresia of all but the single dominant, most mature of the developing follicles.

In contrast to FSH, LH secretion continues to rise slowly during the follicular phase (see ❚Figure 20-17, step ⑦) despite inhibition of GnRH (and thus, indirectly, LH) secretion. This seeming paradox occurs because estrogen alone cannot completely suppress **tonic** (low-level, ongoing) **LH secretion**; to completely inhibit tonic LH secretion, both estrogen and progesterone are required. Because progesterone does not appear until the luteal phase of the cycle, the basal level of circulating LH slowly increases during the follicular phase under incomplete inhibition by estrogen alone.

Control of Ovulation Ovulation and subsequent luteinization of the ruptured follicle are triggered by an abrupt, massive increase in LH secretion (step ⑨). This **LH surge** brings about four major changes in the follicle:

1. It halts estrogen synthesis by the follicular cells (step ⑩).

2. It reinitiates meiosis in the mature follicle's oocyte by blocking release of **oocyte maturation inhibitor** produced by the granulosa cells. This substance is responsible for arresting meiosis in the primary oocytes once they are wrapped within granulosa cells in the fetal ovary.

3. It triggers production of local prostaglandins, which induce ovulation by promoting vascular changes that cause rapid follicular swelling while inducing enzymatic digestion of the follicular wall. Together, these actions lead to rupture of the weakened wall that covers the bulging follicle (step ⑪).

4. It causes differentiation of follicular cells into luteal cells. Because the LH surge triggers both ovulation and luteinization, formation of the corpus luteum automatically follows ovulation (step ⑫). Thus, the midcycle burst in LH secretion is a dramatic point in the cycle; it terminates the follicular phase and initiates the luteal phase (step ⑬).

The two modes of LH secretion—tonic LH secretion (step ⑦) that promotes ovarian hormone secretion and the LH surge (step ⑨) that causes ovulation—not only occur at different
❚Figure 20-19 **Feedback control of FSH and tonic LH secretion during the follicular phase.**

times and produce different effects but also are controlled by different mechanisms. Tonic LH secretion is partially suppressed (step ⑦) by the inhibitory action of the rising, moderate levels of estrogen (step ③) during the follicular phase and is completely suppressed (step ⑭) by the increasing levels of progesterone during the luteal phase (step ⑮). Because tonic LH secretion stimulates both estrogen and progesterone secretion, this is a typical negative-feedback effect. Estrogen and progesterone both suppress LH secretion by inhibiting the ARC nucleus kiss1 neurons.

third ventricular cavity. Thus, females have two sets of kiss1 neurons, one set in the ARC nucleus (the same as in males) that is inhibited by estrogen (and progesterone in females or testosterone in males) for negative feedback and one set in the AVPV nucleus that is stimulated by high levels of estrogen for positive feedback. The high plasma concentration of estrogen acts directly on the AVPV nucleus kiss1 neurons to increase kisspeptin and thereby GnRH release, which increases both LH and FSH secretion. Thus, LH enhances estrogen production by the follicle, and the resultant peak estrogen concentration brings about increased LH secretion. A high estrogen level also acts directly on the anterior pituitary to specifically increase LH secretion by the gonadotropes. The latter effect largely accounts for the much greater surge in LH secretion compared to FSH secretion at midcycle (see ❚Figure 20-17, step **9**). Also, continued inhibin secretion by the follicular cells preferentially inhibits FSH secretion, keeping the FSH levels from rising as high as the LH levels. There is no known role for the modest midcycle surge in FSH that accompanies the pronounced and pivotal LH surge. Because only a mature, preovulatory follicle, not follicles in earlier stages of development, can secrete high-enough levels of estrogen to trigger the LH surge, ovulation is not induced until a follicle has reached the proper size and degree of maturation. In a way, then, the follicle lets the hypothalamus know when it is ready to be stimulated to ovulate. The LH surge lasts for about a day at midcycle, just before ovulation.

Control of the Corpus Luteum LH "maintains" the corpus luteum—that is, after triggering development of the CL, LH stimulates ongoing steroid hormone secretion by this ovarian structure. Under the influence of LH, the CL secretes both progesterone (see ❚Figure 20-17, step **15**) and estrogen (step **16**), with progesterone being its most abundant hormonal product. The plasma progesterone level increases for the first time during the luteal phase. No progesterone is secreted during the follicular phase (except for a small amount a few hours before ovulation). Therefore, the follicular phase is dominated by estrogen and the luteal phase by progesterone.

A transitory drop in the level of circulating estrogen occurs at midcycle (step **10**) as the estrogen-secreting follicle meets its demise at ovulation. The estrogen level climbs again during the luteal phase because of the CL's activity, although it

In contrast, the LH surge is triggered by a *positive-feedback effect*. Whereas the rising, moderate level of estrogen early in the follicular phase *inhibits* LH secretion, the high level of estrogen that occurs during peak estrogen secretion late in the follicular phase (step **8**) *stimulates* LH secretion and initiates the LH surge (❚Figure 20-20). A high estrogen level generates the LH surge by stimulating another set of kisspeptin-releasing neurons unique to females located in the **anteroventral periventricular (AVPV) nucleus**. The AVPV nucleus is positioned in the hypothalamus along the anterior part of the wall of the

does not reach the same peak as during the follicular phase. What keeps the modestly high estrogen level during the luteal phase from triggering another LH surge? Progesterone. Even though a high level of estrogen stimulates LH secretion, progesterone, which dominates the luteal phase, powerfully inhibits LH secretion (step **14**) as well as FSH secretion (step **17**) by acting at both the hypothalamic ARC nucleus and the anterior pituitary (❚ Figure 20-21). Furthermore, the luteal cells secrete inhibin, which selectively inhibits FSH secretion. Inhibition of FSH and LH prevents new follicular maturation and ovulation during the luteal phase. Under progesterone's influence, the reproductive system is gearing up to support the just-released ovum, should it be fertilized, instead of preparing other ova for release.

The corpus luteum functions for an average of 2 weeks and then degenerates if fertilization does not occur (see ❚ Figure 20-17, step **18**). The mechanisms that govern degeneration of the CL are not fully understood. The declining level of circulating LH (step **14**), driven down by inhibitory actions of progesterone, undoubtedly contributes to the CL's downfall. Prostaglandins and estrogen released by the luteal cells themselves may play a role. Demise of the CL terminates the luteal phase and sets the stage for a new follicular phase. As the CL degenerates, plasma progesterone (step **19**) and estrogen (step **20**) levels fall rapidly because these hormones are no longer being produced. Withdrawal of the inhibitory effects of these hormones on the hypothalamus allows FSH (step **21**) and tonic LH (step **22**) secretion to modestly increase again. Under the influence of these gonadotropic hormones, another batch of early developing follicles (step **2**) is recruited and induced to mature as a new follicular phase begins (step **1**).

Cyclic uterine changes are caused by hormonal changes during the ovarian cycle.

The fluctuations in circulating levels of estrogen and progesterone during the ovarian cycle induce profound changes in the uterus, giving rise to the **menstrual**, or **uterine**, **cycle**. Because it reflects hormonal changes during the ovarian cycle, the menstrual cycle averages 28 days, as does the ovarian cycle, although even normal adults vary considerably from this mean. The outward manifestation of the cyclic changes in the uterus is the menstrual bleeding once during each menstrual cycle (that is, once a month). Less obvious changes take place throughout the cycle, however, as the uterus is prepared for implantation, should a released ovum be fertilized, and then is stripped clean of its prepared lining (menstruation) if implantation does not occur, only to repair itself and start preparing for the ovum that will be released during the next cycle.
❚Figure 20-21 Feedback control during the luteal phase.

We briefly examine the influences of estrogen and progesterone on the uterus and then consider the effects of cyclic fluctuations of these hormones on uterine structure and function.

Influences of Estrogen and Progesterone on the Uterus The uterus consists of two main layers: the **myometrium**, the outer smooth muscle layer, and the **endometrium**, the inner lining that contains numerous blood vessels and glands. Estrogen stimulates growth of both the myometrium and the endometrium. It also induces synthesis of progesterone

receptors in the endometrium. Thus, progesterone can exert an effect on the endometrium only after it has been "primed" by estrogen. Progesterone acts on the estrogen-primed endometrium to convert it into a hospitable and nutritious lining suitable for implantation of a fertilized ovum. Under the influence of progesterone, the endometrial connective tissue becomes loose and edematous as a result of an accumulation of electrolytes and water, which facilitates implantation of the fertilized ovum. Progesterone further prepares the endometrium to sustain an early-developing embryo by stimulating the endometrial glands to secrete and store large quantities of glycogen (stored glucose) and by causing tremendous growth of the endometrial blood vessels. Progesterone also reduces the contractility of the uterus to provide a quiet environment for implantation and embryonic growth.

The menstrual cycle consists of three phases: the *menstrual phase*; the *proliferative phase*; and the *secretory,* or *progestational, phase.*

Menstrual Phase The **menstrual phase** is the most overt phase, characterized by discharge of blood and endometrial debris from the vagina (see ❙ Figure 20-17, step 23). By convention, the first day of menstruation is considered the start of a new cycle. It coincides with the end of the ovarian luteal phase and onset of a new follicular phase. As the corpus luteum degenerates because fertilization and implantation of the ovum released during the preceding cycle did not take place (step 18), circulating levels of progesterone and estrogen drop precipitously (steps 19 and 20). Because the net effect of progesterone and estrogen is to prepare the endometrium for implantation of a fertilized ovum, withdrawal of these steroids deprives the highly vascular, nutrient-rich uterine lining of its hormonal support.

The fall in ovarian hormone levels also stimulates release of a uterine prostaglandin that causes vasoconstriction of the endometrial vessels, disrupting the blood supply to the endometrium. The subsequent reduction in O_2 delivery causes death of the endometrium, including its blood vessels. The resulting bleeding through the disintegrating vessels flushes the dying endometrial tissue into the uterine lumen. Most of the uterine lining sloughs during each menstrual period except for a deep, thin layer of epithelial cells and glands, from which the endometrium regenerates. The same local uterine prostaglandin also stimulates mild rhythmic contractions of the uterine myometrium. These contractions help expel the blood and endometrial debris from the uterine cavity out through the vagina as **menstrual flow**. Excessive uterine contractions caused by prostaglandin overproduction produce the **dysmenorrhea** (*menstrual cramps*) some women experience.

The average blood loss during a single menstrual period is 50 to 150 mL. Blood that seeps slowly through the degenerating endometrium clots within the uterine cavity, then is acted on by fibrinolysin, a fibrin dissolver that breaks down the fibrin forming the meshwork of the clot. Therefore, blood in the menstrual flow usually does not clot because it has already clotted and the clot has been dissolved before it passes out of the vagina. When blood flows rapidly through the leaking vessels, however, it may

not be exposed to sufficient fibrinolysin, so when the menstrual flow is most profuse, blood clots may appear. In addition to the blood and endometrial debris, large numbers of leukocytes are found in the menstrual flow. These white blood cells play an important defense role in helping the raw endometrium resist infection.

Menstruation typically lasts for about 5 to 7 days after degeneration of the CL, coinciding in time with the early portion of the ovarian follicular phase (steps 23 and 1). Withdrawal of progesterone and estrogen (steps 19 and 20) on degeneration of the CL leads simultaneously to sloughing of the endometrium (menstruation) (step 23) and rapid development of newly recruited antral follicles in the ovary (step 2) under the influence of rising gonadotropic hormone levels (steps 21 and 22). The drop in gonadal hormone secretion removes inhibitory influences from the hypothalamus and anterior pituitary, so FSH and LH secretion increases and a new follicular phase begins (step 1 again). After 5 to 7 days under the influence of FSH and LH, the newly recruited, rapidly growing antral follicles are secreting enough estrogen (step 3) to promote repair and growth of the endometrium.

Proliferative Phase Thus, menstrual flow ceases, and the **proliferative phase** of the uterine cycle begins concurrent with the last portion of the ovarian follicular phase as the endometrium starts to repair itself and proliferate (step 24) under the influence of estrogen from the newly recruited antral follicles. When the menstrual flow ceases, a thin endometrial layer less than 1 mm thick remains. Estrogen stimulates proliferation of epithelial cells, glands, and blood vessels in the endometrium, increasing this lining to a thickness of 3 to 5 mm. The estrogen-dominant proliferative phase lasts from the end of menstruation to ovulation. Peak estrogen levels (step 8) trigger the LH surge (step 9) responsible for ovulation (step 11).

Secretory, or Progestational, Phase After ovulation, when a new CL is formed (step 12), the uterus enters the **secretory**, or **progestational**, **phase** (step 25), which coincides in time with the ovarian luteal phase (step 13). The CL secretes large amounts of progesterone (step 15) and estrogen (step 16). Progesterone converts the thickened, estrogen-primed endometrium to a richly vascularized, glycogen-filled tissue. This period is called either the *secretory phase* because the endometrial glands are actively secreting glycogen into the uterine lumen for early nourishment of a developing embryo before it implants, or the *progestational* ("before pregnancy") *phase,* referring to the development of a lush endometrial lining capable of supporting an early embryo after implantation. If fertilization and implantation do not occur, the CL degenerates and a new follicular phase and menstrual phase begin again.

Various factors can interfere with the delicate balance of the hypothalamic–pituitary–ovarian–peripheral target organ axis, leading to menstrual irregularities and fertility problems. Among these factors are starvation (a problem for example with anorexia nervosa; see p. 627), stress, and heavy exercise. (For the effects of exercise on this cycle, see the accompanying boxed feature, ❙ A Closer Look at Exercise Physiology).

Menstrual Irregularities: When Cyclists and Other Female Athletes Do Not Cycle

SINCE THE 1970S, AS WOMEN in growing numbers have participated in a variety of sports requiring vigorous training regimens, researchers have become increasingly aware that many women experience changes in their menstrual cycles as a result of athletic participation. These changes are referred to as **athletic menstrual cycle irregularity (AMI)**. The menstrual cycle dysfunction can vary in severity from amenorrhea (cessation of menstrual periods) to oligomenorrhea (cycles at irregular or infrequent intervals) to cycles that are normal in length but are anovulatory (no ovulation) or that have a short or inadequate luteal phase.

In early research studies using surveys and questionnaires to determine the prevalence of the problem, the frequency of these sport-related disorders varied from 2% to 51%. In contrast, the rate of occurrence of menstrual cycle dysfunction in females of reproductive age in the general population is 2% to 5%. A major problem of using surveys to determine the frequency of menstrual cycle irregularity is the questionable accuracy of recall of menstrual periods. Furthermore, without blood tests to determine hormone levels throughout the cycle, a woman would not know whether she was anovulatory or had had a shortened luteal phase. Studies in which hormone levels have been determined throughout the menstrual cycle have demonstrated that seemingly normal cycles in athletes frequently have a short luteal phase (less than two days long with low progesterone levels).

In a study conducted to determine whether strenuous exercise spanning two menstrual cycles would induce menstrual disorders, 28 initially untrained college women with documented ovulation and luteal adequacy served as subjects. The women participated in an eight-week exercise program in which they initially ran 4 miles per day and progressed to 10 miles per day by the fifth week. They were expected to participate daily in 3.5 hours of moderate-intensity sports. Only four women had normal menstrual cycles during the training. Abnormalities resulting from training included abnormal bleeding, delayed menstrual periods, abnormal luteal function, and loss of LH surge. All the women returned to normal cycles within six months after training. The results of this study suggest that the frequency of AMI with strenuous exercise may be much greater than indicated by questionnaire alone. In other studies using low-intensity exercise regimens, AMI was much less frequent.

The mechanisms of AMI are unknown at present, although studies have implicated rapid weight loss, decreased percentage of body fat, dietary insufficiencies, prior menstrual dysfunction, stress, age at onset of training, and the intensity of training as factors that play a role. Epidemiologists have shown that if girls participate in vigorous sports before **menarche** (the first menstrual period), menarche is delayed. On average, athletes have their first period when they are about three years older than their nonathletic counterparts. Furthermore, females who participate in sports before menarche seem to have a higher frequency of AMI throughout their athletic careers than those who begin to train after menarche. Hormonal changes found in female athletes include (1) severely depressed FSH levels, (2) elevated LH levels, (3) low progesterone during the luteal phase, (4) low estrogen levels in the follicular phase, and (5) an FSH–LH environment totally unbalanced as compared to those of age-matched nonathletic women. The preponderance of evidence indicates that cycles return to normal once vigorous training is stopped.

The major problem associated with athletic amenorrhea is a reduction in bone mineral density. Studies have shown that the mineral density in the vertebrae of the lower spine of those with athletic amenorrhea is lower than in athletes with normal menstrual cycles and lower than in age-matched nonathletes. However, amenorrheic runners have higher bone mineral density than amenorrheic nonathletes, presumably because the mechanical stimulus of exercise helps retard bone loss. Studies have shown that amenorrheic athletes are at higher risk for stress-related fractures than athletes with normal menstrual cycles. One study, for example, found stress fractures in 6 of 11 amenorrheic runners but in only 1 of 6 runners with normal menstrual cycles. The mechanism for bone loss is probably the same as is found in postmenopausal osteoporosis—lack of estrogen (see p. 706). The problem is serious enough that an amenorrheic athlete should discuss the possibility of estrogen replacement therapy with her physician.

There may be some positive benefits of athletes' menstrual dysfunction. A recent epidemiological study to determine if the long-term reproductive and general health of women who had been college athletes differed from that of college nonathletes showed that former athletes had less than half the lifetime occurrence rate of cancers of the reproductive system and half the breast cancer occurrence compared to nonathletes. Because these are hormone-sensitive cancers, the delayed menarche and lower estrogen levels found in women athletes may play a key role in decreasing the risk of cancer of the reproductive system and breast.

Fluctuating estrogen and progesterone levels produce cyclical changes in cervical mucus.

Hormonally induced changes also take place in the cervix during the ovarian cycle. Under the influence of estrogen during the follicular phase, the mucus secreted by the cervix becomes abundant, clear, and thin. This change, which is most pronounced when estrogen is at its peak and ovulation is approaching, facilitates passage of sperm through the cervical canal. After ovulation, under the influence of progesterone from the CL, the mucus becomes thick and sticky, essentially plugging up the cervical opening. This plug is an important defense

mechanism, preventing bacteria (that might threaten a possible pregnancy) from entering the uterus from the vagina. Sperm also cannot penetrate this thick mucus barrier.

Pubertal changes in females are similar to those in males.

Regular menstrual cycles are absent in both young and aging females, but for different reasons. The female reproductive system does not become active until puberty. Unlike the fetal testes, the fetal ovaries need not be functional because in the absence of fetal testosterone secretion in a female, the reproductive system is automatically feminized, without requiring the presence of female sex hormones. Puberty occurs in females when hypothalamic GnRH activity increases for the first time. As in the male, the mechanisms that govern the onset of puberty are not clearly understood but are believed to involve melatonin's and leptin's influence on the ARC nucleus kiss1 neurons. Leptin's action might account at least in part for the fact that, on average, heavier girls tend to enter puberty earlier than their leaner counterparts do.

GnRH begins stimulating release of anterior pituitary gonadotropic hormones, which in turn stimulate ovarian activity. The resulting secretion of estrogen by the activated ovaries induces growth and maturation of the female reproductive tract, and development of the female secondary sexual characteristics. Estrogen's prominent action in the latter regard is to promote fat deposition in strategic locations, such as the breasts, buttocks, and thighs, giving rise to the typical curvaceous female figure. Enlargement of the breasts at puberty is the result primarily of fat deposition in the breast tissue, not functional development of the mammary glands. The pubertal rise in estrogen also closes the epiphyseal plates, halting further growth in height, similar to the effect of testosterone-turned-estrogen in males. Three other pubertal changes in females—growth of axillary and pubic hair, the pubertal growth spurt, and development of libido—are attributable to a spurt in adrenal androgen secretion at puberty, not to estrogen.

Menopause is unique to females.

The cessation of a woman's menstrual cycles at **menopause** sometime between the ages of 45 and 55 has traditionally been attributed to the limited supply of ovarian follicles present at birth. According to this proposal, once this reservoir is depleted, ovarian cycles, and hence menstrual cycles, cease. Thus, the termination of reproductive potential in a middle-aged woman is "preprogrammed" at her own birth. Recent evidence suggests, however, that a midlife hypothalamic change instead of aging ovaries may trigger the onset of menopause. Evolutionarily, menopause may have developed as a mechanism that prevented pregnancy in women beyond the time that they could likely rear a child before their own death.

Males do not experience complete gonadal failure as females do, for two reasons. First, a male's germ cell supply is unlimited because mitotic activity of the spermatogonia continues. Second, gonadal hormone secretion in males is not inextricably dependent on gametogenesis, as it is in females. If female sex hormones were produced by separate tissues unrelated to those governing gametogenesis, as are male sex hormones, estrogen and progesterone secretion would not automatically stop when oogenesis stopped.

Menopause is preceded by a period of progressive ovarian failure characterized by increasingly irregular cycles and dwindling estrogen levels. During the period of transition from sexual maturity to cessation of reproductive capability, ovarian estrogen production declines from as much as 300 mg per day to essentially nothing. Postmenopausal women are not completely devoid of estrogen, however, because adipose tissue, the liver, and the adrenal cortex continue to produce up to 20 mg of estrogen per day. In addition to the ending of ovarian and menstrual cycles, the loss of ovarian estrogen following menopause brings about many physical and emotional changes. These changes include vaginal dryness, which can cause discomfort during sex, and gradual atrophy of the genital organs. However, postmenopausal women still have a sex drive because of their adrenal androgens.

Clinical Note Because estrogen has widespread physiological actions beyond the reproductive system, the dramatic loss of ovarian estrogen in menopause affects other body systems, most notably the skeleton and the cardiovascular system. Estrogen helps build strong bones, shielding premenopausal women from the bone-thinning condition of osteoporosis (see p. 706). The postmenopausal reduction in estrogen increases activity of the bone-dissolving osteoclasts and diminishes activity of the bone-building osteoblasts. The result is decreased bone density and a greater incidence of bone fractures.

Estrogen also helps modulate the actions of epinephrine and norepinephrine on the arteriolar walls by promoting local release of the vasodilator nitric oxide. The menopausal diminution of estrogen leads to unstable control of blood flow, especially in the skin vessels. Transient increases in the flow of warm blood through these superficial vessels are responsible for the "hot flashes" that frequently accompany menopause. Vasomotor stability is gradually restored in postmenopausal women so that hot flashes eventually cease.

You have now learned about the events that take place if fertilization does not occur. Because the primary function of the reproductive system is, of course, reproduction, we next turn attention to the sequence of events that take place when fertilization does occur.

The oviduct is the site of fertilization.

Fertilization, the union of male and female gametes, normally occurs in the **ampulla**, the upper third of the oviduct (❙ Figure 20-22). Thus, both the ovum and the sperm must be transported from their gonadal site of production to the ampulla.

Ovum Transport to the Oviduct Unlike the male reproductive tract, which has a continuous lumen from the site of sperm production in the seminiferous tubules to exit of the sperm from the urethra at ejaculation, the ovaries are not in direct contact with the reproductive tract. The ovum is released into the abdominal cavity at ovulation. Normally, however, the oviduct quickly picks up the egg. The dilated end of the oviduct

Oviduct — Optimal site of fertilization — Ampulla of oviduct — Sperm surrounding ovum — Fimbria — Uterus — Ovary — Ovulated ovum — Cervical canal — Vagina 165 million sperm deposited — Penis

❙Figure 20-22 **Ovum and sperm transport to the site of fertilization**.
cups around the ovary and contains **fimbriae**, fingerlike projections that contract in a sweeping motion to guide the released ovum into the oviduct (see ❙Figures 20-2b, p. 719, and 20-22). Furthermore, the fimbriae are lined by cilia—fine, hairlike projections that beat in waves toward the interior of the oviduct—further assuring the ovum's passage into the oviduct (see p. 48). Within the oviduct, the ovum is rapidly propelled by peristaltic contractions and ciliary action to the ampulla.

Conception can take place during a limited time span in each cycle (the **fertile period**). If not fertilized, the ovum begins to disintegrate within 12 to 24 hours and is subsequently phagocytized by cells that line the reproductive tract. Fertilization must therefore occur within 24 hours after ovulation, when the ovum is still viable. Sperm typically survive about 48 hours but can survive up to 5 days in the female reproductive tract, so sperm deposited from 5 days before ovulation to 24 hours after ovulation may be able to fertilize the released ovum, although these times vary considerably.

Clinical Note Occasionally, an ovum fails to be transported into the oviduct and remains instead in the abdominal cavity. Rarely, such an ovum gets fertilized, resulting in an **ectopic abdominal pregnancy**, in which the fertilized egg implants in the rich vascular supply to the digestive organs rather than in its usual site in the uterus (*ectopic* means "out of place"). An abdominal pregnancy often leads to life-threatening hemorrhage because the digestive organ blood supply is not primed to respond appropriately to implantation as the endometrium is. If this unusual pregnancy proceeds to term, the baby must be delivered surgically because the normal vaginal exit is not available. The probability of maternal complications at birth is greatly increased because the digestive vasculature is not designed to "seal itself off" after birth as the endometrium does.

Sperm Transport to the Oviduct After sperm are deposited in the vagina at ejaculation, they must travel through the cervical canal, through the uterus, and then up to the egg in the upper third of the oviduct (❙Figure 20-22). The first sperm

arrive in the oviduct within half an hour after ejaculation. Even though sperm are mobile by means of whiplike contractions of their tails, 30 minutes is too soon for a sperm's mobility to transport it to the site of fertilization. To make this formidable journey, sperm need the help of the female reproductive tract.

The first hurdle is passage through the cervical canal. Throughout most of the cycle, the cervical mucus is too thick to permit sperm penetration. The cervical mucus becomes thin and watery enough to permit sperm to penetrate only when estrogen levels are high, as in the presence of a mature follicle about to ovulate. Sperm migrate up the cervical canal under their own power. The canal remains penetrable for only 2 or 3 days during each cycle, around the time of ovulation.

Once sperm have entered the uterus, contractions of the myometrium churn them around in "washing-machine" fashion. This action quickly disperses sperm throughout the uterine cavity. When sperm reach the oviduct, they are propelled to the fertilization site in the upper end of the oviduct by upward contractions of the oviduct smooth muscle. These myometrial and oviduct contractions that facilitate sperm transport are induced by the high estrogen level just before ovulation, aided by seminal prostaglandins.

New research indicates that when sperm reach the ampulla, ova are not passive partners in conception. Sperm have a specific olfactory receptor (OR) called **hOR17-4** that is identical to one found in the nose for smell perception (see p. 227). This receptor binds to the odorant **bourgeonal**, a molecule that gives rise to the floral odor of lilies of the valley. In the ampulla, bourgeonal serves as a chemoattractant or chemotaxin (see p. 410), attracting sperm and causing them to propel themselves toward the waiting female gamete. Thus sperm "smell" their way to the egg. The source of bourgeonal in the human female reproductive tract appears to be the layer of follicular cells (corona radiata) surrounding the egg at ovulation. Activation of hOR17-4 on binding with bourgeonal triggers a cAMP second-messenger pathway in sperm that brings about intracellular Ca^{2+} release. This Ca^{2+} turns on the microtubule sliding that brings about tail movement and sperm swimming in the direction of a higher concentration of bourgeonal, toward the waiting "perfumed" egg (see p. 49).

Progesterone released into the oviduct from the follicular cells that surround the egg at ovulation is another major chemoattractant. This progesterone binds with fast-responding nongenomic surface membrane receptors on the sperm, unlike this steroid's usual binding to slow-responding intracellular receptors in other target cells. On binding, progesterone opens Ca^{2+}-permeable cation channels called **CatSper** channels found exclusively in the plasma membrane of a sperm tail. The resultant, swift Ca^{2+} entry is crucial for the following fertilization-related events in sperm: (1) capacitation, (2) hyperactivated motility, and (3) the acrosome reaction. Thus CatSper activation is essential for male fertility. You already know about capacitation and will soon learn about the acrosome reaction. We focus now on the motility changes that occur. When Ca^{2+} floods into the cell on progesterone-induced opening of CatSper channels, sperm switch from their usual smooth swimming motion to a highly asymmetric, frantic beating of the tail called

The Reproductive System | **753**

hyperactivated motility. This more powerful type of motility generates the extra thrust needed for sperm to penetrate the corona radiata and zona pellucida to enter the egg.

Fertilization Even around ovulation time, when sperm can penetrate the cervical canal, of the 165 million sperm typically deposited in a single ejaculate, only a few thousand make it to the site of fertilization. That only a very small percentage of the deposited sperm ever reach their destination is one reason sperm concentration must be so high (20 million/mL of semen) for a man to be fertile. The other reason is that the acrosomal enzymes of many sperm are needed to break down the barriers surrounding the ovum.

The tail of the sperm is used to maneuver for final penetration of the ovum. To fertilize an ovum, a sperm must first pass through the corona radiata and zona pellucida surrounding it. The sperm penetrates the corona radiata by means of membrane-bound enzymes in the surface membrane that surrounds the head (❙Figure 20-23a, step **1** and chapter opener photo, p. 715). Sperm can penetrate the zona pellucida only after binding with specific binding sites on the surface of this layer. As for the binding partners, *fertilin,* a plasma membrane protein on the sperm head, binds with *ZP3,* a glycoprotein in the outer layer of the zona pellucida. Only sperm of the same species can bind to these zona pellucida sites and pass through. Binding of the sperm head to ZP3 triggers the Ca^{2+}-dependent **acrosome reaction**, in which the acrosomal membrane disrupts and the acrosomal enzymes are released (❙Figure 20-23 part a, step **2**, and part b). Calcium that enters the sperm tail through the opened CatSper channels rapidly moves within a few seconds to the head, where it participates in the acrosome reaction. The acrosomal enzymes digest the zona pellucida, enabling the sperm, with its tail still beating, to tunnel a path through this protective barrier (step **3**). The first sperm to reach the ovum itself fuses with the plasma membrane of the ovum (actually a secondary oocyte), and its head (bearing its DNA) enters the ovum's cytoplasm (step **4**). The sperm's tail is frequently lost in this process, but the head carries the crucial genetic information. Sperm–egg fusion triggers a chemical change in the ovum's surrounding membrane that makes this outer layer impenetrable to the entry of any more sperm. Following is how this phenomenon, known as **block to polyspermy** ("many sperm") is accomplished. The outermost, or cortical, region of the ovum contains enzyme-filled *cortical granules*. Fertilization-

1 The fertilizing sperm penetrates the corona radiata via membrane-bound enzymes in the plasma membrane of its head and binds to ZP3 receptors on the zona pellucida.

2 Binding of sperm to these receptors triggers the acrosome reaction, in which hydrolytic enzymes in the acrosome are released onto the zona pellucida.

3 The acrosomal enzymes digest the zona pellucida, creating a pathway to the plasma membrane of the ovum. When the sperm reaches the ovum, the plasma membranes of the two cells fuse.

4 The sperm head with its DNA enters the ovum cytoplasm.

5 The sperm stimulates release of enzymes stored in cortical granules in the ovum, which in turn, inactivate ZP3 receptors and harden the zona pellucida, leading to the block to polyspermy.

❙Figure 20-23 **Process of fertilization**.
Figure 20-24 Early stages of development from fertilization to implantation. Note that the fertilized ovum progressively divides and differentiates into a blastocyst as it moves from the site of fertilization in the upper oviduct to the site of implantation in the uterus.

induced release of intracellular Ca^{2+} into the ovum cytosol triggers the exocytosis of these cortical granules into the space between the egg membrane and the zona pellucida (step **5**). These enzymes diffuse into the zona pellucida, where they inactivate the ZP3 receptors so that other sperm reaching the zona pellucida cannot bind with it. The enzymes also harden the zona pellucida and seal off tunnels in progress to keep other penetrating sperm from advancing.

Furthermore, the released Ca^{2+} in the ovum cytosol triggers the second meiotic division of the egg, which is now ready to unite with the sperm to complete the fertilization process.

Within an hour, the sperm and egg nuclei fuse, thanks to a centrosome (microtubule organizing center; see p. 46) provided by the sperm that forms microtubules to bring the male and female chromosome sets together for uniting. In addition to contributing its half of the chromosomes to the fertilized ovum, now called a **zygote**, the victorious sperm also activates ovum enzymes essential for the early embryonic developmental program. Thus, fertilization accomplishes the dual events of combining genes from the two parents to form a genetically unique organism and setting in motion the development of that organism.

The blastocyst implants in the endometrium by means of its trophoblastic enzymes.

During the first 3 to 4 days following fertilization, the zygote remains within the ampulla because a constriction between the ampulla and the remainder of the oviduct canal prevents further movement of the zygote toward the uterus.

The Beginning Steps in the Ampulla The zygote is not idle during this time. It rapidly undergoes a number of mitotic cell divisions to form a solid ball of cells called the *morula* (Figure 20-24). Meanwhile, the rising levels of progesterone from the newly developed CL that formed after ovulation stimulate release of glycogen from the endometrium into the reproductive tract lumen for use as energy by the early embryo. The nutrients stored in the cytoplasm of the ovum can sustain the embryo for less than a day. The concentration of secreted nutrients increases more rapidly in the small confines of the ampulla than in the uterine lumen.

Descent of the Morula to the Uterus About 3 to 4 days after ovulation, progesterone is being produced in sufficient quantities to relax the oviduct constriction, thus permitting the morula to be rapidly propelled into the uterus by oviductal peristaltic contractions and ciliary activity. The temporary delay before the developing embryo passes into the uterus lets enough nutrients accumulate in the uterine lumen to support the embryo until implantation can take place. If the morula arrives prematurely, it dies.

When the morula descends to the uterus, it floats freely within the uterine cavity for another 3 to 4 days, living on endometrial secretions and continuing to divide. During the first 6 to 7 days after ovulation, while the developing embryo is in transit in the oviduct and floating in the uterine lumen, the uterine lining is simultaneously being prepared for implantation under the influence of luteal-phase progesterone. During this time, the uterus is in its secretory, or progestational phase, storing up glycogen and becoming richly vascularized.

❙Figure 20-25 **Implantation of the blastocyst**.

_{Clinical Note} Occasionally, the morula fails to descend into the uterus and continues to develop and implant in the lining of the oviduct. This leads to an **ectopic tubal pregnancy**, which must be terminated. Ninety-five percent of ectopic pregnancies are tubal pregnancies. Such a pregnancy can never succeed because the oviduct cannot expand as the uterus does to accommodate the growing embryo. The first warning of a tubal pregnancy is pain caused by the growing embryo stretching the oviduct. If not removed, the enlarging embryo will rupture the oviduct, causing possibly lethal hemorrhage.

Implantation of the Blastocyst in the Prepared Endometrium By the time the endometrium is suitable for implantation (about a week after ovulation), the morula has descended to the uterus and continued to proliferate and differentiate into a *blastocyst* capable of implantation. The week's delay after fertilization and before implantation allows time for both the endometrium and the developing embryo to prepare for implantation.

A **blastocyst** is a single-layer hollow ball of about 50 cells encircling a fluid-filled cavity, with a dense mass of cells known as the **inner cell mass** grouped together at one side (❙Figure 20-24). The inner cell mass becomes the embryo and then fetus. The rest of the blastocyst is never incorporated into the fetus, instead serving a supportive role during intrauterine life. The thin outermost layer, the **trophoblast**, accomplishes implantation, after which it develops into the fetal portion of the placenta.

When the blastocyst is ready to implant, its surface becomes sticky. By this time, the endometrium is ready to accept the early embryo and it too has become more adhesive through increased formation of cell adhesion molecules (CAMs) that help "Velcro" the blastocyst when it first contacts the uterine lining. The blastocyst adheres to the uterine lining on the side of its inner cell mass (❙Figure 20-25, step **1**). **Implantation** begins when, on contact with the endometrium, the trophoblastic cells overlying the inner cell mass release protein-digesting enzymes. These enzymes digest pathways between the endometrial cells, permitting fingerlike cords of trophoblastic cells to penetrate into the depths of the endometrium, where they continue to digest uterine cells (step **2**). Through its cannibalistic actions, the trophoblast performs the dual functions of accomplishing implantation as it carves out a hole in the endometrium for the blastocyst and making metabolic fuel and raw materials available for the developing embryo as the advancing trophoblastic projections break down the nutrient-rich endometrial tissue. The plasma membranes of the advancing trophoblastic cells degenerate, forming a multinucleated syncytium that eventually becomes the fetal portion of the placenta.

Stimulated by the invading trophoblast, the endometrial tissue at the contact site undergoes dramatic changes that enhance its ability to support the implanting embryo. In response to a chemical messenger released by the blastocyst, the underlying endometrial cells secrete prostaglandins, which locally increase vascularization, produce edema, and enhance nutrient storage. The endometrial tissue so modified at the implantation site is called the **decidua**. It is into this super-rich decidual tissue that the blastocyst becomes embedded. After the

blastocyst burrows into the decidua by means of trophoblastic activity, a layer of endometrial cells covers over the surface of the hole, completely burying the blastocyst within the uterine lining (step ❸). The trophoblastic layer continues to digest the surrounding decidual cells, providing energy for the embryo until the placenta develops.

Contraception Couples wishing to engage in sexual intercourse but avoid pregnancy have available a number of methods of **contraception** ("against conception"). These methods act by blocking one of three major steps in the reproductive process: sperm transport to the ovum, ovulation, or implantation. (See the boxed feature on pp. 758 and 759, ▮Concepts, Challenges, and Controversies, for further details on the ways and means of contraception.)

Preventing Rejection of the Embryo–Fetus What prevents the mother from immunologically rejecting the embryo–fetus, which is actually a "foreigner" to the mother's immune system, being half derived from genetically different paternal chromosomes? Numerous, considerably redundant, and incompletely understood pathways are involved in the fetomaternal immune cross-talk that confers maternal tolerance of the embryo–fetus. Following are examples of pathways currently thought to play a role:

■ *Natural killer (NK) cells,* the cells of the innate immune system that kill foreign cells such as bacteria (see p. 413), accumulate in the maternal decidua. However, *decidual NK (dNK) cells* have an altered function: They are unable to kill fetal cells, unlike NK cell's usual cell-killing role. Instead, they promote fetal tolerance through various means. For example, dNKs lock *decidual dendritic cells* in a tolerance producing state. Dendritic cells are special immune cells that normally play a central role in triggering adaptive immunity (see p. 427). Synergistically, dNKs and decidual dendritic cells induce apoptosis of *maternal cytotoxic T cells* capable of destroying the embryo–fetus, sparing it from immune rejection. Cytotoxic T cells are the killer cells of the adaptive immune system that are programmed to destroy specific foreign cells (see p. 423). Also, dNKs and decidual dendritic cells both promote production of *regulatory T cells* (see p. 427).

■ Production of regulatory T cells doubles or triples in pregnancy. Regulatory T cells suppress maternal cytotoxic T cells that might target the fetus.

■ Trophoblastic cells express a special type of surface identity marker (a unique class I MHC glycoprotein; see p. 428) that allows them to evade interactions with killer cells.

■ Trophoblastic cells produce *Fas ligand*, which binds with *Fas*, a specialized receptor on the surface of approaching activated maternal cytotoxic T cells. This binding triggers apoptosis of these immune cells that are targeted to destroy the developing foreigner.

■ Furthermore, the fetal portion of the placenta, which is derived from trophoblasts, produces an enzyme, *indoleamine 2,3-dioxygenase (IDO),* which destroys tryptophan. Tryptophan, an amino acid, is a critical factor in activation of maternal cytotoxic T cells. Thus, the embryo–fetus, through its tro-

phoblast connection, defends itself against rejection in part by shutting down the activity of the mother's cytotoxic T cells within the placenta that would otherwise attack the developing foreign tissues.

Next, we examine the placenta in further detail.

The placenta is the organ of exchange between maternal and fetal blood.

The glycogen stores in the endometrium are sufficient to nourish the embryo only during its first few weeks. To sustain the growing embryo and then fetus for the duration of intrauterine life, the **placenta**, a specialized organ of exchange between maternal and fetal blood, rapidly develops (▮Figure 20-26, p. 760). The placenta is derived from both trophoblastic and decidual tissue. It is an unusual organ because it is composed of tissues of two organisms: the embryo–fetus and the mother.

Formation of the Placenta and Amniotic Sac By day 12, the embryo is completely embedded in the decidua. By this time, the trophoblastic layer is two cell layers thick and is called the **chorion**. As the chorion continues to release enzymes and expand, it forms an extensive network of cavities within the decidua. As the expanding chorion erodes decidual capillary walls, maternal blood leaks from the capillaries and fills these cavities. The blood is kept from clotting by an anticoagulant produced by the chorion. Fingerlike projections of chorionic tissue extend into the pools of maternal blood. Soon the developing embryo sends out capillaries into these chorionic projections to form **placental villi**. Some villi extend completely across the blood-filled spaces to anchor the fetal portion of the placenta to the endometrial tissue, but most simply project into the pool of maternal blood.

Each placental villus contains embryonic (later fetal) capillaries surrounded by a thin layer of chorionic tissue, which separates the embryonic–fetal blood from the pools of maternal blood in the intervillous ("between villi") spaces. Maternal and fetal blood do not actually mingle, but the barrier between them is extremely thin. To visualize this relationship, think of your hands (the fetal capillary blood vessels) in rubber gloves (the chorionic tissue) immersed in water (the pool of maternal blood). Only the rubber gloves separate your hands from the water. In the same way, only the thin chorionic tissue (plus the capillary wall of the fetal vessels) separates the fetal and maternal blood. All exchanges between these two bloodstreams take place across this extremely thin barrier. This entire system of interlocking maternal (decidual) and fetal (chorionic) structures makes up the placenta. When fully developed, the placental interface for exchange between mother and fetus would be more than 12 m^2 if stretched out flat.

Even though not fully developed, the placenta is well established and operational by 5 weeks after implantation. By this time, the heart of the developing embryo is pumping blood into the placental villi and to the embryonic tissues. Throughout gestation, fetal blood continuously traverses between the placental villi and the circulatory system of the fetus by means of two *umbilical arteries* and one *umbilical vein,* which are wrapped

The Ways and Means of Contraception

T HE TERM *CONTRACEPTION* REFERS TO the process of avoiding pregnancy while engaging in sexual intercourse. A number of methods of contraception are available that range in ease of use and effectiveness (see the accompanying table). These methods can be grouped into three categories based on the means by which they prevent pregnancy: blocking sperm transport to the ovum, preventing ovulation, or blocking implantation. After examining the most common ways in which contraception can be accomplished by each of these means, we will take a glimpse at future contraceptive possibilities on the horizon before concluding with a discussion of terminating unwanted pregnancies.

Blocking Sperm Transport to the Ovum

■ *Natural contraception* or the *rhythm method* of birth control relies on abstinence from intercourse during the woman's fertile period. The woman can predict when ovulation is to occur based on keeping careful records of her menstrual cycles. Because of variability in cycles, this technique is only partially effective. The time of ovulation can be determined more precisely by recording body temperature each morning before getting up. Body temperature rises slightly about a day after ovulation has taken place. The temperature rhythm method is not useful in determining when it is safe to engage in intercourse before ovulation, but it can be helpful in determining when it is safe to resume sex after ovulation.

■ *Coitus interruptus* involves withdrawal of the penis from the vagina before ejaculation occurs. This method is only moderately effective, however, because timing is difficult, and some sperm may pass out of the urethra before ejaculation.

■ *Chemical contraceptives,* such as spermicidal ("sperm-killing") jellies, foams, creams, and suppositories, when inserted into the vagina are toxic to sperm for about an hour after application.

Average Failure Rate of Various Contraceptive Techniques

Contraceptive Method	Average Failure Rate (Annual Pregnancies/100 Women)
None	90
Natural (rhythm) methods	20–30
Coitus interruptus	23
Chemical contraceptives	20
Barrier methods	10–20
Intrauterine device	4
Oral contraceptives	2–2.5
Implanted contraceptives	1

■ *Barrier methods* mechanically prevent sperm transport to the oviduct. For males, the *condom* is a thin, strong rubber or latex sheath placed over the erect penis before ejaculation to prevent sperm from entering the vagina. For females, the *diaphragm* or smaller *cervical cap,* both of which must be fitted by a trained professional, are flexible rubber domes that are inserted through the vagina and positioned over the cervix to block sperm entry into the cervical canal. The *female condom* (or *vaginal pouch*), the latest barrier method, is a long, polyurethane, cylindrical pouch that is closed on one end and open on the other end, with a flexible ring at both ends. The ring at the closed end of the device is inserted into the vagina and fits over the cervix while the ring at the open end of the pouch is positioned outside the vagina over the external genitalia. Barrier methods are often used in conjunction with spermicidal agents for increased effectiveness.

■ *Sterilization,* which involves surgical disruption of either the ductus deferens (*vasectomy*) in men or the oviduct (*tubal ligation*) in women, is considered a permanent method of preventing sperm and ovum from uniting.

Preventing Ovulation

■ *Oral contraceptives,* or *birth control pills,* available only by prescription, prevent ovulation primarily by suppressing gonadotropin secretion. These pills, which contain synthetic estrogenlike and progesteronelike steroids, are taken for three weeks, either in combination or in sequence, and then are withdrawn for one week. These steroids, like the natural steroids produced during the ovarian cycle, inhibit kisspeptin and GnRH and thus FSH and LH secretion. As a result, follicle maturation and ovulation do not take place, so conception is impossible. The endometrium responds to the exogenous steroids by thickening and developing secretory capacity, just as it would respond to the natural hormones. When these synthetic steroids are withdrawn after three weeks, the endometrial lining sloughs and menstruation occurs, as it normally would on degeneration of the corpus luteum (CL). In addition to blocking ovulation, oral contraceptives prevent pregnancy by increasing the viscosity of cervical mucus, which makes sperm penetration more difficult, and by decreasing muscular contractions in the female reproductive tract, which reduces sperm transport to the oviduct. Oral contraceptives have been shown to increase the risk of intravascular clotting, especially in women who also smoke tobacco. Birth control pills have been available for more than 50 years, with only incremental improvements during that time.

■ Several other contraceptive methods contain synthetic female sex hormones and act similarly to birth control pills to prevent ovulation. These include long-acting *subcutaneous* ("under the skin") *implantation* of hormone-containing capsules that gradually release hormones at a nearly steady rate for five years and *birth control patches* impregnated with hormones that are absorbed through the skin.

Blocking Implantation

Medically, pregnancy is not considered to begin until implantation. According to this view, any mechanism that interferes with implantation is said to prevent pregnancy. Not all hold this view, however. Some consider pregnancy to begin at time of fertilization. To them, any interference with implantation is a form of abortion. Therefore, methods of contraception that rely on blocking implantation are more controversial than methods that prevent fertilization from taking place.

Blocking implantation is most commonly accomplished by a physician inserting a small *intrauterine device (IUD)* into the uterus. The presence of this foreign object in the uterus induces a local inflammatory response that prevents implantation of a fertilized ovum.

Emergency Contraception

Emergency contraception is aimed at preventing pregnancy if used within the immediate days following unplanned unprotected sexual intercourse. Emergency contraception is for emergency use only—for instance, if a condom breaks or in the case of rape—and should not be used as a substitute for ongoing contraceptive methods.

The two means of emergency contraception are taking *morning-after pills* and insertion of a *copper IUD*. To greatly reduce the likelihood of an unwanted pregnancy following unprotected intercourse or known contraceptive failure, morning-after pills must be taken within 3 days (not just the morning after) or an IUD must be inserted within 5 days. Following are the mechanisms of action of these emergency contraceptives:

■ Hormonal morning-after pills (such as *Plan B One-Step*) consist of high doses of the same hormones found in birth control pills, either progesteronelike steroids alone or in combination with estrogenlike steroids. These pills, now available over the counter, work by suppressing ovulation and stopping fertilization by affecting sperm motility.

■ An alternative nonhormonal morning-after pill (*Ella*), available by prescription only, is a progesterone receptor modulator that delays or inhibits ovulation.

■ Timely insertion by a health-care professional of a copper IUD prevents fertilization primarily via copper's inhibitory effect on sperm function and also interferes with implantation.

Future Possibilities

■ A future birth control technique is *immunocontraception*—the use of vaccines that prod the immune system to produce antibodies targeted against a particular protein critical to the reproductive process. The contraceptive effects of the vaccines are expected to last about a year. For example, in the testing stage is a vaccine that induces formation of antibodies against human chorionic gonadotropin

(see p. 762) so that this essential CL-supporting hormone is not effective if pregnancy occurs. Another promising immunocontraception approach is aimed at blocking the acrosomal enzymes so that sperm could not enter the ovum.

■ Some scientists are searching for a better *male contraceptive* beyond condoms and irreversible vasectomy. For example, they are seeking ways to manipulate hormones via a "male birth control pill" to block sperm production without depriving the man of testosterone. Still others are trying to interfere with the bond between Sertoli cells and developing sperm so that spermatogenesis cannot proceed to completion. Another approach is blocking testicular synthesis of retinoic acid (a derivative of vitamin A), which is essential for spermatogenesis. Yet another strategy under investigation is injection into the vas deferens of an exit-blocking polymer gel that can later be dissolved if desired—in essence a reversible "vasectomy."

■ One interesting avenue being explored holds hope for a unisex contraceptive that would stop sperm in their tracks and could be used by either males or females. The idea is to use Ca^{2+}-blocking drugs to prevent entry of motility-inducing Ca^{2+} into sperm tails. With no Ca^{2+}, sperm would not be able to maneuver to accomplish fertilization. With the recent discovery of CatSper channels comes an opportunity to interfere with these sperm-specific Ca^{2+} channels, disrupting sperms' fertilizing capacity without having any effect on the female, who lacks these channels.

Terminating Unwanted Pregnancies

■ When contraceptive practices fail or are not used and an unwanted pregnancy results, women often turn to *abortion* to terminate the pregnancy. More than half of the approximately 6.4 million pregnancies in the United States each year are unintended, and about 1.6 million of them end with an abortion. Although surgical removal of an embryo–fetus is legal in the United States, the practice of abortion is fraught with emotional, ethical, and political controversy.

■ In late 2000 the "abortion pill," *RU 486,* or *mifepristone,* was approved for use in the United States amid considerable controversy, even though it had been available in other countries since 1988. This drug terminates an early pregnancy by chemical interference rather than by surgery. RU 486, a progesterone antagonist, binds tightly with the progesterone receptors on the target cells but does not evoke progesterone's usual effects and prevents progesterone from binding and acting. Deprived of progesterone activity, the highly developed endometrial tissue sloughs off, carrying the implanted embryo with it. RU 486 administration is followed in 48 hours by a prostaglandin that induces uterine contractions to help expel the endometrium and embryo.

❙ **Figure 20-26 Developing embryo–fetus, placenta, and amniotic fluid.** (a) The uterus progressively enlarges to accommodate the growing embryo–fetus during pregnancy. (b) During placentation, fingerlike projections of chorionic (fetal) tissue form the placental villi, which protrude into a pool of maternal blood. Decidual (maternal) capillary walls are broken down by the expanding chorion so that maternal blood oozes through the spaces between the placental villi. Fetal placental capillaries branch off the umbilical arteries and project into the placental villi. Fetal blood flowing through these vessels is separated from the maternal blood by only the capillary wall and thin chorionic layer that forms the placental villi. Maternal blood enters through the maternal arterioles, then percolates through the pool of blood in the intervillus spaces. Here, exchanges are made between the fetal and maternal blood before the fetal blood leaves through the umbilical vein and maternal blood exits through the maternal venules. (c) The embryo–fetus floats in a sac that forms during development and is filled with cushioning amniotic fluid.

within the **umbilical cord**, a lifeline between the fetus and the placenta (❙ Figure 20-26). The maternal blood within the placenta is continuously replaced as fresh blood enters through uterine arterioles; percolates through the intervillous spaces, where it exchanges substances with fetal blood in the surrounding villi; and then exits through uterine venules.

Meanwhile, during the time of implantation and early placental development, the inner cell mass forms a fluid-filled **amniotic cavity** between the trophoblast–chorion and the

portion of the inner cell mass destined to become the fetus (see ❙ Figure 20-25, step ❷). The epithelial layer that encloses the amniotic cavity is called the **amniotic sac, or amnion**. As it continues to develop, the amniotic sac eventually fuses with the chorion, forming a single combined membrane that surrounds the embryo–fetus. The fluid in the amniotic cavity, the **amniotic fluid**, which is similar in composition to normal ECF, surrounds and cushions the fetus throughout gestation (❙ Figure 20-26).

Functions of the Placenta During intrauterine life, the placenta performs the functions of the digestive system, the respiratory system, and the kidneys for the "parasitic" fetus. The fetus has these organ systems, but within the uterine environment they cannot (and do not need to) function. Nutrients and O_2 move from the maternal blood across the thin placental barrier into the fetal blood, whereas CO_2 and other metabolic wastes simultaneously move from the fetal blood into the maternal blood. The nutrients and O_2 brought to the fetus in the maternal blood are acquired by the mother's digestive and respiratory systems, and the CO_2 and wastes transferred into the maternal blood are eliminated by the mother's lungs and kidneys, respectively. Thus, the mother's digestive tract, respiratory system, and kidneys serve the fetus's needs and her own.

The means by which materials move across the placenta depends on the substance. Some substances that can permeate the placental membrane, such as O_2, CO_2, water, and electrolytes, cross by simple diffusion. Some traverse the placental barrier by special mediated-transport systems in the placental membranes, such as glucose by facilitated diffusion and amino acids by secondary active transport. Other substances such as cholesterol in the form of LDL (see p. 328) move across by receptor-mediated endocytosis.

Clinical Note Unfortunately, many drugs, environmental pollutants, other chemical agents, and microorganisms in the mother's bloodstream also can cross the placental barrier, and some of them may harm the developing fetus. Individuals born limbless as a result of exposure to *thalidomide,* a tranquilizer prescribed for pregnant women before this drug's devastating effects on the growing fetus were known, serve as a grim reminder of this fact. Similarly, newborns who become "addicted" during gestation by their mother's abuse of a drug such as heroin suffer withdrawal symptoms after birth. Even more common chemical agents such as aspirin, alcohol, and agents in cigarette smoke can reach the fetus and have adverse effects. Furthermore, some infectious agents can cross the placenta, an example being *Listeria monocytogenes*, a bacterium that can contaminate food and cause food poisoning with potentially devastating results for the pregnancy and the fetus. Pregnant women should therefore be cautious about potentially harmful exposure from any source.

The placenta has yet another important responsibility—it becomes a temporary endocrine organ during pregnancy, a topic to which we now turn. During pregnancy, three endocrine systems interact to support and enhance the growth and development of the fetus, to coordinate the timing of parturition, and to prepare the mammary glands for nourishing the baby after birth: placental hormones, maternal hormones, and fetal hormones.

Hormones secreted by the placenta play a critical role in maintaining pregnancy.

The fetally derived portion of the placenta has the remarkable capacity to secrete a number of peptide and steroid hormones essential for maintaining pregnancy. The most important are *human chorionic gonadotropin, estrogen,* and *progesterone* (❚Table 20-5). Serving as the major endocrine organ of pregnancy, the placenta is unique among endocrine tissues in two regards. First, it is a transient tissue. Second, secretion of its hormones is not subject to extrinsic control, in contrast to the stringent, often complex mechanisms that regulate secretion of other hormones. Instead, the type and rate of placental hormone secretion depend primarily on the stage of pregnancy.

❚**TABLE 20-5** Placental Hormones

Hormone	Function
Human chorionic gonadotropin (hCG)	Maintains the corpus luteum of pregnancy
	Stimulates secretion of testosterone by the developing testes in XY embryos
Estrogen (also secreted by the corpus luteum of pregnancy)	Stimulates growth of the myometrium, increasing uterine strength for parturition
	Helps prepare the mammary glands for lactation
Progesterone (also secreted by the corpus luteum of pregnancy)	Suppresses uterine contractions to provide a quiet environment for the fetus
	Promotes formation of a cervical mucus plug to prevent uterine contamination
	Helps prepare the mammary glands for lactation
Human chorionic somatomammotropin (has a structure similar to that of both growth hormone and prolactin)	Reduces maternal use of glucose and promotes the breakdown of stored fat (similar to growth hormone) so that greater quantities of glucose and free fatty acids may be shunted to the fetus
	Helps prepare the mammary glands for lactation (similar to prolactin)
Relaxin (also secreted by the corpus luteum of pregnancy)	Softens the cervix in preparation for cervical dilation at parturition
	Loosens the connective tissue between the pelvic bones in preparation for parturition
Placental PTHrp (parathyroid hormone–related peptide)	Increases maternal plasma Ca^{2+} level for use in calcifying fetal bones; if necessary, promotes localized dissolution of maternal bones, mobilizing their Ca^{2+} stores for use by the developing fetus

Secretion of Human Chorionic Gonadotropin One of the first endocrine events is secretion by the developing chorion of **human chorionic gonadotropin (hCG)**, a peptide hormone that prolongs the life span of the corpus luteum. Recall that, during the ovarian cycle, the CL degenerates and the highly prepared, luteal-dependent uterine lining sloughs off if fertilization and implantation do not occur. When fertilization does occur, the implanted blastocyst saves itself from being flushed out in menstrual flow by producing hCG. This hormone, which is similar to LH and binds to the same receptor as LH, stimulates and maintains the CL so that it does not degenerate. Now called the **corpus luteum of pregnancy**, this ovarian endocrine unit grows even larger and produces increasingly greater amounts of estrogen and progesterone for an additional 10 weeks until the placenta takes over secretion of these steroid hormones. Because of the persistence of estrogen and progesterone, the thick, pulpy endometrial tissue is maintained instead of sloughing. Accordingly, menstruation ceases during pregnancy. Stimulation by hCG is necessary to maintain the CL of pregnancy because LH, which maintains the CL during the normal luteal phase of the uterine cycle, is suppressed through feedback inhibition by the high levels of progesterone.

Maintenance of a normal pregnancy depends on high concentrations of progesterone and estrogen. Thus, hCG production is critical during the first trimester to maintain ovarian output of these hormones. In a male fetus, hCG also stimulates the precursor Leydig cells in the fetal testes to secrete testosterone, which masculinizes the developing reproductive tract.

The secretion rate of hCG increases rapidly during early pregnancy to save the CL from demise. Peak secretion of hCG occurs about 60 days after the end of the last menstrual period (❙Figure 20-27). By the 10th week of pregnancy, hCG output declines to a low rate of secretion that is maintained for the duration of gestation. The fall in hCG occurs because the placenta has begun to secrete substantial quantities of estrogen and progesterone, which inhibit hCG secretion. By this time, the CL of pregnancy is no longer needed for its steroid hormone output because the placenta is secreting sufficient estrogen and progesterone. Therefore the CL of pregnancy is the source of estrogen and progesterone during the first trimester of gestation, and the placenta takes over this role during the last two trimesters. The CL of pregnancy partially regresses as hCG secretion dwindles, but it is not converted into scar tissue until after delivery of the baby.

Clinical Note Human chorionic gonadotropin is eliminated from the body in the urine. Pregnancy diagnosis tests can detect hCG in urine as early as the first month of pregnancy, about 2 weeks after the first missed menstrual period. Because this is before the growing embryo can be detected by physical examination, the test permits early confirmation of pregnancy.

A frequent early clinical sign of pregnancy is **morning sickness**, a daily bout of nausea and vomiting that often occurs in the morning but can take place at any time of day. Because this condition usually appears shortly after implantation and coincides with the time of peak hCG production, scientists speculate that this early placental hormone may trigger the symptoms, perhaps by acting on the chemoreceptor trigger zone next to the vomiting center (see p. 582).
❙Figure 20-27 **Secretion rates of placental hormones.**
FIGURE FOCUS: *(1) Why do estrogen and progesterone levels continue to climb after the first trimester of pregnancy even though human chorionic gonadotropin output has declined substantially? (2) Why do estrogen and progesterone levels drop precipitously at delivery?*

Secretion of Estrogen and Progesterone Why does the developing placenta not start producing estrogen and progesterone in the first place instead of secreting hCG, which in turn stimulates the CL to secrete these two critical hormones? The answer is that, for different reasons, the placenta cannot produce enough estrogen or progesterone in the first trimester of pregnancy. In the case of estrogen, the placenta does not have all the enzymes needed for complete synthesis of this hormone. Estrogen synthesis requires a complex interaction between the placenta and the fetus (❙Figure 20-28). The placenta converts the androgen hormone produced by the fetal adrenal cortex, dehydroepiandrosterone (DHEA), into estrogen. The placenta cannot produce estrogen until the fetus has developed to the point that its adrenal cortex is secreting DHEA into the blood. The placenta extracts DHEA from the fetal blood and converts it into estrogen, which it then secretes into the maternal blood.

Estrogen comes in several variants. The primary estrogen synthesized by the placenta is **estriol**, in contrast to the main estrogen product of the ovaries, estradiol. Because estriol can only be synthesized from fetal DHEA, measurement of estriol levels in the maternal urine can be used clinically to assess the viability of the fetus.

In the case of progesterone, the placenta can synthesize this hormone soon after implantation. Even though the early placenta has the enzymes necessary to convert cholesterol extracted from the maternal blood into progesterone, it does not produce much of this hormone because the amount of progesterone produced is proportional to placental weight. The placenta is simply too small in the first 10 weeks of pregnancy to produce enough progesterone to maintain the endometrial tissue. The notable increase in circulating progester-

one in the last 7 months of gestation reflects placental growth during this period.

Roles of Estrogen and Progesterone During Pregnancy

As noted earlier, high concentrations of estrogen and progesterone are essential to maintain a normal pregnancy. Estrogen stimulates growth of the myometrium, which increases in size throughout pregnancy. The stronger uterine musculature is needed to expel the fetus during labor. Estriol also promotes development of the ducts within the mammary glands, through which milk is ejected during lactation.

Progesterone performs various roles throughout pregnancy. Its main function is to prevent miscarriage by suppressing contractions of the uterine myometrium. Progesterone also promotes formation of a thick mucus plug in the cervical canal to prevent vaginal contaminants from reaching the uterus. Finally, placental progesterone stimulates development of milk glands in the breasts in preparation for lactation.

Maternal body systems respond to the increased demands of gestation.

The period of **gestation (pregnancy)** is about 38 weeks from conception (40 weeks from the end of the last menstrual period). During gestation, the embryo–fetus develops and grows to the point of being able to leave its maternal life-support system. Meanwhile, a number of physical changes within the mother accommodate the demands of pregnancy. The most obvious change is uterine enlargement. The uterus expands and increases in weight more than 20 times, exclusive of its contents. The breasts enlarge and develop the ability to produce milk. Body systems other than the reproductive system also make needed adjustments. The volume of blood increases by 30%, and the cardiovascular system responds to the increasing demands of the growing placental mass. Weight gain during pregnancy is the result only in part of the weight of the fetus. The remainder is mostly from increased weight of the uterus, including the placenta, and increased blood volume. Respiratory activity increases by about 20% to handle the additional fetal requirements for O_2 use and CO_2 removal. Urinary output increases, and the kidneys excrete the additional wastes from the fetus.

The increased metabolic demands of the growing fetus increase nutritional requirements for the mother. In general, the fetus takes what it needs from the mother, even if this leaves the mother with a nutritional deficit. For example, the placental hormone **human chorionic somatomammotropin (hCS)** decreases use of glucose by the mother and mobilizes free fatty acids from maternal adipose stores, similar to the actions of growth hormone (see p. 653). (In fact, hCS has a structure similar to that of both growth hormone and prolactin and exerts similar actions.) The hCS-induced metabolic changes in the mother make available greater quantities of glucose and fatty acids for shunting to the fetus. Also, if the mother does not consume enough Ca^{2+}, yet another placental hormone similar to parathyroid hormone, **parathyroid hormone-related peptide (PTHrp)**, mobilizes Ca^{2+} from the maternal bones to ensure adequate calcification of the fetal bones (❙Table 20-5).

Changes during late gestation prepare for parturition.

Parturition (labor, delivery, or birth) requires (1) dilation of the cervical canal to accommodate passage of the fetus from the uterus through the vagina and to the outside and (2) contractions of the uterine myometrium that are sufficiently strong to expel the fetus.

Several changes take place during late gestation in preparation for the onset of parturition. During the first two trimesters of gestation, the uterus remains relatively quiet because of the inhibitory effect of the high levels of

KEY

→ Pathway for placental synthesis of progesterone
→ Pathway for placental synthesis of estrogen
❙ **Figure 20-28 Secretion of estrogen and progesterone by the placenta.** The placenta secretes increasing quantities of progesterone and estrogen into the maternal blood after the first trimester. The placenta can convert cholesterol into progesterone (*orange pathway*) but lacks some of the enzymes necessary to convert cholesterol into estrogen. However, the placenta can convert DHEA derived from cholesterol in the fetal adrenal cortex into estrogen when DHEA reaches the placenta by means of the fetal blood (*blue pathway*).

progesterone on the uterine muscle. During the last trimester, however, the uterus becomes progressively more excitable, so mild contractions (**Braxton–Hicks contractions)** are experienced with increasing strength and frequency. Sometimes these contractions become regular enough to be mistaken for the onset of labor, a phenomenon called "false labor."

Throughout gestation, the exit of the uterus remains sealed by the rigid, tightly closed cervix. As parturition approaches, the cervix begins to soften (or "ripen") as a result of the dissociation of its tough connective tissue (collagen) fibers. Because of this softening, the cervix becomes malleable so that it can gradually yield, dilating the exit, as the fetus is forcefully pushed against it during labor. This cervical softening is caused largely by **relaxin**, a peptide hormone produced by the CL of pregnancy and by the placenta. Other factors to be described shortly contribute to cervical softening. Relaxin also "relaxes" the birth canal by loosening the connective tissue between pelvic bones.

Meanwhile, the fetus shifts downward (the baby "drops") and is normally oriented so that the head is in contact with the cervix in preparation for exiting through the birth canal. In a **breech birth**, any part of the body other than the head approaches the birth canal first.

Scientists are closing in on the factors that trigger the onset of parturition.

Rhythmic, coordinated contractions, usually painless at first, begin at the onset of labor. As labor progresses, the contractions increase in frequency, intensity, and discomfort. These strong, rhythmic contractions force the fetus against the cervix, dilating the cervix. Then, after having dilated the cervix enough for the fetus to pass through, these contractions force the fetus out through the birth canal.

The exact factors triggering the increase in uterine contractility and thus initiating parturition are not fully established, although much progress has been made in recent years in unraveling the sequence of events. Let us look at what is known about this process.

Role of High Estrogen Levels During early gestation, maternal estrogen levels are relatively low, but as gestation proceeds, placental estrogen secretion continues to rise. In the immediate days before the onset of parturition, soaring levels of estrogen bring about changes in the uterus and cervix to prepare them for labor and delivery (❙ Figures 20-27 and 20-29). First, high levels of estrogen promote synthesis of connexons within the uterine smooth muscle cells. These myometrial cells are not functionally linked to any extent throughout most of gestation. The newly manufactured connexons are inserted in the myometrial plasma membranes to form gap junctions that electrically link together the uterine smooth muscle cells so that they become able to contract as a coordinated unit (see p. 62).

Simultaneously, high levels of estrogen dramatically and progressively increase the concentration of myometrial receptors for oxytocin. Together, these myometrial changes collectively bring about the increased uterine responsiveness to oxytocin that ultimately initiates labor.

In addition to preparing the uterus for labor, the increasing estrogen levels promote production of local prostaglandins that contribute to cervical ripening by stimulating cervical enzymes that degrade local collagen fibers. These prostaglandins also increase uterine responsiveness to oxytocin.

Role of Oxytocin **Oxytocin** is a peptide hormone produced by the hypothalamus, stored in the posterior pituitary, and released into the blood from the posterior pituitary on nervous stimulation by the hypothalamus (see p. 647). Oxytocin exerts its effects via the IP_3/Ca^{2+}/DAG pathway. A powerful uterine muscle stimulant, oxytocin plays the key role in the progression of labor. However, this hormone was once discounted as the trigger for parturition because circulating levels of oxytocin remain constant before the onset of labor. The discovery that uterine responsiveness to oxytocin is 100 times greater at term than in nonpregnant women (because of the connexons and increased concentration of myometrial oxytocin receptors) led to the now widely accepted conclusion that labor begins when myometrial responsiveness to oxytocin reaches a critical threshold that permits onset of strong, coordinated contractions in response to ordinary levels of circulating oxytocin.

Role of Corticotropin-Releasing Hormone For years scientists were baffled by the factors that raise levels of placental estrogen secretion. Recent studies suggest that *corticotropin-releasing hormone* (*CRH*) secreted by the fetal portion of the placenta into both the maternal and the fetal circulations not only drives the manufacture of placental estrogen, thus ultimately dictating the timing of the onset of labor, but also promotes changes in the fetal lungs needed for breathing air (❙ Figure 20-29). Recall that CRH is normally secreted by the hypothalamus and regulates the output of ACTH by the anterior pituitary (see pp. 650 and 675). In turn, ACTH stimulates production of both cortisol and DHEA by the adrenal cortex. In the fetus, much of the CRH comes from the placenta rather than solely from the fetal hypothalamus. The additional cortisol secretion summoned by the extra CRH promotes fetal lung maturation. Specifically, cortisol stimulates synthesis of pulmonary surfactant, which facilitates lung expansion and reduces the work of breathing (see p. 459).

The bumped-up rate of DHEA secretion by the adrenal cortex in response to placental CRH leads to the rising levels of placental estrogen secretion because the placenta converts DHEA from the fetal adrenal gland into estrogen, which enters the maternal bloodstream (see ❙ Figure 20-28). When sufficiently high, this estrogen sets in motion the events that initiate labor. Thus, pregnancy duration and delivery timing are determined largely by the placenta's rate of CRH production. That is, a **"placental clock"** ticks out the length of time until parturition. The timing of parturition is established early in pregnancy, with delivery at the end point of a maturational process that extends throughout most of gestation. The ticking of the placental clock is measured by the rate of placental secretion of CRH. As the pregnancy progresses, CRH levels in maternal plasma rise. Researchers can accurately predict the timing of parturition by measuring the maternal plasma levels of CRH as early as the end of the first trimester. Higher-than-normal levels are associated

The Reproductive System | **765**

with premature deliveries, whereas lower-than-normal levels indicate late deliveries. These and other data suggest that when a critical level of placental CRH is reached, parturition is triggered. This critical CRH level ensures that when labor begins the infant is ready for life outside the womb. It does so by concurrently increasing the fetal cortisol needed for lung maturation and the estrogen needed for the uterine changes that bring on labor. The remaining unanswered puzzle regarding the placental clock: What controls placental secretion of CRH?

Role of Inflammation Surprisingly, new evidence suggests that inflammation plays a central role in the labor process. Key to this inflammatory response is activation of **nuclear factor κB (NF-κB)** in the uterus. NF-κB boosts production of inflammatory cytokines such as *interleukin 8 (IL-8)* (see p. 411) and prostaglandins that increase the sensitivity of the uterus to contraction-inducing chemical messengers and help soften the cervix. What activates NF-κB, setting off an inflammatory cascade that helps prompt labor? Various factors associated with the onset of full-term labor and premature labor can cause an upsurge in NF-κB. These include stretching of the uterine muscle and the presence of a specific pulmonary surfactant protein *SP-A* (stimulated by the action of CRH on the fetal lungs) in the amniotic fluid from the fetus. SP-A promotes migration of fetal macrophages (see p. 393) to the uterus. These macrophages, in turn, produce the inflammatory cytokine *interleukin 1*β *(IL-1*β*)* that activates NF-κB. In this way, fetal lung maturation contributes to the onset of labor.

Clinical Note Bacterial infections and allergic reactions can lead to premature labor by activating NF-κB. Also, multiple-fetus pregnancies are at risk for premature labor, likely because the increased uterine stretching triggers earlier activation of NF-κB.

Parturition is accomplished by a positive-feedback cycle.

Once uterine responsiveness to oxytocin reaches a critical level and regular uterine contractions begin, myometrial contractions progressively increase in frequency, strength, and duration throughout labor until they expel the uterine contents. At the beginning of labor, contractions lasting 30 seconds or less occur about every 25 to 30 minutes; by the end, they last 60 to 90 seconds and occur every 2 to 3 minutes.

As labor progresses, a positive-feedback cycle involving oxytocin and prostaglandin ensues, incessantly increasing myometrial contractions (❙ Figure 20-29). Each uterine contraction begins at the top of the uterus and sweeps downward, forcing the fetus toward the cervix. Pressure of the fetus against the cervix does two things. First, the fetal head pushing against the softened cervix wedges open the cervical canal. Second, stimulation of receptors in the cervix in response to fetal pressure sends a neural signal up the spinal cord to the hypothalamus, which in turn triggers oxytocin release from the posterior pituitary. This additional oxytocin promotes more powerful uterine contractions. As a result, the fetus is pushed more forcefully against the cervix, stimulating the release of even more oxytocin, and so on. This cycle is reinforced as oxytocin stimulates prostaglandin production by the decidua.

As a powerful myometrial stimulant, prostaglandin further enhances uterine contractions. Oxytocin secretion, prostaglandin production, and uterine contractions continue to increase in positive-feedback fashion throughout labor until delivery relieves the pressure on the cervix.

Stages Of Labor Labor is divided into three stages: (1) cervical dilation, (2) delivery of the baby, and (3) delivery of the placenta (❙ Figure 20-30). At the onset of labor or sometime during the first stage, the amniotic sac, or "bag of waters," ruptures. As amniotic fluid escapes out of the vagina, it helps lubricate the birth canal.

1. During the *first stage,* the cervix is forced to dilate to accommodate the diameter of the baby's head, usually to a maximum of 10 cm. This stage is the longest, lasting from several hours to as long as 24 hours in a first pregnancy. If another part of the fetus's body other than the head is oriented against the cervix, it is generally less effective than the head as a wedge. The head has the largest diameter of the baby's body. If the baby approaches the birth canal feet first, the feet may not dilate the cervix enough to let the head pass. In such a case, without medical intervention the baby's head would remain stuck behind the too-narrow cervical opening.

2. The *second stage* of labor, the actual birth of the baby, begins once cervical dilation is complete. When the infant begins to move through the cervix and vagina, stretch receptors in the vagina activate a neural reflex that triggers contractions of the abdominal wall in synchrony with the uterine contractions. These abdominal contractions greatly increase the force pushing the baby through the birth canal. The mother can help deliver the infant by voluntarily contracting the abdominal muscles at this time in unison with each uterine contraction (that is, by "pushing" with each "labor pain"). Stage 2 is usually shorter than the first stage, lasting 30 to 90 minutes. The infant is still attached to the placenta by the umbilical cord at birth. The cord is tied and severed, with the stump shriveling up in a few days to form the **umbilicus (navel)**.

3. Shortly after delivery of the baby, a second series of uterine contractions separates the placenta from the myometrium and expels it through the vagina. Delivery of the placenta, or **afterbirth**, constitutes the *third stage* of labor, typically the shortest stage, being completed within 15 to 30 minutes after the baby is born. After the placenta is expelled, continued contractions of the myometrium constrict the uterine blood vessels supplying the site of placental attachment to prevent hemorrhage.

Uterine Involution After delivery, the uterus shrinks to its pregestational size, a process known as **involution**, which takes 4 to 6 weeks to complete. During involution, the remaining endometrial tissue not expelled with the placenta gradually disintegrates and sloughs off, producing a vaginal discharge called **lochia** that continues for 3 to 6 weeks following parturition. After this period, the endometrium is restored to its nonpregnant state.

Involution occurs largely because of the precipitous fall in circulating estrogen and progesterone when the placental source of these steroids is lost at delivery. The process is facilitated in mothers who breast-feed their infants because oxytocin

is released in response to suckling. In addition to playing an important role in lactation, this periodic nursing-induced release of oxytocin promotes myometrial contractions that help maintain uterine muscle tone, enhancing involution. Involution is usually complete in about 4 weeks in nursing mothers but takes about 6 weeks in those who do not breast-feed.

Lactation requires multiple hormonal inputs.

The female reproductive system supports the new being from the moment of conception through gestation and continues to nourish it during its early life outside the supportive uterine environment. Milk (or its equivalent) is essential for survival of the newborn. Accordingly, during gestation the **mammary glands**, or **breasts**, are prepared for **lactation** (milk production).

The breasts in nonpregnant females consist mostly of adipose tissue and a rudimentary duct system. Breast size is determined by the amount of adipose tissue, which has nothing to do with the ability to produce milk.

Preparation of the Breasts for Lactation Under the hormonal environment present during pregnancy, the mammary glands develop the internal glandular structure and func-

tion necessary for milk production. A breast capable of lactating has a network of progressively smaller ducts that branch out from the nipple and terminate in lobules (**I** Figure 20-31a). Each lobule is made up of a cluster of saclike epithelial-lined, milk-producing glands known as **alveoli**. (Both milk-producing sacs in the breast and air sacs in the lungs are called *alveoli,* which means "little cavities.") Milk is synthesized by the alveolar epithelial cells and then secreted into the alveolar lumen, which is drained by a milk-collecting duct that transports the milk to the surface of the nipple (**I** Figure 20-31b).

During pregnancy, the high concentration of *estrogen* promotes extensive duct development, whereas the high level of *progesterone* stimulates abundant alveolar–lobular formation. Elevated concentrations of *prolactin* (an anterior pituitary hormone stimulated by the rising levels of estrogen) and *human chorionic somatomammotropin* (*hCS,* a placental hormone that has a structure similar to that of both growth hormone and prolactin) also contribute to mammary gland development by inducing the synthesis of enzymes needed for milk production. So great is the commitment to preparing the breasts for infant nutrition that the pituitary gland doubles or triples in size during pregnancy as a result of the estrogen-induced increase in the number of prolactin-secreting cells.

Figure 20-31 Mammary gland anatomy. The alveolar epithelial cells secrete milk into the lumen. Contraction of the surrounding myoepithelial cells ejects the secreted milk out through the duct.

In addition to preparing the mammary glands for lactation, prolactin and hCS also promote fetal growth by stimulating production of the insulin-like growth factors, IGF-I and IGF-II (see p. 654). Surprisingly, growth hormone secreted by the fetal anterior pituitary does not control growth of the fetus.

Prevention of Lactation During Gestation Most of these changes in the breasts occur during the first half of gestation, so the mammary glands are fully capable of producing milk by the middle

TABLE 20-6 Actions of Estrogen and Progesterone

Estrogen

Effects on sex-specific tissues

Is essential for egg maturation and release

Stimulates growth and maintenance of the entire female reproductive tract

Stimulates granulosa cell proliferation, which leads to follicle maturation

Thins the cervical mucus to permit sperm penetration

Enhances transport of sperm to the oviduct by stimulating upward contractions of the uterus and oviduct

Stimulates growth of the endometrium and myometrium

Induces synthesis of endometrial progesterone receptors

Triggers onset of parturition by increasing uterine responsiveness to oxytocin during late gestation through a twofold effect: by inducing synthesis of myometrial oxytocin receptors and by increasing myometrial gap junctions so that the uterus can contract as a coordinated unit in response to oxytocin

Other reproductive effects

Promotes development of secondary sexual characteristics

If at a low or moderate level, inhibits secretion of kisspeptin, GnRH, and gonadotropins

If at a high level, is responsible for triggering the LH surge by stimulating secretion of kisspeptin and GnRH

Stimulates duct development in the breasts during gestation

Inhibits milk-secreting actions of prolactin during gestation

Nonreproductive effects

Promotes fat deposition

Increases bone density

Closes the epiphyseal plates

Improves blood cholesterol profile by increasing HDL and decreasing LDL

Promotes vasodilation by increasing nitric oxide production in arterioles (cardioprotective)

Progesterone

Prepares a suitable environment for nourishment of a developing embryo and then fetus

Causes a thick mucus plug to form in the cervical canal

Inhibits secretion of kisspeptin, GnRH, and gonadotropins

Inhibits uterine contractions during gestation

Stimulates alveolar development in the breasts during gestation

Inhibits milk-secreting actions of prolactin during gestation

of pregnancy. However, milk secretion does not occur until parturition. The high estrogen and progesterone concentrations during the last half of pregnancy prevent lactation by blocking prolactin's stimulatory action on milk secretion. Prolactin is the primary stimulant of milk secretion. Thus, even though the high levels of placental steroids promote development of the milk-producing

machinery in the breasts, they prevent these glands from becoming operational until the baby is born and milk is needed.

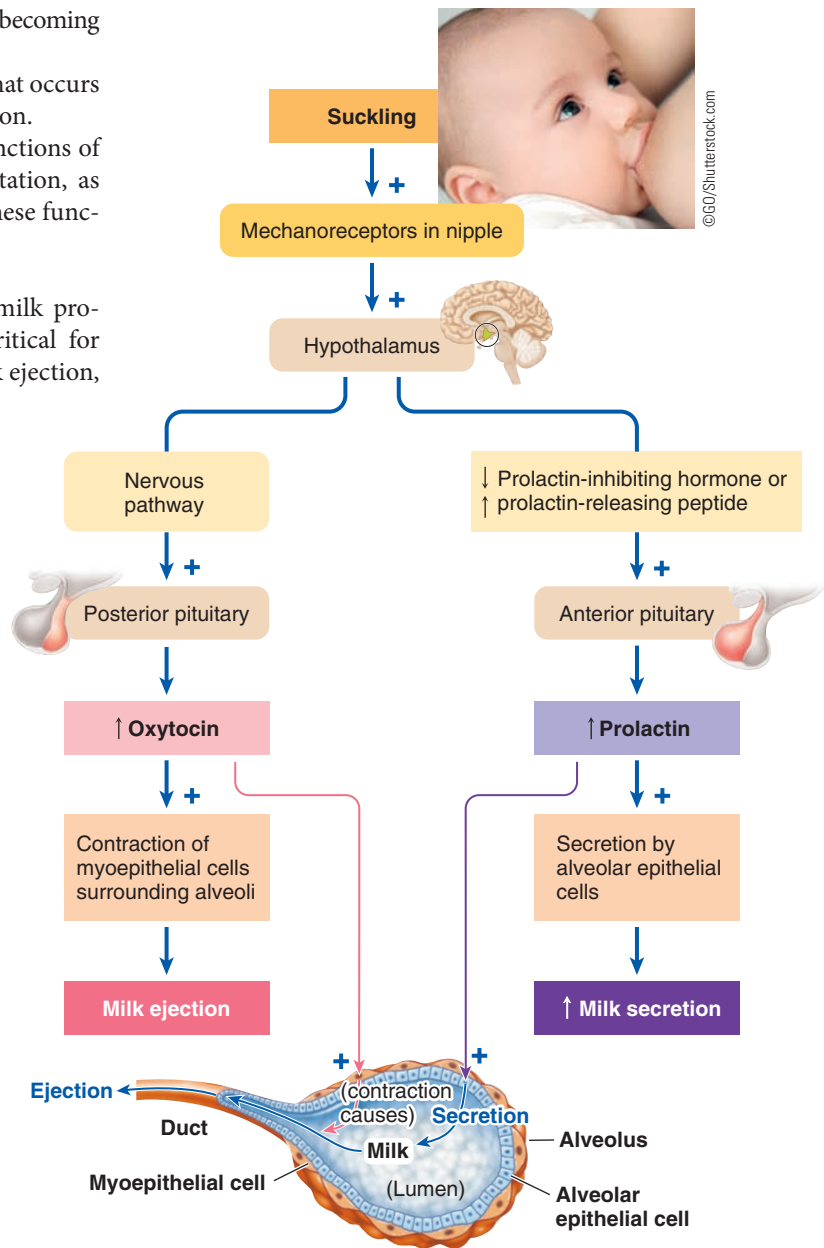
The abrupt decline in estrogen and progesterone that occurs with loss of the placenta at parturition initiates lactation.

We have now completed our discussion of the functions of estrogen and progesterone during gestation and lactation, as well as throughout the reproductive life of females. These functions are summarized in ▮Table 20-6.

Stimulation of Lactation via Suckling Once milk production begins after delivery, two hormones are critical for maintaining lactation: (1) *oxytocin,* which causes milk ejection, and (2) *prolactin,* which promotes milk secretion. **Milk ejection**, or **milk letdown**, refers to the forced expulsion of milk from the lumen of the alveoli out through the ducts. A neuroendocrine reflex triggered by suckling stimulates release of both of these hormones (▮Figure 20-32).

■ *Oxytocin release and milk ejection.* The infant cannot directly suck milk out of the alveolar lumen. Instead, milk must be actively squeezed out of the alveoli into the ducts, and hence toward the nipple, by contraction of specialized **myoepithelial cells** (smooth-musclelike epithelial cells) that surround each alveolus (see ▮Figure 20-31b). The infant's suckling of the breast stimulates sensory nerve endings in the nipple, initiating action potentials that travel up the spinal cord to the hypothalamus. Thus activated, the hypothalamus triggers a burst of oxytocin release from the posterior pituitary. Oxytocin in turn stimulates contraction of the myoepithelial cells in the breasts to bring about milk ejection. Milk letdown continues only as long as the infant continues to nurse. In this way, the milk ejection reflex ensures that the breasts release milk only when required and in the amount needed by the baby. Even though the alveoli may be full of milk, the milk cannot be released without oxytocin. The reflex can become conditioned to stimuli other than suckling, however. For example, the infant's cry can trigger milk letdown, causing a spurt of milk to leak from the nipples. In contrast, psychological stress, acting through the hypothalamus, can easily inhibit milk ejection. For this reason, a positive attitude toward breast-feeding and a relaxed environment are essential for successful breast-feeding.

