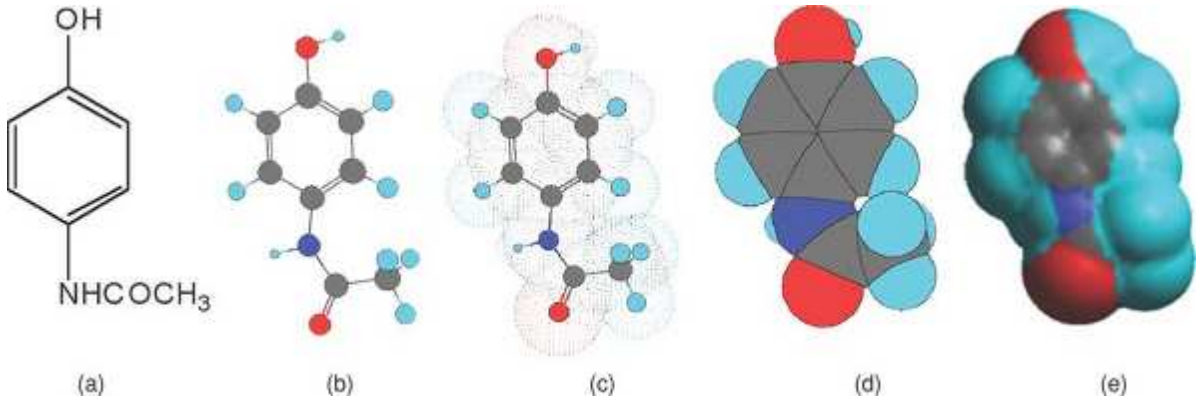

Fig. 3.1. Visualization of a drug molecule N-(4-hydroxy-phenyl)-acetamide (Tylenol or acetaminophen) computerized with different levels of graphic representations. (A) Molecular structure of the drug Tylenol. (B) Ball-stick model showing atomic positions and types. (C) Ball-stick model with van der Waals dot surfaces. (D) Space-filled model showing van der Walls radii of the oxygen, nitrogen, and carbon atoms. (E) Solvent accessible surface model (solid) (solvent radius, 1.4Å). (See black and white image.)

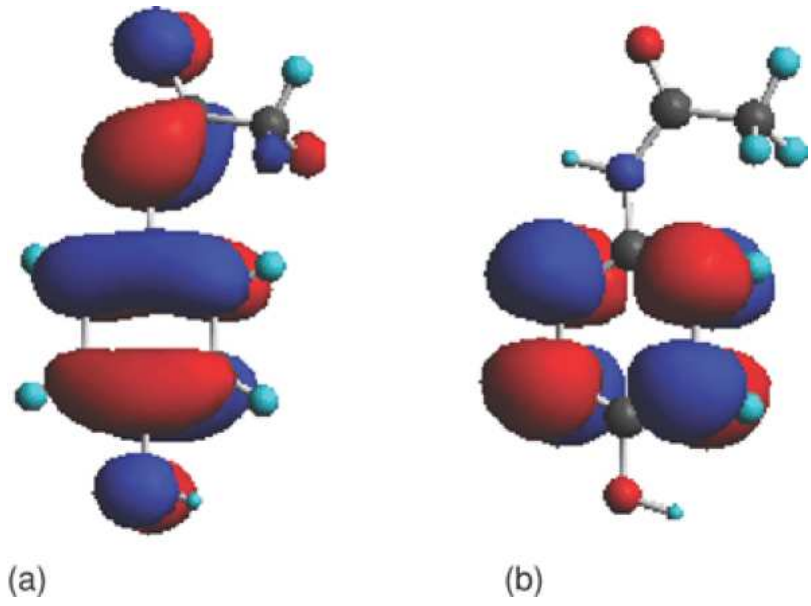

Fig. 3.3. Graphic visualization of molecular orbital surface

HOMO/LUMO calculation for the drug molecule acetaminophen. (See black and white image.)