■ *Prolactin release and milk secretion.* Suckling not only triggers oxytocin release but also stimulates prolactin secretion. Prolactin output by the anterior pituitary is controlled by two hypothalamic secretions: **prolactin-inhibiting hormone (PIH)** and **prolactin-releasing peptide (PrRP)**. PIH is now known to be *dopamine,* which also serves as a neurotransmitter in the brain.

Throughout most of the female's life, PIH is the dominant influence, so prolactin concentrations normally remain low. During lactation, a burst in prolactin secretion occurs each time the infant suckles. Afferent impulses initiated in the nipple on suckling are carried by the spinal cord to the hypothalamus. This


▮Figure 20-32 **Suckling reflexes.**

reflex ultimately leads to prolactin release by the anterior pituitary, although it is unclear whether this is from inhibition of PIH secretion, stimulation of PrRP secretion, or both. Prolactin then acts on the alveolar epithelium to promote secretion of milk to replace the ejected milk (▮Figure 20-32). Prolactin exerts its effect by means of the JAK/STAT signaling pathway (see p. 116).

Concurrent stimulation by suckling of both milk ejection and milk production ensures that the rate of milk synthesis keeps pace with the baby's needs for milk. The more the infant nurses, the more milk is removed by letdown and the more milk is produced for the next feeding.

In addition to prolactin, which is the most important factor controlling synthesis of milk, at least four other hormones are essential for their permissive role in ongoing milk production: cortisol, insulin, parathyroid hormone, and growth hormone.

Breast-feeding is advantageous to both the infant and the mother.

Nutritionally, **milk** is composed of water, triglyceride fat, the carbohydrate lactose (milk sugar), a number of proteins, vitamins, and the minerals calcium and phosphate.

Advantages of Breast-Feeding for the Infant In addition to nutrients, milk contains a host of immune cells, antibodies, and other chemicals that help protect the infant against infection until it can mount an effective immune response on its own a few months after birth. **Colostrum**, the milk produced for the first 5 days after delivery, contains lower concentrations of fat and lactose but higher concentrations of immunoprotective components. All human babies acquire some passive immunity during gestation by antibodies passing across the placenta from the mother to the fetus (see p. 421). These antibodies are short lived, however, and they often do not persist until the infant can fend for itself immunologically. Breast-fed babies gain additional protection during this vulnerable period through a variety of mechanisms:

- Breast milk contains an abundance of *immune cells*—both B and T lymphocytes, macrophages, and neutrophils (see pp. 392–393)—that produce antibodies and destroy pathogenic microorganisms outright. These cells are especially plentiful in colostrum.
- *Secretory IgA,* a special type of antibody, is present in great amounts in breast milk. Secretory IgA consists of two IgA antibody molecules (see p. 417) joined with a so-called secretory component that helps protect the antibodies from destruction by the infant's acidic gastric juice and digestive enzymes. The collection of IgA antibodies that a breast-fed baby receives is specifically aimed against the particular pathogens in the environment of the mother—and, accordingly, of the infant as well. Appropriately, therefore, these antibodies protect against the infectious microbes that the infant is most likely to encounter.
- Some components in mother's milk, such as *mucus,* adhere to potentially harmful microorganisms, preventing them from attaching to and crossing the intestinal mucosa.
- *Lactoferrin* is a breast-milk constituent that thwarts growth of harmful bacteria by decreasing the availability of iron, a mineral needed for multiplication of these pathogens (see p. 411).
- *Bifidus factor* in breast milk promotes multiplication of the nonpathogenic microorganism *Lactobacillus bifidus* in the infant's digestive tract. Growth of this harmless bacterium helps crowd out potentially harmful bacteria.
- Other components in breast milk promote maturation of the baby's digestive system so that it is less vulnerable to diarrhea-causing bacteria and viruses.
- Still other factors in breast milk hasten development of the infant's immune capabilities.

Thus, breast milk helps protect infants from disease in a variety of ways.

Some studies hint that in addition to the benefits of breast milk during infancy, breast-feeding may reduce the risk of developing certain serious diseases later in life. Examples include allergies such as asthma, autoimmune diseases such as Type 1 diabetes mellitus, and cancers such as lymphoma.

Infants who are bottle-fed on a formula made from cow's milk or another substitute do not have the protective advantage provided by human milk and, accordingly, have a higher incidence of infections of the digestive tract, respiratory tract, and ears than breast-fed babies do. Also, the digestive system of a newborn is better equipped to handle human milk than cow milk–derived formula, so bottle-fed babies tend to have more digestive upsets.

Advantages of Breast-Feeding for the Mother Breast-feeding is also advantageous for the mother. Oxytocin release triggered by nursing hastens uterine involution. In addition, suckling suppresses the menstrual cycle because prolactin (sometimes termed "nature's contraceptive") inhibits GnRH, thereby suppressing FSH and LH secretion. Lactation, therefore, tends to prevent ovulation, decreasing the likelihood of another pregnancy (although it is not a reliable means of contraception). This mechanism permits all the mother's resources to be directed toward the newborn instead of being shared with a new embryo.

Cessation of Milk Production at Weaning When the infant is weaned, two mechanisms contribute to cessation of milk production. First, without suckling, prolactin secretion is not stimulated, removing the main stimulus for continued milk synthesis and secretion. Also, in the absence of suckling, oxytocin is not released and milk letdown does not occur. Because milk production does not immediately shut down, milk accumulates in the alveoli, engorging the breasts. The resulting pressure buildup acts directly on the alveolar epithelial cells to suppress further milk production. Cessation of lactation at weaning therefore results from a lack of suckling-induced stimulation of both prolactin and oxytocin secretion.

The end is a new beginning.

Reproduction is an appropriate way to end our discussion of physiology from cells to systems. The single cell resulting from the union of male and female gametes divides mitotically and differentiates into a multicellular individual made up of a number of body systems that interact cooperatively to maintain homeostasis (that is, stability in the internal environment). All the life-supporting homeostatic processes introduced throughout this book begin again at the start of a new life.

Check Your Understanding 20.4

1. List and describe the stages of follicular development and indicate the status of the gamete in each of these stages.
2. Tell what ovarian hormones the follicle and the corpus luteum secrete, state the effects of these hormones on the uterus, and indicate during which phase of the ovarian cycle each of the phases of the uterine cycle takes place.
3. Define *zygote, blastocyst, inner cell mass, trophoblast, decidua, chorion, placenta, embryo,* and *fetus.*
4. Discuss the role of oxytocin during parturition and during breast-feeding.

Homeostasis: Chapter in Perspective

The reproductive system is unique in that it is not essential for homeostasis or for survival of the individual but is essential for sustaining the thread of life from generation to generation. Reproduction depends on the union of male and female gametes (reproductive cells), each with a half set of chromosomes, to form a new individual with a full, one-of-a-kind set of chromosomes. Unlike the other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are remarkably different, befitting their different roles in the reproductive process.

The male system is designed to continuously produce huge numbers of mobile spermatozoa that are delivered to the female during the sex act. Male gametes must be produced in abundance for two reasons: (1) Only a small percentage of them survive the hazardous journey through the female reproductive tract to the site of fertilization, and (2) the cooperative effort of many spermatozoa is required to break down the barriers surrounding the female gamete (ovum or egg) to enable one spermatozoon to penetrate and unite with the ovum.

The female reproductive system undergoes complex changes on a cyclic monthly basis. During the first half of the cycle, a single nonmotile ovum is prepared for release. During the second half, the reproductive system is geared toward preparing a suitable environment for supporting the ovum if fertilization (union with a spermatozoon) occurs. If fertilization does not occur, the prepared supportive environment within the uterus sloughs off, and the cycle starts again as a new ovum is prepared for release. If fertilization occurs, the female reproductive system adjusts to support growth and development of the new individual until it can survive on its own on the outside.

There are three important parallels in the male and female reproductive systems, even though they differ considerably in structure and function. First, the same set of undifferentiated reproductive tissues in the embryo can develop into either a male or a female system, depending on the presence or absence, respectively, of male-determining factors. Second, the same hormones—namely, hypothalamic kisspeptins and GnRH and anterior pituitary FSH and LH—control reproductive function in both sexes. In both cases, gonadal steroids and inhibin act in negative-feedback fashion to control hypothalamic and anterior pituitary output, with the exception that a high estrogen level in females induces an ovulation-triggering surge in LH secretion in positive-feedback fashion. Third, the same events take place in the developing gamete's nucleus during sperm formation and egg formation, although males produce millions of sperm in a day, whereas females produce only about 400 ova in a lifetime.

Review Exercises   Answers begin on p. A-53

Reviewing Terms and Facts

1. It is possible for a genetic male to have the anatomic appearance of a female. *(True or false?)*

2. Testosterone secretion essentially ceases from birth until puberty. *(True or false?)*

3. Females do not experience erection. *(True or false?)*

4. Most of the lubrication for sexual intercourse is provided by the female. *(True or false?)*

5. If a follicle does not reach maturity during one ovarian cycle, it can finish maturing during the next cycle. *(True or false?)*

6. Rising, moderate levels of estrogen inhibit tonic LH secretion, whereas high levels of estrogen stimulate the LH surge. *(True or false?)*

7. Spermatogenesis takes place within the _____ of the testes, stimulated by the hormones _____ and _____.

8. During estrogen production by the follicle, the _____ cells under the influence of the hormone _____ produce androgens, and the _____ cells under the influence of the hormone _____ convert these androgens into estrogens.

9. The source of estrogen and progesterone during the first 10 weeks of gestation is the _____. The source of these hormones during the last two trimesters of gestation is the _____.

10. Detection of _____ in the urine is the basis of pregnancy diagnosis tests.

11. Which of the following statements concerning chromosomal distribution is *incorrect?*

   a. All human somatic cells contain 23 chromosomal pairs for a total diploid number of 46 chromosomes.

   b. Each gamete contains 23 chromosomes, one member of each chromosomal pair.

   c. During meiotic division, the members of the chromosome pairs regroup themselves into the original combinations derived from the individual's mother and father for separation into haploid gametes.

   d. Sex determination depends on the combination of sex chromosomes, an XY combination being a genetic male and XX a genetic female.

   e. The sex chromosome content of the fertilizing sperm determines the sex of the offspring.

12. When the corpus luteum degenerates,
    a. circulating levels of estrogen and progesterone rapidly decline.
    b. FSH and LH secretion start to rise as the inhibitory effects of the gonadal steroids are withdrawn.
    c. the endometrium sloughs off.
    d. both (a) and (b) occur.
    e. all of the above

13. Match the following:
    1. secrete(s) prostaglandins
    2. increase(s) motility and fertility of sperm
    3. secrete(s) an alkaline fluid
    4. provide(s) fructose
    5. act(s) as the storage site for sperm
    6. concentrate(s) the sperm a 100-fold
    7. secrete(s) fibrinogen
    8. provide(s) clotting enzymes
    9. contain(s) erectile tissue

    (a) epididymis and ductus deferens
    (b) prostate gland
    (c) seminal vesicles
    (d) bulbourethral glands
    (e) penis

14. Using the following answer code, indicate when each event takes place during the ovarian cycle:
    1. rapid development of recruited antral follicles
    2. secretion of estrogen
    3. secretion of progesterone
    4. menstruation
    5. repair and proliferation of the endometrium
    6. increased vascularization and glycogen storage in the endometrium

    (a) occurs during the follicular phase
    (b) occurs during the luteal phase
    (c) occurs during both the follicular and the luteal phases

Understanding Concepts
(Answers at www.cengagebrain.com)

1. What constitutes the primary reproductive organs, gametes, sex hormones, reproductive tract, accessory sex glands, external genitalia, and secondary sexual characteristics in males and in females?

2. List the essential reproductive functions of the male and of the female.

3. Discuss what determines genetic sex, gonadal sex, and phenotypic sex in males and in females.

4. Of what functional significance is the scrotal location of the testes?

5. Discuss the source and functions of testosterone.

6. Describe the three major stages of spermatogenesis. Discuss the functions of each part of a spermatozoon. What are the roles of Sertoli cells?

7. Discuss the control of testicular function.

8. Compare the sex act in males and females.

9. Compare oogenesis with spermatogenesis.

10. Discuss the structure of, gamete status in, stimulation of, and hormonal secretion (if any) by each of the following: primordial follicle, preantral follicle, early antral follicle, recruitable antral follicle, mature follicle, and corpus luteum.

11. How are the ovum and spermatozoa transported to the site of fertilization? Describe the process of fertilization.

12. Describe the process of implantation and placenta formation.

13. What are the functions of the placenta? What hormones does the placenta secrete?

14. What is the role of human chorionic gonadotropin?

15. What factors contribute to the initiation of parturition? What are the stages of labor? What is the role of oxytocin?

16. Describe the hormonal factors that play a role in lactation.

17. Summarize the actions of estrogen and progesterone.

Applying Clinical Reasoning

Maria A., who is in her second month of gestation, has been experiencing severe abdominal cramping. Her physician has diagnosed her condition as a tubal pregnancy: The developing embryo is implanted in the oviduct instead of in the uterine endometrium. Why must this pregnancy be surgically terminated?

Thinking at a Higher Level

1. The hypothalamus releases GnRH in pulsatile bursts once every 2 to 3 hours, with no secretion occurring between bursts. The blood concentration of GnRH depends on the frequency of these bursts of secretion. A promising line of research for a new method of contraception involves administration of GnRHlike drugs. In what way could such drugs act as contraceptives when GnRH is the hypothalamic hormone that triggers the chain of events leading to ovulation? (Hint: The anterior pituitary is "programmed" to respond only to the normal pulsatile pattern of GnRH.)

2. Occasionally, testicular tumors composed of interstitial cells of Leydig may secrete up to 100 times the normal amount of testosterone. When such a tumor develops in young children, they grow up much shorter than their genetic potential. Explain why. What other symptoms would be present?

3. What type of sexual dysfunction might arise in men taking drugs that inhibit sympathetic nervous system activity as part of the treatment for high blood pressure?

4. Explain the physiologic basis for administering a posterior pituitary extract to induce or facilitate labor.

5. The symptoms of menopause are sometimes treated with supplemental estrogen and progesterone. Why wouldn't treatment with GnRH or FSH and LH also be effective?

A Review of Chemical Principles

By Spencer Seager, Weber State University, and Lauralee Sherwood

A.1 Chemical Level of Organization in the Body

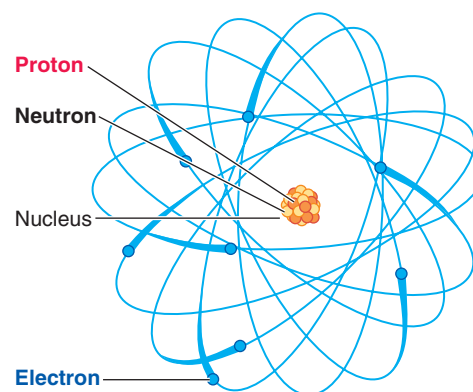
Matter is anything that occupies space and has mass, including all living and nonliving things in the universe. **Mass** is the amount of matter in an object. **Weight,** in contrast, is the effect of gravity on that mass. The more gravity exerted on a mass, the greater the weight of the mass. An astronaut has the same mass whether on Earth or in space but is weightless in the zero gravity of space.

Atoms

All matter is made up of tiny particles called **atoms.** These particles are too small to be seen individually, even with the most powerful electron microscopes available today.

Even though extremely small, atoms consist of three types of even smaller subatomic particles. The types of atoms vary in the numbers of these subatomic particles they contain. **Protons** and **neutrons** are particles of nearly identical mass, with protons carrying a positive charge and neutrons having no charge. **Electrons** have a much smaller mass than protons and neutrons and are negatively charged. An atom consists of two regions—a dense, central *nucleus* made of protons and neutrons surrounded by a three-dimensional *electron cloud,* where electrons move rapidly around the nucleus in orbitals (❚Figure A-1). The magnitude of the charge of a proton exactly matches that of an electron, but it is opposite in sign, being positive. In all atoms, the number of protons in the nucleus is equal to the number of electrons moving around the nucleus, so their charges balance and the atoms are neutral.

Elements and atomic symbols

A pure substance composed of only one type of atom is called an **element.** A pure sample of the element carbon contains only carbon atoms, even though the atoms might be arranged in the form of diamond or in the form of graphite (pencil "lead"). Each element is designated by an **atomic symbol,** a one- or two-letter chemical shorthand form of the element's name. Usually these symbols are easy to follow, because they are derived from the English name for the element. Thus, H stands for *hydrogen,* C for *carbon,* and O for *oxygen.* In a few cases, the atomic symbol is based on the element's Latin name—for example, Na for *sodium* (*natrium* in Latin) and K for *potassium*


❚Figure A-1 **The atom.** The atom consists of two regions. The central nucleus contains protons and neutrons and makes up 99.9% of the mass. Surrounding the nucleus is the electron cloud, where the electrons move rapidly around the nucleus. (Figure not drawn to scale.)

(kalium). Of the 109 known elements, 26 are normally found in the body. Four elements—hydrogen, carbon, oxygen, and nitrogen—comprise 96% of the body's mass.

Compounds and molecules

Pure substances composed of more than one type of atom are known as **compounds.** Pure water, for example, is a compound that contains atoms of hydrogen and atoms of oxygen in a 2:1 ratio, regardless of whether the water is in the form of liquid, solid (ice), or vapor (steam). A **molecule** is the smallest unit of a pure substance that has the properties of that substance and is capable of a stable, independent existence. For example, a molecule of water consists of two atoms of hydrogen and one atom of oxygen, held together by chemical bonds.

Atomic number

Exactly what are we talking about when we refer to a "type" of atom? That is, what makes hydrogen, carbon, and oxygen atoms different? The answer is the number of protons in the nucleus. Regardless of where they are found, all hydrogen atoms have 1 proton in the nucleus, all carbon atoms have 6, and all oxygen atoms have 8. These numbers also represent the number of electrons moving around each nucleus, because the number of electrons and number of protons in an atom are equal. The number of protons in the nucleus of an atom of an element is called the **atomic number** of the element.

Atomic weight

As expected, tiny atoms have tiny masses. For example, the actual mass of a hydrogen atom is 1.67×10^{-24} g, that of a carbon atom is 1.99×10^{-23} g, and that of an oxygen atom is 2.66×10^{-23} g. These very small numbers are inconvenient to work with in calculations, so a system of relative masses has been developed. These relative masses simply compare the actual masses of the atoms with one another. Suppose the actual masses of two people were determined to be 45.50 and 113.75 kg. Their relative masses are determined by dividing each mass by the smaller mass of the two: $45.50/45.50 = 1.00$, and $113.75/45.50 = 2.50$. Thus, the relative masses of the two people are 1.00 and 2.50; these numbers simply express that the mass of the heavier person is 2.50 times that of the other person. The relative masses of atoms are called **atomic masses,** or **atomic weights,** and they are given in *atomic mass units (amu).* In this system, hydrogen atoms, the least massive of all atoms, have an atomic weight of 1.01 amu. The atomic weight of carbon atoms is 12.01 amu, and that of oxygen atoms is 16.00 amu. Thus, oxygen atoms have a mass about 16 times that of hydrogen atoms. ❙Table A-1 gives the atomic weights and some other characteristics of the elements that are most important physiologically.

A.2 Chemical Bonds

Because all matter is made up of atoms, atoms must somehow be held together to form matter. The forces holding atoms together are called **chemical bonds.** Not all chemical bonds are formed in the same way, but all involve the electrons of atoms. Whether one atom bonds with another depends on the number and arrangement of its electrons. An atom's electrons are arranged in electron shells, to which we now turn our attention.

❙**TABLE A-1** Characteristics of Selected Elements

Name and Symbol	Number of Protons	Atomic Number	Atomic Weight (amu)
Hydrogen (H)	1	1	1.01
Carbon (C)	6	6	12.01
Nitrogen (N)	7	7	14.01
Oxygen (O)	8	8	16.00
Sodium (Na)	11	11	22.99
Magnesium (Mg)	12	12	24.31
Phosphorus (P)	15	15	30.97
Sulfur (S)	16	16	32.06
Chlorine (Cl)	17	17	35.45
Potassium (K)	19	19	39.10
Calcium (Ca)	20	20	40.08

Electron shells

Electrons tend to move around the nucleus in a specific pattern. The orbitals, or pathways traveled by electrons around the nucleus, are arranged in an orderly series of concentric layers known as **electron shells,** which consecutively surround the nucleus. Each electron shell can hold a specific number of electrons. The first shell, closest to the nucleus (innermost), can contain a maximum of only 2 electrons, no matter what the element is. The second shell can hold a total of 8 more electrons. The third shell also can hold a maximum of 8 electrons. As the number of electrons increases with increasing atomic number, still more electrons occupy successive shells, each at a greater distance from the nucleus. Each successive shell from the nucleus has a higher **energy level.** Because the negatively charged electrons are attracted to the positively charged nucleus, it takes more energy for an electron to overcome the nuclear attraction and orbit farther from the nucleus. Thus, the first electron shell has the lowest energy level and the outermost shell of an atom has the highest energy level.

In general, electrons belong to the lowest energy shell possible, up to the maximum capacity of each shell. For example, hydrogen atoms have only 1 electron, so it is in the first shell. Helium atoms have 2 electrons, which are both in the first shell and fill it. Carbon atoms have 6 electrons, 2 in the first shell and 4 in the second shell, whereas the 8 electrons of oxygen are arranged with 2 in the first shell and 6 in the second shell.

Bonding characteristics of an atom and valence

Atoms tend to undergo processes that result in a filled outermost electron shell. Thus, the electrons of the outer or higher-energy shell determine the bonding characteristics of an atom and its ability to interact with other atoms. Atoms that have a vacancy in their outermost shell tend to give up, accept, or share electrons with other atoms (whichever is most favorable energetically) so that all participating atoms have filled outer shells. For example, an atom that has only 1 electron in its outermost shell may empty this shell so that its remaining shells are full. By contrast, another atom that lacks only 1 electron in its outer shell may acquire the deficient electron from the first atom to fill all its shells to the maximum. The number of electrons an atom loses, gains, or shares to achieve a filled outer shell is known as the atom's **valence.** A **chemical bond** is the force of attraction that holds participating atoms together as a result of an interaction between their outermost electrons.

Consider sodium atoms (Na) and chlorine atoms (Cl) (❙Figure A-2). Sodium atoms have 11 electrons: 2 in the first shell, 8 in the second shell, and 1 in the third shell. Chlorine atoms have 17 electrons: 2 in the first shell, 8 in the second shell, and 7 in the third shell. Because 8 electrons are required to fill the second and third shells, sodium atoms have 1 electron more than is needed to provide a filled second shell, whereas chlorine atoms have 1 fewer electron than is needed to fill the third shell. Each sodium atom can lose an electron to a chlorine atom, leaving each sodium atom with 10 electrons; 8 of these are in the second shell, which is full and is now the outer shell occupied by electrons. By accepting 1 electron, each chlorine atom now
Figure A-2 Ions and ionic bonds. Sodium (Na) and chlorine (Cl) atoms both have partially filled outermost shells. Therefore, sodium tends to give up its lone electron in the outer shell to chlorine, filling chlorine's outer shell. As a result, sodium becomes a positively charged ion and chlorine becomes a negatively charged ion known as chloride. The oppositely charged ions attract each other, forming an ionic bond.

has a total of 18 electrons, with 8 of them in the third, or outer, shell, which is now full.

Ions; ionic bonds

Recall that atoms are electrically neutral because they have an identical number of positively charged protons and negatively charged electrons. By giving up and accepting electrons, the sodium atoms and chlorine atoms have achieved filled outer shells, but now each atom is unbalanced electrically. Although each sodium atom now has 10 electrons, it still has 11 protons in the nucleus and a net electrical charge, or valence, of +1. Similarly, each chlorine atom now has 18 electrons but only 17 protons. Thus, each chlorine atom has a −1 charge. Such charged atoms are called **ions.** Positively charged ions are called **cations**; negatively charged ions are called **anions.** As a helpful hint to keep these terms straight, imagine the "t" in *cation* as standing for a "+" sign and the first "n" in *anion* as standing for "negative."

Note that both a cation and an anion are formed whenever an electron is transferred from one atom to another. Because opposite charges attract, sodium ions (Na^+) and charged chlorine atoms, now called *chloride* ions (Cl^-), are attracted toward each other. This electrical attraction that holds cations and anions together is known as an **ionic bond.** Ionic bonds hold Na^+ and Cl^- together in the compound **sodium chloride, NaCl,** which is common table salt. A sample of sodium chloride actually contains sodium and chloride ions in a three-dimensional geometrical arrangement called a *crystal lattice.* The ions of opposite charge occupy alternate sites within the lattice (**I** Figure A-3).

Covalent bonds

It is not favorable, energywise, for an atom to give up or accept more than three electrons. Nevertheless, carbon atoms, which have four electrons in their outer shell, form compounds. They do so by another bonding mechanism, *covalent bonding.* Atoms that would have to lose or gain four or more electrons to achieve outer-

shell stability usually bond by *sharing* electrons. Shared electrons actually orbit around *both* atoms. Thus, a carbon atom can share its 4 outer electrons with the 4 electrons of 4 hydrogen atoms, as shown in Equation A-1, where the outer-shell electrons are shown as dots around the symbol of each atom. (The resulting compound is methane, CH_4, a gas made up of individual CH_4 molecules.)

$$\underset{\text{electron pairs}}{\underset{\text{Shared}}{}} \qquad \dot{\underset{.}{C}}\cdot\, +\, 4\cdot H \rightarrow H\!:\!\!\underset{\underset{\text{H}}{H}}{\overset{\overset{\text{H}}{\cdots}}{C}}\!:\!H \qquad \text{Eq. A-1}$$

shells by sharing one electron pair made from the single electrons of each atom, as shown in Equation A-2:

$$H\cdot \; + \; \cdot H \rightarrow H \!:\! H \qquad \text{Eq. A-2}$$

Thus, hydrogen gas consists of individual H_2 molecules (**I** Figure A-4a). (A subscript following a chemical symbol indicates the number of that type of atom present in the molecule.) Several other nonmetallic elements also exist as molecules because covalent bonds form between identical atoms; oxygen (O_2) is an example (**I** Figure A-4b).

Often, an atom can form covalent bonds with more than one atom. One of the most familiar examples is water (H_2O), consisting of two hydrogen atoms each forming a single covalent bond with one oxygen atom (**I** Figure A-4c). Equation A-3 represents the formation of water's covalent bonds:

$$\begin{array}{c} H\cdot \\ + \; \cdot \ddot{\underset{..}{O}} : \; \rightarrow H \!:\! \ddot{\underset{..}{O}} : \qquad \text{Eq. A-3} \\ H\cdot \qquad\qquad\quad H \end{array}$$
The water molecule is sometimes represented as

$$\begin{array}{c} H — O \\ | \\ H \end{array}$$

where the nonshared electron pairs are not shown and the covalent bonds, or shared pairs, are represented by dashes.

Nonpolar and polar molecules

The electrons between two atoms in a covalent bond are not always shared equally. When the atoms sharing an electron pair are identical, such as two oxygen atoms, the electrons are attracted equally by both atoms and so are shared equally. The result is a **nonpolar molecule.** The term *nonpolar* implies no difference at the two ends (two "poles") of the bond. Because both atoms within the molecule exert the same pull on the shared electrons, each shared electron spends the same amount of time orbiting each atom. Thus, both atoms remain electrically neutral in a nonpolar molecule such as O_2.

When the sharing atoms are not identical, unequal sharing of electrons occurs because atoms of different elements do not exert the same pull on shared electrons. For example, an oxygen atom strongly attracts electrons when it is bonded to other atoms. A **polar molecule** results from the unequal sharing of electrons between different types of atoms covalently bonded together. The water molecule is a good example of a polar molecule. The oxygen atom pulls the shared electrons more strongly than do the

Each electron that is shared by two atoms is counted toward the number of electrons needed to fill the outer shell of each atom. Thus, each carbon atom shares four pairs, or 8 electrons, and thus has 8 in its outer shell. Each hydrogen atom shares one pair, or 2 electrons, and thus has a filled outer shell. (Remember, hydrogen atoms need only two electrons to complete their outer shell, which is the first shell.) The sharing of a pair of electrons by atoms binds them together by means of a **covalent bond** (**I** Figure A-4). Covalent bonds are the strongest of chemical bonds—that is, they are the hardest to break.

Covalent bonds also form between some identical atoms. For example, two hydrogen atoms can complete their outer

I Figure A-5 A polar molecule. A water molecule is an example of a polar molecule, in which the distribution of shared electrons is not uniform. Because the oxygen atom pulls the shared electrons more strongly than the hydrogen atoms do, the oxygen side of the molecule is slightly negatively charged and the hydrogen sides are slightly positively charged.

I Figure A-6 A hydrogen bond. A hydrogen bond is formed by the attraction of a positively charged hydrogen end of a polar molecule to the negatively charged end of another polar molecule.

hydrogen atoms within each of the two covalent bonds. Consequently, the electron of each hydrogen atom tends to spend more time away orbiting around the oxygen atom than at home around the hydrogen atom. Because of this nonuniform distribution of electrons, the oxygen side of the water molecule where the shared electrons spend more time is slightly negative, and the two hydrogens that are visited less frequently by the electrons are slightly more positive (**I** Figure A-5). Note that the entire water molecule has the same number of electrons as it has protons, so as a whole it has no net charge. This is unlike ions, which have an electron excess or deficit. Polar molecules have a balanced number of protons and electrons but an unequal distribution of the shared electrons among the atoms making up the molecule.

Hydrogen bonds

Polar molecules are attracted to other polar molecules. In water, for example, an attraction exists between the positive hydrogen ends of some molecules and the negative oxygen ends of others. Hydrogen is not a part of all polar molecules, but when it is covalently bonded to an atom that strongly attracts electrons to form a covalent molecule, the attraction of the positive (hydrogen) end of the polar molecule to the negative end of another polar molecule is called a **hydrogen bond** (**I** Figure A-6). Thus, the polar attractions of water molecules to each other are an example of hydrogen bonding.

A.3 Chemical Reactions

Processes in which chemical bonds are broken, formed, or both are called **chemical reactions.** Reactions are represented by equations in which the reacting substances (**reactants**) are typically written on the left, the newly produced substances (**products**) are written on the right, and an arrow meaning "yields" points from the reactants to the products. These conventions are illustrated in Equation A-4:

$$A + B \rightarrow C + D \qquad \text{Eq. A-4}$$
$$\underbrace{}_{\text{Reactants}} \quad \underbrace{}_{\text{Products}}$$

Balanced equations

A chemical equation is a "chemical bookkeeping" ledger that describes what happens in a reaction. By the **law of conservation of mass,** the total mass of all materials entering a reaction
equals the total mass of all the products. Thus, the total number of atoms of each element must always be the same on the left and right sides of the equation, because no atoms are lost. Such equations in which the same number of atoms of each type appears on both sides are called **balanced equations.** When writing a balanced equation, the number *preceding* a chemical symbol designates the number of independent (unjoined) atoms, ions, or molecules of that type, whereas a number written as a subscript *following* a chemical symbol denotes the number of a particular atom within a molecule. The absence of a number indicates "one" of that particular chemical. Let us look at a specific example, the oxidation of glucose (the sugar that cells use as fuel), as shown in Equation A-5:

$$\underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{oxygen}}{6\,O_2} \rightarrow \underset{\substack{\text{carbon}\\\text{dioxide}}}{6\,CO_2} + \underset{\text{water}}{6\,H_2O} \qquad \text{Eq. A-5}$$
According to this equation, 1 molecule of glucose reacts with 6 molecules of oxygen to produce 6 molecules of carbon dioxide and 6 molecules of water. Note the following balance in this reaction:

■ 6 carbon atoms on the left (in 1 glucose molecule) and 6 carbon atoms on the right (in 6 carbon dioxide molecules)

■ 12 hydrogen atoms on the left (in 1 glucose molecule) and 12 on the right (in 6 water molecules, each containing 2 hydrogen atoms)

■ 18 oxygen atoms on the left (6 in 1 glucose molecule plus 12 more in the 6 oxygen molecules) and 18 on the right (12 in 6 carbon dioxide molecules, each containing 2 oxygen atoms, and 6 more in the 6 water molecules, each containing 1 oxygen atom)

Reversible and irreversible reactions

Under appropriate conditions, the products of a reaction can be changed back to the reactants. For example, carbon dioxide gas dissolves in and reacts with water to form carbonic acid, H_2CO_3:

$$CO_2 + H_2O \rightarrow H_2CO_3 \qquad \text{Eq. A-6}$$

Carbonic acid is not very stable, however, and as soon as some is formed, part of it decomposes to give carbon dioxide and water:

$$H_2CO_3 \rightarrow CO_2 + H_2O \qquad \text{Eq. A-7}$$
Reactions that go in both directions are called **reversible reactions.** Double arrows pointing in both directions usually represent them:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \qquad \text{Eq. A-8}$$

Theoretically, every reaction is reversible. Often, however, conditions are such that a reaction, for all practical purposes, goes in only one direction; such a reaction is called **irreversible.** For example, an irreversible reaction takes place when an explosion occurs, because the products do not remain in the vicinity of the reaction site to get together to react.

Catalysts; enzymes

The rates (speeds) of chemical reactions are influenced by a number of factors, of which catalysts are one of the most important. A **catalyst** is a "helper" molecule that speeds up a reaction without being used up in the reaction. Living organisms use catalysts known as **enzymes.** These enzymes exert amazing influence on the rates of chemical reactions that take place in the organisms. Reactions that take weeks or even months to occur under normal laboratory conditions take place in seconds under the influence of enzymes in the body. One of the fastest-acting enzymes is **carbonic anhydrase (ca)**, which catalyzes the reaction between carbon dioxide and water to form carbonic acid. This reaction is important in the transport of carbon dioxide from tissue cells, where it is produced metabolically, to the lungs, where it is excreted. The equation for the reaction was shown in Equation A-6. (Carbonic anhydrase indirectly catalyzes this reaction by converting $CO_2 + H_2O$ directly to $H^+ + HCO_3^-$, which can form H_2CO_3. In the absence of ca, $CO_2 + H_2O$ slowly, directly form H_2CO_3. The reactions both with and without catalyst are commonly shown as in Equation A-6; see p. 550 for specific details.) Each molecule of carbonic anhydrase catalyzes the conversion of 36 million CO_2 molecules per minute! Enzymes are important in essentially every chemical reaction that takes place in living organisms.

A.4 Molecular and Formula Weight and the Mole

Because molecules are made up of atoms, the relative mass of a molecule is simply the sum of the relative masses (atomic weights) of the atoms found in the molecule. The relative masses of molecules are called **molecular masses** or **molecular weights.** The molecular weight of water, H_2O, is thus the sum of the atomic weights of two hydrogen atoms and one oxygen atom, or 1.01 amu + 1.01 amu + 16.00 amu = 18.02 amu.

Not all compounds exist in the form of molecules. Ionically bonded substances such as sodium chloride consist of three-dimensional arrangements of sodium ions (Na^+) and chloride ions (Cl^-) in a 1:1 ratio. The formulas for ionic compounds reflect only the ratio of the ions in the compound and should not be interpreted in terms of molecules. Thus, the formula for sodium chloride, NaCl, indicates that the ions combine in a 1:1 ratio. It is convenient to apply the concept of relative masses to ionic compounds even though they do not exist as molecules. The **formula weight** for such compounds is defined as the sum of the atomic weights of the atoms found in the formula. Thus, the formula weight of NaCl is equal to the sum of the atomic weights of one sodium atom and one chlorine atom, or 22.99 amu + 35.45 amu = 58.44 amu.

As you have seen, chemical reactions can be represented by equations and discussed in terms of numbers of molecules, atoms, and ions reacting with one another. To carry out reactions in the laboratory, however, a scientist cannot count out numbers of reactant particles but instead must be able to weigh the correct amount of each reactant. Using the mole concept makes this task possible. A **mole** (abbreviated *mol*) of a pure element or compound is the amount of material contained in a sample of the pure substance that has a mass in grams equal to the substance's atomic weight (for elements) or the molecular weight or formula weight (for compounds). Thus, 1 mol of potassium, K, would be a sample of the element with a mass of 39.10 g. Similarly, 1 mol of H_2O would have a mass of 18.02 g, and 1 mol of NaCl would be a sample with a mass of 58.44 g.

Atomic weights, molecular weights, and formula weights are relative masses, which leads to a fundamental characteristic of moles. For example, 1 mol of oxygen atoms has a mass of 16.00 g, and 1 mol of hydrogen atoms has a mass of 1.01 g. Thus, the ratio of the masses of 1 mol of each element is 16.00 to 1.01, the same as the ratio of the atomic weights for the two elements. Recall that these atomic weights compare the relative masses of oxygen and hydrogen. Accordingly, the number of oxygen atoms present in 16 g of oxygen (1 mol of oxygen) is the same as the number of hydrogen atoms present in 1.01 g of hydrogen. Therefore, 1 mol of oxygen contains exactly the same number of oxygen atoms as the number of hydrogen atoms in 1 mol of hydrogen. Thus, it is possible and sometimes useful to think of a mole as a specific number of particles. This number, called **Avogadro's number,** is equal to 6.02×10^{23}.

A.5 Solutions, Colloids, and Suspensions

In contrast to a compound, a **mixture** consists of two or more types of elements or molecules physically blended together (intermixed) instead of being linked by chemical bonds. A compound has very different properties from the individual elements of which it is composed. For example, the solid, white NaCl (table salt) crystals you use to flavor your food are different from either sodium (a silvery white metal) or chlorine (a poisonous yellow–green gas found in bleach). By comparison, each component of a mixture retains its chemical properties. If you mix salt and sugar together, each retains a distinct taste and other individual properties. The constituents of a compound can only be separated by chemical means—bond breakage. By contrast, the components of a mixture can be separated by

physical means, such as filtration or evaporation. The most common mixtures in the body are mixtures of water and various other substances. These mixtures are categorized as *solutions, colloids,* or *suspensions,* depending on the size and nature of the substance mixed with water.

Solutions

Most chemical reactions in the body take place between reactants that have dissolved to form solutions. **Solutions** are homogenous mixtures containing a relatively large amount of one substance called the **solvent** (the dissolving medium) and smaller amounts of one or more substances called **solutes** (the dissolved particles). Saltwater, for example, contains mostly water, which is thus the solvent, and a smaller amount of salt, which is the solute. Water is the solvent in most solutions found in the human body.

Electrolytes versus nonelectrolytes

When ionic solutes are dissolved in water to form solutions, the resulting solution will conduct electricity. This is not true for most covalently bonded solutes. For example, a salt–water solution conducts electricity, but a sugar–water solution does not. When salt dissolves in water, the solid lattice of Na^+ and Cl^- is broken down, and the individual ions are separated and distributed uniformly throughout the solution. These mobile, charged ions conduct electricity through the solution. Solutes that form ions in solution and conduct electricity are called **electrolytes.** When sugar dissolves, however, individual covalently bonded sugar molecules leave the solid and become uniformly distributed throughout the solution. These uncharged molecules cannot conduct a current. Solutes that do not form conductive solutions are called **nonelectrolytes.**

Measures of concentration

The amount of solute dissolved in a specific amount of solution can vary. For example, a salt–water solution might contain 1 g of salt in 100 mL of solution, or it could contain 10 g of salt in 100 mL of solution. Both solutions are salt–water solutions, but they have different concentrations of solute. The **concentration** of a solution indicates the relationship between the amount of solute and the amount of solution. Concentrations can be given in various units.

Molarity Concentrations given in terms of **molarity (M)** give the number of moles of solute in exactly 1 liter of solution. Thus, a half molar (0.5 M) solution of NaCl would contain one-half mole, or 29.22 g, of NaCl in each liter of solution.

Normality When the solute is an electrolyte, it is sometimes useful to express the concentration of the solution in a unit that gives information about the amount of ionic charge in the solution. This is done by expressing concentration in terms of **normality (N).** The normality of a solution gives the number of equivalents of solute in exactly 1 liter of solution. An **equivalent** of an electrolyte is the amount that produces 1 mole of positive (or negative) charges when it dissolves. The number of equiva-

lents of an electrolyte can be calculated by multiplying the number of moles of electrolyte by the total number of positive charges produced when one formula unit of the electrolyte dissolves. Consider NaCl and calcium chloride ($CaCl_2$) as examples. The ionization reactions for one formula unit of each solute are

$$NaCl \rightarrow Na^+ + Cl^- \qquad \text{Eq. A-9}$$

$$CaCl_2 \rightarrow Ca^{2+} + 2\ Cl^- \qquad \text{Eq. A-10}$$
Thus, 1 mol of NaCl produces 1 mole of positive charges (Na^+) and so contains 1 equivalent:

$$(1 \text{ mol NaCl}) \times 1 = 1 \text{ equivalent}$$

where the number 1 used to multiply the 1 mol of NaCl came from the +1 charge on Na^+.

One mole of $CaCl_2$ produces 1 mol of Ca^{2+}, which is 2 moles of positive charge. Thus, 1 mol of $CaCl_2$ contains 2 equivalents:

$$(1 \text{ mol CaCl}_2) \times 2 = 2 \text{ equivalents}$$

where the number 2 used in the multiplication came from the +2 charge on Ca^{2+}.

If two solutions were made such that one contained 1 mol of NaCl per liter and the other contained 1 mol of $CaCl_2$ per liter, the NaCl solution would contain 1 equivalent of solute per liter and would be 1 normal (1 N). The $CaCl_2$ solution would contain 2 equivalents of solute per liter and would be 2 normal (2 N).

Osmolarity Another expression of concentration frequently used in physiology is **osmolarity (Osm/L)**, which indicates the total *number* of solute particles in a liter of solution instead of the relative weights of the specific solutes. The osmolarity of a solution is the product of molarity (M) and *n,* where *n* is the number of moles of solute particles obtained when 1 mole of solute dissolves. Because nonelectrolytes such as glucose do not dissociate in solution, $n = 1$ and the osmolarity ($n \times M$) is equal to the molarity of the solution. For electrolyte solutions, the osmolarity exceeds the molarity by a factor equal to the number of ions produced on dissociation of each molecule in solution. For example, because a NaCl molecule dissociates into two ions, Na^+ and Cl^-, the osmolarity of a 1 M solution of NaCl is $2 \times 1\ M = 2$ Osm/L.

Colloids and suspensions

In solutions, solute particles are ions or small molecules. By contrast, the particles in colloids and suspensions are much larger than ions or small molecules. In colloids and suspensions, these particles are known as **dispersed-phase particles** instead of *solutes.* When the dispersed-phase particles are no more than about 100 times the size of the largest solute particles found in a solution, the mixture is called a **colloid.** The dispersed-phase particles of colloids generally do not settle out. All dispersed-phase particles of colloids carry electrical charges of the same sign. Thus, they repel each other. The constant buffeting from these collisions keeps the particles from settling. The most abundant colloids in the body are small functional proteins that are dispersed in the body fluids. An example is the colloidal dispersion of the plasma proteins in the blood (see p. 357).

When dispersed-phase particles are larger than those in colloids, if the mixture is left undisturbed the particles settle out because of the force of gravity. Such mixtures are usually called **suspensions.** The major example of a suspension in the body is the mixture of blood cells suspended in the plasma (see p. 381). The constant movement of blood as it circulates through the blood vessels keeps the blood cells rather evenly dispersed within the plasma. However, if a blood sample is placed in a test tube and treated to prevent clotting, the heavier blood cells gradually settle to the bottom of the tube.

A.6 Inorganic and Organic Chemicals

Chemicals are commonly classified into two categories: inorganic and organic.

Distinction between inorganic and organic chemicals

The original criterion used for this classification was the origin of the chemicals. Those that came from living or once-living sources were *organic,* and those that came from other sources were *inorganic.* Today, the basis for classification is the element carbon. **Organic** chemicals are generally those that contain carbon. All others are classified as **inorganic.** A few carbon-containing chemicals are also classified as inorganic; the most common are pure carbon in the form of diamond and graphite, carbon dioxide (CO_2), carbon monoxide (CO), carbonates such as limestone ($CaCO_3$), and bicarbonates such as baking soda ($NaHCO_3$).

The unique ability of carbon atoms to bond to one another and form networks of carbon atoms results in an interesting fact. Even though organic chemicals all contain carbon, millions of these compounds have been identified. Some were isolated from natural plant or animal sources, and many have been synthesized in laboratories. Inorganic chemicals include all the other 108 elements and their compounds. The number of known inorganic chemicals made up of all these other elements is estimated to be about 250,000, compared to millions of organic compounds made up predominantly of carbon.

Monomers and polymers

Another result of carbon's ability to bond to itself is the large size of some organic molecules. Organic molecules range in size from methane (CH_4), a small, simple molecule with one carbon atom, to molecules such as DNA that contain as many as a million carbon atoms. Organic molecules that are essential for life are called **biological molecules,** or **biomolecules** for short. Some biomolecules are rather small organic compounds, including *simple sugars, fatty acids, amino acids,* and *nucleotides.* These small, single units, known as **monomers** (meaning "single unit"), are building blocks for the synthesis of larger biomolecules, including *complex carbohydrates, lipids, proteins,* and *nucleic acids,* respectively. These larger organic molecules are called **polymers** (meaning "many units"), reflecting that they are made by the bonding together

of a number of smaller monomers. For example, starch is formed by linking many glucose molecules together. Very large organic polymers are often referred to as **macromolecules,** reflecting their large size (*macro* means "large"). Macromolecules include many naturally occurring molecules, such as DNA and structural proteins, as well as many molecules that are synthetically produced, such as synthetic textiles (for example, nylon) and plastics.

A.7 Acids, Bases, and Salts

Acids, bases, and salts may be inorganic or organic compounds.

Acids and bases

Acids and bases are chemical opposites, and salts are produced when acids and bases react with each other. In 1887, Swedish chemist Svante Arrhenius proposed a theory defining acids and bases. He said that an *acid* is any substance that dissociates, or breaks apart, when dissolved in water and in the process releases a hydrogen ion (H^+). Similarly, *bases* are substances that dissociate when dissolved in water and in the process release a hydroxyl ion (OH^-). Hydrogen chloride (HCl) and sodium hydroxide ($NaOH$) are examples of Arrhenius acids and bases; their dissociations in water are represented in Equations A-11 and A-12, respectively:

$$HCl \rightarrow H^+ + Cl^- \qquad \text{Eq. A-11}$$

$$NaOH \rightarrow Na^+ + OH^- \qquad \text{Eq. A-12}$$

Note that the hydrogen ion is a bare proton, the nucleus of a hydrogen atom. Also note that both HCl and $NaOH$ would behave as electrolytes.

Arrhenius did not know that free hydrogen ions cannot exist in water. They covalently bond to water molecules to form hydronium ions, as shown in Equation A-13:

$$\qquad \text{Eq. A-13}$$
In 1923 Johannes Brønsted in Denmark and Thomas Lowry in England proposed an acid–base theory that took this behavior into account. They defined an **acid** as any hydrogen-containing substance that donates a proton (hydrogen ion) to another substance (an acid is a *proton donor*) and a **base** as any substance that accepts a proton (a base is a *proton acceptor*). According to these definitions, the acidic behavior of HCl given in Equation A-11 is rewritten as shown in Equation A-14:

$$HCl + H_2O \rightleftharpoons H_3O^+ + Cl^- \qquad \text{Eq. A-14}$$
Note that this reaction is reversible and the hydronium ion is represented as H_3O^+. In Equation A-14, HCl acts as an acid (hydrochloric acid) in the forward (left-to-right) reaction, whereas H_2O acts as a base. In the reverse reaction (right-to-left), H_3O^+ gives up a proton and thus is an acid, whereas, Cl^- accepts the proton and so is a base. It is still a common practice to use equations such as Equation A-11 to simplify the repre-

sentation of the dissociation of an acid, even though scientists recognize that equations like Equation A-14 are more correct.

When acids or bases are used as solutes in solutions, the concentrations can be expressed as normalities the same as for salts. An equivalent of acid is the amount that gives up 1 mol of H^+ in solution. Thus, 1 mol of HCl is also 1 equivalent, but 1 mol of H_2SO_4 (sulfuric acid) is 2 equivalents. Bases are described in a similar way, but an equivalent is the amount of base that gives 1 mol of OH^-.

Salts; neutralization reactions

At room temperature, **inorganic salts** are crystalline solids that contain the positive ion (cation) of an Arrhenius base such as NaOH and the negative ion (anion) of an acid such as HCl. Salts can be produced by mixing solutions of appropriate acids and bases, allowing a **neutralization reaction** to occur. In neutralization reactions, the acid and base react to form a salt and water. Most salts that form are water soluble and can be recovered by evaporating the water. Equation A-15 is a neutralization reaction:

$$HCl + NaOH \rightarrow NaCl + H_2O \qquad \text{Eq. A-15}$$
See Chapter 15 for a discussion of acid–base balance in the body.

A.8 Functional Groups of Organic Molecules

Organic molecules consist of carbon and one or more additional elements covalently bonded to one another in "Tinker Toy" fashion. The simplest organic molecules, **hydrocarbons** (such as methane and petroleum products), have only hydrogen atoms attached to carbon backbones of varying lengths. All biomolecules always have elements besides hydrogen added to the carbon backbone. The carbon backbone forms the stable portion of most biomolecules. Other atoms covalently bonded to the carbon backbone, either alone or in clusters, form functional groups. **Functional groups** are specific combinations of atoms that generally react in the same way, regardless of the number of carbon atoms in the molecule to which they are attached. For example, all *aldehydes* contain a functional group that includes one carbon atom, one oxygen atom, and one hydrogen atom covalently bonded in a specific way:

$$
\begin{array}{c}
\text{O} \\
\parallel \\
(-\text{C}-\text{H})
\end{array}
$$
The carbon atom in an aldehyde group forms a single covalent bond with the hydrogen atom and a **double bond** (a bond in which two covalent bonds are formed between the same atoms, designated by a double line between the atoms) with the oxygen atom. The aldehyde group is attached to the rest of the molecule by a single covalent bond extending to the left of the carbon atom. Most aldehyde reactions are the same regardless of the size and nature of the rest of the molecule to which the aldehyde group is attached. Reactions of physiological importance often occur between two functional groups or between one functional group and a small molecule such as water.

A.9 Carbohydrates

Carbohydrates are organic compounds of tremendous biological and commercial importance. They are widely distributed in nature and include such familiar substances as starch, table sugar, and cellulose. Carbohydrates have five important functions in living organisms: They provide energy, serve as a stored form of chemical energy, provide dietary fiber, supply carbon atoms for the synthesis of cell components, and form part of the structural elements of cells.

Chemical composition of carbohydrates

Carbohydrates contain carbon, hydrogen, and oxygen. They acquired their name because most of them contain these three elements in an atomic ratio of one carbon to two hydrogens to one oxygen. This ratio suggests that the general formula is CH_2O and that the compounds are simply carbon hydrates ("watered" carbons), or carbohydrates. It is now known that they are not hydrates of carbon, but the name persists. All carbohydrates have a large number of functional groups per molecule. The most common functional groups in carbohydrates are *alcohol, ketone,* and *aldehyde*

$$
(-\text{OH}), \quad (\overset{\displaystyle \text{O}}{\underset{}{\overset{\parallel}{-\text{C}-}}}), \quad (\overset{\displaystyle \text{O}}{\underset{}{\overset{\parallel}{-\text{C}-\text{H}}}})
$$
Alcohol Ketone Aldehyde
or functional groups formed by reactions between pairs of these three.

Types of carbohydrates

The simplest carbohydrates are simple sugars, also called **monosaccharides.** As their name indicates, they consist of single, simple-sugar units called saccharides (*mono* means "one"). The molecular structure of glucose, an important monosaccharide, is shown in ❚ Figure A-7a. In solution, most glucose molecules assume the ring form shown in ❚ Figure A-7b. Other common monosaccharides are *fructose, galactose,* and *ribose* .

Disaccharides are sugars formed by linking two monosaccharide molecules together through a covalent bond (*di* means "two"). Some common examples of disaccharides are *sucrose*

(a) Chain form of glucose   (b) Ring form of glucose
❚ Figure A-7 **Forms of glucose.**

(common table sugar) and *lactose* (milk sugar). Sucrose molecules are formed from one glucose and one fructose molecule. Lactose molecules each contain one glucose and one galactose unit.

Because of the many functional groups on carbohydrate molecules, large numbers of simple carbohydrate molecules are able to bond together and form long chains and branched networks. The resultant substances, **polysaccharides,** contain many saccharide units (*poly* means "many"). Three common polysaccharides made up entirely of glucose units are glycogen, starch, and cellulose:

■ *Glycogen* is a storage carbohydrate found in animals. It is a highly branched polysaccharide that averages a branch every 8 to 12 glucose units. The structure of glycogen is represented in ❙Figure A-8, where each circle represents one glucose unit.

■ *Starch,* a storage carbohydrate of plants, consists of two fractions, amylose and amylopectin. Amylose consists of long, essentially unbranched chains of glucose units. Amylopectin is a highly branched network of glucose units averaging 24 to 30 glucose units per branch. Thus, it is less highly branched than glycogen.

■ *Cellulose,* a structural carbohydrate of plants, exists in the form of long, unbranched chains of glucose units. The bonding between the glucose units of cellulose is slightly different from the bonding between the glucose units of glycogen and starch. Humans have digestive enzymes that catalyze the breaking (hydrolysis) of the glucose-to-glucose bonds in starch but lack the necessary enzymes to hydrolyze cellulose glucose-to-glucose bonds. Thus, starch is a food for humans, but cellulose is not. Cellulose is the indigestible fiber in our diets.

A.10 Lipids

Lipids are a diverse group of organic molecules made up of substances with widely different compositions and molecular structures. Unlike carbohydrates, which are classified on the basis of their *molecular structure,* substances are classified as lipids on the basis of their *solubility.* **Lipids** are insoluble in water but soluble in nonpolar solvents such as alcohol.

Lipids are the waxy, greasy, or oily compounds found in plants and animals. These compounds repel water, a useful characteristic of the protective wax coatings found on some plants. Fats and oils are energy rich and have relatively low densities. These properties account for the use of fats and oils as stored energy in plants and animals. Still other lipids occur as structural components, especially in cellular membranes. The oily plasma membrane that surrounds each cell serves as a barrier that separates the intracellular contents from the surrounding extracellular fluid (see pp. 4, 22, and 56).

Simple lipids

Simple lipids contain just two types of components: fatty acids and alcohols. **Fatty acid molecules** consist of a hydrocarbon chain with a *carboxyl* functional group (—COOH) on the end. The hydrocarbon chain can be of variable length, but natural fatty acids always contain an even number of carbon atoms. The
❙Figure A-8 **A simplified representation of glycogen.** Each circle represents a glucose molecule.

hydrocarbon chain can also contain one or more double bonds between carbon atoms. Fatty acids with no double bonds are called **saturated fatty acids,** whereas those with double bonds are called **unsaturated fatty acids.** The more double bonds present, the higher the degree of unsaturation. Saturated fatty acids predominate in dietary animal products (for example, meat, eggs, and dairy products), whereas unsaturated fatty acids are prevalent in plant products (for example, grains, vegetables, and fruits). Consumption of a greater proportion of saturated than unsaturated fatty acids is linked with a higher incidence of cardiovascular disease (see p. 329).

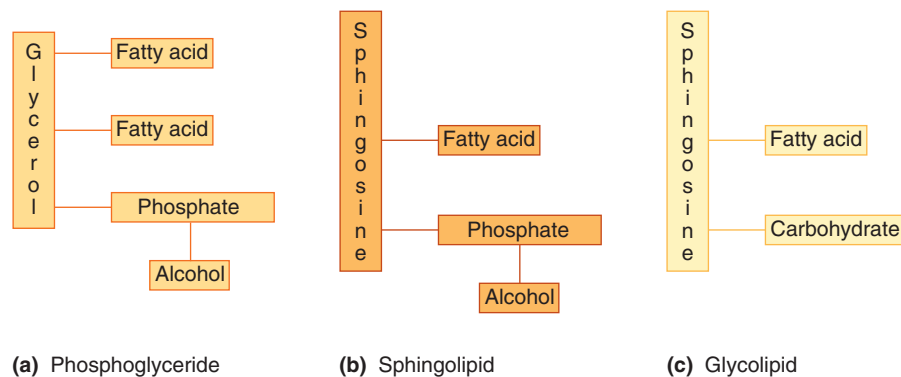
The most common alcohol found in simple lipids is **glycerol** (glycerin), a three-carbon alcohol that has three alcohol functional groups (—OH).

Simple lipids called fats and oils are formed by a reaction between the carboxyl group of three fatty acids and the three alcohol groups of glycerol. The resulting lipid is an E-shaped molecule called a **triglyceride.** Such lipids are classified as fats or oils on the basis of their melting points: *fats* are solids at room temperature, whereas *oils* are liquids. Their melting points depend on the degree of unsaturation of the fatty acids of the triglyceride. The melting point goes down with increasing degree of unsaturation. Thus, oils contain more unsaturated fatty acids than fats do. Examples of the components of fats and oils and a typical triglyceride molecule are shown in ❙Figure A-9.

When triglycerides form, a molecule of water is released as each fatty acid reacts with glycerol. Adipose tissue in the body contains triglycerides. When the body uses adipose tissue as an energy source, the triglycerides react with water to release free fatty acids into the blood. The fatty acids can be used as an immediate energy source by many organs. In the liver, free fatty acids are converted into compounds called **ketone bodies** (see p. 689). Two of the ketone bodies are acids, and one is *acetone* (found in nail polish remover). Excess ketone bodies are produced during diabetes mellitus, a condition in which most cells resort to using fatty acids as an energy source because the cells are unable to take up adequate amounts of glucose in the face of inadequate insulin action (see p. 694).

Complex lipids

Complex lipids have more than two types of components. The different complex lipids usually contain three or more of the following components: glycerol, fatty acids, a phosphate group,
IFigure A-9 Triglyceride components and structure.

(a) Phosphoglyceride (b) Sphingolipid (c) Glycolipid


IFigure A-10 **Examples of complex lipids.** In parts (b) and (c), sphingosine is an alcohol similar to glycerol.

an alcohol other than glycerol, and a carbohydrate. Those that contain phosphate are called **phospholipids.** IFigure A-10 contains representations of a few complex lipids; it emphasizes the components but does not give details of the molecular structures.

Steroids are lipids that have a unique structural feature consisting of a fused carbon ring system that contains three six-membered rings and a single five-membered ring (IFigure A-11). Different steroids possess this characteristic ring structure but have different functional groups and carbon chains attached.

Cholesterol, a steroidal alcohol, is the most abundant steroid in the human body. It is a component of cell membranes and is used by the body to produce other important steroids that include bile salts, male and female sex hormones, and adrenocortical hormones. The structures of cholesterol and cortisol, an important adrenocortical hormone, are given in IFigure A-12.

A.11 Proteins

The name *protein* is derived from the Greek word *proteios,* which means "of first importance." It is certainly an appropriate term for these important biological compounds. Proteins

are indispensable components of all living things, where they play crucial roles in all biological processes. Proteins are the main structural component of cells, and enzymes, all of which are proteins, catalyze all chemical reactions in the body.

Chemical composition of proteins

Proteins are macromolecules made up of monomers called **amino acids.** Hundreds of different amino acids, both natural and synthetic, are known, but only 20 are commonly found in natural proteins. From this limited pool of 20 amino acids, cells build thousands of types of proteins, each with a distinct function, in much the same way that composers create diverse music from a relatively small number of notes. Different proteins are constructed by varying the types and numbers of amino acids used and by varying the order in which they are linked together. However, proteins are not built haphazardly, by randomly linking together amino acids. Every protein in the body is deliberately and precisely synthesized under the direction of the blueprint laid down in the person's genes. Thus, amino acids are assembled in a specific pattern to produce a given protein that can accomplish a particular structural or functional task in the body. (See pp. 23–24. More information about protein synthesis can be found at the book's Web site at **www .cengagebrain.com**.)

Peptide bonds

Each amino acid molecule has three important parts: an amino functional group (—NH$_2$), a carboxyl functional group (—COOH), and a characteristic side chain or R group. These components are shown in expanded form in IFigure A-13. Amino acids form long chains as a result of reactions between the amino group of one amino acid and the carboxyl group of another amino acid. This reaction is illustrated in Equation A-16:

Eq. A-16
(a) Detailed steroid ring system
(b) Simplified steroid ring system

❚Figure A-11 **The steroid ring system.**

Cholesterol

Cortisol
❚Figure A-12 **Examples of steroidal compounds.**

The covalent bond formed in the reaction is called a **peptide bond** (❚Figure A-14). Notice that after the two molecules react, the ends of the product still have an amino group and a carboxyl group that can react to extend the chain length.

On a molecular scale, proteins are immense molecules. Their size can be illustrated by comparing a glucose molecule to a mol-
❚Figure A-13 **The general structure of amino acids.**
❚Figure A-14 **A peptide bond.** In forming a peptide bond, the carboxyl group of one amino acid reacts with the amino group of another amino acid.

❚Figure A-15 **A portion of the primary protein structure of human insulin.**

ecule of hemoglobin, a protein. Glucose has a molecular weight of 180 amu and a molecular formula of $C_6H_{12}O_6$. Hemoglobin, a relatively small protein, has a molecular weight of 65,000 amu and a molecular formula of $C_{2952}H_{4664}O_{832}\,N_{812}\,S_8Fe_4$.

Levels of protein structure

The many atoms in a protein are not arranged randomly. In fact, proteins have a high degree of structural organization that plays an important role in their behavior in the body.

Primary Structure The first level of protein structure is called the **primary structure.** It is simply the order in which amino acids are bonded together to form the protein chain. Amino acids are frequently represented by three-letter abbreviations, such as Gly for glycine and Arg for arginine. When this practice is followed, the primary structure of a protein can be represented as in ❚Figure A-15, which shows part of the primary structure of human insulin, or as in ❚Figure A-16a, which depicts a portion of the primary structure of hemoglobin.
Figure A-16 **Levels of protein structure.** Proteins can have four levels of structure. (a) The primary structure is a particular sequence of amino acids bonded in a chain. (b) At the secondary level, hydrogen bonding occurs between various amino acids within the chain, causing the chain to assume a particular shape. The most common secondary protein structure in the body is the alpha helix. (c) The tertiary structure is formed by the folding of the secondary structure into a functional three-dimensional configuration. (d) Many proteins have a fourth level of structure composed of several polypeptides, as exemplified by hemoglobin.

Secondary Structure The second level of protein structure, called the **secondary structure,** results when hydrogen bonding occurs between the amino hydrogen of one amino acid and the carboxyl oxygen

$$\begin{array}{c} O \\ \parallel \\ (-C-) \end{array}$$
of another amino acid in the same chain. As a result of this hydrogen bonding, the involved portion of the chain typically assumes a coiled, helical shape called an *alpha (α) helix,* which is by far the most common secondary structure found in the body (❙Figure A-16b). Other secondary structures such as *beta (β) pleated sheets* and *random coils* can also form, depending on the pattern of hydrogen bonding between amino acids located in different parts of the same chain.

Tertiary and Quaternary Structure The third level of structure in proteins is the **tertiary structure.** It results when functional groups of the side chains of amino acids in the protein chain react with each other. Several types of interactions are possible, as shown in ❙Figure A-17. Tertiary structures can be visualized by letting a length of wire represent the chain of amino acids in the primary structure of a protein. Next imagine that the wire is wound around a pencil to form a helix, which represents the secondary structure. The pencil is removed, and the helical structure is now folded back on itself or carefully wadded into a ball. Such folded or spherical structures represent the tertiary structure of a protein (see ❙Figure A-16c).

All functional proteins exist in at least a tertiary structure. Sometimes, several polypeptides interact with one another to form a fourth level of protein structure, the **quaternary structure.** For example, hemoglobin contains four highly folded polypeptide chains (the **globin** portion) (see ❙Figure A-16d). Four iron-containing *heme* groups, one tucked within the interior of each of the folded polypeptide subunits, complete the quaternary structure of hemoglobin (see ❙Figure 11-2, p. 383).

Hydrolysis and denaturation

In addition to serving as enzymes that catalyze the many essential chemical reactions of the body, proteins can undergo reactions themselves. Two of the most important are hydrolysis and denaturation.

Hydrolysis Notice that according to Equation A-16, the formation of peptide bonds releases water molecules. Under appropriate conditions, it is possible to reverse such reactions by adding water to the peptide bonds and breaking them. **Hydrolysis** ("breakdown by H_2O") reactions of this type convert large proteins into smaller fragments or even into individual amino acids. Hydrolysis is the means by which digestive enzymes break down ingested food into small units that can be absorbed from the digestive tract lumen into the blood.

Denaturation Denaturation of proteins occurs when the bonds holding a protein in its characteristic shape are broken so that the protein chain takes on a random, disorganized conformation. Denaturation can result when proteins are heated (including when body temperature rises too high; see p. 627), subjected to extremes of pH (see p. 549), or treated with specific chemicals such as alcohol. In some instances, denaturation is accompanied by coagulation or precipitation, as illustrated by the changes that occur in the white of an egg as it is fried.

A.12 Nucleic Acids

Nucleic acids are high-molecular-weight macromolecules responsible for storing and using genetic information in living cells and passing it on to future generations. These important biomolecules are classified into two categories: **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA).** DNA is found primarily in the cell's nucleus, and RNA is found primarily in the cytoplasm that surrounds the nucleus.

Both types of nucleic acid are made up of units called **nucleotides,** which in turn are composed of three simpler components: Each nucleotide contains an organic nitrogenous base (either thymine, adenine, cytosine, or guanine), a sugar, and a phosphate group. The three components are chemically bonded together, with the sugar molecule lying between the base and the phosphate. In RNA the sugar is ribose, whereas in DNA it is deoxyribose. When nucleotides bond together to form nucleic acid chains, the bonding is between the phosphate of one nucleotide and the sugar of another. The resulting nucleic acids consist of polynucleotide strands of alternating phosphates and sugar molecules, with a base molecule extending out of the strand from each sugar molecule (❙Figure A-18).

DNA takes the form of two strands that coil around each other to form the well-known double helix. Some RNA occurs in essentially straight chains, whereas in other types the chain forms specific loops or helices (see the book's Web site for further details).
❙Figure A-17 Side chain interactions leading to the tertiary protein structure.

A.13 High-Energy Biomolecules

Not all nucleotides are used to construct nucleic acids. One important nucleotide—**adenosine triphosphate (ATP)**—is used as the body's primary energy carrier. Certain bonds in ATP temporarily store energy that is harnessed during the metabolism of foods and make it available to the parts of the cells where it is needed to do specific cellular work (see pp. 34–40). Let us see how ATP functions in this role. Structurally, ATP is a modified RNA (ribose-containing) nucleotide that has adenine as its base and two additional phosphates bonded in sequence to the original nucleotide phosphate. Thus, as its name implies, adenosine triphosphate has three phosphates attached in a string to *adenosine,* the composite of ribose and adenine (❚Figure A-19). Attaching these additional phosphates requires considerable energy input. The high-energy input used to create these **high-energy phosphate bonds** is "stored" in the bonds for later use. Most energy transfers in the body involve ATP's terminal phosphate bond. When energy is needed, the third phosphate is cleaved off by hydrolysis, yielding *adenosine diphosphate (ADP)* and an inorganic phosphate (P_i) and releasing energy in the process (Equation A-17):

$$ATP \rightarrow ADP + P_i + \text{energy for use by cell} \qquad \text{Eq. A-17}$$

Why use ATP as an energy currency that cells can cash in by splitting the high-energy phosphate bonds as needed? Why not just directly use the energy released during the oxidation of nutrient molecules such as glucose? If all the chemical energy stored in glucose were to be released at once, most of the energy would be squandered because the cell could not capture much of the energy for immediate use. Instead, the energy trapped within the glucose bonds is gradually released and harnessed as cellular "bite-size pieces" in the form of the high-energy phosphate bonds of ATP.

Under the influence of an enzyme, ATP can be converted to a cyclic form of adenosine monophosphate, which contains only one phosphate group, the other two having been cleaved off. The resultant molecule, called **cyclic AMP** or **cAMP,** serves as an intracellular messenger, affecting the activities of a number of enzymes involved in important reactions in the body (see p. 122).
KEY

= Sugar–phosphate backbone of polynucleotide strand

❚Figure A-18 **Nucleotides in a polynucleotide strand.** A nucleotide consists of an organic nitrogenous base (thymine, adenine, cytosine, or guanine), a sugar, and a phosphate. Sugar–phosphate bonds link adjacent nucleotides together to form a polynucleotide strand with bases projecting to one side. The sugar–phosphate backbone is identical in all polynucleotides, but the sequence of the bases varies. This base variation determines the genetic code in DNA.
❚Figure A-19 **The structure of ATP.**

Answers

Chapter 1 Introduction to Physiology and Homeostasis

Check Your Understanding

1.1 (Questions on p. 2.)

1. *Physiology* is the study of body functions.

2. to increase the surface area across which nutrients can be absorbed from the digestive tract into the blood

1.2 (Questions on p. 7.)

1. *Chemical level:* Various atoms and molecules make up all body structures. *Cellular level:* Specific chemicals are organized into living cells, which are the basic units of both structure and function. *Tissue level:* Groups of cells of similar specialization are organized into tissues. *Organ level:* An organ is made up of several tissue types that act together as a unit to perform a particular function or functions. *Body system level:* A body system is a collection of related organs that interact to accomplish a common activity essential for survival of the whole body. *Organism level:* The body systems are structurally and functionally packaged together into the whole body, which is a single, multicellular organism capable of living independently in the surrounding external environment.

2. Every cell performs *basic cell functions* essential for its survival, including (1) obtaining food and O_2 from the environment surrounding the cell; (2) performing chemical reactions using food and O_2 to provide energy for the cell; (3) eliminating to the surrounding environment wastes produced by these reactions; (4) synthesizing proteins and other components needed by the cell; (5) largely controlling exchanges between the cell and surrounding environment; (6) moving materials within the cell or, in the case of some cells, moving the cell; (7) being sensitive and responsive to changes in the surrounding environment; and (8) reproducing (except for nerve cells and muscle cells).

3. *muscle tissue* (skeletal muscle attached to bones, cardiac muscle in the heart, and smooth muscle in the walls of hollow organs); *nervous tissue* (in the brain, spinal cord, nerves, and special sense organs); *epithelial tissue* (skin, linings of hollow organs, exocrine glands, and endocrine glands); and *connective tissue* (loose connective tissue, tendons, bone, and blood)

1.3 (Questions on p. 16.)

1. The *external environment* is the surrounding environment in which an organism lives. The *internal environment* is the fluid inside the body and outside the cells in which the cells live. The *intracellular fluid* is the fluid collectively within all body cells. The *extracellular fluid* is the fluid inside the body and outside the cells and constitutes the internal environment. The extracellular fluid is made up of the *plasma,* the fluid portion of the blood, and *interstitial fluid,* the fluid that surrounds and bathes the cells.

2. *Homeostasis* is the maintenance of a relatively stable internal environment.

3. See Figure 1-7, p 12.

1.4 (Questions on p. 18.)

1. *Intrinsic controls* are inherent compensatory responses that act locally in an organ; *extrinsic controls* are systemic controls initiated outside an organ by the regulatory systems (nervous or endocrine systems) to alter the organ's activity.

2. In *negative feedback,* the output of a control system drives a controlled variable in the opposite direction of an initial change, thus counteracting the change. In *positive feedback,* the output of a control system drives a controlled variable in the same direction as the initial change, thus enhancing the change.

3. See Figure 1-9a, p. 17.

Figure Focus

FIGURE 1-4 (P. 6): Milk-secreting glands are exocrine; they secrete through ducts to the outside. An endocrine gland secretes the hormone oxytocin into the blood.

FIGURE 1-8 (P. 14): The urinary, digestive, endocrine, and skeletal systems all contribute to maintaining the proper concentration of calcium in the blood. The circulatory system merely transports this electrolyte.

FIGURE 1-9 (P. 17): go up

Reviewing Terms and Facts

(Questions on p. 19.)

1. e **2.** b **3.** c **4.** T **5.** F **6.** T **7.** muscle tissue, nervous tissue, epithelial tissue, connective tissue **8.** secretion **9.** exocrine, endocrine, hormones **10.** intrinsic, extrinsic **11.** 1.d, 2.g, 3.a, 4.e, 5.b, 6.j, 7.h, 8.i, 9.c, 10.f

Applying Clinical Reasoning

(Questions on p. 19.)

Loss of fluids threatens the maintenance of proper plasma volume and blood pressure. Loss of acidic digestive juices threatens the maintenance of the proper pH in the internal fluid environment. The urinary system helps restore the proper plasma volume and pH by reducing the amount of water and acid eliminated in the urine. The respiratory system helps restore the pH by adjusting the rate of removal of acid-forming CO_2. Adjustments in the circulatory system help maintain blood pressure despite fluid loss. Increased thirst encourages increased fluid intake to help restore plasma volume. These compensatory changes in the urinary, respiratory, and circulatory systems, and the sensation of thirst, are all regulated by the two regulatory systems, the nervous and endocrine systems. Furthermore, the endocrine system makes internal adjustments to help maintain the concentration of nutrients in the internal environment even though no new nutrients are being absorbed from the digestive system.

Thinking at a Higher Level

(Questions on p. 20.)

1. The respiratory system eliminates internally produced CO_2 to the external environment. A decrease in CO_2 in the internal environment brings about a reduction in respiratory activity (that is, slower, shallower breathing) so that CO_2 produced within the body is allowed to accumulate instead of being blown off as rapidly as normal to the external environment. The extra CO_2 retained in the body increases the CO_2 levels in the internal environment to normal.

2. (b) (c) (b)

3. b

4. immune defense system

5. When a person is engaged in strenuous exercise, the temperature-regulating center in the brain brings about widening of the blood vessels of the skin. The resultant increased blood flow through the skin carries the extra heat generated by the contracting muscles to the body surface, where it can be lost to the surrounding environment.

Chapter 2 Cell Physiology

Check Your Understanding

2.1 (Questions on p. 22.)

1. See Table 2-1, p. 22.

2. These cells are all about the same size.

2.2 (Questions on p. 25.)

1. *DNA* provides the genetic code for protein synthesis and serves as a genetic blueprint during cell replication. The DNA code is transcribed into *messenger RNA* (*mRNA*), which is translated into the specified protein by ribosomes that contain *ribonucleic RNA* (*rRNA*). *Transfer RNA* (*tRNA*) delivers the appropriate amino acids to their designated site in the protein under construction.

2. The *genome* is all of the genetic information coded in a complete single set of DNA in a typical body cell. The *proteome* is the complete set of proteins coded for by the genome. *Epigenetics* refers to the environmentally induced modifications that influence gene activity without altering the gene's DNA code.

3. *Cytoplasm* is the portion of the cell interior not occupied by the nucleus. It consists of organelles, cytosol, and cytoskeleton. *Organelles* are distinct, highly organized structures that perform specialized functions within the cell. The *cytosol* is the gel-like portion of cytoplasm that surrounds the organelles. The *cytoskeleton* is a scaffolding of proteins within the cytoplasm that serves as the cell's "bone" and "muscle" by providing support and enabling movement.

2.3 (Questions on p. 28.)

1. The endoplasmic reticulum (ER) is one continuous, extensive organelle. The *rough ER* consists of stacks of relatively flattened interconnected sacs studded with ribosomes that synthesize proteins. The *smooth ER* is a meshwork of tiny interconnected tubules that in most cells serves as a central packaging and discharge site for products synthesized by the ER.

2. A *ribosome* is a nonmembranous organelle consisting of a large and a small subunit that are brought together to serve as the "workbench" for protein synthesis. When messenger RNA moves through a groove formed between the two subunits, the ribosome translates the mRNA into chains of amino acids in the ordered sequence dictated by the DNA code.

3. secreted out of the cell or used for construction of new membrane

4. Misfolded, damaged, or unneeded intracellular proteins are tagged with *ubiquitin*. *Proteasomes* break down ubiquinated proteins into recyclable building blocks.

2.4 (Questions on p. 30.)

1. The *Golgi complex* consists of a stack of flattened, slightly curved, membrane-enclosed sacs. It (1) processes raw materials synthesized by the ER into their final form and (2) sorts and directs the finished products to their final destinations.

2. *Secretion* is release to the cell's exterior by exocytosis of a specific product synthesized by the cell for a particular function.

3. The v-SNARE docking marker of a secretory vesicle can bind lock-and-key fashion only with the t-SNARE docking-marker acceptor on the targeted plasma membrane, thus ensuring that secretory vesicles can dock only with the plasma membrane to release their contents to the cell's exterior.

2.5 (Questions on p. 33.)

1. *Hydrolytic enzymes* catalyze hydrolysis, the breakdown of organic molecules by the addition of water at a bond site.

2. See Figure 2-9, p. 32.

3. *Autophagy* is selective self-digestion of dysfunctional organelles by lysosomes.

2.6 (Questions on p. 33.)

1. Peroxisomes detoxify various wastes and foreign compounds within the cell by means of *oxidative enzymes* that use oxygen to strip hydrogen from these organic molecules.

2. hydrogen peroxide (H_2O_2)

2.7 (Questions on p. 41.)

1. See Figure 2-10a, p. 34.

2. The three stages of *cellular respiration* are (1) glycolysis in the cytosol, (2) the citric acid cycle in the mitochondrial matrix, and (3) oxidative phosphorylation (consisting of the electron transport system and chemiosmosis) at the mitochondrial inner membrane.

3. In *anaerobic conditions* 2 molecules of ATP are produced (by glycolysis) and in *aerobic conditions* 32 molecules of ATP are produced (2 by glycolysis, 2 by the citric acid cycle, and 28 by oxidative phosphorylation) from one glucose molecule.

4. *Apoptosis* is intentional suicide of a cell that is no longer useful. *Necrosis* is uncontrolled, accidental death of useful, injured cells.

2.8 (Questions on p. 42.)

1. When closed, *vaults* are hollow, octagonal-shaped barrels. When open, each half looks like unfolded flowers with eight "petals" attached to a central ring.

2. Vaults are thought to serve as cellular "trucks" that carry cargo (either mRNA or the ribosomal subunits) from the nucleus to cytoplasmic sites of protein synthesis.

2.9 (Questions on p. 44.)

1. (1) intermediary metabolism, (2) protein synthesis by free ribosomes, and (3) storage of nutrients (as glycogen and fat) and secretory vesicles

2. *Intermediary metabolism* encompasses the intracellular chemical reactions involving the degradation, synthesis, and transformation of simple sugars, amino acids, and fatty acids.

2.10 (Questions on p. 51.)

1. (1) *microtubules* (maintain asymmetric cell shapes, serve as highways for transport of secretory vesicles, provide movement of cilia and flagella, form mitotic spindle); (2) *microfilaments* (play a key role in cellular contractile systems, serve as mechanical stiffeners); and (3) *intermediate filaments* (help resist mechanical stress)

2. A *motor protein* attaches to a particle to be transported, then walks along a microtubular "highway" by alternately attaching and releasing its "feet" as it cyclically swings the rear foot ahead of the front foot, stepping on one tubulin molecule after another.

3. A duplicated *centriole* moves from the centrosome to a position just under the plasma membrane, where microtubules grow outward from the centriole to form a cilium or flagellum. The centriole remains at the base of this motile appendage as the basal body of the structure.

4. In a process called *treadmilling* in amoeboid movement, actin filaments extend forward at the leading edge through the addition of actin molecules that have been removed from the rear of the filament and transferred to the front of the filament, an action that pushes a pseudopod (a fingerlike protrusion) forward. In treadmilling, the filament does not get any longer, it just advances forward.

Figure Focus

FIGURE 2-3 (P. 27): A *transport vesicle* contains a mixture of proteins that have been newly synthesized by the rough ER. A *secretory vesicle* contains a specific finished protein product that has been modified and sorted by the Golgi complex.

FIGURE 2-6 (P. 29): The surface membrane increases during exocytosis and decreases during endocytosis.

FIGURE 2-13 (P. 36): 3 NADH and 1 $FADH_2$ are generated for each "turn" of the citric acid cycle. Because glycolysis splits glucose into two pyruvate molecules, each of which enters one "turn" of the citric acid cycle, 6 NADH and 2 $FADH_2$ are produced by this cycle for every glucose molecule processed.

FIGURE 2-14 (P. 39): from air breathed in

FIGURE 2-15 (P. 39): 32 ATPs with O_2, 2 ATPs without O_2

FIGURE 2-21 (P. 47): Without its microtubule "highway" intact, the damaged neuron cannot transport secretory products from the cell body to the axon terminal for release to the ECF or debris from the axon terminal to the cell body for degradation by lysosomes. Failure to transport these materials to their sites of elimination from the cell leads to their accumulation within the cell, which can lead to disruption of cellular activities and ultimately death of the neuron.

Reviewing Terms and Facts

(Questions on p. 52.)

1. plasma membrane **2.** deoxyribonucleic acid (DNA), nucleus **3.** nucleus, organelles, cytoplasm **4.** organelles, cytosol, cytoskeleton **5.** endoplasmic reticulum, Golgi complex **6.** oxidative **7.** adenosine triphosphate (ATP) **8.** F **9.** F **10.** 1.b, 2.c, 3.c, 4.a, 5.b, 6.c, 7.a, 8.c, 9.c **11.** 1.b, 2.a, 3.b, 4.b

Solving Quantitative Exercises

(Questions on p. 53.)

1. b

2.

24 moles O_2/day × 6 moles ATP/mole O_2 = 144 moles ATP/day

144 moles ATP/day × 507 g ATP/mole = 73,000 g ATP/day

1000 g/2.2 lb = 73,000 g/x lb

1000 x = 160,600

x = approximately 160 lb

3. 144 mol/day (7300 cal/mol) $=$ 1,051,200 cal/day (1051 kilocal/day)

4. About 2/3 of the water in the body is intracellular. Because a person's mass is about 60% water, for a 150-pound (68-kg) person,

68 kg(0.6)(2/3) = 27.2 kg

is the mass of water. Assume that 1 mL of body water weighs 1 g. Then the total volume in the person's cells is about 27.2 liters. The volume of an average cell is

$$\frac{4}{3} \pi (1 \times 10^{-3} \text{ cm})^3 \approx 4.2 \times 10^{-9} \text{ cm}^3 = 4.2 \times 10^{-9} \text{ mL}$$

So, the number of cells in a 68-kg person is about

$$27.2 \text{ liters} \left(\frac{1000 \text{ mL}}{1 \text{ L}} \right) \left(\frac{1 \text{ cell}}{4.2 \times 10^{-9} \text{ mL}} \right) = 6.476 \times 10^{12} \text{ cells}$$

5. $150 \text{ mg} \left(\frac{1 \text{ mL}}{0.015 \text{ mg}} \right) = 10,000 \text{ mL } (10 \text{ L})$

Applying Clinical Reasoning

(Question on p. 53.)

Some hereditary forms of male sterility involving nonmotile sperm have been traced to defects in the cytoskeletal components of the sperm's flagella. These same individuals usually also have long histories of recurrent respiratory tract disease because the same types of defects are present in their respiratory cilia, which are unable to clear mucus and inhaled particles from the respiratory system.

Thinking at a Higher Level

(Questions on p. 53.)

1. The *chief cells* have an extensive rough endoplasmic reticulum, with this organelle being responsible for synthesizing these cells' protein secretory product, namely, pepsinogen. Because the parietal cells do not secrete a protein product to the cells' exterior, they do not need an extensive rough endoplasmic reticulum.

2. With *cyanide poisoning*, the cellular activities that depend on ATP expenditure, such as synthesis of new chemical compounds, membrane transport, and mechanical work, could not continue. The resultant inability of the heart to pump blood and failure of the respiratory muscles to accomplish breathing would lead to imminent death.

3. catalase

4. ATP is required for muscle contraction. Muscles are able to store limited supplies of nutrient fuel for use in the generation of ATP. During *anaerobic exercise*, muscles generate ATP from these nutrient stores by means of glycolysis, which yields 2 molecules of ATP per glucose molecule processed. During *aerobic exercise*, muscles can generate ATP by means of oxidative phosphorylation, which yields 32 molecules of ATP per glucose molecule processed. Because glycolysis inefficiently generates ATP from nutrient fuels, it rapidly depletes the muscle's limited stores of fuel, and ATP can no longer be produced to sustain the muscle's contractile activity. Aerobic exercise, in contrast, can be sustained for prolonged periods. Not only does oxidative phosphorylation use far less nutrient fuel to generate ATP, but it can be supported by nutrients delivered to the muscle by means of the blood instead of relying on stored fuel in the muscle. Intense anaerobic exercise outpaces the ability to deliver supplies to the muscle by the blood, so the muscle must rely on stored fuel and inefficient glycolysis, thus limiting anaerobic exercise to brief periods of time before energy sources are depleted.

5. skin. The mutant keratin weakens the skin cells of patients with *epidermolysis bullosa* so that the skin blisters in response to even a light touch.

Chapter 3 The Plasma Membrane and Membrane Potential

Check Your Understanding

3.1 (Questions on p. 60.)

1. See Figure 3-2, p. 57.

2. Under an electron microscope, the plasma membrane has a "sandwich" appearance with two dark layers separated by a light mid-

dle layer. The two dark layers are the hydrophilic polar regions of the lipid and protein molecules that take up a stain, whereas the light middle layer is the poorly stained hydrophobic core made up of the nonpolar regions of these molecules.

3. (1) form channels, (2) serve as carriers, (3) serve as docking-marker acceptors, (4) function as membrane-bound enzymes, (5) serve as receptors, (6) serve as cell adhesion molecules (CAMs), and (7) are important in "self" recognition

3.2 (Questions on p. 63.)

1. the biological "glue" that holds neighboring cells together; consists of an intricate meshwork of proteins in a watery, gel-like substance (interstitial fluid)

2. (1) *desmosome* (adhering junction that spot-rivets two adjacent but nontouching cells, anchoring them together in tissues subject to considerable stretching); (2) *tight junction* (impermeable junction that joins the lateral edges of epithelial cells near their luminal borders, thus preventing movement of materials between the cells); and (3) *gap junction* (communicating junction made up of small connecting tunnels that permit movement of charge-carrying ions and small molecules between two adjacent cells)

3. See Figure 3-4, p. 61.

3.3 (Questions on p. 63.)

1. Lipid-soluble substances of any size can permeate the plasma membrane without assistance by dissolving in the lipid bilayer. Small water-soluble substances (ions) can pass through the membrane without assistance through open channels specific for them.

2. *Passive forces* do not require energy and *active forces* require energy to produce movement across the plasma membrane.

3.4 (Questions on p. 70.)

1. movement down a concentration gradient (including osmosis) and movement along an electrical gradient

2. *Osmotic pressure* is a "pulling" pressure; it is a measure of the tendency for osmotic flow of water into a solution resulting from its relative concentration of nonpenetrating solutes and water. *Hydrostatic (fluid) pressure* is a "pushing" pressure; it is the pressure exerted by a stationary fluid on an object.

3. See Figure 3-13, p. 69.

3.5 (Questions on p. 77.)

1. See Figure 3-15, p. 71.

2. In *facilitated diffusion,* the carrier undergoes spontaneous changes in shape as a result of thermal energy. In *primary active transport,* phosphorylation (binding of the phosphate group derived from the carrier splitting ATP) increases affinity of the carrier for its passenger ion; this binding causes the carrier to change its shape. In *secondary active transport,* the change in shape of a cotransport carrier that binds both Na^+ and the transported solute is driven by a Na^+ concentration gradient established by a primary active transport mechanism.

3. Symport and antiport are both secondary active transport mechanisms. In *symport,* the cotransported solute moves uphill in the same direction the driving ion moves downhill. In *antiport,* the cotransported solute moves uphill in the opposite direction the driving ion moves downhill.

3.6 (Questions on p. 84.)

1. a separation of opposite charges across the membrane, or a difference in the relative number of cations and anions in the ECF and ICF

2. Because the resting membrane is 25 to 30 times more permeable to K^+ than to Na^+, K^+ passes through more readily than Na^+. The substantially larger movement of K^+ out of the cell influences the resting membrane potential to a much greater extent than the smaller movement of Na^+ into the cell does. As a result, the resting potential (-70 mV) is closer to the equilibrium potential for K^+ (-90 mV) than to the equilibrium potential for Na^+ ($+60$ mV). The resting potential is less than the K^+ equilibrium potential because the limited entry of Na^+ neutralizes some of the potential that would be created by K^+ alone.

3. In a *steady state,* opposing passive and active forces exactly counterbalance each other. In a *dynamic equilibrium,* opposing passive forces exactly counterbalance each other. In both cases, no net change takes place, but energy is used to maintain this constancy in a steady state, but no energy is needed in a dynamic equilibrium.

Figure Focus

FIGURE 3-5 (P. 62): Tight junctions prevent specialized membrane proteins from migrating between the luminal and basolateral parts of the plasma membrane of epithelial cells.

FIGURE 3-13 (P. 69): As the penetrating solutes enter the cell, ICF osmolarity increases and the osmolarity of the solution surrounding the cell decreases As water enters the cell down the resulting osmotic gradient, cell volume increases. Thus the solution is hypotonic; even though it has the same beginning osmolarity as the red blood cells, it has a lower concentration of nonpenetrating solutes than the cells do.

FIGURE 3-16 (P. 74): If insufficient ATP were available to run the Na^+–K^+ pump, the Na^+ concentration would fall in the ECF and rise in the ICF, whereas the K^+ concentration would rise in the ECF and fall in the ICF. Passive movement of these ions down their concentration gradients across the plasma membrane through leak channels would not be adequately counterbalanced by active pumping of these ions across the membrane against their concentration gradients.

FIGURE 3-18 (P. 76): When both Na^+ and glucose are present in the digestive tract lumen, they are cotransported via SGLT across the digestive tract wall into the blood. Water follows osmotically, helping rehydrate a child who has dehydrating diarrhea.

FIGURE 3-20 (P. 81): more negative. Because the ECF K^+ concentration is lower but its ICF concentration is the same, the concentration gradient for K^+ to exit the cell is greater than normal. Therefore the opposing electrical gradient at E_{K^+} must be greater than normal to exactly counterbalance the larger concentration gradient. That is, E_{K^+} must be more negative. The same conclusion can be reached by using the Nernst equation. Plugging a value less than the normal 5mM extracellular concentration of K^+ into the equation yields a value more negative than -90mV.

Reviewing Terms and Facts

(Questions on p. 85.)

1. T **2.** T **3.** T **4.** negative, positive **5.** 1.b, 2.a, 3.b, 4.a, 5.c, 6.b, 7.a, 8.b **6.** 1.a, 2.a, 3.b, 4.a, 5.b, 6.a, 7.b **7.** 1.c, 2.b, 3.a, 4.a, 5.c, 6.b, 7.c, 8.a, 9.b

Solving Quantitative Exercises

(Questions on p. 86.)

1. $E = \dfrac{61\ mV}{z} \log \dfrac{C_o}{C_i}$

a. $\dfrac{61\ mV}{2} \log \dfrac{1 \times 10^{-3}}{100 \times 10^{-9}} = +122\ mV$

b. $\dfrac{61\ mV}{-1} \log \dfrac{110 \times 10^{-3}}{10 \times 10^{-3}} = -63.5\ mV$

2. $I_x = G_x(V_m - E_x)$

$E_{Na^+} = 61\ mV \log \dfrac{145\ mM}{15\ mM} = 60.1\ mV$

a. $= 1\ ns\ (-70\ mV - 60.1\ mV)$

$= 1\ ns\ (-130\ mV)$

$= -130\ pA\ (A = amperes)$

b. entering

c. with concentration gradient; with electrical gradient

3. $V_m = 61 \log \dfrac{P_{K^+}\left[K^+\right]_o + P_{Na^+}\left[Na^+\right]_o}{P_{K^+}\left[K^+\right]_i + P_{Na^+}\left[Na^+\right]_i}$

$= 61 \log \dfrac{(1)(10) + (0.04)(150)}{(1)(150) + (0.04)(15)}$

$= 61 \log \dfrac{10 + 6}{150 + 0.6}$

$= 61 \log 0.1062$

Because the log of 0.106 is -0.974

$V_m = 61\,(-0.974) = -59\text{ mV}$

Therefore, the resting membrane potential is less than normal (that is, slightly depolarized compared to normal).

Applying Clinical Reasoning

(Questions on p. 86.)

As Cl^- is secreted by the intestinal cells into the intestinal tract lumen, Na^+ follows passively along the established electrical gradient. Water passively accompanies this salt (Na^+ and Cl^-) secretion by osmosis. The toxin produced by the cholera pathogen prevents the normal inactivation of the mechanism (cAMP pathway; see p. 123) that opens the Cl^- channels in the luminal membranes of the intestinal cells. Increased, ongoing secretion of Cl^- and the subsequent passively induced secretion of Na^+ and water are responsible for the severe diarrhea that characterizes cholera.

Thinking at a Higher Level

(Questions on p. 86.)

1. d. active transport. Leveling off of the curve designates saturation of a carrier molecule, so carrier-mediated transport is involved. The graph indicates that active transport is being used instead of facilitated diffusion because the concentration of the substance in the intracellular fluid is greater than the concentration in the extracellular fluid at all points until after the transport maximum is reached. Thus, the substance is being moved *against* a concentration gradient, so active transport must be the method of transport being used.

2. c. As Na^+ moves from side 1 to side 2 down its concentration gradient, Cl^- remains on side 1, unable to permeate the membrane. The resultant separation of charges produces a membrane potential, negative on side 1 because of unbalanced chloride ions and positive on side 2 because of unbalanced sodium ions. Sodium does not continue to move to side 2 until its concentration gradient is dissipated because of the development of an opposing electrical gradient.

3. Osmolarity refers to the concentration of all particles in a solution, both penetrating and nonpenetrating, yet only nonpenetrating solutes contribute to the tonicity of a solution. Therefore, a solution with a mixture of penetrating and nonpenetrating solutes may have an osmolarity of 300 mOsm/L, the same as in the ICF, but be hypotonic to the cells because the solution's concentration of nonpenetrating solutes is less than the concentration of nonpenetrating solutes inside the cells. The entire osmolarity of the ICF at 300 mOsm/L is attributable to nonpenetrating solutes.

4. more positive. Because the electrochemical gradient for Na^+ is inward, the membrane potential would become more positive as a result of an increased influx of Na^+ into the cell if the membrane were more permeable to Na^+ than to K^+. (Indeed, this is what happens during the rising phase of an action potential once threshold potential is reached; see Chapter 4.)

5. vesicular transport. The maternal antibodies in the infant's digestive tract lumen are taken up by the intestinal cells by endocytosis and are extruded on the opposite side of the cell into the interstitial fluid by exocytosis. The antibodies are picked up from the intestinal interstitial fluid by the blood supply to the region.

Chapter 4 Principles of Neural and Hormonal Communication

Check Your Understanding

4.1 (Questions on p. 89.)

1. nerve and muscle

2. See Figure 4-1, p. 88.

3. *Voltage-gated channels* open or close in response to changes in membrane potential. *Chemically gated channels* change conformation in response to binding of a specific extracellular chemical messenger to a surface membrane receptor. *Mechanically gated channels* respond to mechanical deformation such as stretching. *Thermally gated channels* respond to heat or cold.

4.2 (Questions on p. 90.)

1. The stronger a triggering event, the larger the graded potential. The longer the duration of a triggering event, the longer the duration of the graded potential.

2. An increase in the difference in potential increases current flow. An increase in resistance decreases current flow.

3. Spread of graded potentials is decremental because leakage of charge-carrying ions through open channels in the plasma membrane results in progressive loss of current with increasing distance from the initial site of the change in potential.

4.3 (Questions on p. 102.)

1. See Figure 4-6, p. 94.

2. (1) *closed but capable of opening* (at resting potential to threshold); (2) *open* (*activated*) (from threshold to the peak of an action potential—that is, throughout the rising phase); and (3) *closed and not capable of opening* (*inactivated*) (from the peak of an action potential until return to resting potential—that is, throughout the falling phase)

3. See Figure 4-7a, p. 95.

4. Saltatory conduction is faster than contiguous conduction because the action potential jumps from one node of Ranvier to the next in saltatory conduction, skipping over the myelinated sections of the axon, whereas the action potential must be regenerated within every section of an unmyelinated axon from beginning to end during contiguous conduction.

4.4 (Questions on p. 113.)

1. Because the presynaptic terminal releases the neurotransmitter and the subsynaptic membrane of the postsynaptic neuron has receptor-channels for the neurotransmitter, the synapse can operate only in the direction from presynaptic to postsynaptic neuron.

2. See Figure 4-15, p. 106.

3. *Temporal summation* is the summing of several EPSPs occurring very close together in time as a result of rapid, repetitive firing of a single presynaptic neuron. *Spatial summation* is the summing of EPSPs originating simultaneously from several different presynaptic neurons.

4. A *neurotransmitter* is a chemical messenger released from a presynaptic neuron that binds to and alters the permeability and thereby the potential of a postsynaptic neuron at a synapse. Neurotransmitters produce EPSPs or IPSPs. A *neuromodulator* is a chemical messenger that binds to nonsynaptic sites on a neuron and does not

Appendix C **A-23**

produce EPSPs or IPSPs but instead acts slowly to bring about long-term changes that subtly modulate (depress or enhance) synaptic activity. For example, neuromodulators may alter the synthesis and release of neurotransmitter from a presynaptic neuron or vary formation of receptors for the neurotransmitter in the postsynaptic neuron.

4.5 (Questions on p. 118.)

1. a cell influenced by a particular extracellular chemical messenger

2. *Paracrines* are secreted by local cells and exert short-range effects on neighboring target cells. *Neurotransmitters* are secreted by neurons and exert short-range effects on the target cells they innervate. *Hormones* are secreted into the blood by endocrine-gland cells and exert long-range effects on distant target cells. *Neurohormones* are released into the blood by neurons and exert long-range effects on distant target cells.

3. (1) by opening or closing chemically gated *receptor-channels,* (2) by activating *receptor-enzyme complexes,* or (3) by activating second-messenger pathways via *G-protein-coupled receptors.*

4. *Protein kinases* transfer a phosphate group from ATP to a particular intracellular protein (phosphorylate the protein), thereby activating it. *Protein phosphatases* remove phosphate groups from a designated protein (dephosphorylate the protein), thereby inactivating it.

4.6 (Questions on p. 120.)

1. *Cytokines* are *protein* signal molecules secreted by immune and other cells that largely act locally to regulate immune responses. *Eicosanoids* are *lipid* signal molecules derived from arachidonic acid in the plasma membrane of most cells that act locally to regulate diverse cell activities throughout the body.

2. The enzyme *phospholipase A$_2$* splits arachidonic acid from the plasma membrane. The enzyme *cyclooxygenase* leads to formation of prostaglandins and thromboxanes from arachidonic acid. The enzyme *lipooxygenase* leads to formation of leukotrienes from arachidonic acid.

3. NSAIDs provide pain relief by inhibiting cyclooxygenase, thus blocking conversion of arachidonic acid into pain-intensifying prostaglandins.

4.7 (Questions on p. 127.)

1. See Table 4-5, p. 120.

2. Cyclic AMP always brings about the cellular response by modifying a designated, preexisting protein within the target cell. The type of protein altered by cAMP depends on the unique specialization of a particular cell type. In this way, a common second messenger such as cAMP can induce widely differing responses in different cells because it modifies different proteins that lead to different cell events.

3. When the complex consisting of a lipophilic hormone bound with its intracellular receptor binds with DNA at a specific attachment site known as the *hormone response element,* this binding activates a specific gene that leads to synthesis of a new protein that carries out the cellular response.

4.8 (Questions on p. 129)

1. Neural specificity depends on the anatomic proximity of the neurotransmitter-secreting neuronal terminal to the target organ to which it is "wired." Specificity of the "wireless" endocrine system depends on specialization of target cell receptors for a specific circulating hormone.

2. The nervous system enables you to turn the pages of this book, and the endocrine system maintains your blood glucose levels.

Figure Focus

FIGURE 4-3 (P. 91): by K$^+$ leaking out down its electrochemical gradient through K$^+$ leak channels

FIGURE 4-4 (P. 91): False. The magnitude at the peak of an action potential is 30 mV (positive inside), whereas the magnitude at resting potential is 70 mV (negative inside).

FIGURE 4-6 (P. 94): During the *rising phase,* the Na$^+$ channel is open and activated (both its activation and inactivation gates are open) and the K$^+$ channel is closed (its activation gate is closed). During the falling phase, the Na$^+$ channel is closed and inactivated (its activation gate is open but its inactivation gate is closed) and the K$^+$ channel is open (its activation gate is open).

FIGURE 4-8 (P. 97): A graded potential produced in the dendrites and cell body in response to a triggering event spreads to the axon hillock. If the graded potential is of sufficient magnitude at the axon hillock to bring this region to threshold, an action potential is initiated here; that is, the axon hillock becomes an "active area." Local current flow between an active area and adjacent inactive area reduces the potential in the inactive area to threshold, triggering an action potential in the previously inactive area. Simultaneously, the old active area returns to resting potential. Local current flow between the new active area and the adjacent inactive area next to it triggers an action potential in this next area, and so on as the action potential propagates to the end of the axon.

FIGURE 4-17 (P. 111): As a result of presynaptic facilitation, the potential in postsynaptic cell C would depolarize to a greater extent (have a larger EPSP) in response to stimulation by excitatory terminal D than it would have if terminal D itself was not simultaneously stimulated by excitatory terminal E. Stimulation of terminal D by terminal E causes greater release of excitatory neurotransmitter from D.

FIGURE 4-25 (P. 123): No. Protein kinase activated by the cAMP pathway phosphorylates and thereby activates different designated proteins in different cell types.

FIGURE 4-28 (P. 127): A lipophilic hormone diffuses into the cell and binds to the steroid hormone receptor in the cytoplasm (or in the case of some hormones in the nucleus). Subsequent events that take place in the nucleus include binding of the hormone receptor complex with DNA's hormone response element, activation of the gene by this binding, and subsequent transcription of mRNA by the activated gene. The new mRNA exits the nucleus to enter the cytoplasm, where ribosomes "read" mRNA to synthesize the designated protein, which, once released from the ribosome and processed into its final folded form, brings about the desired response.

Reviewing Terms and Facts

(Questions on p. 130.)

1. T **2.** F **3.** F **4.** F **5.** T **6.** F **7.** nerve and muscle **8.** refractory period **9.** axon hillock **10.** synapse **11.** temporal summation **12.** spatial summation **13.** convergence, divergence **14.** G protein **15.** receptor-channel, receptor-enzyme, G-protein-coupled receptor **16.** prostaglandins, thromboxanes, leukotrienes **17.** 1.b, 2.a, 3.a, 4.b, 5.b, 6.a **18.** 1.a, 2.b, 3.a, 4.b, 5.d, 6.b, 7.b, 8.b, 9.a, 10.b, 11.a, 12.c

Solving Quantitative Exercises

(Questions on p. 131.)

1. a. 0.6 m (1 sec/0.7 m) = 0.8571 sec
b. 0.6 m (1 sec/120 m) = 0.005 sec
c. unmyelinated: 0.8591 sec; myelinated: 0.007 sec
d. unmyelinated: 0.8621 sec; myelinated: 0.01 sec

2. Total conduction time for the single axon is 1/60 sec. Let v m/sec be the unknown conduction velocity for the three neurons. Our equation for the total conduction time then is

$$\frac{1}{60}\ \text{sec} = \left(\frac{1}{v} \times 1\ \text{m}\right) + 0.002\ \text{sec}$$

Solving for v, we obtain

$$v\ \text{m/sec} = 1\ \text{m}/(1/60\ \text{sec} - 0.002\ \text{sec}) = 68.18\ \text{m/sec}$$

3. 25×10^{-3} V $\left[\dfrac{3.3 \ \mu S/cm^2 (240 \ \mu S/cm^2)}{(3.3 + 240) \ \mu S/cm^2} \right]$ log $\dfrac{240(145)}{3.3(4)}$

$= 25 \times 10^{-3}(11.1361)V \times \mu S/cm^2 = 0.2784 \ \mu A/cm^2$

Applying Clinical Reasoning

(Question on p. 131.)

Initiation and propagation of action potentials does not occur in nerve fibers acted on by local anesthetic because blockage of Na^+ channels by the local anesthetic prevents the massive opening of voltage-gated Na^+ channels at threshold potential. As a result, pain impulses (action potentials in nerve fibers that carry pain signals) are not initiated and propagated to the brain and therefore do not reach the level of conscious awareness.

Thinking at a Higher Level

(Questions on p. 132.)

1. accelerate. During an action potential, Na^+ enters and K^+ leaves the cell. Repeated action potentials would eventually "run down" the Na^+ and K^+ concentration gradients were it not for the Na^+–K^+ pump returning the Na^+ that entered back to the outside and the K^+ that left back to the inside. Indeed, the rate of pump activity is accelerated by the increase in both ICF Na^+ and ECF K^+ concentrations that occurs as a result of action potential activity, thus hastening the restoration of the concentration gradients.

2. c. The action potentials would stop as they met in the middle. As the two action potentials moving toward each other both reached the middle of the axon, the two adjacent patches of membrane in the middle would be in a refractory period, so further propagation of either action potential would be impossible.

3. The hand could be pulled away from the hot stove by flexion of the elbow accomplished by summation of EPSPs at the cell bodies of the neurons controlling the biceps muscle, thus bringing these neurons to threshold. The subsequent action potentials generated in these neurons would stimulate contraction of the biceps. Simultaneous contraction of the triceps muscle, which would oppose the desired flexion of the elbow, could be prevented by generation of IPSPs at the cell bodies of the neurons controlling this muscle. These IPSPs would keep the triceps neurons from reaching threshold and firing so that the triceps would not be stimulated to contract.

The arm could deliberately be extended despite a painful finger prick by voluntarily generating EPSPs to override the reflex IPSPs at the neuronal cell bodies controlling the triceps while simultaneously generating IPSPs to override the reflex EPSPs at the neuronal cell bodies controlling the biceps.

4. An EPSP, being a graded potential, spreads decrementally from its site of initiation in the postsynaptic neuron. If presynaptic neuron A (near the axon hillock of the postsynaptic cell) and presynaptic neuron B (on the opposite side of the postsynaptic cell body) both initiate EPSPs of the same magnitude and frequency, the EPSPs from A are of greater strength when they reach the axon hillock than the EPSPs from B. An EPSP from B decreases more in magnitude as it travels farther before reaching the axon hillock, the region of lowest threshold and thus the site of action potential initiation. Temporal summation of the larger EPSPs from A may bring the axon hillock to threshold and initiate an action potential in the postsynaptic neuron, whereas temporal summation of the weaker EPSPs from B at the axon hillock may not be sufficient to bring this region to threshold. Thus, the proximity of a presynaptic neuron to the axon hillock can bias its influence on the postsynaptic cell.

5. Estrogen acting on estrogen-dependent breast cancer cells promotes survival of these cells. By interfering with the ability of estrogen to bind with its receptors in the breast cancer cells, selective estrogen receptor modulators (SERMs) prevent estrogen from promoting survival of these cells. SERMs are taken for a number of years following removal of cancerous breast tissue with the goal of thwarting any cancer cells that may remain in the body.

Because SERMs interfere with estrogen (a lipophilic steroid hormone) binding with its receptors, which are located inside the target cell, one can infer that SERMs must also enter the target cell. Therefore, SERMs must be lipophilic, so they could be taken orally without risk of being destroyed by protein-digesting enzymes in the digestive tract.

Chapter 5 The Central Nervous System

Check Your Understanding

5.1 (Questions on p. 138.)

1. See Figure 5-1, p. 134.

2. An *afferent neuron* has a sensory receptor at its peripheral ending, a long peripheral axon (afferent fiber), a cell body devoid of presynaptic inputs located adjacent to the spinal cord, and a short central axon that terminates in the spinal cord. Afferent neurons relay signals from the periphery to the CNS. The cell body of an *efferent neuron* lies in the CNS and has many presynaptic inputs converging on it. Its long peripheral axon (efferent fiber) branches into axon terminals at the effector organ. Efferent neurons carry instructions from the CNS to effector organs. In contrast to afferent and efferent neurons, which lie primarily in the PNS, *interneurons* lie entirely in the CNS. The cell body of an interneuron receives converging input from afferent neurons and other interneurons and its diverging output terminates on efferent neurons or other interneurons. Interneurons are important in integrating afferent information and formulating an efferent response and for accomplishing all higher mental functions associated with the "mind."

3. astrocytes, oligodendrocytes, microglia, and ependymal cells

5.2 (Questions on p. 141.)

1. dura mater, arachnoid mater, and pia mater

2. CSF is a shock-absorbing fluid that surrounds and cushions the brain and spinal cord.

3. Tight junctions anatomically prevent transport between the cells that form the walls of brain capillaries, and highly selective membrane-bound carriers physiologically restrict transport through these cells. Together, these mechanisms constitute the blood–brain barrier.

5.3 (Questions on p. 144.)

1. act or process of "knowing," including both awareness and judgment

2. 1. brain stem
   2. cerebellum
   3. forebrain
      a. diencephalon
         (1) hypothalamus
         (2) thalamus
      b. cerebrum
         (1) basal nuclei
         (2) cerebral cortex

3. Without its convolutions, the human cortex would take up to three times the area it does and would not fit like a cover over the underlying structures.

5.4 (Questions on p. 153.)

1. See Figure 5-11, p. 148.

2. primary motor cortex, supplementary motor area, premotor cortex, and posterior parietal cortex

3. the ability of the brain to change or be functionally remodeled in response to the demands placed on it

4. *Broca's area* governs speaking ability. It commands facial and tongue muscles to speak words. *Wernicke's area* is concerned with language comprehension. It is important in understanding spoken and written messages and plans coherent content of spoken words.

5.5 (Questions on p. 155.)

1. (1) inhibit muscle tone, (2) maintain purposeful motor activity while suppressing useless patterns of movement, and (3) coordinate slow, sustained movements related to posture

2. All sensory input on its way to the higher cortex synapses in the thalamus, which screens out insignificant signals and routes the important signals to appropriate areas of the cortex. In this way the thalamus serves as a relay station for preliminary processing of sensory input.

3. hypothalamus

5.6 (Questions on p. 157.)

1. emotions, basic survival and sociosexual behavioral patterns, motivation, and learning

2. amygdala

3. norepinephrine, dopamine, and serotonin

5.7 (Questions on p. 163.)

1. the process of transferring and fixing short-term memory traces into long-term memory stores

2. *Short-term memory* involves transient modifications in the function of preexisting synapses, such as increased neurotransmitter release from a presynaptic neuron or increased responsiveness of a postsynaptic neuron to neurotransmitter. *Long-term memory* involves gene activation and protein synthesis that leads to relatively permanent structural or functional changes, such as formation of new synapses.

3. With *long-term potentiation*, in response to increased use at a given preexisting synapse, modifications take place in the postsynaptic neuron and/or presynaptic neuron that enhance the future ability of the presynaptic neuron to excite the postsynaptic neuron.

4. The hippocampus is important for *declarative memories,* the "what" memories of specific people, places, objects, facts, and events that often result after only one experience. The cerebellum plays an essential role in the "how to" *procedural memories* involving motor skills gained through repetitive training. The prefrontal association cortex is the major orchestrator of *working memory*, which temporarily holds currently relevant data—both new information and knowledge retrieved from memory stores—and manipulates and relates them to accomplish complex reasoning functions.

5.8 (Questions on p. 166.)

1. The *vestibulocerebellum* maintains balance and controls eye movements. The *spinocerebellum* enhances muscle tone and coordinates skilled, voluntary movements. The *cerebrocerebellum* plays a role in planning and initiating voluntary activity and stores procedural memories.

2. A *resting tremor* is an involuntary, useless, or unwanted movement, such as hands rhythmically shaking, and is often associated with Parkinson's disease. An *intention tremor* is characterized by oscillating to-and-fro movements of a limb as it approaches an intended destination, and is often associated with cerebellar disease.

5.9 (Questions on p. 172.)

1. (1) origin of most cranial nerves; (2) contains centers for control of circulation, respiration, and digestion; (3) helps regulate muscle reflexes involved in equilibrium and posture; (4) receives all incoming sensory synaptic input and is the origin of the reticular activating system; and (5) contains some of the centers that govern sleep.

2. refers to subjective awareness of the external world and self

3. (1) an *arousal system,* which is regulated by a group of neurons in the hypothalamus and involves the reticular activating system in the brain stem; (2) a *slow-wave sleep center* in the hypothalamus that contains sleep-on neurons that induce slow-wave sleep; and (3) a *paradoxical sleep center* in the brain stem, which houses REM sleep-on neurons that switch from slow-wave to REM sleep

5.10 (Questions on p. 178.)

1. See Figure 5-24, p. 174.

2. A *tract* is a bundle of nerve fibers (axons of long interneurons) with similar function that travel up (ascending tract) or down (descending tract) in the white matter of the spinal cord. A *ganglion* is a collection of neuronal cell bodies located outside the CNS. A *center,* or *nucleus,* is a functional collection of neuronal cell bodies located within the CNS. A *nerve* is a bundle of peripheral axons (both afferent and efferent fibers), enclosed by a connective-tissue covering and following the same pathway.

3. receptor, afferent pathway, integrating center, efferent pathway, effector

4. (1) as *spinal* or *cranial*, (2) as *innate* or *conditioned*, (3) as *somatic* or *autonomic*, and (4) as *monosynaptic* or *polysynaptic*

Figure Focus

FIGURE 5-1 (P. 134): When you are *taking a walk,* the afferent division of the PNS receives sensory stimuli, and the CNS issues commands to skeletal muscles acting via the somatic nervous system component of the efferent division of the PNS. When you are *digesting a meal*, the afferent division of the PNS receives sensory stimuli (such as the smell and taste of the food) and visceral stimuli (for example, the protein and fat content of the food and distention of the digestive tract). The CNS issues commands to the smooth muscle of the digestive tract and the exocrine glands that secrete digestive juices via the autonomic nervous system component of the efferent division of PNS.

FIGURE 5-9 (P. 147): (1) pyramidal cells, (2) stellate cells

FIGURE 5-11 (P. 148): (1) occipital lobe, (2) frontal lobe, (3) parietal lobe, (4) temporal lobe

FIGURE 5-13 (P. 151): (1) no, (2) yes

FIGURE 5-17 (P. 161): No. Even though binding of glutamate to an NMDA receptor-channel opens this channel's gate, Mg^{2+} still blocks the channel. Mg^{2+} must be driven out of the channel by depolarization before Ca^{2+} can enter through the NMDA receptor-channel to bring about long-term potentiation. The single EPSP produced by Na^+ entry when glutamate binds to and opens the AMPA receptor-channel does not depolarize the postsynaptic neuron sufficiently to drive Mg^{2+} out. Other EPSPs must occur concurrently via input from this or other presynaptic inputs to depolarize the postsynaptic membrane enough to drive Mg^{2+} out, thereby allowing long-term potentiation to occur.

FIGURE 5-19 (P. 167): Auditory impulses initiated by your alarm going off are carried by afferent fibers that synapse within the reticular formation in the brain stem. Ascending fibers that originate in the reticular formation and compose the reticular activating system subsequently carry signals upward to arouse and activate the cerebral cortex.

FIGURE 5-21 (P. 170): Most stage 4 deep, slow-wave sleep occurs during the first three hours of the sleep period. Slow-wave sleep occupies progressively less time and only passes through its lighter stages, whereas REM sleep occupies progressively more time, throughout the remainder of this cyclical sleep pattern.

Reviewing Terms and Facts

Applying Clinical Reasoning

(Question on p. 180.)

The deficits following the stroke—numbness and partial paralysis on the upper right side of the body and inability to speak—are indicative of damage to the left somatosensory cortex and left primary motor cortex in the regions devoted to the upper part of the body plus Broca's area.

Thinking at a Higher Level

(Questions on p. 180.)

1. Only the left hemisphere has language ability. When sharing of information between the two hemispheres is prevented as a result of severance of the corpus callosum, the left hemisphere cannot verbally identify visual information presented only to the right hemisphere because the left hemisphere is unaware of the information. However, the information can be recognized by nonverbal means, of which the right hemisphere is capable.

2. c. A severe blow to the back of the head is most likely to traumatize the visual cortex in the occipital lobe.

3. Insulin excess drives too much glucose into insulin-dependent cells so that the blood glucose falls below normal and insufficient glucose is delivered to the non-insulin-dependent brain. Therefore, the brain, which depends on glucose as its energy source, does not receive adequate nourishment.

4. Salivation when seeing or smelling food, striking the appropriate letter on the keyboard when typing, and many of the actions involved in driving a car are conditioned reflexes. You undoubtedly will have many other examples.

5. Strokes occur when a portion of the brain is deprived of its vital O_2 and glucose supply because the cerebral blood vessel supplying the area either is blocked by a clot or has ruptured. Although a clot-dissolving drug could be helpful in restoring blood flow through a cerebral vessel blocked by a clot, such a drug would be detrimental in the case of a ruptured cerebral vessel sealed by a clot. Dissolution of a clot sealing a ruptured vessel would lead to renewed hemorrhage through the vessel and make the problem worse.

Chapter 6 The Peripheral Nervous System: Afferent Division; Special Senses

Check Your Understanding

6.1 (Questions on p. 189.)

1. A *stimulus* is a change detectable by the body. A *receptor potential* is a graded potential change in a receptor in response to a stimulus. A *labeled line* is a committed, incoming neural pathway carrying information regarding a particular sensory modality detected by a specialized receptor type at a specific site in the periphery and delivered to a defined area in the somatosensory cortex. *Perception* is the conscious interpretation of the external world as created by the brain from the sensory input it receives.

2. See Figure 6-4, p. 185.

3. The receptive field size for a sensory neuron on your tongue would be smaller than for a sensory neuron on your back because your tongue has greater discriminative ability than your back does.

6.2 (Questions on p. 192.)

1. Pain is a multidimensional experience because the sensation of pain is accompanied by motivated behavioral responses and emotional reactions.

2. *A-delta fibers* constitute a fast pain pathway that carries signals arising from mechanical and thermal nociceptors. *C fibers* constitute a slow pain pathway that carries impulses from polymodal nociceptors.

3. *Endogenous opioids* serve as endogenous analgesics by binding with opiate receptors at the synaptic knob of afferent pain fibers where they inhibit release of the pain neurotransmitter, substance P, thereby blocking further transmission of the pain signal.

6.3 (Questions on p. 211.)

1. See Figure 6-19a, p. 198.

2. When a photopigment absorbs light, retinal changes to the all-*trans* form, activating the photopigment. The activated photopigment activates the G protein transducin, which then activates the intracellular enzyme phosphodiesterase. In the dark the second messenger cGMP had been keeping chemically gated Na^+ channels open, resulting in a passive, inward, depolarizing Na^+ leak (dark current). Activated phosphodiesterase degrades cGMP, permitting these chemically gated Na^+ channels to close, stopping the depolarizing Na^+ leak and causing hyperpolarization of the photoreceptor (the receptor potential).

3. See Table 6-3, p. 204.

4. All of the axons of the ganglion cells in the retina of one eye are bundled together into the *optic nerve* that exits the eye. At the *optic chiasm*, located underneath the hypothalamus, the fibers in the two optic nerves carrying information from the medial halves of each retina cross to the opposite side, but those from the lateral halves remain on the original side. This partial crossover brings together information from the same half of the visual field as viewed by both eyes. These reorganized bundles of fibers that leave the optic chiasm are known as *optic tracts*, which synapse in the thalamus. The thalamus separates the visual information it receives and relays it via fiber bundles known as *optic radiations* to different zones in the visual cortex.

6.4 (Questions on p. 224.)

1. The *middle ear* amplifies the tympanic membrane vibrations and converts them into wavelike movements in the inner ear fluid at the same frequency as the original sound waves.

2. *Pitch discrimination* depends on which region of the basilar membrane naturally vibrates maximally with a given sound frequency. *Loudness discrimination* depends on the amplitude of the vibrations. *Timbre discrimination* depends on overtones of varying frequencies causing many points along the basilar membrane to vibrate simultaneously but less intensely than the fundamental tone.

3. The stereocilia of an auditory hair cell are organized into rows of graded heights, from short to tall. *Tip links* that connect the mechanically gated channel of a stereocilium to its next tallest member are stretched when the stereocilia all bend toward their tallest member, thereby pulling the channels open and permitting K^+ entry into the hair cell. When the tip links slacken as the stereocilia bend away from their tallest member, the channels close and K^+ entry into the hair cell ceases.

4. See Figure 6-40, p. 222.

6.5 (Questions on p. 230.)

1. *salty* (stimulated by chemical salts); *sour* (caused by free H^+ in acids); *sweet* (evoked by the particular configuration of glucose or by artificial sweeteners, which are organic molecules similar in structure to glucose but have no calories); *bitter* (elicited by alkaloids and poisonous substances, thus discouraging ingestion of potentially dangerous compounds); *umami* (triggered by amino acids, especially glutamate, as in meat)

2. *Gustducin* is the G protein activated in the second-messenger pathways involved in perception of bitter, sweet, and umami tastes.

3. An odorant is dissected into various components, and each olfactory receptor responds to a particular odor component that may be shared in common by multiple scents. Each glomerulus in the olfac-

tory bulb receives signals only from receptors that detect a particular odor component. Odor discrimination is based on different patterns of glomeruli (the "smell files") activated by various scents.

Figure Focus

FIGURE 6-3 (P. 184): An acid-monitoring neuron's receptor potential, frequency of action potentials in its afferent fiber, and rate of neurotransmitter release at its axon terminals would all increase if body fluids became too acidic. These neuronal responses would all decrease if body fluids became too alkaline.

FIGURE 6-9 (P. 191): Oxycontin binds to the opiate receptors at the afferent pain-fiber terminal and suppresses the terminal's release of substance P, a pain neurotransmitter.

FIGURE 6-20 (P. 199): yes for rods, no for cones

FIGURE 6-25 (P. 202): A high concentration of cGMP in the photoreceptor in the dark keeps Na^+ channels open, leading to a depolarizing dark current. On absorption of light, the photoreceptor's adequate stimulus, a chain of events is initiated that leads to decreased concentration of cGMP, thereby closing the Na^+ channels and subsequently bringing about hyperpolarization. Hyperpolarization of the photoreceptor causes decreased release of neurotransmitter. The on-center ganglion cells' response to decreased neurotransmitter release is depolarization and subsequent initiation and propagation of action potentials.

FIGURE 6-35 (P. 216): The spiral shape of the cochlea steers the low-frequency sound waves toward the region of the basilar membrane that responds maximally to these bass sounds.

FIGURE 6-37 (P. 218): Uniquely, the endolymph that surrounds the stereocilia has a higher K^+ concentration than inside the hair cell. Therefore, when the stereocilia's K^+ channels open, K^+ enters the cell, leading to depolarization. In sharp contrast, a postsynaptic neuron at an inhibitory synapse is surrounded by ECF that has a lower K^+ concentration than inside the cell. As a result, when K^+ channels open, K^+ leaves the neuron, leading to hyperpolarization (an IPSP).

FIGURE 6-40 (P. 222): As you somersault forward, the endolymph moves backward, in the opposite direction of the forward roll.

FIGURE 6-44 (P. 229): Each separate odor component of a cologne's fragrance (such as floral, fruity, or woody) is detected by one of a thousand different olfactory receptor types, each of which sends this information to a specific glomerulus (or "smell file") in the olfactory bulb for further processing.

Reviewing Terms and Facts

(Questions on p. 231.)

1. transduction **2.** adequate stimulus **3.** F **4.** T **5.** T **6.** T **7.** F **8.** F **9.** T **10.** T **11.** F **12.** 1.f, 2.h, 3.l, 4.d, 5.i, 6.e, 7.b, 8.j, 9.a, 10.g, 11.c, 12.k **13.** 1.a, 2.b, 3.c, 4.c, 5.c, 6.a, 7.b, 8.b

Solving Quantitative Exercises

(Questions on p. 232.)

1. The slow pain pathway takes about (1.3 m) (1 sec/12 m) = 0.1083 sec. The fast pathway takes (1.3 m) (1 sec/30 m) = 0.0433 sec. The difference is 0.1083 sec − 0.0433 sec = 0.065 sec = 65 msec.

2. a. The amount of light entering the eye is proportional, approximately, to the area of the open pupil. Recall that the area of a circle is πr^2. Let r be the pupil radius and A_1 be the original pupil area. Halving the diameter also halves the radius, so the new pupil area is

$$\pi \left(\frac{1}{2} r \right)^2 = \frac{1}{4} \pi r^2 = \frac{1}{4} A_1$$

Therefore, the amount of light allowed into the eye is a quarter of what it was originally.

b. The area of a rectangle is hw, where h is the height and w the width. Halving either dimension halves the area and hence the amount of light allowed into the eye.

c. The cat's pupil can be considered more precise. Think about the coarse and fine adjustments on a microscope. Fine adjustment translates rotations of the knob into much smaller movement of the stage than coarse adjustment does.

3. a. Solve the following for I:

$$\beta = (10 \text{ dB}) \log_{10} (I/I_0)$$
$$I = I_0 10^{B/10} W/m^2$$

Therefore,

$$I_1 = 10^{-12} (10^{20/10}) = 10^{-12} (10^2) = 10^{-10} \text{ W/m}^2$$
$$I_2 = 10^{-12} (10^{70/10}) = 10^{-12} (10^7) = 10^{-5} \text{ W/m}^2$$
$$I_3 = 10^{-12} (10^{120/10}) = 10^{-12} (10^{12}) = 1 \text{ W/m}^2$$
$$I_4 = 10^{-12} (10^{170/10}) = 10^{-12} (10^{17}) = 10^5 \text{ W/m}^2$$

b. Because of the logarithm in the definition of decibel, the sound intensity increases exponentially with respect to sound level. This fact should be clear from the definition of dB solved for I. This result implies that the human ear performs well throughout an enormous range of sound intensities.

Applying Clinical Reasoning

(Questions on p. 232.)

Syncope most frequently occurs as a result of inadequate delivery of blood carrying sufficient oxygen and glucose supplies to the brain. Possible causes include circulatory disorders such as impaired pumping of the heart or low blood pressure; respiratory disorders resulting in poorly oxygenated blood; anemia, in which the oxygen-carrying capacity of the blood is reduced; or low blood glucose resulting from improper endocrine management of blood glucose levels. *Vertigo,* in contrast, typically results from a dysfunction of the vestibular apparatus, arising, for example, from viral infection or trauma, or abnormal neural processing of vestibular information, as, for example, with a brain tumor.

Thinking at a Higher Level

(Questions on p. 232.)

1. Pain is a conscious warning that tissue damage is occurring or about to occur. A patient unable to feel pain because of a nerve disorder does not consciously take measures to withdraw from painful stimuli and thus prevent more serious tissue damage.

2. Pupillary dilation (mydriasis) can be deliberately induced by ophthalmic instillation of either an adrenergic drug (such as epinephrine or related compound) or a cholinergic blocking drug (such as atropine or related compound). Adrenergic drugs produce mydriasis by causing contraction of the sympathetically supplied radial (dilator) muscle of the iris. Cholinergic blocking drugs cause pupillary dilation by blocking parasympathetic activity to the circular (constrictor) muscle of the iris so that action of the adrenergically controlled radial muscle of the iris is unopposed.

3. The defect would be in the left optic tract or optic radiation.

4. Rod deterioration associated with *retinitis pigmentosa* leads to tunnel vision, in which the person's field of vision is a constricted circular view as from within a tunnel looking out, because of loss of peripheral vision (where most rods are located) and retention of central vision (where most cones are located).

5. Fluid accumulation in the middle ear in accompaniment with middle ear infections impedes the normal movement of the tympanic

membrane, ossicles, and oval window in response to sound. All these structures vibrate less vigorously in the presence of fluid, causing temporary hearing impairment. Chronic fluid accumulation in the middle ear is sometimes relieved by surgical implantation of drainage tubes in the eardrum. Hearing is restored to normal as the fluid drains to the exterior. Usually, the tube "falls out" as the eardrum heals and pushes out the foreign object.

Chapter 7 The Peripheral Nervous System: Efferent Division

Check Your Understanding

7.1 (Questions on p. 241.)

1. See Figure 7-2, p. 235.

2. The *sympathetic nervous system* dominates in emergency or stressful (fight-or-flight) situations and promotes responses that prepare the body for strenuous physical activity. The *parasympathetic nervous system* dominates in quiet, relaxed (rest-and-digest) situations and promotes "general housekeeping" activities such as digestion.

3. The *adrenal medulla* is a modified sympathetic ganglion that does not give rise to postganglionic fibers but instead, on stimulation by the preganglionic fiber, secretes the hormones epinephrine and norepinephrine into the blood.

7.2 (Questions on p. 244.)

1. The *autonomic nervous system* innervates cardiac muscle, smooth muscle, most exocrine glands, some endocrine glands, and adipose tissue. The *somatic nervous system* innervates skeletal muscles.

2. Motor neurons are considered the *final common pathway* because the only way any other parts of the nervous system can influence skeletal muscle activity is by acting, in common, on these motor neurons.

7.3 (Questions on p. 248.)

1. *Acetylcholine (ACh)* is the neuromuscular junction neurotransmitter. When it is released from the motor-neuron terminal button in response to an action potential, it binds with and opens nonspecific cation receptor-channels in the motor end plate of the muscle fiber. The resultant ion movement leads to an end-plate potential, which initiates a contraction-inducing action potential that is propagated throughout the muscle fiber. *Acetylcholinesterase (AChE)* is an enzyme in the motor end-plate membrane that inactivates ACh. By removing ACh, AChE permits the choice of allowing relaxation to take place (no more ACh released) or keeping the contraction going (more ACh released), depending on the body's momentary needs.

2. An EPP is larger than an EPSP. Because of its magnitude, an EPP is normally large enough to promote sufficient local current flow to bring the muscle membrane adjacent to the motor end plate to threshold, thus initiating an action potential. Thus, one-to-one transmission of action potentials occurs between a motor neuron and a muscle fiber at a neuromuscular junction. By contrast, one EPSP is not of sufficient magnitude to bring the postsynaptic neuron to threshold. Summation of EPSPs arising from multiple presynaptic action potentials is needed to initiate an action potential in the postsynaptic neuron.

3. *Myasthenia gravis* is an autoimmune condition caused by erroneous production of antibodies against the motor end-plate ACh receptor-channels. As a result, insufficient ACh receptor-channels are available for binding with contraction-inducing ACh released at a neuromuscular junction, leading to the extreme muscular weakness characteristic of the disease. The condition is treated with a drug such as neostigmine that temporarily inhibits AChE, thus prolonging activity of ACh at the neu-

romuscular junction so that an EPP of sufficient magnitude to initiate an action potential and subsequent contraction can develop through binding of ACh at the limited number of available ACh receptor-channels.

Figure Focus

FIGURE 7-2 (P. 235): (1) all autonomic preganglionic fibers and parasympathetic postganglionic fibers, (2) both parasympathetic and sympathetic, (3) only parasympathetic

FIGURE 7-4 (P. 244): An *axon terminal* is the small end branch of a motor neuron that terminates on a single muscle cell (muscle fiber). A *neuromuscular junction* consists of both the neuronal (axon terminal) and muscle cell (motor end plate) components of this junction. Within a neuromuscular junction the axon terminal divides into fine branches, each of which ends in an enlarged *terminal button.*

FIGURE 7-5 (P. 245): by (1) interfering with release of ACh from the synaptic vesicles, (2) blocking binding of ACh to the receptor-channels, or (3) inhibiting AChE action

Reviewing Terms and Facts

1. T **2.** F **3.** c **4.** c **5.** sympathetic, parasympathetic **6.** adrenal medulla **7.** motor end plate **8.** 1.a, 2.b, 3.a, 4.b, 5.a, 6.a, 7.b **9.** 1.b, 2.b, 3.a, 4.a, 5.b, 6.b, 7.a **10.** 1.c,f, 2.a, 3.d,f, 4.e, 5.e, 6.b,f

Solving Quantitative Exercises

(Question on p. 249.)

1. $t = \dfrac{x^2}{2D} = \dfrac{(200 \text{ nm})^2}{2 \times 10^{-5} \text{ cm}^2/\text{sec}}$

$= \dfrac{4 \times 10^{-14} \text{ m}^2 \cdot \text{sec}}{2 \times 10^{-5} \text{ cm}^2} \left(\dfrac{10^4 \text{ cm}^2}{\text{m}^2} \right) = 20 \text{ μsec}$

Applying Clinical Reasoning

(Question on p. 249.)

Drugs that block β_1 receptors are useful for prolonged treatment of angina pectoris because they interfere with sympathetic stimulation of the heart during exercise or emotionally stressful situations. By preventing increased cardiac metabolism and thus an increased need for oxygen delivery to the cardiac muscle during these situations, beta blockers can reduce the frequency and severity of angina attacks.

Thinking at a Higher Level

(Questions on p. 250.)

1. By promoting arteriolar constriction, epinephrine administered in conjunction with local anesthetics reduces blood flow to the region and thus helps the anesthetic stay in the region instead of being carried away by the blood.

2. No. Atropine blocks the effect of acetylcholine at muscarinic receptors but does not affect nicotinic receptors. Nicotinic receptors are present on the motor end plates of skeletal muscle fibers.

3. The voluntarily controlled external urethral sphincter is composed of skeletal muscle and supplied by the somatic nervous system.

4. By interfering with normal acetylcholine activity at the neuromuscular junction, α-bungarotoxin leads to skeletal muscle paralysis, with death ultimately occurring as a result of an inability to contract the diaphragm and breathe.

5. If the motor neurons that control the respiratory muscles, especially the diaphragm, are destroyed by poliovirus or amyotrophic lat-

eral sclerosis, the person is unable to breathe and dies (unless breathing is assisted by artificial means).

Chapter 8 Muscle Physiology

Check Your Understanding

8.1 (Questions on p. 256.)

1. A *muscle fiber* is composed of *myofibrils* that extend the entire length of the muscle fiber; in general, larger diameter muscle fibers have a greater number of myofibrils. A *whole muscle* is composed of muscle fibers that extend the entire length of the muscle; in general, larger diameter muscles have more muscle fibers.

2. See Figure 8-2c, d, and e, p. 253.

3. The regulatory protein, troponin, binds to both actin and tropomyosin. In the relaxed state, troponin assumes a conformation that causes tropomyosin to cover the myosin cross-bridge binding sites on the actin molecules.

8.2 (Questions on p. 262.)

1. See Figure 8-7, p. 257.

2. The dihydropyridine receptors serve as voltage-gated sensors that are activated by an action potential as it propagates along the T tubule. The activated dihydropyridine receptors trigger opening of Ca^{2+}-release channels (ryanodine receptors) in the adjacent lateral sacs of the sarcoplasmic reticulum, thereby permitting Ca^{2+} release from the lateral sacs. This released Ca^{2+} repositions the troponin–tropomyosin complex so that actin and the myosin cross bridges can interact to accomplish contraction.

3. See the cross-bridge cycle in Figure 8-12, p. 261. ATP binds to the myosin head and causes the head to detach from the actin molecule. During the cocking of the myosin head, ATP is hydrolyzed to ADP and P_i. When the myosin head binds to actin, P_i is released from the head during the power stroke. ADP is released from the myosin head after the power stroke.

4. During *rigor mortis*, the cytosolic Ca^{2+} concentration rises owing to leaky membranes, bringing about binding of previously energized myosin cross bridges to actin. However, no fresh ATP is available to bind with the myosin cross bridge and permit its detachment from actin. Therefore myosin and actin remain locked together, producing a "stiffness of death."

8.3 (Questions on p. 269.)

1. Muscle tension generated by sarcomere shortening stretches the series-elastic component (tendon). The stretched tendon transmits the generated tension to the bone to which it is attached.

2. Refer to Figure 8-17, p. 265. Changing the power arm from 5 cm to 10 cm would reduce the force needed to support the 5 kg load; a 17.5 kg muscle force would be required (at the new lever ratio of 1:3.5). The trade-off for this improved mechanical advantage would be slower movement of the hand (at 3.5 cm/unit of time) as the biceps shortens at 1 cm/unit of time.

3. Greater strength of contraction can be achieved through motor unit recruitment, twitch summation–tetanus, positioning the muscle at its optimal length, the absence of fatigue, and hypertrophy of a muscle (strength training).

4. In twitch summation, the level of cytosolic Ca^{2+} is increased by repeated release of Ca^{2+} from the lateral sacs. In addition, with repeated excitation of a skeletal muscle cell, insufficient time is available between action potentials for the sarcoplasmic reticulum to pump all of the released Ca^{2+} back into the lateral sacs. The sustained, elevated cytosolic Ca^{2+} leads to prolonged exposure of myosin cross-bridge binding sites for interaction with actin and thus greater power stroke opportunities.

8.4 (Questions on p. 275.)

1. ATP is expended (1) to cock the head of the myosin molecule to permit a power stroke, (2) to pump released Ca^{2+} back into the lateral sacs against a concentration gradient, and (3) to run the Na^+–K^+ pump to maintain the concentrations of these ions in the ECF and ICF following an action potential in the skeletal muscle cell. Also, (4) binding (but not splitting) of a fresh molecule of ATP lets the cross bridge detach from actin at the end of a power stroke.

2. The leg (drumstick) muscles of a turkey consist primarily of red muscle fibers, which have a large number of mitochondria, high levels of myoglobin, low glycogen content, and relatively few glycolytic enzymes. The turkey's leg muscles are built for endurance, not for speed or power. In contrast, the turkey's breast muscles, composed primarily of white muscle fibers, have relatively few mitochondria, low levels of myoglobin, high glycogen content, and an abundance of glycolytic enzymes. The breast muscles are built for speed and power, but lack endurance (for example, turkeys can fly only a very short distance).

3. ATP comes from all of these sources during the course of the race, but oxidative phosphorylation is responsible for generating the largest amount of ATP expended in this event.

8.5 (Questions on p. 286.)

1. (1) *Somatic reflexes* are automatic, purposeful responses brought about by skeletal muscles without conscious effort. They are integrated by the spinal cord or brain stem. (2) *Voluntary movements* are goal-directed movements initiated and terminated consciously and integrated by the cerebral cortex. (3) *Rhythmic movements* are stereotypical movements repeated in a general pattern, like walking. They are initiated and terminated consciously by the cerebral cortex, but their reflexlike execution is accomplished without conscious effort by lower CNS levels.

2. The following have direct input to motor neurons: (1) afferent neurons, (2) the primary motor cortex, and (3) the brain stem as part of the multineuronal motor system.

3. See Figure 8-25, p. 284, which depicts this monosynaptic reflex; components include muscle spindle receptors, afferent neuron, efferent neuron (alpha motor neuron), and quadriceps femoris muscle.

8.6 (Questions on p. 294.)

1. In both skeletal and smooth muscle, ATP-powered cross-bridge stroking causes the thin filaments to slide in relation to the stationary thick filaments. In skeletal muscle, the myosin molecules are arranged so that no heads are located in the bare H zone in the middle of the sarcomere, and all cross-bridge stroking pulls the surrounding thin filaments toward the center of the sarcomere. In smooth muscle, the heads of the myosin molecules are located throughout the entire length of the thick filaments (no bare zone), and the heads are arranged to pull half of the surrounding thin filaments in one direction and the other half in the opposite direction within the same region of the thick filament. In skeletal muscle, the thin filaments are made up of actin, troponin, and tropomyosin. In smooth muscle, the thin filaments are made up of only actin and tropomyosin; the filaments lack the regulatory protein, troponin. Smooth muscle has 10 to 15 thin filaments per thick filament; in skeletal muscle the ratio is 2 to 1. The thick filaments are considerably longer in smooth muscle than in skeletal muscle, thereby allowing smooth muscle to develop tension when stretched to 2½ times its resting muscle length.

2. *Multiunit smooth muscle* is neurogenic and consists of multiple discrete muscle fiber units that must be separately stimulated by nerves and function independently of one another. *Single-unit smooth muscle* is myogenic and organized into a sheet of muscle fibers interconnected via gap junctions to form a functional syncytium that becomes excited and contracts as a single unit.

3. In *skeletal muscle,* the sarcoplasmic reticulum is the sole source of contraction-inducing Ca^{2+}. Contraction of *cardiac muscle* is a result

of Ca^{2+} influx from the ECF and intracellular Ca^{2+} release from the sarcoplasmic reticulum. The source of Ca^{2+} in *smooth muscle* is predominantly from the ECF; the sarcoplasmic reticulum is poorly developed in smooth muscle.

Figure Focus

FIGURE 8-2 (P. 253): A cross section through the H zone would have only thick filaments; a cross section through the I band would have only thin filaments; the cross section through the A band in part (c) has both thick and thin filaments.

FIGURE 8-7 (P. 257): The H zone disappears.

FIGURE 8-12 (P. 261): Each cross-bridge cycle uses one ATP molecule. The fresh ATP molecule that binds to the cross bridge to permit its detachment from actin is the same ATP that is split and energizes the cross bridge for the subsequent power stroke.

FIGURE 8-17 (P. 265): 42 kg. The power arm of the lever is 4 cm, and the load arm is 28 cm for a lever ratio of 1:7 (4 cm:28 cm). Thus, to lift a 6 kg backpack with one hand, the child must generate an upward applied force in the biceps muscle of 42 kg. (With a lever ratio of 1:7, the muscle must exert seven times the force of the load; 7×6 kg = 42 kg.)

FIGURE 8-19 (P. 267): A muscle fiber develops considerably more tension during tetanus than during a single twitch. Because of repetitive action potentials during tetanus, the cytosolic Ca^{2+} concentration remains elevated, thereby keeping the troponin–tropomyosin complex pulled aside so that more of the cross bridges can participate in the cycling process for a longer time.

FIGURE 8-20 (P. 269): 70%

FIGURE 8-32 (P. 291): (1) true, (2) false

Reviewing Terms and Facts

(Questions on p. 295.)

1. F **2.** F **3.** F **4.** T **5.** concentric, eccentric **6.** alpha, gamma **7.** denervation atrophy, disuse atrophy, age-related atrophy (sarcopenia) **8.** tone **9.** functional syncytium **10.** Latch phenomenon **11.** b **12.** 1.f, 2.d, 3.c, 4.e, 5.b, 6.g, 7.a **13.** d, e, f

Solving Quantitative Exercises

(Questions on p. 296.)

1. a. For the weekend athlete, the lever ratio is 70 cm/9 cm. So the velocity at the end of the arm is 2.6 m/sec (70/9) = 20.2 m/sec (about 45 mph).

b. For the professional ballplayer, the lever ratio is 90 cm/9 cm. So

$$10x = 85 \text{ mph}$$
$$x = 8.5 \text{ mi/hr}(1609 \text{ m/mi})(1 \text{ hr/3600 sec})$$
$$= 3.8 \text{ m/sec}$$

2. The force–velocity curve is as follows:
a. The shape of the curve indicates that it takes time to develop force and that the greater the force developed, the more time is needed.

b. The maximum velocity does not change when F_0 is increased, but the muscle is able to lift heavier loads or to generate more force. The maximum load does not increase when the cross-bridge cycling rate increases, but the muscle is able to lift lighter loads faster. If the muscle increases in size, b increases, and the entire curve shifts up with respect to the v axis.

Applying Clinical Reasoning

(Questions on p. 296.)

The muscles in the immobilized leg have undergone disuse atrophy. The physician or physical therapist can prescribe regular resistance-type exercises that specifically use the atrophied muscles to help restore them to their normal size.

Thinking at a Higher Level

(Questions on p. 296.)

1. By placing increased demands on the heart to sustain increased delivery of O_2 and nutrients to working skeletal muscles, regular aerobic exercise induces changes in cardiac muscle that enable it to use O_2 more efficiently, such as increasing the number of capillaries supplying blood to the heart muscle. Intense exercise of short duration, such as weight training, in contrast, does not induce cardiac efficiency. Because this type of exercise relies on anaerobic glycolysis for ATP formation, no demands are placed on the heart for increased delivery of blood to the working muscles.

2. The length of the thin filaments is represented by the distance between a Z line and the edge of the adjacent H zone. This distance remains the same in a relaxed and contracted myofibril, leading to the conclusion that the thin filaments do not change in length during muscle contraction.

3. Regular bouts of anaerobic, short-duration, high-intensity resistance training would be recommended for competitive downhill skiing. By promoting hypertrophy of the fast-glycolytic fibers, such exercise better adapts the muscles to activities that require intense strength for brief periods, such as a swift, powerful descent downhill. In contrast, regular aerobic exercise would be more beneficial for competitive cross-country skiers. Aerobic exercise induces metabolic changes within the oxidative fibers that enable the muscles to use O_2 more efficiently. These changes, which include an increase in mitochondria and capillaries within the oxidative fibers, adapt the muscles to better endure the prolonged activity of cross-country skiing without fatiguing.

4. (a) If the gamma motor neurons are activated and the alpha motor neurons are not activated, the intrafusal fibers contract and stretch the noncontractile portion of the muscle spindle. This causes the primary and secondary receptors to increase their rate of firing. (b) If the gamma motor neurons are not activated and the alpha motor neurons are activated, the receptors decrease their rate of firing or stop firing because the muscle spindle slackens as the whole muscle shortens.

5. Because the site of voluntary control to overcome the micturition reflex is at the external urethral sphincter and not the bladder, the external urethral sphincter must be skeletal muscle, which is innervated by the voluntarily controlled somatic nervous system, and the bladder must be smooth muscle, which is innervated by the involuntarily controlled autonomic nervous system. The only other type of involuntarily controlled muscle besides smooth muscle is cardiac muscle, which is found only in the heart. Therefore, the bladder must be smooth, not cardiac, muscle.

Chapter 9 Cardiac Physiology

Check Your Understanding

9.1 (Questions on p. 303.)

1. See Figure 9-1, p. 298.

2. The *right* and *left atrioventricular* (*AV valves*) let blood flow from the atria to the ventricles during ventricular filling but prevent backflow of blood from the ventricles into the atria during ventricular emptying. The *aortic* and *pulmonary semilunar valves* let blood flow from the ventricles into the aorta and pulmonary arteries during ventricular emptying but prevent backflow of blood from these major arteries into the ventricles during ventricular filling.

3. Adjacent cardiac muscle cells are joined end to end at specialized structures called *intercalated discs,* within which are two types of membrane junctions: desmosomes that hold the cells together mechanically and gap junctions that permit spread of electrical current between the cells.

9.2 (Questions on p. 314.)

1. See Figure 9-7, p. 304 and Figure 9-10, p. 308.

2. *SA node* (70–80 action potentials/min), *AV node* (40–60 action potentials/min), and *Bundle of His and Purkinje fibers* (20–40 action potentials/min)

3. refers to excitation-induced entry of a small amount of Ca^{2+} into the cytosol from the ECF through voltage-gated surface membrane Ca^{2+} channels triggering the opening of Ca^{2+}-release channels in the sarcoplasmic reticulum, thereby inducing a much larger release of Ca^{2+} into the cytosol from these intracellular stores.

4. See Figure 9-14, p. 312. The electrical activity associated with atrial repolarization occurs simultaneously with ventricular depolarization and is masked by the QRS complex on a normal ECG.

9.3 (Questions on p. 318.)

1. *Systole* is the period of contraction and emptying and *diastole* is the period of relaxation and filling during the cardiac cycle.

2. (1) aortic pressure > atrial pressure > ventricular pressure, (2) aortic pressure > ventricular pressure > atrial pressure, (3) ventricular pressure > aortic pressure > atrial pressure, (4) aortic pressure > ventricular pressure > atrial pressure

3. *End-diastolic volume (EDV)* is the volume of blood in the ventricle at the end of diastole when filling is complete. *End-systolic volume (ESV)* is the volume of blood in the ventricle at the end of systole when emptying is complete. *Stroke volume (SV)* is the volume of blood ejected by each ventricle with each contraction. EDV − ESV = SV.

9.4 (Questions on p. 325.)

1. *Parasympathetic stimulation* decreases heart rate and has no effect on stroke volume. *Sympathetic stimulation* increases heart rate and increases stroke volume by increasing the contractile strength of the heart.

2. See Figure 9-21 on p. 322.

3. The extent of ventricular filling is referred to as the *preload* because it is the workload imposed on the heart before contraction begins. The arterial blood pressure is called the *afterload* because it is the workload imposed on the heart after the contraction has begun.

9.5 (Questions on p. 331.)

1. The heart receives most of its blood supply during diastole because blood flow through the coronary vessels is substantially reduced during systole as a result of (1) the contracting myocardium compressing the coronary arteries and (2) the open aortic valve partially blocking the entrance to the coronary arteries.

2. When the heart is more active metabolically (that is, when it is pumping harder) and needs more O_2, the cardiac cells form and release more adenosine from ATP during this stepped-up metabolic activity.

Adenosine promotes vasodilation of the coronary vessels, allowing more O_2-rich blood to flow to the more active cardiac cells to match their increased O_2 demand.

3. An *atherosclerotic plaque* consists of a lipid-rich core covered by an abnormal overgrowth of smooth muscle cells, topped off by a collagen-rich connective tissue cap.

Figure Focus

FIGURE 9-1 (P. 298): right, systemic, pulmonary, left, pulmonary, systemic

FIGURE 9-7 (P. 304): The rate of slow depolarization would be decreased. A lower ECF K^+ concentration would increase the K^+ concentration gradient between a cardiac pacemaker cell and the ECF. The resultant increased movement of K^+ outward down this increased gradient would oppose the diminished outflow of K^+ caused by the slow closure of K^+ channels that contributes to development of the pacemaker potential.

FIGURE 9-10 (P. 308): Entry of Ca^{2+} through L-type Ca^{2+} channels in cardiac contractile cells is responsible for the plateau phase of the action potential, whereas its entry through these channels in autorhythmic cells is responsible for the rising phase of the action potential.

FIGURE 9-14 (P. 312): during the *PR segment:* atria completely depolarized, ventricles still at resting potential; during the *ST segment:* atria completely repolarized, ventricles completely depolarized; during the *TP segment:* atria and ventricles both completely depolarized

FIGURE 9-16 (P. 316): No. When diastolic time is reduced in half as a result of increased heart rate, filling is nearly the same as at normal heart rate because much of ventricular filling occurs early in diastole during the rapid filling phase.

FIGURE 9-17 (P. 317): The pressure difference between points 4 and 6 would be less in the right-sided loop than in the left-sided loop because the ventricular pressure that must be developed to open the pulmonary valve is less than the pressure needed to open the aortic valve. The volume difference between points 6 and 8 would be the same in both loops because both ventricles eject the same stroke volume.

FIGURE 9-24 (P. 324): A transplanted heart that does not have any innervation adjusts the cardiac output to meet the body's changing needs by means of both intrinsic control (the Frank–Starling mechanism) and extrinsic hormonal influences, such as the effect of epinephrine on the rate and strength of cardiac contraction.

Reviewing Terms and Facts

(Questions on p. 332.)

1. F **2.** F **3.** F **4.** F **5.** T **6.** F **7.** heart, blood vessels, blood **8.** endothelium, myocardium, epicardium **9.** intercalated discs, desmosomes, gap junctions **10.** 80% **11.** adenosine **12.** d **13.** e **14.** 1.e, 2.a, 3.d, 4.b, 5.f, 6.c **15.** AV, systole, semilunar, diastole **16.** 1.b, 2.c, 3.a, 4.b, 5.a, 6.b, 7.b, 8.c, 9.c, 10.a, 11.b, 12.c

Solving Quantitative Exercises

(Questions on p. 333.)

1. CO = HR × SV

40 liters/min = HR × 0.07 liter
HR = (40 liters/min)/(0.07 liter) = 571 beats/min

This rate is not physiologically possible.

2. ESV = EDV − SV
= 125 mL − 85 mL
= 40 mL

3. Ejection fraction = SV/EDV
  a. Ejection fraction = 70/135 = 52%
  b. Ejection fraction = 100/135 = 74%
  c. Ejection fraction = 140/175 = 80%

Applying Clinical Reasoning

(Questions on p. 333.)

The most likely diagnosis is atrial fibrillation. This condition is characterized by rapid, irregular, uncoordinated depolarizations of the atria. Many of these depolarizations reach the AV node at a time when it is not in its refractory period, thus bringing about frequent ventricular depolarizations and a rapid heartbeat. However, because impulses reach the AV node erratically, the ventricular rhythm and thus the heartbeat are also very irregular as well as being rapid.

Ventricular filling is only slightly reduced despite the fact that the fibrillating atria are unable to pump blood because most ventricular filling occurs during diastole before atrial contraction. Because of the erratic heartbeat, variable lengths of time are available between ventricular beats for ventricular filling. However, most ventricular filling occurs early in ventricular diastole after the AV valves first open, so even though the filling period may be shortened, the extent of filling may be near normal. Only when the ventricular filling period is very short is ventricular filling substantially reduced.

Cardiac output, which depends on stroke volume and heart rate, usually is not seriously impaired with atrial fibrillation. Because ventricular filling is only slightly reduced during most cardiac cycles, stroke volume, as determined by the Frank–Starling mechanism, is likewise only slightly reduced. Only when the ventricular filling period is very short and the cardiac muscle fibers are operating on the lower end of their length–tension curve is the resultant ventricular contraction weak. When the ventricular contraction becomes too weak, the ventricles eject a small or no stroke volume. During most cardiac cycles, however, the slight reduction in stroke volume is often offset by the increased heart rate so that cardiac output is usually near normal. Furthermore, if the mean arterial blood pressure falls because the cardiac output does decrease, increased sympathetic stimulation of the heart brought about by the baroreceptor reflex helps restore cardiac output to normal by shifting the Frank–Starling curve to the left.

On those cycles when ventricular contractions are too weak to eject enough blood to produce a palpable wrist pulse, if the heart rate is determined directly, either by the apex beat or via the ECG, and the pulse rate is taken concurrently at the wrist, the heart rate exceeds the pulse rate, producing a pulse deficit.

Thinking at a Higher Level

(Questions on p. 333.)

1. Because, at a given heart rate, the interval between a premature beat and the next normal beat is longer than the interval between two normal beats, the heart fills for a longer period of time following a premature beat before the next period of contraction and emptying begins. Because of the longer filling time, the end-diastolic volume is larger, and, according to the Frank–Starling law of the heart, the subsequent stroke volume is also correspondingly larger.

2. Trained athletes' hearts are stronger and can pump blood more efficiently so that the resting stroke volume is larger than in an untrained person. For example, if the resting stroke volume of a strong-hearted athlete is 100 mL, a resting heart rate of only 50 beats/minute produces a normal resting cardiac output of 5000 mL/minute. An untrained individual with a resting stroke volume of 70 mL, in contrast, must have a heart rate of about 70 beats/minute to produce a comparable resting cardiac output.

3. The direction of flow through a patent ductus arteriosus is the reverse of the flow that occurs through this vascular connection during fetal life. With a patent ductus arteriosus, some of the blood present in the aorta is shunted into the pulmonary artery because, after birth, the aortic pressure is greater than the pulmonary artery pressure. This abnormal blood flow produces a "machinery murmur," which lasts throughout the cardiac cycle but is more intense during systole and less intense during diastole. Thus, the murmur waxes and wanes with each beat of the heart, sounding somewhat like a washing machine as the agitator rotates back and forth. The murmur is present throughout the cardiac cycle because a pressure differential between the aorta and pulmonary artery is present during both systole and diastole. The murmur is more intense during systole because more blood is diverted through the patent ductus arteriosus as a result of the greater pressure differential between the aorta and pulmonary artery during ventricular systole than during ventricular diastole. Typically, the systolic aortic pressure is 120 mm Hg, and the systolic pulmonary arterial pressure is 24 mm Hg, for a pressure differential of 96 mm Hg. By contrast, the diastolic aortic pressure is normally 80 mm Hg, and the diastolic pulmonary arterial pressure is 8 mm Hg, for a pressure differential of 72 mm Hg.

4. In left bundle-branch block, the right ventricle becomes completely depolarized more rapidly than the left ventricle. As a result, the right ventricle contracts before the left ventricle, and the right AV valve is forced closed before closure of the left AV valve. Because the two AV valves do not close in unison, the first heart sound is "split"—that is, two distinct sounds in close succession can be detected as closure of the left valve lags behind closure of the right valve.

5. Lub-whistle-dup-swish-lub-whistle-dup-swish, and so on

Chapter 10 The Blood Vessels and Blood Pressure

Check Your Understanding

10.1 (Questions on p. 339.)

1. digestive tract, kidneys, and skin

2. $F = \Delta P/R$

   $R \propto 1/r^4$

3. *arteries* (passageway from heart to organs, serve as pressure reservoir); *arterioles* (primary resistance vessels, determine distribution of cardiac output); *capillaries* (site of exchange, determine distribution of ECF between plasma and interstitial fluid); and *veins* (passageway to heart from organs, serve as blood reservoir); microcirculation = arterioles, capillaries, and venules

10.2 (Questions on p. 343.)

1. an abundance of elastin fibers that allow the arteries to stretch to accommodate the extra volume of blood pumped into them during systole, then to recoil and drive the extra blood forward into the remaining vasculature during diastole

2. See Figure 10-7a, p. 342.

3. 105 mm Hg

10.3 (Questions on p. 350.)

1. See Figure 10-9, p. 344.

2. See Figure 10-11a, p. 347. *Active hyperemia* refers to the local increase in blood flow to an organ to meet increased local needs when the organ is more active metabolically. More active cells need more blood to bring in extra O_2 and nutrients and to remove the additional wastes they generate. Active hyperemia occurs when the endothelial cells that line the arterioles in the vicinity release nitric oxide in response to local chemical changes that occur in the more active organ (such as decreased O_2). Nitric oxide causes local arteriolar vasodilation

by relaxing the arteriolar smooth muscle, allowing more blood to flow into the organ.

    3. local arteriolar myogenic and chemical mechanisms that keep tissue blood flow fairly constant despite rather wide deviations in mean arterial driving pressure

    4. (determinants of mean arterial pressure):

Mean arterial pressure = cardiac output × total peripheral resistance

    (calculation of mean arterial pressure):

    Mean arterial pressure = diastolic pressure + 1/3 pulse pressure

10.4 (Questions on p. 360.)

    1. *Diffusion* down concentration gradients is the primary means by which individual solutes cross the capillary walls. *Bulk flow* is responsible for the distribution of ECF between the plasma and the interstitial fluid.

    2. The forces that tend to move fluid out of the capillary are capillary blood pressure (main force) and interstitial fluid–colloid osmotic pressure (if plasma proteins are abnormally present in the interstitial fluid). The forces that tend to move fluid into the capillary are plasma-colloid osmotic pressure (main force) and interstitial fluid hydrostatic pressure (minor contributor). At the arteriolar end of the capillary, the outward forces exceed the inward forces, causing ultrafiltration, but at the venular end of the capillary, the inward forces exceed the outward forces, causing reabsorption. The reason for this shift in balance is a steady decline of the outward capillary blood pressure along the capillary's length while the inward forces remain constant.

    3. When interstitial fluid enters a lymphatic vessel, it is called *lymph*.

10.5 (Questions on p. 365.)

    1. Because veins have little elastin and little inherent myogenic tone, they are highly distensible and have little elastic recoil (that is, they stretch easily and do not tend to snap back when stretched). As a result, they easily distend to accommodate an extra volume of blood with only a small increase in venous pressure.

    2. volume of blood being returned to and pumped out by the heart

    3. Sympathetically induced venous vasoconstriction, skeletal muscle pump, respiratory pump, and cardiac-suction effect all enhance venous return. Venous valves prevent blood from moving backward in the veins.

10.6 (Questions on p. 377.)

    1. See Figure 10-33b, p. 368.

    2. *Secondary hypertension* is high blood pressure that occurs secondary to another known primary problem. *Primary hypertension* is high blood pressure for which the underlying cause is unknown. *Orthostatic hypotension* results from insufficient compensatory responses to gravitational shifts in blood when a person moves from lying down to standing up. *Circulatory shock* occurs when blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained.

    3. The baroreceptors do not respond to bring blood pressure back to normal during hypertension because they adapt (are "reset") to maintain blood pressure at the new, higher level.

Figure Focus

FIGURE 10-3 (P. 338): Because $F = \Delta P/R$ and $R \propto 1/r^A$, F in vessel 3 is 2 times that in vessel 2 and 32 times that in vessel 1, and F in vessel 4 is 16 times that in vessel 2 and 256 times that in vessel 1.

FIGURE 10-7 (P. 342): (1) 125 mm Hg, (2) 77 mm Hg, (3) 48 mm Hg, (4) 93 mm Hg, (5) no, (6) yes, (7) no

FIGURE 10-11 (P. 347): *Triggering cause:* (a) ↑ local metabolic activity, (b) occlusion of local blood supply, (c) ↓ mean arterial (driving) pressure. *Local mediators*: (a) and (b) vasodilating paracrines, (c) myogenic relaxation. *Compensatory result:* (a) ↑ O_2 delivery and CO_2 re-

moval, (b) ↑ O_2 delivery and CO_2 removal following removal of occlusion, (c) blood flow to tissue normal despite ↓ driving pressure.

FIGURE 10-20 (P. 356): ultrafiltration = 13 mm Hg, reabsorption = 7 mm Hg. The volume of the interstitial fluid would increase compared to normal, resulting in edema.

FIGURE 10-26 (P. 363): (c), (a), (b), (d)

FIGURE 10-29 (P. 366): ↓ RAAS activity → ↓ salt and water conservation → ↓ blood volume → ↓ venous return → ↓ stroke volume → ↓ cardiac output → ↓ mean arterial pressure. Also, ↓ angiotensin II → ↓ extrinsic vasoconstrictor effect → ↑ arteriolar radius → ↓ total peripheral resistance → ↓ mean arterial pressure.

FIGURE 10-35 (P. 376): A compensatory ↑ cardiac output (CO) in response to hemorrhage is brought about by ↑ heart rate (HR), ↑ stroke volume (SV), and ↑ plasma volume. (1) HR increases as a result of (a) ↑ sympathetic and (b) ↓ parasympathetic activity to the heart. (2) SV increases in two ways: (a) ↑ sympathetic activity to the heart → ↑ contractility of the heart → ↑ SV, and (b) ↑ sympathetic activity to the veins → venous vasoconstriction → ↑ venous return → ↑ SV. (3) Plasma volume increases by three means: (a) ↑ sympathetic activity to the arterioles → arteriolar vasoconstriction → ↓ renal blood flow → ↓ urine output → plasma volume conserved, (b) fluid shift from interstitial fluid into plasma across capillaries → ↑ plasma volume, and (c) ↑ thirst → ↑ plasma volume.

Reviewing Terms and Facts

(Questions on p. 377.)

    1. T **2.** F **3.** T **4.** T **5.** F **6.** T **7.** resistance **8.** autoregulation **9.** flow rate, velocity of flow **10.** vasoconstriction, vasodilation **11.** a, c, d, e, f **12.** 1.a, 2.a, 3.b, 4.a, 5.b, 6.a

Solving Quantitative Exercises

(Questions on p. 378.)

    1. (120 mm Hg)/(30 L/min) = 4 PRU

    2. a. 90 mm Hg + (180 mm Hg − 90 mm Hg)/3 = 120 mm Hg

    b. Because the other forces acting across the capillary wall, such as plasma-colloid osmotic pressure, typically do not change with age, one would suspect fluid loss from the capillaries into the tissues as a result of the increase in capillary blood pressure.

    3. systemic: (95 mm Hg)/(19 PRU) = 95 mm Hg/(19 mm Hg/liters/min) = 5 L/min

    pulmonary: (20 mm Hg)/(4 PRU) = 5 L/min

    4. e

Applying Clinical Reasoning

(Question on p. 379.)

    The abnormally elevated levels of epinephrine found with a *pheochromocytoma* bring about secondary hypertension by (1) increasing the heart rate; (2) increasing cardiac contractility, which increases stroke volume; (3) causing venous vasoconstriction, which increases venous return and subsequently stroke volume by means of the Frank–Starling mechanism; and (4) causing arteriolar vasoconstriction, which increases total peripheral resistance. Increased heart rate and stroke volume both lead to increased cardiac output. Increased cardiac output and increased total peripheral resistance both lead to increased arterial blood pressure.

Thinking at a Higher Level

(Questions on p. 379.)

    1. An elastic support stocking increases external pressure on the remaining veins in the limb to produce a favorable pressure gradient

that promotes venous return to the heart and minimizes swelling that would result from fluid retention in the extremity.

2. The classmate has apparently fainted because of insufficient blood flow to the brain as a result of pooling of blood in the lower extremities brought about by standing still for a prolonged time. When the person faints and assumes a horizontal position, the pooled blood quickly returns to the heart, improving cardiac output and blood flow to his brain. Trying to get the person up would be counterproductive, so the classmate trying to get him up should be advised to let him remain lying down until he recovers on his own.

3. The drug is apparently causing the arteriolar smooth muscle to relax by causing the release of a local vasoactive chemical mediator from the endothelial cells that induces relaxation of the underlying smooth muscle.

4. Decreased synthesis of plasma proteins as a result of insufficient dietary protein intake reduces the plasma-colloid osmotic pressure, leading to increased ultrafiltration and decreased reabsorption across the capillaries. Accumulation in the abdominal cavity of the resultant excess fluid that exits the capillaries is responsible for the markedly distended abdomen in *kwashiorkor*.

5. When sitting relatively immobile for a prolonged period in cramped seating during an airplane flight, blood tends to pool in the deep veins of the legs, leading to an increased risk of *deep venous thrombosis (DVT)* because blood clots tend to form in pooled blood that moves through the veins slowly. To reduce your risk of developing a DVT during a long flight, exercise your leg muscles while seated (for example, lifting your bended legs up and down, pushing the floor with the balls of your feet, stretching your legs out beneath the seat in front of you), getting up and walking in the aisle when allowed to do so, and staying hydrated (to maintain adequate circulating blood volume).

Chapter 11 The Blood

Check Your Understanding

11.1 (Questions on p. 383.)
1. See Figure 11-1, p. 381.
2. The *hematocrit* is the packed cell volume in a centrifuged blood sample; it essentially represents the percentage of erythrocytes in the total blood volume.
3. Plasma proteins (1) exert an osmotic effect important in the distribution of ECF between the vascular and interstitial compartments, (2) buffer pH changes, (3) transport many substances that are poorly soluble in plasma, (4) include clotting factors, (5) include inactive precursor molecules, and (6) include antibodies.

11.2 (Questions on p. 392.)
1. Four anatomic features of erythrocytes contribute to the efficiency with which they transport O_2. (1) Most importantly, they are stuffed full of O_2-carrying hemoglobin, with 98.5% of the O_2 in the blood being bound to hemoglobin. (2) Their unique biconcave shape provides a larger surface area for diffusion of O_2 across the membrane than a spherical cell of the same volume would. (3) Their thinness enables O_2 to diffuse rapidly from the exterior to the innermost regions of the cell. (4) Their membrane flexibility enables them to deform so that they can squeeze through capillaries less than half their diameter on their O_2 delivery route.
2. O_2, CO_2, H^+, CO, and NO
3. *Erythropoietin,* which the kidneys secrete into the blood in response to reduced O_2 delivery, stimulates increased erythrocyte production by the red bone marrow.

11.3 (Questions on p. 394.)
1. *Immunity* is the body's ability to resist or eliminate potentially harmful foreign material or abnormal cells. The *immune system* de-

fends against disease-producing microorganisms, paves the way for tissue repair by removing worn-out cells and tissue debris, and defends against cancer cells that arise.
2. See Figure 11-8, p. 393.
3. *Neutrophils* are phagocytic specialists, act like suicide bombers by releasing neutrophil extracellular traps (NETs) during a unique type of programmed cell death, are the first defenders on the scene of bacterial invasion, and are important in inflammatory responses. *Eosinophils* are important in allergic reactions and attack parasitic worms. *Basophils* release histamine that is important in allergic reactions and heparin that speeds up removal of fat particles from the blood. *Monocytes* leave the blood and set up residence in tissues throughout the body, where they mature into large tissue phagocytes known as macrophages. *B lymphocytes* produce antibodies. *T lymphocytes* accomplish cell-mediated immunity by releasing chemicals that punch holes in virally invaded body cells and in cancer cells.

11.4 (Questions on p. 400.)
1. The plasma protein von Willebrand factor (vWF) adheres to exposed collagen at a vessel defect. Circulating platelets attach to binding sites on vWF. Collagen activates the bound platelets, which release ADP that causes passing-by platelets to become sticky and pile on top of the growing *platelet plug* at the defect site in a positive-feedback fashion.
2. See Figure 11-13, p. 398.
3. The same factor (factor XII, Hageman factor) that activates the fast cascade of reactions that leads to clot formation also activates a fast cascade that leads to plasmin activation. Activated plasmin, a fibrinolytic enzyme, is trapped in the clot, which it later dissolves by slowly breaking down the clot's fibrin meshwork.

Figure Focus

FIGURE 11-1 (P. 381): 63%, below normal

FIGURE 11-4 (P. 385): The rate of erythropoiesis would be decreased because of the failing kidneys' reduced ability to secrete erythropoietin.

FIGURE 11-7 (P. 389): (1) A transfusion reaction would occur. The type B donor red blood cells would be attacked by the anti-B antibodies in the recipient's plasma, leading to agglutination or hemolysis of the donor cells. (2) Nothing would happen to the type O donor red blood cells because type O cells bear no antigens and therefore would not be attacked by the anti-A antibodies in the type B recipient's plasma.

FIGURE 11-9 (P. 394): platelets, basophils, eosinophils, neutrophils, erythrocytes, and monocytes

FIGURE 11-13 (P. 398): (1) by a cascade of reactions initiated by activation of factor XII (Hageman factor) on exposure to collagen in a damaged vessel or to a foreign surface (intrinsic pathway) or (2) by tissue thromboplastin released from damaged tissue (extrinsic pathway)

Reviewing Terms and Facts

(Questions on p. 401.)
1. T **2.** F **3.** T **4.** T **5.** F **6.** lymphocytes **7.** liver **8.** d **9.** a **10.** 1.c, 2.f, 3.b, 4.a, 5.g, 6.d, 7.h, 8.e, 9.f **11.** 1.e, 2.c, 3.b, 4.d, 5.g, 6.f, 7.a, 8.h

Solving Quantitative Exercises

(Questions on p. 402.)
1. a. $(15\ g)/(100\ mL) = (150\ g/L)$

$(150\ g/L) \times (1\ mole/66 \times 10^3\ g) = 2.27\ mM$

b. $(2.27\ mM) \times (4\ O_2/Hb) = 9.09\ mM$

c. $(9.09 \times 10^{-3}\ moles\ O_2/L\ blood) \times$
$(22.4\ liters\ O_2/1\ mole\ O_2) = 204\ mL\ O_2/L\ blood$

2. Normal blood contains 5×10^9 RBCs/mL.

Normal blood volume is 5 liters.

Thus, a normal person has $(5 \times 10^9$ RBCs/mL$) \times (5000$ mL$) = 25 \times 10^{12}$ RBCs.

The normal hematocrit (Hct) is 45%, whereas the anemic has a Hct of 30%. This represents a loss of 1/3 of the RBCs, that is, 8.3×10^{12} RBCs. If RBCs are produced at a rate of 3×10^6 RBCs/sec, then the time to reestablish the Hct is 8.3×10^{12} RBCs/(3×10^6 RBCs/sec) $= 2.77 \times 10^6$ sec $= 32$ days.

Thus, it takes about a month to replace a hemorrhagic loss of RBCs of this magnitude.

3. $v = 1.5 \times \exp(2h)$; calculate v for $h = 0.4$ and $h = 0.7$.

When $h = 0.4$, $v = 1.5 \times \exp(0.8) = 3.3$.

When $h = 0.7$, $v = 1.5 \times \exp(1.4) = 6.1$.

$6.1/3.3 = 1.85$, that is, an 85% increase in viscosity. Because resistance is directly proportional to viscosity, the resistance also increases by 85%.

Applying Clinical Reasoning

(Questions on p. 402.)

1. Heather's firstborn Rh-positive child did not have hemolytic disease of the newborn because the fetal and maternal blood did not mix during gestation. Consequently, Heather did not produce any maternal antibodies against the fetus's Rh factor during gestation.

2. Because a small amount of the infant's blood likely entered the maternal circulation during the birthing process, Heather would produce antibodies against the Rh factor as she was first exposed to it at that time. During any subsequent pregnancies with Rh-positive fetuses, Heather's maternal antibodies against the Rh factor could cross the placental barrier and bring about destruction of fetal erythrocytes.

3. If any Rh factor that accidentally mixed with the maternal blood during the birthing process were immediately tied up by Rh immunoglobulin administered to the mother, the Rh factor would not be available to induce maternal antibody production. Thus, no anti-Rh antibodies would be present in the maternal blood to threaten the RBCs of an Rh-positive fetus in a subsequent pregnancy. (The exogenously administered Rh immunoglobulin, being a passive form of immunity, is short-lived. In contrast, the active immunity that would result if Heather were exposed to Rh factor would be long-lived.)

4. Rh immunoglobulin must be administered following the birth of every Rh-positive child Heather bears to sop up any Rh factor before it can induce antibody production. Once an immune attack against Rh factor is launched, subsequent treatment with Rh immunoglobulin does not reverse the situation. Thus, if Heather were not treated with Rh immunoglobulin following the birth of a first Rh-positive child, and a second Rh-positive child developed hemolytic disease of the newborn, administration of Rh immunoglobulin following the second birth would not prevent the condition in a third Rh-positive child. Nothing could be done to eliminate the long-lived maternal antibodies already present.

Thinking at a Higher Level

(Questions on p. 402.)

1. No. You cannot conclude that a person with a hematocrit of 62 definitely has polycythemia. With 62% of the whole-blood sample consisting of erythrocytes (normal being 45%), the number of erythrocytes compared to the plasma volume is definitely elevated. However, the person *may* have polycythemia, in which the number of erythrocytes is abnormally high, or may be dehydrated, in which case a normal number of erythrocytes is concentrated in a smaller-than-normal plasma volume.

2. If the genes that direct fetal hemoglobin F synthesis could be reactivated in a patient with sickle cell anemia, a portion of the abnormal hemoglobin S that causes the erythrocytes to warp into defective sickle-shaped cells would be replaced by "healthy" hemoglobin F, thus sparing a portion of the RBCs from premature rupture. Hemoglobin F would not completely replace hemoglobin S because the gene for synthesis of hemoglobin S would still be active.

3. A person with type A positive blood could safely receive a transfusion of type A positive, type A negative, type O positive, or type O negative blood (considering the ABO and Rh blood systems).

4. Most heart-attack deaths are attributable to the formation of abnormal clots that prevent normal blood flow. The sought-after chemicals in the "saliva" of bloodsucking creatures are agents that break up or prevent the formation of these abnormal clots.

Although genetically engineered tissue–plasminogen activator (tPA) is already being used as a clot-busting drug, this agent brings about degradation of fibrinogen as well as fibrin. Thus, even though the life-threatening clot in the coronary circulation is dissolved, the fibrinogen supplies in the blood are depleted for up to 24 hours until the liver synthesizes new fibrinogen. If the patient sustains a ruptured vessel in the interim, insufficient fibrinogen might be available to form a blood-staunching clot. For example, many patients treated with tPA suffer hemorrhagic strokes within 24 hours of treatment due to incomplete sealing of a ruptured cerebral vessel. Therefore, scientists are searching for better alternatives to combat abnormal clot formation by examining the naturally occurring chemicals produced by bloodsucking creatures that permit them to suck a victim's blood without the blood clotting.

5. When considering the symptoms of porphyria, one could imagine how tales of vampires—blood-craving, hairy, fanged, monstrous-looking creatures who roamed in the dark and were warded off by garlic—might easily have evolved from people's encounters with victims of this condition. This possibility is especially likely when considering how stories are embellished and distorted as word of mouth passes them along.

Chapter 12 Body Defenses

Check Your Understanding

12.1 (Questions on p. 407.)

1. *Immunity* is the body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells.

2. *Innate immune responses* are inherent defense mechanisms that nonselectively defend against foreign or abnormal material of any type, even on initial exposure to it. *Adaptive immune responses* are selectively targeted against a particular foreign material to which the body has already been exposed and has had an opportunity to prepare for an attack aimed discriminatingly at the enemy.

3. *TLRs, RLRs,* and *NLRs* are a trio of pattern recognition receptors that recognize unique, telltale patterns characteristic of particular pathogens or other targets of the innate immune system. TLRs (toll-like receptors) function at the surface of phagocytes to recognize *PAMPs* (pathogen-associated molecular patterns) and *DAMPs* (damage-associated molecular patterns), in response to which the phagocyte engulfs the pathogen or damaged cell and secretes chemicals that enhance inflammation. Similarly, RLRs and NLRs are pattern recognition receptors located inside cells that recognize viral nucleic acid and intracellular PAMPs, respectively, leading to responses appropriate for the invader recognized.

12.2 (Questions on p. 415.)

1. (1) *Inflammation* is a nonspecific response to foreign invasion or tissue damage mediated largely by phagocytes and macrophages

that destroy or incapacitate the invaders, remove debris, and prepare for subsequent healing and repair. (2) *Interferon* is released by virally invaded cells and nonspecifically, transiently interferes with replication of the same or unrelated viruses in other host cells. (3) *Natural killer cells* nonspecifically destroy virally invaded cells and cancer cells by releasing chemicals that directly lyse these cells on first exposure to them. (4) The *complement system* is a group of inactive plasma proteins that, when sequentially activated, destroy foreign cells by forming holes in their plasma membranes.

2. *Chemotaxins* are chemical mediators that attract phagocytic cells to a site of tissue damage or invasion by microorganisms. *Opsonins* are chemical mediators that enhance phagocytosis by linking a bacterium to a phagocyte.

3. When the complement cascade is activated by exposure to microorganism-specific carbohydrates or to antibodies produced against the microorganism, the final five complement components assemble into a large, doughnut-shaped protein complex, the *membrane attack complex,* which embeds itself in the surface membrane of the nearby microorganisms. This hole-punching lets water leak into the victim cell, causing it to swell and burst.

12.3 (Questions on p. 416.)

1. *antibody mediated immunity* accomplished by B lymphocytes and *cell-mediated* immunity accomplished by T lymphocytes

2. An *antigen* is a large, foreign, unique molecule that triggers a specific immune response against itself.

12.4 (Questions on p. 422.)

1. An *antibody* is Y-shaped. The *Fab* regions on the tip of each arm are variable among antibodies and determine with which specific antigen the antibody can bind lock-and-key fashion. The *Fc* tail region, which is constant for a given antibody class, binds with a particular antibody mediator, thereby determining what the antibody does once it binds with antigen.

2. neutralization of bacterial toxins, agglutination, activation of the complement system, enhancement of phagocytosis by acting as opsonins, and stimulation of natural killer cells

3. See Figure 12-12, p. 420.

12.5 (Questions on p. 435.)

1. *Cytotoxic,* or *killer, T cells* destroy virus-invaded host cells and cancer cells by secreting (1) perforin, which forms hole-punching complexes in the victim cell; or (2) granzymes, which trigger the victim cell to self-destruct through apoptosis. *Helper T cells* secrete cytokines that amplify the activities of other immune cells. *Regulatory T cells* suppress immune responses; they inhibit both innate and adaptive immune responses in check-and-balance fashion to minimize harmful immune pathology.

2. *Antigen-presenting cells* process and present antigen, complexed with MHC molecules (self-antigens), on their surface to T cells. T cells cannot interact with antigen without this "formal introduction."

3. clonal deletion, clonal anergy, active suppression by regulatory T cells, receptor editing, and immunological tolerance

4. In the process of *immune surveillance,* natural killer cells, cytotoxic T cells, macrophages, and the interferon they collectively secrete normally eradicate newly arisen cancer cells before they have a chance to multiply and spread.

12.6 (Questions on p. 438.)

1. autoimmune responses, immune complex diseases, and allergies

2. See Table 12-5, p. 439.

3. In contrast to *IgG antibodies,* which freely circulate and immediately amplify innate defense mechanisms on binding with their specific antigen, *IgE antibodies* specific for different antigens attach by their tail portions to mast cells and basophils in the absence of antigen. Binding of an appropriate antigen triggers the rupture of the cell's granules, which contain histamine and other inflammatory chemical mediators that spew forth into the surrounding tissue, where they cause the allergic response.

12.7 (Questions on p. 442.)

1. The skin consists of an outer epidermis and inner dermis. The *epidermis* has an inner layer of living cube-shaped cells and an outer keratinized layer of dead, flattened cells. The epidermis has no direct blood supply, instead getting its nourishment from the underlying *dermis*, a connective tissue layer that has an abundance of blood vessels. The skin is anchored to muscle or bone by the *hypodermis*, a layer of loose connective tissue that often contains an abundance of fat cells, in which case it is called *adipose tissue*.

2. (1) *Melanocytes* produce the pigment melanin, which is responsible for different skin colors. (2) *Keratinocytes* produce keratin, which gives rise to the outer protective keratinized layer of the epidermis. (3) *Langerhans cells* present antigen to helper T cells. (4) *Granstein cells* are immune-suppressive cells.

3. The *mucus escalator* refers to the cilia lining the respiratory airways constantly beating to move up and out the bacteria- and dust-laden mucus coating the airway interior.

Figure Focus

FIGURE 12-2 (P. 408): (1) activated resident macrophages; (2) by squeezing out amoeboid fashion between adjacent endothelial cells, a process called *diapedesis*

FIGURE 12-3 (P. 409): *Histamine* promotes (1) local arteriolar vasodilation, which brings about increased blood delivery to the injured tissue, and (2) increased local capillary permeability, which leads to local accumulation of fluid. Collectively, the extra blood and associated inflammatory mediators in the vicinity give rise to the undesirable gross manifestations of *inflammation*—swelling, redness, heat, and pain—as well as to unpleasant systemic responses such as fever. The desirable outcome is designated by the box "Defense against foreign invader; tissue repair."

FIGURE 12-5 (P. 413): *Interferon* released by virally invaded cells binds with all uninvaded cells and causes them to produce inactive enzymes capable of breaking down viral messenger RNA and of inhibiting virally directed protein synthesis. These viral-blocking enzymes are activated if these forewarned cells are invaded by any virus.

FIGURE 12-11 (P. 419): by (1) activating the complement system, which can destroy the bacteria via membrane attack complexes; (2) serving as opsonins to enhance phagocytosis; and (3) stimulating natural killer cells, which release chemicals that destroy the bacteria

FIGURE 12-15 (P. 425): The *membrane attack complex* is a porelike channel formed in victim cells by activated complement proteins C5 through C9. The resulting osmotic flux of water into the cell causes it to rupture. Perforin molecules released by a killer cell on binding with a target cell form similar lethal pores in the victim cell.

FIGURE 12-20 (PP. 430-431): *Helper T cells* bind (1) with an *APC,* which processes and presents the antigen to helper T cells with matching TCRs and secretes cytokines that activate these T cells, and (2) with *B cells* that have internalized and display the same antigen, whereupon the helper T cells secrete cytokines that stimulate B cell proliferation to produce a clone of these selected effector cells.

FIGURE 12-24 (P. 439): Only the *dermis* is supplied by blood. The epidermis, which has no direct blood supply, is nourished by diffusion of nutrients from the underlying dermis. As newly forming cells in the inner layer of the epidermis push the older cells in its outer layer farther from their nutrient supply, these older cells die and become the outermost keratinized layer of the skin.

Reviewing Terms and Facts

(Questions on p. 442.)

1. Solving Quantitative Exercises

(Question on p. 444.)

1. *NEP* = net outward pressure − net inward pressure

$$NEP = (P_C + \pi_{IF}) - (P_{IF} + \pi_P)$$

Note for this problem, $(P_{IF} + \pi_P) = (25 \text{ mm Hg} + 1 \text{ mm Hg}) = 26 \text{ mm Hg}$, is constant for all cases.

Normal ($\pi_{IF} = 0$ mm Hg)

Arteriolar end NEP	(37 + 0) − 26 = +11 mm Hg
Venular end NEP	(17 + 0) − 26 = −9 mm Hg
Average NEP	(+11 − 9)/2 = +1 mm Hg (outward)

a. ($\pi_{IF} = 5$ mm Hg)

Arteriolar end NEP	(37 + 5) − 26 = +16 mm Hg
Venular end NEP	(17 + 5) − 26 = −4 mm Hg
Average NEP	(+16 − 4)/2 = +6 mm Hg (outward)
Condition	mild edema

b. ($\pi_{IF} = 10$ mm Hg)

Arteriolar end NEP	(37 + 10) − 26 = +21 mm Hg
Venular end NEP	(17 + 10) − 26 = +1 mm Hg
Average NEP	(+21 + 1)/2 = +11 mm Hg (outward)
Condition	Extreme edema

Applying Clinical Reasoning

(Questions on p. 444.)

If offending allergens bind with IgG antibodies instead of IgE antibodies, no allergy symptoms result because IgG antibodies do not attach to mast cells and basophils like IgE antibodies do.

Thinking at a Higher Level

(Questions on p. 444.)

1. See Table 12-3, p. 430 for a summary of immune responses to bacterial invasion and Table 12-2, p. 426 for a summary of defenses against viral invasion.

2. A vaccine against a particular microbe can be effective only if it induces formation of antibodies or activated T cells against a stable antigen that is present on all microbes of this type. It has not been possible to produce a vaccine against HIV because it frequently mutates. Specific immune responses induced by vaccination against one form of HIV may prove to be ineffective against a slightly modified version of the virus.

3. Failure of the thymus to develop would lead to an absence of T lymphocytes and no cell-mediated immunity after birth. This outcome would seriously compromise the individual's ability to defend against viral invasion and cancer.

4. Researchers are working on ways to "teach" the immune system to view foreign tissue as "self" as a means of preventing the immune

systems of organ-transplant patients from rejecting the foreign tissue while leaving the patients' immune defense capabilities fully intact. The immunosuppressive drugs now used to prevent transplant rejection cripple the recipients' immune defense systems and leave the patients more vulnerable to microbial invasion.

5. The skin cells visible on the body's surface are all dead.

Chapter 13 The Respiratory System

Check Your Understanding

13.1 (Questions on p. 450.)

1. (1) ventilation or gas exchange between the atmosphere and alveoli in the lungs, (2) exchange of O_2 and CO_2 between air in the alveoli and blood in the pulmonary capillaries, (3) transport of O_2 and CO_2 in the blood between the lungs and the tissues, and (4) exchange of O_2 and CO_2 between the blood in the systemic capillaries and the tissue cells. The respiratory system is involved in steps 1 and 2; the circulatory system is involved in steps 2, 3, and 4.

2. Only 0.5 µm separates the air in the alveoli from the blood in the pulmonary capillaries, and the alveolar air–blood interface presents a tremendous surface area (75 m^2) for exchange. The thinness and extensive surface area of the alveolar membrane facilitate gas exchange because the rate of diffusion is inversely proportional to the thickness and directly proportional to the surface area of this interface.

3. *Type I alveolar cells* form the walls of the alveoli, *Type II alveolar cells* secrete pulmonary surfactant, and wandering *alveolar macrophages* are phagocytic specialists that scavenge within the lumen of the alveoli.

13.2 (Questions on p. 465.)

1. During *normal quiet breathing*, the diaphragm and external intercostal muscles contract during inspiration, expanding the chest wall and thoracic cavity. The lungs passively follow along, with the intra-alveolar pressure dropping from 760 to 759 mm Hg as the lungs enlarge. Air moves into the lungs down its pressure gradient from the atmosphere until the intra-alveolar pressure equilibrates with the atmospheric pressure of 760 mm Hg. When these inspiratory muscles relax, the chest and lungs passively recoil to their preinspiratory size, increasing the intra-alveolar pressure to 761 mm Hg. Air moves out of the lungs down its pressure gradient to the atmosphere as a passive expiration occurs. During *strenuous exercise*, the diaphragm and external intercostal muscles contract more vigorously and the accessory inspiratory muscles (muscles in the neck) come into play to expand the chest and lungs even more than during quiet breathing. During this forceful inspiration, the intra-alveolar pressure drops even farther, for example to 758 mm Hg, so more air flows into the lungs before equilibration with atmospheric pressure is achieved. During active, or forced, expiration, the inspiratory muscles relax and the expiratory muscles (the abdominal muscles and the internal intercostal muscles) contract to reduce the volume of the chest even more than during passive expiration, allowing the lungs to recoil to a greater extent. As a result, the intra-alveolar pressure increases even more than during quiet breathing, for example to 762 mm Hg, so more air leaves the lungs before equilibrating with atmospheric pressure.

2. *Compliance* is a measure of how much effort is required to stretch the lungs; specifically, it is a measure of the change in lung volume resulting from a given change in the transmural pressure gradient. *Elastic recoil* refers to how readily the lungs rebound after having been stretched.

3. The forces that keep the alveoli open are the transmural pressure gradient and pulmonary surfactant (which opposes alveolar surface tension), and the forces that promote alveolar collapse are elastic recoil and alveolar surface tension.

4. See Figure 13-15b, p. 461.

13.3 (Questions on p. 471.)

1. *Partial pressure* is the individual pressure exerted independently by a particular gas within a mixture of gases.

2. See Figure 13-22, p. 469.

3. See Table 13-5, p. 470.

13.4 (Questions on p. 478.)

1. See Table 13-6, p. 472.

2. See Figure 13-24, p. 473.

3. *Hypoventilation* results in accumulation of CO_2 because less CO_2 is blown off to the atmosphere than is produced. Because CO_2 generates acid, the excess H^+ leads to respiratory acidosis. *Hyperventilation* leads to a reduction in CO_2 because CO_2 is blown off more rapidly than it is produced. As a result, less H^+ is generated from CO_2 than normal, leading to respiratory alkalosis.

13.5 (Questions on p. 487.)

1. The *medullary respiratory center* is the primary respiratory control center. It contains the dorsal respiratory group (DRG) and ventral respiratory group (VRG). The *DRG* consists mostly of inspiratory neurons that alternately fire to cause inspiration and cease firing to bring about expiration during quiet breathing. The *VRG* is composed of inspiratory neurons and expiratory neurons that remain inactive during quiet breathing but are called into play by the DRG as an overdrive mechanism to cause forceful inspiration and active expiration during periods when demands for ventilation are increased. The *pneumotaxic center* in the pons helps switch off the DRG inspiratory neurons, and the *apneustic center* in the pons prevents these inspiratory neurons from being switched off, in a check-and-balance system. The *pre-Bötzinger complex* generates the basic respiratory rhythm and drives the rhythmic firing of the DRG inspiratory neurons.

2. The *peripheral chemoreceptors* are stimulated when the arterial P_{O_2} falls to the point of being life threatening (<60 mm Hg). In turn, they stimulate the medullary inspiratory neurons as an emergency mechanism to maintain ventilation during a time when such a low arterial P_{O_2} directly depresses the respiratory center. The peripheral chemoreceptors are also responsive to changes in arterial H^+ concentration and adjust ventilation accordingly to help maintain acid–base balance by altering the rate at which H^+-generating CO_2 is eliminated from the body. The peripheral chemoreceptors are weakly stimulated by increased arterial P_{CO_2}.

3. The major mechanism controlling ventilation under resting conditions is specifically aimed at regulating the brain-ECF H^+ concentration, which in turn directly reflects changes in arterial P_{CO_2} because CO_2 that enters the brain ECF generates H^+ to which the central chemoreceptors are highly responsive. The central chemoreceptors adjust ventilation accordingly to keep the brain-ECF H^+ and thus arterial P_{CO_2} normal.

Figure Focus

FIGURE 13-4 (P. 449): from alveolar air across the alveolar fluid lining, through a Type I alveolar cell forming the wall of an alveolus, through the interstitial fluid, across an endothelial cell forming the wall of a pulmonary capillary and into the blood

FIGURE 13-12 (P. 455): Airflow would double if intra-alveolar pressure falls to 758 mm Hg instead of 759 mm Hg at the same resistance because $F = \Delta P/R$.

FIGURE 13-17 (P. 463): VC is reduced in *obstructive lung disease* because the lungs cannot empty as completely as normal. Because residual volume is increased, less additional air can be inspired beyond the

tidal volume on maximal inspiratory effort before the normal total lung capacity is reached, and less air than usual can be expired on maximal expiratory effort. VC is reduced in *restrictive lung disease* because the lungs cannot expand and fill as completely as normal. Less air than usual can be inspired beyond the tidal volume on maximal inspiratory effort before the reduced total lung capacity is reached. The lungs can empty as normal on maximal expiratory effort, but not as much air is available to be expired during a VC measurement because of the reduced inspiratory capacity.

FIGURE 13-20 (P. 467): (1) bottom, (2) bottom, (3) top

FIGURE 13-21 (P. 467): $P_{O_2} = 630$ mm Hg $\times$ 0.21 $= 132$ mm Hg

FIGURE 13-24 (P. 473): (1) If P_{CO_2} declines from 100 mm Hg to 75 mm Hg, % Hb saturation decreases from 97.5% to 95%. (2) If P_{CO_2} declines from 40 mm Hg to 15 mm Hg, % Hb saturation decreases from 75% to 19%.

Solving Quantitative Exercises

(Questions on p. 489.)

For general reference for questions 1 and 2:

$$P_{AO_2} = P_{IO_2} - (V_{O_2}/V_A) \times 863 \text{ mm Hg}$$
$$P_{ACO_2} = (V_{CO_2}/V_A) \times 863 \text{ mm Hg}$$

1. $V_A = 3$ L/min
$V_{O_2} = 0.3$ L/min, RQ $= 1$, therefore $V_{CO_2} = 0.3$ L/min
$P_{ACO_2} = (0.3 \text{ L/min/3 L/min}) \times 863$ mm Hg
$\qquad = 86.3$ mm Hg

2. a. 380 mm Hg $\times$ 0.21 $= 79.8$ mm Hg
b. $P_{AO_2} = 79.8$ mm Hg $-$ (0.06) $\times$ 431.5 mm Hg
$\qquad\quad = 79.8$ mm Hg $-$ 25.8 mm Hg
$\qquad\quad = 54$ mm Hg

c. $P_{ACO_2} = (0.2 \text{ L/min/4.2 L/min}) \times 431.5$ mm Hg
$\qquad\quad\ = 20.5$ mm Hg

3. $TV = 350$ mL, BR $= 12$/min, $V_A = 0.8 \times V_E$, $DS = ?$
$V_A = BR \times (TV - DS)$
$V_E = BR \times TV$
$0.8 = V_A/V_E = [BR \times (TV - DS)]/(BR \times TV)$
$\qquad = 1 - (DS/TV)$
$0.8 = 1 - (DS/350 \text{ mL})$
$DS/350 \text{ mL} = 0.2$
$DS = 0.2(350 \text{ mL}) = 70$ mL

Applying Clinical Reasoning

(Questions on p. 489.)

Emphysema is characterized by a collapse of smaller respiratory airways and a breakdown of alveolar walls. Because of the collapse of smaller airways, airway resistance is increased with emphysema. As with other chronic obstructive pulmonary diseases, expiration is impaired to a greater extent than inspiration because airways are naturally dilated slightly more during inspiration than expiration as a result

of the greater transmural pressure gradient during inspiration. Because airway resistance is increased, a patient with emphysema must produce larger-than-normal intra-alveolar pressure changes to accomplish a normal tidal volume. Unlike quiet breathing in a normal person, the accessory inspiratory muscles (neck muscles) and the muscles of active expiration (abdominal muscles and internal intercostal muscles) must be brought into play to inspire and expire a normal tidal volume of air.

The spirogram would be characteristic of chronic obstructive pulmonary disease. Because the patient experiences more difficulty emptying the lungs than filling them, the total lung capacity would be essentially normal, but the functional residual capacity and the residual volume would be elevated as a result of the additional air trapped in the lungs following expiration. Because the residual volume is increased, the inspiratory capacity and vital capacity are reduced. Also, the FEV_1 is markedly reduced because the airflow rate is decreased by the airway obstruction. The FEV_1–to–vital capacity ratio is much lower than the normal 80%.

Because of the reduced surface area for exchange as a result of a breakdown of alveolar walls, gas exchange would be impaired. Therefore, arterial P_{CO_2} would be elevated and arterial P_{O_2} reduced compared to normal.

Ironically, administering O_2 to this patient to relieve his hypoxic condition would markedly depress his drive to breathe by elevating the arterial P_{O_2} and removing the primary driving stimulus for respiration. Because of this danger, O_2 therapy should either not be administered or administered extremely cautiously.

Thinking at a Higher Level

(Questions on p. 490.)

1. Total atmospheric pressure decreases with increasing altitude, yet the percentage of O_2 in the air remains the same. At an altitude of 30,000 feet, the atmospheric pressure is only 226 mm Hg. Because 21% of atmospheric air consists of O_2, the P_{O_2} of inspired air at 30,000 feet is only 47.5 mm Hg, and alveolar P_{O_2} is even lower at about 20 mm Hg. At this low P_{O_2}, hemoglobin is only about 30% saturated with O_2—much too low to sustain tissue needs for O_2.

The P_{O_2} of inspired air can be increased by two means when flying at high altitude. First, by pressurizing the plane's interior to a pressure comparable to that of atmospheric pressure at sea level, the P_{O_2} of inspired air within the plane is 21% of 760 mm Hg, or the normal 160 mm Hg. Accordingly, alveolar and arterial P_{O_2} and percent hemoglobin saturation are likewise normal. In the emergency situation of failure to maintain internal cabin pressure, breathing pure O_2 can raise the P_{O_2} considerably above that accomplished by breathing normal air. When a person is breathing pure O_2, the entire pressure of inspired air is attributable to O_2. For example, with a total atmospheric pressure of 226 mm Hg at an altitude of 30,000 feet, the P_{O_2} of inspired pure O_2 is 226 mm Hg, which is more than adequate to maintain normal arterial hemoglobin saturation.

2. (a) normal, (b) normal, (c) normal, (d) below normal, (e) below normal, (f) below normal

3. a. Hypercapnia would not accompany the hypoxia associated with cyanide poisoning. In fact, CO_2 levels decline because oxidative metabolism is blocked by the tissue poisons so that CO_2 is not being produced.

b. Hypercapnia could but may not accompany the hypoxia associated with pulmonary edema. Pulmonary diffusing capacity is reduced in pulmonary edema, but O_2 transfer suffers more than CO_2 transfer because the diffusion constant for CO_2 is 20 times that for O_2. As a result, hypoxia occurs much more readily than hypercapnia in these circumstances. Hypercapnia does occur, however, when pulmonary diffusing capacity is severely impaired.

c. Hypercapnia would accompany the hypoxia associated with restrictive lung disease because ventilation is inadequate to meet the metabolic needs for both O_2 delivery and CO_2 removal. Both O_2 and CO_2 exchange between the lungs and atmosphere are equally affected.

d. Hypercapnia would not accompany the hypoxia associated with high altitude. In fact, arterial P_{CO_2} levels actually decrease. One of the compensatory responses in acclimatization to high altitudes is reflex stimulation of ventilation as a result of the reduction in arterial P_{O_2}. This compensatory hyperventilation to obtain more O_2 blows off too much CO_2 in the process, so arterial P_{CO_2} levels decline below normal.

e. Hypercapnia would not accompany the hypoxia associated with severe anemia. Reduced O_2-carrying capacity of the blood has no influence on blood CO_2 content, so arterial P_{CO_2} levels are normal.

f. Hypercapnia would accompany the circulatory hypoxia associated with congestive heart failure. Just as the diminished blood flow fails to deliver adequate O_2 to the tissues, it also fails to remove sufficient CO_2.

g. Hypercapnia would accompany the hypoxic hypoxia associated with obstructive lung disease because ventilation would be inadequate to meet the metabolic needs for both O_2 delivery and CO_2 removal. Both O_2 and CO_2 exchange between the lungs and atmosphere would be equally affected.

4. Voluntarily hyperventilating before going underwater lowers the arterial P_{CO_2} but does not increase the O_2 content in the blood. Because the P_{CO_2} is below normal, the person can hold his or her breath longer than usual before the arterial P_{CO_2} increases to the point that he or she is driven to surface for a breath. Therefore, the person can stay underwater longer. The risk, however, is that the O_2 content of the blood, which was normal, not increased, before going underwater, continues to fall. Therefore, the O_2 level in the blood can fall dangerously low before the CO_2 level builds to the point of driving the person to take a breath. Low arterial P_{O_2} does not stimulate respiratory activity until it has plummeted to 60 mm Hg. Meanwhile, the person may lose consciousness and drown due to inadequate O_2 delivery to the brain. If the person does not hyperventilate so that both the arterial P_{CO_2} and O_2 content are normal before going underwater, the buildup of CO_2 drives the person to the surface for a breath before the O_2 levels fall to a dangerous point.

5. c. The arterial P_{O_2} is less than the alveolar P_{O_2}, and the arterial P_{CO_2} is greater than the alveolar P_{CO_2}. Because pulmonary diffusing capacity is reduced, arterial P_{O_2} and P_{CO_2} do not equilibrate with alveolar P_{O_2} and P_{CO_2}. O_2 exchange is affected to a greater extent than CO_2 exchange because of CO_2's greater diffusion constant.

If the person is administered 100% O_2, the alveolar P_{O_2} increases and the arterial P_{O_2} increases accordingly. Even though arterial P_{O_2} does not equilibrate with alveolar P_{O_2}, it is higher than when the person is breathing atmospheric air.

The arterial P_{CO_2} remains the same whether the person is administered 100% O_2 or is breathing atmospheric air. The alveolar P_{CO_2} and thus the blood-to-alveolar P_{CO_2} gradient are not changed by breathing 100% O_2 because the P_{CO_2} in atmospheric air and 100% O_2 are both essentially zero (P_{CO_2} in atmospheric air = 0.23 mm Hg).

Chapter 14 The Urinary System

Check Your Understanding

14.1 (Questions on p. 498.)

1. The functional unit of the kidney is the *nephron,* which is made up of a vascular component and a tubular component that are inti-

mately related structurally and functionally. The vascular component consists of an afferent arteriole that carries blood to the glomerulus; the glomerulus, which is a tuft of capillaries that filters a protein-free plasma into the tubular component; an efferent arteriole that carries blood from the glomerulus; and peritubular capillaries that wrap around and exchange materials with the tubular component. The tubular component begins with Bowman's capsule that cups around the glomerulus and collects the filtrate; the proximal tubule across which uncontrolled exchanges take place between the tubular fluid and peritubular capillary blood; the loop of Henle, which plays a key role in producing urine of varying concentration depending on the body's needs; and the distal tubule and collecting duct across which controlled exchanges take place between the tubular fluid and blood. The fluid exiting the collecting duct is urine.

2. See Figure 14-6, p. 497.

3. *Cortical nephrons* are the most abundant type of nephron. The *juxtamedullary nephrons* are important in establishing the medullary vertical osmotic gradient. The glomeruli of cortical nephrons lie in the outer cortex, whereas the glomeruli of juxtamedullary nephrons lie in the inner part of the cortex next to the medulla. The loops of Henle of cortical nephrons dip only slightly into the medulla, but the juxtamedullary nephrons have long loops of Henle that plunge deep into the medulla. The juxtamedullary nephrons' peritubular capillaries form hairpin loops known as vasa recta. See Figure 14-5, p. 496.

14.2 (Questions on p. 505.)

1. See Table 14-1, p. 500.

2. Mechanisms of autoregulation of the GFR: (1) a *myogenic* mechanism, which responds to changes in pressure within the nephron's vascular component; and (2) a *tubuloglomerular feedback* mechanism, which senses changes in the salt level in the fluid flowing through the nephron's tubular component. Autoregulation prevents inappropriate fluctuations in the GFR in response to changes in the mean arterial driving pressure within the range of 80 to 180 mm Hg.

3. Extrinsic control of the GFR is accomplished by sympathetic nervous system input to the afferent arterioles aimed at regulating arterial blood pressure. When arterial blood pressure falls, sympathetically induced afferent arteriolar vasoconstriction decreases glomerular capillary blood pressure, causing a decrease in GFR. The resultant reduction in urine volume conserves fluid and salt that would have been lost from the body in urine. This saved fluid helps to restore plasma volume and blood pressure to normal in the long term. The opposite compensatory effect takes place when arterial blood pressure is too high.

14.3 (Questions on p. 514.)

1. See Figure 14-14, p. 506.

2. The kidneys secrete the enzymatic hormone renin in response to reduced NaCl, ECF volume, and arterial blood pressure. Renin activates angiotensinogen, a plasma protein produced by the liver, into angiotensin I, which is converted into angiotensin II by angiotensin-converting enzyme produced in the lungs. Angiotensin II stimulates the adrenal cortex to secrete the hormone aldosterone, which stimulates Na^+ reabsorption by the kidneys. The resulting retention of Na^+ exerts an osmotic effect that holds more H_2O in the ECF. Together, the conserved Na^+ and H_2O help correct the original stimuli that activated this hormonal system.

3. (1) 250 mg/min filtered, (2) 200 mg/min reabsorbed (a T_m worth of the substance), (3) 50 mg/min excreted

14.4 (Questions on p. 517.)

1. secretion of H^+, K^+, and organic anions and cations

2. The *proximal tubule cells* actively reabsorb K^+ in constant, unregulated fashion. The *principal cells* of the distal and collecting tubules actively secrete K^+. Potassium secretion by the late tubule is varied in a controlled fashion by aldosterone to regulate the rate of K^+ excretion and maintain the desired plasma K^+ concentration.

3. The removal of foreign organic compounds from the body is hastened via secretion by the organic ion secretory systems in the proximal tubule. The liver helps rid the body of foreign compounds that are not ionic in their original form by converting these compounds into an anionic form.

14.5 (Questions on p. 532.)

1. (1) clearance rate = GFR, (2) clearance rate < GFR, (3) clearance rate > GFR

2. The juxtamedullary nephrons' long loop of Henle establishes the medullary vertical osmotic gradient, their vasa recta preserves the gradient, and the collecting ducts of all nephrons use the gradient, in conjunction with vasopressin, to produce urine of varying concentrations.

3. *Vasopressin,* which is secreted into the blood by the posterior pituitary in response to a H_2O deficit, increases the permeability of the distal and collecting tubules to H_2O. Vasopressin activates the cAMP pathway within the principal cells lining these tubules when it binds with V_2 receptors specific for it at the basolateral membrane of these cells. cAMP increases the opposite luminal membrane's permeability to H_2O by promoting the insertion of AQP-2 water channels into the membrane. Water enters the cell from the tubular lumen through the inserted water channels and exits the cell through different, permanently positioned water channels at the basolateral border to enter the blood, in this way being reabsorbed to correct the H_2O deficit.

4. The *micturition reflex* is initiated when bladder filling activates stretch receptors in the bladder wall. Afferent input from the stretch receptors, via interneurons, stimulates the parasympathetic nerve to the bladder, leading to bladder contraction and mechanical opening of the internal urethral sphincter, and simultaneously inhibits the motor neuron to the external urethral sphincter, leading to opening of this sphincter. Bladder contraction expels urine through the open sphincters to the outside.

Figure Focus

FIGURE 14-4 (P. 495): The afferent arteriole has a larger diameter than the efferent arteriole has.

FIGURE 14-6 (P. 497): Substances can *enter* the tubular fluid via glomerular filtration or tubular secretion and can leave the tubular fluid by means of tubular reabsorption or urine excretion.

FIGURE 14-16 (P. 508): When blood pressure falls as a result of excessive fluid loss via sweating, in the short term the baroreceptor reflex increases sympathetic activity to the heart and arterioles, leading respectively to increased cardiac output and increased total peripheral resistance, which together produce a compensatory increase in blood pressure. An increase in ECF volume, particularly blood volume, is important in the long term for restoring blood pressure to normal without having to sustain the adjustments in cardiac output and total peripheral resistance. Multiple pathways increase blood volume. Afferent arteriolar vasoconstriction occurring as part of the baroreceptor reflex brings about a reduction in the GFR, which leads to conservation of fluid and salt that would have been lost in the urine. More importantly, the original decrease in NaCl, ECF volume, and arterial blood pressure resulting from heavy sweating collectively trigger increased activity of the renin–angiotensin–aldosterone system, which causes increased Na^+ reabsorption, with H_2O osmotically following along. This extra fluid reabsorption expands the blood volume. Furthermore, angiotensin II activated as part of the RAAS stimulates vasopressin secretion, which leads to increased water reabsorption; promotes thirst, which leads to increased fluid intake; and also causes arteriolar vasoconstriction, which contributes to short-term compensation for the fall in blood pressure.

FIGURE 14-18 (P. 511): (1) at *200* mg/100 mL: 250 mg/min filtered, 250 mg/min reabsorbed, 0 mg/min excreted; (2) at *300* mg/100 mL: 375 mg/min filtered, 375 mg/min reabsorbed, 0 mg/min excreted; (3) at *400* mg/100 mL: 500 mg/min filtered, 375 mg/min reabsorbed, 125 mg/min excreted

FIGURE 14-20 (P. 513): In the early part of the proximal tubule, the urea concentration in the tubular fluid is the same as its concentration in the surrounding interstitial fluid and peritubular capillary blood, so no concentration gradient exists for passive diffusion of urea out of the tubule. By the late part of the proximal tubule, however, the urea concentration in the tubular fluid has increased above its concentration in the surrounding fluids as a result of extensive reabsorption of water by the proximal tubule. Therefore, urea is passively reabsorbed down this concentration gradient in the late part of the proximal tubule.

FIGURE 14-21 (P. 515): (1) This Na^+ is reabsorbed into the peritubular capillary blood. (2) This K^+ is recycled as it diffuses from the tubular cell (into which it had been pumped) back into the lateral space through K^+ leak channels located in the basolateral membrane.

FIGURE 14-27 (P. 525): (1) By blocking NaCl transport (reabsorption) by the ascending limb, *loop diuretics* prevent generation of the vertical osmotic gradient in the medullary interstitial fluid, abolishing the driving force for osmotic free water reabsorption in the collecting duct. Because the tubular fluid cannot be concentrated and water conserved, more urine than usual is formed. (2) Because of the vasopressin deficiency associated with *diabetes insipidus*, the kidneys are unable to increase the water permeability of the distal and collecting tubules sufficiently to permit free water reabsorption down the medullary vertical osmotic gradient to conserve water and concentrate urine as needed. As a result, more urine than usual is formed.

Reviewing Terms and Facts

(Questions on p. 533.)

1. F **2.** F **3.** T **4.** T **5.** T **6.** nephron **7.** potassium **8.** 500 **9.** 1.b, 2.a, 3.b, 4.b, 5.a, 6.b, 7.b, 8.b, 9.b **10.** e **11.** b **12.** b, e, a, d, c **13.** c, e, d, a, b, f **14.** g, c, d, a, f, b, e **15.** 1.a, 2.a, 3.c, 4.b, 5.d

Solving Quantitative Exercises

(Questions on p. 534.)

1.

	Patient 1	Patient 2
GFR	125 mL/min	124 mL/min
RPF	620 mL/min	400 mL/min
RBF	1127 mL/min	727 mL/min
FF	0.20	0.31

All of Patient 1's values are within the normal range. Patient 2's *GFR* is normal, but he has a low renal plasma flow and a high filtration fraction. Therefore, his *GFR* is too high for that *RPF*. This might imply enlarged filtration slits or a "leaky" glomerulus in general. The low *RPF* may imply low renal blood pressure, perhaps from a partially blocked renal artery.

2. filtered load = $GFR \times$ plasma concentration
= (0.125 L/min) $\times$ (145 mmol/L)
= 18.125 mmol/min

3. $GFR = (U \times [I]_U)/[I]_B$
$U = (GFR \times [I]_B)/[I]_U$
= (125 mL/min)(3 mg/L)/(300 mg/L)
= 1.25 mL/min

4. Clearance rate of a substance = $\dfrac{\text{urine concentration of a substance} \times \text{urine flow rate}}{\text{plasma concentration of the substance}}$

$= \dfrac{7.5 \text{ mg/mL} \times 2 \text{ mL/min}}{0.2 \text{ mg/mL}}$

= 75 mL/min

Because a clearance rate of 75 mL/min is less than the average GFR of 125 mL/min, the substance is being reabsorbed.

Applying Clinical Reasoning

(Question on p. 534.)

prostate enlargement

Thinking at a Higher Level

(Questions on p. 534.)

1. (1) Glucose in the urine is indicative of diabetes mellitus. (2) Protein in the urine is indicative of kidney disease. (3) Na^+ in the urine is normal.

2. The longer loops of Henle in desert rats (known as *kangaroo rats*) permit a greater magnitude of countercurrent multiplication and thus a larger medullary vertical osmotic gradient. As a result, these rodents can produce urine that is concentrated up to an osmolarity of almost 6000 mOsm/L, which is five times more concentrated than maximally concentrated human urine at 1200 mOsm/L. Because of this tremendous concentrating ability, kangaroo rats never have to drink; the H_2O produced metabolically within their cells during oxidation of foodstuff (food + $O_2 \rightarrow CO_2$ + H_2O + energy) is sufficient for their needs.

3. Aldosterone stimulates Na^+ reabsorption and K^+ secretion by the renal tubules. Therefore, the most prominent features of Conn's syndrome (hypersecretion of aldosterone) are hypernatremia (elevated Na^+ levels in the blood) caused by excessive Na^+ reabsorption, hypophosphatemia (below-normal K^+ levels in the blood) caused by excessive K^+ secretion, and hypertension (elevated blood pressure) caused by excessive salt and water retention.

4. e. 300/300. If the ascending limb were permeable to water, it would not be possible to establish a vertical osmotic gradient in the interstitial fluid of the renal medulla, nor would the ascending limb fluid become hypotonic before entering the distal tubule. As the ascending limb pumped NaCl into the interstitial fluid, water would osmotically follow, so both the interstitial fluid and the ascending limb would remain isotonic at 300 mOsm/L. With the tubular fluid entering the distal tubule being 300 mOsm/L instead of the normal 100 mOsm/L, it would not be possible to produce urine with an osmolarity less than 300 mOsm/L. Likewise, in the absence of the medullary vertical osmotic gradient, it would not be possible to produce urine more concentrated than 300 mOsm/L, no matter how much vasopressin was present.

5. Because the descending pathways between the brain and the motor neurons supplying the external urethral sphincter and pelvic diaphragm are no longer intact, the accident victim can no longer voluntarily control micturition. Therefore, bladder emptying in this individual is governed entirely by the micturition reflex.

Chapter 15 Fluid and Acid–Base Balance

Check Your Understanding

15.1 (Questions on p. 537.)

1. *inputs* = ingestion or metabolic production; *outputs* = excretion or metabolic consumption

2. *stable balance:* when total body input of a substance equals its total body output; *positive balance:* when the gains via input for a substance exceed its losses via output; *negative balance:* when losses for a substance exceed its gains

15.2 (Questions on p. 547.)

1. See Table 15-1, p. 537.

2. *ECF volume* is regulated by maintaining salt balance and is important to help maintain blood pressure. *ECF osmolarity* is regulated by maintaining free water balance and is important to prevent swelling or shrinking of cells.

3. Maintenance of salt balance is accomplished by controlling salt output in the urine. Salt excretion is controlled primarily by the renin–angiotensin–aldosterone system regulating the amount of Na^+ reabsorbed and to a lesser extent by the baroreceptor reflex controlling the GFR and thus of the amount of Na^+ filtered. Maintenance of water balance is accomplished primarily by controlling water output in the urine via vasopressin regulating the amount of free H_2O reabsorbed, and to a lesser extent by controlling water input via thirst.

4. When the ECF is hypertonic, water osmotically leaves the cells, causing them to shrink. When the ECF is hypotonic, water osmotically enters the cells, causing them to swell.

15.3 (Questions on p. 562.)

1. Only a narrow pH range is compatible with life because even small changes in $[H^+]$ have dramatic effects on normal cell function. Changes in $[H^+]$ (1) cause changes in excitability of nerve and muscle cells, which can lead to death by depressing the CNS in the case of severe acidosis or causing spasm of the respiratory muscles in the case of severe alkalosis; (2) alter enzyme activity, thus disturbing life-supporting metabolic activity catalyzed by these enzymes; and (3) influence $[K^+]$, which can lead to fatal cardiac abnormalities.

2. The following sources continually add H^+ to the body fluids: (1) carbonic acid formed from continuously generated CO_2; (2) inorganic acids (phosphoric and sulfuric acid) produced during the breakdown of dietary proteins that contain phosphorus and sulfur; and (3) organic acids (such as fatty acids and lactic acid) resulting from intermediary metabolism.

3. *Henderson–Hasselbalch equation:* $pH = pK + \log[HCO_3^-]/[H_2CO_3]$

Because $[HCO_3^-]$ is controlled by kidney function, and $[H_2CO_3]$, which is a reflection of $[CO_2]$, is controlled by respiratory function, pH can be shifted up or down by kidney and respiratory influences.

4. metabolic acidosis. To compensate, the ECF buffers take up extra H^+, the lungs blow off additional H^+-generating CO_2, and the kidneys excrete more H^+ and conserve more HCO_3^-.

Figure Focus

FIGURE 15-1 (P. 536): Input from the external environment via ingestion, excretion to the external environment in the urine, and storage within the body as calcium phosphate crystals, which harden bone.

FIGURE 15-3 (P. 541): Excess Na^+ is eliminated from the body by increasing urinary excretion of Na^+ by (1) increasing the GFR via the baroreceptor reflex, which increases the amount of Na^+ filtered, and (2) decreasing the amount of Na^+ reabsorbed via the renin–angiotensin–aldosterone system.

FIGURE 15-10 (P. 555): In *Type A intercalated cells*, the H^+ pumps are located at the luminal membrane where they accomplish H^+ secretion; in *Type B intercalated cells*, the H^+ pumps are located at the basolateral membrane where they accomplish H^+ reabsorption.

FIGURE 15-13 (P. 560): false. $[HCO_3^-]$ increases not only during metabolic alkalosis but also during compensation for respiratory acidosis.

Reviewing Terms and Facts

(Questions on p. 563.)

1. T **2.** F **3.** F **4.** T **5.** T **6.** intracellular fluid **7.** $[H_2CO_3]$, $[HCO_3^-]$ **8.** b **9.** a, d, e **10.** b, e **11.** c **12.** 1. metabolic acidosis, 2. diabetes mellitus, 3. pH = 7.1, 4. respiratory alkalosis, 5. anxiety, 6. pH = 7.7, 7. respiratory acidosis, 8. pneumonia, 9. pH = 7.1, 10. metabolic alkalosis, 11. vomiting, 12. pH = 7.7

Solving Quantitative Exercises

(Questions on p. 564.)

1. $pH = 6.1 + \log [HCO_3^-]/(0.03 \text{ mM/mm Hg} \times 40 \text{ mm Hg})$
$7.4 = 6.1 + \log [HCO_3^-]/1.2 \text{ mM}$
$\log [HCO_3^-]/1.2 \text{ mM} = 7.4 - 6.1 = 1.3$
$[HCO_3^-] = 1.2 \text{ mM} \times (10^{1.3}) = 24 \text{ mM}$

2. $pH = -\log [H^+]$, $[H^+] = 10^{-pH}$
$[H^+] = 10^{-6.8} = 158 \text{ nM}$ for pH = 6.8
$[H^+] = 10^{-8.0} = 10 \text{ nM}$ for pH = 8.0

3. Note that distilled water can permeate all barriers, so it distributes equally among all compartments. Because saline does not enter cells, it stays in the ECF. The resultant distributions are summarized in the chart at the bottom of the page. Clearly, saline is better at expanding the plasma volume.

Ingested Fluid	Compartment	Size of Compartment before Ingestion (liters)	Size of Compartment after Ingestion (liters)	% Increase in Size of Compartment after Ingestion
Distilled water	TBW	42	43	2%
	ICF (2/3 TBW)	28	28.667	2%
	ECF (1/3 TBW)	14	14.333	2%
	plasma (20% ECF)	2.8	2.866	2%
	ISF (80% ECF)	11.2	11.466	2%
Saline	TBW	42	43	2%
	ICF	28	28	0%
	ECF	14	15	7%
	plasma	2.8	3	7%
	ISF	11.2	12	7%

Applying Clinical Reasoning

(Questions on p. 564.)

The resultant prolonged diarrhea leads to dehydration and metabolic acidosis as a result of, respectively, excessive loss in the feces of fluid and $NaHCO_3$ that normally would have been absorbed into the blood.

Compensatory measures for dehydration have included increased vasopressin secretion, resulting in increased water reabsorption by the distal and collecting tubules and a subsequent reduction in urine output. Simultaneously, fluid intake has been encouraged by increased thirst. The metabolic acidosis has been combated by removal of excess H^+ from the ECF by the HCO_3^- member of the H_2CO_3:HCO_3^- buffer system, by increased ventilation to reduce the amount of acid-forming CO_2 in the body fluids, and by the kidneys excreting extra H^+ and conserving HCO_3^-.

Thinking at a Higher Level

(Questions on p. 564.)

1. The rate of urine formation increases when alcohol inhibits vasopressin secretion and the kidneys are unable to reabsorb water from the distal and collecting tubules. Because extra free water that normally would have been reabsorbed from the distal parts of the tubule is lost from the body in the urine, the body becomes dehydrated and the ECF osmolarity increases following alcohol consumption. That is, more fluid is lost in the urine than is consumed in the alcoholic beverage as a result of alcohol's action on vasopressin. Thus, the imbibing person experiences a water deficit and still feels thirsty, despite the recent fluid consumption.

2. If a person loses 1500 mL of salt-rich sweat and drinks 1000 mL of water without replacing the salt during the same time period, there is still a volume deficit of 500 mL, and the body fluids are hypotonic (the remaining salt in the body is diluted by the ingestion of 1000 mL of free H_2O). As a result, the hypothalamic osmoreceptors (the dominant input) signal the vasopressin-secreting cells to *decrease* vasopressin secretion and thus increase urinary excretion of the extra free water that is making the body fluids too dilute. Simultaneously, the left atrial volume receptors signal the vasopressin-secreting cells to *increase* vasopressin secretion to conserve water during urine formation and thus help relieve the volume deficit. These two conflicting inputs to the vasopressin-secreting cells are counterproductive. For this reason, it is important to replace both water and salt following heavy sweating or abnormal loss of other salt-rich fluids. If salt is replaced along with water intake, the ECF osmolarity remains close to normal and the vasopressin-secreting cells receive signals only to increase vasopressin secretion to help restore the ECF volume to normal.

3. When a dextrose solution equal in concentration to that of normal body fluids is injected intravenously, the ECF volume is expanded but the ECF and ICF are still osmotically equal. Therefore, no net movement of water occurs between the ECF and ICF. When the dextrose enters the cell and is metabolized, however, the ECF becomes hypotonic as this solute leaves the plasma. If the excess free water is not excreted in the urine rapidly enough, water moves into the cells by osmosis.

4. Because baking soda ($NaHCO_3$) is readily absorbed from the digestive tract, treatment of gastric hyperacidity with baking soda can lead to metabolic alkalosis as too much HCO_3^- is absorbed. Treatment with antacids that are poorly absorbed is safer because these products remain in the digestive tract and do not produce an acid–base imbalance.

5. c. The hemoglobin buffer system buffers CO_2-generated H^+. In the case of respiratory acidosis accompanying severe pneumonia, the $H^+ + Hb \rightarrow HHb$ reaction shifts toward the HHb side, thus removing some of the extra free H^+ from the blood.

Chapter 16 The Digestive System

Check Your Understanding

16.1 (Questions on p. 573.)

1. (1) *carbohydrates*, absorbable units = monosaccharides, principally glucose, (2) *proteins*, absorbable units = primarily amino acids and a few small polypeptides, (3) *fats*, absorbable units = monoglycerides and free fatty acids

2. See Figure 16-2, p. 571.

3. Pacemaker cells called interstitial cells of Cajal (ICC) generate slow-wave potentials that cyclically bring the membrane closer to or farther from threshold potential. Slow-wave potentials spread via gap junctions from ICCs to the surrounding smooth muscle cells, which themselves are interconnected by gap junctions into functional syncytia. If the slow waves reach threshold at the peaks of depolarization, a volley of action potentials is triggered at each peak, resulting in rhythmic cycles of contraction in the sheet of smooth muscle cells driven by the pacemaker. The slow-wave frequency varies regionally in the digestive tract. Contractions within the tract occur at the rate of slow-wave frequency within a given section of tract.

16.2 (Questions on p. 575.)

1. *mucus:* facilitates swallowing by moistening food particles to hold them together and by providing lubrication; *amylase:* begins digestion of dietary starches; *lysosyme:* exerts antibacterial actions by lysing bacteria, binding IgA antibodies, secreting lactoferrin that binds iron needed for bacterial multiplication, and rinsing away material that may serve as a food source for bacteria

2. A *simple salivary reflex* occurs when receptors in the oral cavity are activated by the presence of food in the mouth and send impulses to the salivary center to trigger salivation. A *conditioned salivary reflex* occurs without oral stimulation via inputs that arise outside the mouth (such as sight and smell of food) that act through the cerebral cortex to stimulate the salivary center.

3. *Parasympathetic stimulation* induces production of a large volume of watery saliva that is rich in enzymes. *Sympathetic stimulation* produces a small volume of thick saliva that is rich in mucus.

16.3 (Questions on p. 578.)

1. During swallowing, respiration is temporarily inhibited while the entrance to the trachea is closed off to prevent food from entering the respiratory airways. Contraction of the laryngeal muscles tightly aligns the vocal folds across the glottis. For further protection, the epiglottis folds downward over the closed glottis.

2. The *pharyngoesophageal sphincter* at the upper end of the esophagus separates the pharynx from the esophagus and prevents air from entering the esophagus and stomach during breathing. This sphincter remains tonically contracted except during a swallow, when it opens. The *gastroesophageal sphincter* at the lower end of the esophagus separates the esophagus from the stomach and prevents reflux of gastric contents into the esophagus. It relaxes during a swallow.

16.4 (Questions on p. 588.)

1. A strong peristaltic contraction in the stomach antrum pushes the luminal contents downward toward a slightly open pyloric sphincter. A small portion of the chyme is forced through the sphincter before the peristaltic wave reaches the sphincter and closes it tightly. When food that is moving forward hits the closed sphincter, it is tossed backward, only to be propelled forward again by the next peristaltic wave. This *retropulsion* (cycles of food being moved forward and backward in the antrum) shears and grinds the food into smaller pieces and thoroughly mixes it with gastric secretions, converting it into chyme before emptying.

2. *Mucous cells*: mucus; *chief cells*: pepsinogen; *parietal cells*: HCl, intrinsic factor; *ECL cells*: histamine; *G cells*: gastrin; *D cells*: somatostatin

3. The cephalic phase of gastric secretion occurs in response to food-related stimuli "in the head." Such stimuli include thinking about, tasting, smelling, seeing, chewing, and swallowing food. The response is mediated by vagal activation of the chief and parietal secretory cells (which secrete HCl and pepsinogen, respectively) and the endocrine G cells (which secrete the hormone gastrin that further stimulates the chief and parietal cells).

4. The following components of the gastric mucosal barrier enable the stomach to contain potent HCl without injuring itself: (1) The luminal membranes of the gastric mucosal cells are impermeable to H^+ so that HCl cannot penetrate into the cells, (2) tight junctions that join the cells prevent HCl from penetrating between them, (3) the surface mucous cells secrete mucus that serves as a physical barrier to acid penetration, and (4) HCO_3^- secreted with the mucus serves as a chemical barrier that neutralizes acid in the vicinity of the mucosa. Finally, the entire stomach lining undergoes significant turnover, with the cells being replaced every 3 days.

16.5 (Questions on p. 598.)

1. The *pancreatic proteolytic enzymes* (trypsinogen, chymotrypsinogen, and procarboxypeptidase), when activated, digest dietary proteins and peptide fragments to small peptide chains and amino acids. *Pancreatic amylase* converts dietary starches into the disaccharide maltose (mostly) and the polysaccharide α-limit dextrins. *Pancreatic lipase* hydrolyzes dietary triglycerides into monoglycerides and free fatty acids, the absorbable units of fat.

2. The pancreas produces proteolytic enzymes for digesting food proteins, but these enzymes could also digest the proteins of the cells that produce them if they were not stored in inactive form until they are secreted. These inactive enzymes are stored in secretory zymogen granules in the pancreatic acinar cells until appropriate stimuli induce their secretion. They are activated to protein-digesting enzymes (trypsin, chymotrypsin, and carboxypeptidase) only when they reach the duodenal lumen, where they act on food, not the pancreatic cells.

3. Bile salts contribute to dietary fat digestion by their detergent action (fat emulsification) in the small intestine. Intestinal mixing movements break up large fat globules into smaller droplets. The droplets do not recoalesce into the large globule because bile salts adsorb on the surface of the smaller droplets, creating a *lipid emulsion* consisting of many small fat droplets suspended in the watery chyme. This action increases the surface area of fat available for attack by pancreatic lipase.

16.6 (Questions on p. 610.)

1. The alternating *segmentation* contractions chop and thoroughly mix the chyme as they squeeze the small intestine contents both forward and backward to adjacent segments with each round of contraction. Segmentation also slowly propels the contents forward; because the frequency of segmentation declines along the length of the small intestine, more chyme on average is pushed forward than is pushed backward.

2. Three major structural features increase the surface area of the small intestine available for absorption: (1) Large *circular folds* on the small-intestine luminal surface increase the surface area threefold, (2) microscopic fingerlike projections known as *villi* that sit atop the circular folds increase the surface area another 10-fold, and (3) a multitude of hairlike protrusions referred to as *microvilli* or the *brush border* on each villus surface collectively increase the surface area another 20-fold. Together these three adaptations increase the absorptive surface area of the small intestine approximately 600 times greater than compared to a completely smooth tube of the same length and diameter.

3. Absorption of most dietary carbohydrate and protein is accomplished by secondary active transport that involves the cotransport of Na^+ and the nutrient molecule into the absorptive cell. Although the cotransporter does not use ATP directly, the Na^+–K^+ pump (which directly uses energy) establishes a Na^+ concentration gradient that drives the cotransporter to move Na^+ downhill and move the nutrient molecule uphill into the cell across the luminal membrane. The nutrient molecules move out of the cell into the blood across the basal membrane by facilitated diffusion, completing the absorptive process.

16.7 (Questions on p. 614.)

1. Large-intestine *haustral contractions* are very similar to small-intestine *segmentation contractions* in that both are rhythmic, autonomous, oscillating ringlike contractions initiated by pacemaker cells, but haustral contractions occur much less frequently (once every 30 minutes) than segmentation contractions (9 to 12 per minute). Haustral contractions, which are nonpropulsive, shuffle the colonic content back and forth, facilitating salt and water absorption and thereby compacting the content and forming a firm fecal mass. In contrast, segmentation in the small intestine is both a slowly propulsive and mixing movement.

2. The *NaHCO₃* produced by the *large intestine* mainly serves to protect the large intestine from acid produced during colonic fermentation by the intestinal bacteria. The primary role of *pancreatic* NaHCO₃ secreted into the duodenal lumen is to neutralize the acidic chyme that empties from the stomach, thereby protecting the small intestine from acid damage in addition to creating an alkaline environment that optimizes pancreatic digestive enzyme activity.

3. The gut *microbiota* (1) promote colon motility, (2) enhance mucosal integrity, (3) aid immune function, (4) compete with potential gut pathogens, (5) help digest food, and (6) influence the brain and behavior.

16.8 (Questions on p. 615.)

1. *Trophic hormones* induce growth of their target tissues. For example, gastrin is trophic to the gastric mucosa in addition to stimulating secretion by the parietal and chief cells. The significance is that the hormone helps maintain the gastric mucosa, despite harsh conditions, thereby maintaining the secretory capabilities of this stomach lining.

2. *secretin*: stomach smooth muscle and parietal cells (acts as an enterogastrone to inhibit gastric motility and acid secretion), pancreatic duct cells (stimulates NaHCO₃ secretion); *CCK*: stomach smooth muscle and parietal cells (acts as an enterogastrone), pancreatic acinar cells (stimulates secretion of pancreatic digestive enzymes), gallbladder (causes contraction), sphincter of Oddi (causes relaxation), and brain (signals satiety)

3. *GIP* stimulates insulin secretion in feedforward fashion.

Figure Focus

FIGURE 16-3 (P. 573): Extrinsic autonomic nerves can be activated via receptors in the digestive tract that respond to local changes in the digestive tract and by external influences arising from outside the digestive tract. Extrinsic autonomic nerves directly control smooth muscle motility, digestive exocrine gland secretion, and gastrointestinal hormone secretion and further indirectly control these effectors by acting through the intrinsic nerve plexuses and GI hormones.

FIGURE 16-4 (P. 574): Eating food increases salivary secretion via the simple salivary reflex, whereas smelling food increases salivary secretion by means of a conditioned salivary reflex.

FIGURE 16-5 (P. 577): After being pushed out of the stomach and up the esophagus into the pharynx, vomit can accidentally pass through an open glottis into the trachea (that is, be aspirated) instead of passing into the mouth and out. This can happen if a person tries to inspire while vomit is in the pharynx.

FIGURE 16-8 (P. 584): Gastric HCl secretion is reduced and the venous blood leaving the stomach is not as alkaline as normal.

FIGURE 16-12 (P. 592): The fat (especially) and protein in the bacon and eggs stimulate release of CCK. The acid in the orange juice stimulates release of secretin. Even more importantly, HCl secreted by the stomach in response to protein-triggered gastrin release is emptied into the duodenum, where it potently stimulates secretin secretion. The carbohydrate in the toast has no direct effect on GI hormones.

FIGURE 16-13 (P. 593): (1) hepatic artery, (2) hepatic portal vein, (3) hepatic vein

FIGURE 16-23 (P. 606): Fructose is absorbed passively by facilitated diffusion. Glucose and galactose are absorbed by secondary active transport.

Reviewing Terms and Facts

(Questions on p. 616.)

1. F **2.** T **3.** T **4.** F **5.** F **6.** F **7.** long, short **8.** medulla **9.** chyme **10.** three **11.** vitamin B_{12}, bile salts **12.** bile salts **13.** 1.c, 2.e, 3.b, 4.a, 5.f, 6.d **14.** b **15.** 1.c, 2.c, 3.d, 4.a, 5.e, 6.c, 7.a, 8.b, 9.c, 10.b, 11.d, 12.b

Solving Quantitative Exercises

(Questions on p. 617.)

1. a. $r = 0.5$ cm, area $= 4\pi (0.25) = \pi$ cm^2

volume $= \left(\frac{4}{3}\pi\right)(0.5)^3 = 0.5236$ cm^3

area/volume $= 6$

b. Each new droplet's volume is 5.236×10^{-3} cm^3, so the average radius is therefore 0.1077 cm. The area of a sphere with that radius is

$4\pi (0.1077$ cm$)^2 = 0.1458$ cm^2

area/volume $= 27.8$

c. Area emulsified/area droplet $= (100)(0.1458$ cm$^2)/\pi$ cm^2

$= 4.64$

Thus, the total surface area of all 100 emulsified droplets is 4.64 times the area of the original larger lipid droplet.

d. Volume emulsified/volume droplet $= (100)(5.236 \times 10^{-3}$ cm$^3)/$ 0.5236 cm$^3 = 1.0$.

Thus, the total volume did not change as a result of emulsification, as would be expected because the total volume of the lipid is conserved during emulsification. The volume originally present in the large droplet is divided up among the 100 emulsified droplets.

Applying Clinical Reasoning

(Question on p. 617.)

A person whose bile duct is blocked by a gallstone experiences a painful "gallbladder attack" after eating a high-fat meal because the ingested fat triggers the release of cholecystokinin, which stimulates gallbladder contraction. As the gallbladder contracts and bile is squeezed into the blocked bile duct, the duct becomes distended before the blockage. This distension is painful.

The feces are grayish white because no bilirubin-containing bile enters the digestive tract when the bile duct is blocked. Bilirubin, when acted on by bacterial enzymes, is responsible for the brown color of feces, which are grayish white in its absence.

Thinking at a Higher Level

(Questions on p. 617.)

1. Patients who have had their stomachs removed must eat small quantities of food frequently instead of consuming the typical three meals a day because they have lost the ability to store food in the stom-ach and meter it into the small intestine at an optimal rate. If a person without a stomach consumed a large meal that entered the small intestine all at once, the luminal contents would quickly become too hypertonic as digestion of the large nutrient molecules into a multitude of small, osmotically active, absorbable units outpaced the more slowly acting process of absorption of these units. As a consequence of this increased luminal osmolarity, water would enter the small-intestine lumen from the plasma by osmosis, resulting in circulatory disturbances and intestinal distension. To prevent this "dumping syndrome" from occurring, the patient must "feed" the small intestine only small amounts of food at a time so that absorption of the digestive end products can keep pace with their rate of production. The person has to consciously take over metering the delivery of food into the small intestine because the stomach is no longer present to assume this responsibility.

2. The gut-associated lymphoid tissue launches an immune attack against any pathogenic (disease-causing) microorganisms that enter the readily accessible digestive tract and escape destruction by salivary lysozyme or gastric HCl. This action defends against entry of these potential pathogens into the body proper. The large number of immune cells in the gut-associated lymphoid tissue is adaptive as a first line of defense against foreign invasion when considering that the surface area of the digestive tract lining represents the largest interface between the body proper and the external environment.

3. Defecation would be accomplished entirely by the defecation reflex in a patient paralyzed from the waist down because of lower spinal-cord injury. Voluntary control of the external anal sphincter would be impossible because of interruption in the descending pathway between the primary motor cortex and the motor neuron supplying this sphincter.

4. When insufficient glucuronyl transferase is available in the neonate to conjugate all of the bilirubin produced during erythrocyte degradation with glucuronic acid, the extra unconjugated bilirubin cannot be excreted into the bile. Therefore, this extra bilirubin remains in the body, giving rise to mild jaundice in the newborn.

5. Removal of the stomach leads to pernicious anemia because of the resultant lack of intrinsic factor, which is necessary for absorption of vitamin B_{12}. Removal of the terminal ileum leads to pernicious anemia because this is the only site where vitamin B_{12} can be absorbed.

Chapter 17 Energy Balance and Temperature Regulation

Check Your Understanding

17.1 (Questions on p. 627.)

1. *External work* is the energy expended by skeletal muscles to move external objects or to move the body in relation to the environment. *Internal work* constitutes all biological energy expenditure that does not accomplish mechanical work outside the body; it includes skeletal muscle activity associated with postural maintenance and shivering and all energy-expending activities essential for sustaining life, such as pumping blood or breathing. *Metabolic rate* is the rate at which energy is expended during both external and internal work: Metabolic rate = energy expenditure/unit of time. *Appetite signals* give the sensation of hunger, driving us to eat. *Satiety signals* give the sensation of being full, suppressing the desire to eat. *Adiposity signals* are indicative of the size of fat stores in adipose tissue and are important in the long-term control of body weight. *Adipokines* refer to hormones secreted by adipocytes. *Visceral fat* is the deep, "bad" fat that surrounds the abdominal organs and is likely to be chronically inflamed and secrete harmful adipokines. *Subcutaneous fat* is deposited under the skin (it is the fat you can pinch) and is less harmful than visceral fat.

2. The basal metabolic rate can be determined indirectly by measuring a person's O_2 uptake per unit of time and multiplying this value by the energy equivalent of O_2, which is 4.8 kilocalories of energy liberated per liter of O_2 consumed. This technique is based on the fact that a direct relationship exists between the volume of O_2 used and the quantity of heat produced as follows: Food + O_2 → CO_2 + H_2O + energy (mostly transformed into heat).

3. See Table 17-2, p. 624.

17.2 (Questions on p. 635.)

1. *radiation:* transfer of heat energy from a warmer object to a cooler object in the form of heat waves that travel through space; *conduction:* transfer of heat between objects of differing temperatures that are in direct contact with each other; *convection:* transfer of heat energy by air currents; *evaporation:* conversion of a liquid such as sweat to a gaseous vapor, a process that requires heat, which is absorbed from the skin

2. See Table 17-3, p. 633.

3. the environmental temperature range within which core temperature can be kept constant by varying skin blood flow without calling into play supplementary heat-production mechanisms such as shivering or heat-loss measures such as sweating.

Figure Focus

FIGURE 17-2 (P. 622): Increased leptin released by expanded body fat stores inhibits the appetite-enhancing pathway and stimulates the appetite-suppressing pathway. It does so by inhibiting secretion of NPY, which is a potent appetite stimulator, and by stimulating secretion of melanocortins, which are appetite suppressors. Farther downstream in the appetite-enhancing pathway, orexins, which are potent stimulators of food intake, are inhibited by the higher level of melanocortins, and their excitation by NPY is suppressed by the decline in NPY. Simultaneously, downstream in the appetite-suppressing pathway, corticotropin-releasing hormone and similar appetite suppressing mediators are stimulated by the stepped-up secretion rate of melanocortins, and their inhibition by NPY is reduced as NPY's rate of secretion drops. Furthermore, the decrease in NPY and increase in melanocortins work together at the satiety center to decrease food intake.

FIGURE 17-4 (P. 629): Assume environmental temperature is lower than body temperature, which it would be on a warm (not hot) afternoon. The person gains heat by radiation from the sun and by heat generated internally by jogging. The person loses heat to the surrounding air by radiation and conduction. Further loss of heat takes place via convection as a result of the person's movement during jogging, coupled with the effect of any wind. Also, if the person sweats, evaporative heat loss occurs.

FIGURE 17-5 (P. 631): Because eccrine sweat glands are stimulated to secrete by binding at their muscarinic receptors of acetylcholine released from sympathetic nerve fibers, drugs that block this action prevent secretion of evaporative heat-losing sweat, leading to increased risk of heat-related disorders.

Reviewing Terms and Facts

(Questions on p. 636.)

1. F **2.** F **3.** F **4.** F **5.** T **6.** T **7.** T **8.** T **9.** F **10.** arcuate nucleus **11.** shivering **12.** nonshivering thermogenesis **13.** sweating **14.** b **15.** 1.b, 2.a, 3.c, 4.a, 5.d, 6.c, 7.b, 8.d, 9.c, 10.b

Solving Quantitative Exercises

(Questions on p. 637.)

1. From physics we know that $\Delta T(°C) = \Delta U/(C \times m)$. Also note that $\Delta U/t = BMR$ (i.e., the rate of using energy is the basal metabolic

rate). m represents the mass of body fluid; for a typical person, this is 42 L.

$$(42 \text{ L}) \times (1 \text{ kg/L}) = 42 \text{ kg}$$
$$C = 1.0 \text{ kcal/(kg-°C)}$$

Given that water boils at 100°C and normal body temperature is 37°C, we need to change the temperature by 63°C. Thus,

$$t = (\Delta T \times C \times m)/BMR = (63°C)[1.0 \text{ kcal/(kg-°C)}] \,(42 \text{ kg})/$$
$$(75 \text{ kcal/hr}) = 35 \text{ hr}$$

At the higher metabolic rate during exercise,

$$t = (63°C)[1.0 \text{ kcal/(kg-°C)}](42 \text{ kg})/(1000 \text{ kcal/hr}) = 2.6 \text{ hr}$$

Applying Clinical Reasoning

(Question on p. 637.)

Cooled tissues need less nourishment than they do at normal body temperature because of their pronounced reduction in metabolic activity. The lower O_2 need of cooled tissues accounts for the occasional survival of drowning victims who have been submerged in icy water considerably longer than one could normally survive without O_2.

Thinking at a Higher Level

(Questions on p. 637.)

1. CCK serves as a satiety signal: It serves as a signal to stop eating when enough food has been consumed to meet the body's energy needs, even though the food is still in the digestive tract. Therefore, when drugs that inhibit CCK release are administered to experimental animals, the animals overeat because this satiety signal is not released.

2. Do not go on a "crash diet." Be sure to eat a nutritionally balanced diet that provides all essential nutrients, but reduce total caloric intake, especially by cutting down on high-fat foods. Spread out consumption of the food throughout the day instead of just eating several large meals. Avoid bedtime snacks. Burn more calories through a regular exercise program.

3. Engaging in heavy exercise on a hot day is dangerous because of problems arising from trying to eliminate the extra heat generated by the exercising muscles. First, there are conflicting demands for distribution of the cardiac output—temperature-regulating mechanisms trigger skin vasodilation to promote heat loss from the skin surface, whereas metabolic changes within the exercising muscles induce local vasodilation in the muscles to match the increased metabolic needs with increased blood flow. Further aggravating the problem of conflicting demands for blood flow is the loss of effective circulating plasma volume resulting from the loss of a large volume of fluid through another important cooling mechanism, sweating. Therefore, it is difficult to maintain an effective plasma volume and blood pressure and simultaneously keep the body from overheating when engaging in heavy exercise in the heat, so heat exhaustion is likely to ensue.

4. When a person is soaking in a hot bath, loss of heat by radiation, conduction, convection, and evaporation is limited to the small surface area of the body exposed to the cooler air. Heat is being gained by conduction at the larger skin surface area exposed to the hotter water.

5. The thermoconforming fish would not run a fever when it has a systemic infection because it has no mechanisms for regulating internal heat production or for controlling heat exchange with its environment. The fish's body temperature varies capriciously with the external environment no matter whether it has a systemic infection or not. It is not able to maintain body temperature at a "normal" set point or an elevated set point (i.e., a fever).

Chapter 18 Principles of Endocrinology; The Central Endocrine Glands

Check Your Understanding

18.1 (Questions on p. 646.)

1. The primary function of a *tropic hormone* is to regulate hormone secretion by another endocrine gland.

2. (1) *Negative feedback* maintains the plasma concentration of a hormone at a given set level because the output of the hormonal control system counteracts a change in the input. For example when the concentration of a hormone falls, the control system triggers increased secretion of the hormone, which feeds back to shut off the stimulatory response when the set level is achieved. (2) *Neuroendocrine reflexes* produce a sudden increase in hormone secretion (that is, "turn up the thermostat setting") in response to a specific stimulus, which is often external to the body. (3) *Diurnal (circadian) rhythms* are rhythmic fluctuations up and down in the secretion rate of many hormones as a function of the time of day.

3. *Down regulation* is a reduction in the number of target-cell receptors in the face of a prolonged increase in a hormone. *Permissiveness* refers to one hormone having to be present in adequate amounts to permit another hormone to fully exert its effects. *Synergism* results when the combined effect of two hormones is greater than the sum of their separate effects. *Antagonism* takes place when one hormone decreases the effectiveness of another hormone.

18.2 (Questions on p. 652.)

1. See Figure 18-6, p. 651.

2. *posterior pituitary hormones:* vasopressin (antidiuretic hormone, ADH) and oxytocin; *anterior pituitary hormones:* growth hormone (GH, somatotropin); thyroid-stimulating hormone (TSH, thyrotropin); adrenocorticotropic hormone (ACTH, corticotropin); follicle-stimulating hormone (FSH); luteinizing hormone (LH); and prolactin (PRL); *hypophysiotropic hormones:* thyrotropin-releasing hormone (TRH); corticotropin-releasing hormone (CRH); gonadotropin-releasing hormone (GnRH); growth hormone–releasing hormone (GHRH); somatostatin (growth hormone–inhibiting hormone, GHIH); prolactin-releasing peptide (PrRP); and dopamine (prolactin-inhibiting hormone, PIH)

3. The hypothalamus controls hormonal output from the posterior pituitary by a neural connection and controls hormonal output from the anterior pituitary by a vascular connection. The posterior pituitary is a neural extension of the hypothalamus. Neuronal cell bodies in the hypothalamus produce vasopressin and oxytocin, which are transported down the axons that pass through the connecting stalk to the posterior pituitary, where these hormones are stored in the neuronal terminals. When stimulated by the hypothalamus, these hormones are independently released into the systemic blood. The hypothalamus secretes hypophysiotropic hormones into the hypothalamic–hypophyseal portal system, a capillary-to-capillary vascular link that transports them through the connecting stalk to the anterior pituitary, where they control the secretion of hormones produced by the anterior pituitary into the systemic blood.

18.3 (Questions on p. 660.)

1. GH directly ↑ fatty acid levels in the blood by enhancing the breakdown of triglyceride stores in adipose tissue and ↑ blood glucose levels by decreasing glucose uptake by muscles and increasing glucose output by the liver, thus mobilizing fat stores as a major energy source for muscle while conserving glucose for the glucose-dependent brain. GH also directly and indirectly (via insulin-like growth factor-I [IGF-I]) brings about protein synthesis, ↓ blood amino acids in the process.

2. GH does not act directly to bring about most of its growth-producing actions (increased cell division, enhanced protein synthesis, and bone growth). Instead, GH stimulates the liver to release IGF-I, which directly mediates these growth-promoting actions. GH's only direct growth-promoting action is to stimulate protein synthesis, which it does in conjunction with IGF-I.

3. Bone grows in *thickness* by osteoblasts adding new bone on top of the outer surface of existing bone simultaneously with osteoclasts expanding the marrow cavity. Bone grows in *length* as chondrocytes (cartilage cells) in the epiphyseal plate form a new-growth template that is replaced by bone through osteoblast activity after the old chondrocytes die.

18.4 (Questions on p. 663.)

1. The self-induced rhythmic firing of the neurons in the *suprachiasmatic nucleus (SCN)* (brought about by cyclic synthesis and degradation of clock proteins) establishes many of the body's inherent daily rhythms. The fluctuating levels of clock proteins bring about cyclic changes in neural output from the SCN that lead to cyclic changes in effector organs throughout the day. Accordingly, the SCN is the *master biological clock* or pacemaker for the body's diurnal (circadian) rhythms.

2. *Melanopsin* is the receptor for light found in special retinal ganglion cells that informs the SCN about the absence or presence of light. The SCN relays the message regarding the light status to the pineal gland, which increases secretion of the hormone *melatonin* in the dark. Fluctuations in melatonin secretion help entrain the body's biological rhythm established by the SCN (which on its own cycles a bit slower than the 24-hour environmental cycle) to stay in sync with the external light–dark cycle.

3. *The optic nerve pathway* carries visual information from the rods and cones in the eyes to the visual cortex in the occipital lobes. The *retino-hypothalamic tract* carries circadian rhythm-related information from the light-detecting melanopsin-secreting retinal ganglion cells to the SCN.

Figure Focus

FIGURE 18-3 (P. 646): Because the pituitary gland lies beneath the optic chiasm (the point at which half of the nerve fibers passing from the eyes cross over on their way to the visual cortex), enlargement of this gland as a result of an anterior pituitary tumor can cause visual disturbances by pressing against this part of the visual pathway.

FIGURE 18-5 (P. 649): TSH, ACTH, GH, LH, and FSH

FIGURE 18-7 (P. 652): *across hypothalamic capillaries:* hypophysiotropic hormones enter blood; *across anterior pituitary capillaries;* hypophysiotropic hormones leave blood, anterior pituitary hormones enter blood

FIGURE 18-10 (P. 656): GHRH stimulates and somatostatin (GHIH) inhibits growth hormone (GH) secretion by the anterior pituitary. GH stimulates IGF-I secretion by the liver. In negative-feedback fashion, GH and IGF-I both inhibit GHRH secretion and stimulate somatostatin secretion by the hypothalamus. IGF-I also inhibits GH secretion by the anterior pituitary.

Reviewing Terms and Facts

(Questions on p. 663.)

1. T **2.** T **3.** F **4.** T **5.** T **6.** T **7.** tropic **8.** down regulation **9.** epiphyseal plate **10.** suprachiasmatic nucleus **11.** 1.c, 2.b, 3.b, 4.a, 5.a, 6.c, 7.b

Applying Clinical Reasoning

(Question on p. 664.)

Hormonal replacement therapy following pituitary gland removal should include thyroid hormone (the thyroid gland does not produce sufficient thyroid hormone in the absence of TSH) and glu-

cocorticoid (because of the absence of ACTH), especially in stress situations. If indicated, male or female sex hormones can be replaced, even though these hormones are not essential for survival. For example, testosterone in males plays an important role in libido. Growth hormone and prolactin need not be replaced because their absence produces no serious consequences in this individual. Vasopressin may have to be replaced if the blood at the hypothalamus picks up insufficient quantities of this hormone in the absence of the posterior pituitary.

Thinking at a Higher Level

(Questions on p. 664.)

1. The concentration of hypothalamic releasing and inhibiting hormones would be considerably lower (in fact, almost nonexistent) in a systemic venous blood sample compared to the concentration of these hormones in a sample of hypothalamic–hypophyseal portal blood. These hormones are secreted into the portal blood for local delivery between the hypothalamus and anterior pituitary. Any portion of these hormones picked up by the systemic blood at the anterior pituitary capillary level is greatly diluted by the much larger total volume of systemic blood compared to the extremely small volume of blood within the portal vessel.

2. Above normal. Without sufficient iodine, the thyroid gland is unable to synthesize enough thyroid hormone. The resultant reduction in negative-feedback activity by the reduced level of thyroid hormone would lead to increased TSH secretion. Despite the elevated TSH, however, the thyroid gland still could not secrete adequate thyroid hormone because of the iodine deficiency.

3. If CRH and/or ACTH are elevated in accompaniment with the excess cortisol secretion, the condition is secondary to a defect at the hypothalamic/anterior pituitary level. If CRH and ACTH levels are below normal in accompaniment with the excess cortisol secretion, the condition is caused by a primary defect at the adrenal cortex level, with the excess cortisol inhibiting the hypothalamus and anterior pituitary in negative-feedback fashion.

4. Males with *testicular feminization syndrome* would be unusually tall because of the inability of testosterone (aromatized to estradiol) to promote closure of the epiphyseal plates of the long bones in the absence of testosterone receptors.

5. Full-grown athletes sometimes illegally take supplemental doses of growth hormone because it promotes increased skeletal muscle mass through its and IGF-I's-protein anabolic effect. However, excessive growth hormone can have detrimental side effects, such as possibly causing diabetes or high blood pressure.

Chapter 19 The Peripheral Endocrine Glands

Check Your Understanding

19.1 (Questions on p. 671.)

1. A *thyroid follicle,* the functional unit of the thyroid gland, is a hollow sphere consisting of a single layer of follicular cells enclosing an inner lumen filled with *colloid,* which serves as an extracellular storage site for thyroid hormone. Colloid is filled with *thyroglobulin,* a large glycoprotein within which are incorporated the thyroid hormones in their various stages of synthesis. During synthesis, attachment of one iodide to tyrosine yields *MIT* (monoiodotyrosine), and attachment of two iodides to tyrosine yields *DIT* (di-iodotyrosine). Coupling of one MIT and one DIT yields T_3 (tri-iodothyronine), and coupling of two DITs yields T_4 (tetraiodothyronine or thyroxine). T_3 and T_4 are collectively referred to as thyroid hormone.

2. The *iodide trap* is the powerful symporter that transports iodide against its concentration gradient from the blood into the follicular cell.

3. See Figure 19-3, p. 669.

19.2 (Questions on p. 682.)

1. (1) *mineralocorticoids:* aldosterone (promotes Na^+ retention and K^+ elimination during urine formation); (2) *glucocorticoids:* cortisol (increases blood glucose at the expense of protein and fat stores and helps the body adapt to stress); and (3) *sex hormones:* dehydroepiandrosterone (governs androgen-dependent processes in the female, such as growth of pubic and axillary hair, enhancing pubertal growth spurt, and maintaining the sex drive)

2. ACTH stimulates the adrenal cortex to secrete cortisol but has no effect on aldosterone.

3. *epinephrine* and *norepinephrine,* which are stored in chromaffin granules, from which they are secreted into the blood by exocytosis on stimulation by preganglionic sympathetic fibers

19.3 (Questions on p. 685.)

1. (1) ↑ epinephrine: reinforces sympathetic nervous system in "fight-or-flight responses"; mobilizes energy stores (↑ blood glucose and blood fatty acids); (2) ↑ CRH–ACTH–cortisol: mobilizes energy stores and metabolic building blocks (↑ blood glucose, blood fatty acids, and blood amino acids); (3) ↑ glucagon and ↓ insulin: act in concert to ↑ blood glucose and blood fatty acids; (4) ↑ renin–angiotensin–aldosterone and ↑ vasopressin: conserve salt and H_2O to expand plasma volume; angiotensin II and vasopressin cause arteriolar vasoconstriction. These actions help sustain blood pressure if acute loss of plasma volume occurs.

2. The hypothalamus (1) increases sympathetic nervous system activity, which (a) prepares the body for "fight or flight"; (b) promotes arteriolar vasoconstriction that reduces blood flow to the kidneys, thereby triggering ↑ renin–angiotensin–aldosterone activity; and (c) stimulates the adrenal medulla to ↑ epinephrine secretion. Epinephrine reinforces the sympathetic nervous system and additionally acts on the pancreas to ↑ glucagon and ↓ insulin secretion. The hypothalamus further (2) secretes CRH, thereby ↑ CRH–ACTH–cortisol activity; and (3) stimulates the posterior pituitary to ↑ vasopressin secretion.

19.4 (Questions on p. 701.)

1. *Glycogenesis* is the conversion of glucose to glycogen, *glycogenolysis* is the conversion of glycogen to glucose, and *gluconeogenesis* is the conversion of amino acids to glucose.

2. *Insulin* ↓ blood glucose and promotes carbohydrate storage by facilitating glucose transport into most cells via transporter recruitment and by stimulating glycogenesis and inhibiting glycogenolysis and gluconeogenesis. It ↓ blood fatty acids and promotes triglyceride storage by increasing the entry of fatty acids and glucose into adipose cells, promoting triglyceride synthesis, and inhibiting lipolysis. It ↓ blood amino acids and enhances protein synthesis by promoting active transport of amino acids into muscles, stimulating protein synthesis, and inhibiting protein degradation. *Glucagon* ↑ blood glucose and reduces carbohydrate stores by increasing hepatic glucose production via decreasing glycogenesis and by promoting glycogenolysis and gluconeogenesis. It ↑ blood fatty acids and reduces fat stores by promoting lipolysis and inhibiting triglyceride synthesis. It ↑ blood ketone levels by enhancing conversion of fatty acids to ketone bodies by the liver. Glucagon inhibits protein synthesis and promotes protein degradation in the liver but not in muscle, the body's major protein store, so it does not have any significant effect on blood amino acid levels.

3. Increased blood glucose stimulates the pancreatic β cells, thus increasing insulin secretion, and inhibits the pancreatic α cells, thus decreasing glucagon secretion.

4. *Type 1 diabetes mellitus* is caused by autoimmune destruction of β cells, so it is characterized by a lack of insulin secretion. Its onset most commonly begins in childhood. *Type 2 diabetes mellitus,* which is characterized by reduced sensitivity of insulin's target cells, most commonly arises in adulthood.

19.5 (Questions on p. 712.)

1. Following is the distribution of body Ca^{2+}: 99% in the skeleton and teeth, 0.9% in the cells, and 0.1% in the ECF. Of the Ca^{2+} in the ECF, half is bound in complexes and not available to participate in chemical reactions, and the other half is free Ca^{2+} that is biologically active. This free ECF Ca^{2+} plays a vital role in neuromuscular excitability, excitation–contraction coupling in cardiac and smooth muscle, stimulus–secretion coupling, excitation–secretion coupling, maintenance of tight junctions, and blood clotting.

2. *Calcium homeostasis* refers to maintenance of a constant free plasma Ca^{2+} concentration. *Calcium balance* refers to maintenance of a constant total amount of Ca^{2+} in the body.

3. PTH acts on bone, kidneys, and the intestine to increase plasma Ca^{2+} as follows: PTH stimulates a fast exchange of Ca^{2+} from the small labile pool of Ca^{2+} in the bone fluid into the plasma by activating Ca^{2+} pumps in the osteocytic–osteoblastic bone membrane. It induces a slow exchange of Ca^{2+} from the stable pool of Ca^{2+} in the bone minerals of the bone itself into the plasma by stimulating osteoclasts to dissolve bone. PTH acts on the kidneys to conserve Ca^{2+} and eliminate PO_4^{3-} during urine formation and to activate vitamin D. PTH indirectly increases Ca^{2+} and PO_4^{3-} absorption from the small intestine via its role in activating vitamin D, which directly promotes the intestinal absorption of these ingested electrolytes.

Figure Focus

FIGURE 19-2 (P. 667): Potential targets for blocking synthesis of T_3 and T_4 are inhibiting the iodide trap (symporter) or blocking TPO action. Indeed, drugs are available for both targets. However, drugs that inhibit the iodide trap are rarely used because of toxic side effects. Drugs that block TPO action are in common use. These so-called *thionamides* prevent conversion of iodide to active I^-, inhibit attachment of active I^- to tyrosine in thyroglobulin, and halt coupling of iodotyrosines into thyroid hormone.

FIGURE 19-3 (P. 669): T_3 and T_4 concentrations would be decreased because insufficient iodide would be available for their synthesis. The resultant reduction in negative feedback by thyroid hormone at the hypothalamus and anterior pituitary would lead to increased TRH and TSH concentrations.

FIGURE 19-7 (P. 672): Cortisol and dehydroepiandrosterone secretion would increase; aldosterone secretion would not be affected.

FIGURE 19-8 (P. 673): True

FIGURE 19-13 (P. 684): (1) pathways that lead to mobilization of energy stores and metabolic building blocks: hypothalamus stimulates ↑ CRH–ACTH–cortisol secretion → ↑ blood glucose, blood fatty acids, and blood amino acids; hypothalamus stimulates sympathetic nervous system, which stimulates the adrenal medulla to increase epinephrine secretion, which acts on the endocrine pancreas to ↑ glucagon and ↓ insulin → ↑ blood glucose and blood fatty acids. (2) pathways that lead to salt and H_2O conservation: hypothalamus stimulates posterior pituitary to release vasopressin → ↑ H_2O reabsorption during urine formation; hypothalamus stimulates the sympathetic nervous system, which causes arteriolar vasoconstriction, including the afferent arterioles, leading to decreased blood flow through the kidneys, which triggers ↑ renin–angiotensin–aldosterone → ↑ salt and osmotic H_2O reabsorption during urine formation.

FIGURE 19-16 (P. 691): hepatic glucose production and transport of glucose into cells

FIGURE 19-17 (P. 693): Glucose that enters the β cell by facilitated diffusion is phosphorylated to glucose-6-phosphate, whose oxidation generates ATP, which closes the ATP-sensitive K^+ channels. The resultant reduced exit of K^+ depolarizes the β cell, an action that opens voltage-gated Ca^{2+} channels. Ca^{2+} entry triggers exocytosis of insulin vesicles, in this way causing insulin secretion.

FIGURE 19-24 (P. 708): (a), (d), (b), (c)

Applying Clinical Reasoning

(Question on p. 714.)

"Diabetes of bearded ladies" is descriptive of both excess cortisol and excess adrenal androgen secretion. Excess cortisol secretion causes hyperglycemia and glucosuria. Glucosuria promotes osmotic diuresis, which leads to dehydration and a compensatory increased sensation of thirst. All these symptoms—hyperglycemia, glucosuria, polyuria, and polydipsia—mimic diabetes mellitus. Excess adrenal androgen secretion in females promotes masculinizing characteristics, such as beard growth. Simultaneous hypersecretion of both cortisol and adrenal androgen most likely occurs secondary to excess CRH–ACTH secretion because ACTH stimulates both cortisol and androgen production by the adrenal cortex.

Thinking at a Higher Level

(Questions on p. 714.)

1. The midwestern United States is no longer an endemic goiter belt, even though the soil is still iodine poor because individuals living in this region obtain iodine from iodine-supplemented nutrients, such as iodinated salt, and from seafood and other naturally iodine-rich foods shipped from coastal regions.

2. Anaphylactic shock is an extremely serious allergic reaction brought about by massive release of chemical mediators in response to exposure to a specific allergen—such as one associated with a bee sting—to which the individual has been highly sensitized. These chemical mediators bring about circulatory shock (severe hypotension) through a twofold effect: (1) by relaxing arteriolar smooth muscle, thus causing widespread arteriolar vasodilation and a resultant fall in total peripheral resistance and arterial blood pressure; and (2) by causing a generalized increase in capillary permeability, resulting in a shift of fluid from the plasma into the interstitial fluid. This shift decreases the effective circulating volume, further reducing arterial blood pressure. Additionally, these chemical mediators bring about pronounced bronchoconstriction, making it impossible for the victim to move sufficient air through the narrowed airways. Because these responses take place rapidly and can be fatal, people allergic to bee stings are advised to keep injectable epinephrine in their possession. By promoting arteriolar vasoconstriction through its action on α_1 receptors in arteriolar smooth muscle and promoting bronchodilation through its action on β_2 receptors in bronchiolar smooth muscle (see Table 7-2, p. 240), epinephrine counteracts the life-threatening effects of the anaphylactic reaction to the bee sting.

3. An infection elicits the stress response, which brings about increased secretion of cortisol and epinephrine, both of which increase the blood glucose level. This becomes a problem for diabetic patients

who have to bring down the elevated blood glucose by injecting additional insulin or, preferably, by reducing carbohydrate intake and/or exercising (difficult to do when sick) to use up some of the extra blood glucose. In a normal individual, the check-and-balance system between insulin and the other hormones that oppose insulin's actions helps maintain the blood glucose within reasonable limits during the stress response.

4. The presence of Chvostek's sign results from increased neuromuscular excitability caused by moderate hyposecretion of parathyroid hormone.

5. If malignancy-associated hypercalcemia arose from metastatic tumor cells that invaded and destroyed bone, both hypercalcemia and hyperphosphatemia would result as $Ca_3(PO_4)_2$ salts were released from the destructed bone. The fact that hypophosphatemia, not hyperphosphatemia, often accompanies malignancy-associated hypercalcemia led investigators to rule out bone destruction as the cause of the hypercalcemia. Instead, they suspected that the tumors produced a substance that mimics the actions of PTH in promoting concurrent hypercalcemia and hypophosphatemia.

Chapter 20 The Reproductive System

Check Your Understanding

20.1 (Questions on p. 723.)

1. *testes* in males and *ovaries* in females. In both sexes, these primary reproductive organs perform the dual function of producing gametes (sperm in males and ova in females) and secreting sex hormones (testosterone in males and estrogen and progesterone in females).

2. *Genetic sex* depends on the combination of sex chromosomes at fertilization, with males having an XY and females having an XX combination. *Gonadal sex* depends on whether testes or ovaries develop. The indifferent gonadal ridge develops into testes during the seventh week of intrauterine life under the influence of the testis-determining factor (TDF) secreted under direction of the sex-determining region of the Y chromosome (SRY). Because female embryos do not have a Y chromosome, they lack the masculinizing SRY and TDF, so by default the gonadal ridge develops into ovaries during the ninth week of gestation. *Phenotypic sex,* the apparent anatomic sex of an individual, is hormonally mediated and depends on the genetically determined gonadal sex. Embryos of both sexes have the same undifferentiated external genitals and two duct systems, the Wolffian ducts and the Müllerian ducts. The fetal testes secrete testosterone, which transforms the Wolffian ducts into a male reproductive tract and, when converted into dihydrotestosterone, promotes development of the external genitals along male lines. Müllerian-inhibiting factor causes degeneration of the Müllerian ducts. In the absence of these masculinizing secretions, the Wolffian ducts degenerate, the *Müllerian* ducts develop into a female reproductive tract, and the undifferentiated external genitalia develop along female lines. The sex of the developing fetus can easily be distinguished by 10 to 12 weeks of gestation.

3. See chart below.

20.2 (Questions on p. 732.)

1. See Table 20-1, p. 725

2. The *seminiferous tubules* are the highly coiled tubular component of the testes where spermatogenesis takes place. The *Leydig cells,* which lie in the interstitial spaces between the seminiferous tubules, secrete testosterone. *Sertoli cells* are epithelial cells that lie in close association with and protect, nurse, and enhance the developing sperm cells throughout their development in the seminiferous tubules. Sertoli cells also secrete inhibin and are the site of action for control of spermatogenesis by both testosterone and FSH. *Spermatogenesis* is the sequence of steps by which relatively undifferentiated primordial germ cells proliferate and are converted into extremely specialized, motile spermatozoa. *Spermiogenesis* refers to the remodeling or packaging of the haploid spermatids into spermatozoa. *Spermiation* is the final release of a mature spermatozoon from the Sertoli cell to which it has been attached throughout development. *Spermatogonia* are the undifferentiated primordial germ cells that have a diploid number of single strand chromosomes. Two mitotic divisions of a spermatogonium yield four *primary spermatocytes,* each with a diploid number of double strand chromosomes. The first meiotic division of these primary spermatocytes yields eight *secondary spermatocytes,* each with a haploid number of double strand chromosomes. The second meiotic division of these secondary spermatocytes yields 16 *spermatids,* each with a haploid number of single strand chromosomes. The spermatids are packaged into highly specialized *spermatozoa,* each with a haploid number of single strand chromosomes.

3. See Figure 20-9, p. 729

4. See Table 20-2, p. 732

20.3 (Questions on p. 736.)

1. (1) *excitement phase* (erection and heightened sexual awareness); (2) *plateau phase* (intensification of sexual responses and systemic responses, such as increased heart rate, blood pressure, respiratory rate, and muscle tension); (3) *orgasmic phase* (ejaculation in

Embryonic Structure	Reproductive Structure Derived from This Embryonic Structure in Males	Reproductive Structure Derived from This Embryonic Structure in Females
Gonadal ridge	Testes	Ovaries
Genital tubercle	Penis	Clitoris
Urethral folds	Cord of erectile tissue that surrounds the urethra in the penis	Labia minora
Genital swellings	Scrotum and prepuce	Labia majora
Wolffian ducts	Epididymis, ductus deferens, ejaculatory duct, and seminal vesicles	Nothing; ducts degenerate
Müllerian ducts	Nothing; ducts degenerate	Oviducts, uterus, cervix, and upper vagina
Urogenital sinus	Prostate gland, bulbourethral gland	Lower vagina

males, orgasm in both sexes); and (4) *resolution phase* (return to pre-arousal state)

2. The *male sex act* includes erection and ejaculation. *Erection,* hardening of the normally flaccid penis to permit its entry into the vagina, is accomplished by engorgement of the penis erectile tissue with blood as a result of marked parasympathetically induced vasodilation of the penile arterioles and mechanical compression of the veins. *Ejaculation* occurs in two phases: The *emission phase,* emptying of sperm and accessory sex gland secretions (semen) into the urethra, is accomplished by sympathetically induced contraction of smooth muscle in the walls of the reproductive ducts and accessory sex glands. The *expulsion phase,* the forceful expulsion of semen from the penis, is accomplished by motor-neuron-induced contraction of the skeletal muscles at the base of the penis.

3. *Orgasm*, which culminates the sex act, is characterized in both sexes by involuntary rhythmic contractions of pelvic muscles at 0.8-second intervals and identical peak systemic responses, such as heavy breathing, markedly elevated heart rate, and generalized skeletal muscle contraction, all of which are associated with a feeling of intense pleasure, release, and complete gratification. The only differences between male and female orgasms are no accompanying ejaculation in females, and males become refractory to further sexual stimulation following an orgasm but females do not.

20.4 (Questions on p. 770.)

1. See Table 20-4, p. 743

2. The ovarian *follicle* secretes estrogen; the *corpus luteum* secretes progesterone (most) and estrogen. *Estrogen* stimulates growth of the endometrium and myometrium and induces synthesis of progesterone receptors in the endometrium. *Progesterone* acts on the estrogen-primed endometrium to convert it into a hospitable and nutritious lining (with loose, edematous connective tissue, glycogen stores, and increased blood supply) suitable for implantation. The *menstrual phase* of the uterine cycle takes place during the first half of the ovarian follicular phase, after the end of the last cycle when the estrogen and progesterone supply was withdrawn on degeneration of the corpus luteum. The highly developed uterine lining sloughs (menstruation) simultaneous with the beginning of a new follicular phase under the influence of rising FSH and LH on withdrawal of the inhibitory actions of estrogen and progesterone. The *proliferative phase* of the uterine cycle occurs during the last half of the ovarian follicular phase as the endometrium stops sloughing and starts to repair itself and proliferate under the influence of rising levels of estrogen from the newly recruited, rapidly growing antral follicles. Peak estrogen secretion causes the LH surge, which triggers ovulation, ending both the ovarian follicular phase and the uterine proliferative phase. The *secretory,* or *progestational, phase* of the uterine cycle begins concurrent with the ovarian luteal phase as progesterone from the corpus luteum converts the thickened, estrogen-primed endometrium to a lush environment capable of supporting an early embryo should the released egg be fertilized and implant.

3. *zygote:* fertilized ovum, following union of the male and female chromosomes; *blastocyst:* a single-layer hollow ball of about 50 cells resulting from mitotic cell divisions of the zygote; the blastocyst is the developmental stage that implants in the endometrium; *inner cell mass:* a dense mass on one side of the blastocyst that is destined to become the fetus; *trophoblast:* the thin outermost layer of the blastocyst that accomplishes implantation, after which it develops into the fetal part of the placenta; *decidua:* the endometrial tissue modified at the implantation site to enhance its ability to support the implanting embryo; *chorion:* the thickened trophoblastic layer after implantation is complete; *placenta:* the specialized organ of exchange between the maternal and fetal blood that is derived from both trophoblastic embryonic tissue and decidual maternal tissue and that secretes peptide and steroid hormones essential for maintaining pregnancy; *embryo:* the product of fertilization during the first 2 months of intrauterine development when tissue differentiation is taking place; *fetus:* the product of fertilization during the last 7 months of gestation after differentiation is complete and tremendous tissue growth and maturation occur

4. During *parturition,* a positive-feedback loop involving *oxytocin,* a powerful uterine muscle stimulant, is responsible for the progression of labor. Oxytocin promotes uterine muscle contractions that force the fetus against the cervix, dilating it and triggering a neuroendocrine reflex that results in secretion of even more oxytocin, which stimulates even stronger contractions, and so on as labor progresses until the cervix is dilated sufficiently for the baby to be pushed out. During *breast-feeding,* oxytocin causes milk ejection (milk letdown) by stimulating contraction of the myoepithelial cells surrounding the milk-secreting alveoli.

Figure Focus

FIGURE 20-3 (P. 720): The individual would have testes; a male reproductive tract (epididymis, ductus deferens, ejaculatory duct); seminal vesicles; and female external genitalia (clitoris, labia).

FIGURE 20-7 (P. 727): (1) 16 (2) *Spermatogonium* has 46 chromosomes; spermatozoon has 23 chromosomes.

FIGURE 20-9 (P. 729): (1) *LH* stimulates Leydig cells to secrete testosterone. (2) LH secretion is inhibited by testosterone inhibiting kisspeptin and subsequently GnRH secretion at the hypothalamus and selectively inhibiting LH secretion at the anterior pituitary. (3) *FSH* acts on Sertoli cells to stimulate spermatogenesis and secretion of inhibin. (4) FSH secretion is inhibited via testosterone's inhibition of kisspeptin and subsequently GnRH at the hypothalamus. Furthermore, inhibin selectively inhibits FSH secretion at the anterior pituitary.

FIGURE 20-14 (P. 743): (1) stages *without influence by ovarian cycle*: resting primordial follicle, preantral follicle, early antral follicle (steps 1, 2, and 3 in figure); (2) stages during follicular phase: recruitable antral follicle, dominant mature follicle (steps 4 and 5); (3) stages during luteal phase: developing and degenerating corpus luteum (steps 7, 8, and 9)

FIGURE 20-17 (P. 745): *Day 8:* FSH is high but declining and LH secretion is on the rise. FSH and LH stimulate oocyte development and follicular growth; the ovarian cycle is in the follicular phase. Increased estrogen secretion by the follicle is just beginning. No progesterone is secreted. The endometrium is repairing itself and starting to thicken under the influence of rising estrogen levels. The uterine cycle is in the proliferative phase, following the preceding menstrual phase. *Day 21:* FSH and LH secretion are declining under the influence of peak progesterone levels from the mature corpus luteum. The ovarian cycle is in the luteal phase. The estrogen level is elevated but not as high as at its peak at the end of the follicular phase when it triggered the LH surge responsible for ovulation and formation of the CL. Under the influence of high progesterone levels, the endometrium is undergoing vascular and secretory changes to prepare for implantation should the released ovum be fertilized. The uterine cycle is in the secretory phase.

FIGURE 20-18 (P. 746): granulosa cells

FIGURE 20-20 (P. 748): In negative-feedback fashion, rising, moderate levels of estrogen inhibit kisspeptin and subsequently GnRH at the hypothalamus and selectively inhibit FSH secretion at the anterior pituitary, thus suppressing secretion of the factors promoting estrogen secretion (although LH continues to slowly rise [tonic LH secretion] under incomplete suppression by estrogen). By contrast, in positive-feedback fashion, LH-induced high levels of estrogen stimulate a different population of kisspeptin-secreting neurons at the hypothalamus and selectively stimulate LH secretion at the anterior pituitary, giving rise to the LH surge that triggers ovulation.

FIGURE 20-27 (P. 762): (1) The placenta secretes estrogen and progesterone after the first trimester. (2) The concentrations of these hormones drop precipitously at delivery when the placenta is delivered and no longer secreting hormones.

Reviewing Terms and Facts

(Questions on p. 771.)

1. T **2.** T **3.** F **4.** T **5.** F **6.** T **7.** seminiferous tubules, FSH, testosterone **8.** thecal, LH, granulosa, FSH **9.** corpus luteum of pregnancy, placenta **10.** human chorionic gonadotropin **11.** c **12.** e **13.** 1.c, 2.a, 3.b, 4.c, 5.a, 6.a, 7.c, 8.b, 9.e **14.** 1.a, 2.c, 3.b, 4.a, 5.a, 6.b

Applying Clinical Reasoning

(Question on p. 772.)

The first warning of a tubal pregnancy is pain caused by stretching of the oviduct by the growing embryo. A tubal pregnancy must be surgically terminated because the oviduct cannot expand as the uterus does to accommodate the growing embryo. If not removed, the enlarging embryo ruptures the oviduct, causing possibly lethal hemorrhage.

Thinking at a Higher Level

(Questions on p. 772.)

1. The anterior pituitary responds only to the normal pulsatile pattern of GnRH and does not secrete gonadotropins in response to continuous exposure to GnRH. In the absence of FSH and LH secretion, ovulation and other events of the ovarian cycle do not ensue, so continuous GnRH administration may find use as a contraceptive technique.

2. Testosterone hypersecretion in a young boy causes premature closure of the epiphyseal plates so that he stops growing before he reaches his genetic potential for height. The child would also display signs of precocious pseudopuberty, characterized by premature development of secondary sexual characteristics, such as deep voice, beard, enlarged penis, and sex drive.

3. A potentially troublesome side effect of drugs that inhibit sympathetic nervous system activity as part of the treatment for high blood pressure is males' inability to carry out the sex act. Both divisions of the autonomic nervous system are required for the male sex act. Parasympathetic activity is essential for accomplishing erection, and sympathetic activity is important for ejaculation.

4. Posterior pituitary extract contains an abundance of stored oxytocin, which can be administered to induce or facilitate labor by increasing uterine contractility. Exogenous oxytocin is most successful in inducing labor if the woman is near term because of the increasing concentration of myometrial oxytocin receptors and formation of gap junctions between the uterine smooth muscle cells at that time.

5. GnRH or FSH and LH are not effective in treating the symptoms of menopause because the ovaries are no longer responsive to the gonadotropins. Thus, treatment with these hormones would not cause estrogen and progesterone secretion. In fact, GnRH, FSH, and LH levels are already elevated in postmenopausal women because of lack of negative feedback by the ovarian hormones.

Glossary

A band One of the dark bands that alternate with light (I) bands to create a striated appearance in a skeletal or cardiac muscle fiber when these fibers are viewed with a light microscope

absorption The transfer of digested nutrients and ingested liquids from the digestive tract lumen into the blood or lymph

absorptive state The metabolic state following a meal when nutrients are being absorbed and stored; fed state

accessory digestive organs Exocrine organs outside the wall of the digestive tract that empty their secretions through ducts into the digestive tract lumen

accessory sex glands Glands that empty their secretions into the reproductive tract

accommodation The ability to adjust the strength of the lens in the eye so that both near and far sources can be focused on the retina

acetylcholine (ACh) (ass′-uh-teal-KŌ–lēn) The neurotransmitter released from all autonomic preganglionic fibers, parasympathetic postganglionic fibers, and motor neurons

acetylcholinesterase (AChE) (ass′-uh-teal-kō-luh-NES-tuh-rās) An enzyme present in the motor end-plate membrane of a skeletal muscle fiber that inactivates acetylcholine

ACh See *acetylcholine*

AChE See *acetylcholinesterase*

acid A hydrogen-containing substance that yields a free hydrogen ion and anion on dissociation

acidosis (ass-i-DŌ-sus) Blood pH of less than 7.35

acini (ĀS-i-ni) The secretory component of saclike exocrine glands, such as digestive enzyme–producing pancreatic glands or milk-producing mammary glands

acquired immune responses Responses that are selectively targeted against particular foreign material to which the body has previously been exposed; see also *antibody-mediated immunity* and *cell-mediated immunity*

ACTH See *adrenocorticotropic hormone*

actin The contractile protein forming the backbone of the thin filaments in muscle fibers

action potential A brief, rapid, large change in membrane potential that serves as a long-distance electrical signal in an excitable cell

active expiration Emptying of the lungs more completely than when at rest by contracting the expiratory muscles; also called *forced expiration*

active force A force that requires expenditure of cellular energy (ATP) in the transport of a substance across the plasma membrane

active reabsorption When any one of the five steps in the transepithelial transport of a substance reabsorbed across the kidney tubules requires energy expenditure

active transport Active carrier-mediated transport involving transport of a substance against its concentration gradient across the plasma membrane

acuity Discriminative ability; the ability to discern between two different points of stimulation

adaptation A reduction in receptor potential despite sustained stimulation of the same magnitude

adenosine diphosphate (ADP) (uh-DEN-uh-sēn) The two-phosphate product formed from the splitting of ATP to yield energy for the cell's use

adenosine triphosphate (ATP) The body's common energy "currency," which consists of an adenosine with three phosphate groups attached; splitting of the high-energy, terminal phosphate bond provides energy to power cellular activities

adenylyl cyclase (ah-DEN-il-il si-klās) The membrane-bound enzyme activated by a G-protein intermediary in response to binding of an extracellular messenger with a surface membrane receptor that, in turn, activates cyclic AMP, an intracellular second messenger

adequate stimulus The type of stimulus to which a specific receptor type responds, such as a photoreceptor responding to light

ADH See *vasopressin*

adipocytes Fat cells in adipose tissue; store triglyceride fat and secrete hormones termed *adipokines*

adipokines Hormones secreted by adipose tissue that play important roles in energy balance and metabolism; some trigger inflammation in fat

adipose tissue The tissue specialized for storage of triglyceride fat; found under the skin in the hypodermis or surrounding the abdominal viscera

ADP See *adenosine diphosphate*

adrenal cortex (uh-DRĒ-nul) The outer portion of the adrenal gland; secretes three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex hormones

adrenal medulla (muh-DŪL-uh) The inner portion of the adrenal gland; secretes the hormones epinephrine and norepinephrine into the blood in response to sympathetic stimulation

adrenergic fibers (ad′-ruh-NUR-jik) Nerve fibers that release norepinephrine as their neurotransmitter

adrenocorticotropic hormone (ACTH) (ad-rē′-nō-kor′-tuh-kō-TRŌP-ik) An anterior pituitary hormone that stimulates cortisol secretion by the adrenal cortex and promotes growth of the adrenal cortex

aerobic Referring to a condition in which oxygen is available

aerobic exercise Exercise that can be supported by ATP formation accomplished by oxidative phosphorylation because adequate O_2 is available to support the muscle's modest energy demands; also called *endurance-type exercise*

afferent arteriole (AF-er-ent ar-TIR-ē-ōl) The vessel that carries blood into the glomerulus of the kidney's nephron

afferent division The portion of the peripheral nervous system that carries information from the periphery to the central nervous system

afferent neuron Neuron that possesses a sensory receptor at its peripheral ending and carries information to the central nervous system

after hyperpolarization (hī′-pur-pō-luh-ruh-ZĀ-shun) A slight, transient hyperpolarization that sometimes occurs at the end of an action potential

agonist A substance that binds to a neurotransmitter's receptors and mimics the neurotransmitter's response

agranulocytes (ā-GRAN-yuh-lō-sits′) Leukocytes that do not contain granules, including lymphocytes and monocytes

albumin (al-BEW-min) The smallest and most abundant plasma proteins; binds and transports many water-insoluble substances in the blood; contributes extensively to plasma-colloid osmotic pressure

aldosterone (al-dō-steer-OWN) or (al-DOS-tuh-rōn) The adrenocortical hormone that stimulates Na^+ reabsorption and K^+ secretion by the distal and collecting tubules of the kidney's nephron during urine formation

alkalosis (al′-kuh-LŌ-sus) Blood pH of greater than 7.45

allergy Acquisition of an inappropriate specific immune reactivity to a normally harmless environmental substance

all-or-none law An excitable membrane either responds to a stimulus with a maximal action potential that spreads nondecrementally throughout the membrane or does not respond with an action potential at all

alpha (α) cells The endocrine pancreatic cells that secrete the hormone glucagon

alpha motor neuron A motor neuron that innervates ordinary skeletal muscle fibers

alveolar surface tension (al-VĒ-ō-lur) The surface tension of the fluid lining the alveoli in the lungs; see *surface tension*

alveolar ventilation The volume of air exchanged between the atmosphere and alveoli per minute; alveolar ventilation = (tidal volume − dead space volume) × respiratory rate

alveoli (of lungs) (al-VĒ-ō-lī) The air sacs across which O_2 and CO_2 are exchanged between the blood and air in the lungs

alveoli (of mammary glands) Clusters of saclike, epithelial-lined milk-producing glands at the terminal end of the milk ducts in the breasts

amines (AH-mēnz) Hormones derived from the amino acid tyrosine, including thyroid hormone and catecholamines

amoeboid movement (uh-MĒ-boid) "Crawling" movement of white blood cells, similar to the means by which amoebas move

AMPA receptor One of two types of receptor-channels on a postsynaptic membrane to which the neurotransmitter glutamate binds, this one leading to the formation of EPSPs

anabolism (ah-NAB-ō-li-zum) The buildup, or synthesis, of larger organic molecules from small organic molecular subunits

anaerobic (an'-uh-RŌ-bik) Referring to a condition in which oxygen is not present

anaerobic exercise High-intensity exercise that can be supported by ATP formation accomplished by anaerobic glycolysis for brief periods of time when O_2 delivery to a muscle is inadequate to support oxidative phosphorylation

analgesic (an-al-JĒ-zic) Pain relieving

anatomy The study of body structure

androgen A masculinizing "male" sex hormone; includes testosterone from the testes and dehydro-epiandrosterone from the adrenal cortex

anemia A reduction below normal in O_2-carrying capacity of the blood

anion (AN-ī-on) Negatively charged ion that has gained one or more electrons in its outer shell

ANP See *atrial natriuretic peptide*

antagonism Actions opposing each other; in the case of hormones, when one hormone causes the loss of another hormone's receptors, reducing the effectiveness of the second hormone

antagonist A substance that blocks a neurotransmitter's receptor, thus preventing the neurotransmitter from binding and producing a response

anterior pituitary The glandular portion of the pituitary that synthesizes, stores, and secretes growth hormone, TSH, ACTH, FSH, LH, and prolactin

antibody An immunoglobulin produced by a specific activated B lymphocyte (plasma cell) against a particular antigen; binds with the specific antigen against which it is produced and promotes the antigenic invader's destruction by augmenting nonspecific immune responses already initiated against the antigen

antibody-mediated immunity A specific immune response accomplished by antibody production by B cells

antidiuretic hormone (ADH) (an'-ti-dī'-yū-RET-ik) See *vasopressin*

antigen A large, complex molecule that triggers a specific immune response against itself when it gains entry into the body

antioxidant A substance that helps inactivate biologically damaging free radicals

antiport The form of secondary active transport in which the driving ion and transported solute move in opposite directions across the plasma membrane; also called *countertransport* or *exchange*

antral follicle A developing ovarian follicle that is secreting estrogen and forming an antrum

antrum (of ovary) The fluid-filled cavity formed within a developing ovarian follicle

antrum (of stomach) The lower portion of the stomach

aorta (a-OR-tah) The large vessel that carries blood from the left ventricle

aortic valve A one-way valve that permits the flow of blood from the left ventricle into the aorta during ventricular emptying but prevents the backflow of blood from the aorta into the left ventricle during ventricular relaxation

apoptosis (ā-pop-TŌ-sis) Programmed cell death; deliberate self-destruction of a cell

aquaporin Water channel

aqueous humor (Ā-kwē-us) or (AK-we-us) The clear, watery fluid in the anterior chamber of the eye; provides nourishment for the cornea and lens

arcuate nucleus (ARE-kyou-it') The subcortical brain region housing neurons that secrete appetite-enhancing neuropeptide Y and those that secrete appetite-suppressing melanocortins

aromatase An enzyme that converts testosterone to estrogen outside of the testes

arterioles (ar-TIR-ē-ōlz) The highly muscular, high-resistance vessels that branch from arteries, the caliber of which can be changed to regulate the amount of blood distributed to the various tissues

artery A vessel that carries blood away from the heart

ascending tract A bundle of nerve fibers of similar function that travels up the spinal cord to transmit signals derived from afferent input to the brain

astrocyte A type of glial cell in the brain; major functions include holding the neurons together in proper spatial relationship, inducing the brain capillaries to form tight junctions important in the blood–brain barrier, and enhancing synaptic activity

atmospheric pressure The pressure exerted by the weight of the air in the atmosphere on objects on Earth's surface; equals 760 mm Hg at sea level

ATP See *adenosine triphosphate*

ATPase An enzyme that can split ATP

ATP synthase The mitochondrial enzyme that catalyzes the synthesis of ATP from ADP and inorganic phosphate

atrial natriuretic peptide (ANP) (Ā-trē-al NĀ-tree-ur-eh'tik) A peptide hormone released from the cardiac atria that promotes urinary loss of Na^+

atrioventricular (AV) node (ā'-trē-ō-ven-TRIK-yuh-lur) A small bundle of specialized cardiac cells at the junction of the atria and ventricles that is the only site of electrical contact between the atria and ventricles

atrioventricular (AV) valve A one-way valve that permits the flow of blood from the atrium to the ventricle during filling of the heart but prevents the backflow of blood from the ventricle to the atrium during emptying of the heart

atrium (**atria,** plural) (Ā-tree-um) An upper chamber of the heart that receives blood from the veins and transfers it to the ventricle

atrophy (AH-truh-fē) Decrease in mass of an organ

autoimmune disease Disease characterized by erroneous production of antibodies against one of the body's own tissues

autonomic nervous system The portion of the efferent division of the peripheral nervous system that innervates smooth and cardiac muscle and exocrine glands; subdivided into the sympathetic and the parasympathetic nervous systems

autophagy Selective self-digestion of cell parts such as worn-out organelles by lysosomes

autoregulation The ability of an organ to adjust its own rate of blood flow despite changes in the driving mean arterial blood pressure

autorhythmicity The ability of an excitable cell to rhythmically initiate its own action potentials

AV nodal delay The delay in impulse transmission between the atria and ventricles at the AV node, which allows enough time for the atria to become completely depolarized and contract, emptying their contents into the ventricles, before ventricular depolarization and contraction occur

AV valve See *atrioventricular (AV) valve*

axon A single, elongated tubular extension of a neuron that conducts action potentials away from the cell body; also known as a *nerve fiber*

axon hillock The first portion of a neuronal axon plus the region of the cell body from which the axon leaves; the site of action potential initiation in most neurons

axon terminals The branched endings of a neuronal axon, which release a neurotransmitter that influences target cells in close association with the axon terminals

balance concept The balance between input of a substance through ingestion or metabolic production and its output through excretion or metabolic consumption

baroreceptor reflex An autonomically mediated reflex response that influences the heart and blood vessels to oppose a change in mean arterial blood pressure

baroreceptors Receptors located within the circulatory system that monitor blood pressure

basal ganglia See *basal nuclei*

basal metabolic rate (BMR) (BĀ-sul) The minimal waking rate of internal energy expenditure; the body's "idling speed"

basal nuclei Several masses of gray matter located deep within the white matter of the cerebrum of the brain; play an important inhibitory role in motor control

base A substance that can combine with a free hydrogen ion and remove it from solution

basic electrical rhythm (BER) Self-induced electrical activity of the digestive tract smooth muscle

basilar membrane (BAS-ih-lar) The membrane that forms the floor of the middle compartment of the cochlea and bears the organ of Corti, the sense organ for hearing

basophils (BĀY-sō-fills) White blood cells that synthesize, store, and release histamine, which is important in allergic responses, and heparin, which hastens the removal of fat particles from the blood

BER See *basic electrical rhythm*

beta (β) cells The endocrine pancreatic cells that secrete the hormone insulin

bicarbonate (HCO_3^-) The anion resulting from dissociation of carbonic acid, H_2CO_3

bile An alkaline solution containing bile salts and bilirubin secreted by the liver, stored in the gallbladder, and emptied into the small-intestine lumen

bile salts Cholesterol derivatives secreted in the bile that facilitate fat digestion through their detergent action and facilitate fat absorption through their micellar formation

biliary system (BIL-ē-air'-ē) The bile-producing system, consisting of the liver, gallbladder, and associated ducts

bilirubin (bill-eh-RŪ-bin) A bile pigment that is a waste product derived from the degradation of hemoglobin during the breakdown of old red blood cells

bipolar cells Neurons in the retina on which photoreceptors terminate and which in turn terminate on retinal ganglion cells

blastocyst The developmental stage of the fertilized ovum by the time it is ready to implant; consists of a single-layered sphere of cells encircling a fluid-filled cavity

blood–brain barrier (BBB) Special structural and functional features of the brain capillaries that limit access of materials from the blood into the brain tissue

B lymphocytes (B cells) White blood cells that produce antibodies against specific targets to which they have been exposed

body of the stomach The main, or middle, part of the stomach

body system A collection of organs that perform related functions and interact to accomplish a common activity that is essential for survival of the whole body; for example, the digestive system

bone marrow The soft, highly cellular tissue that fills the internal cavities of bones and is the source of most blood cells

Bowman's capsule The beginning of the tubular component of the kidney's nephron that cups around the glomerulus and collects the glomerular filtrate as it is formed

Boyle's law (boils) At any constant temperature, the pressure exerted by a gas varies inversely with the volume of the gas

brain stem The portion of the brain that is continuous with the spinal cord, serves as an integrating link between the spinal cord and higher brain levels, and controls many life-sustaining processes, such as breathing, circulation, and digestion

bronchioles (BRONG-kē-ōlz) The small, branching airways within the lungs

bronchoconstriction Narrowing of the respiratory airways

bronchodilation Widening of the respiratory airways

brown fat A special type of adipose tissue especially capable of converting the chemical energy from food into heat

brush border The collection of microvilli projecting from the luminal border of epithelial cells lining the digestive tract and kidney tubules

buffer See *chemical buffer system*

bulbourethral glands (bul-bō-you-RĒTH-ral) Male accessory sex glands that secrete mucus for lubrication

bulk flow Movement in bulk of a protein-free plasma across the capillary walls between the blood and surrounding interstitial fluid; encompasses ultrafiltration and reabsorption

bundle of His (hiss) A tract of specialized cardiac cells that rapidly transmits an action potential down the interventricular septum of the heart

C cells The thyroid cells that secrete calcitonin

calcitonin (kal′-suh-TŌ-nun) A hormone secreted by the thyroid C cells that lowers plasma Ca^{2+} levels

calcium balance Maintenance of a constant total amount of Ca^{2+} in the body; accomplished by slowly responding adjustments in intestinal Ca^{2+} absorption and in urinary Ca^{2+} excretion

calcium homeostasis Maintenance of a constant free plasma Ca^{2+} concentration, accomplished by rapid exchanges of Ca^{2+} between the bone and ECF and, to a lesser extent, by modifications in urinary Ca^{2+} excretion

calcium-induced calcium release When in cardiac muscle cells the excitation-induced entry of a small amount of Ca^{2+} from the ECF through voltage-gated surface membrane receptors triggers the opening of Ca^{2+}-release channels in the sarcoplasmic reticulum, causing a much larger release of Ca^{2+} into the cytosol from this intracellular store

calmodulin (kal′-MA-jew-lin) An intracellular Ca^{2+} binding protein that, on activation by Ca^{2+}, induces a change in structure and function of another intracellular protein; especially important in smooth muscle excitation–contraction coupling

cAMP See *cyclic adenosine monophosphate*

CAMs See *cell adhesion molecules*

capillaries The thin-walled, pore-lined smallest of blood vessels, across which exchange between the blood and surrounding tissues takes place

carbonic anhydrase (an-HĪ-drās) The enzyme found in erythrocytes, kidney tubular cells, and a few other specialized cells that catalyzes the direct conversion of CO_2 and H_2O into H^+ and HCO_3^-

cardiac cycle One period of systole and diastole

cardiac muscle The specialized muscle found only in the heart

cardiac output (CO) The volume of blood pumped by each ventricle each minute; cardiac output = stroke volume × heart rate

cardiovascular control center The integrating center located in the medulla of the brain stem that controls mean arterial blood pressure

carrier-mediated transport Transport of a substance across the plasma membrane facilitated by a carrier molecule

carrier molecules Membrane proteins that, by undergoing reversible changes in shape so that specific binding sites are alternately exposed at either side of the membrane, can bind with and transfer particular substances unable to cross the plasma membrane on their own

cascade A series of sequential reactions that culminates in a final product, such as a clot

catabolism (kuh-TAB-ō-li-zum) The breakdown, or degradation, of large, energy-rich molecules within cells

catalase (KAT-ah-lās) An antioxidant enzyme found in peroxisomes that decomposes potent hydrogen peroxide (H_2O_2) into harmless H_2O and O_2

catecholamines (kat′-uh-KŌ-luh-means) Amine hormones derived from tyrosine and secreted largely by the adrenal medulla

cations (KAT-i-onz) Positively charged ions that have lost one or more electrons from their outer shell

CatSper channels Ca^{2+}-permeable channels found exclusively in the plasma membrane of sperm tails, which when opened in response to egg-released progesterone permit Ca^{2+} entry that triggers hyperactivated motility of sperm

CCK See *cholecystokinin*

cell The smallest unit capable of carrying out the processes associated with life; the basic unit of both structure and function in living organisms

cell adhesion molecules (CAMs) Proteins that protrude from the surface of the plasma membrane and form loops or other appendages that the cells use to grip one another and the surrounding connective tissue fibers

cell body The portion of a neuron that houses the nucleus and organelles

cell-mediated immunity A specific immune response accomplished by activated T lymphocytes, which directly attack unwanted cells

cellular respiration The entire series of chemical reactions involving the intracellular breakdown of nutrient-rich molecules to yield energy, using O_2 and producing CO_2 in the process

center A functional collection of cell bodies within the central nervous system

central chemoreceptors (kē-mō-rē-SEP-turz) Receptors located in the medulla near the respiratory center that respond to changes in ECF H^+ concentration resulting from changes in arterial P_{CO_2} and adjust respiration accordingly

central lacteal (LAK-tē-ul) The initial lymphatic vessel that supplies each of the small-intestinal villi

central nervous system (CNS) The brain and spinal cord

central sulcus (SUL-kus) A deep infolding of the brain surface that runs roughly down the middle of the lateral surface of each cerebral hemisphere and separates the parietal and frontal lobes

centrioles (SEN-trē-ōlz) A pair of short, cylindrical structures within a cell that form the mitotic spindle during cell division

centrosome The cell's microtubule organizing center located near the nucleus and consisting of the pair of centrioles surrounded by an amorphous mass of proteins; also called the *cell center*

cerebellum (ser′-uh-BEL-um) The part of the brain attached at the rear of the brain stem and concerned with maintaining proper position of the body in space and subconscious coordination of motor activity

cerebral cortex The outer shell of gray matter in the cerebrum; site of initiation of all voluntary motor output and final perceptual processing of all sensory input as well as integration of most higher neural activity

cerebral hemispheres The cerebrum's two halves, which are connected by a thick band of neuronal axons

cerebrospinal fluid (CSF) (ser′-uh-brō-SPĪ-nul) or (sah-REE-brō-SPĪ-nul) A special cushioning fluid that is produced by, surrounds, and flows through the central nervous system

cerebrum (SER-uh-brum) or (sah-REE-brum) The division of the brain that consists of the basal nuclei and cerebral cortex

channels Small, water-filled passageways through the plasma membrane; formed by membrane proteins that span the membrane and provide highly selective passage for small water-soluble substances such as ions

chemical bonds The forces holding atoms together

chemical buffer system A mixture in a solution of two or more chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution

chemically gated channels Channels in the plasma membrane that open or close in response to the binding of a specific chemical messenger with a membrane receptor site that is in close association with the channel

chemical mediator A chemical secreted by a cell that influences an activity outside the cell

chemical synapse The most abundant type of junction between two neurons in which an action potential in a presynaptic neuron alters the postsynaptic neuron's potential by means of a chemical messenger, a neurotransmitter

chemiosmosis (kē-ma-OS-mō-sis) ATP production in mitochondria catalyzed by ATP synthase, which is activated by flow of H^+ down a concentration gradient established by the electron transport system

chemoreceptor (kē-mō-rē-sep′-tur) A sensory receptor sensitive to specific chemicals

chemotaxin (kē-mō-TAK-sin) A chemical released at an inflammatory site that attracts phagocytes to the area

chief cells The cells in the gastric pits that secrete pepsinogen

cholecystokinin (CCK) (kō′-luh-sis-tuh-kī-nun) A hormone released from the duodenal mucosa primarily in response to the presence of fat; inhibits gastric motility and secretion, stimulates pancreatic enzyme secretion, stimulates gallbladder contraction, and acts as a satiety signal

cholesterol A type of fat molecule that serves as a precursor for steroid hormones and bile salts and is a stabilizing component of the plasma membrane

cholinergic fibers (kō′-lin-ER-jik) Nerve fibers that release acetylcholine as their neurotransmitter

chromaffin granules The granules that store catecholamines in adrenomedullary cells

chyme (kim) A thick liquid mixture of food and digestive juices

cilia (SILL-ē-ah) Motile, hairlike protrusions from the surface of cells lining the respiratory airways and the oviducts

ciliary body The portion of the eye that produces aqueous humor and contains the ciliary muscle

ciliary muscle A circular ring of smooth muscle within the eye whose contraction increases the strength of the lens to accommodate for near vision

circadian rhythm (sir-KĀ-dē-un) Repetitive oscillations in the set point of various body activities, such as hormone levels and body temperature, that are very regular and have a frequency of one cycle every 24 hours, usually linked to light–dark cycles; diurnal rhythm; biological rhythm

circulatory shock When mean arterial blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained

citric acid cycle A cyclic series of biochemical reactions that processes the intermediate breakdown products of nutrient molecules, generating carbon dioxide and preparing hydrogen carrier molecules for entry into the high-energy-yielding electron transport system

clot a mass of activated fibrin threadlike molecules that form a netlike meshwork that traps blood cells, thereby transforming blood in the vicinity from a flowing liquid into a nonflowing gel

CNS See *central nervous system*

cochlea (KOK-lē-uh) The snail-shaped portion of the inner ear that houses the receptors for sound

cognition The act of "knowing," including both awareness and judgment

collecting tubule The last portion of tubule in the kidney's nephron that empties into the renal pelvis

colloid (KOL-oid) The thyroglobulin-containing substance enclosed within the thyroid follicles

colloid osmotic pressure The osmotic force across the capillary wall resulting from the uneven colloidal dispersion of plasma proteins between the blood and interstitial fluid

competition When several closely related substances compete for the same carrier binding sites

complement system A collection of plasma proteins that are activated in cascade fashion on exposure to invading microorganisms, ultimately producing a membrane attack complex that destroys the invaders

compliance The distensibility of a hollow, elastic structure, such as a blood vessel or the lungs; a measure of how easily the structure can be stretched

concave surface Curved in, as a surface of a lens that diverges light rays

concentration gradient A difference in concentration of a particular substance between two adjacent areas

conditioned reflex A reflex response that occurs as a result of learning; also called *acquired reflex*

conduction The transfer of heat between objects of differing temperature that are in direct contact

cones The eye's photoreceptors used for color vision in the light

connective tissue Tissue that serves to connect, support, and anchor various body parts; distinguished by relatively few cells dispersed within an abundance of extracellular material

contiguous conduction The means by which an action potential is propagated throughout a nonmyelinated nerve fiber; local current flow between an active and adjacent inactive area brings the inactive area to threshold, triggering an action potential in a previously inactive area

contractility (of heart) The strength of contraction of the heart at any given end-diastolic volume

control center See *integrator*

controlled variable Some factor that can vary but is held within a narrow range by a control system

convection Transfer of heat energy by air or water currents

convergence The converging of many presynaptic terminals from thousands of other neurons on a single neuronal cell body and its dendrites so that activity in the single neuron is influenced by the activity of many other neurons

convex surface Curved out, as a surface in a lens that converges light rays

core temperature The temperature within the inner core of the body (abdominal and thoracic organs, central nervous system, and skeletal muscles) that is homeostatically maintained at about 100°F

cornea (KOR-nē-ah) The clear, anteriormost outer layer of the eye through which light rays pass to the interior of the eye

coronary circulation The blood vessels that supply the heart muscle

corpus callosum (ka-LŌ-sum) The thick band of nerve fibers that connects the two cerebral hemispheres structurally and functionally

corpus luteum (LOO-tē-um) The ovarian structure that develops from a ruptured follicle after ovulation

cortical nephrons The most abundant type of nephrons, whose glomeruli lie in the outer layer of the renal cortex and whose short loops of Henle dip only slightly into the renal medulla

corticotropes Anterior pituitary cells that secrete adrenocorticotropic hormone

cortisol (KORT-uh-sol) The adrenocortical hormone that plays an important role in carbohydrate, protein, and fat metabolism and helps the body resist stress

cotransport See *symport*

countercurrent multiplication The means by which long loops of Henle establish the vertical osmotic gradient in the renal medulla, making it possible to put out urine of variable concentration depending on the body's needs

countertransport See *antiport*

cranial nerves The 12 pairs of peripheral nerves, most of which arise from the brain stem

cross bridges The myosin molecules' globular heads that protrude from a thick filament within a muscle fiber and interact with the actin molecules in the thin filaments to bring about shortening of the muscle fiber during contraction

CSF See *cerebrospinal fluid*

current The flow of electrical charge, such as by movement of positive charges toward a more negatively charged area

cyclic adenosine monophosphate (cyclic AMP or cAMP) An intracellular second messenger derived from ATP

cyclic guanosine monophosphate (cyclic GMP or cGMP) An intracellular second messenger similar to cAMP

cytokines Protein signal molecules secreted by immune and other cells that largely act locally to regulate immune responses

cytoplasm (SĪ-tō-plaz′-um) The portion of the cell interior not occupied by the nucleus

cytoskeleton The complex intracellular protein network that acts as the "bone and muscle" of the cell

cytosol (SĪ-tuh-sol′) The semiliquid portion of the cytoplasm not occupied by organelles

cytotoxic T cells (sī-tō-TOK-sik) The population of T cells that destroys host cells bearing foreign antigen, such as body cells invaded by viruses or cancer cells

DAG See *diacylglycerol*

dead-space volume The volume of air that occupies the respiratory airways as air is moved in and out and that is not available to participate in exchange of O_2 and CO_2 between the alveoli and atmosphere

dehydration A water deficit in the body

dehydroepiandrosterone (DHEA) (dē-HĪ-drō-epi-and-ro-steer-own) The androgen secreted by the adrenal cortex in both sexes

dendrites Projections from the surface of a neuron's cell body that carry signals toward the cell body

deoxyribonucleic acid (DNA) (dē-OK-sē-rī-bō-new-klā-ik) The cell's genetic material, which is found within the nucleus and provides codes for protein synthesis and serves as a blueprint for cell replication

depolarization (de′-pō-luh-ruh-ZĀ-shun) A reduction in membrane potential from resting potential; movement of the potential from resting toward 0 mV

dermis The connective tissue layer that lies under the epidermis in the skin; contains the skin's blood vessels and nerves

descending tract A bundle of nerve fibers of similar function that travels down the spinal cord to relay messages from the brain to efferent neurons

desmosome (dez′-muh-sōm) An adhering junction between two adjacent but nontouching cells formed by the extension of filaments between the cells' plasma membranes; most abundant in tissues that are subject to considerable stretching

DHEA See *dehydroepiandrosterone*

diacylglycerol (DAG) (die-ACE-sul-gli-sir-all) A component cleaved from phosphatidylinositol bisphosphate (PIP$_2$) in the plasma membrane that serves as a second messenger in response to binding of an extracellular (first) messenger with a G-protein-coupled receptor

diaphragm (DIE-uh-fram) A dome-shaped sheet of skeletal muscle that forms the floor of the thoracic cavity; the major inspiratory muscle

diastole (dī-AS-tō-lē) The period of cardiac relaxation and filling

diencephalon (dī′-un-SEF-uh-lan) The division of the brain that consists of the thalamus and hypothalamus

differentiation The process of each type of cell becoming specialized during development of a multicellular organism to carry out a particular function

diffusion Random collisions and intermingling of molecules as a result of their continuous thermally induced random motion

digestion The process by which the structurally complex foodstuffs of the diet are broken down into smaller absorbable units by the enzymes produced within the digestive system

dihydropyridine receptors (die-HIGH-dro-PEER-ih-deen) Voltage-gated receptors on the T tubules that trigger the opening of adjoining ryanodine receptors on the sarcoplasmic reticulum during excitation–contraction coupling

diploid number (DIP-loid) A complete set of 46 chromosomes (23 pairs), as found in all human somatic cells

discriminative ability See *acuity*

distal tubule A highly convoluted tubule that extends between the loop of Henle and the collecting duct in the kidney's nephron

diurnal rhythm (dī-URN′-ul) Repetitive oscillations in hormone levels that are very regular and have a frequency of one cycle every 24 hours, usually linked to the light–dark cycle; circadian rhythm; biological rhythm

divergence The diverging, or branching, of a neuron's axon terminals so that activity in this single neuron influences the many other cells with which its terminals synapse

DNA See *deoxyribonucleic acid*

dorsal root ganglion A cluster of afferent neuronal cell bodies located adjacent to the spinal cord

down regulation A reduction in the number of receptors for (and thereby the target cell's sensitivity to) a particular hormone as a direct result of the effect that an elevated level of the hormone has on its receptors

dynamic equilibrium When two opposing passive movements exactly counterbalance each other so that no net movement takes place, with no energy needed to maintain this constancy

dynein (DIE-neen) The motor protein that "walks" along microtubular "highways" toward the cell center, such as in transporting debris from the axon terminal to the cell body for destruction by lysosomes

ECG See *electrocardiogram*

ECM See *extracellular matrix*

edema (i-DĒ-muh) Swelling of tissues as a result of excess interstitial fluid

EDV See *end-diastolic volume*

EEG See *electroencephalogram*

effector The component of a control system that accomplishes the output commanded by the integrator

effector organs The muscles or glands innervated by the nervous system that carry out the nervous system's orders to bring about a desired effect, such as a particular movement or secretion

efferent division (EF-er-ent) The portion of the peripheral nervous system that carries instructions from the central nervous system to effector organs

efferent neuron Neuron that carries information from the central nervous system to an effector organ

efflux (Ē-flux) Movement out of the cell

eicosanoids (ī-KŌ-sa-noydz) A group of lipid signal molecules derived from arachidonic acid in the phospholipid tails of the plasma membrane, including the prostaglandins, prostacyclins, thromboxanes, and leukotrienes, that act locally to regulate diverse cellular processes throughout the body

elastic recoil Rebound of the lungs after having been stretched

electrical gradient A difference in charge between two adjacent areas

electrical synapse The least common type of junction between two neurons in which an action potential in a presynaptic neuron spreads directly to the postsynaptic neuron via gap junctions

electrocardiogram (ECG) The graphic record of the electrical activity that reaches the surface of the body as a result of cardiac depolarization and repolarization

electrochemical gradient The simultaneous existence of an electrical gradient and concentration (chemical) gradient for a particular ion

electroencephalogram (EEG) (i-lek′-trō-in-SEF-uh-luh-gram′) A graphic record of the collective postsynaptic potential activity in the cell bodies and dendrites located in the cortical layers of the brain under a recording electrode

electrolytes Solutes that form ions in solution and conduct electricity

electron transport system The series of electron carriers in the mitochondrial inner membrane that transfer electrons from higher to lower energy levels, with the released energy being used to establish the H$^+$ concentration gradient in the mitochondria that powers ATP synthesis

embolus (EM-bō-lus) A freely floating clot

embryo The product of fertilization during the first two months of intrauterine life when tissue differentiation is taking place

embryonic stem cells (ESCs) Undifferentiated cells resulting from the early divisions of a fertilized egg that ultimately give rise to all the mature, specialized cells of the body while at the same time renewing themselves

end-diastolic volume (EDV) The volume of blood in the ventricle at the end of diastole, when filling is complete

endocrine axis A three-hormone sequence consisting of (1) a hypothalamic hypophysiotropic hormone that controls the output of (2) an anterior pituitary tropic hormone that regulates secretion of (3) a target endocrine gland hormone, which exerts the final physiological effect

endocrine glands Ductless glands that secrete hormones into the blood

endocytic vesicle A small, intracellular, membrane-enclosed vesicle in which extracellular material is trapped

endocytosis (en′-dō-sī-TŌ-sis) Internalization of extracellular material within a cell as a result of the plasma membrane forming a pouch that contains the extracellular material, then sealing at the surface of the pouch to form an endocytic vesicle

endogenous opiates (en-DAJ′-eh-nus Ō′-pē-ātz) Endorphins and enkephalins, which bind with opiate receptors and are important in the body's natural analgesic system

endogenous pyrogen (pī′-ruh-jun) A chemical released from macrophages during inflammation that acts by means of local prostaglandins to raise the set point of the hypothalamic thermostat to produce a fever

endolymph The fluid within the cochlear duct and vestibular organs in the inner ear

endometrium (en′-dō-MĒ-trē-um) The lining of the uterus

endoplasmic reticulum (ER) (en′-dō-PLAZ-mik ri-TIK-yuh-lum) An organelle consisting of a continuous membranous network of fluid-filled tubules (smooth ER) and flattened sacs, partially studded with ribosomes (rough ER); synthesizes proteins and lipids for formation of new cell membrane and manufactures products for secretion

endothelium (en′-dō-THĒ-lē-um) The thin, single-celled layer of epithelial cells lining the entire circulatory system

end-plate potential (EPP) The graded receptor potential that occurs at the motor end plate of a skeletal muscle fiber in response to binding with acetylcholine

end-systolic volume (ESV) The volume of blood in the ventricle at the end of systole, when emptying is complete

endurance-type exercise See *aerobic exercise*

energy balance The balance between energy input by means of food intake and energy output by means of external work and internal work

enteric nervous system The extensive network of nerve fibers consisting of the myenteric plexus and submucous plexus within the digestive tract wall that endows the tract with considerable self-regulation

enterogastrones (ent′-uh-rō-GAS-trōnz) Hormones secreted by the duodenal mucosa that inhibit gastric motility and secretion; include secretin and cholecystokinin

enterohepatic circulation (en′-tur-ō-hi-PAT-ik) The recycling of bile salts and other bile constituents between the small intestine and liver by means of the hepatic portal vein

enzyme A special protein molecule that speeds up a particular chemical reaction in the body

eosinophils (ē′-uh-SIN-uh-fils) White blood cells that are important in allergic responses and in combating internal parasite infestations

ependymal cells (eh-PEN-dim-ul) The glial cells lining the ventricles of the brain, which serve as neural stem cells

epidermis (ep′-uh-DER-mus) The outer layer of the skin, consisting of numerous layers of epithelial cells, with the outermost layers being dead and flattened

epididymis The male accessory reproductive organ that stores sperm and increases their motility and fertility before ejaculation

epigenetics Environmentally induced modifications of gene activity that do not alter the gene's DNA code

epinephrine (ep′-uh-NEF-rin) The primary hormone secreted by the adrenal medulla; important in preparing the body for "fight-or-flight" responses and in regulating arterial blood pressure; adrenaline

epiphyseal plate (eh-pif-i-SĒ-al) A layer of cartilage that separates the diaphysis (shaft) of a long bone from the epiphysis (flared end); the site at which bones grow longer before the cartilage ossifies (turns into bone)

epithelial tissue (ep′-uh-THĒ-lē-ul) A functional grouping of cells specialized in the exchange of materials between the cell and its environment; lines and covers various body surfaces and cavities and forms secretory glands

EPSP See *excitatory postsynaptic potential*

equilibrium The sense of body orientation and motion

equilibrium potential (E_x) The potential that exists when the concentration gradient and opposing electrical gradient for a given ion exactly counterbalance each other so that there is no net movement of the ion

erythrocytes (i-RITH-ruh-sīts) Red blood cells, which are plasma membrane–enclosed bags of hemoglobin that transport O_2 and, to a lesser extent, CO_2 and H^+ in the blood; RBCs

erythropoiesis (i-rith′-rō-poi-Ē-sus) Erythrocyte production by the bone marrow

erythropoietin The hormone released from the kidneys in response to a reduction in O_2 delivery to the kidneys; stimulates the bone marrow to increase erythrocyte production

ESCs See *embryonic stem cells*

esophagus (i-SOF-uh-gus) A straight muscular tube that extends between the pharynx and stomach

estrogen Feminizing "female" sex hormone

ESV See *end-systolic volume*

evaporation The transfer of heat from the body surface by the transformation of water from a liquid to a gaseous state

exchange See *antiport*

excitable tissue Tissue capable of producing electrical signals when excited; includes nervous and muscle tissue

excitation–contraction coupling The series of events linking muscle excitation (the presence of an action potential) to muscle contraction (filament sliding and sarcomere shortening)

excitatory postsynaptic potential (EPSP) (pōst′-si-NAP-tik) A small depolarization of the postsynaptic membrane in response to neurotransmitter binding, bringing the membrane closer to threshold

excitatory synapse (SIN-aps′) Synapse in which the postsynaptic neuron's response to neurotransmitter release is a small depolarization of the postsynaptic membrane, bringing the membrane closer to threshold

exercise physiology The study of both the functional changes that occur in response to a single session of exercise and the adaptations that result from regular, repeated exercise sessions

exocrine glands Glands that secrete through ducts to the outside of the body or into a cavity that communicates with the outside

exocytosis (eks′-Ō-sī-TŌ-sis) Fusion of a membrane-enclosed intracellular vesicle with the plasma membrane, followed by the opening of the vesicle and the emptying of its contents to the outside

expiration A breath out

expiratory muscles The skeletal muscles whose contraction reduces the size of the thoracic cavity and lets the lungs recoil to a smaller size, bringing about movement of air from the lungs to the atmosphere

external environment The environment surrounding the body

external genitalia The externally visible portions of the reproductive system

external intercostal muscles Inspiratory muscles whose contraction elevates the ribs, thereby enlarging the thoracic cavity

external work Energy expended by contracting skeletal muscles to move external objects or to move the body in relation to the environment

extracellular fluid (ECF) All the fluid outside the cells of the body; consists of interstitial fluid and plasma

extracellular matrix (ECM) An intricate meshwork of fibrous proteins embedded in the interstitial fluid secreted by local cells

extrinsic controls Regulatory mechanisms initiated outside an organ that alter the activity of the organ; accomplished by the nervous and endocrine systems

extrinsic nerves The nerves originating outside the digestive tract that innervate the various digestive organs

facilitated diffusion Passive carrier-mediated transport involving transport of a substance down its concentration gradient across the plasma membrane

fatigue Inability to maintain muscle tension at a given level despite sustained stimulation

feedback A response that occurs after a change has been detected; may be *negative feedback* or *positive feedback*

feedforward A response designed to prevent an anticipated change in a controlled variable

feeding signals Appetite signals that give rise to the sensation of hunger and promote the desire to eat

fetus The product of fertilization during the last 7 months of gestation when differentiation is complete and tremendous growth and maturation occur

fibrinogen (fi-BRIN-uh-jun) A large, soluble plasma protein that when converted into an insoluble, threadlike molecule forms the meshwork of a clot during blood coagulation

Fick's law of diffusion The rate of net diffusion of a substance across a membrane is directly proportional to the substance's concentration gradient, the lipid solubility of the substance, and the surface area of the membrane and inversely proportional to the substance's molecular weight and the diffusion distance

fight-or-flight response The changes in activity of the various organs innervated by the autonomic nervous system in response to sympathetic stimulation, which collectively prepare the body for strenuous physical activity in the face of an emergency or stressful situation, such as a physical threat from the outside environment

firing When an excitable cell undergoes an action potential

first messenger An extracellular messenger, such as a hormone, that binds with a surface membrane receptor and activates an intracellular second messenger to carry out the desired cellular response

flagellum (fluh-JEL-um) The single, long, whip-like appendage that serves as the tail of a spermatozoon

flow rate (of blood or air) The volume of blood or air passing through a blood vessel or airway, respectively, per unit of time

fluid balance Maintenance of ECF volume (for long-term control of blood pressure) and ECF osmolarity (for maintaining normal cell volume)

follicle (of ovary) A developing ovum and the surrounding specialized cells

follicle-stimulating hormone (FSH) An anterior pituitary hormone that stimulates ovarian follicular development and estrogen secretion in females and stimulates sperm production in males

follicular cells (of ovary) (fah-LIK-you-lar) Collectively, the granulosa and thecal cells

follicular cells (of thyroid gland) The cells that form the walls of the colloid-filled follicles in the thyroid gland and secrete thyroid hormone

follicular phase The phase of the ovarian cycle dominated by the presence of maturing antral follicles before ovulation

Frank–Starling law of the heart Intrinsic control of the heart such that increased venous return resulting in increased end-diastolic volume leads to an increased strength of contraction and increased stroke volume; that is, the heart normally pumps out all the blood returned to it

free radicals Very unstable electron-deficient particles that are highly reactive and destructive

frontal lobes The lobes of the cerebral cortex at the top of the brain in front of the central sulcus, which are responsible for voluntary motor output, speaking ability, and elaboration of thought

FSH See *follicle-stimulating hormone*

fuel metabolism See *intermediary metabolism*

functional syncytium (sin-sish′-ē-um) A group of smooth or cardiac muscle cells that are interconnected by gap junctions and function electrically and mechanically as a single unit

functional unit The smallest component of an organ that can perform all the functions of the organ

gametes (GAM-ētz) Reproductive, or germ, cells, each containing a haploid set of chromosomes; sperm and ova

gamma motor neuron A motor neuron that innervates the fibers of a muscle–spindle receptor

ganglion (GAN-glē-un) A collection of neuronal cell bodies located outside the central nervous system

ganglion cells The nerve cells in the outermost layer of the retina whose axons form the optic nerve

gap junction A communicating junction formed between adjacent cells by small connecting tunnels that permit passage of charge-carrying ions between the cells so that electrical activity in one cell is spread to the adjacent cell

gastrin A hormone secreted by the pyloric gland area of the stomach that stimulates the parietal and chief cells to secrete a highly acidic gastric juice

gastrointestinal hormone Hormones secreted into the blood by the endocrine cells in the digestive tract mucosa that control motility and secretion in other parts of the digestive system

gene expression The multistep process by which information encoded in a gene is used to direct synthesis of a protein

genome All of the genetic information coded in a complete single set of DNA in a typical body cell

gestation Pregnancy

ghrelin (GRELL-in) The "hunger" hormone, a potent appetite stimulator secreted by the empty stomach

glands Epithelial tissue derivatives that are specialized for secretion

glial cells (glē-ul) Connective tissue cells of the CNS, which support the neurons both physically and metabolically, including astrocytes, oligodendrocytes, ependymal cells, and microglia

gliotransmitters Chemical mediators released from glial cells that influence neurons and other glial cells

glomerular filtration (glow-MAIR-yū-lur) Filtration of a protein-free plasma from the glomerular capillaries into the tubular component of the kidney's nephron as the first step in urine formation

glomerular filtration rate (GFR) The rate at which glomerular filtrate is formed

glomerulus (in kidney) (glow-MAIR-yū-lus) A ball-like tuft of capillaries in the kidney's nephron that filters water and solute from the blood as the first step in urine formation

glomerulus (in olfactory bulb) A ball-like neural junction within the olfactory bulb that serves as a "smell file" sorting different scent components

glucagon (GLOO-kuh-gon) The pancreatic hormone that raises blood glucose and blood fatty-acid levels

glucocorticoids (gloo′-kō-KOR-ti-koidz) Adrenocortical hormones that are important in intermediary metabolism and in helping the body resist stress; primarily cortisol

gluconeogenesis (gloo′-kō-nē-ō-JEN-uh-sus) The conversion of amino acids into glucose

glycogen (GLĪ-kō-jen) The storage form of glucose in the liver and muscle

glycogenesis (glī′-kō-JEN-i-sus) The conversion of glucose into glycogen

glycogenolysis (glī′-kō-juh-NOL-i-sus) The conversion of glycogen to glucose

glycolysis (glĪ-KOL-uh-sus) A biochemical process taking place in the cell's cytosol that breaks down glucose into pyruvate molecules

GnRH See *gonadotropin-releasing hormone*

Golgi complex (GOL-jē) An organelle consisting of sets of stacked, flattened membranous sacs; processes raw materials transported to it from the endoplasmic reticulum into finished products and sorts and directs the finished products to their final destination

gonadotropes Anterior pituitary cells that secrete gonadotropin-releasing hormone

gonadotropin-releasing hormone (GnRH) (gō-nad′-uh-TRŌ-pin) The hypothalamic hormone that stimulates the release of FSH and LH from the anterior pituitary

gonadotropins FSH and LH; hormones that control secretion of the sex hormones by the gonads

gonads (GŌ-nadz) The primary reproductive organs, which produce the gametes and secrete the sex hormones; testes and ovaries

G protein A membrane-bound intermediary, which, when activated on binding of an extracellular first messenger to a surface receptor, activates effector proteins on the intracellular side of the membrane in the cAMP second-messenger system

G-protein-coupled receptor (GPCR) A type of receptor that activates the associated G protein on binding with an extracellular chemical messenger

gradation of contraction Variable magnitudes of tension produced in a single whole muscle

graded potential A local change in membrane potential that occurs in varying grades of magnitude; serves as a short-distance signal in excitable tissues

grand postsynaptic potential (GPSP) The total composite potential in a postsynaptic neuron resulting from the sum of all EPSPs and IPSPs occurring at the same time

granulocytes (gran′-yuh-lō-sīts) Leukocytes that contain granules, including neutrophils, eosinophils, and basophils

granulosa cells (gran′-yuh-LŌ-suh) The layer of cells immediately surrounding a developing oocyte within an ovarian follicle

gray matter The portion of the central nervous system composed primarily of densely packaged neuronal cell bodies and dendrites

growth factors Cytokines important in development

growth hormone (GH) An anterior pituitary hormone that is primarily responsible for regulating overall body growth and is also important in intermediary metabolism; somatotropin

H⁺ See *hydrogen ion*

haploid number (HAP-loid) The number of chromosomes found in gametes; a half set of chromosomes, one member of each pair, for a total of 23 chromosomes in humans

Hb See *hemoglobin*

hCG See *human chorionic gonadotropin*

helper T cells The population of T cells that enhances the activity of other immune-response effector cells

hematocrit (hi-MAT′-uh-krit) The percentage of blood volume occupied by erythrocytes as they are packed down in a centrifuged blood sample

hemoglobin (Hb) (HĒ-muh-glō′-bun) A large iron-bearing protein molecule in erythrocytes that binds with and transports most O_2 in the blood; also carries some of the CO_2 and H^+ in the blood

hemolysis (hē-MOL-uh-sus) Rupture of red blood cells

hemostasis (hē′-mō-STĀ-sus) The stopping of bleeding from an injured vessel

hepatic portal system (hi-PAT-ik) A complex vascular connection between the digestive tract and liver such that venous blood from the digestive system drains into the liver for processing of absorbed nutrients before being returned to the heart

hippocampus (hip-ō-CAM-pus) The elongated, medial portion of the temporal lobe that is a part of the limbic system and is especially crucial for forming long-term memories

histamine A chemical released from mast cells or basophils that brings about vasodilation and increased capillary permeability; important in allergic responses and inflammation

homeostasis (hō′-mē-ō-STĀ-sus) Maintenance by the highly coordinated, regulated actions of the body systems of relatively stable chemical and physical conditions in the internal fluid environment that bathes the body cells

homeostatic control system A regulatory system that includes a sensor, integrator, and effectors that work together to bring about a corrective adjustment that opposes an original deviation from a normal set point

hormone A long-distance chemical mediator secreted by an endocrine gland into the blood, which transports it to its target cells

hormone response element (HRE) The specific attachment site on DNA for a given steroid hormone and its nuclear receptor

host cell A body cell infected by a virus

HRE See *hormone response element*

human chorionic gonadotropin (hCG) (kō-rē-ON-ik gō-nad′-uh-TRŌ-pin) A hormone secreted by the developing placenta that stimulates and maintains the corpus luteum of pregnancy

hydrogen ion (H⁺) The cationic portion of a dissociated acid

hydrolysis (hĪ-DROL-uh-sis) The digestion of a nutrient molecule by the addition of water at a bond site

hydrostatic (fluid) pressure (hī-drō-STAT-ik) The pressure exerted by fluid on the walls that contain it

hyperglycemia (hī′-pur-glĪ-SĒ-mē-uh) Elevated blood glucose concentration

hyperplasia (hī-pur-PLĀ-zē-uh) An increase in the number of cells

hyperpolarization An increase in membrane potential from resting potential; potential becomes even more negative than at resting potential

hypersecretion Too much of a particular hormone secreted

hypertension (hī′-pur-TEN-chun) Sustained, above-normal mean arterial blood pressure

hypertonic solution (hī′-pur-TON-ik) A solution with osmolarity greater than that of normal body fluids; more concentrated than normal

hypertrophy (hī-PUR-truh-fē) Increase in the size of an organ as a result of an increase in the size of its cells

hyperventilation Overbreathing; when the rate of ventilation is in excess of the body's metabolic needs for CO_2 removal

hypophysiotropic hormones (hi-PŌ-fiz-ē-ō-TRŌ-pik) Hormones secreted by the hypothalamus that regulate the secretion of anterior pituitary hormones; see also *releasing hormone* and *inhibiting hormone*

hyposecretion Too little of a particular hormone secreted

hypotension (hī-pō-TEN-chun) Sustained, below-normal mean arterial blood pressure

hypothalamic–hypophyseal portal system (hī-pō-thuh-LAM-ik hĪ-pō-FIZ-ē-ul) The vascular connection between the hypothalamus and anterior pituitary gland used for the pickup and delivery of hypophysiotropic hormones

hypothalamus (hī′-pō-THAL-uh-mus) The brain region beneath the thalamus that regulates many aspects of the internal fluid environment, such as water and salt balance and food intake; serves as an important link between the autonomic nervous system and endocrine system

hypotonic solution (hī′-pō-TON-ik) A solution with osmolarity less than that of normal body fluids; more dilute than normal

hypoventilation Underbreathing; ventilation inadequate to meet the metabolic needs for O_2 delivery and CO_2 removal

hypoxia (hī-POK-sē-uh) Insufficient O_2 at the cellular level

I band One of the light bands that alternate with dark (A) bands to create a striated appearance in a skeletal or cardiac muscle fiber when these fibers are viewed with a light microscope

ICF See *intracellular fluid*

IGF See *insulin-like growth factor*

immune surveillance Recognition and destruction of newly arisen cancer cells by the immune system

immunity The body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells

immunoglobulins (im′-ū-nō-GLOB-yū-lunz) Antibodies; gamma globulins

impermeable Prohibiting passage of a particular substance through the plasma membrane

implantation The burrowing of a blastocyst into the endometrial lining

inclusion A nonpermanent mass of stored material, such as glycogen or triglycerides (fat), in a cell

incretin A hormone released by the digestive tract that stimulates insulin secretion by the pancreas

indoleamine A type of amine hormone derived from the amino acid tryptophan and secreted by the pineal gland

inflammation An innate, nonspecific series of highly interrelated events, especially involving neutrophils, macrophages, and local vascular changes, that are set into motion in response to foreign invasion or tissue damage

influx Movement into the cell

inhibin (in-HIB-un) A hormone secreted by the Sertoli cells of the testes or by the ovarian follicles that inhibits FSH secretion

inhibiting hormone A hypothalamic hormone that inhibits the secretion of a particular anterior pituitary hormone

inhibitory postsynaptic potential (IPSP) (pōst′-si-NAP-tik) A small hyperpolarization of the postsynaptic membrane in response to neurotransmitter binding, thereby moving the membrane farther from threshold

inhibitory synapse (SIN-aps′) Synapse in which the postsynaptic neuron's response to neurotransmitter release is a small hyperpolarization of the postsynaptic membrane, moving the membrane farther from threshold

innate immune responses Inherent defense responses that nonselectively defend against foreign or abnormal material, even on initial exposure to it; see also *inflammation, interferon, natural killer cells,* and *complement system*

innate reflex A built-in, unlearned reflex response

inorganic Referring to substances that do not contain carbon; from nonliving sources

inositol trisphosphate (IP₃) A component cleaved from phosphatidylinositol bisphosphate (PIP₂) in the plasma membrane that mobilizes the Ca^{2+} second-messenger system in response to binding of an extracellular (first) messenger to a G-protein-coupled receptor

insensible loss Loss of water of which the person is not aware from the lungs or nonsweating skin

inspiration A breath in

inspiratory muscles The skeletal muscles whose contraction enlarges the thoracic cavity, bringing about lung expansion and movement of air into the lungs from the atmosphere

insulin (IN-suh-lin) The pancreatic hormone that lowers blood levels of glucose, fatty acids, and amino acids and promotes their storage

insulin-like growth factor (IGF) Synonymous with *somatomedin;* hormone secreted by the liver into the blood on stimulation by growth hormone that acts directly on target cells to promote growth, with other tissues producing IGF that acts locally as a paracrine to promote growth

integral protein A plasma-membrane protein that extends through the thickness of the membrane

integrator A region that determines efferent output based on processing of afferent input; also called a *control center*

integument (in-TEG-yuh-munt) The skin and underlying connective tissue

intercalated cells Cells in the distal and collecting tubules of the kidney important in renal control of acid–base balance

intercostal muscles (int-ur-KOS-tul) The muscles that lie between the ribs; see also *external intercostal muscles* and *internal intercostal muscles*

interferon (in′-tur-FĒR-on) A chemical released from virus-invaded cells that provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells

intermediary metabolism The collective set of intracellular chemical reactions that involve the degradation, synthesis, and transformation of small nutrient molecules; also known as *fuel metabolism*

intermediate filaments Threadlike cytoskeletal elements that play a structural role in parts of the cells subject to mechanical stress

internal environment The body's aqueous extracellular environment, which consists of the plasma and interstitial fluid and which must be homeostatically maintained for the cells to make life-sustaining exchanges with it

internal intercostal muscles Expiratory muscles whose contraction pulls the ribs downward and inward, thereby reducing the size of the thoracic cavity

internal respiration The intracellular metabolic processes carried out within the mitochondria that use O_2 and produce CO_2 during the derivation of energy from nutrient molecules

internal work All forms of biological energy expenditure that do not accomplish mechanical work outside the body

interneuron Neuron that lies entirely within the central nervous system and is important for integrating peripheral responses to peripheral information as well as for the abstract phenomena associated with the "mind"

interstitial fluid (in′-tur-STISH-ul) The portion of the extracellular fluid that surrounds and bathes all the body cells

intra-alveolar pressure (in′-truh-al-VĒ-uh-lur) The pressure within the alveoli

intracellular fluid (ICF) The fluid collectively contained within all the body cells

intrapleural pressure (in′-truh-PLOOR-ul) The pressure within the pleural sac

intrinsic controls Local control mechanisms inherent to an organ

intrinsic factor A special substance secreted by the parietal cells of the stomach that must be combined with vitamin B_{12} for this vitamin to be absorbed by the intestine; deficiency produces pernicious anemia

intrinsic nerve plexuses Interconnecting networks of nerve fibers within the digestive tract wall

involuntary muscle Muscle innervated by the autonomic nervous system and not subject to voluntary control; cardiac and smooth muscle

ion An atom that has gained or lost one or more of its electrons, so it is not electrically balanced

IP₃ See *inositol trisphosphate*

IPSP See *inhibitory postsynaptic potential*

iris A pigmented smooth muscle that forms the colored portion of the eye and controls pupillary size

islets of Langerhans (LAHNG-er-honz) The endocrine portion of the pancreas that secretes the hormones insulin and glucagon into the blood

isometric contraction (ī′-sō-MET-rik) A muscle contraction in which muscle tension develops at constant muscle length

isotonic contraction A muscle contraction in which muscle tension remains constant as the muscle fiber changes length

isotonic solution (ī′-sō-TON-ik) A solution with osmolarity equal to that of normal body fluids

janus kinase (JAK) An enzyme attached to the cytosolic side of a surface-membrane receptor for several specific hormones; binding of the hormone to the receptor activates the JAK enzymes, which phosphorylate STAT that turns on gene transcription resulting in the synthesis of new proteins that carry out the cellular response dictated by the hormone

juxtaglomerular apparatus (juks′-tuh-glō-MAIR-ū-lur) A cluster of specialized vascular and tubular cells at a point where the ascending limb of the loop of Henle passes through the fork formed by the afferent and efferent arterioles of the same nephron in the kidney

juxtamedullary nephrons (juks′-tuh-MED-you-lair-ee) Nephrons whose glomeruli lie in the renal cortex next to the medulla and whose long loops of Henle dip deeply into the medulla; establish the medullary vertical osmotic gradient

keratin (CARE-uh-tin) The protein found in the intermediate filaments in skin cells that give the skin strength and help form a waterproof outer layer

killer (K) cells Cells that destroy a target cell that has been coated with antibodies by lysing its membrane

kinesin (kī-NĒ′-sin) The motor protein that transports secretory vesicles along the microtubular highway within neuronal axons by "walking" along the microtubule to the end of the axon

kisspeptin A neurotransmitter released from kiss1 neurons in the hypothalamus that controls gonadotropin-releasing hormone (GnRH) secretion, thus regulating the reproductive hormonal axis; may play a role in the onset of puberty

lactate (lactic acid) An end product formed from pyruvate (pyruvic acid) during the anaerobic process of glycolysis

lactation Milk production by the mammary glands

larynx (LARE-inks) The "voice box" at the entrance of the trachea; contains the vocal cords

lateral inhibition The phenomenon in which the most strongly activated signal pathway originating from the center of a stimulus area inhibits the less excited pathways from the fringe areas by means

of lateral inhibitory connections within sensory pathways

lateral sacs The expanded saclike regions of a muscle fiber's sarcoplasmic reticulum; store and release calcium, which plays a key role in triggering muscle contraction

law of mass action If the concentration of one of the substances involved in a reversible reaction is increased, the reaction is driven toward the opposite side, and if the concentration of one of the substances is decreased, the reaction is driven toward that side

leak channels Unregulated, ungated channels that are open all the time

left ventricle The heart chamber that pumps blood into the systemic circulation

length–tension relationship The relationship between the length of a muscle fiber at the onset of contraction and the tension the fiber can achieve on a subsequent contraction

lens A transparent, biconvex structure of the eye that refracts (bends) light rays and whose strength can be adjusted to accommodate for vision at different distances

leptin A hormone released from adipose tissue that plays a key role in long-term regulation of body weight by acting on the hypothalamus to suppress appetite

leukocytes (LOO-kuh-sĪts) White blood cells, which are the immune system's mobile defense units

leukotrienes (loo-ko-TRĪ-eenz) Locally acting eicosanoids derived from the plasma membrane that are especially important in development of asthma

Leydig cells (LĪ-dig) The interstitial cells of the testes that secrete testosterone

LH See *luteinizing hormone*

LH surge The burst in LH secretion that occurs at midcycle of the ovarian cycle and triggers ovulation

limbic system (LIM-bik) A functionally interconnected ring of forebrain structures that surrounds the brain stem and is concerned with emotions, basic survival and sociosexual behavioral patterns, motivation, and learning

lipase (LĪ-payz) An enzyme secreted primarily by pancreatic acinar cells that digests dietary fat

lipid emulsion A suspension of small fat droplets held apart as a result of adsorption of bile salts on their surface

loop of Henle (HEN-lē) A hairpin loop that extends between the proximal and distal tubule of the kidney's nephron

lumen (LOO-men) The interior space of a hollow organ or tube

luteal phase (LOO-tē-ul) The phase of the ovarian cycle dominated by the presence of a corpus luteum

luteinization (loot′-ē-un-uh-ZĀ-shun) Formation of a postovulatory corpus luteum in the ovary

luteinizing hormone (LH) An anterior pituitary hormone that stimulates ovulation, luteinization, and secretion of estrogen and progesterone in females and testosterone secretion in males

lymph Interstitial fluid that is picked up by the lymphatic vessels and returned to the venous system, meanwhile passing through the lymph nodes for defense purposes

lymphocytes White blood cells that provide immune defense against targets for which they are specifically programmed

lymphoid tissues Tissues that produce and store lymphocytes, such as lymph nodes and tonsils

lysosomes (LĪ-sō-sōmz) Organelles consisting of membrane-enclosed sacs containing powerful hydrolytic enzymes that destroy unwanted material within the cell, such as internalized foreign material or cellular debris

macrophages (MAK-ruh-fājs) Large, tissue-bound phagocytes

mast cells Cells located within connective tissue that synthesize, store, and release histamine, as during allergic responses

mature follicle The dominant recruited follicle that grows the largest and is ovulated

mean arterial blood pressure The average pressure responsible for driving blood forward through the arteries into the tissues throughout the cardiac cycle; mean arterial blood pressure = cardiac output × total peripheral resistance

mechanically gated channels Channels that open or close in response to stretching or other mechanical deformation

mechanoreceptor (meh-CAN-ō-rē-SEP-tur) or (mek′-uh-nō-rē-SEP-tur) A sensory receptor sensitive to mechanical energy, such as stretching or bending

medullary respiratory center (MED-you-LAIR-ē) Several aggregations of neuronal cell bodies within the medulla that provide output to the respiratory muscles and receive input important for regulating the magnitude of ventilation

megakaryocyte A large bone-marrow bound cell that sheds off blood-borne platelets from its outer edges

meiosis (mī-ō-sis) Cell division in which the chromosomes replicate followed by two nuclear divisions so that only a half set of chromosomes is distributed to each of four new daughter cells

melanocyte-stimulating hormone (MSH) (mel-AH-nō-sīt) A hormone produced by the pituitary in lower vertebrates that regulates skin coloration for camouflage in these species; in humans, is secreted as a paracrine by the hypothalamus for control of food intake and by keratinocytes in the skin to control dispersion of melanin granules from melanocytes during tanning

melatonin (mel-uh-TŌ-nin) A hormone secreted by the pineal gland during darkness that helps entrain the body's biological rhythms with the external light and dark cues

membrane attack complex A collection of the five final activated components of the complement system that aggregate to form a porelike channel in the plasma membrane of an invading microorganism, with the resultant leakage leading to destruction of the invader

membrane potential A separation of charges across the membrane; a slight excess of negative charges lined up along the inside of the plasma membrane and separated from a slight excess of positive charges on the outside

memory cells B or T cells that are newly produced in response to a microbial invader but that do not participate in the current immune response against the invader; instead, they remain dormant, ready to launch a swift, powerful attack should the same microorganism invade again in the future

meninges (men-IN-geez) Three membranes that wrap the brain and spinal cord

menstrual cycle (men′-stroo-ul) The cyclic changes in the uterus that accompany the hormonal changes in the ovarian cycle

menstrual phase The phase of the menstrual cycle characterized by sloughing of endometrial debris and blood out through the vagina

messenger RNA (mRNA) Carries the transcribed genetic blueprint for synthesis of a particular protein from nuclear DNA to the cytoplasmic ribosomes where the protein is synthesized

metabolic acidosis (met-uh-bol′-ik) Acidosis resulting from any cause other than excess accumulation of carbonic acid in the body

metabolic alkalosis (al′-kuh-LŌ-sus) Alkalosis caused by a relative deficiency of noncarbonic acid

metabolic rate Energy expenditure per unit of time

metabolism All chemical reactions that occur within the body cells

micelle (mī-SEL) A water-soluble aggregation of bile salts, lecithin, and cholesterol that has a hydrophilic shell and a hydrophobic core; carries the water-insoluble products of fat digestion to their site of absorption

microbiome The collective genomes of the microbiota that inhabit the human body

microbiota The community of microbes that live peacefully and usefully with their human host

microfilaments Cytoskeletal elements made of actin molecules (and myosin molecules in muscle cells); play a major role in various cellular contractile systems and serve as a mechanical stiffener for microvilli

microglia Glial cells that serve as the immune defense cells of the CNS

microtubules Cytoskeletal elements made of tubulin molecules arranged into long, slender, unbranched tubes that help maintain asymmetric cell shapes and coordinate complex cell movements

microvilli (mī′-krō-VIL-ī) Actin-stiffened, non-motile, hairlike projections from the luminal surface of epithelial cells lining the digestive tract and kidney tubules; tremendously increase the surface area of the cell exposed to the lumen

micturition (mik-too-RISH-un) or (mik-chuh-RISH-un) The process of bladder emptying; urination

milk ejection The squeezing out of milk produced and stored in the alveoli of the breasts by means of contraction of the myoepithelial cells that surround each alveolus

mineralocorticoids (min-uh-rul-ō-KOR-ti-koidz) The adrenocortical hormones that are important in Na$^+$ and K$^+$ balance; primarily aldosterone

mitochondria (mī-tō-KON-drē-uh) The energy organelles, which contain the enzymes for oxidative phosphorylation

mitosis (mī-TŌ-sis) Cell division in which the chromosomes replicate before nuclear division so that each of the two daughter cells receives a full set of chromosomes

mitotic spindle The system of microtubules assembled during mitosis along which the replicated chromosomes are moved away from each other toward opposite sides of the cell before cell division

modality The energy form to which sensory receptors respond, such as heat, light, pressure, and chemical changes

molecule A chemical substance formed by the linking of atoms; the smallest unit of a given chemical substance

monocytes (MAH-nō-sīts) White blood cells that emigrate from the blood, enlarge, and become tissue macrophages

monosaccharides (mah′-nō-SAK-uh-rīdz) Simple sugars, such as glucose; the absorbable unit of digested carbohydrates

motility Muscular contractions of the digestive tract wall that mix and propel forward the luminal contents

motor activity Movement of the body accomplished by contraction of skeletal muscles

motor end plate The specialized portion of a skeletal muscle fiber that lies immediately underneath the terminal button of the motor neuron and possesses receptor sites for binding acetylcholine released from the terminal button

motor neurons The neurons that innervate skeletal muscle and whose axons constitute the somatic nervous system

motor protein Specialized protein molecule with "feet" that can be alternately swung forward enabling the molecule to "walk" along a microtubular highway, carrying cargo from one part of the cell to another

motor unit One motor neuron plus all the muscle fibers it innervates

motor unit recruitment The progressive activation of a muscle fiber's motor units to accomplish increasing gradations of contractile strength

mucosa (mew-KŌ-sah) The innermost layer of the digestive tract that lines the lumen

multiunit smooth muscle A smooth muscle mass consisting of multiple discrete units that function independently of one another and that must be separately stimulated by autonomic nerves to contract

muscarinic receptor (MUS-ka-rin′-ik) Type of cholinergic receptor found at the effector organs of all parasympathetic postganglionic fibers

muscle fiber A single muscle cell, which is relatively long and cylindrical in shape

muscle tension See *tension*

muscle tissue A functional grouping of cells specialized for contraction and force generation

myelin (MĪ-uh-lun) An insulative lipid covering that surrounds myelinated nerve fibers at regular intervals along the axon's length; each patch of myelin is formed by a separate myelin-forming cell that wraps itself jelly-roll fashion around the neuronal axon

myelinated fibers Neuronal axons covered at regular intervals with insulative myelin

myocardial ischemia (mĪ-ō-KAR-dē-ul is-KĒ-mē-uh) Inadequate blood supply to the heart tissue

myocardium (mī′-ō-KAR-dē-um) The cardiac muscle within the heart wall

myofibril (mī′-ō-FĪB-rul) A specialized intracellular structure of muscle cells that contains the contractile apparatus

myogenic activity Muscle-produced, nerve-independent contractile activity

myometrium (mī′-ō-mē-TRĒ-um) The smooth muscle layer of the uterus

myosin (MĪ-uh-sun) The protein forming the thick filaments in muscle fibers

Na⁺–K⁺ pump A carrier that actively transports Na^+ out of the cell and K^+ into the cell

Na⁺ load See *sodium* (*Na⁺*) *load*

natural killer (NK) cells Naturally occurring, lymphocytelike cells that nonspecifically destroy virus-infected cells and cancer cells by directly lysing their membranes on first exposure to them

negative balance Situation in which the losses for a substance exceed its gains so that the total amount of the substance in the body decreases

negative feedback A regulatory mechanism in which a change in a controlled variable triggers a response that opposes the change, thus maintaining a relatively steady set point for the regulated factor

nephron (NEF-ron′) The functional unit of the kidney; consisting of an interrelated vascular and tubular component, it is the smallest unit that can form urine

nerve A bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway

nerve fiber See *axon*

nervous system One of the two major regulatory systems of the body; in general, coordinates rapid activities of the body, especially those involving interactions with the external environment

nervous tissue A functional grouping of cells specialized for initiation and transmission of electrical signals

net diffusion The difference between the opposing movements of two types of molecules in a solution

net filtration pressure The net difference in the hydrostatic and osmotic forces acting across the glomerular membrane that favors the filtration of a protein-free plasma into Bowman's capsule

NETs See *neutrophil extracellular traps*

neurogenic activity Contractile activity in muscle cells initiated by nerves

neuroglia See *glial cells*

neurohormones Hormones released into the blood by neurosecretory neurons

neuromodulators (ner′ō-MA-jew-lā′-torz) Chemical messengers that bind to neuronal receptors at nonsynaptic sites and bring about long-term changes that subtly depress or enhance synaptic effectiveness

neuromuscular junction The juncture between a motor neuron and a skeletal muscle fiber

neuron (NER-on) A nerve cell specialized to initiate, propagate, and transmit electrical signals, typically consisting of a cell body, dendrites, and an axon

neuropeptide Y (NPY) A potent appetite stimulator secreted by the hypothalamic arcuate nucleus

neuropeptides Large, slow-acting peptide molecules released from axon terminals along with classical neurotransmitters; most neuropeptides function as neuromodulators

neurotransmitter The chemical messenger released from the axon terminal of a neuron in response to an action potential that influences another neuron or an effector with which the neuron is anatomically linked

neutrophil extracellular traps (NETs) A web of prepared fibers released into the ECF by neutrophils when they undergo an unusual type of programmed cell death; bind with bacteria and contain bacteria-killing chemicals

neutrophils (new′-truh-filz) White blood cells that are phagocytic specialists and important in inflammatory responses and defense against bacterial invasion

nicotinic receptor (nick′-ō-TIN-ik) Type of cholinergic receptor found at all autonomic ganglia and the motor end plates of skeletal muscle fibers

nitric oxide A local chemical mediator released from endothelial cells and other tissues; its effects range from causing local arteriolar vasodilation to acting as a toxic agent against foreign invaders to serving as a unique type of neurotransmitter

NMDA receptor One of two types of receptor-channels on a postsynaptic membrane to which the neurotransmitter glutamate binds, this one being both chemically mediated and voltage dependent and permitting Ca^{2+} entry when open

nociceptor (nō-sē-SEP-tur) A pain receptor, sensitive to tissue damage

nodes of Ranvier (RAN-vē-ā) The portions of a myelinated neuronal axon between the segments of insulative myelin; the axonal regions where the axonal membrane is exposed to the ECF and membrane potential exists

norepinephrine (nor′-ep-uh-NEF-run) The neurotransmitter released from sympathetic postganglionic fibers; noradrenaline

NPY See *neuropeptide Y*

nucleus (of brain) (NŪ-klē-us) A functional aggregation of neuronal cell bodies within the brain

nucleus (of cells) A distinct spherical structure, usually located near the center of a cell, that contains the cell's genetic material, deoxyribonucleic acid (DNA)

O₂–Hb dissociation curve A graphic depiction of the relationship between arterial P_{O_2} and percent hemoglobin saturation

occipital lobes (ok-SIP′-ut-ul) The posterior lobes of the cerebral cortex, which initially process visual input

oligodendrocytes (ol-i-gō′-DEN-drō-sitz) The myelin-forming cells of the central nervous system

oogenesis (ō′-ō-JEN-uh-sus) Egg production

opsonin (OP′-suh-nun) Body-produced chemical that links bacteria to macrophages, thereby making the bacteria more susceptible to phagocytosis

optic nerve The bundle of nerve fibers leaving the retina that relay information about visual input

optimal length (*l_o*) The length before the onset of contraction of a muscle fiber at which maximal force can be developed on a subsequent contraction

organ A distinct structural unit composed of two or more types of primary tissue organized to perform one or more particular functions; for example, the stomach

organ of Corti (KOR-tē) The sense organ of hearing within the inner ear that contains hair cells whose hairs are bent in response to sound waves, setting up action potentials in the auditory nerve

organelles (or′-gan-ELZ) Distinct, highly organized, membrane-bound intracellular compartments, each containing a specific set of chemicals for carrying out a particular cellular function

organic Referring to substances that contain carbon; originally from living or once-living sources

organism A living entity, whether unicellular or multicellular

osmolarity (oz′-mo-LAIR-ut-ē) A measure of the concentration of a solution given in terms of milliosmoles/liter (mOsm/L), the number of millimoles of solute particles in a liter of solution

osmosis (os-MŌ-sis) Movement of water across a membrane down its own concentration gradient toward the area of higher solute concentration

osmotic pressure (os-MAH-tic) A measure of the tendency for osmotic flow of water into a solution resulting from its relative concentration of nonpenetrating solutes and water

osteoblasts (OS-tē-ō-blasts′) Bone cells that produce the organic matrix of bone

osteoclasts Bone cells that dissolve bone in their vicinity

osteocytes Retired osteoblasts entombed within the bone that they have laid down around themselves that continue to participate in calcium and phosphate exchange between the bone fluid and plasma

otolith organs (ŌT′-ul-ith) Sense organs in the inner ear that provide information about rotational changes in head movement; include the utricle and saccule

oval window The membrane-covered opening that separates the air-filled middle ear from the upper compartment of the fluid-filled cochlea in the inner ear

overhydration Water excess in the body

ovulation (ov′-yuh-LĀ-shun) Release of an ovum from a mature ovarian follicle

oxidative phosphorylation (fos′-for-i-LĀ-shun) The entire sequence of mitochondrial biochemical reactions that uses oxygen to extract energy from the nutrients in food and transforms it into ATP, producing CO_2 and H_2O in the process; includes the electron transport system and chemiosmosis

oxyhemoglobin (ok-si-HĒ-muh-glō-bun) Hemoglobin combined with O_2

oxyntic mucosa (ok-SIN-tic) The mucosa lining the body and fundus of the stomach, which contains gastric pits that lead to the gastric glands lined by mucous neck cells, parietal cells, and chief cells

oxytocin (ok′-sē-TŌ-sun) A hypothalamic hormone stored in the posterior pituitary that stimulates uterine contraction and milk ejection

pacemaker activity Self-excitable activity of an excitable cell in which its membrane potential gradually depolarizes to threshold on its own

pacemaker potential A self-induced slow depolarization to threshold occurring in a pacemaker cell as a result of shifts in passive ionic fluxes across the membrane accompanying automatic changes in channel permeability

pancreas (PAN-krē-us) A mixed gland composed of an exocrine portion that secretes digestive enzymes and an aqueous alkaline secretion into the duodenal lumen and an endocrine portion that secretes the hormones insulin and glucagon into the blood

paracellular transport Between-cell movement across an epithelial sheet

paracrine (PEAR-uh-krin) A local chemical messenger whose effect is exerted only on neighboring cells in the immediate vicinity of its site of secretion

parasympathetic nervous system (pear′-uh-sim-puh-THET-ik) The subdivision of the autonomic nervous system that dominates in quiet, relaxed situations and promotes body maintenance activities such as digestion and emptying of the urinary bladder

parathyroid glands (pear′-uh-THĪ-roid) Four small glands located on the posterior surface of the thyroid gland that secrete parathyroid hormone

parathyroid hormone (PTH) A hormone that raises plasma Ca^{2+} levels

parietal cells (puh-RĪ-ut-ul) The stomach cells that secrete hydrochloric acid and intrinsic factor

parietal lobes The lobes of the cerebral cortex that lie at the top of the brain behind the central sulcus, which contain the somatosensory cortex

partial pressure (P_x) The individual pressure exerted independently by a particular gas within a mixture of gases

partial pressure gradient A difference in the partial pressure of a gas between two regions that promotes the movement of the gas from the region of higher partial pressure to the region of lower partial pressure

parturition (par′-too-RISH-un) Delivery of a baby

passive expiration Expiration accomplished during quiet breathing as a result of elastic recoil of the lungs on relaxation of the inspiratory muscles, with no energy expenditure required

passive force A force that does not require expenditure of cellular energy to accomplish transport of a substance across the plasma membrane

passive reabsorption Reabsorption when none of the steps in the transepithelial transport of a substance across the kidney tubules requires energy expenditure

pathogens (PATH-uh-junz) Disease-causing microorganisms, such as bacteria or viruses

pathophysiology (path′-ō-fiz-ē-OL-ō-gē) Abnormal functioning of the body associated with disease

pepsin; pepsinogen (pep-SIN-uh-jun) An enzyme secreted in inactive form by the stomach that, once activated, begins protein digestion

peptide hormones Hormones that consist of a chain of specific amino acids of varying length

peptide YY$_{3-36}$ A satiety signal secreted by the small and large intestines that inhibits appetite and serves as a mealtime terminator

percent hemoglobin saturation A measure of the extent to which the hemoglobin present is combined with O_2

perception The conscious interpretation of the external world as created by the brain from a pattern of nerve impulses delivered to it from sensory receptors

peripheral chemoreceptors (kē′-mō-rē-SEP-turz) The carotid and aortic bodies, which respond to changes in arterial P_{O_2}, P_{CO_2}, and H^+ and adjust respiration accordingly

peripheral nervous system (PNS) Nerve fibers that carry information between the central nervous system and other parts of the body

peripheral protein A plasma-membrane protein that studs the surface instead of penetrating the membrane

peristalsis (per′-uh-STOL-sus) Ringlike contractions of the circular smooth muscle of a tubular organ that move progressively forward with a stripping motion, pushing the contents of the organ ahead of the contraction

peritubular capillaries (per′-i-TŪ-bū-lur) Capillaries that intertwine around the tubules of the kidney's nephron; they supply the renal tissue and participate in exchanges between the tubular fluid and blood during the formation of urine

permeable Permitting passage of a particular substance

permissiveness When one hormone must be present in adequate amounts for the full exertion of another hormone's effect

peroxisomes (puh-ROK′-suh-sōmz) Saclike organelles containing powerful oxidative enzymes that detoxify various wastes produced within the cell or foreign compounds that have entered the cell

pH The logarithm to the base 10 of the reciprocal of the hydrogen ion concentration; pH = log 1/[H^+]

phagocytosis (fag′-ō-sī-TŌ-sus) A type of endocytosis in which large, multimolecular, solid particles are engulfed by a cell

pharynx (FARE-inks) The back of the throat, which serves as a common passageway for the digestive and respiratory systems

phasic smooth muscle Smooth muscle that contracts in bursts, triggered by the generation of action potentials

phosphorylation (fos′-for-i-LĀ-shun) Addition of a phosphate group to a molecule

photoreceptor A sensory receptor responsive to light

phototransduction The mechanism of converting light stimuli into electrical activity by the rods and cones of the eye

physiology (fiz-ē-OL-ō-gē) The study of body functions

pineal gland (PIN-ē-ul) A small endocrine gland located in the center of the brain that secretes the hormone melatonin

pinocytosis (pin-ō-cī-TŌ-sus) A type of endocytosis in which the cell internalizes fluid

pitch The tone of a sound, determined by the frequency of vibrations (that is, whether a sound is a C or G note)

pituitary gland (pih-TWO-ih-tair-ee) A small endocrine gland connected by a stalk to the hypothalamus; consists of the anterior pituitary and posterior pituitary

placenta (plah-SEN-tah) The organ of exchange between the maternal and fetal blood; also secretes hormones that support the pregnancy

plaque A deposit of cholesterol and other lipids, perhaps calcified, and thickened, abnormal smooth-muscle cells within blood vessel walls as a result of atherosclerosis

plasma The liquid portion of the blood

plasma cell An antibody-producing derivative of an activated B lymphocyte

plasma clearance The volume of plasma that is completely cleared of a given substance by the kidneys per minute

plasma-colloid osmotic pressure (KOL-oid os-MOT-ik) The force caused by the unequal distribution of plasma proteins between the blood and surrounding fluid that encourages fluid movement into the capillaries

plasma membrane A protein-studded lipid bilayer that encloses each cell, separating it from the extracellular fluid

plasma proteins The proteins in the plasma, which perform a number of important functions; include albumins, globulins, and fibrinogen

plasticity (plas-TIS-uh-tē) The ability of portions of the brain to assume new responsibilities in response to the demands placed on it

platelets (PLĀT-lets) Specialized cell fragments in the blood that participate in hemostasis by forming a plug at a vessel defect

pleural sac (PLOOR-ul) A double-walled, closed sac that separates each lung from the thoracic wall

pluripotent stem cells Precursor cells; for example, those that reside in the bone marrow and continuously divide and differentiate to give rise to each of the types of blood cells

polarization The state of having membrane potential

polycythemia (pol-ē-sī-THĒ-mē-uh) Excess circulating erythrocytes, accompanied by an elevated hematocrit

polysaccharides (pol′-ē-SAK-uh-rīdz) Complex carbohydrates, consisting of chains of interconnected glucose molecules

pool (of a substance) Total quantity of any particular substance in the ECF

positive balance Situation in which the gains via input for a substance exceed its losses via output so that the total amount of the substance in the body increases

positive feedback A regulatory mechanism in which the input and the output in a control system continue to enhance each other so that the controlled variable is progressively moved further from a steady state

postabsorptive state The metabolic state after a meal is absorbed during which endogenous energy stores must be mobilized and glucose must be spared for the glucose-dependent brain; fasting state

posterior pituitary The neural portion of the pituitary that stores and releases into the blood on hypothalamic stimulation two hormones produced by the hypothalamus, vasopressin and oxytocin

postganglionic fiber (pōst′-gan-glē-ON-ik) The second neuron in the two-neuron autonomic nerve pathway; originates in an autonomic ganglion and terminates on an effector organ

postsynaptic neuron (pōst′-si-NAP-tik) The neuron that conducts its action potentials away from a synapse

power stroke The ATP-powered cross-bridge binding and bending that pulls the thin filaments in closer together between the thick filaments during contraction of a muscle fiber

preganglionic fiber The first neuron in the two-neuron autonomic nerve pathway; originates in the central nervous system and terminates on an autonomic ganglion

pressure gradient A difference in pressure between two regions that drives the movement of blood or air from the region of higher pressure to the region of lower pressure

presynaptic facilitation Enhanced release of neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal

presynaptic inhibition A reduction in the release of a neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal

presynaptic neuron (prē-si-NAP-tik) The neuron that conducts its action potentials toward a synapse

primary active transport A carrier-mediated transport system in which energy is directly required to operate the carrier and move the transported substance against its concentration gradient

primary motor cortex The portion of the cerebral cortex that lies anterior to the central sulcus and is responsible for voluntary motor output

primodial follicle A primary oocyte surrounded by a single layer of granulosa cells in the ovary

principal cells Cells in the distal and collecting tubules of the kidney that are the site of action of aldosterone and vasopressin

progestational phase See *secretory phase*

prolactin (PRL) (prō-LAK-tun) An anterior pituitary hormone that stimulates breast development and milk production in females

proliferative phase The phase of the menstrual cycle during which the endometrium repairs itself and thickens following menstruation; lasts from the end of the menstrual phase until ovulation

pro-opiomelanocortin (prō-ōp′-Ē-ō-ma-LAN-ō-kor′-tin) A large precursor molecule that can be variably cleaved into adrenocorticotropic hormone, melanocyte-stimulating hormone, and endorphin

proprioception (prō′-prē-ō-SEP-shun) Awareness of position of body parts in relation to one another and to surroundings

prostaglandins (pros′-tuh-GLAN-dins) Local chemical mediators that are derived from a component of the plasma membrane, arachidonic acid

prostate gland A male accessory sex gland that secretes an alkaline fluid, which neutralizes acidic vaginal secretions

proteasome A nonmembranous organelle that degrades misfolded, damaged, or unneeded intracellular proteins that have been tagged with ubiquitin

protein kinase (KĪ-nase) An enzyme that phosphorylates and thereby induces a change in the shape and function of a particular intracellular protein

proteolytic enzymes (prōt′-ē-uh-LIT-ik) Enzymes that digest protein

proteome The complete set of proteins that can be synthesized using the genetic codes in the genome

proximal tubule (PROKS-uh-mul) A highly convoluted tubule that extends between Bowman's capsule and the loop of Henle in the kidney's nephron

PTH See *parathyroid hormone*

pulmonary artery (PULL-mah-nair-ē) The large vessel that carries blood from the right ventricle to the lungs

pulmonary circulation The closed loop of blood vessels carrying blood between the heart and lungs

pulmonary surfactant (sur-FAK-tunt) A phospholipoprotein complex secreted by the Type II alveolar cells that intersperses between the water molecules that line the alveoli, thereby lowering the surface tension within the lungs

pulmonary valve A one-way valve that permits the flow of blood from the right ventricle into the pulmonary artery during ventricular emptying but prevents the backflow of blood from the pulmonary artery into the right ventricle during ventricular relaxation

pulmonary veins The large vessels that carry blood from the lungs to the heart

pulmonary ventilation The volume of air breathed in and out in one minute; pulmonary ventilation = tidal volume × respiratory rate

pupil An adjustable round opening in the center of the iris through which light passes to the interior portions of the eye

Purkinje fibers (pur-KIN-jē) Small terminal fibers that extend from the bundle of His and rapidly transmit an action potential throughout the ventricular myocardium

pyloric gland area (PGA) (pī-LŌR-ik) The specialized region of the mucosa in the antrum of the stomach that secretes gastrin

pyloric sphincter (pī-LŌR-ik SFINGK-tur) The juncture between the stomach and duodenum

PYY$_{3-36}$ See *peptide YY$_{3-36}$*

RAAS See *renin–angiotensin–aldosterone system*

radiation Emission of heat energy from the surface of a warm body in the form of electromagnetic waves

reabsorption The net movement of interstitial fluid into the capillary

receptive field The circumscribed region surrounding a sensory neuron within which the neuron responds to stimulus information

receptor See *sensory receptor* or *receptor (in membrane)*

receptor (in membrane) Membrane protein that binds with a specific extracellular chemical messenger, bringing about membrane and intracellular events that alter the activity of the particular cell

receptor potential The graded potential change that occurs in a sensory receptor in response to a stimulus; generates action potentials in the afferent neuron fiber

receptor-channel A type of receptor that is an integral part of a channel that opens (or closes) on binding with an extracellular messenger

receptor-enzyme A type of receptor that functions as an enzyme on binding with an extracellular chemical messenger

receptor-mediated endocytosis Import of a particular large molecule from the ECF into a cell by formation and pinching off of an endocytic pouch in response to binding of the molecule to a surface membrane receptor specific for it

reduced hemoglobin Hemoglobin that is not combined with O_2

reflex Any response that occurs automatically without conscious effort; the components of a reflex arc include a receptor, afferent pathway, integrating center, efferent pathway, and effector

refraction Bending of a light ray

refractory period (rē-FRAK-tuh-rē) The time period when a recently activated patch of membrane is refractory (unresponsive) to further stimulation, which prevents the action potential from spreading backward into the area through which it has just passed and ensures the unidirectional propagation of the action potential away from the initial site of activation

regulatory proteins Troponin and tropomyosin, which play a role in regulating muscle contraction by either covering or exposing the sites of interaction between actin and the myosin cross bridges

regulatory T cells A class of T lymphocytes that suppresses the activity of other lymphocytes

releasing hormone A hypothalamic hormone that stimulates the secretion of a particular anterior pituitary hormone

renal cortex An outer granular-appearing region of the kidney

renal medulla (RĒ-nul muh-DUL-uh) An inner striated-appearing region of the kidney

renal threshold The plasma concentration at which the T_m of a particular substance is reached and the substance first starts appearing in the urine

renin (RĒ-nin) An enzymatic hormone released from the kidneys in response to a decrease in NaCl or ECF volume or arterial blood pressure; activates angiotensinogen

renin–angiotensin–aldosterone system (RAAS) (an′jē-ō-TEN-sun al-dō-steer-OWN) The salt-conserving system triggered by release of renin from the kidneys, which activates angiotensin, stimulating aldosterone secretion and Na$^+$ reabsorption by the kidney tubules during the formation of urine

repolarization (rē′-pō-luh-ruh-ZĀ-shun) Return of membrane potential to resting potential following a depolarization

reproductive tract The system of ducts specialized to transport or house the gametes after they are produced

residual volume The minimum volume of air remaining in the lungs even after a maximal expiration

resistance Hindrance of blood or air flow through a blood vessel or respiratory airway, respectively

respiration The sum of processes that accomplish ongoing passive movement of O_2 from the atmosphere to the tissues, as well as the continual passive movement of metabolically produced CO_2 from the tissues to the atmosphere

respiratory acidosis (as-i-DŌ-sus) Acidosis resulting from abnormal retention of CO_2 arising from hypoventilation

respiratory airways The system of tubes that conducts air between the atmosphere and the alveoli of the lungs

respiratory alkalosis (al′-kuh-LŌ-sus) Alkalosis caused by excessive loss of CO_2 from the body as a result of hyperventilation

respiratory rate Breaths per minute

resting membrane potential The membrane potential that exists when an excitable cell is not displaying an electrical signal

reticular activating system (RAS) (ri-TIK-ū-lur) Ascending fibers that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex

reticular formation A network of interconnected neurons that runs throughout the brain stem and initially receives and integrates all synaptic input to the brain

retina The innermost layer in the posterior region of the eye that contains the eye's photoreceptors (rods and cones)

rhythmic activities Stereotypical movements that repeat in a general manner, like walking; started and stopped consciously by the cerebral cortex but executed subconsciously by lower CNS levels

ribonucleic acid (RNA) (rī-bō-new-KLĀ-ik) A nucleic acid that exists in three forms (messenger RNA, ribosomal RNA, and transfer RNA), which participate in gene transcription and protein synthesis

ribosomes (RĪ-bō-sōmz) Special ribosomal RNA–protein complexes that synthesize proteins under the direction of nuclear DNA

right atrium (Ā-trē′-um) The heart chamber that receives venous blood from the systemic circulation

right ventricle The heart chamber that pumps blood into the pulmonary circulation

RNA See *ribonucleic acid*

rods The eye's photoreceptors used for night vision

rough ER The flattened, ribosome-studded sacs of the endoplasmic reticulum that synthesize proteins for export or for use in membrane construction

round window The membrane-covered opening that separates the lower chamber of the cochlea in the inner ear from the middle ear

ryanodine receptors (rye-ah-NO-deen) Receptors on the sarcoplasmic reticulum that bind with dihydropyridine receptors on the adjoining T tubule and serve as Ca^{2+}-release channels during excitation–contraction coupling

SA node See *sinoatrial node*

salivary amylase (AM-uh-lās′) An enzyme produced by the salivary glands that begins carbohydrate digestion in the mouth and continues it in the stomach after the food and saliva have been swallowed

salt balance Balance between salt intake and salt output; important in controlling ECF volume

saltatory conduction (SAL-tuh-tōr′-ē) The means by which an action potential is propagated throughout a myelinated fiber, with the impulse jumping over the myelinated regions from one node of Ranvier to the next

sarcomere (SAR-kō-mir) The functional unit of skeletal muscle; the area between two Z lines within a myofibril

sarcoplasmic reticulum (ri-TIK-yuh-lum) A fine meshwork of interconnected tubules that surrounds a muscle fiber's myofibrils; contains expanded lateral sacs, which store calcium that is released into the cytosol in response to a local action potential

satiety signals (suh-TĪ-ut-ē) Signals that lead to the sensation of fullness and suppress the desire to eat

saturation The condition in which all binding sites on a carrier molecule are occupied

Schwann cells (shwahn) The myelin-forming cells of the peripheral nervous system

sclera (SKLAIR-a) The visible, white, outer layer of the eye

second messenger An intracellular chemical that is activated by binding of an extracellular first messenger to a surface receptor site, triggering a preprogrammed series of biochemical events that alter activity of intracellular proteins controlling a particular cellular activity

secondary active transport A transport mechanism in which a carrier molecule for glucose or an amino acid is driven by a Na^+ concentration gradient established by the energy-dependent Na^+–K^+ pump to transfer the glucose or amino acid uphill without directly expending energy to operate the carrier

secondary sexual characteristics The many external characteristics that are not directly involved in reproduction but that distinguish males and females

secretin (si-KRĒT-n) A hormone released from the duodenal mucosa primarily in response to the presence of acid; inhibits gastric motility and secretion and stimulates secretion of $NaHCO_3$ solution from the pancreas and liver

secretion Release to a cell's exterior, on appropriate stimulation, of substances produced by the cell

secretory phase The phase of the menstrual cycle characterized by the development of a lush endometrial lining capable of supporting a fertilized ovum; also known as the *progestational phase*

secretory vesicles (VES-i-kuls) Membrane-enclosed sacs containing proteins that have been synthesized and processed by the endoplasmic reticulum and Golgi complex of the cell and which are released to the cell's exterior by exocytosis on appropriate stimulation

segmentation The small intestine's primary method of motility; consists of oscillating, ringlike contractions of the circular smooth muscle along the small intestine's length

selectively permeable membrane A membrane that permits some particles to pass through while excluding others

self-antigens Antigens that are characteristic of a person's cells

semen (SĒ-men) A mixture of accessory sex gland secretions and sperm

semicircular canal Sense organ in the inner ear that detects rotational or angular acceleration or deceleration of the head

semilunar valves (sem′-ī-LEW-nur) The aortic and pulmonary valves

seminal vesicles (VES-i-kuls) Male accessory sex glands that supply fructose to ejaculated sperm and secrete prostaglandins

seminiferous tubules (sem′-uh-NIF-uh-rus) The highly coiled tubules within the testes that produce spermatozoa

sensor The component of a control system that monitors the magnitude of the controlled variable

sensory afferent Pathway into the central nervous system carrying information that reaches the level of consciousness

sensory input Input from somatic sensation and special senses

sensory receptor An afferent neuron's peripheral ending, which is specialized to respond to a particular stimulus in its environment

sensory transduction The conversion of stimulus energy into a receptor potential

Sertoli cells (sur-TŌL-lē) Cells located in the seminiferous tubules that support spermatozoa during their development

serum Plasma minus fibrinogen and other clotting precursors

set point The desired level at which homeostatic control mechanisms maintain a controlled variable

sex hormones The steroid hormones secreted by the gonads that govern reproductive function and are responsible for the development of masculine and feminine characteristics; testosterone in males and estrogens and progesterone in females

signal molecule An extracellular chemical messenger that initiates signal transduction in a cell

signal transducers and activators of transcription (STAT) A cytosolic protein that, when phosphorylated by JAK enzymes, moves to the nucleus and turns on gene transcription resulting in synthesis of designated proteins that carry out the effect dictated by the hormone that sets the JAK/STAT signal transduction pathway in motion

signal transduction The sequence of events in which incoming signals from extracellular chemical messengers are conveyed into a target cell where they are transformed into the dictated cellular response

single-unit smooth muscle The most abundant type of smooth muscle; made up of muscle fibers interconnected by gap junctions so that they become excited and contract as a unit; also known as *visceral smooth muscle*

sinoatrial (SA) node (sī-nō-Ā-trē-ul) A small specialized autorhythmic region in the right atrial wall of the heart that has the fastest rate of spontaneous depolarizations and serves as the normal pacemaker of the heart

skeletal muscle Striated muscle, which is attached to the skeleton and is responsible for movement of the bones in purposeful relation to one another; innervated by the somatic nervous system and under voluntary control

slow-wave potentials Self-excitable activity of an excitable cell in which its membrane potential undergoes gradually alternating depolarizing and hyperpolarizing swings

smooth ER The tubules of the endoplasmic reticulum that package newly synthesized proteins in transport vesicles

smooth muscle Involuntary muscle in the walls of hollow organs and tubes innervated by the autonomic nervous system

sodium (Na$^+$) load The total amount of Na$^+$ in the body, which determines the ECF volume through its osmotic effect

somatic cells (sō-MAT-ik) Body cells, as contrasted with reproductive cells

somatic nervous system The portion of the efferent division of the peripheral nervous system that innervates skeletal muscles; consists of the axonal fibers of the alpha motor neurons

somatic sensation Sensory information arising from the body surface, including somesthetic sensation and proprioception

somatosensory cortex The region of the parietal lobe immediately behind the central sulcus; the site of initial processing of somesthetic and proprioceptive input

somatotropes Anterior pituitary cells that secrete growth hormone

somesthetic sensation (SŌ-mes-THEH-tik) Awareness of sensory input such as touch, pressure, temperature, and pain from the body's surface

sound waves Traveling vibrations of air in which regions of high pressure caused by compression of air molecules alternate with regions of low pressure caused by rarefaction of the molecules

spatial summation The summing of several postsynaptic potentials arising from the simultaneous activation of several excitatory (or several inhibitory) synapses

special senses Vision, hearing, equilibrium, taste, and smell

specificity Ability of carrier molecules to transport only specific substances across the plasma membrane

spermatogenesis (spur′-mat-uh-JEN-uh-sus) Sperm production

sphincter (sfink-tur) A voluntarily controlled ring of skeletal muscle that controls passage of contents through an opening into or out of a hollow organ or tube

spinal reflex A reflex that is integrated by the spinal cord

spleen A lymphoid tissue in the upper left part of the abdomen that stores lymphocytes and platelets and destroys old red blood cells

STAT See *signal transducers and activators of transcription*

state of equilibrium State of a system in which no net change is occurring

steady state State of a system in which no net movement occurs because passive forces and active forces exactly counterbalance each other, with energy being used to maintain the constancy

stem cells Relatively undifferentiated cells that can give rise to highly differentiated, specialized cells while at the same time making new stem cells

stereocilia The auditory and vestibular hair cells that transduce mechanical movements into electrical signals

steroids (STEER-oidz) Hormones derived from cholesterol

stimulus A detectable physical or chemical change in the environment of a sensory receptor

stress The generalized, nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis

stretch reflex A monosynaptic reflex in which an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle terminates directly on the efferent neuron supplying the same muscle to cause it to contract and counteract the stretch

stroke volume (SV) The volume of blood pumped out of each ventricle with each contraction, or beat, of the heart

subcortical regions The brain regions that lie under the cerebral cortex, including the basal nuclei, thalamus, and hypothalamus

submucosa The connective tissue layer of the digestive tract that lies under the mucosa and contains the larger blood and lymph vessels and a nerve network

substance P The neurotransmitter released from pain fibers

subsynaptic membrane (sub-sih-NAP-tik) The portion of the postsynaptic cell membrane that lies immediately underneath a synapse and contains receptor sites for the synapse's neurotransmitter

suprachiasmatic nucleus (soup′-ra-kī-as-MAT-ik) A cluster of nerve cell bodies in the hypothalamus that serves as the master biological clock, acting as the pacemaker establishing many of the body's circadian rhythms

surface tension The force at the liquid surface of an air–water interface resulting from the greater attraction of water molecules to the surrounding water molecules than to the air above the surface; a force that tends to decrease the area of a liquid surface and resists stretching of the surface

sympathetic nervous system The subdivision of the autonomic nervous system that dominates in emergency ("fight-or-flight") or stressful situations and prepares the body for strenuous physical activity

symport The form of secondary active transport in which the driving ion and transported solute move in the same direction across the plasma membrane; also called *cotransport*

synapse (SIN-aps) The specialized junction between two neurons where an action potential in the presynaptic neuron influences the membrane potential of the postsynaptic neuron, typically by releasing a chemical messenger that diffuses across the small cleft between the neurons

synergism (SIN-er-jiz′-um) The result of several complementary actions in which the combined effect is greater than the sum of the separate effects

systemic circulation (sis-TEM-ik) The closed loop of blood vessels carrying blood between the heart and body systems

systole (SIS-tō-lē) The period of cardiac contraction and emptying

T₃ See *tri-iodothyronine*

T₄ See *thyroxine*

T lymphocytes (T cells) White blood cells that accomplish cell-mediated immune responses against targets to which they have been previously exposed; see also *cytotoxic T cells, helper T cells,* and *regulatory T cells*

T tubule See *transverse tubule*

tactile (TACK-til) Referring to touch

target cells The cells that a particular extracellular chemical messenger, such as a hormone or a neurotransmitter, influences

target-cell receptors Receptors located on a target cell that are specific for a particular chemical mediator

temporal lobes The lateral lobes of the cerebral cortex, which initially process auditory input

temporal summation The summing of several postsynaptic potentials that occur very close together in time because of successive firing of a single presynaptic neuron

tension The force produced during muscle contraction by shortening of the sarcomeres, resulting in stretching and tightening of the muscle's elastic connective tissue and tendon, which transmit the tension to the bone to which the muscle is attached

terminal button A motor neuron's enlarged knoblike ending that terminates near a skeletal muscle fiber and releases acetylcholine in response to an action potential in the neuron

testosterone (tes-TOS-tuh-rōn) The male sex hormone, secreted by the Leydig cells of the testes

tetanus (TET′-n-us) A smooth, maximal muscle contraction that occurs when the fiber is stimulated so rapidly that it does not have a chance to relax at all between stimuli

tetraiodothyronine See *thyroxine*

thalamus (THAL-uh-mus) The brain region that serves as a synaptic integrating center for preliminary processing of all sensory input on its way to the cerebral cortex

thecal cells (THĀY-kel) The outer layer of specialized ovarian connective tissue cells in a maturing follicle

thermoreceptor (thur′-mō-rē-SEP-tur) A sensory receptor sensitive to heat and cold

thick filaments Specialized cytoskeletal structures within skeletal muscle that are made up of myosin molecules and interact with the thin filaments to shorten the fiber during muscle contraction

thin filaments Specialized cytoskeletal structures within skeletal muscle that are made up of actin, tropomyosin, and troponin molecules and interact with the thick filaments to shorten the fiber during muscle contraction

thoracic cavity (thō-RAS-ik) Chest cavity

threshold potential The critical potential that must be reached before an action potential is initiated in an excitable cell

thrombus An abnormal clot attached to the inner lining of a blood vessel

transcellular transport Transport across an epithelial barrier through, not between, the cells

thymus (THī-mus) A lymphoid gland located midline in the chest cavity that processes T lymphocytes and produces the hormone thymosin, which maintains the T-cell lineage

thyroglobulin (thī′-rō-GLOB-yuh-lun) A large, complex molecule on which all steps of thyroid hormone synthesis and storage take place

thyroid gland A bilobed endocrine gland that lies over the trachea and secretes the hormones thyroxine and tri-iodothyronine, which regulate overall basal metabolic rate, and calcitonin, which contributes to control of calcium balance

thyroid hormone Collectively, the hormones secreted by the thyroid follicular cells, namely, thyroxine and tri-iodothyronine

thyroid-stimulating hormone (TSH) An anterior pituitary hormone that stimulates secretion of thyroid hormone and promotes growth of the thyroid gland; thyrotropin

thyrotropes Anterior pituitary cells that secrete thyroid-stimulating hormone

thyroxine (thī-ROCKS-in) The most abundant hormone secreted by the thyroid gland; important in the regulation of overall metabolic rate; also known as *tetraiodothyronine* or T_4

tidal volume The volume of air entering or leaving the lungs during a single breath

tight junction An impermeable junction between two adjacent epithelial cells formed by the sealing together of the cells' lateral edges near their luminal borders; prevents passage of substances between the cells

tip links Cell adhesion molecules that link the tips of stereocilia of hair cells in adjacent rows in the cochlea and vestibular organs and that pull open mechanically gated channels in the stereocilia during signal transduction

tissue (1) A functional aggregation of cells of a single specialized type, such as nerve cells forming nervous tissue; (2) the aggregate of various cellular and extracellular components that make up a particular organ, such as lung tissue

tissue-specific stem cells Partially differentiated cells that can generate the highly differentiated, specialized cell types composing a particular tissue

titin A giant, highly elastic protein that extends in both directions from the M line along the length of the thick filament to the Z lines and is responsible for the parallel elastic component of the muscle fiber

T_m See *transport maximum* and *tubular maximum*

tone The ongoing baseline of activity in a given system or structure, as in muscle tone, sympathetic tone, or vascular tone

tonic smooth muscle Smooth muscle that is partially contracted at all times in the absence of action potentials

tonicity A measure of the effect a solution has on cell volume when the solution surrounds the cell

total peripheral resistance The resistance offered by all the peripheral blood vessels, with arteriolar resistance contributing most extensively

trachea (TRĀ-kē-uh) The "windpipe"; the conducting airway that extends from the pharynx and branches into two bronchi, each entering a lung

tract A bundle of nerve fibers (axons of long interneurons) with a similar function within the spinal cord

transduction Conversion of stimuli into action potentials by sensory receptors

transepithelial transport (tranz-ep-i-THĒ-lē-al) The entire sequence of steps involved in the transfer of a substance across the epithelium between either the renal tubular lumen or digestive tract lumen and the blood

transmural pressure gradient The pressure difference across the lung wall (intra-alveolar pressure is greater than intrapleural pressure) that stretches the lungs to fill the thoracic cavity, which is larger than the unstretched lungs

transport maximum (T_m) The maximum rate of a substance's carrier-mediated transport across the membrane when the carrier is saturated; known as *tubular maximum* in transepithelial transport across the kidney tubules

transport vesicle Membranous sac enclosing newly synthesized proteins that buds off the smooth endoplasmic reticulum and moves the proteins to the Golgi complex for further processing and packaging for their final destination

transporter recruitment The phenomenon of inserting additional transporters (carriers) for a particular substance into the plasma membrane, thereby increasing membrane permeability to the substance, in response to an appropriate stimulus

transverse (T) tubule A perpendicular infolding of the surface membrane of a muscle fiber; rapidly spreads surface electric activity into the central portions of the muscle fiber

triglycerides (trī-GLIS-uh-rīdz) Neutral fats composed of one glycerol molecule with three fatty acid molecules attached

tri-iodothyronine (T_3) (trī-ī-ō-dō-THĪ-ro-nēn) The most potent hormone secreted by the thyroid follicular cells; important in the regulation of overall metabolic rate

trophic hormone A hormone that helps maintain the structural integrity of its target gland

trophoblast (TRŌF-uh-blast′) The outer layer of cells in a blastocyst that is responsible for accomplishing implantation and developing the fetal portion of the placenta

tropic hormone (TRŌ-pik) A hormone whose primary function is to regulate the secretion of another hormone

tropomyosin (trōp′-uh-Mī-uh-sun) One of the regulatory proteins in the thin filaments of muscle fibers

troponin (trō-PŌ-nun) One of the regulatory proteins in the thin filaments of muscle fibers

TSH See *thyroid-stimulating hormone*

tubular maximum (T_m) The maximum amount of a substance that the renal tubular cells can actively transport within a given time period; the kidney cells' equivalent of transport maximum

tubular reabsorption The selective transfer of substances from tubular fluid into peritubular capillaries during urine formation

tubular secretion The selective transfer of substances from peritubular capillaries into the tubular lumen during urine formation

tunneling nanotubes Long, thin, hollow filaments between cells that can transfer larger cargo considerably longer distances from cell to cell than gap junctions can

twitch A brief, weak contraction that occurs in response to a single action potential in a muscle fiber

twitch summation The addition of two or more muscle twitches as a result of rapidly repetitive stimulation, resulting in greater tension in the fiber than that produced by a single action potential

tympanic membrane (tim-PAN-ik) The eardrum, which is stretched across the entrance to the middle ear and which vibrates when struck by sound waves funneled down the external ear canal

Type I alveolar cells (al-VĒ-ō-lur) The single layer of flattened epithelial cells that forms the wall of the alveoli within the lungs

Type II alveolar cells The cells within the alveolar walls that secrete pulmonary surfactant

tyrosine kinase A type of receptor-enzyme that brings about the dictated cellular response on binding with an extracellular chemical messenger by phosphorylating the amino acid tyrosine in designated intracellular proteins

ultrafiltration The net movement of a protein-free plasma out of the capillary into the surrounding interstitial fluid

umami A meaty or savory taste

ureter (yū-RĒ-tur) A duct that transmits urine from the kidney to the bladder

urethra (yū-RĒ-thruh) A tube that carries urine from the bladder out of the body

urine excretion The elimination of substances from the body in the urine; anything filtered or secreted and not reabsorbed is excreted

vagus nerve (VĀ-gus) The tenth cranial nerve, which serves as the major parasympathetic nerve

varicosities Swellings in autonomic postganglionic fibers that simultaneously release neurotransmitter over a large area of an innervated organ

vascular tone The state of partial constriction of arteriolar smooth muscle that establishes a baseline of arteriolar resistance

vasoconstriction (vā′-zō-kun-STRIK-shun) The narrowing of a blood vessel lumen as a result of contraction of the vascular circular smooth muscle

vasodilation The enlargement of a blood vessel lumen as a result of relaxation of the vascular circular smooth muscle

vasopressin (vā-zō-PRES-sin) A hormone secreted by the hypothalamus, then stored and released from the posterior pituitary; increases the permeability of the distal and collecting tubules of the kidneys to water and promotes arteriolar vasoconstriction; also known as *antidiuretic hormone (ADH)*

vaults Nonmembranous organelles shaped like octagonal barrels; believed to serve as transporters for messenger RNA or the ribosomal subunits from the nucleus to sites of protein synthesis

vein A vessel that carries blood toward the heart

vena cava (venae cavae, plural) (VĒ-nah CĀV-ah; VĒ-nē cāv-ē) A large vein that empties blood into the right atrium

venous return (VĒ-nus) The volume of blood returned to each atrium per minute from the veins

ventilation The mechanical act of moving air in and out of the lungs; breathing

ventricle (of brain) (VEN-tri-kul) One of four interconnected chambers within the brain through which cerebrospinal fluid flows

ventricle (of heart) A lower chamber of the heart that pumps blood into the arteries

vertical osmotic gradient A progressive increase in the concentration of the interstitial fluid in the renal medulla from the cortical boundary down to the renal pelvis; important in the ability of the kidneys to put out urine of variable concentration, depending on the body's needs

vesicle (VES-i-kul) A small, intracellular, fluid-filled, membrane-enclosed sac

vesicular transport Movement of large molecules or multimolecular materials into or out of the cell within a vesicle, as in endocytosis or exocytosis

vestibular apparatus (veh-STIB-yuh-lur) The component of the inner ear that provides information essential for the sense of equilibrium and for coordinating head movements with eye and postural movements; consists of the semicircular canals, utricle, and saccule

villus (**villi,** plural) (VIL-us) Microscopic fingerlike projections from the inner surface of the small intestine

virulence (VIR-you-lentz) The disease-producing power of a pathogen

visceral afferent A pathway into the central nervous system that carries subconscious information derived from the internal viscera

visceral smooth muscle (VIS-uh-rul) See *single-unit smooth muscle*

viscosity (vis-KOS-i-tē) The friction developed between molecules of a fluid as they slide over each other during flow of the fluid; the greater the viscosity, the greater the resistance to flow

visible light The portion of the electromagnetic spectrum to which the eyes' photoreceptors are responsive (wavelengths between 400 and 700 nanometers)

vital capacity The maximum volume of air that can be moved out during a single breath following a maximal inspiration

vitreous humor The jellylike substance in the posterior cavity of the eye between the lens and retina

voltage-gated channels Channels in the plasma membrane that open or close in response to changes in membrane potential

voluntary movement Goal-directed movement initiated and terminated at will and integrated by the cerebral cortex

voluntary muscle Muscle innervated by the somatic nervous system and subject to voluntary control; skeletal muscle

water balance The balance between water intake and water output; important in controlling ECF osmolarity

white matter The portion of the central nervous system composed of myelinated nerve fibers

Z line A flattened disclike cytoskeletal protein that connects the thin filaments of two adjoining sarcomeres

zona fasciculata (zō-nah fa-SIK-ū-lah-ta) The middle and largest layer of the adrenal cortex; major source of cortisol

zona glomerulosa (glō-MAIR-yū-lō-sah) The outermost layer of the adrenal cortex; sole source of aldosterone

zona reticularis (ri-TIK-yuh-lair-us) The innermost layer of the adrenal cortex; produces cortisol, along with the zona fasciculata

zygote A fertilized ovum

1.1 Introduction to Physiology (p. 2)

■ *Physiology* is the study of body functions.

■ Physiologists explain body function in terms of the mechanisms of action involving cause-and-effect sequences of physical and chemical processes.

■ Physiology and anatomy are closely interrelated because body functions highly depend on the structure of the body parts that carry them out.

1.2 Levels of Organization in the Body (pp. 2–7)

■ The human body is a complex combination of specific *atoms* and *molecules*.

■ These nonliving chemicals are organized in a precise way to form *cells,* the smallest entities capable of carrying out life processes. Cells are the body's structural and functional living building blocks. *(Review Figure 1-2.)*

■ The *basic functions* performed by each cell for its own survival include (1) obtaining O_2 and nutrients, (2) performing energy-generating chemical reactions, (3) eliminating wastes, (4) synthesizing proteins and other cell components, (5) controlling movement of materials between the cell and its environment, (6) moving materials throughout the cell, (7) responding to the environment, and (8) reproducing.

■ In addition to its basic functions, each cell in a multicellular organism performs a *specialized function* essential for survival of the organism.

■ Cells of similar structure and specialized function combine to form the four *primary tissues* of the body: muscle, nervous, epithelial, and connective. *(Review Figure 1-3.)*

■ *Glands* are derived from epithelial tissue and specialized for secretion. *Exocrine glands* secrete through ducts to the body surface or into a cavity that communicates with the outside; *endocrine glands* secrete hormones into the blood. *(Review Figure 1-4.)*

■ *Organs* are combinations of two or more types of tissues that act together to perform one or more functions. An example is the stomach. *(Review Figure 1-3.)*

■ *Body systems* are collections of organs that perform related functions and interact to accomplish a common activity essential for survival of the whole body. An example is the digestive system. *(Review Figure 1-5.)*

■ Body systems combine to form the *organism,* or whole body.

1.3 Concept of Homeostasis (pp. 7–16)

■ The fluid inside the cells of the body is *intracellular fluid (ICF);* the fluid outside the cells is *extracellular fluid (ECF).*

■ Because most body cells are not in direct contact with the external environment, cell survival depends on maintaining a relatively stable *internal fluid environment* with which the cells directly make life-sustaining exchanges.

■ The ECF serves as the body's internal environment. It consists of the *plasma* and the *interstitial fluid*. *(Review Figure 1-6.)*

■ *Homeostasis* is the maintenance of a dynamic steady state in the internal environment.

■ The factors of the internal environment that must be homeostatically maintained are its (1) concentration of nutrients; (2) concentration of O_2 and CO_2; (3) concentration of waste products; (4) pH; (5) concentrations of water, salt, and other electrolytes; (6) volume and pressure; and (7) temperature. *(Review Figure 1-8.)*

■ The functions performed by the 11 body systems are directed toward maintaining homeostasis. These functions ultimately depend on the specialized activities of the cells that make up the system. Thus, *homeostasis is essential for each cell's survival, and each cell contributes to homeostasis. (Review Figures 1-7 and 1-8.)*

1.4 Homeostatic Control Systems (pp. 16–18)

■ A *homeostatic control system* is a network of body components working together to maintain a controlled variable in the internal environment relatively constant near an optimal set point despite changes in the variable.

■ Homeostatic control systems can be classified as (1) *intrinsic (local) controls,* which are inherent compensatory responses of an organ to a change, and (2) *extrinsic (systemic) controls,* which are responses of an organ triggered by factors external to the organ—namely, by the nervous and endocrine systems.

■ Both intrinsic and extrinsic control systems generally operate on the principle of *negative feedback:* A change in a controlled variable triggers a response that drives the variable in the opposite direction of the initial change, thus opposing the change. *(Review Figure 1-9.)*

■ In *positive feedback,* a change in a controlled variable triggers a response that drives the variable in the same direction as the initial change, thus amplifying the change. Positive feedback is uncommon in the body but is important in several instances, such as during childbirth.

■ *Feedforward mechanisms* respond in anticipation of a change in a regulated variable.

Figure 1-8 Role of the body systems in maintaining homeostasis.

BODY SYSTEMS
Made up of cells organized according to specialization to maintain homeostasis
See Chapter 1.

HOMEOSTASIS
A dynamic steady state of the constituents in the internal fluid environment that surrounds and exchanges materials with the cells
See Chapter 1.
Factors homeostatically maintained:
• Concentration of nutrient molecules
  See Chapters 16, 17, 18, and 19.
• Concentration of O_2 and CO_2
  See Chapter 13.
• Concentration of waste products
  See Chapter 14.
• pH *See Chapter 15.*
• Concentration of water, salts, and other electrolytes
  See Chapters 14, 15, 18, and 19.
• Temperature *See Chapter 17.*
• Volume and pressure
  See Chapters 10, 14, and 15.

Body systems maintain homeostasis

Homeostasis is essential for survival of cells

CELLS
Need homeostasis for their own survival and for performing specialized functions essential for survival of the whole body
See Chapters 1, 2, and 3.
Need a continual supply of nutrients and O_2 and ongoing elimination of acid-forming CO_2 to generate the energy needed to power life-sustaining cellular activities as follows:
Food + O_2 →CO_2 + H_2O + energy
See Chapters 13, 15, 16, and 17.

Cells make up body systems

NERVOUS SYSTEM
Acts through electrical signals to control rapid responses of the body; also responsible for higher functions—e.g., consciousness, memory, and creativity
See Chapters 4, 5, 6, and 7.

RESPIRATORY SYSTEM
Obtains O_2 from and eliminates CO_2 to the external environment; helps regulate pH by adjusting the rate of removal of acid-forming CO_2
See Chapters 13 and 15.

URINARY SYSTEM
Is important in regulating the volume, electrolyte composition, and pH of the internal environment; removes wastes and excess water, salt, acid, and other electrolytes from the plasma and eliminates them in the urine
See Chapters 14 and 15.

DIGESTIVE SYSTEM
Obtains nutrients, water, and electrolytes from the external environment and transfers them into the plasma; eliminates undigested food residues to the external environment
See Chapter 16.

REPRODUCTIVE SYSTEM
Is not essential for homeostasis, but essential for perpetuation of the species
See Chapter 20.

ENDOCRINE SYSTEM
Acts by means of hormones secreted into the blood to regulate processes that require duration rather than speed—e.g., metabolic activities and water and electrolyte balance
See Chapters 4, 18, and 19.

INTEGUMENTARY SYSTEM
Serves as a protective barrier between the external environment and the remainder of the body; the sweat glands and adjustments in skin blood flow are important in temperature regulation
See Chapters 12 and 17.

IMMUNE SYSTEM
Defends against foreign invaders and cancer cells; paves the way for tissue repair
See Chapter 12.

MUSCULAR AND SKELETAL SYSTEMS
Support and protect body parts and allow body movement; heat-generating muscle contractions are important in temperature regulation; calcium is stored in the bone
See Chapters 8, 17, 18, and 19.

CIRCULATORY SYSTEM
Transports nutrients, O_2, CO_2, wastes, electrolytes, and hormones throughout the body
See Chapters 9, 10, and 11.

Regulate

EXTERNAL ENVIRONMENT

2.1 Cell Theory and Discovery (p. 22)

■ The complex organization and interaction of the chemicals within a cell confer the unique characteristics of life. The cell is the smallest unit capable of carrying out life processes.

■ Cells are the living building blocks of the body. The structure and function of a *multicellular organism* ultimately depend on the structural and functional capabilities of its cells. *(Review Table 2-1.)*

■ Cells are too small for the unaided eye to see.

■ Using early microscopes, investigators learned that all plant and animal tissues consist of individual cells.

■ Scientists now know that a cell is a complex, highly organized, compartmentalized structure.

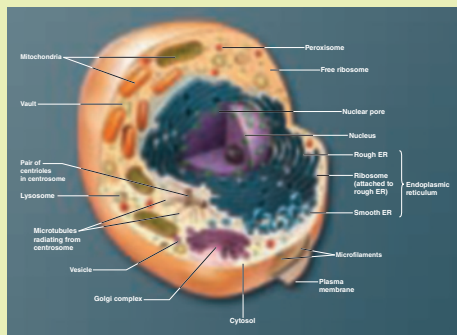
2.2 An Overview of Cell Structure (pp. 22–25)

■ Cells have three major subdivisions: the plasma membrane, the nucleus, and the cytoplasm. *(Review Figure 2-1.)*

■ The *plasma membrane* encloses the cell and separates the intracellular fluid (ICF) and extracellular fluid (ECF). It also controls movement into and out of the cell.

■ The *nucleus* contains *deoxyribonucleic acid (DNA),* the cell's genetic material. Three types of *ribonucleic acid (RNA)* play a role in the protein synthesis coded by DNA: *messenger RNA (mRNA),* which transcribes DNA's genetic code for delivery to a ribosome; *ribosomal RNA (rRNA)*, which is part of a ribosome that reads the mRNA code and translates it into a designated protein; and *transfer RNA (tRNA),* which delivers the appropriate amino acids to the protein under construction. The *genome* is all of the genetic information coded in a complete single set of DNA. The *proteome* is the complete set of proteins that can be expressed by protein-coding genes in the genome.

■ The *cytoplasm* consists of cytosol, a complex gel-like mass laced with organelles and a cytoskeleton.

■ *Organelles* are highly organized structures that serve a specific function. *Membranous organelles* are bound by a membrane that separates the organelle's contents from the surrounding cytosol. They include the endoplasmic reticulum, Golgi complex, lysosomes, peroxisomes, and mitochondria. *Nonmembranous organelles* are not surrounded by membrane and


include ribosomes, proteasomes, vaults, and centrioles. *(Review Figure 2-1 and Table 2-2, p. 45.)*

2.3 Endoplasmic Reticulum and Segregated Synthesis (pp. 25–28)

■ The *endoplasmic reticulum (ER)* is a single, complex, membranous network that encloses a fluid-filled lumen.

■ The primary function of the ER is to synthesize proteins and lipids that are either (1) secreted to the exterior of the cell, such as enzymes and hormones, or (2) used to produce new cell components, particularly plasma membrane.

■ The two types of ER are *rough ER* (flattened interconnected sacs studded with ribosomes) and *smooth ER* (interconnected tubules with no ribosomes). *(Review Figure 2-2a and b.)*

■ During protein synthesis, a large and a small ribosomal subunit unite to form a *ribosome* that translates mRNA. *(Review Figure 2-2c.)* The rough-ER ribosomes synthesize proteins that are released into the ER lumen, where they are separated from the cytosol. Also entering the lumen are lipids produced within the membranous walls of the ER.

■ Synthesized products move from the rough ER to the smooth ER, where they are packaged and discharged as *transport vesicles*. Transport vesicles are formed as a portion of the smooth ER "buds off." *(Review Figure 2-3.)*

■ Misfolded proteins in the ER lumen are tagged with *ubiquitin* and moved out to a *proteasome,* which degrades them. Other unwanted intracellular proteins are also marked with ubiquitin for destruction by proteasomes. *(Review Figure 2-4.)*

2.4 Golgi Complex and Exocytosis (pp. 28–30)

■ Transport vesicles move to and fuse with the *Golgi complex,* which consists of a stack of separate, flattened, membrane-enclosed sacs. *(Review Figures 2-3 and 2-5 and chapter opener.)*

■ The Golgi complex serves a twofold function: (1) to modify into finished products the newly synthesized molecules delivered to it in crude form from the ER, and (2) to sort, package, and direct molecular traffic to appropriate intracellular and extracellular destinations.

■ *Secretion* refers to the release of a specific product synthesized by the cell for a particular purpose. The Golgi complex of secretory cells packages proteins for export from the cell in *secretory vesicles* released by *exocytosis* on appropriate stimulation. *(Review Figures 2-3, 2-6a, and 2-7.)*

2.5 Lysosomes and Endocytosis (pp. 30–33)

■ *Lysosomes* are membrane-enclosed sacs that contain powerful *hydrolytic (digestive) enzymes. (Review Figure 2-8.)*

■ Serving as the intracellular "digestive system," lysosomes destroy foreign materials such as bacteria that have been internalized by the cell and demolish worn-out cell parts to make way for replacement parts.

■ Extracellular material is brought into the cell by *endocytosis* for attack by lysosomal enzymes. The three forms of endocytosis are *pinocytosis* (nonselective uptake of ECF; "cell drinking"),

receptor-mediated endocytosis (selective import of a specific large molecule), and *phagocytosis* (engulfment of a large multi-molecular particle; "cell eating"). *(Review Figures 2-6b and 2-9.)*

■ *Autophagy* is selective self-digestion of cell parts such as worn-out organelles by lysosomes.

2.6 Peroxisomes and Detoxification (p. 33)

■ *Peroxisomes* are small membrane-enclosed sacs containing powerful *oxidative enzymes. (Review Figure 2-8.)*

■ They carry out particular oxidative reactions that detoxify various wastes and toxic foreign compounds that have entered the cell. During these detoxification reactions, peroxisomes generate potent *hydrogen peroxide (H_2O_2)*, which they decompose into harmless water and oxygen by means of *catalase*.

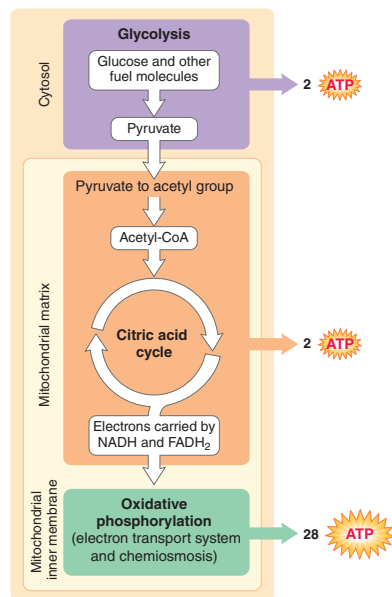
2.7 Mitochondria and ATP Production (pp. 33–41)

■ The rod-shaped *mitochondria* are enclosed by two membranes, a smooth outer membrane and an inner membrane consisting of a series of shelves, the *cristae,* which project into an interior gel-filled cavity, the *matrix*. *(Review Figure 2-10a and chapter opener, p. 21.)*

■ Mitochondria are the energy organelles of the cell. They efficiently convert the energy in food molecules to the usable energy stored in ATP molecules. Cells use ATP as an energy source for synthesis of new chemical compounds, for membrane transport, and for mechanical work.

■ *Cellular respiration* refers collectively to the intracellular reactions in which energy-rich molecules are broken down to form ATP, using O_2 and producing CO_2 in the process. Cellular respiration includes the sequential dismantling of nutrient molecules and subsequent ATP production in three stages: (1) *glycolysis* in the cytosol, (2) the *citric acid cycle* in the mitochondrial matrix, and (3) *oxidative phosphorylation* at the mitochondrial inner membrane. *(Review Figure 2-11.)*

❙Figure 2-11   Stages of cellular respiration.

■ *Oxidative phosphorylation* includes the electron transport system and chemiosmosis by ATP synthase. The *electron transport system* extracts high-energy electrons from hydrogens released during nutrient breakdown during glycolysis and the citric acid cycle and transfers them to successively lower energy levels. The free energy released during this process is used to create a hydrogen ion (H^+) gradient across the mitochondrial inner membrane. The flow of H^+ down this gradient activates *ATP synthase,*


an enzyme that synthesizes ATP in a process called *chemiosmosis. (Review Figures 2-12 through 2-15.)*

■ A cell is more efficient at converting food energy into ATP when O_2 is available. Without O_2 (an *anaerobic* condition), a cell can produce only 2 molecules of ATP for every glucose molecule processed by glycolysis. With O_2 (an *aerobic* condition), the mitochondria can yield another 30 molecules of ATP for every glucose molecule processed (2 from the citric acid cycle and 28 from oxidative phosphorylation). *(Review Figure 2-15.)*

2.8 Vaults as Cellular Trucks (pp. 41–42)

■ *Vaults* are hollow, octagonal structures that are the same shape and size as the nuclear pores. *(Review Figure 2-17.)* They are believed to be cellular trucks that dock at the nuclear pores and pick up cargo for transport from the nucleus.

■ The leading proposals are that vaults may transport mRNA or the ribosomal subunits from the nucleus to the cytoplasmic sites of protein synthesis.

2.9 Cytosol: Cell Gel (pp. 42–44)

■ The *cytosol* contains the enzymes involved in intermediary metabolism and the ribosomal machinery essential for synthesis of these enzymes and other cytosolic proteins.

■ Many cells store unused nutrients within the cytosol as glycogen granules or fat droplets. These nonpermanent masses of stored material are called *inclusions*. *(Review Figure 2-18.)*

■ Also present in the cytosol are various secretory, transport, and endocytic vesicles.

2.10 Cytoskeleton: Cell "Bone and Muscle" (pp. 44–51)

■ The *cytoskeleton,* which extends throughout the cytosol, serves as the "bone and muscle" of the cell. *(Review Table 2-2.)*

■ The three types of cytoskeletal elements—microtubules, microfilaments, and intermediate filaments—each consist of different proteins and perform various roles. *(Review Figure 2-19.)*

■ The *centrosome* (cell center) consists of a pair of *centrioles* surrounded by an amorphous mass. *(Review Figure 2-20.)* The centrosome and its centrioles form and organize microtubules as needed to serve various functions.

■ *Microtubules,* made of tubulin, maintain asymmetric cell shapes, serve as highways for intracellular transport by motor proteins, are the main component of cilia and flagella, and make up the mitotic spindle. *(Review Figures 2-19a and 2-21 through 2-23.)*

■ *Microfilaments,* made of actin in most cells, are important in various cellular contractile systems, including amoeboid movement and muscle contraction. They also serve as mechanical stiffeners for microvilli. *(Review Figures 2-19b and 2-24 through 2-26.)*

■ *Intermediate filaments* are irregular threadlike proteins that help cells resist mechanical stress. Different proteins make up intermediate filaments in various cell types. Intermediate filaments are especially abundant in skin cells, where they are composed of keratin. *(Review Figure 2-19c.)*

Chapter 3
Study Card

3.1 Membrane Structure and Functions (pp. 56–60)

■ All cells are bounded by a *plasma membrane,* a thin lipid bilayer that is interspersed with proteins and has carbohydrates attached on the outer surface.

■ The appearance of the plasma membrane in an electron microscope as a trilaminar structure (two dark lines separated by a light interspace) is produced by the arrangement of its molecules. The phospholipids orient themselves to form a bilayer with a hydrophobic interior (light interspace) sandwiched between hydrophilic outer and inner surfaces (dark lines). *(Review Figures 3-1, 3-2, and 3-3 and chapter opener.)*

■ The *lipid bilayer* forms the structural boundary of the cell, serving as a barrier for water-soluble substances and being responsible for the fluid nature of the membrane. Cholesterol molecules tucked between the phospholipids contribute to the fluidity and stability of the membrane.

■ According to the *fluid mosaic model* of membrane structure, the lipid bilayer is embedded with proteins. *(Review Figure 3-3.) Membrane proteins,* which vary in type and distribution among cells, serve as (1) channels for passage of small ions across the membrane; (2) carriers for transport of specific substances into or out of the cell; (3) docking-marker acceptors where secretory vesicles dock and release their contents; (4) membrane-bound enzymes that govern specific chemical reactions; (5) receptors for detecting and responding to chemical messengers that alter cell function; and (6) cell adhesion molecules that help hold cells together and are a structural link between the plasma membrane and the intracellular cytoskeleton.

■ *Membrane carbohydrates* on the outer surface of the cell serve as self-identity markers. *(Review Figure 3-3.)* They are important in recognition of "self" in cell-to-cell interactions such as tissue formation and tissue growth.
❘Figure 3-3 Fluid mosaic model of plasma membrane structure.

3.2 Cell-to-Cell Adhesions (pp. 60–63)

■ The *extracellular matrix (ECM)* serves as a biological "glue" between the cells of a tissue. The ECM consists of a watery, gel-like substance interspersed with three major types of protein fibers: *collagen* (provides tensile strength), *elastin* (permits stretch and recoil), and *fibronectin* (promotes cell adhesion).

■ Many cells are further joined by specialized cell junctions, of which there are three types: desmosomes, tight junctions, and gap junctions.

■ *Desmosomes* serve as adhering junctions to hold cells together mechanically and are especially important in tissues subject to a great deal of stretching. *(Review Figure 3-4.)*

■ *Tight junctions* actually fuse cells to each other, preventing the passage of materials between cells and thereby permitting only regulated passage of materials through the cells. These impermeable junctions are found in the epithelial sheets that separate compartments with very different chemical compositions. *(Review Figure 3-5.)*

■ *Gap junctions* are communicating junctions between two adjacent, but not touching, cells. They form small tunnels that permit exchange of ions and small molecules between the cells. Such movement of ions plays a key role in the spread of electrical activity to synchronize contraction in heart and smooth muscle. *(Review Figure 3-6.)*

3.3 Overview of Membrane Transport (p. 63)

■ Materials can pass between the ECF and ICF by *unassisted* and *assisted* means.

■ Transport mechanisms may also be *passive* (the particle moves across the membrane without the cell expending energy) or *active* (the cell expends energy to move the particle across the membrane). *(Review Table 3-2, p. 78.)*

3.4 Unassisted Membrane Transport (pp. 63–70)

■ Nonpolar (lipid-soluble) molecules of any size cross the membrane unassisted by dissolving in and passively moving through the lipid bilayer down concentration gradients. *(Review Figures 3-7 and 3-8.)* Small ions cross the membrane unassisted by passively moving along electrochemical gradients through open protein channels specific for the ion. *(Review Figure 3-3.)*

■ In *osmosis,* water moves passively down its own concentration gradient across a selectively permeable membrane to an area of higher concentration of nonpenetrating solutes. Penetrating solutes do not have an osmotic effect. *(Review Figures 3-9 through 3-12.)*

■ The *osmolarity* of a solution is a measure of its total number of solute particles, both penetrating and nonpenetrating, both molecules and ions, per liter. The *osmotic pressure* of a solution is the pressure that must be applied to the solution to completely stop osmosis. The *tonicity* of a solution refers to the effect the solution has on cell volume and depends on the solution's relative concentration of nonpenetrating solutes compared to the concentration of nonpenetrating solutes in the cell it surrounds. *(Review Figure 3-13.)*

3.5 Assisted Membrane Transport (pp. 70–77)

■ In *carrier-mediated transport,* small polar molecules and selected ions are transported across the membrane by specific

membrane carrier proteins. *Carriers* open to one side of the membrane where a passenger binds to a binding site specific for it and then change shape so that the binding site is exposed to the opposite side of the membrane where the passenger is released. Carrier-mediated transport may be passive and move the particle down its concentration gradient (*facilitated diffusion*) *(review Figure 3-14)* or active and move the particle against its concentration gradient (*active transport)*. Carriers exhibit a *transport maximum* (T_m) when saturated. *(Review Figure 3-15.)*

■ The two forms of active transport include primary active transport and secondary active transport. *Primary active transport* requires the direct use of ATP to drive the pump. One of the most important examples of primary active transport is the Na⁺–K⁺ pump, which concentrates Na⁺ in the ECF and K⁺ in the ICF. *(Review Figure 3-16.) Secondary active transport* is driven by an ion (usually Na⁺) concentration gradient established by a primary active-transport system. The two types of secondary active transport are symport (or cotransport) and antiport (or countertrans-

port or exchange). In *symport* both the cotransported solute and driving ion (Na⁺) are moved in the same direction (both moving into the cell), with the cotransported solute moving uphill and the driving ion moving downhill. In *antiport* the coupled solute and driving ion are moved in opposite directions (solute moving out of and Na⁺ moving into the cell), with the solute moving uphill and the driving ion moving downhill. *(Review Figures 3-17 and 3-18.)*
■ Large polar molecules and multimolecular particles can leave or enter the cell by being wrapped in a piece of membrane to form vesicles that can be internalized *(endocytosis)* or externalized *(exocytosis). (Review Figures 2-6, 2-7, and 2-9.)*

■ Cells are differentially selective in what enters or leaves because they possess varying numbers and kinds of channels, carriers, and mechanisms for vesicular transport.

■ Large polar molecules (too large for channels and not lipid soluble) for which there are no special transport mechanisms are unable to cross the membrane.

3.6 Membrane Potential (pp. 77–84)

■ All cells have a *membrane potential,* which is a separation of opposite charges across the plasma membrane. *(Review Figure 3-19.)*

■ The *Na⁺–K⁺* pump makes a small direct contribution to membrane potential because it transports more Na⁺ out than K⁺ in. *(Review Figure 3-16.)* However, the primary role of the Na⁺–K⁺ pump is to actively maintain a greater concentration of Na⁺ outside and a greater concentration of K⁺ inside the cell. These concentration gradients tend to passively move K⁺ out of and Na⁺ into the cell. *(Review Table 3-3 and Figures 3-20 and 3-21.)*

■ Because the resting membrane is 25 to 30 times more permeable to K⁺ than to Na⁺, substantially more K⁺ leaves the cell than Na⁺ enters, resulting in an excess of positive charges outside the cell. This leaves an unbalanced excess of negative charges, in the form of large protein anions (A⁻), trapped inside the cell. *(Review Table 3-3 and Figure 3-22.)*

■ When the resting membrane potential of –70 mV is achieved, no further net movement of K⁺ and Na⁺ takes place because any further leaking of these ions down their concentration gradients is quickly reversed by the Na⁺–K⁺ pump.

■ The distribution of Cl⁻ across the membrane is passively driven by the established membrane potential so that Cl⁻ is concentrated in the ECF.
❚Figure 3-16 Na⁺–K⁺ pump, an example of primary active transport.

(a) **Symport** (b) **Antiport**

❚Figure 3-17 Secondary active transport.

❚Figure 3-22 Effect of concurrent K⁺ and Na⁺ movement on establishing the resting membrane potential.

4.1 Introduction to Neural Communication (pp. 88–89)

■ Nerve and muscle cells are *excitable tissues* because they can rapidly alter their membrane permeabilities and undergo transient membrane potential changes when excited. These rapid changes in potential serve as electrical signals.

■ Compared to resting potential, a membrane becomes *depolarized* when the magnitude of its negative potential is reduced (becomes less negative) and *hyperpolarized* when the magnitude of its negative potential is increased (becomes more negative). *(Review Figure 4-1.)*

■ Changes in potential are brought about by *triggering events* that alter membrane permeability, in turn leading to changes in ion movement across the membrane.

■ The two kinds of potential change are: (1) graded potentials, the short-distance signals, and (2) action potentials, the long-distance signals. *(Review Table 4-1, p. 98.)*

4.2 Graded Potentials (pp. 89–91)

■ *Graded potentials* are local changes in membrane potential that occur in varying degrees of magnitude. A graded potential, usually a depolarization, occurs in a small, specialized region of an excitable cell membrane. The site undergoing a potential change is called an active area. Graded potentials spread decrementally by local current flow between the active area and adjacent inactive areas and die out over a short distance. *(Review Figures 4-2 and 4-3.)*

■ The magnitude of a graded potential varies directly with the magnitude of the triggering event.

4.3 Action Potentials (pp. 91–102)

■ *Action potentials* are brief, rapid, large changes in membrane potential during which the potential reverses.

■ During an action potential, depolarization of the membrane from resting potential (-70 mV) to *threshold potential* (-50 mV) triggers sequential changes in permeability caused by conformational changes in voltage-gated Na^+ and K^+ channels. These permeability changes bring about a brief reversal of membrane potential, with Na^+ influx causing the *rising phase* (from threshold to $+30$ mV), followed by K^+ efflux causing the *falling phase* (from peak back to resting). *(Review Figures 4-4 through 4-6.)*

■ Before an action potential returns to resting, it regenerates an identical new action potential in the area next to it by means of current flow that brings the previously inactive area to threshold. This self-perpetuating cycle continues until the action potential spreads undiminished throughout the cell membrane.

■ There are two types of action potential propagation: (1) *contiguous conduction* in unmyelinated fibers, in which the action potential spreads along every portion of the membrane; and (2) the more rapid, *saltatory conduction* in myelinated fibers, in which the impulse jumps from one node of Ranvier to the next over sections of the fiber covered with insulating myelin. *(Review Figures 4-8, 4-11, and 4-12.)*

■ The Na^+–K^+ pump gradually restores the ions that moved during propagation of the action potential to their original location, to maintain the concentration gradients.

■ It is impossible to restimulate the portion of the membrane where the impulse has just passed until it has recovered from its *refractory period,* ensuring the one-way propagation of action potentials. *(Review Figures 4-9 and 4-10.)*

■ Action potentials occur either maximally in response to stimulation or not at all *(all-or-none law).*

■ Variable strengths of stimuli are coded by varying the frequency of action potentials, not their magnitude, in an activated nerve fiber.

4.4 Synapses and Neuronal Integration (pp. 102–113)

■ One neuron directly interacts with another neuron primarily through a *chemical synapse. (Review Figures 4-13 and 4-14 and chapter opener, p. 87.)*

■ Most neurons have four different functional parts. *(Review Figure 4-7.)*

1. The *dendrite/cell body* region (the input zone) serves as the *postsynaptic* component that binds with and responds to neurotransmitters released from other neurons.

2. The *axon hillock* (the trigger zone) is where action potentials are initiated because it has the lowest threshold and thus reaches threshold first in response to an excitatory graded potential change.

3. The *axon,* or *nerve fiber* (the conducting zone), conducts action potentials in undiminished fashion from the axon hillock to the axon terminals.

4. The *axon terminals* (the output zone) serve as the *presynaptic* component, releasing a *neurotransmitter* that influences other postsynaptic cells in response to action potential propagation down the axon.

■ The released neurotransmitter combines with receptor-channels on the postsynaptic neuron. *(Review Figure 4-14.)* (1) If nonspecific cation channels that permit passage of both Na^+ and K^+ are opened, the resultant ionic fluxes cause an *EPSP,* a small depolarization that brings the postsynaptic cell closer to threshold. (2) If either K^+ or Cl^- channels are opened, the likelihood that the postsynaptic neuron reaches threshold is diminished when an *IPSP,* a small hyperpolarization, is produced. *(Review Figure 4-15.)*

■ If the dominant activity is in its excitatory inputs, the postsynaptic cell is likely to be brought to threshold and have an action potential. This can be accomplished by either (1) *temporal summation* (EPSPs from a single, repetitively firing, presynaptic input occurring so close together in time that they add together) or (2) *spatial summation* (adding of EPSPs occurring simultaneously from several different presynaptic inputs). *(Review Figure 4-16.)* If inhibitory inputs dominate, the postsynaptic potential is brought further than usual from threshold. If excitatory and in-

hibitory activity to the postsynaptic neuron is balanced, the membrane remains close to resting.

■ Even though there are a number of different neurotransmitters, each synapse always releases the same neurotransmitter to produce a given response when combined with a particular receptor. *(Review Table 4-2.)*

■ Synaptic pathways between neurons are incredibly complex as a result of *convergence* of neuronal input and *divergence* of its output. Usually, many presynaptic inputs converge on a single neuron and jointly control its level of excitability. This same neuron, in turn, diverges to synapse with and influence the excitability of many other cells. *(Review Figure 4-18.)*

4.5 Intercellular Communication and Signal Transduction (pp. 113–118)

■ Intercellular communication is accomplished *directly* via (1) gap junctions or (2) transient direct linkup of cells' complementary surface markers. *(Review Figure 4-19.)*

■ More commonly cells communicate *indirectly* with one another to carry out various coordinated activities by dispatching *extracellular chemical messengers,* which act on particular *target cells* to bring about the desired response. There are four types of extracellular chemical messengers, which differ in their source and in the distance and means by which they get to their site of action: (1) *paracrines* (local chemical messengers); (2) *neurotransmitters* (short-range chemical messengers released by neurons); (3) *hormones* (long-range chemical messengers secreted into the blood by endocrine glands); and (4) *neurohormones* (long-range chemical messengers secreted into the blood by neurosecretory neurons). *(Review Figure 4-19.)*

■ Transfer of the signal carried by the extracellular messenger into the cell for execution is known as *signal transduction*.

■ An extracellular chemical messenger that cannot gain entry to the cell, such as a peptide hormone (the first messenger), triggers the desired cellular response by binding to the target cell membrane and (1) opening *receptor-channels;* (2) activating *receptor-enzymes,* such as tyrosine kinase; or (3) activating an intracellular *second messenger* via *G-protein-coupled receptors. (Review Table 4-3 and Figures 4-21 and 4-22.)*

4.6 Introduction to Paracrine Communication (pp. 118–120)

■ *Paracrines* act on neighboring cells; *autocrines* act on the cell that secretes them. Most of these local signal molecules are either cytokines or eicosanoids.

■ *Cytokines* are protein signal molecules secreted mostly by immune cells but also by some nonimmune cells for the primary purpose of regulating immune responses. Some cytokines help control cell growth and differentiation, in which case they are specifically termed *growth factors*.

■ *Eicosanoids* are lipid signal molecules derived from arachidonic acid, a fatty acid constituent in the plasma membrane. The three main classes of eicosanoids are *prostaglandins, thrombocytes,* and *leukotrienes*, which collectively exert a multitude of local effects throughout the body. *(Review Figure 2-23 and Table 4-4.)*

4.7 Introduction to Hormonal Communication (pp. 120–127)

■ *Hormones* are long-distance chemical messengers secreted by the endocrine glands into the blood, which transports them to specific target sites where they control a particular function by altering protein activity within the target cells.

■ Hormones are grouped into two categories based on their solubility differences: (1) *hydrophilic (water-soluble) hormones,* which include peptides (most hormones) and catecholamines (secreted by the adrenal medulla); and (2) *lipophilic (lipid-soluble) hormones,* which include steroid hormones (the sex hormones and those secreted by the adrenal cortex) and thyroid hormone. *(Review Table 4-5.)*

■ Hydrophilic *peptide hormones* are synthesized and packaged for export by the endoplasmic reticulum–Golgi complex, stored in secretory vesicles, and released by exocytosis on appropriate stimulation. They dissolve freely in the blood for transport to their target cells.

■ At their target cells, hydrophilic hormones bind with surface membrane receptors, triggering a chain of intracellular events by means of a second-messenger pathway (typically either the cAMP pathway or the IP_3–Ca^{2+}/DAG pathway) that ultimately alters preexisting cell proteins, usually enzymes, leading to the target cell's response to the hormone. *(Review Figures 4-25 and 4-26.)* Through this cascade of reactions, the initial signal is greatly amplified. *(Review Figure 4-27.)*

■ *Steroids* are synthesized by modifying stored cholesterol via enzymes specific for each steroidogenic tissue. Steroids are not stored in endocrine cells. Being lipophilic, they diffuse out through the lipid membrane barrier as soon as they are synthesized. Control of steroids is directed at their synthesis.

■ Lipophilic steroids and thyroid hormone are both transported in the blood largely bound to carrier plasma proteins, with only free, unbound hormone being biologically active.

■ Lipophilic hormones readily cross the lipid membrane barriers of their target cells and bind with receptors inside the cell. Once the hormone binds with the receptor, the hormone receptor complex binds with DNA and activates a gene, which leads to the synthesis of new enzymatic or structural intracellular proteins that carry out the hormone's effect on the target cell. *(Review Figure 4-28.)*

4.8 Comparison of the Nervous and Endocrine Systems (pp. 127–129)

■ The nervous and endocrine systems are the two main regulatory systems of the body. *(Review Table 4-6.)* The nervous system is anatomically "wired" to its target organs, whereas the "wireless" endocrine system secretes blood-borne hormones that reach distant target organs.

■ Specificity of neural action depends on the anatomic proximity of the neurotransmitter-releasing neuronal terminal to its target organ. Specificity of endocrine action depends on specialization of target cell receptors for a specific circulating hormone.

■ In general, the nervous system coordinates rapid responses, whereas the endocrine system regulates activities that require duration rather than speed.

5.1 Organization and Cells of the Nervous System (pp. 134–138)

■ The nervous system consists of the *central nervous system (CNS),* which includes the brain and spinal cord, and the *peripheral nervous system (PNS),* which includes the nerve fibers carrying information to (afferent division) and from (efferent division) the CNS. *(Review Figure 5-1.)*

■ Three functional classes of neurons—afferent neurons, efferent neurons, and interneurons—compose the excitable cells of the nervous system. *(Review Figure 5-2.) Afferent neurons* inform the CNS about conditions in both the external and internal environment. *Efferent neurons* carry instructions from the CNS to effector organs (muscles and glands). *Interneurons* are responsible for integrating afferent information and formulating an efferent response, and for all higher mental ("mind") functions.

■ *Glial cells* form the connective tissue within the CNS and physically, metabolically, and functionally support the neurons. The glial cells are *astrocytes, oligodendrocytes, microglia,* and *ependymal cells*. *(Review Figures 5-3 and 5-4.)*

5.2 Protection and Nourishment of the Brain (pp. 139–142)

■ Neurons cannot divide to replace damaged cells, but several protective devices shelter the brain: (1) The brain is wrapped in three layers of protective membranes—the *meninges*—and is further surrounded by a hard, bony covering. (2) *Cerebrospinal fluid (CSF)* flows within and around the brain to cushion it against physical jarring. *(Review Figure 5-6.)* (3) Protection against chemical injury is conferred by a *blood–brain barrier (BBB)* that limits access of blood-borne substances to the brain.

■ The brain depends on a constant blood supply for delivery of O_2 and glucose because it cannot generate ATP in the absence of either of these substances.

5.3 Overview of the Central Nervous System (pp. 142–144)

■ The parts of the brain from the lowest, most primitive level to the highest, most sophisticated level are the brain stem, cerebellum, hypothalamus, thalamus, basal nuclei, and cerebral cortex. *(Review Figure 5-7 and Table 5-1.)*

5.4 Cerebral Cortex (pp. 144–153)

■ The *cerebral cortex* is the outer shell of gray matter that caps an underlying core of white matter. *Gray matter* consists primarily of neuronal cell bodies, dendrites, and glial cells. The cerebral cortex is organized into six layers, each containing varying numbers of *stellate cells* (neurons that process sensory input) and *pyramidal cells* (neurons that send output to motor neurons).

The *white matter* consists of bundles of nerve fibers that interconnect various areas. *(Review Figures 5-9 and 5-14.)*

■ Ultimate responsibility for many discrete functions is localized in particular regions of the cortex as follows: (1) the *occipital lobes* house the visual cortex; (2) the auditory cortex is in the *temporal lobes*; (3) the *parietal lobes* process somatosensory (somesthetic and proprioceptive) input; and (4) voluntary motor movement is set into motion by the motor areas in the *frontal lobes*. *(Review Figures 5-8 and 5-10 through 5-12.)*
▌Figure 5-11 **Functional areas of the cerebral cortex.**

■ *Language* ability depends on the integrated activity of two primary language areas—*Broca's area* and *Wernicke's area*— typically located only in the left cerebral hemisphere. *(Review Figures 5-11 and 5-13.)*

■ The *association areas* are regions of the cortex not specifically assigned to processing sensory input or commanding motor output or language ability. These areas provide an integrative link between diverse sensory information and purposeful action; they also play a key role in higher brain functions such as memory and decision making. They include the *prefrontal association cortex, the parietal–temporal–occipital association cortex,* and the *limbic association cortex*. *(Review Figure 5-11.)*

5.5 Basal Nuclei, Thalamus, and Hypothalamus (pp. 153–155)

■ The subcortical brain structures include the basal nuclei, thalamus, and hypothalamus. *(Review Figures 5-14 and 5-15.)*

■ The *basal nuclei* inhibit muscle tone; coordinate slow, sustained postural contractions; and suppress useless patterns of movement.

■ The *thalamus* serves as a relay station for preliminary processing of sensory input. It also accomplishes a crude awareness of sensation and some degree of consciousness.

■ The *hypothalamus* regulates body temperature, thirst, urine output, and food intake; extensively controls the autonomic nervous system and endocrine system; and is part of the limbic system.

5.6 Emotion, Behavior, and Motivation (pp. 155–157)

■ The *limbic system,* which includes portions of the hypothalamus and other structures that encircle the brain stem, plays an

important role in emotion, basic behavioral patterns, motivation, and learning. *(Review Figure 5-16.)*

■ *Emotion* refers to subjective feelings and moods and the physical responses associated with these feelings.

■ *Basic behavioral patterns* triggered by the limbic system are aimed at survival (such as attack) and perpetuation of the species (such as mating behavior). Higher cortical centers can reinforce, modify, or suppress these basic behaviors.

■ *Motivation* is the ability to direct behavior toward specific goals.

■ *Norepinephrine*, *dopamine*, and *serotonin* are the key neurotransmitters in pathways for emotions and behavior.

5.7 Learning and Memory (pp. 157–163)

■ *Learning* refers to acquiring knowledge or skills as a result of experience, instruction, or both. *Memory* is storage of acquired knowledge for later recall and use.

■ There are two types of memory: (1) *short-term memory* with limited capacity and brief retention, coded by modifying activity at preexisting synapses; and (2) *long-term memory* with large storage capacity and enduring retention, involving relatively permanent structural or functional changes, such as forming new synapses between existing neurons. Enhanced protein synthesis underlies these long-term changes. *(Review Table 5-2.)*

■ *The hippocampus* plays a role in *consolidation*, the transfer of short-term memory to long-term memory. *Long-term potentiation (LTP),* a prolonged increase in the strength of existing synaptic connections in activated pathways, might be the link between short-term memory and consolidation of long-term memory. *(Review Figure 5-17.)*

■ The *hippocampus* and associated structures are especially important in *declarative,* or "what," *memories* of specific objects, facts, and events. The *cerebellum* and associated structures are especially important in *procedural,* or "how to," *memories* of motor skills gained through repetitive training.

■ The *prefrontal association cortex* is the site of *working memory,* which temporarily holds currently relevant data—both new information and knowledge retrieved from memory stores—and manipulates and relates them to accomplish the higher-reasoning processes of the brain.

5.8 Cerebellum (pp. 163–166)

■ The *cerebellum,* attached at the back of the brain stem beneath the cortex, consists of three functionally distinct parts. *(Review Figure 5-18.)*

■ The *vestibulocerebellum* helps maintain balance and controls eye movements. The *spinocerebellum* enhances muscle tone and helps coordinate voluntary movement, especially fast, phasic motor activities. The *cerebrocerebellum* plays a role in initiating voluntary movement and in storing procedural memories.

5.9 Brain Stem (pp. 166–172)

■ The *brain stem* is an important link between the spinal cord and higher brain levels.

■ The brain stem is the origin of the *cranial nerves. (Review Table 5-3.)* It also contains *centers* that control cardiovascular, respiratory, and digestive function. It further regulates postural muscle reflexes. Finally, it controls the overall degree of cortical alertness via the *reticular activating system,* or *RAS,* and plays a key role in the sleep–wake cycle. *(Review Figure 5-19.)*

■ *Consciousness* is the subjective awareness of the external world and self. The normal states of consciousness are wakefulness and sleep.

■ *Sleep* is an active process, not just the absence of wakefulness. While sleeping, a person cyclically alternates between slow-wave sleep and paradoxical (REM) sleep. *Slow-wave sleep* is characterized by slow waves on the EEG and little change in behavior pattern from the waking state except for not being consciously aware of the external world. *Paradoxical,* or *REM, sleep* is characterized by an EEG pattern similar to that of an alert, awake individual; rapid eye movements, dreaming, and abrupt changes in behavior pattern occur. *(Review Table 5-4 and Figures 5-20 and 5-21.)*

■ The prevailing *state of consciousness* depends on the cyclical interplay among an *arousal system* originating in the brain stem (RAS) and commanded by hypocretin-secreting neurons in the hypothalamus, (2) a *slow-wave sleep center* consisting of sleep-on neurons in the hypothalamus, and (3) an *REM sleep center* consisting of REM sleep-on neurons in the brain stem.

■ The leading theories of why we need sleep fall into the categories of (1) restoration and recovery, (2) memory consolidation, and (3) synaptic homeostasis.

5.10 Spinal Cord (pp. 172–178)

■ Extending from the brain stem, the *spinal cord* descends through a canal formed by surrounding protective vertebrae. *(Review Figures 5-22 and 5-23.)*

■ The spinal cord has two functions. (1) It serves as the link between the brain and the peripheral nervous system. All communication up and down the spinal cord is located in *ascending* and *descending tracts* in the cord's outer white matter. *(Review Figures 5-25 and 5-26.)* (2) It is the integrating center for spinal reflexes. The basic *reflex arc* includes a receptor, an afferent pathway, an integrating center, an efferent pathway, and an effector.

■ The centrally located gray matter of the spinal cord contains the cell bodies of efferent neurons and the interneurons interposed between afferent input and efferent output. *(Review Figures 5-24 and 5-27.)*

■ A *nerve* is a bundle of peripheral neuronal axons, both afferent and efferent, wrapped in connective tissue and following the same pathway. *Spinal nerves* supply specific body regions and are attached to the spinal cord in paired fashion throughout its length. *(Review Figures 5-22 through 5-24 and 5-28.)*

■ The 31 pairs of spinal nerves along with the 12 pairs of cranial nerves that arise from the brain stem constitute the peripheral nervous system. *(Review Figure 5-23.)*

6.1 Receptor Physiology (pp. 182–189)

■ The *afferent division* of the PNS carries information about the internal and the external environment to the CNS.

■ *Sensory receptors* are specialized peripheral endings of afferent neurons. *(Review Figure 6-1.)* Each receptor type (photoreceptor, mechanoreceptor, thermoreceptor, osmoreceptor, chemoreceptor, or nociceptor) responds to its *adequate stimulus* (a change in the energy form, or *modality,* to which it is responsive), translating the stimulus energy form into electrical signals.

■ A stimulus typically brings about a graded, depolarizing *receptor potential* by opening channels that allow net Na^+ entry. Receptor potentials, if of sufficient magnitude, ultimately generate action potentials in the afferent fiber next to the receptor. These action potentials self-propagate along the afferent fiber to the CNS. *(Review Figures 6-1 and 6-2.)* The strength of the stimulus determines the magnitude of the receptor potential, which in turn determines the frequency of action potentials generated. *(Review Figure 6-3 and Table 6-1.)*

■ The magnitude of the receptor potential is also influenced by the extent of receptor *adaptation,* which is a reduction in receptor potential despite sustained stimulation. (1) *Tonic receptors* adapt slowly or not at all and thus provide continuous information about the stimuli they monitor. (2) *Phasic receptors* adapt rapidly and frequently exhibit off responses, thereby providing information about changes in the energy form they monitor. *(Review Figure 6-4.)*

■ *Visceral afferent information* remains mostly subconscious. *Sensory afferent information* reaches the level of conscious awareness, including (1) somatic sensation (somesthetic sensation and proprioception) and (2) special senses.

■ Discrete *labeled-line* pathways lead from the receptors to the CNS so that the CNS can decipher information about the type and location of stimuli. *(Review Table 6-1.)*

■ The term *receptive field* refers to the area surrounding a receptor within which the receptor can detect stimuli. The *acuity,* or *discriminative ability,* of a body region varies inversely with the size of its receptive fields and also depends on the extent of *lateral inhibition* in the afferent pathways arising from receptors in the region. *(Review Figures 6-6 and 6-7.)*

■ *Perception* is the conscious interpretation of the external world that the brain creates from sensory input. What the brain perceives from its input is an abstraction and not reality. *(Review Figure 6-8.)* The only stimuli that can be detected are those for which receptors are present. Furthermore, as sensory signals ascend through progressively more complex processing, parts of the information may be suppressed or enhanced.

6.2 Pain (pp. 189–192)

■ Painful experiences are elicited by *nociceptors* responding to noxious stimuli and consist of two components: the perception of pain coupled with emotional and behavioral responses to it. The three categories of pain receptors are *mechanical, thermal,* and *polymodal* nociceptors. The latter respond to all kinds of damaging stimuli, including chemicals released from injured tissues.

■ Pain signals are transmitted over two afferent pathways: a *fast pathway* via A-delta fibers that carry sharp, prickling pain signals and a *slow pathway* via C fibers that carry dull, aching, persistent pain signals. *(Review Table 6-2.)*

■ Afferent pain fibers terminate in the spinal cord on ascending pathways that transmit the signal to the brain for processing. Descending pathways from the brain use *endogenous opioids* to suppress the release of *substance P,* a pain-signaling neurotransmitter from the afferent pain-fiber terminal. Thus, these descending pathways block further transmission of the pain signal and serve as a built-in *analgesic system*. *(Review Figure 6-9.)*

6.3 Eye: Vision (pp. 192–211)

■ Light is a form of electromagnetic radiation, with *visible light* being only a small band in the total electromagnetic spectrum. *(Review Figures 6-12 and 6-13.)*

■ The *eye* houses the light-sensitive *photoreceptors* essential for vision—the rods and cones found in its *retina* layer. *(Review Figures 6-10; 6-20, p. 199; and 6-24, p. 201; and Tables 6-3, p. 204, and 6-4, p. 208.)*

■ The *iris* controls the size of the *pupil* to adjust the amount of light permitted to enter the eye. *(Review Figure 6-11.)*

■ The *cornea* and *lens* are the primary *refractive* structures that bend incoming light rays to focus the image on the retina. The cornea contributes most to the total refractive ability of the eye. The strength of the lens can be adjusted through action of the *ciliary muscle* to *accommodate* for differences in near and far vision. *(Review Figures 6-14 through 6-19.)*

■ *Rods* and *cones* have three parts: a photopigment-containing outer segment, a metabolically specialized inner segment, and a neurotransmitter-secreting synaptic terminal. *(Review Figures 6-20, 6-24, and 6-25.)*

■ Rods and cones secrete neurotransmitter in the dark. They are activated when their *photopigments* differentially absorb various wavelengths of light. Photopigments consist of *opsin,* a membrane protein, and *retinal,* a vitamin A derivative. During *phototransduction,* light absorption by retinal causes a biochemical change in the photopigment that, through a series of steps, hyperpolarizes the photoreceptor, leading to decreased neurotransmitter release. Further retinal processing by *on-center* and *off-center bipolar and ganglion cells* eventually converts this light-induced signal into a change in the rate of action potential propagation in the visual pathway leaving the retina. *(Review Figures 6-24, 6-25, and 6-26.)*

- Cones display high acuity but can be used only for *day vision* because of their low sensitivity to light. According to the *trichromatic theory,* different ratios of stimulation of three cone types (red, blue, and green) by varying wavelengths of light lead to *color vision*. According to the *opponent-process theory,* color vision depends on further processing of three opponent pairs of colors that are mutually exclusive (red/green, blue/yellow, and black/white). *(Review Table 6-3 and Figures 6-27 through 6-29.)*

- Rods provide only indistinct vision in shades of gray, but because they are very sensitive to light, they can be used for *night vision*. *(Review Table 6-3.)*

- The visual message is transmitted via a complex crossed and uncrossed pathway to the *visual cortex* in the occipital lobe of the brain for perceptual processing. *(Review Figure 6-30.)*

6.4 Ear: Hearing and Equilibrium (pp. 211–224)

- The *ear* performs two unrelated functions: (1) *hearing,* which involves the *external ear, middle ear,* and *cochlea of the inner ear;* and (2) *sense of equilibrium,* which involves the *vestibular apparatus of the inner ear.* The ear receptor cells located in the inner ear—the *hair cells* in the cochlea and vestibular apparatus—are *mechanoreceptors. (Review Figure 6-31 and Table 6-6, p. 225.)*

- *Hearing* depends on the ear's ability to convert airborne sound waves into mechanical deformations of auditory hair cells, thereby initiating neural signals. *Sound waves* consist of high-pressure regions of compression alternating with low-pressure regions of rarefaction of air molecules. The *pitch (tone)* of a sound is determined by the frequency of its waves, the *loudness (intensity)* by the amplitude of the waves, and the *timbre (quality)* by its characteristic overtones. *(Review Figures 6-32 and 6-33 and Table 6-5.)*

- Sound waves are funneled through the *ear canal* to the *tympanic membrane,* which vibrates in sync with the waves. *Middle ear bones* bridging the gap between the tympanic membrane and inner ear amplify the tympanic movements and transmit them to the *oval window,* whose movement sets up traveling waves in the cochlear fluid. *(Review Figures 6-34 and 6-35.)*

- These waves, which are at the same frequency as the original sound waves, set the *basilar membrane* in motion. Various regions of this membrane selectively vibrate more vigorously in response to different frequencies of sound. Its narrow, stiff end near the oval window vibrates best with high-frequency pitches, and its wide, flexible end near the helicotrema vibrates best with low-frequency pitches. *(Review Figure 6-35.)*

- On top of the basilar membrane are the receptive inner hair cells of the *organ of Corti,* whose *stereocilia* ("hairs") are bent as the basilar membrane is deflected up and down in relation to the overhanging stationary *tectorial membrane,* which the hairs contact. *(Review Figures 6-34, 6-36, and 6-37.)*

- *Pitch discrimination* depends on which region of the basilar membrane naturally vibrates maximally with a given frequency.

Loudness discrimination depends on the amplitude of the vibrations. Hair bending in the region of maximal basilar membrane vibration is transduced into neural signals that are transmitted to the *auditory cortex* in the temporal lobe of the brain for sound perception. *(Review Figure 6-38.)*

- The vestibular apparatus in the inner ear consists of (1) the *semicircular canals,* which detect rotational acceleration or deceleration in any direction; and (2) the *utricle* and the *saccule,* which collectively detect changes in the rate of linear movement in any direction and provide information important for determining head position in relation to gravity. Neural signals are generated in response to the mechanical deformation of vestibular hair cells by specific movement of fluid and related structures within these sense organs. *(Review Figures 6-40 and 6-41.)*

- Vestibular input goes to the *vestibular nuclei* in the brain stem and to the *cerebellum* for use in maintaining balance and posture, controlling eye movement, and perceiving motion and orientation.

6.5 Chemical Senses: Taste and Smell (pp. 224–230)

- *Taste* and *smell* are chemical senses. In both cases, attachment of specific dissolved molecules to binding sites on a *chemoreceptor* causes receptor potentials that, in turn, set up neural impulses signaling the presence of the chemical.

- *Taste receptors* are housed in *taste buds* on the tongue; *olfactory receptors* are located in the *olfactory mucosa* in the upper part of the nasal cavity. *(Review Figures 6-42 and 6-43.)*

- Both sensory pathways include two routes: one to the *limbic system* for emotional and behavioral processing and one to the *cortex* for conscious perception and fine discrimination.

- Taste and olfactory receptors are continuously renewed, unlike visual and hearing receptors, which are irreplaceable.

- The five *primary tastes* are salty, sour, sweet, bitter, and umami (a meaty, "amino-acid" taste). *Taste discrimination* beyond the primary tastes depends on the patterns of stimulation of the taste buds by *tastants*. Each taste receptor responds to one of the primary tastes. Salty and sour tastants bring about receptor potentials in taste buds by directly affecting membrane channels, whereas the other three categories of tastants act through second-messenger pathways to bring about receptor potentials.

- The 1000 different types of olfactory receptors each respond to only one discrete component of an odor, an *odorant*. Odorants act through second-messenger pathways to trigger receptor potentials. The afferent signals arising from the olfactory receptors are sorted according to scent component by the *glomeruli* within the *olfactory bulb*. *Odor discrimination* depends on the patterns of activation of the glomeruli. *(Review Figure 6-44.)*

7.1 Autonomic Nervous System (pp. 234–241)

■ The CNS controls muscles and glands by transmitting signals to these effector organs through the *efferent division* of the PNS.

■ There are two types of efferent output: the *autonomic nervous system,* which is under involuntary control and supplies cardiac and smooth muscle and most exocrine and some endocrine glands, and the *somatic nervous system,* which is subject to voluntary control and supplies skeletal muscle. *(Review Table 7-4, p. 242, and Table 7-5, p. 243.)*

■ The autonomic nervous system consists of two subdivisions—the *sympathetic* and *parasympathetic nervous systems*. *(Review Figures 7-2 and 7-3 and Tables 7-1 and 7-3.)*

■ An autonomic nerve pathway consists of a two-neuron chain. The *preganglionic fiber* originates in the CNS and synapses with the cell body of the *postganglionic fiber* in a ganglion outside the CNS. The postganglionic fiber ends on the effector organ. *(Review Figures 7-1, 7-2, and 7-3 and Table 7-3.)*

■ All preganglionic fibers and parasympathetic postganglionic fibers are *cholinergic,* that is, release *acetylcholine (ACh).* Sympathetic postganglionic fibers are *adrenergic,* that is, release *norepinephrine. (Review Figure 7-2 and Table 7-2.)*
I Figure 7-2 **Autonomic nervous system**.

■ Postganglionic fibers have numerous swellings, or *varicosities,* that simultaneously release neurotransmitter over a large area of the innervated organ. *(Review Figures 7-1 and 8-33, p. 292.)*

■ The *adrenal medulla,* an endocrine gland, is a modified sympathetic ganglion that secretes the hormones epinephrine and to a lesser extent norepinephrine into the blood in response to stimulation by the sympathetic preganglionic fiber that innervates it. *(Review Figure 7-2.)*

■ The same neurotransmitter elicits different responses in different tissues. Thus, the response depends on specialization of the tissue cells, not on the properties of the messenger. *(Review Tables 7-1 and 7-2.)*

■ Tissues innervated by the autonomic nervous system possess one or more of several different receptor types for the postganglionic chemical messengers (and for the related adrenomedullary hormone epinephrine). Cholinergic receptors include *nicotinic* and *muscarinic receptors*; adrenergic receptors include α_1, α_2, β_1, and β_2 receptors. *(Review Figure 7-2 and Tables 7-1, 7-2, and 7-3.)*

I TABLE 7-2 Properties of Autonomic Receptor Types

Receptor Type	Neurotransmitter Affinity	Effector(s) with Receptor Type	Mechanism of Action at Effector	Effect on Effector
Nicotinic	ACh from autonomic preganglionic fibers	All autonomic postganglionic cell bodies; adrenal medulla	Opens nonspecific cation receptor-channels	Excitatory
	ACh from motor neurons	Motor end plates of skeletal muscle fibers	Opens nonspecific cation receptor-channels	Excitatory
Muscarinic	ACh from parasympathetic postganglionic fibers	Cardiac muscle, smooth muscle, glands	Activates various G-protein-coupled receptor pathways, depending on effector	Excitatory or inhibitory, depending on effector
α_1	Greater affinity for NE (from sympathetic postganglionic fibers) than for E (from the adrenal medulla)	Most sympathetic target tissues	Activates IP_3–Ca^{2+} second-messenger pathway	Excitatory
α_2	Greater affinity for NE than for E	Digestive organs	Inhibits cAMP	Inhibitory
β_1	Equal affinity for NE and for E	Heart	Activates cAMP	Excitatory
β_2	Affinity for E only	Smooth muscles of arterioles and bronchioles	Activates cAMP	Inhibitory

■ A given autonomic fiber either excites or inhibits activity in the organ it innervates. *(Review Tables 7-1 and 7-2.)*

■ Most visceral organs are innervated by both sympathetic and parasympathetic fibers, which in general produce opposite effects in a particular organ. *Dual innervation* of organs by both branches of the autonomic nervous system permits precise control over an organ's activity. *(Review Figure 7-2 and Table 7-1.)*

■ The sympathetic system dominates in emergency or stressful *("fight-or-flight")* situations and promotes responses that prepare the body for strenuous physical activity. The parasympathetic system dominates in quiet, relaxed *("rest-and-digest")* situations and promotes body-maintenance activities such as digestion. *(Review Tables 7-1 and 7-3.)*

I TABLE 7-3 Comparison of the Sympathetic and the Parasympathetic Nervous System

Feature	Sympathetic System	Parasympathetic System
Origin of preganglionic fiber	Thoracic and lumbar regions of the spinal cord	Brain and sacral region of the spinal cord
Origin of postganglionic fiber	Sympathetic ganglion chain (near the spinal cord) or collateral ganglia (about halfway between spinal cord and effector organs)	Terminal ganglia (in or near effector organs)
Fiber length	Short preganglionic fibers, long postganglionic fibers	Long preganglionic fibers, short postganglionic fibers
Neurotransmitter released	Preganglionic: ACh	Preganglionic: ACh
	Postganglionic: NE	Postganglionic: ACh
Types of receptors for neurotransmitters	For preganglionic neurotransmitter: nicotinic	For preganglionic neurotransmitter: nicotinic
	For postganglionic neurotransmitter: α_1, α_2, β_1, β_2	For postganglionic neurotransmitter: muscarinic
Dominance	Dominates in "fight-or-flight" situations	Dominates in "rest-and-digest" situations

■ Visceral afferent input is used by the CNS to direct appropriate autonomic output to maintain homeostasis. Autonomic activities are controlled by multiple areas of the CNS, including the spinal cord, medulla, hypothalamus, and prefrontal association cortex.

7.2 Somatic Nervous System (pp. 242–244)

■ The somatic nervous system consists of the axons of *motor neurons,* which originate in the spinal cord or brain stem and end on skeletal muscle. *(Review Figure 7-4 and Table 7-4.)*

■ *ACh*, the neurotransmitter released from a motor neuron, stimulates muscle contraction.

■ Motor neurons are the *final common pathway* by which various regions of the CNS exert control over skeletal muscle activity. The areas of the CNS that influence skeletal muscle activity by acting through the motor neurons are the spinal cord, motor regions of the cortex, basal nuclei, cerebellum, and brain stem.

ITABLE 7-4	Comparison of the Autonomic and the Somatic Nervous System	
Feature	**Autonomic Nervous System**	**Somatic Nervous System**
Site of origin	Sympathetic: lateral horn of thoracic and lumbar spinal cord Parasympathetic: brain and sacral spinal cord	Ventral horn of spinal cord for most; those supplying muscles in head originate in brain
Number of neurons from CNS to effector organ	Two-neuron chain (preganglionic and postganglionic)	Single neuron (motor neuron)
Organs innervated	Cardiac muscle, smooth muscle, most exocrine and some endocrine glands	Skeletal muscle
Type of innervation	Most effector organs dually innervated by the two antagonistic branches of this system (sympathetic and parasympathetic)	Effector organs innervated only by motor neurons
Neurotransmitter at effector organs	May be ACh (parasympathetic terminals) or NE (sympathetic terminals)	Only ACh
Effects on effector organs	Either stimulation or inhibition (antagonistic actions of two branches)	Stimulation only (inhibition possible only centrally through IPSPs on dendrites and cell body of motor neuron)
Type of control	Under involuntary control	Subject to voluntary control; much activity subconsciously coordinated
Higher centers involved in control	Spinal cord, medulla, hypothalamus, prefrontal association cortex	Spinal cord, motor cortex, basal nuclei, cerebellum, brain stem

IFigure 7-4 **Motor neuron innervating skeletal muscle cells.**

7.3 Neuromuscular Junction (pp. 244–248)

■ When a motor neuron reaches a muscle, it branches into axon terminals. Each axon terminal forms a *neuromuscular junction* with a single muscle cell (fiber). The axon terminal splits into multiple fine branches, each of which ends in an enlarged *terminal button. (Review Figure 7-4 and chapter opener, p. 233.)*

■ The specialized region of the muscle cell membrane underlying the axon-terminal complex is called the *motor end plate*. Because these structures do not make direct contact, signals are passed between a terminal button and muscle fiber by chemical means. *(Review Figure 7-5.)*

■ An action potential in the axon terminal causes the release of ACh from its storage vesicles in the terminal button. The released ACh diffuses across the space separating the nerve and muscle cells and binds to special receptor-channels on the underlying motor end plate. This binding triggers the opening of these nonspecific cation channels. The subsequent ion movements depolarize the motor end plate, producing the *end-plate potential (EPP). (Review Figure 7-5.)*

■ Local current flow between the depolarized end plate and adjacent muscle cell membrane brings these adjacent areas to threshold, initiating an action potential that is propagated throughout the muscle fiber. This muscle action potential triggers muscle contraction. *(Review Figure 7-5.)*

■ Membrane-bound *acetylcholinesterase,* an enzyme in the motor end plate, inactivates ACh, ending the EPP and, subsequently, the action potential and resultant contraction. *(Review Figure 7-5.)*

1 An action potential in a motor neuron is propagated to the terminal button.

2 This local action potential triggers the opening of voltage-gated Ca^{2+} channels and the subsequent entry of Ca^{2+} into the terminal button.

3 Ca^{2+} triggers the release of acetylcholine (ACh) by exocytosis from a portion of the vesicles.

4 ACh diffuses across the space separating the nerve and muscle cells and binds with receptor-channels specific for it on the motor end plate of the muscle cell membrane.

5 This binding brings about the opening of these nonspecific cation channels, leading to a relatively large movement of Na^+ into the muscle cell compared to a smaller movement of K^+ outward.

6 The result is an end-plate potential. Local current flow occurs between the depolarized end plate and the adjacent membrane.

7 This local current flow opens voltage-gated Na^+ channels in the adjacent membrane.

8 The resultant Na^+ entry reduces the potential to threshold, initiating an action potential, which is propagated throughout the muscle fiber.

9 ACh is subsequently destroyed by acetylcholinesterase, an enzyme located on the motor end-plate membrane, terminating the muscle cell's response.

IFigure 7-5 **Events at a neuromuscular junction.**

Chapter 8
Study Card

8.1 Structure of Skeletal Muscle (pp. 252–256)

■ *Muscles*, contraction specialists, can develop tension, shorten, produce movement, and accomplish work.

■ The three types of muscle are *skeletal, cardiac* and *smooth*. Skeletal muscle and cardiac muscle are *striated,* whereas smooth muscle is *unstriated*. Skeletal muscle is *voluntary,* whereas cardiac muscle and smooth muscle are *involuntary*. *(Review Figure 8-1.)*

■ *Skeletal muscles* are made up of bundles of long, thick, cylindrical muscle cells, called *muscle fibers,* wrapped in connective tissue. Muscle fibers are packed with *myofibrils,* each myofibril consisting of alternating, slightly overlapping stacked sets of thick and thin filaments. This arrangement leads to a skeletal muscle fiber's striated microscopic appearance, which consists of alternating dark *A bands* and light *I bands*. A *sarcomere*, the area between two Z lines, is the *functional unit* of skeletal muscle. *(Review Figures 8-2 and 8-3 and chapter opener.)*

■ *Thick filaments* consist of the protein *myosin*. *Cross bridges* made up of the myosin molecules' globular heads project from each thick filament toward the surrounding thin filaments. A cross bridge has an actin binding site and an ATPase site. *(Review Figures 8-2 and 8-4.)*

■ *Thin filaments* consist primarily of the protein *actin,* which can bind and interact with the myosin cross bridges to bring about contraction. In the resting state two other proteins, *tropomyosin* and *troponin,* lie across the thin filament surface and cover actin's binding site for attachment with a cross bridge, thus preventing this cross-bridge interaction. *(Review Figures 8-2 and 8-5.)*

8.2 Molecular Basis of Skeletal Muscle Contraction (pp. 256–262)

■ During *excitation-contraction coupling,* excitation of a skeletal muscle fiber by its motor neuron brings about contraction through a series of events resulting in the thin filaments sliding closer together between the thick filaments. *(Review Figure 8-7.)*

■ This *sliding filament mechanism* of muscle contraction is switched on by Ca^{2+} release from the *lateral sacs of the sarcoplasmic reticulum* in response to the spread of a muscle fiber action potential into the central portions of the fiber via the *T tubules*. *(Review Figures 8-9, 8-10, and 8-11.)*

■ *Released Ca^{2+}* binds to troponin, slightly repositioning tropomyosin to uncover actin's cross-bridge binding sites. *(Review Figures 8-6 and 8-11.)*

■ Binding of actin to a myosin cross bridge triggers cross-bridge stroking, powered by energy stored in the myosin head from prior splitting of ATP by myosin ATPase. During a *power stroke* the cross bridge bends toward the thick filament's center, "row-ing" in the thin filament to which it is attached. *(Review Figures 8-8, 8-11, and 8-12.)*

■ When a fresh ATP attaches to the cross bridge, myosin and actin detach, the cross bridge returns to its original shape, and the cycle is repeated. Repeated cycles of cross-bridge activity slide the thin filaments inward step by step. *(Review Figures 8-8 and 8-12.)*

■ When the action potential ends, the lateral sacs actively take up the Ca^{2+}, troponin and tropomyosin slip back into their blocking position, and *relaxation* occurs. *(Review Figure 8-11.)*

■ The entire contractile response lasts up to 100 times longer than the action potential. *(Review Figure 8-13.)*

8.3 Skeletal Muscle Mechanics (pp. 262–269)

■ *Tension* is generated within a muscle by the *contractile component* (sarcomere shortening brought about by cross-bridge cycling). To move the bone to which the muscle's insertion is attached, this internal tension is transmitted to the bone as the contractile component stretches and tightens the muscle's *series-elastic component* (tendon). The *load* is the opposing force exerted on the muscle by the weight of an object. *(Review Figure 8-14.)*

■ The three primary types of muscle contraction are (1) *isotonic* (literally constant tension) in which the load remains constant as the muscle changes length (shortens in a *concentric* contraction and lengthens in an *eccentric* contraction), (2) *isokinetic* (constant velocity) in which the velocity of shortening remains constant as the muscle changes length, and (3) *isometric* (constant length) in which the muscle length does not change as tension increases.

■ The *velocity,* or speed, of shortening is inversely proportional to the load. *(Review Figure 8-16.)*

■ The amount of *work* accomplished by a contracting muscle equals the magnitude of the load times the distance the load is moved. Many muscles are part of a *lever system* that amplifies the distance and velocity of shortening of a muscle at the expense of the muscle having to exert increased force to move a load. *(Review Figure 8-17.)* The amount of energy consumed by a contracting muscle that is realized as external work varies from 0% to 25%; the remaining energy is converted to heat.

■ *Gradation* of whole-muscle contraction can be accomplished by (1) varying the number of muscle fibers contracting within the muscle and (2) varying the tension developed by each contracting fiber. *(Review Table 8-2, p. 275.)*

■ The number of fibers contracting depends on (1) size of the muscle (number of muscle fibers present), (2) extent of *motor unit recruitment* (how many motor neurons supplying the muscle are active), and (3) size of each motor unit (how many muscle fibers are activated simultaneously by a single motor neuron). A *motor unit* is a motor neuron plus all of the muscle fibers it innervates. *(Review Figure 8-18 and Table 8-2.)*

■ Two variable factors that affect fiber tension are (1) frequency of stimulation, which determines the extent of twitch summation; and (2) length of the fiber before the onset of contraction *(length–tension relationship)*. *(Review Table 8-2.)*

- *Twitch summation* is an increase in tension accompanying repetitive stimulation of a muscle fiber. After undergoing an action potential, a muscle cell membrane recovers from its refractory period and can be restimulated while some contractile activity remains so that the twitches induced by the two rapidly successive action potentials sum. If the muscle fiber is stimulated so rapidly that it does not have a chance to start relaxing between stimuli, a smooth, sustained maximal contraction known as *tetanus* occurs. *(Review Figure 8-19.)*

- Tension also depends on fiber length at the onset of contraction. At *optimal length* (l_o), maximal opportunity for cross-bridge interaction occurs because of optimal overlap of thick and thin filaments, so the greatest tension can develop. Less tension can develop at shorter or longer lengths. *(Review Figure 8-20.)*

8.4 Skeletal Muscle Metabolism and Fiber Types (pp. 269–275)

- Three pathways furnish the ATP needed for muscle contraction and relaxation: (1) the transfer of high-energy phosphates from stored *creatine phosphate* to ADP, providing the first source of ATP at the onset of exercise; (2) *oxidative phosphorylation,* which efficiently extracts large amounts of ATP from nutrients if enough O_2 is available to support this system; and (3) *glycolysis,* which can synthesize ATP in the absence of O_2 but uses large amounts of stored glycogen and produces lactate in the process. *(Review Figure 8-21.)*

- The three types of skeletal muscle fibers are classified by the pathways they use for ATP synthesis (oxidative or glycolytic) and the rapidity with which they split ATP and subsequently contract (slow twitch or fast twitch): (1) *slow-oxidative fibers,* (2) *fast-oxidative fibers,* and (3) *fast-glycolytic fibers*. *(Review Table 8-1 and Figure 8-22.)*

8.5 Control of Motor Movement (pp. 276–286)

- Motor activity is classified as (1) involuntary *somatic reflex responses,* (2) *voluntary movements,* and (3) *rhythmic activities* voluntarily initiated but subconsciously coordinated.

- Control of motor movement depends on activity in three types of presynaptic inputs that converge on the motor neurons supplying various muscles: (1) *afferent neurons* as part of spinal reflex pathways; (2) the *corticospinal (pyramidal) motor system,* which originates in the primary motor cortex and is concerned with discrete, intricate movements of the hands; and (3) the *multineuronal (extrapyramidal) motor system,* which originates in the brain stem and is involved with postural adjustments and involuntary movements of the trunk and limbs. The final motor output from the brain stem is influenced by the cerebellum, basal nuclei, and cerebral cortex. *(Review Table 8-3.)*

- Initiation and adjustment of motor commands depend on continuous afferent input, especially feedback about changes in muscle length (monitored by *muscle spindles*) and tension (monitored by *Golgi tendon organs*). *(Review Figure 8-23.)*

- When a whole muscle is stretched, the stretch of its muscle spindles triggers the *stretch reflex,* which results in reflex contraction of that muscle. This reflex resists any passive changes in muscle length. *(Review Figures 8-24 and 8-25.)*

8.6 Smooth and Cardiac Muscle (pp. 286–294)

- *Smooth muscle cells* are spindle shaped and much smaller than skeletal muscle fibers. The thick and thin filaments of smooth muscle are oriented diagonally in a diamond-shaped lattice instead of running longitudinally, so the fibers are not striated. *(Review Figures 8-28 and 8-29.)*

- In smooth muscle, cytosolic Ca^{2+}, which enters from the ECF and is also released from sparse intracellular stores, activates cross-bridge cycling by initiating a series of biochemical reactions that result in phosphorylation of the *light chains* of the myosin cross bridges to enable them to bind with actin. *(Review Figures 8-30 and 8-31.)*

- Smooth muscle in different organs is highly diversified and can be classified in various ways: phasic or tonic, multiunit or single-unit, and neurogenic or myogenic.

- *Phasic smooth muscle* displays bursts of pronounced contraction in response to action potentials. *Tonic smooth muscle* is partially contracted at all times in the absence of action potentials because of ongoing Ca^{2+} entry through open surface-membrane Ca^{2+} channels.

- *Multiunit smooth muscle* is *neurogenic,* requiring stimulation of individual muscle fibers by its autonomic nerve supply to trigger contraction. *Single-unit smooth muscle* is *myogenic;* it can initiate its own contraction. A few specialized, self-excitable, noncontractile cells in phasic, single-unit smooth muscle spontaneously depolarize to threshold as a result of *pacemaker potentials* (spontaneous drift to threshold) or *slow-wave potentials* (spontaneous alternating depolarizing and hyperpolarizing swings in potential). When threshold is reached and an action potential is initiated, this electrical activity spreads by means of gap junctions to the surrounding contractile cells within the *functional syncytium,* so the entire sheet of smooth muscle becomes excited and contracts as a single unit. *(Review Figure 8-32.)*

- The level of tension in smooth muscle depends on the level of cytosolic Ca^{2+}. The autonomic nervous system *(review Figure 8-33)*, along with hormones and local metabolites, can modify the rate and strength of contractions by altering cytosolic Ca^{2+} concentration.

- Smooth muscle contractions are slow and energy efficient, enabling this type of muscle to economically sustain long-term contractions without fatigue. This economy, coupled with single-unit smooth muscle's ability to exist at various lengths with little change in tension, makes single-unit smooth muscle ideally suited for its task of forming the walls of hollow organs that can distend.

- *Cardiac muscle* is found only in the heart. It has highly organized striated fibers, like skeletal muscle. Like single-unit smooth muscle, some specialized, self-excitable cardiac muscle fibers can generate action potentials, which spread throughout the heart with the aid of gap junctions. *(Review Table 8-4.)*

9.1 Anatomy of the Heart (pp. 298–303)

■ The circulatory system is the transport system of the body.

■ The three basic components of the circulatory system are the *heart* (the pump), the *blood vessels* (the passageways), and the *blood* (the transport medium).

■ The heart is positioned midline in the thoracic cavity at an angle with its wide base lying toward the right and its pointed apex toward the left.

■ The heart is a dual pump that provides the driving pressure for blood flow through the *pulmonary circulation* (between the heart and lungs) and *systemic circulation* (between the heart and other body systems). *(Review Figures 9-1 and 9-2.)*

■ The heart has four chambers: Each half of the heart consists of an *atrium,* or venous input chamber, and a *ventricle,* or arterial output chamber. The right atrium receives O_2-poor blood from the systemic circulation and the right ventricle pumps it into the pulmonary circulation. The left atrium receives O_2-rich blood from the pulmonary circulation and the left ventricle pumps it into the systemic circulation. *(Review Figures 9-1 and 9-2.)*

Superior vena cava (returns blood from head, upper limbs)
Right pulmonary veins (return blood from right lung)
Pulmonary semilunar valve (shown open)
Right atrium
Right atrioventricular valve (shown open)
Right ventricle
Inferior vena cava (returns blood from trunk, legs)
To systemic circulation (upper body)
To systemic circulation (lower body)
Aorta
Right and left pulmonary arteries (to lungs)
Left pulmonary veins (return blood from left lung)
Left atrium
Aortic semilunar valve (shown open)
Left atrioventricular valve (shown open)
Left ventricle
Septum

KEY
■ O_2-rich blood
■ O_2-poor blood

(a) Blood flow through the heart

■ Four heart valves direct blood in the right direction and keep it from flowing in the other direction. The *right* and *left atrioventricular (AV) valves* direct blood from the atria to the ventricles during diastole and prevent backflow of blood from the ventricles to the atria during systole. The *aortic* and *pulmonary semilunar valves* direct blood from the ventricles to the aorta and pulmonary artery, respectively, during systole and prevent backflow of blood from these major vessels to the ventricles during diastole. *(Review Figures 9-3, 9-4, and 9-5.)*

■ Contraction of the spirally arranged cardiac muscle fibers produces a wringing effect important for efficient pumping. Also important for efficient pumping is that the muscle fibers in each chamber contract as a coordinated unit. The branching cardiac muscle fibers are interconnected by *intercalated discs,* which contain (1) desmosomes that hold the cells together mechani-

cally and (2) gap junctions that permit spread of electrical current between cells joined together into a functional syncytium. *(Review Figure 9-6.)*

9.2 Electrical Activity of the Heart (pp. 303–314)

■ The self-excitable heart initiates its rhythmic contractions. *Autorhythmic cells* are 1% of the cardiac muscle cells; they do not contract but are specialized to initiate and conduct action potentials. The other 99% of cardiac cells are *contractile cells* that contract in response to the spread of an action potential initiated by autorhythmic cells.

■ Autorhythmic cells display a *pacemaker potential,* a slow drift to threshold potential, as a result of a complex interplay of inherent changes in ion movement across the membrane. The first half of the pacemaker potential results from opening of unique *funny channels* that permit entry of Na^+ at the same time K^+ channels slowly close so that exit of K^+ slowly declines. Both of these actions gradually depolarize the membrane toward threshold. The final boost to threshold results from Ca^{2+} entry on opening of *T-type Ca^{2+} channels.* The rising phase of the action potential is the result of further Ca^{2+} entry on opening of *L-type Ca^{2+} channels* at threshold. The falling phase results from K^+ efflux on opening of K^+ channels at the peak of the action potential. Slow closure of these K^+ channels at the end of repolarization contributes to the next pacemaker potential. *(Review Figure 9-7.)*

■ The cardiac impulse originates at the *SA node,* the *pacemaker* of the heart, which has the fastest rate of spontaneous depolarization to threshold. *(Review Figures 9-8 and 9-9.)*

■ Once initiated, the action potential spreads throughout the right and left atria, partially facilitated by specialized conduction pathways but mostly by cell-to-cell spread of the impulse through gap junctions. *(Review Figure 9-8.)*

■ The impulse passes from the atria into the ventricles through the *AV node,* the only point of electrical contact between these chambers. The action potential is delayed briefly at the AV node, ensuring that atrial contraction precedes ventricular contraction to allow complete ventricular filling. *(Review Figure 9-8.)*

■ The impulse then travels rapidly down the interventricular septum via the *bundle of His* and rapidly disperses throughout the myocardium by means of the *Purkinje fibers.* The rest of the ventricular cells are activated by cell-to-cell spread of the impulse through gap junctions. *(Review Figure 9-8.)*

■ Thus, the atria contract as a single unit, followed after a brief delay by a synchronized ventricular contraction.

■ The action potentials of cardiac contractile cells exhibit a prolonged positive phase, or *plateau,* accompanied by a prolonged period of contraction, which ensures adequate ejection time. This plateau is primarily the result of activation of slow L-type Ca^{2+} channels. *(Review Figure 9-10.)*

■ Ca^{2+} entry though the L-type channels in the T tubules triggers a much larger release of Ca^{2+} from the sarcoplasmic reticulum. This *Ca^{2+}-induced Ca^{2+} release* leads to cross-bridge cycling and contraction. *(Review Figure 9-11.)*

■ Because a long refractory period occurs in conjunction with this prolonged plateau phase, summation and tetanus of cardiac mus-

cle are impossible, ensuring the alternate periods of contraction and relaxation essential for pumping of blood. *(Review Figure 9-12.)*

■ The spread of electrical activity throughout the heart can be recorded from the body surface. In this *electrocardiogram (ECG)*, the *P wave* represents atrial depolarization; the *QRS complex*, ventricular depolarization; and the *T wave*, ventricular repolarization. Atrial repolarization is masked by the QRS complex. *(Review Figures 9-13, 9-14, and 9-15.)*
I Figure 9-14 Electrocardiogram waveforms in lead II and electrical status of heart associated with each waveform.

9.3 Mechanical Events of the Cardiac Cycle (pp. 314–318)

■ The *cardiac cycle* consists of three important events *(Review Figure 9-16)*:

1. The generation of electrical activity as the heart autorhythmically depolarizes and repolarizes. *(Review Figure 9-14).*

2. Mechanical activity consisting of alternate periods of *systole* (contraction and emptying) and *diastole* (relaxation and filling), which are initiated by the rhythmic electrical cycle.

3. Directional flow of blood through the heart chambers, guided by valve opening and closing induced by pressure changes that are generated by mechanical activity.

■ The atrial pressure curve remains low throughout the entire cardiac cycle, with only minor fluctuations (normally varying between 0 and 8 mm Hg). The aortic pressure curve remains high the entire time, with moderate fluctuations (normally varying between a systolic pressure of 120 mm Hg and a diastolic pressure of 80 mm Hg). The left ventricular pressure curve fluctuates dramatically because ventricular pressure must be below the low atrial pressure to allow the AV valve to open during the *ventricular filling phase*, and, to force the aortic valve open to allow emptying, it must be above the high aortic pressure during the *ejection phase*. Therefore, ventricular pressure normally varies from 0 mm Hg during diastole to slightly more than 120 mm Hg during systole. During the

periods of *isovolumetric ventricular contraction* and *relaxation,* ventricular pressure is above the low atrial pressure and below the high aortic pressure, so all valves are closed and no blood enters or leaves the ventricles. *(Review Figures 9-16 and 9-17.)*

■ The *end-diastolic volume (EDV)* is the volume of blood in the ventricle when filling is complete at the end of diastole. The *end-systolic volume (ESV)* is the volume of blood remaining in the ventricle when ejection is complete at the end of systole. The *stroke volume (SV)* is the volume of blood pumped out by each ventricle each beat. *(Review Figures 9-16 and 9-17.)*

■ Valve closing gives rise to two normal heart sounds. The *first heart sound* is caused by closing of the AV valves and signals the onset of ventricular systole. The *second heart sound* is the result of closing of the aortic and pulmonary valves at the onset of diastole. *(Review Figure 9-16.)*

■ Defective valve function produces turbulent blood flow, which is audible as a *heart murmur.* Abnormal valves may be either *stenotic* and not open completely or *insufficient (leaky)* and not close completely. *(Review Figure 9-18.)*

9.4 Cardiac Output and Its Control (pp. 319–325)

■ *Cardiac output (CO),* the volume of blood ejected by each ventricle each minute, is determined by heart rate times stroke volume. *(Review Figure 9-24, p. 324.)*

■ *Heart rate (HR),* the number of beats per minute, varies by altering the balance of parasympathetic and sympathetic influence on the SA node. Parasympathetic stimulation slows HR, and sympathetic stimulation speeds it up. *(Review Table 9-1 and Figure 9-19.)*

■ *Stroke volume* depends on (1) the extent of ventricular filling, with an increased EDV resulting in a larger SV by means of the length–tension relationship *(Frank–Starling law of the heart,* a form of intrinsic control); and (2) the extent of sympathetic stimulation, with increased sympathetic stimulation resulting in increased *contractility* of the heart, that is, increased strength of contraction and increased SV at a given EDV (extrinsic control). *(Review Table 9-1 and Figures 9-20 through 9-23.)*

■ The *preload* of the heart (the workload imposed on the heart before contraction begins) is the extent of filling. The *afterload* of the heart (the workload imposed on the heart after contraction has begun) is the arterial blood pressure.

9.5 Nourishing the Heart Muscle (pp. 326–331)

■ Cardiac muscle is supplied with O_2 and nutrients by blood delivered to it by the *coronary circulation,* not by blood within the heart chambers. *(Review Figure 9-29 and chapter opener, p. 297.)*

■ Most coronary blood flow occurs during diastole because during systole the contracting heart muscle compresses the coronary vessels.

■ Coronary blood flow is normally varied to keep pace with cardiac oxygen needs. *(Review Figure 9-26.)*

■ Coronary blood flow may be compromised by development of *atherosclerotic plaques,* which can lead to *ischemic heart disease* ranging in severity from mild chest pain on exertion to fatal *heart attacks*. *(Review Figures 9-27 through 9-29.)*

10.1 Patterns and Physics of Blood Flow (pp. 336–339)

■ Materials can be exchanged between various parts of the body and with the external environment by means of the blood vessel network that transports blood to and from all organs. *(Review Figure 10-1 and chapter opener.)*

■ *Reconditioning organs* that replenish nutrient supplies and remove metabolic wastes from the blood receive a greater percentage of the cardiac output (CO) than is warranted by their metabolic needs. These reconditioning organs can better tolerate reductions in blood supply than can organs that receive blood solely for meeting their metabolic needs. The reconditioning organs are the digestive organs, kidneys, and skin.

■ The brain is especially vulnerable to reductions in its blood supply. Therefore, maintaining adequate flow to this vulnerable organ is a high priority in circulatory function.

■ The *flow rate* of blood through a vessel (in volume per unit of time) is directly proportional to the pressure gradient and inversely proportional to the resistance ($F = \Delta P/R$). The *pressure gradient (ΔP)* is the difference in pressure between the beginning and end of a vessel. The pressure imparted to the blood by cardiac contraction establishes the higher pressure at the beginning of a vessel. The lower pressure at the end is the result of frictional losses as flowing blood rubs against the vessel wall. *(Review Figure 10-2.)*

■ *Resistance (R),* the hindrance to blood flow through a vessel, is influenced most by the vessel's radius. Resistance is inversely proportional to the fourth power of the radius ($R \propto 1/r^4$), so small changes in radius profoundly influence flow. As the radius increases, resistance decreases and flow increases, and vice versa. *(Review Figure 10-3.)*

■ Blood flows in a closed loop between the heart and the organs. The *arteries* transport blood from the heart throughout the body. The *arterioles* regulate the amount of blood that flows through each organ. The *capillaries* are the actual site where materials are exchanged between blood and surrounding tissue cells. The *veins* return blood from the tissue level back to the heart. *(Review Figure 10-4 and Table 10-1.)*

10.2 Arteries (pp. 339–343)

■ Arteries are large-radius, low-resistance *passageways from the heart to the organs*. They also serve as a *pressure reservoir*. Because of their elasticity, owing to their abundant elastin fibers, arteries expand to accommodate the extra volume of blood pumped into them by cardiac contraction and then recoil to continue driving the blood forward when the heart is relaxing. *(Review Table 10-1 and Figures 10-5 and 10-6.)*

■ *Systolic pressure* (average 120 mm Hg) is the peak pressure exerted by the ejected blood against the vessel walls during car-

diac systole. *Diastolic pressure* (average 80 mm Hg) is the minimum pressure in the arteries when blood is draining off into the vessels downstream during cardiac diastole. When blood pressure is 120/80, *pulse pressure* (the difference between systolic and diastolic pressures) is 40 mm Hg. The average driving pressure throughout the cardiac cycle is the *mean arterial pressure (MAP)*, which can be estimated using the following equation: MAP = diastolic pressure + 1/3 pulse pressure. *(Review Figure 10-7.)*

10.3 Arterioles (pp. 343–350)

■ Arterioles are the *major resistance vessels*. Their high resistance produces a large drop in mean pressure between the arteries and capillaries. This decline enhances blood flow by contributing to the pressure differential between the heart and organs. *(Review Figure 10-8.)*

■ Arterioles have a thick layer of circular smooth muscle, variable contraction of which alters arteriolar caliber and resistance. *Tone,* a baseline of contractile activity, is maintained in arterioles at all times. Arteriolar *vasodilation* (expansion of arteriolar caliber above tone level) decreases resistance and increases blood flow through the vessel, whereas *vasoconstriction* (narrowing of the vessel) increases resistance and decreases flow. *(Review Table 10-1 and Figure 10-9.)* Arteriolar caliber is subject to both local (intrinsic) controls and extrinsic controls.

■ *Local controls* primarily involve local chemical changes associated with changes in the level of metabolic activity in an organ, such as local changes in O_2, which cause the release of *vasoactive paracrines* from the *endothelial cells* in the vicinity. Examples include vasodilating *nitric oxide* and vasoconstricting *endothelin*. These vasoactive mediators act on the underlying arteriolar smooth muscle to bring about an appropriate change in the caliber of the arterioles supplying the organ. By adjusting the resistance to blood flow, the local control mechanism *matches an organ's blood flow to its momentary metabolic needs*. *(Review Figures 10-9, 10-10, 10-11, and 10-13 and Tables 10-2 and 10-3.)*

■ Other local influences include (1) *histamine release* (important in inflammatory and allergic reactions); (2) *myogenic response to stretch* (important in *autoregulation,* which keeps tissue blood flow fairly constant despite changes in mean arterial driving pressure) *(review Figures 10-11 and 10-12)*; (3) *chemical response to shear stress* (which resists changes in the force exerted parallel to the vessel surface by flowing blood); and (4) *local application of heat or cold* (important therapeutically). *(Review Figure 10-13).*

■ Local control factors can adjust arteriolar caliber independently in different organs. Such adjustments are important in *variably distributing cardiac output*. *(Review box figure on p. 371.)*

■ *Extrinsic control* is accomplished primarily by sympathetic and to a lesser extent by hormonal influence over arteriolar smooth muscle. Extrinsic controls are important in determining *total peripheral resistance (TPR)*, the total resistance offered by all systemic vessels, most of which is due to arteriolar resistance. TPR in turn plays a key role in *maintaining MAP*: MAP = CO × TPR. Arterioles are richly supplied with *sympathetic nerve fibers,*

whose increased activity produces generalized vasoconstriction and a subsequent increase in TPR, thus increasing MAP. Decreased sympathetic activity produces generalized arteriolar vasodilation, which lowers MAP. These extrinsically controlled adjustments of arteriolar caliber help maintain the appropriate pressure head for driving blood forward to the tissues. Most arterioles are not supplied by parasympathetic nerves. Hormones that extrinsically influence arteriolar radius are *norepinephrine, epinephrine, vasopressin,* and *angiotensin II,* all of which cause generalized arteriolar vasoconstriction. *(Review Figure 10-13.)*

10.4 Capillaries (pp. 350–360)

■ The thin-walled, small-radius, extensively branched capillaries are ideally suited to serve as *sites of exchange* between the blood and surrounding tissue cells. Anatomically, the surface area for exchange is maximized and diffusion distance is minimized in the capillaries. Furthermore because of their large total cross-sectional area, the *velocity of blood flow* through capillaries (in distance per unit of time) is relatively slow, providing adequate time for exchanges to take place. *(Review Figures 10-14 through 10-16 and Table 10-1, p. 339.)*

■ Two types of passive exchanges—diffusion and bulk flow—take place across capillary walls.

■ Individual solutes are exchanged primarily by *diffusion down concentration gradients*. Lipid-soluble substances pass directly through the single layer of endothelial cells lining a capillary, whereas water-soluble substances pass through water-filled pores between the endothelial cells. Plasma proteins generally do not escape. *(Review Figures 10-17 and 10-19.)*

■ Imbalances in physical pressures acting across capillary walls are responsible for *bulk flow* of fluid through the pores. (1) Fluid is forced out of the first portion of the capillary *(ultrafiltration),* where outward pressures (mainly capillary blood pressure; [P_C]) exceed inward pressures (mainly plasma-colloid osmotic pressure [π_P]). (2) Fluid is returned to the capillary *(reabsorption)* along its last half, when outward pressures fall below inward pressures. The reason for the shift in balance down the capillary's length is the continuous decline in P_C while π_P remains constant. Bulk flow is responsible for the distribution of the ECF between plasma and interstitial fluid. *(Review Figures 10-8, p. 343, and 10-20.)*

■ Normally, slightly more fluid is filtered than is reabsorbed. The extra fluid, any leaked proteins, and bacteria in the tissue are picked up as *lymph* by the *lymphatic system*. Bacteria are destroyed as lymph passes through lymph nodes on the way to being returned to the venous system. *(Review Figures 10-20 through 10-22.)*

10.5 Veins (pp. 360–365)

■ Veins are large-radius, low-resistance *passageways from the organs to the heart*. In addition, the thin-walled, highly distensible veins, as *capacitance vessels,* can passively stretch to store a larger volume of blood and therefore act as a *blood reservoir*. The capacity of veins to hold blood can change markedly with little change in venous pressure. At rest, the veins contain more than 60% of the total blood volume. *(Review Table 10-1, p. 339, and Figure 10-24.)*

■ The primary force that produces *venous return* is the *pressure gradient* between the veins and atrium (that is, what remains of the driving pressure imparted to the blood by cardiac contraction). *(Review Figures 10-8, p. 343, and 10-25.)*

■ Venous return is enhanced by sympathetically induced *venous vasoconstriction* and by external compression of the veins from contraction of surrounding skeletal muscles *(skeletal muscle pump),* both of which drive blood out of the veins. These actions help counter the effects of gravity on the venous system. *(Review Figures 10-25 and 10-26.)*

■ One-way *venous valves* ensure that blood is driven toward the heart and kept from flowing back toward the tissues. *(Review Figure 10-27.)*

■ Venous return is also enhanced by the *respiratory pump* and the *cardiac suction* effect. Respiratory activity produces a less-than-atmospheric pressure in the chest cavity, thus establishing an external pressure gradient that encourages flow from the lower veins that are exposed to atmospheric pressure to the chest veins that empty into the heart. In addition, slightly negative pressures created within the atria during ventricular systole and within the ventricles during ventricular diastole exert a suctioning effect that further enhances venous return and facilitates cardiac filling. *(Review Figures 10-25 and 10-28.)*

10.6 Blood Pressure (pp. 365–377)

■ Regulation of MAP depends on control of its two main determinants, CO and TPR. Control of CO, in turn, depends on regulation of HR and SV, whereas TPR is determined primarily by the degree of arteriolar vasoconstriction. *(Review Figure 10-29.)*

■ Short-term regulation of blood pressure is accomplished mainly by the *baroreceptor reflex. Carotid sinus and aortic arch baroreceptors* continuously monitor MAP. When they detect a deviation from normal, they signal the medullary *cardiovascular center,* which responds by adjusting autonomic output to the heart and blood vessels to restore blood pressure to normal. *(Review Figures 10-30 through 10-33.)*

■ Long-term control of blood pressure involves maintaining proper plasma volume through the kidneys' control of salt and water balance. *(Review Figure 10-29.)*
▮Figure 10-32 **Summary of the effects of the parasympathetic and sympathetic nervous systems on factors that influence mean arterial blood pressure.**

11.1 Plasma (pp. 381–383)

■ Blood consists of three types of cellular elements—*erythrocytes (red blood cells), leukocytes (white blood cells),* and *platelets (thrombocytes)*—suspended in the liquid plasma. *(Review chapter opener, Figure 11-1, and Table 11-1.)*

■ The 5- to 5.5-L volume of blood in an adult consists of 42% to 45% erythrocytes, less than 1% leukocytes and platelets, and 55% to 58% plasma. The percentage of whole-blood volume occupied by erythrocytes is the *hematocrit. (Review Figure 11-1.)*
I Figure 11-1 Hematocrit and types of blood cells.

■ *Plasma* is a complex liquid consisting of 90% water that serves as a transport medium for substances being carried in the blood. The most abundant inorganic constituents in plasma are Na^+ and Cl^-, and the most plentiful organic constituents are *plasma proteins*. All plasma constituents are freely diffusible across the capillary walls except the plasma proteins, which remain in the plasma where they perform a variety of important functions. Plasma proteins include the *albumins, globulins* (α, β, and γ), and *fibrinogen. (Review Table 11-1.)*

11.2 Erythrocytes (pp. 383–392)

■ Erythrocytes are specialized for their primary function of O_2 *transport* in the blood. Their biconcave shape maximizes the surface area available for diffusion of O_2 into cells of this volume. *(Review Figure 11-1 and chapter opener.)* Erythrocytes do not contain a nucleus or organelles (these are extruded during development) but instead are packed full of *hemoglobin,* an iron-containing molecule that can loosely and reversibly bind with O_2. Because O_2 is poorly soluble in blood, hemoglobin is indispensable for O_2 transport. Each hemoglobin molecule can carry four O_2 molecules. *(Review Figures 11-2 and 11-3.)*

■ Hemoglobin also contributes to CO_2 transport and buffering of blood by reversibly binding with CO_2 and H^+.

■ Unable to replace cell components, erythrocytes are destined to a short life span of about 120 days.

■ Undifferentiated *pluripotent stem cells* in the *red bone marrow* give rise to all cellular elements of the blood. *(Review Figures 11-3 and 11-9, p. 394.)* Erythrocyte production *(erythropoiesis)* by the red marrow normally keeps pace with the rate of erythrocyte loss, keeping the red cell count constant. Erythropoiesis is stimulated by *erythropoietin,* a hormone secreted by the kidneys in response to reduced O_2 delivery. *(Review Figure 11-4.)*
I Figure 11-4 Control of erythropoiesis.

■ The major *ABO blood types* depend on the presence of specific antigens on the surface of erythrocytes. The red blood cells of *type A* blood have A antigen; those of *type B* blood have B antigen, those of *type AB* blood have both A and B antigen, and those of *type O* blood have no A or B antigen. Type A blood has anti-B antibodies, type B blood has anti-A antibodies, type AB blood has no anti-A or anti-B antibodies, and type O blood has both anti-A and anti-B antibodies. These antibodies cause the RBCs with the corresponding antigens to agglutinate (clump) or rupture, causing a *transfusion reaction* if incoming donor cells are exposed to corresponding antibodies in recipient blood. *(Review Table 11-2 and Figure 11-7.)*

11.3 Leukocytes (pp. 392–394)

■ Leukocytes are the *defense corps* of the body. They attack foreign invaders (the most common of which are bacteria and viruses), clean up cellular debris, and destroy cancer cells that arise in the body. Leukocytes and certain plasma proteins make up the *immune system.*

■ The five types of leukocytes are categorized microscopically by differences in nuclear shape, presence or absence of granules, and staining properties. The *polymorphonuclear granulocytes* include neutrophils, eosinophils, and basophils. The *mononuclear agranulocytes* include monocytes and lymphocytes. *(Review Figure 11-8.)*

■ Each of the leukocyte types has a different task: (1) *Neutrophils,* the phagocytic specialists, are important in engulfing bacteria and debris. (2) *Eosinophils* specialize in attacking parasitic worms and play a role in allergic responses. (3) *Basophils* release two chemicals: *histamine,* which is also important in allergic

responses; and *heparin,* which helps clear fat particles from the blood. (4) *Monocytes,* on leaving the blood, set up residence in the tissues and greatly enlarge to become the large tissue phagocytes known as *macrophages.* (5) *Lymphocytes* provide immune defense against bacteria, viruses, and other targets for which they are specifically programmed. Their defense tools include production of antibodies that mark the victim for destruction by phagocytosis or other means (for *B lymphocytes*) and release of chemicals that punch holes in the victim (for *T lymphocytes*). *(Review Figure 11-8 and Table 11-1, p. 382.)*

■ Leukocytes are present in the blood only while in transit from their site of production and storage in the bone marrow (and also in the lymphoid tissues in the case of the lymphocytes) to their site of action in the tissues. *(Review Figure 11-9.)* At any given time, most leukocytes are out in the tissues on surveillance or performing actual combat missions.
IFigure 11-9 Blood cell production (hemopoiesis).

■ All leukocytes have a limited life span and must be replenished by ongoing differentiation and proliferation of precursor cells. The total number and percentage of each of the different types of leukocytes are produced at variable rates depending on the momentary defense needs of the body. Factors that regulate production of the different types of leukocyte are released from invaded or injured tissues and from activated leukocytes.

11.4 Platelets and Hemostasis (pp. 395–400)

■ Platelets are cell fragments derived from large *megakaryocytes* in the bone marrow. *(Review Figures 11-9 and 11-10.)*

■ Platelets play a role in *hemostasis,* the arrest of bleeding from an injured vessel. The three main steps in hemostasis are (1) *vascular spasm,* which reduces blood flow through an injured vessel; (2) *platelet plugging;* and (3) *clot formation.*

■ Platelet aggregation at the site of vessel injury quickly plugs the defect. Platelets start to aggregate by adhering to *von Willebrand factor,* which binds to *exposed collagen* in the damaged vessel wall. These aggregated platelets secrete *ADP* and *thromboxane A_2,* which together cause other passing-by platelets to pile on, setting up a positive-feedback cycle as the platelet plug grows to fill in the defect. Normal adjacent endothelium secretes inhibitory chemicals that prevent platelets from adhering to the surrounding undamaged parts of the vessel. *(Review Figure 11-11.)*
IFigure 11-11 Platelet activation, formation of a platelet plug, and prevention of platelet aggregation at adjacent normal vessel lining.

■ *Clot formation* reinforces the platelet plug and converts blood in the vicinity of a vessel injury into a nonflowing gel.

■ Most factors necessary for clotting are always present in the plasma in inactive precursor form. When a vessel is damaged, exposed collagen initiates a *clotting cascade* of reactions involving successive activation of these clotting factors, ultimately converting fibrinogen into fibrin via the *intrinsic clotting pathway.* *(Review Figure 11-13.)*

■ *Fibrin,* an insoluble threadlike molecule, is laid down as the meshwork of the clot; the meshwork in turn entangles blood cellular elements to complete clot formation. *(Review Figure 11-12.)*

■ Blood that has escaped into the tissues clots on exposure to *tissue thromboplastin,* which sets the *extrinsic clotting pathway* into motion. *(Review Figure 11-13.)*

■ Clots form quickly. When no longer needed, they are slowly dissolved by *plasmin,* a fibrinolytic factor also activated by exposed collagen. *(Review Figure 11-14.)*

■ Thus, exposed collagen simultaneously initiates platelet aggregation and clot formation and sets the stage for later clot dissolution.

Chapter 12
Study Card

12.1 Immune System: Targets, Effectors, Components (pp. 405–407)

■ Foreign invaders and newly arisen mutant cells are immediately confronted with multiple interrelated defense mechanisms aimed at destroying and eliminating anything that is not part of the normal self. These mechanisms, collectively referred to as *immunity,* include both innate and adaptive immune responses. *Innate immune responses* are nonspecific responses that nonselectively defend against foreign material even on initial exposure to it. *Adaptive immune responses* are specific responses that selectively target particular invaders for which the body has been specially prepared after a prior exposure.

■ The most common invaders are bacteria and viruses. *Bacteria* are self-sustaining, single-celled organisms that produce disease by virtue of the destructive chemicals they release. *Viruses* are protein-coated nucleic acid particles that invade host cells and take over the cellular metabolic machinery for their own survival to the detriment of the host cell.

■ *Leukocytes* and their derivatives are the major effector cells of the immune system and are reinforced by a number of different *plasma proteins*. Leukocytes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes.

■ Immune cells also clean up cellular debris, preparing the way for tissue repair, and help defend against cancer.

12.2 Innate Immunity (pp. 408–415)

■ Innate immune responses include inflammation, interferon, natural killer (NK) cells, and the complement system.

■ *Inflammation* is a nonspecific response to foreign invasion or tissue damage mediated largely by the professional phagocytes (neutrophils and monocytes-turned-macrophages). Phagocytes have receptors, such as *toll-like receptors (TLRs),* which recognize and bind with a foreign cell's telltale markers, for example, carbohydrates found in bacterial cell walls but not in human cells. The phagocytic cells destroy foreign and damaged cells both by phagocytosis and by release of lethal chemicals. *(Review Figures 12-2 and 12-3 and chapter opener.)* Phagocytic secretions also augment inflammation, induce systemic manifestations such as fever, and enhance adaptive immune responses.

■ Histamine-induced vasodilation and increased permeability of local capillaries at the site of invasion or injury permit enhanced delivery of more phagocytic leukocytes and inactive plasma protein precursors crucial to defense, such as complement components. These vascular changes also largely produce the observable local manifestations of inflammation—swelling, redness, heat, and pain. *(Review Figure 12-3.)*

■ *Interferon* is nonspecifically released by virus-infected cells and transiently inhibits viral multiplication in other cells to which it binds. *(Review Figure 12-5.)*

■ *NK cells* nonspecifically lyse and destroy virus-infected cells and cancer cells on first exposure to them.

■ On being activated by microbes at the site of invasion or by antibodies produced against the microbes, the *complement system* directly destroys the foreign invaders by lysing their membranes and also augments other aspects of the inflammatory process, such as by acting as *opsonins* that enhance phagocytosis. The complement system lyses the targeted cells by forming a hole-punching *membrane attack complex* that inserts into the victim cell's membrane, leading to osmotic rupture of the cell. *(Review Figures 12-4 and 12-6.)*

12.3 Adaptive Immunity: General Concepts (pp. 415–416)

■ Not only is the adaptive immune system able to recognize foreign molecules as different from self-molecules—so that destructive immune reactions are not unleashed against the body itself—but it can also distinguish between millions of different foreign molecules. *Lymphocytes*, the effector cells of adaptive immunity, are each uniquely equipped with surface membrane receptors that can bind with only one specific complex foreign molecule, known as an *antigen*.

■ The two classes of adaptive immune responses are *antibody-mediated immunity* accomplished by plasma cells derived from *B lymphocytes (B cells),* and *cell-mediated immunity* accomplished by *T lymphocytes (T cells). (Review Table 12-4, p. 434.)*

■ B cells develop from a lineage of lymphocytes that originally matured within the bone marrow. The T-cell lineage comes from lymphocytes that migrated from the bone marrow to the thymus to complete their maturation. New B and T cells arise from lymphocyte colonies in *lymphoid tissues*. *(Review Figures 12-1, p. 406, and 12-7 and Table 12-1.)*

12.4 B Lymphocytes: Antibody-Mediated Immunity (pp. 416–422)

■ Each B cell recognizes specific free extracellular antigen, such as that found on the surface of bacteria.

■ After being activated by binding of its receptor (a *B-cell receptor,* or *BCR*) with its specific antigen, a B cell rapidly proliferates, producing a *clone* that can specifically wage battle against the invader. Most lymphocytes in the expanded B-cell clone become antibody-secreting *plasma cells* that participate in the *primary response* against the invader. Some of the new lymphocytes do not participate in the attack but become *memory cells* that lie in wait, ready to launch a swifter and more forceful *secondary response* should the same foreigner ever invade the body again. *(Review Figures 12-8, 12-9, 12-12, and 12-13.)*

■ *Antibodies* are **Y**-shaped molecules. The antigen-binding sites on the tips of each arm determine with what specific antigen the antibody can bind. Properties of the antibody's tail portion determine what the antibody does once it binds with antigen. There are five subclasses of antibodies, depending on differences in the biological activity of their tail portion: IgM, IgG, IgE, IgA, and IgD immunoglobulins. *(Review Figure 12-10.)*

■ *Antibodies* do not directly destroy antigenic material. Instead, they exert their protective effect by physically hindering antigens

through neutralization or agglutination or by intensifying lethal innate immune responses already called into play by the foreign invasion. Antibodies activate the complement system, enhance phagocytosis, and stimulate NK cells. *(Review Figure 12-11 and Table 12-3, p. 430.)*

12.5 T Lymphocytes: Cell-Mediated Immunity (pp. 422–435)

■ T cells accomplish cell-mediated immunity by being in direct contact with their targets and by releasing *cytokines,* which are protein signal molecules other than antibodies released by leukocytes that regulate immune function.

■ There are three types of T cells: cytotoxic, helper, and regulatory T cells.

■ The targets of *cytotoxic (CD8$^+$) T cells* are virally invaded cells and cancer cells, which they destroy by releasing *perforin* molecules that form a lethal hole-punching complex that inserts into the membrane of the victim cell or by releasing *granzymes* that trigger the victim cell to undergo apoptosis. *(Review Figures 12-14 and 12-15 and Table 12-2.)*

■ *Helper (CD4$^+$) T cells* bind with other immune cells and release cytokines that augment the activity of these other cells. B cells cannot convert to plasma cells and produce antibodies in response to T-dependent antigen without the help of helper cells. *(Review Figure 12-20.)*

■ *Regulatory (CD4$^+$CD25$^+$) T cells (T$_{regs}$)* secrete cytokines that suppress other immune cells, putting the brake on immune responses in check-and-balance fashion.

■ Like B cells, T cells bear receptors (*T-cell receptors* or *TCRs*) that are antigen specific *(review Figure 12-8, p. 416)*, undergo clonal selection, exert primary and secondary responses, and form memory pools for long-lasting immunity against targets to which they have already been exposed.

■ Helper T cells can recognize and bind with antigen only when it has been processed and presented to them by *antigen-presenting cells (APCs),* such as macrophages and dendritic cells. *(Review Figures 12-17 and 12-18.)*

1. Dendritic cell engulfs a bacterium.

2. Large molecules of engulfed bacterium are broken down by lysosomes to produce antigenic peptides.

3. New MHC molecule has been synthesized by endoplasmic reticulum–Golgi complex.

4. Antigenic peptides bind to newly formed MHC molecules.

5. Antigen is displayed on cell surface bound to MHC molecule—the cell is now an antigen-presenting cell (APC).

Antigen-MHC complex on cell surface (can bind with matching helper T cell)

⏐Figure 12-18 Generation of an antigen-presenting cell when a dendritic cell engulfs a bacterium.

■ Lymphocytes produced by chance that can attack the body's cells are eliminated or suppressed so that they are prevented from functioning. In this way, the body is able to "tolerate" (not attack) its own antigens, a process known as *self-tolerance*.

■ B and T cells have different targets because their requirements for antigen recognition differ. B cells recognize freely circulating antigen, such as bacteria, that can lead to antigen destruction at long distances via antibodies. T cells, in contrast, have a dual binding requirement of foreign antigen in association with self-antigens on the surface of one of the body's cells. *(Review Figures 12-19 and 12-20.)*

■ The *self-antigens* on cell surfaces are *class I* or *class II MHC molecules,* which are unique for each individual. Cytotoxic T cells can bind only with virus-infected host cells or cancer cells, which always bear class I MHC self-antigen in association with foreign or abnormal antigen. Helper T cells can bind only with APCs and B cells that bear the class II MHC self-marker in association with foreign antigen. The APCs activate helper T cells, and helper T cells activate B cells. Thus, such differential binding ensures that the appropriate specific immune response ensues. *(Review Figures 12-19 and 12-20.)*

■ In the process of *immune surveillance,* natural killer cells, cytotoxic T cells, macrophages, and the interferon they collectively secrete normally eradicate newly arisen cancer cells before they have a chance to spread. *(Review Figure 12-22.)*

12.6 Immune Diseases (pp. 435–438)

■ *Immune diseases* are of two types: *immunodeficiency diseases* (insufficient immune responses) or *inappropriate immune attacks* (excessive or mistargeted immune responses).

■ Inappropriate attacks include *autoimmune diseases, immune complex diseases,* and *allergies (hypersensitivities),* of which there are two types: (1) *immediate hypersensitivities* involving the production of IgE antibodies by B cells that trigger release of histamine from mast cells and basophils to bring about a swift response to the allergen, and (2) *delayed hypersensitivities* involving a more slowly responding cell-mediated, symptom-producing response by T cells against the allergen. *(Review Figure 12-23 and Table 12-5.)*

12.7 External Defenses (pp. 438–442)

■ The body surfaces exposed to the outside environment—both the outer covering of skin and the linings of internal cavities that communicate with the external environment—serve not only as mechanical barriers to deter would-be pathogenic invaders but also play an active role in thwarting entry of bacteria and other unwanted materials.

■ The *skin* consists of two layers: an outer keratinized *epidermis* and an inner vascularized, connective tissue *dermis*. The epidermis contains pigment-producing *melanocytes,* keratin-producing *keratinocytes,* immune-enhancing *Langerhans cells,* and immune-suppressive *Granstein cells*. *(Review Figure 12-24.)*

■ The other main routes by which potential pathogens enter the body are the digestive system, the urogenital system, and the respiratory system, which are all defended by various antimicrobial strategies.

13.1 Respiratory Anatomy (pp. 446–450)

■ *Cellular respiration* refers to the intracellular metabolic reactions that use O_2 and produce CO_2 during energy-yielding oxidation of nutrient molecules. *External respiration* refers to the transfer of O_2 and CO_2 between the external environment and tissue cells. The respiratory and circulatory systems function together to accomplish external respiration. *(Review Figure 13-1.)*

■ The *respiratory system* exchanges air between the atmosphere and lungs. The airways conduct air from the atmosphere to the *alveoli,* across which O_2 and CO_2 are exchanged between air in these air sacs and blood in the surrounding *pulmonary capillaries*. The extremely thin alveolar walls are formed by *Type I alveolar cells*. *Type II alveolar cells* secrete pulmonary surfactant. *(Review Figures 13-2 and 13-4 and chapter opener.)*

■ The *lungs* consist of the smaller airways, alveoli, pulmonary arteries, and highly elastic connective tissue. They are housed within the closed compartment of the *thorax,* the volume of which can be changed by contractile activity of surrounding *respiratory muscles.* Each lung is surrounded by a double-walled, closed *pleural sac*. *(Review Figure 13-5.)*

13.2 Respiratory Mechanics (pp. 450–466)

■ *Ventilation,* or *breathing,* is the process of cyclically moving air in and out of the lungs so that old alveolar air that has given up O_2 and picked up CO_2 can be exchanged for fresh air.

■ Ventilation is mechanically accomplished by alternately shifting the direction of the pressure gradient for airflow between the atmosphere and alveoli through the cyclic expansion and recoil of the lungs. When *intra-alveolar pressure* decreases as a result of lung expansion during *inspiration,* air flows into the lungs from the higher atmospheric pressure. When intra-alveolar pressure increases as a result of lung recoil during *expiration,* air flows out of the lungs toward the lower atmospheric pressure. *(Review Figures 13-6, 13-9, 13-12, and 13-13.)*

■ Alternate contraction and relaxation of the inspiratory muscles (primarily the *diaphragm*) indirectly produce periodic inflation and deflation of the lungs by cyclically expanding and compressing the thoracic cavity, with the lungs passively following its movements. *(Review Figures 13-10 and 13-11.)*

■ The lungs follow the movements of the thoracic cavity by virtue of the *transmural pressure gradient* across the lung wall resulting from the *intrapleural pressure* being subatmospheric and thus less than the intra-alveolar pressure. *(Review Figures 13-6, 13-7, and 13-13.)*

■ Because energy is required for contracting the inspiratory muscles, inspiration is an active process, but expiration is passive during quiet breathing because it is accomplished by elastic recoil of the lungs when the inspiratory muscles relax, at no energy expense. *(Review Figure 13-11a, b, and c.)*

■ For more forceful active expiration, contraction of the expiratory muscles (namely, the *abdominal muscles*) further decreases the size of the thoracic cavity and lungs, which further increases the intra-alveolar–to–atmospheric-pressure gradient. *(Review Figures 13-10 and 13-11d.)*

■ The larger the *pressure gradient* between the alveoli and atmosphere in either direction, the larger the *airflow rate* because air flows until intra-alveolar pressure equilibrates with atmospheric pressure. *(Review Figures 13-12 and 13-13.)*

■ Besides being directly proportional to the pressure gradient, airflow rate is also inversely proportional to *airway resistance*. *(Review Table 13-1.)* Because airway resistance, which depends on the caliber of the conducting airways, is normally very low, airflow rate usually depends primarily on the pressure gradient between the alveoli and atmosphere.

■ The lungs can be stretched to varying degrees during inspiration and then recoil to their preinspiratory size during expiration because of their elastic behavior. *Pulmonary compliance* refers to the distensibility of the lungs—how much they stretch in response to a given change in the transmural pressure gradient. *Elastic recoil* refers to the snapping back of the lungs to their resting position during expiration.

■ Pulmonary elastic behavior depends on the *elastin fibers* in the lung and on *alveolar surface tension*. Alveolar surface tension, which is the result of attractive forces between the surface water molecules lining each alveolus, tends to resist the alveolus being stretched on inflation (decreases compliance) and tends to return it back to a smaller surface area during deflation (increases lung rebound). *(Review Table 13-2.)*

■ If the alveoli were lined by water alone, the surface tension would be so great that the lungs would be poorly compliant and would tend to collapse. *Pulmonary surfactant* intersperses between the water molecules and lowers alveolar surface tension, thereby increasing compliance and counteracting the tendency for alveoli to collapse. *(Review Figure 13-14 and Table 13-2.)*

■ The lungs can be filled to about 5.5 liters on maximal inspiration or emptied to about 1 liter on maximal expiration. Normally the lungs operate at "half full." Lung volume typically varies from about 2 to 2.5 liters as an average *tidal volume* of 500 mL of air is moved in and out with each breath. *(Review Figures 13-15 and 13-16.)*

■ The amount of air moved in and out of the lungs in one minute, the *pulmonary ventilation,* is equal to tidal volume times respiratory rate. Not all the air moved in and out is available for gas exchange with the blood because part occupies the conducting airways (*anatomic dead space*). *Alveolar ventilation,* the volume of air exchanged between the atmosphere and alveoli in one minute, is a measure of the air actually available for gas exchange with the blood. Alveolar ventilation equals (tidal volume minus dead space volume) times respiratory rate. *(Review Figure 13-18 and Table 13-3.)*

■ Even though ventilation and perfusion rates are both higher at the bottom than at the top of the lungs (with the ventilation–

perfusion ratio being higher at the top), local controls act on bronchiolar and pulmonary arteriolar smooth muscle to match airflow and blood flow to each area of the lung as much as possible. *(See Figures 13-19 and 13-20.)*

13.3 Gas Exchange (pp. 466–471)

■ O_2 and CO_2 move across body membranes by passive diffusion down partial pressure gradients. The *partial pressure* of a gas in air is that portion of the total atmospheric pressure contributed by this individual gas, which in turn is directly proportional to the percentage of this gas in the air. The partial pressure of a gas in blood depends on the amount of this gas dissolved in the blood. *(Review Figure 13-21.)*

■ Net diffusion of O_2 occurs first between the alveoli and blood and then between the blood and tissues as a result of the O_2 partial pressure gradients created by continuous use of O_2 in the cells and continuous replenishment of fresh alveolar O_2 provided by ventilation. Net diffusion of CO_2 occurs first between the tissues and blood and then between the blood and alveoli, as a result of the CO_2 partial pressure gradients created by continuous production of CO_2 in the cells and continuous removal of alveolar CO_2 through ventilation. *(Review Figure 13-22.)*

■ Other factors that influence the rate of gas exchange are surface area and thickness of the membrane across which the gas is diffusing and the diffusion constant of the gas in the membrane (Fick's law of diffusion). *(Review Table 13-5.)*

13.4 Gas Transport (pp. 471–478)

■ Because O_2 and CO_2 are not very soluble in blood, they must be transported primarily by mechanisms other than simply being physically dissolved. Only 1.5% of the O_2 is *physically dissolved* in the blood, with 98.5% chemically *bound to hemoglobin (Hb)*. *(Review Table 13-6.)*

■ The primary factor that determines the extent to which Hb and O_2 are combined (the *% Hb saturation*) is the P_{O_2} of the blood, depicted by an S-shaped curve known as the O_2–Hb dissociation curve. In the P_{O_2} range of the pulmonary capillaries (the plateau portion of the curve), Hb is still almost fully saturated even if the blood P_{O_2} falls as much as 40%. This provides a margin of safety by ensuring near-normal O_2 delivery to the tissues despite a substantial reduction in arterial P_{O_2}. In the P_{O_2} range in the systemic capillaries (the steep portion of the curve), Hb unloading increases greatly in response to a small local decline in blood P_{O_2} associated with increased cellular metabolism. In this way, more O_2 is provided to match the increased tissue needs. *(Review Figure 13-24.)*
❙Figure 13-24 Oxygen–hemoglobin (O_2–Hb) dissociation (saturation) curve.

■ Increased P_{CO_2}, increased acid, and increased temperature at the tissue level shift the O_2–Hb curve to the right, facilitating the unloading of O_2 from Hb for tissue use. *(Review Figure 13-26.)*

■ *Hemoglobin* facilitates a large net transfer of O_2 between alveoli and blood and between blood and tissue cells by acting as a storage depot to keep P_{O_2} (that is, dissolved O_2 concentration) low, despite a considerable increase in the total O_2 content of the blood. *(Review Figure 13-25.)*

■ CO_2 picked up at the systemic capillaries is transported in blood by three means: (1) 10% is *physically dissolved,* (2) 30% is *bound to Hb,* and (3) 60% takes the form of *bicarbonate (HCO_3^-)*. The erythrocyte enzyme *carbonic anhydrase* catalyzes conversion of CO_2 to HCO_3^- according to the reaction $CO_2 + H_2O \rightarrow H^+ + HCO_3^-$. These reactions are all reversed in the lungs as CO_2 is eliminated to the alveoli. *(Review Table 13-6 and Figure 13-27.)*

13.5 Control of Respiration (pp. 479–488)

■ Ventilation involves two aspects, both subject to neural control: (1) rhythmic cycling between inspiration and expiration and (2) regulation of ventilation magnitude, which depends on control of respiratory rate and depth of tidal volume.

■ Respiratory rhythm is established by the *pre-Bötzinger complex,* which displays pacemaker activity and drives the inspiratory neurons located in the *dorsal respiratory group (DRG)* of the *medullary respiratory control center*. When these neurons fire, impulses ultimately reach the inspiratory muscles to bring about inspiration. *(Review Figure 13-29.)*

■ When the inspiratory neurons stop firing, the inspiratory muscles relax and passive expiration takes place. For active expiration, the expiratory muscles are activated at this time by expiratory neurons in the *ventral respiratory group (VRG)* of the medullary respiratory control center. *(Review Figure 13-29.)*

■ This basic rhythm is smoothed out by the apneustic and pneumotaxic centers located in the pons. The *apneustic center* prolongs inspiration; the more powerful *pneumotaxic center* limits inspiration. *(Review Figure 13-29.)*

■ Three chemical factors play a role in determining the magnitude of ventilation: P_{CO_2}, P_{O_2}, H+ concentration of the arterial blood. *(Review Table 13-8.)*

■ The dominant factor in the ongoing regulation of ventilation is arterial P_{CO_2}, an increase of which is the most potent chemical stimulus for increasing ventilation. Changes in arterial P_{CO_2} alter ventilation by bringing about corresponding changes in the brain-ECF H+ concentration, to which the *central chemoreceptors* are very sensitive. *(Review Figure 13-31.)*

■ The *peripheral chemoreceptors* are responsive to an increase in arterial H+ concentration, which likewise reflexly brings about increased ventilation. The resulting adjustment in arterial H+-generating CO_2 is important in maintaining the acid–base balance of the body. *(Review Figure 13-30.)*

■ The peripheral chemoreceptors also reflexly increase ventilation in response to a marked reduction in arterial P_{O_2} (<60 mm Hg), serving as an emergency mechanism to increase respiration when arterial P_{O_2} levels fall below the safety range provided by the plateau portion of the O_2–Hb curve.

■ Respiration activity can also be voluntarily modified.

14.1 Kidneys: Anatomy, Functions, and Basic Processes (pp. 492–498)

- Each of the pair of *kidneys* consists of an outer *renal cortex* and inner *renal medulla*. The kidneys form *urine*. They eliminate unwanted plasma constituents in the urine while conserving materials of value to the body. Urine from each kidney is collected in the *renal pelvis,* then transmitted from both kidneys through the pair of *ureters* to the single *urinary bladder,* where urine is stored until emptied through the *urethra* to the outside. *(Review Figures 14-1 and 14-2.)*

- The urine-forming functional unit of the kidneys, the *nephron,* is composed of interrelated vascular and tubular components. The *vascular component* consists of two capillary networks in series, the first being the *glomerulus,* a tuft of capillaries that filters large volumes of protein-free plasma into the tubular component. The second capillary network consists of the *peritubular capillaries,* which nourish the renal tissue and participate in exchanges between the tubular fluid and plasma. *(Review Figures 14-3 and 14-4 and chapter opener.)*

- The tubular component begins with *Bowman's capsule,* which cups around the glomerulus to catch the filtrate, then continues a specific tortuous course to ultimately empty into the renal pelvis. *(Review Figure 14-3.)* As the filtrate passes through various regions of the tubule, cells lining the tubules modify it, returning to the plasma only those materials necessary for maintaining proper ECF composition and volume. What is left behind in the tubules is excreted as urine.

- The kidneys perform three basic processes: (1) *glomerular filtration,* the nondiscriminating movement of protein-free plasma from the blood into the tubules; (2) *tubular reabsorption,* the selective transfer of specific constituents in the filtrate back into peritubular capillary blood; and (3) *tubular secretion,* the highly specific movement of selected substances from peritubular capillary blood into the tubular fluid. Everything filtered or secreted but not reabsorbed is excreted as urine. *(Review Figure 14-6.)*

14.2 Glomerular Filtration (pp. 498–505)

- Glomerular filtrate is produced when part of the plasma flowing through each glomerulus is passively forced under pressure through the *glomerular membrane* into the underlying Bowman's capsule. The *net filtration pressure* causing filtration results from a high glomerular capillary blood pressure that favors filtration outweighing the combined opposing forces of plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure. *(Review Figures 14-7 and 14-8 and Table 14-1.)*

- Of the cardiac output, 20% to 25% is delivered to the kidneys to be acted on by renal regulatory and excretory processes. Of the plasma flowing through the kidneys, normally 20% is filtered through the glomeruli, for an average *glomerular filtration rate (GFR)* of 125 mL/min.

- The *juxtaglomerular apparatus* consists of specialized vascular and tubular cells next to the glomerulus where the tubular and vascular components come into close proximity. *Myogenic mechanisms* and *tubuloglomerular feedback,* triggered by the juxtaglomerular apparatus, *autoregulate* glomerular blood flow and the GFR despite transient changes in the driving mean arterial blood pressure in the range of 80 to 180 mm Hg. *(Review Figures 14-9 through 14-11.)*

- The GFR can be deliberately altered by changing the glomerular capillary blood pressure via sympathetic influence on the *afferent arterioles* as part of the baroreceptor reflex response that compensates for changed arterial blood pressure. When blood pressure falls too low, sympathetically induced afferent arteriolar vasoconstriction lowers glomerular blood pressure and GFR. When blood pressure rises too high, reduced sympathetic activity causes afferent arteriolar vasodilation, leading to a rise in GFR. As the GFR is altered, the amount of fluid lost in urine changes correspondingly, adjusting plasma volume as needed to help restore blood pressure to normal on a long-term basis. *(Review Figures 14-4, p. 495, 14-10, and 14-12.)*

14.3 Tubular Reabsorption (pp. 505–514)

- After the filtrate is formed, the tubules handle each filtered substance discretely, so that even though the initial glomerular filtrate is identical to plasma (with the exception of plasma proteins), the concentrations of different constituents are variously altered as the filtered fluid flows through the tubular system. *(Review Table 14-2, p. 517.)*

- The reabsorptive capacity of the tubular system is tremendous. More than 99% of the filtered plasma is returned to the blood through reabsorption. On average, 124 mL out of the 125 mL filtered per minute are reabsorbed.

- Tubular reabsorption involves *transepithelial transport* from the tubular lumen into the peritubular capillary plasma. This process may be active (requiring energy) or passive (using no energy). *(Review Figure 14-14.)*

- The pivotal event to which most reabsorptive processes are linked is the *active reabsorption of Na^+*, driven by the energy-dependent Na^+–K^+ pump in the *basolateral membrane* of the tubular cells. The transport of Na^+ out of the cells into the *lateral spaces* between adjacent cells by this carrier induces the net reabsorption of Na^+ from the tubular lumen to the peritubular capillary plasma. *(Review Figure 14-15.)*

- Most Na^+ reabsorption takes place early in the nephron in constant unregulated fashion, but in the distal and collecting tubules, the reabsorption of a small percentage of the filtered Na^+ is variable and controlled, mostly by the *renin–angiotensin–aldosterone system (RAAS)*. *(Review Figure 14-16 and Table 14-3, p. 528.)*

- Because Na^+ and its attendant anion, Cl^-, are the major osmotically active ions in the ECF, the ECF volume is determined by the *Na^+ load (total amount of Na^+)* in the body. In turn, the

plasma volume, which reflects the total ECF volume, is important in the long-term determination of arterial blood pressure. Whenever the Na^+ load, ECF volume, plasma volume, and arterial blood pressure are below normal, the juxtaglomerular apparatus secretes *renin,* an enzymatic hormone that triggers RAAS, ultimately leading to increased aldosterone secretion by the adrenal cortex. *Aldosterone* increases Na^+ reabsorption from the distal portions of the tubule, thus correcting for the original reduction in Na^+, ECF volume, and blood pressure. *(Review Figures 14-11 and 14-16.)*

■ By contrast, Na^+ reabsorption is inhibited by the natriuretic peptides, *ANP* and *BNP,* hormones released from the cardiac atria and ventricles, respectively, in response to expansion of the ECF volume and a subsequent increase in blood pressure. *(Review Figure 14-17.)*

■ In addition to driving the reabsorption of Na^+, the energy used by the Na^+–K^+ pump is ultimately responsible for the reabsorption of *organic nutrients* (glucose or amino acids) from the proximal tubule by secondary active transport. *(Review Figure 3-18, p. 76.)*

■ Other electrolytes actively reabsorbed by the tubules, such as PO_4^{3-} and Ca^{2+}, have independently functioning carrier systems within the proximal tubule.

■ Because the electrolyte and nutrient carriers can become saturated, each exhibits a *maximal carrier-limited transport capacity (T_m)*. Once the filtered load of an actively reabsorbed substance exceeds the T_m, reabsorption proceeds at a constant maximal rate, and any additional filtered quantity of the substance is excreted in the urine. *(Review Figure 14-18.)*

■ Active Na^+ reabsorption also drives the passive reabsorption of Cl^- (via an electrical gradient), H_2O (by osmosis), and *urea* (down a urea concentration gradient created as a result of extensive osmotic-driven H_2O reabsorption). Sixty-five percent of the filtered H_2O is reabsorbed from the proximal tubule in unregulated fashion, driven by active Na^+ reabsorption. *(Review Figure 14-19 and Table 14-3, p. 528.)* Reabsorption of H_2O increases the concentration of other substances remaining in the tubular fluid, most of which are filtered waste products. The small urea molecules are the only waste products that can passively permeate the tubular membranes, so urea is the only waste product partially (50%) reabsorbed as a result of being concentrated. *(Review Figure 14-20.)*

■ The other waste products, which are not reabsorbed, remain in the urine in highly concentrated form.

14.4 Tubular Secretion (pp. 514–517)

■ Tubular secretion involves transepithelial transport from the peritubular capillary plasma into the tubular lumen. By tubular secretion, the kidney tubules can selectively add some substances to the quantity already filtered. Secretion of substances hastens their excretion in the urine.

■ The most important secretory systems are for (1) H^+ (helps regulate acid–base balance); (2) K^+ (keeps the plasma K^+ concentration at the level needed to maintain normal membrane ex-

citability in the heart, other muscles, and nerves); and (3) *organic ions* (accomplishes more efficient elimination of foreign organic compounds from the body). H^+ is secreted in the proximal, distal, and collecting tubules. K^+ is secreted only in the distal and collecting tubules under control of aldosterone. Organic ions are secreted only in the proximal tubule. *(Review Figures 14-21 and 14-22 and Table 14-2.)*

14.5 Urine Excretion and Plasma Clearance (pp. 517–532)

■ Of the 125 mL/min of glomerular filtrate formed, normally only 1 mL/min remains in the tubules to be excreted as urine. Only wastes and excess electrolytes not wanted by the body are left behind, dissolved in a given volume of H_2O to be eliminated in the urine.

■ Because the excreted material is removed or "cleared" from the plasma, the term *plasma clearance* refers to the volume of plasma cleared of a particular substance each minute by renal activity. *(Review Figure 14-23.)*

■ The kidneys can excrete urine of varying volumes and concentrations to either conserve or eliminate H_2O, depending on whether the body has a H_2O deficit or excess, respectively. The kidneys can produce urine ranging from 0.3 mL/min at 1200 mOsm/L to 25 mL/min at 100 mOsm/L by reabsorbing variable amounts of H_2O from the distal portions of the nephron.

■ This variable reabsorption is made possible by a *vertical osmotic gradient* in the medullary interstitial fluid, established by the *long loops of Henle* of the *juxtamedullary nephrons* via *countercurrent multiplication* and preserved by the *vasa recta* of these nephrons via *countercurrent exchange*. *(Review Figures 14-5, p. 496; 14-24; 14-25; and 14-28.)* This vertical osmotic gradient, to which the hypotonic (100 mOsm/L) tubular fluid is exposed as it passes through the distal portions of the nephron, establishes a passive driving force for progressive reabsorption of H_2O from the tubular fluid, but the actual extent of H_2O reabsorption depends on the amount of *vasopressin (antidiuretic hormone)* secreted. *(Review Figure 14-27.)*

■ Vasopressin increases the permeability of the distal and collecting tubules to H_2O; they are impermeable to H_2O in its absence. *(Review Figure 14-26.)* Vasopressin secretion increases in response to a H_2O deficit, increasing H_2O reabsorption. Its secretion is inhibited in response to a H_2O excess, reducing H_2O reabsorption. Thus vasopressin-controlled H_2O reabsorption helps correct any fluid imbalances.

■ Once formed, *urine* is propelled by peristaltic contractions through the ureters from the kidneys to the urinary bladder for temporary storage.

■ The *bladder* can accommodate up to 250 to 400 mL of urine before stretch receptors within its wall initiate the *micturition reflex*. *(Review Figure 14-30.)* This reflex causes involuntary emptying of the bladder by simultaneous bladder contraction and opening of both the *internal* and the *external urethral sphincters*. Micturition can transiently be voluntarily prevented by deliberately tightening the external sphincter and pelvic diaphragm. *(Review Figures 14-2, p. 494, and 14-29.)*

Chapter 15
Study Card

15.1 Balance Concept (pp. 536–537)

■ The *internal pool* of a substance is the quantity of that substance in the ECF. The *inputs* to the pool are by way of ingestion or metabolic production of the substance. The *outputs* from the pool are by way of excretion or metabolic consumption of the substance. *(Review Figure 15-1.)*

■ Input must equal output to maintain a *stable balance* of the substance.

15.2 Fluid Balance (pp. 537–547)

■ On average, the body fluids compose 60% of total body weight. This figure varies, depending on how much fat (a tissue with a low H_2O content) a person has. Two thirds of the body H_2O is in the ICF. The remaining third, in the ECF, is distributed between plasma (20% of ECF) and interstitial fluid (80% of ECF). *(Review Table 15-1.)*

■ Because all plasma constituents are freely exchanged across the capillary walls, the plasma and interstitial fluid are nearly identical in composition, except for the lack of plasma proteins in the interstitial fluid. In contrast, the ECF and ICF have markedly different compositions because the plasma membrane barriers are highly selective as to what materials are transported into or out of the cells. *(Review Figure 15-2.)*

■ The components of fluid balance are *control of ECF volume* by maintaining salt balance and *control of ECF osmolarity* by maintaining water balance. *(Review Tables 15-2, 15-3, and 15-5, p. 547.)*

■ Because of the osmotic holding power of Na^+, the major ECF cation, a change in the body's total Na^+ content, or load, causes a corresponding change in ECF volume, including plasma volume, which alters arterial blood pressure in the same direction. Appropriately, in the long run, *Na^+-regulating mechanisms* compensate for changes in ECF volume and arterial blood pressure. *(Review Table 15-5.)*

■ Salt intake is not controlled in humans, but control of salt output in the urine is closely regulated to maintain *salt balance*. Blood pressure–regulating mechanisms can vary the GFR, and thus the amount of Na^+ filtered, by adjusting the radius of the afferent arterioles supplying the glomeruli. Blood pressure–regulating mechanisms can also vary aldosterone secretion to adjust Na^+ reabsorption by the renal tubules. Varying Na^+ filtration and Na^+ reabsorption can adjust how much Na^+ is excreted in the urine to regulate plasma volume and thus arterial blood pressure in the long term. *(Review Figure 15-3.)*

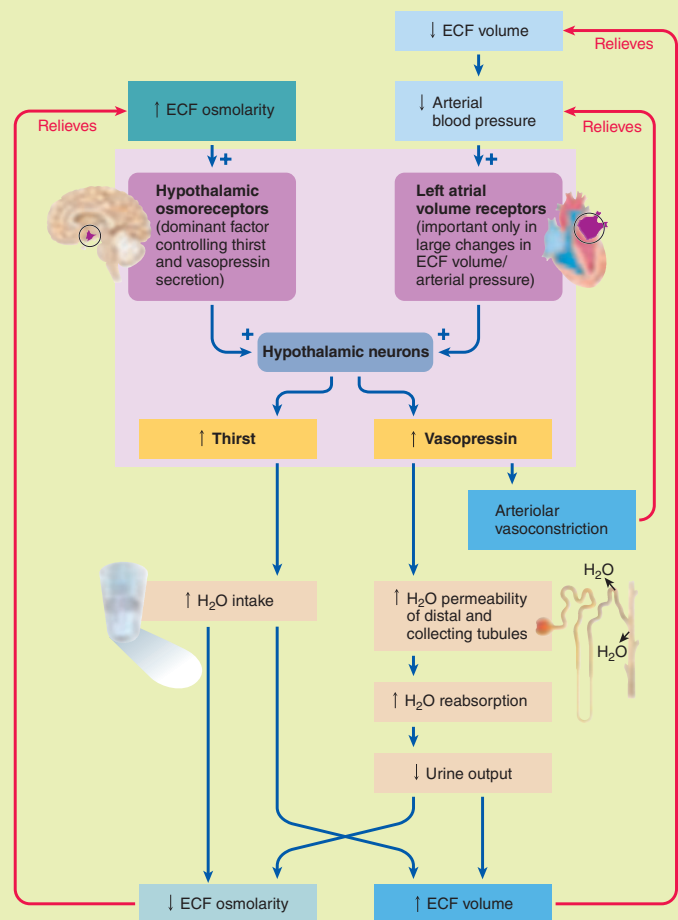
■ ECF osmolarity must be closely regulated to prevent osmotic shifts of H_2O between the ECF and ICF because cell swelling or shrinking is harmful, especially to brain neurons. Excess free H_2O in the ECF dilutes ECF solutes; the resulting ECF hypotonicity

drives H_2O into the cells. An ECF free H_2O deficit, by contrast, concentrates ECF solutes, so H_2O leaves the cells to enter the hypertonic ECF. *(Review Table 15-5.)*

■ To prevent these harmful fluxes, changes in ECF osmolarity are primarily detected and corrected by the systems that maintain *free H_2O balance* (H_2O without accompanying solute).

■ Free H_2O balance is regulated largely by vasopressin and, to a lesser degree, by thirst. Both of these factors are governed primarily by *hypothalamic osmoreceptors*, which monitor ECF osmolarity, and to a lesser extent by *left atrial volume receptors*, which monitor vascular "fullness." The amount of *vasopressin* secreted determines the extent of free H_2O reabsorption by distal portions of the nephrons, thereby determining the volume of urinary output. *(Review Figure 15-4 and Table 15-4.)*

■ Simultaneously, intensity of *thirst* controls the volume of fluid intake. However, because the volume of fluid drunk is often not directly correlated with the intensity of thirst, control of urinary output by vasopressin is the most important regulatory mechanism for maintaining H_2O balance.



ıFigure 15-4 Control of increased vasopressin secretion and thirst during a H_2O deficit.

15.3 Acid–Base Balance (pp. 547–562)

■ *Acids* liberate *free hydrogen ions (H^+)* into solution; *bases* bind with free hydrogen ions and remove them from solution. *(Review Figure 15-5.)*

■ *Acid–base balance* refers to regulation of [H$^+$] in the body fluids. To precisely maintain [H$^+$], input of H$^+$ by metabolic production of acids within the body must continually be matched with H$^+$ output by urinary excretion of H$^+$ and respiratory removal of H$^+$-generating CO_2. Furthermore, between the time of this generation and its elimination, H$^+$ must be buffered within the body to prevent marked fluctuations in [H$^+$].

■ Hydrogen ion concentration is often expressed in terms of *pH*, which is the logarithm of 1/[H$^+$].

■ The *normal pH* of the plasma is *7.4*, slightly alkaline compared to neutral H_2O, which has a pH of 7.0. A pH lower than normal (higher [H$^+$] than normal) indicates a state of *acidosis*. A pH higher than normal (lower [H$^+$] than normal) characterizes a state of *alkalosis*. *(Review Figure 15-6.)*
■ Fluctuations in [H$^+$] have profound effects, most notably (1) changes in neuromuscular excitability, with acidosis depressing excitability, especially in the CNS, and alkalosis producing overexcitability of both the PNS and CNS; (2) disruption of normal metabolic reactions by altering the structure and function of all enzymes; and (3) alterations in plasma [K$^+$] (which affect cardiac function) brought about by H$^+$-induced changes in the rate of K$^+$ elimination by the kidneys.

■ The primary challenge in controlling acid–base balance is maintaining normal plasma alkalinity despite continual addition of H$^+$ to the plasma from ongoing metabolic activity. The major source of H$^+$ is from *CO_2-generated H$^+$*.

■ The *three lines of defense* for resisting changes in [H$^+$] are *first* the chemical buffer systems, *second* respiratory control of pH, and *third* renal control of pH.

■ *Chemical buffer systems* each consist of a pair of chemicals involved in a reversible reaction, one that can liberate H$^+$ and the other that can bind H$^+$. By acting according to the law of mass action, a buffer pair acts immediately to minimize any changes in pH. The four chemical buffers are (1) *H_2CO_3: HCO_3^-*, (2) *proteins*, (3) *hemoglobin*, and (4) *phosphate*. *(Review Figure 15-8 and Table 15-6.)*

■ The relationship between pH and the members of the H_2CO_3:HCO_3^- buffer pair is represented in the *Henderson–Hasselbalch equation*: pH = pK + log [HCO_3^-]/[CO_2], with [CO_2] reflecting [H_2CO_3]. [HCO_3^-] is controlled by the kidneys; [CO_2] is controlled by the lungs. pK is a constant at 6.1, and the normal ratio of [HCO_3^-]/[CO_2] is 20/1 (the log of which is 1.3), for a normal pH of 7.4.

■ The *respiratory system* normally eliminates metabolically produced CO_2 so that CO_2-generated H$^+$ does not accumulate in the body fluids.

■ When chemical buffers alone have been unable to immediately minimize a pH change, the respiratory system responds within a few minutes by altering its rate of CO_2 removal. An increase in [H$^+$] from sources other than CO_2 stimulates respiration so that more H$^+$-forming CO_2 is blown off, compensating for acidosis by reducing generation of CO_2-associated H$^+$. Conversely, a fall in [H$^+$] depresses respiratory activity so that CO_2 and thus H$^+$ generated from this source can accumulate in the body fluids to compensate for alkalosis. *(Review Table 15-7.)*

■ The *kidneys* are the most powerful line of defense. They require hours to days to compensate for a deviation in body-fluid pH. However, not only can they eliminate the normal amount of H$^+$ produced from non-CO_2 sources, but they can also alter their rate of H$^+$ removal in response to changes in both non-CO_2 and CO_2-generated acids. In contrast, the lungs can adjust only H$^+$ generated from CO_2. Furthermore, the kidneys can regulate [HCO_3^-] in body fluids.

■ The kidneys compensate for acidosis by secreting the excess H$^+$ in the urine while adding new HCO_3^- to the plasma to expand the HCO_3^- buffer pool. During alkalosis, the kidneys conserve H$^+$ by reducing its secretion in urine. They also eliminate HCO_3^-, which is in excess because less HCO_3^- than usual is tied up buffering H$^+$ when H$^+$ is in short supply. *(Review Figures 15-9 through 15-12 and Table 15-8.)*
❙Figure 15-12 Control of the rate of tubular H$^+$ secretion and HCO_3^- reabsorption.

■ Secreted H$^+$ must be buffered in the tubular fluid to prevent the H$^+$ concentration gradient from becoming so great that it blocks further H$^+$ secretion. Normally, H$^+$ is buffered by the urinary phosphate buffer pair, which is abundant in the tubular fluid because excess dietary phosphate spills into the urine to be excreted from the body. In acidosis, when all the phosphate buffer is already used up in buffering the extra secreted H$^+$, the kidneys secrete *NH_3* into the tubular fluid to serve as a buffer so that H$^+$ secretion can continue.

■ The four types of acid–base imbalances are *respiratory acidosis, respiratory alkalosis, metabolic acidosis,* and *metabolic alkalosis*. Respiratory acid–base disorders stem from deviations from normal [CO_2], whereas metabolic acid–base imbalances include all deviations in pH other than those caused by abnormal [CO_2] and are always accompanied by deviations from normal [HCO_3^-]. *(Review Figure 15-13 and Table 15-9.)*

Chapter 16
Study Card

16.1 General Aspects of Digestion (pp. 566–573)

■ The four basic digestive processes are *motility, secretion, digestion,* and *absorption*.

■ Three classes of energy-rich nutrients are digested into absorbable units: (1) Dietary *carbohydrates* in the form of the polysaccharides starch (amylose and amylopectin) and glycogen are digested into monosaccharides, mostly glucose. (2) Dietary *proteins* are digested into amino acids and a few small polypeptides. (3) Dietary *fats* (triglycerides) are digested into monoglycerides and free fatty acids. *(Review Figure 16-1.)*

■ The digestive system consists of the *digestive tract* and *accessory digestive organs* (salivary glands, exocrine pancreas, and biliary system). *(Review Table 16-1.)*

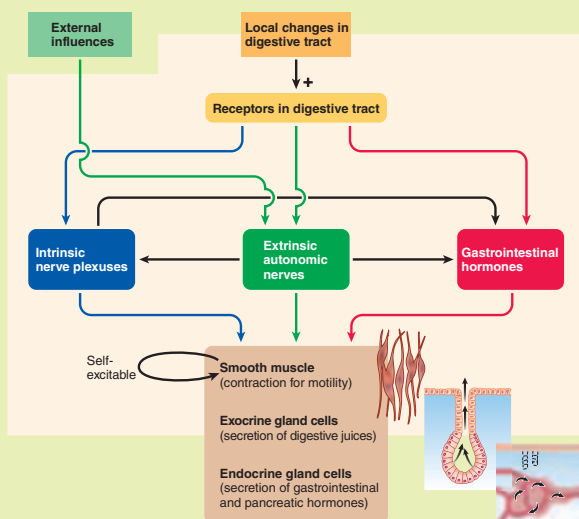
■ The *lumen* of the digestive tract (a tube that runs from the mouth to the anus) is continuous with the external environment, so its contents are technically outside the body; this arrangement permits digestion of food without self-digestion occurring in the process.

■ The *digestive tract wall* has four layers. From innermost outward, they are the *mucosa, submucosa, muscularis externa,* and *serosa*. *(Review Figure 16-2.)*

■ Digestive activities are carefully regulated by synergistic autonomous, neural (both intrinsic and extrinsic), and hormonal mechanisms to ensure that ingested food is maximally made available to the body. *(Review Figure 16-3.)*

16.2 Mouth (pp. 573–575)

■ *Motility:* Food enters the digestive system through the mouth, where it is chewed and mixed with saliva.



IFigure 16-3 Summary of pathways controlling digestive system activities.

■ *Secretion and digestion:* The salivary enzyme, *amylase,* begins to digest polysaccharides into the disaccharide *maltose,* a process that continues in the stomach after swallowing. Salivary secretion is controlled by a *salivary center* in the medulla, mediated by autonomic nerves to the salivary glands. *(Review Figures 16-1 and 16-4.)*

■ *Absorption:* No food is absorbed from the mouth.

16.3 Pharynx and Esophagus (pp. 575–578)

■ *Motility:* The tongue propels the bolus of food to the rear of the throat, which initiates the *swallowing reflex*. The *swallowing center* in the medulla coordinates a complex group of activities that result in closure of the respiratory passages and propulsion of food through the pharynx and esophagus into the stomach. *(Review Figure 16-5.)*

■ *Secretion, digestion, and absorption:* The esophageal secretion, *mucus*, is protective. No nutrient digestion or absorption occurs here.

16.4 Stomach (pp. 578–588)

■ *Motility:* Gastric motility includes filling, storage, mixing, and emptying. *Gastric filling* is facilitated by vagally mediated *receptive relaxation* of the stomach. *Gastric storage* takes place in the body of the stomach, where peristaltic contractions of the thin muscle walls are too weak to mix the contents. *Gastric mixing* in the thick-muscled antrum results from vigorous peristaltic contractions and retropulsion. *(Review Figures 16-6 and 16-7.)*

■ *Gastric emptying* is influenced by factors in both the stomach and duodenum. (1) Increased volume and fluidity of chyme in the stomach promote emptying. (2) Fat, acid, hypertonicity, and distension in the duodenum (the dominant factors controlling gastric emptying) delay gastric emptying until the duodenum is ready to process more chyme. They do so by inhibiting stomach peristaltic activity via the *enterogastric reflex* and the enterogastrones, *secretin* and *cholecystokinin (CCK),* which are secreted by the duodenal mucosa. *(Review Figure 16-7 and Table 16-2.)*

■ *Secretion:* Gastric secretions into the stomach lumen include (1) *HCl* (from the *parietal cells*), which activates pepsinogen; (2) *pepsinogen* (from the *chief cells*), which, once activated, initiates protein digestion; (3) *mucus* (from the *mucous cells*), which provides a protective coating; and (4) *intrinsic factor* (from the parietal cells), which is needed for vitamin B_{12} absorption. *(Review Table 16-3 and Figures 16-8 and 16-9.)*

■ The stomach also secretes the hormone *gastrin,* which plays a dominant role in stimulating gastric secretion, and the paracrines *histamine* and *somatostatin,* which stimulate and inhibit gastric secretion, respectively. *(Review Table 16-3.)*

■ Gastric secretion is increased before and during a meal via excitatory vagal and intrinsic nerve responses along with the stimulatory actions of gastrin and histamine. After the meal empties, gastric secretion is reduced by withdrawal of stimulatory factors, release of inhibitory somatostatin, and inhibitory actions of the enterogastric reflex and enterogastrones. *(Review Tables 16-4 and 16-5.)*

- **Digestion and absorption:** Carbohydrate digestion continues by swallowed salivary amylase in the body of the stomach. Protein digestion is initiated by pepsin in the antrum of the stomach, where vigorous peristaltic contractions mix the food with gastric secretions, converting it to a thick liquid mixture known as *chyme. (Review Table 16-6, p. 600.)* No nutrients are absorbed from the stomach.

16.5 Pancreatic and Biliary Secretions (pp. 588–598)

- Pancreatic exocrine secretions and bile from the liver both enter the duodenal lumen.

- *Pancreatic exocrine secretions* include (1) potent *digestive enzymes* from the *acinar cells,* which digest all three categories of foodstuff; and (2) an *aqueous NaHCO₃ solution* from the *duct cells,* which neutralizes the acidic contents emptied into the duodenum from the stomach. *Secretin* stimulates the pancreatic duct cells, and *CCK* stimulates the acinar cells. *(Review Figures 16-10 through 16-12.)*

- The pancreatic digestive enzymes include (1) the proteolytic enzymes *trypsinogen, chymotrypsinogen,* and *procarboxypeptidase,* which are secreted in inactive form and are activated in the duodenal lumen on exposure to *enteropeptidase* and activated trypsin; (2) *pancreatic amylase,* which continues carbohydrate digestion; and (3) *lipase,* which accomplishes fat digestion. *(Review Table 16-6.)*

- The *liver* performs many metabolic functions. Its contribution to digestion is secretion of bile-salt containing *bile. Bile salts* aid fat digestion through their detergent action (forming a *lipid emulsion*) and facilitate fat absorption by forming water-soluble *micelles* that carry the water-insoluble products of fat digestion to their absorption site. *(Review Figures 16-14 through 16-17 and 16-24, p. 607.)*

- Between meals, bile is stored and concentrated in the *gallbladder,* which is stimulated by CCK to contract and empty into the duodenum during meal digestion. After participating in fat digestion and absorption, bile salts are reabsorbed and returned via the *hepatic portal system* to the liver, where they are resecreted and also act as a potent *choleretic* to stimulate secretion of more bile. *(Review Figures 16-13 and 16-15.)*

- Bile also contains *bilirubin,* a derivative of degraded hemoglobin, which is the major excretory product in the feces.

16.6 Small Intestine (pp. 598–610)

- **Motility:** *Segmentation,* the small intestine's primary motility during digestion of a meal, thoroughly mixes the chyme with digestive juices to facilitate digestion; it also exposes the products of digestion to the absorptive surfaces. *(Review Figure 16-18.)* Between meals, the *migrating motility complex (MMC)* sweeps the lumen clean.

- **Secretion:** The juice secreted by the small intestine does not contain any digestive enzymes. The enzymes synthesized by the small intestine act within the *brush-border membrane* of the epithelial cells. *(Review Figures 16-22a and 16-23a.)*

- **Digestion:** The small intestine is the *main site for digestion and absorption*. Carbohydrate and protein digestion continues in the small-intestine lumen by the pancreatic enzymes and is completed by the small-intestine brush-border enzymes (*disaccharidases* and *aminopeptidases,* respectively). Fat is digested entirely in the small-intestine lumen, by pancreatic lipase. *(Review Table 16-6.)*

- **Absorption:** The small-intestine lining is remarkably adapted to its digestive and absorptive function. Its folds bear a rich array of fingerlike projections, the *villi,* which have a multitude of even smaller hairlike protrusions, the *microvilli* (brush border). Together, these surface modifications tremendously increase the area available to house the membrane-bound enzymes and to accomplish absorption. *(Review Figures 16-19 through 16-21 and chapter opener, p. 565.)* This lining is replaced about every three days to ensure it is optimally healthy despite harsh lumen conditions.

- The energy-dependent process of Na⁺ absorption provides the driving force for Cl⁻, water, glucose, and amino acid absorption. All these absorbed products enter the blood. *(Review Figures 16-22b and 16-23b.)*

- Because they are not soluble in water, the products of fat digestion must undergo a series of transformations that enable them to be passively absorbed, eventually entering the lymph. *(Review Figure 16-24.)*

- The small intestine absorbs almost everything presented to it, from ingested food to digestive secretions to sloughed epithelial cells. In contrast to the almost complete, unregulated absorption of ingested nutrients, water, and most electrolytes, the amount of iron and calcium absorbed is variable and subject to control. Only a small amount of fluid and indigestible food residue passes on to the large intestine. *(Review Figure 16-25 and Table 16-7.)*

16.7 Large Intestine (pp. 610–614)

- **Motility:** The colon *(review Figure 16-26)* concentrates and stores undigested food residues (fiber—that is, plant cellulose) and bilirubin until they can be eliminated in the feces. *Haustral contractions* slowly shuffle the colonic contents back and forth to mix and facilitate absorption of most of the remaining fluid and electrolytes. *Mass movements* several times a day, usually after meals, propel the feces long distances. Movement of feces into the rectum triggers the *defecation reflex*.

- **Secretion, digestion, and absorption:** The alkaline mucus secretion is protective. The colon secretes no digestive enzymes. However, colonic bacteria (the *microbiota*) ferment for their own use some of the fiber that cannot be digested by human digestive enzymes. The colon absorbs some of these bonus nutrients. Absorption of some of the remaining salt and water converts the colonic contents into *feces.*

16.8 Overview of the GI Hormones (pp. 614–615)

- The three major GI hormones are gastrin from the stomach mucosa and secretin and cholecystokinin (CCK) from the duodenal mucosa. *Gastrin* is released primarily in response to protein in the stomach, and its effects promote digestion of protein. *Secretin* is released primarily in response to acid in the duodenum, and its effects neutralize the acid. *CCK* is released primarily in response to fat in the duodenum, and its effects optimize conditions for digesting fat.

17.1 Energy Balance (pp. 619–627)

■ *Energy input* to the body in the form of *food energy* must equal energy output because energy cannot be created or destroyed. *Energy output* or expenditure includes (1) *external work,* performed by skeletal muscles to move an external object or move the body through the external environment; and (2) *internal work,* which consists of all other energy-dependent activities that do not accomplish external work, including active transport, smooth and cardiac muscle contraction, glandular secretion, and protein synthesis. *(Review Figure 17-1.)*

■ Only about 25% of the chemical energy in food is harnessed to do biological work. The rest is immediately converted to heat. Furthermore, all the energy expended to accomplish internal work is eventually converted into heat, and 75% of the energy expended by working skeletal muscles is lost as heat. Therefore, most of the energy in food ultimately appears as *body heat*.
■ The *metabolic rate* (energy expenditure per unit of time) is measured in kilocalories of heat produced per hour.

■ The *basal metabolic rate (BMR)* is a measure of the body's minimal waking rate of internal energy expenditure.

■ For a neutral *energy balance,* the energy in ingested food must equal energy expended in performing external work and transformed into heat. If more energy is consumed than is expended, the extra energy is stored in the body, primarily as adipose tissue, so body weight increases. If more energy is expended than is available in the food, body energy stores are used to support energy expenditure, so body weight decreases.

■ Usually, *body weight* remains fairly constant over a prolonged period of time (except during growth) because food intake is adjusted to match energy expenditure on a long-term basis. *Food intake* is controlled primarily by the hypothalamus by means of complex regulatory mechanisms in which hunger and satiety are important components. *Feeding* or *appetite signals* give rise to the sensation of hunger and promote eating, whereas *satiety signals* lead to the sensation of fullness and suppress eating. *(Review Table 17-2, p. 624.)*

■ The *arcuate nucleus* of the hypothalamus plays a key role in energy homeostasis by virtue of the two clusters of appetite-

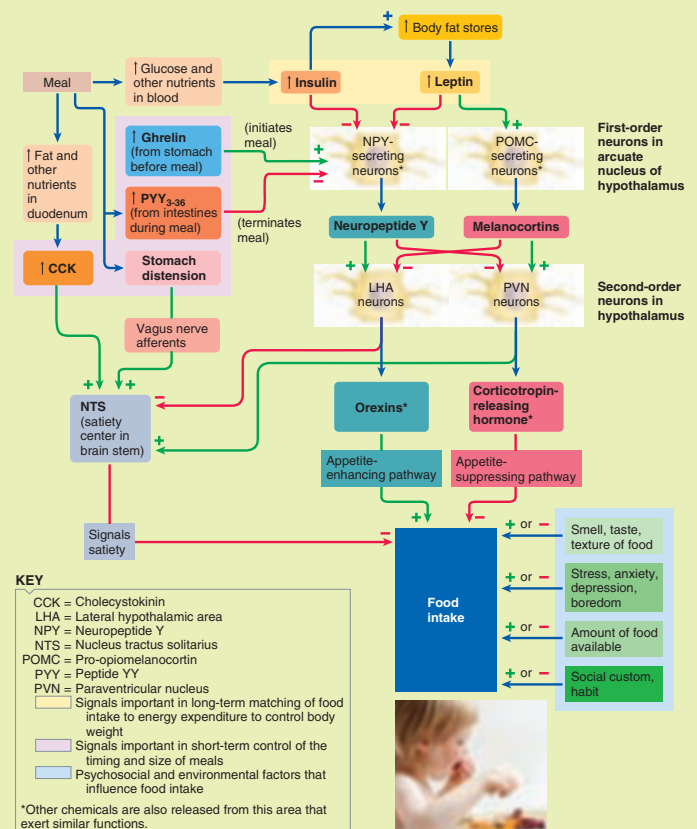
regulating neurons it contains: neurons that secrete *neuropeptide Y (NPY),* which increases appetite and food intake; and neurons that secrete *melanocortins,* which suppress appetite and food intake. *(Review Figure 17-2.)*

■ *Adipocytes* in fat stores secrete the hormone *leptin,* which reduces appetite and decreases food consumption by inhibiting the NPY-secreting neurons and stimulating the melanocortin-secreting neurons. This mechanism is important in the long-term matching of energy intake with energy output, thus maintaining body weight. *(Review Figure 17-2.)* Adipocytes and macrophages in adipose tissue also secrete other adipokines that largely cause inflammation in obese fat stores and set off a low-grade systemic inflammation that has detrimental metabolic consequences.

■ *Insulin* released by the endocrine pancreas in response to increased glucose and other nutrients in the blood also inhibits the NPY-secreting neurons and contributes to long-term control of energy balance and body weight.

■ NPY and melanocortins bring about their effects by acting on the *lateral hypothalamus area (LHA)* and *paraventricular nucleus (PVN)* to alter the release of chemical messengers from these areas. The LHA secretes *orexins,* which are potent stimulators of food intake, whereas the PVN releases neuropeptides such as *corticotropin-releasing hormone,* which decrease food intake. *(Review Figure 17-2.)*

■ Short-term control of the timing and size of meals is mediated primarily by the actions of two peptides secreted by the digestive tract. (1) *Ghrelin,* a mealtime initiator, is secreted by the stomach before a meal and signals hunger. Its secretion drops



I Figure 17-2 Factors that influence food intake.

when food is consumed. Ghrelin stimulates appetite and promotes feeding behavior by stimulating the NPY-secreting neurons. (2) PYY_{3-36}, a mealtime terminator, is secreted by the small and large intestines during a meal and signals satiety. Its secretion is lowest before a meal. PYY_{3-36} inhibits the NPY-secreting neurons. *(Review Figure 17-2.)*

■ The *nucleus tractus solitarius (NTS)* in the brain stem serves as the *satiety center* and in this capacity also plays a key role in short-term control of meals. The NTS receives input from the higher hypothalamic areas concerned with control of energy balance and food intake and input from the digestive tract. Satiety signals acting through the NTS to inhibit further food intake include *stomach distension* and increased *cholecystokinin (CCK),* a hormone released from the duodenum in response to nutrients in the digestive tract lumen. *(Review Figure 17-2.)*

■ Psychosocial and environmental factors can also influence food intake above and beyond the internal signals that govern feeding behavior. *(Review Figure 17-2.)*

17.2 Temperature Regulation (pp. 627–635)

■ The body can be thought of as a heat-generating *core* (internal organs, CNS, and skeletal muscles) surrounded by a *shell* of variable insulating capacity (the skin).

■ The *skin* exchanges heat energy with the external environment, with the direction and amount of heat transfer depending on the environmental temperature and the momentary insulating capacity of the shell. The four physical means by which heat is exchanged are (1) *radiation* (net movement of heat energy via electromagnetic waves); (2) *conduction* (exchange of heat energy by direct contact); (3) *convection* (transfer of heat energy by means of air currents); and (4) *evaporation* (extraction of heat energy from the body by the heat-requiring conversion of liquid H_2O to H_2O vapor). Because heat energy moves from warmer to cooler objects, radiation, conduction, and convection can be channels for either heat loss or heat gain, depending on whether surrounding objects are cooler or warmer, respectively, than the body surface. Normally, they are avenues for heat loss, along with evaporation resulting from sweating. *(Review Figure 17-4.)*

■ To prevent serious cell malfunction, the core temperature must be held constant at about *100°F* (equivalent to an average oral temperature of *98.2°F*) by continuously balancing heat gain and heat loss despite changes in environmental temperature and variation in internal heat production. *(Review Figure 17-3.)*

■ This thermoregulatory balance is controlled by the *hypothalamus*. The hypothalamus is apprised of the skin temperature by *peripheral thermoreceptors* and of the core temperature by *central thermoreceptors,* the most important of which are located in the hypothalamus itself. *(Review Figure 17-5.)*

■ The primary means of *heat gain* is heat production by metabolic activity, the biggest contributor being skeletal muscle contraction. *(Review Figure 17-5.)*

■ *Heat loss* is adjusted by sweating and by controlling to the greatest extent possible the temperature gradient between the skin and surrounding environment. The latter is accomplished by regulating the caliber of the skin's arterioles. (1) *Skin vasocon-*

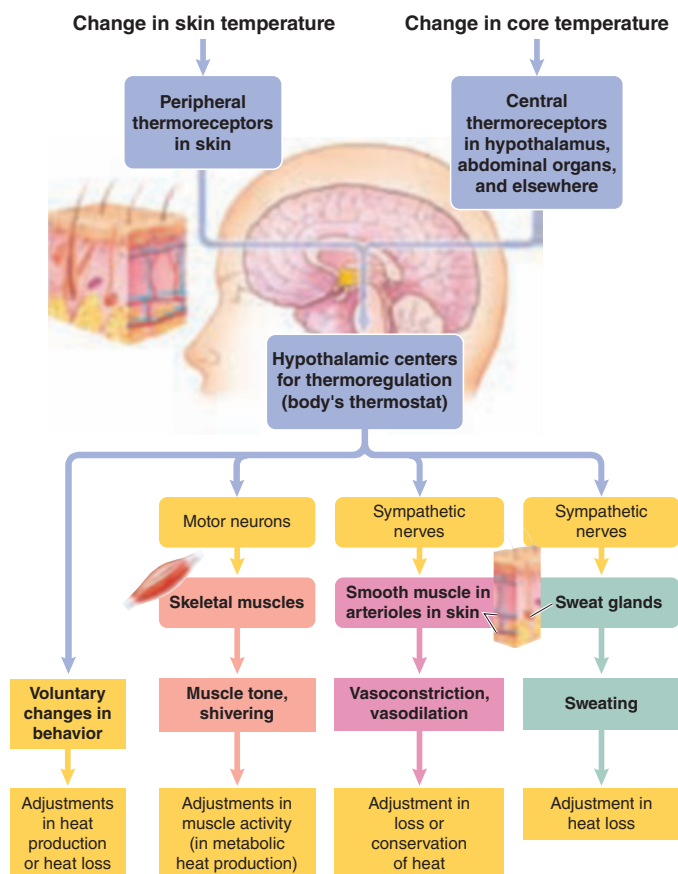
striction reduces the flow of warmed blood through the skin so that skin temperature falls. The layer of cool skin between the core and environment increases the insulating barrier between the warm core and the external air. (2) *Skin vasodilation* brings more warmed blood through the skin so that skin temperature approaches the core temperature, thus reducing the insulative capacity of the skin. *(Review Figure 17-5.)*

■ On exposure to cool surroundings, the core temperature starts to fall as heat loss increases because of the larger-than-normal skin-to-air temperature gradient. The *posterior hypothalamus* responds to reduce the heat loss by inducing skin vasoconstriction while simultaneously increasing heat production through heat-generating *shivering*. *(Review Table 17-3.)*

■ Conversely, in response to a rise in core temperature (resulting either from excessive internal heat production accompanying exercise or from excessive heat gain on exposure to a hot environment), the *anterior hypothalamus* triggers heat-loss mechanisms, such as skin vasodilation and *sweating*, while simultaneously decreasing heat production, such as by reducing muscle tone. *(Review Table 17-3.)*

■ In both cold and heat responses, voluntary behavioral actions also help maintain thermal homeostasis.

■ A *fever* occurs when *endogenous pyrogen* released from macrophages in response to infection raises the hypothalamic set point. An elevated core temperature develops as the hypothalamus initiates cold-response mechanisms to raise the core temperature to the new set point. *(Review Figure 17-6.)*



❙Figure 17-5 Major thermoregulatory pathways.

## 18.1 General Principles of Endocrinology (pp. 639–646)

■ *Hormones* are long-distance chemical messengers secreted by the ductless *endocrine glands* into the blood, which transports the hormones to specific target cells where they control a particular function by altering protein activity.

■ Hormones are grouped into two categories based on differences in their solubility and are further grouped according to their chemical structure—*hydrophilic hormones* (peptide hormones, catecholamines, and indoleamines) and *lipophilic hormones* (steroid hormones and thyroid hormone).

■ The *endocrine system* is especially important in regulating organic metabolism, H_2O and electrolyte balance, growth, and reproduction and in helping the body cope with stress. *(Review Figure 18-1 and Table 18-2, pp. 644–645.)*

■ Some hormones are *tropic*, meaning their function is to stimulate and maintain other endocrine glands.

■ The *effective plasma concentration* of each hormone is normally controlled by regulated changes in the rate of hormone secretion. Secretory output of endocrine cells is primarily influenced by two types of direct regulatory inputs: (1) neural input, which increases hormone secretion in response to a specific need and governs diurnal variations in secretion; and (2) input from another hormone, which involves either stimulatory input from a tropic hormone or inhibitory input from a target-cell hormone in negative-feedback fashion. *(Review Figures 18-2 and 18-6, p. 651.)*

■ The effective plasma concentration of a hormone can also be influenced by its rate of removal from the blood by metabolic inactivation and excretion and, for some hormones, by its rate of peripheral activation or its extent of binding to plasma proteins.

■ *Endocrine dysfunction* arises when too much or too little of any particular hormone is secreted or when there is decreased target-cell responsiveness to a hormone. *(Review Table 18-1.)*

■ Target-cell sensitivity to a given plasma concentration of a hormone to which the target cell is responsive can be modified by (1) *down regulation* (number of receptors decreases in the face of a prolonged increase in the hormone), (2) *permissiveness* (one hormone increases the effectiveness of another hormone), (3) *synergism* (combined effect of two hormones is greater than the sum of their separate effects), and (4) *antagonism* (one hormone decreases the effectiveness of another hormone).

18.2 Hypothalamus and Pituitary (pp. 646–652)

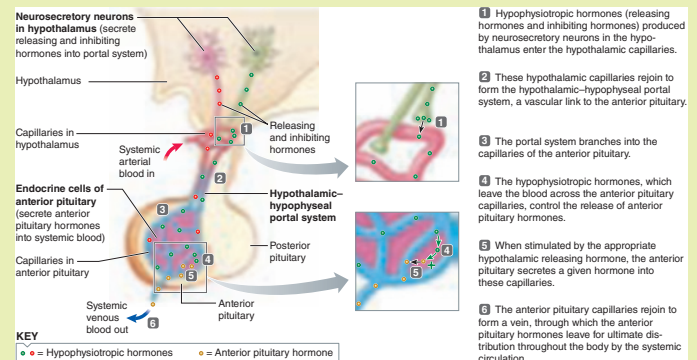
■ The *pituitary gland* consists of two distinct lobes, the posterior pituitary and the anterior pituitary. *(Review Figure 18-3.)*

■ The *hypothalamus*, a portion of the brain, secretes nine peptide hormones. Two are stored in the posterior pituitary, and

seven are carried through a special vascular link—the *hypothalamic–hypophyseal portal system*—to the anterior pituitary, where they regulate the release of particular anterior pituitary hormones. *(Review Figures 18-4 and 18-7.)*

■ The *posterior pituitary* is a neural extension of the hypothalamus. Cell bodies of neurosecretory neurons in the hypothalamus synthesize two small peptide hormones, *vasopressin* and *oxytocin*, which pass down the axon to be stored in nerve terminals within the posterior pituitary. These hormones are independently released from the posterior pituitary into the blood in response to action potentials originating in the hypothalamus. *(Review Figure 18-4.)*

■ The *anterior pituitary* secretes six different peptide hormones produced by five distinct cell types in the gland. Five anterior pituitary hormones are tropic. (1) *Thyroid-stimulating hormone (TSH)* stimulates secretion of thyroid hormone. (2) *Adrenocorticotropic hormone (ACTH)* stimulates secretion of cortisol by the adrenal cortex. (3 and 4) The *gonadotropic hormones—follicle-stimulating hormone (FSH)* and *luteinizing hormone (LH)*—stimulate production of gametes (eggs and sperm) and secretion of sex hormones. (5) *Growth hormone (GH)* largely stimulates growth indirectly by stimulating liver secretion of IGF-I, which in turn promotes growth. GH exerts metabolic effects also. (6) *Prolactin (PRL)* stimulates milk secretion and is not tropic. *(Review Figure 18-5 and chapter opener, p. 638.)*

■ The anterior pituitary releases its hormones into the blood at the bidding of *releasing hormones* and *inhibiting hormones* from the hypothalamus. The hypothalamus, in turn, is influenced by a variety of neural and hormonal controlling inputs. *(Review Table 18-3 and Figures 18-6 and 18-7.)*


IFigure 18-7 **Vascular link between the hypothalamus and anterior pituitary.**

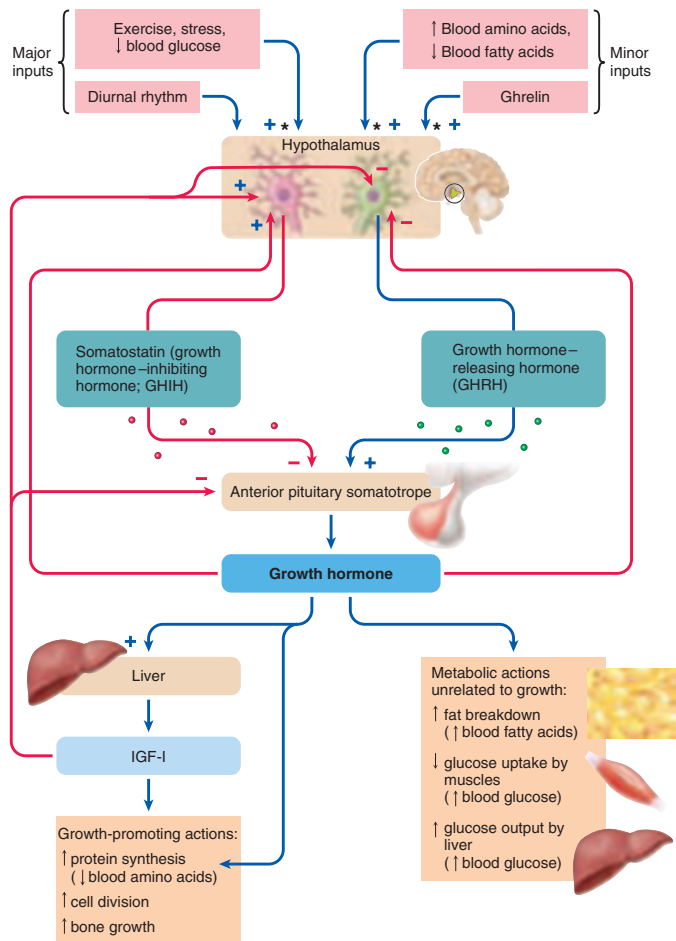
■ Both the hypothalamus and anterior pituitary are inhibited in negative-feedback fashion by the product of the target endocrine gland in the *hypothalamus–anterior pituitary–target-gland axis*. *(Review Figure 18-6.)*

18.3 Endocrine Control of Growth (pp. 652–660)

■ *Growth* depends not only on growth hormone and other growth-influencing hormones such as thyroid hormone, insulin, and the sex hormones but also on genetic determination, an adequate diet, and freedom from chronic disease or stress. Major growth spurts occur the first few years after birth and during puberty. *(Review Figure 18-8.)*

- GH directly promotes growth by stimulating protein synthesis. GH indirectly promotes growth by triggering secretion of *IGF-I*, which causes growth by stimulating protein synthesis and cell division in soft tissues and lengthening and thickening of bones. *(Review Figures 18-9 and 18-10.)*

- GH also directly exerts metabolic effects unrelated to growth, such as conserving carbohydrates and mobilizing fat stores. *(Review Figure 18-10.)*

- GH secretion by the anterior pituitary is regulated by two hypothalamic hormones, *growth hormone–releasing hormone (GHRH)* and *growth hormone–inhibiting hormone (somatostatin)*. In negative-feedback fashion, IGF-I and GH both inhibit GHRH and stimulate somatostatin. *(Review Figure 18-10.)*


*These factors all increase growth hormone secretion, but it is unclear whether they do so by stimulating GHRH or inhibiting somatostatin (GHIH), or both.

❙Figure 18-10 Control of growth hormone secretion.

- GH levels are not highly correlated with periods of rapid growth. The primary signals for increased GH secretion are related to metabolic needs rather than growth, namely, deep sleep (during diurnal rhythm), exercise, stress, and low blood glucose.

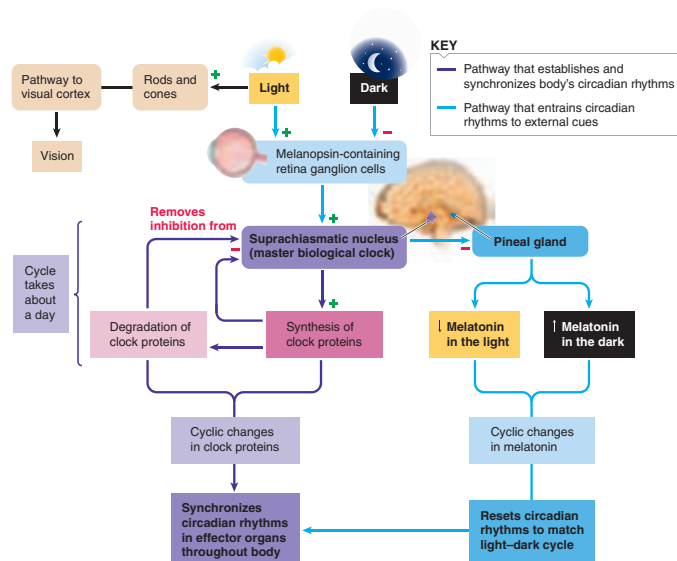
18.4 Pineal Gland and Circadian Rhythms (pp. 660–663)

- The *suprachiasmatic nucleus (SCN)* is the body's *master biological clock*. Self-induced cyclic variations in the concentration of SCN clock proteins bring about cyclic changes in neural discharge from this area. Each cycle takes about a day and drives the body's *circadian (daily) rhythms*. *(Review Figure 18-13.)*

- The inherent rhythm of this endogenous oscillator is a bit longer than 24 hours. Therefore, each day the body's circadian rhythms must be *entrained* or adjusted to keep pace with environmental cues so that the internal rhythms are synchronized with the external light–dark cycle.

- In the eyes, special *melanopsin*-containing photoreceptors that respond to light but are not involved in vision send input to the SCN. Acting through the SCN, the *pineal gland* secretes the hormone melatonin in rhythmic cycles that fluctuate with the light–dark cycle, decreasing in the light and increasing in the dark. *Melatonin*, in turn, resets the body's natural circadian rhythms, such as diurnal (day–night) variations in hormone secretion and body temperature, to march in step with external cues such as the light–dark cycle. *(Review Figure 18-13.)*

- Other proposed roles for melatonin include (1) promoting sleep; (2) influencing reproductive activity, including the onset of puberty; (3) acting as an antioxidant to remove damaging free radicals; and (4) enhancing immunity.



❙Figure 18-13 Synchronization and entrainment of circadian rhythms.

19.1 Thyroid Gland (pp. 666–671)

■ The bow-tie-shaped *thyroid gland* contains two types of endocrine secretory cells: (1) *follicular cells*, which produce the iodide-containing hormones, T_4 (*thyroxine* or *tetraiodothyronine*) and T_3 (*tri-iodothyronine*), collectively known as *thyroid hormone*; and (2) *C cells*, which synthesize a Ca^{2+}-regulating hormone, *calcitonin*. (*Review Figure 19-1 and chapter opener.*)

■ Most steps of thyroid hormone synthesis take place on large *thyroglobulin* molecules within the *colloid*, an "inland" extracellular site within the interior of the spherical thyroid follicles. Dietary iodine is transported as *iodide (I^-)* from the blood into the follicular cells by the iodide pump, an energy-dependent symporter. From the follicular cells, I^- enters the colloid where it iodinates the amino acid *tyrosine* within thyroglobulin, yielding *monoiodothyronine (MIT)* and *di-iodothyronine (DIT)*. Coupling of MIT and DIT produces T_3; coupling of two DITs produces T_4. Thyroid hormone is secreted by follicular cells phagocytizing a piece of colloid and freeing T_4 and T_3, which enter the blood. (*Review Figure 19-2.*)

■ Thyroid hormone is the primary determinant of the basal metabolic rate of the body. By accelerating metabolic rate, it increases heat production. It also enhances the actions of the sympathetic catecholamines and is essential for normal growth and for development and function of the nervous system.

■ Thyroid hormone secretion is regulated by a negative-feedback system between hypothalamic TRH, anterior pituitary TSH, and thyroid gland T_3 and T_4. The feedback loop maintains thyroid hormone levels relatively constant. Cold exposure in newborn infants is the only input for increasing TRH and thus thyroid hormone secretion. (*Review Figure 19-3.*)

19.2 Adrenal Glands (pp. 672–682)

■ Each *adrenal gland* (of the pair) consists of two separate endocrine organs—an outer, steroid-secreting adrenal cortex and an inner, catecholamine-secreting adrenal medulla. (*Review Figure 19-7.*)

■ Each steroid hormone is produced by stepwise modifications of cholesterol via specific enzymes present in a given steroidogenic endocrine gland. The *adrenal cortex* has enzymes to produce three categories of steroid hormones: *mineralocorticoids* (primarily aldosterone), *glucocorticoids* (primarily cortisol), and *adrenal sex hormones* (primarily the weak androgen, dehydroepiandrosterone). (*Review Figure 19-8.*)

■ *Aldosterone* regulates Na^+ and K^+ balance and is important for blood pressure homeostasis, which is achieved secondarily by the osmotic effect of Na^+ in maintaining the plasma volume, a lifesaving effect. Control of aldosterone secretion is related to Na^+ and K^+ balance and to blood pressure regulation and is not influenced by ACTH. Aldosterone is controlled by the renin–angiotensin–aldosterone system (RAAS) and by a direct effect of K^+ on the adrenal cortex. (*Review Figure 14-22, p. 516).*

■ *Cortisol* helps regulate fuel metabolism and is important in stress adaptation. It increases blood levels of glucose, amino acids, and fatty acids and spares glucose for use by the glucose-dependent brain. The mobilized organic molecules are available for use as needed for energy or repair. Cortisol secretion is regulated by a negative-feedback loop involving hypothalamic CRH and pituitary ACTH. Stress is the most potent stimulus for increasing activity of the CRH–ACTH–cortisol axis. Cortisol also displays a characteristic diurnal rhythm. (*Review Figures 18-2, p. 642; 18-6, p. 651; 19-9, p. 675; and 19-13, p. 684.*)

■ *Dehydroepiandrosterone (DHEA)* governs the sex drive and growth of axillary and pubertal hair in females. It has no observable effect in males, in whom it is overpowered by testosterone. DHEA is under control of CRH–ACTH but negatively feeds back to the gonadotropin loop.

■ The *adrenal medulla* consists of modified sympathetic postganglionic neurons known as *chromaffin cells*, which secrete the catecholamine epinephrine into the blood in response to sympathetic stimulation. (*Review Figure 7-2, p. 235.*) *Epinephrine* reinforces the sympathetic system in mounting fight-or-flight responses and in maintaining arterial blood pressure. It also increases blood glucose and blood fatty acids. The primary stimulus for increased epinephrine secretion is activation of the sympathetic system by stress. (*Review Figure 19-13.*)

19.3 Integrated Stress Response (pp. 682–685)

■ The term *stress* refers to the generalized nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory ability to maintain homeostasis. The term *stressor* refers to any noxious stimulus that elicits the stress response. (*Review Figure 19-12.*)

■ In addition to specific responses to various stressors, all stressors produce a similar *generalized stress response*: (1) increased sympathetic and epinephrine activity, which prepares the body for fight-or-flight; (2) activation of the CRH–ACTH–cortisol axis, which helps the body cope with stress by mobilizing metabolic resources; (3) elevation of blood glucose and fatty acids through decreased insulin and increased glucagon secretion; and (4) maintenance of blood volume and blood pressure through increased activity of RAAS and vasopressin. All these actions are coordinated by the hypothalamus. (*Review Figure 19-13.*)

19.4 Endocrine Pancreas and Control of Fuel Metabolism (pp. 685–701)

■ *Intermediary*, or *fuel*, *metabolism* is, collectively, the synthesis (anabolism), breakdown (catabolism), and transformations of the three classes of energy-rich organic nutrients—carbohydrate, fat, and protein—within the body. Glucose and fatty acids derived from carbohydrates and fats, respectively, are primarily used as metabolic fuels, whereas amino acids derived from proteins are primarily used for synthesis of structural and enzymatic proteins. (*Review Figure 19-14 and Tables 19-2 and 19-3.*)

■ During the *absorptive state* following a meal, excess absorbed nutrients not immediately needed for energy production or protein synthesis are stored to a limited extent as glycogen in the liver and muscle but mostly as triglycerides in adipose tissue. During the *postabsorptive state* between meals when no new nutrients are entering the blood, the glycogen and triglyceride stores are catabolized to release nutrient molecules into the blood. If necessary, body proteins are degraded to release amino acids for conversion into glucose (*gluconeogenesis*). The blood glucose concentration must be maintained above a critical level even during the postabsorptive state because the brain depends on blood-delivered glucose as its energy source. Tissues not dependent on glucose switch to fatty acids as their metabolic fuel, sparing glucose for the brain. *(Review Table 19-4.)*

■ Blood glucose concentration is controlled by factors that regulate glucose uptake by cells and glucose output by the liver. *(Review Figure 19-16.)*

■ The shifts in metabolic pathways between the absorptive and postabsorptive state are controlled by hormones, the most important being insulin. *Insulin* is secreted by the β cells of the islets of Langerhans, the endocrine portion of the pancreas. *(Review Figure 19-15 and Table 19-5, p. 700.)*

■ Insulin is an anabolic hormone; it promotes the cellular uptake of glucose, fatty acids, and amino acids and enhances their conversion into glycogen, triglycerides, and proteins, respectively. In so doing, it lowers the blood concentrations of these small organic molecules. Insulin secretion is increased during the absorptive state, primarily by a direct effect of an elevated blood glucose on the β cells via excitation–secretion coupling. Insulin directs nutrients into cells during this state. *(Review Figures 19-17 through 19-20.)*

■ *Glucagon*, secreted by the pancreatic α cells, mobilizes the energy-rich molecules from their stores during the postabsorptive state. Glucagon, which is secreted in response to a direct effect of a fall in blood glucose on the α cells, in general opposes the actions of insulin. *(Review Figures 19-15 and 19-20.)*

19.5 Parathyroid Glands and Control of Calcium Metabolism (pp. 701–702)

■ Changes in the concentration of *free, diffusible plasma* Ca^{2+}, the biologically active form of this ion, produce profound and life-threatening effects, most notably on neuromuscular excitability. Hypercalcemia reduces excitability, whereas hypocalcemia brings about overexcitability of nerves and muscles. If the overexcitability is severe enough, fatal spastic contractions of respiratory muscles can occur.

■ Control of Ca^{2+} metabolism involves two aspects—regulation of Ca^{2+} homeostasis and regulation of Ca^{2+} balance—and depends on hormonal control of exchanges between the ECF and three compartments: *bone*, *kidneys*, and *intestine*. Regulation of Ca^{2+} *homeostasis* (maintenance of a constant free plasma Ca^{2+} concentration) involves rapid exchanges between bone and the ECF and to a lesser extent to adjustments in urinary Ca^{2+} excretion. Regulation of Ca^{2+} *balance* (maintenance of a constant total amount of Ca^{2+} in the body) is accomplished by adjustments in Ca^{2+} absorption from the intestine and urinary Ca^{2+} excretion.

■ *Bone* consists of an *organic extracellular matrix*, the *osteoid*, which is hardened by precipitation of $Ca_3(PO_4)_2$ *(calcium phosphate)* crystals. Bone constantly undergoes remodeling by means of bone-dissolving *osteoclasts* and bone-building *osteoblasts*. Entombed *osteocytes* are "retired" osteoblasts that have deposited bone around themselves. Osteoblasts and osteocytes are interconnected by long cytoplasmic arms that extend through the tiny canals that permeate the hardened bone, forming a continuous *osteocytic–osteoblastic bone membrane*. *(Review Figures 19-22 through 19-24.)*

■ Three hormones regulate the plasma concentration of Ca^{2+} (and concurrently regulate PO_4^{3-})—*parathyroid hormone (PTH)* secreted by the parathyroid glands, *calcitonin*, and *vitamin D*. *(Review Figure 19-21.)*

■ *PTH*, whose secretion is directly increased by a fall in plasma Ca^{2+} concentration, acts directly on bone and kidneys and indirectly on the intestine to raise plasma Ca^{2+}. In so doing, it is essential for life by preventing the fatal consequences of hypocalcemia. PTH promotes Ca^{2+} movement across the osteocytic–osteoblastic bone membrane from the bone fluid into the plasma in the short term and promotes localized dissolution of bone in the long term by enhancing osteoclasts and suppressing osteoblasts. *(Review Figures 19-24 and 19-25.)*

■ Dissolution of the $Ca_3(PO_4)_2$ bone crystals releases Ca^{2+} and PO_4^{3-} into the plasma. PTH acts on the kidneys to enhance the reabsorption of filtered Ca^{2+} thereby reducing the urinary excretion of Ca^{2+} and increasing its plasma concentration. Simultaneously, PTH reduces renal PO_4^{3-} reabsorption, in this way increasing PO_4^{3-} excretion and lowering plasma PO_4^{3-} levels. This is important because a rise in plasma PO_4^{3-} would force the redeposition of some of the plasma Ca^{2+} back into the bone. *(Review Figure 19-27.)*

■ PTH facilitates activation of *vitamin D*, which in turn stimulates Ca^{2+} and PO_4^{3-} absorption from the intestine. The skin can synthesize vitamin D from cholesterol when exposed to sunlight, but frequently this endogenous source is inadequate, so vitamin D must be supplemented by dietary intake. From either source, vitamin D must be activated first by the liver and then by the kidneys (the site of PTH regulation of vitamin D activation) before it can exert its effect. *(Review Figure 19-26.)*

■ *Calcitonin*, a hormone produced by the C cells of the thyroid gland, is secreted in response to an increase in plasma Ca^{2+} and lowers plasma Ca^{2+} by inhibiting activity of bone osteoclasts. Calcitonin is unimportant except during the rare condition of hypercalcemia. *(Review Figures 19-1 and 19-25.)*

20.1 Uniqueness of the Reproductive System (pp. 716–723)

■ Both sexes produce *gametes* (reproductive cells), *sperm* in males and *ova (eggs)* in females, each of which bears one member of each of the 23 pairs of chromosomes present in human cells. Union of a sperm and an ovum at fertilization results in the beginning of a new individual with 23 complete pairs of chromosomes, half from each parent.

■ The *reproductive system* is anatomically and functionally distinct in males and females. Males produce sperm and deliver them into the female. Females produce ova, accept sperm delivery, and provide a suitable environment for supporting development of a fertilized ovum until the new individual can survive on its own in the external world.

■ In both sexes, the reproductive system consists of (1) a pair of *gonads*, testes in males and ovaries in females, which are the primary reproductive organs that produce the gametes and secrete sex hormones; (2) a *reproductive tract* composed of a system of ducts that transport or house the gametes after they are produced; and (3) *accessory sex glands* that provide supportive secretions for the gametes. The *external genitalia* are the externally visible parts of the reproductive system. *(Review Figures 20-1 and 20-2.) Secondary sexual characteristics* are the distinguishing features between males and females not directly related to reproduction.

■ *Sex determination* is a genetic phenomenon dependent on the combination of sex chromosomes at the time of fertilization: An XY combination is a genetic male, and an XX combination, a genetic female. *Sexual differentiation* refers to the embryonic development of the gonads, reproductive tract, and external genitalia along male or female lines, which gives rise to the apparent anatomic sex of the individual. In the presence of masculinizing factors, a male reproductive system develops; in their absence, a female system develops. *(Review Figures 20-3 through 20-5.)*

20.2 Male Reproductive Physiology (pp. 723–732)

■ The *testes* are located in the *scrotum*. The cooler temperature in the scrotum than in the abdominal cavity is essential for spermatogenesis (sperm production), which occurs in the testes' highly coiled *seminiferous tubules*. *Leydig cells* in the interstitial spaces between these tubules secrete the male sex hormone testosterone into the blood. *(Review Figures 20-6 and 20-7.)*

■ *Testosterone* is secreted before birth to masculinize the developing reproductive system; then its secretion ceases until puberty, at which time it begins once again and continues throughout life. Testosterone is responsible for maturation and maintenance of the entire male reproductive tract, for development of secondary sexual characteristics, and for stimulating libido. *(Review Table 20-1.)*

■ The testes are regulated by the anterior pituitary gonadotropic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are under control of hypothalamic gonadotropin-releasing hormone (GnRH), which itself is under control of arcuate nucleus kisspeptins. *(Review Figure 20-9.)*

■ Testosterone secretion is regulated by LH stimulation of the Leydig cells, and in negative-feedback fashion, testosterone inhibits LH secretion. *(Review Figure 20-9.)*

■ *Spermatogenesis* requires both testosterone and FSH. Testosterone stimulates the mitotic and meiotic divisions required to transform the undifferentiated diploid germ cells, the spermatogonia, into undifferentiated haploid spermatids. FSH stimulates the remodeling of spermatids into highly specialized motile spermatozoa. *(Review Figures 20-6, 20-7, 20-9, and 20-13, p. 740.)*

■ A *spermatozoon* consists only of a DNA-packed head bearing an enzyme-filled acrosome at its tip for penetrating the ovum, a midpiece containing the mitochondria for energy production, and a whiplike motile tail. *(Review Figure 20-8 and chapter opener, p. 715.)*

■ Also present in the seminiferous tubules are *Sertoli cells*, which protect, nurse, and enhance the germ cells throughout their development. FSH stimulates Sertoli cells to secrete *inhibin*, a hormone that inhibits FSH secretion, completing the negative-feedback loop. *(Review Figures 20-6b and d and 20-9.)*

■ The still-immature sperm are flushed out of the seminiferous tubules into the epididymis by fluid secreted by the Sertoli cells. The *epididymis* and *ductus deferens* store and concentrate the sperm and increase their motility and fertility before ejaculation. During ejaculation, the sperm are mixed with secretions released by the accessory glands. *(Review Figure 20-6a and Table 20-2.)*

■ The *seminal vesicles* supply fructose for energy and prostaglandins, which promote smooth muscle motility in both the male and female reproductive tracts to enhance sperm transport. The seminal vesicles also contribute the bulk of the semen. The *prostate gland* contributes an alkaline fluid to neutralize the acidic vaginal secretions. The *bulbourethral glands* release lubricating mucus. *(Review Table 20-2.)*

20.3 Sexual Intercourse between Males and Females (pp. 732–736)

■ The *male sex act* consists of erection and ejaculation, which are part of a much broader systemic *sexual response cycle*. *(Review Table 20-3.)*

■ *Erection* is a hardening of the normally flaccid *penis* that enables it to penetrate the female vagina. Erection is accomplished by marked vasocongestion of the penis brought about by reflexly induced vasodilation of the arterioles supplying the penile erectile tissue. *(Review Figures 20-1, p. 717, and 20-10.)*

■ When sexual excitation reaches a critical peak, *ejaculation* occurs. It consists of two stages: (1) *emission*, the emptying of semen (sperm and accessory sex gland secretions) into the urethra; and (2) *expulsion* of semen from the penis. The latter is accompanied by a set of characteristic systemic responses and intense pleasure referred to as *orgasm*. *(Review Table 20-3.)*

- Females experience a sexual response cycle similar to that of males, with both having excitation, plateau, orgasmic, and resolution phases. Like the penis, the highly vascular *clitoris* undergoes erection (but not ejaculation). *(Review Figure 20-2d, p. 719.)* During sexual response, the outer portion of the vagina constricts to grip the penis, and the inner part expands to create space for sperm deposition.

20.4 Female Reproductive Physiology (pp. 736–770)

- In the nonpregnant state, female reproductive function is controlled by a complex, cyclic, both negative- and positive-feedback system among the hypothalamus (kisspeptins and GnRH), anterior pituitary (FSH and LH), and ovaries (estrogen, progesterone, and inhibin).

- The *ovaries* perform the dual and interrelated functions of oogenesis (producing ova) and secretion of estrogen and progesterone. *(Review Table 20-6, p. 768.)* Two related ovarian endocrine units sequentially accomplish these functions: the follicle and the corpus luteum.

- The same steps in chromosome replication and division take place in *oogenesis* as in spermatogenesis, but the timing and end result are markedly different. Spermatogenesis is accomplished within two months, but the similar steps in oogenesis take anywhere from 12 to 50 years to complete on a cyclic basis from the onset of puberty until menopause. A female is born with a limited, nonrenewable supply of germ cells, whereas postpubertal males can produce several hundred million sperm each day. Each primary oocyte yields only one cytoplasm-rich ovum along with three doomed cytoplasm-poor polar bodies that disintegrate, whereas each primary spermatocyte yields four equally viable spermatozoa. *(Review Figures 20-12, 20-13, and 20-7, p. 727.)*

- Oogenesis and estrogen secretion take place within an *ovarian follicle* during the first half of each reproductive cycle (the *follicular phase*) under the influence of FSH, LH, and estrogen. *(Review Figures 20-14 through 20-19.)*

- At approximately midcycle, the maturing follicle releases a single ovum *(ovulation).* Ovulation is triggered by an *LH surge* brought about by the high level of estrogen produced by the mature follicle. *(Review Figures 20-14, 20-16, 20-17, and 20-20.)*

- LH converts the empty follicle into a *corpus luteum (CL)*, which produces progesterone and estrogen during the last half of the cycle (the *luteal phase*). This endocrine unit prepares the uterus for implantation if the released ovum is fertilized. *(Review Figures 20-14, 20-17, and 20-21.)*

- If fertilization and implantation do not occur, the CL degenerates, withdrawing hormonal support for the highly developed uterine lining, causing it to disintegrate and slough, producing *menstrual flow*. Simultaneously, a new follicular phase is initiated. *(Review Figures 20-14 and 20-17.)*

- Menstruation ceases and the uterine lining *(endometrium)* repairs itself under the influence of rising estrogen levels from the newly maturing follicle. *(Review Figure 20-17.)*

- If *fertilization* does take place, it occurs in the *oviduct* as the released egg and sperm deposited in the vagina are both transported to this site. *(Review Figures 20-22 and 20-23.)*

- The fertilized ovum begins to divide mitotically. Within a week it grows and differentiates into a *blastocyst* capable of implantation. *(Review Figure 20-24.)*

- Meanwhile, the endometrium has become richly vascularized and stocked with stored glycogen under the influence of luteal-phase progesterone. *(Review Figure 20-17, p. 745.)* Into this especially prepared lining the blastocyst *implants* by means of enzymes released by the *trophoblasts*, which form the blastocyst's outer layer. These enzymes digest the nutrient-rich endometrial tissue, accomplishing the dual function of carving a hole in the endometrium for implantation of the blastocyst while simultaneously releasing nutrients from the endometrial cells for use by the developing embryo. *(Review Figure 20-25.)*

- After implantation, an interlocking combination of fetal and maternal tissues, the placenta, develops. The *placenta* is the organ of exchange between maternal and fetal blood and also acts as a transient, complex endocrine organ that secretes a number of hormones essential for pregnancy. *Human chorionic gonadotropin (hCG), estrogen,* and *progesterone* are the most important of these hormones. hCG maintains the *CL of pregnancy*, which secretes estrogen and progesterone during the first trimester of gestation until the placenta takes over this function in the last two trimesters. High levels of estrogen and progesterone are essential for maintaining a normal pregnancy. *(Review Figures 20-26 through 20-28 and Table 20-5.)*

- At *parturition*, rhythmic contractions of increasing strength, duration, and frequency accomplish the *three stages of labor*: dilation of the cervix, birth of the baby, and delivery of the placenta (afterbirth). *(Review Figure 20-30.)*

- Parturition is initiated by a complex interplay of multiple maternal and fetal factors. Once the contractions are initiated at the onset of labor, a positive-feedback cycle is established that progressively increases their force. As contractions push the fetus against the cervix, secretion of *oxytocin*, a powerful uterine muscle stimulant, is reflexly increased. The extra oxytocin causes stronger contractions, giving rise to even more oxytocin release, and so on. This positive-feedback cycle progressively intensifies until cervical dilation and delivery are complete. *(Review Figure 20-29.)*

- During gestation, the *breasts (mammary glands)* are specially prepared for *lactation*. The elevated levels of placental estrogen and progesterone, respectively, promote development of the ducts and alveoli in the mammary glands. *(Review Figure 20-31.)*

- *Prolactin* stimulates the synthesis of enzymes essential for milk production by the alveolar epithelial cells. However, the high gestational level of estrogen and progesterone prevents prolactin from promoting milk production. Withdrawal of the placental steroids at parturition initiates lactation.

- Lactation is sustained by suckling, which triggers the release of oxytocin and prolactin. Oxytocin causes *milk ejection (letdown)* by stimulating the *myoepithelial cells* surrounding the alveoli to squeeze the secreted milk out through the ducts. Prolactin stimulates secretion of more milk to replace the milk the baby nurses. *(Review Figures 20-31 and 20-32.)*

ANATOMICAL TERMS USED TO INDICATE DIRECTION AND ORIENTATION

Anterior	situated in front of or in the front part of
Posterior	situated behind or toward the rear
Ventral	toward the belly or front surface of the body; synonymous with anterior
Dorsal	toward the back surface of the body; synonymous with posterior
Medial	denoting a position nearer the midline of the body or a body structure
Lateral	denoting a position toward the side or farther from the midline of the body or a body structure
Superior	toward the head
Inferior	away from the head
Proximal	closer to a reference point
Distal	farther from a reference point
Sagittal section	a vertical plane that divides the body or a body structure into right and left sides
Longitudinal section	a plane that lies parallel to the length of the body or a body structure
Cross section	a plane that runs perpendicular to the length of the body or a body structure
Frontal or coronal section	a plane parallel to and facing the front part of the body
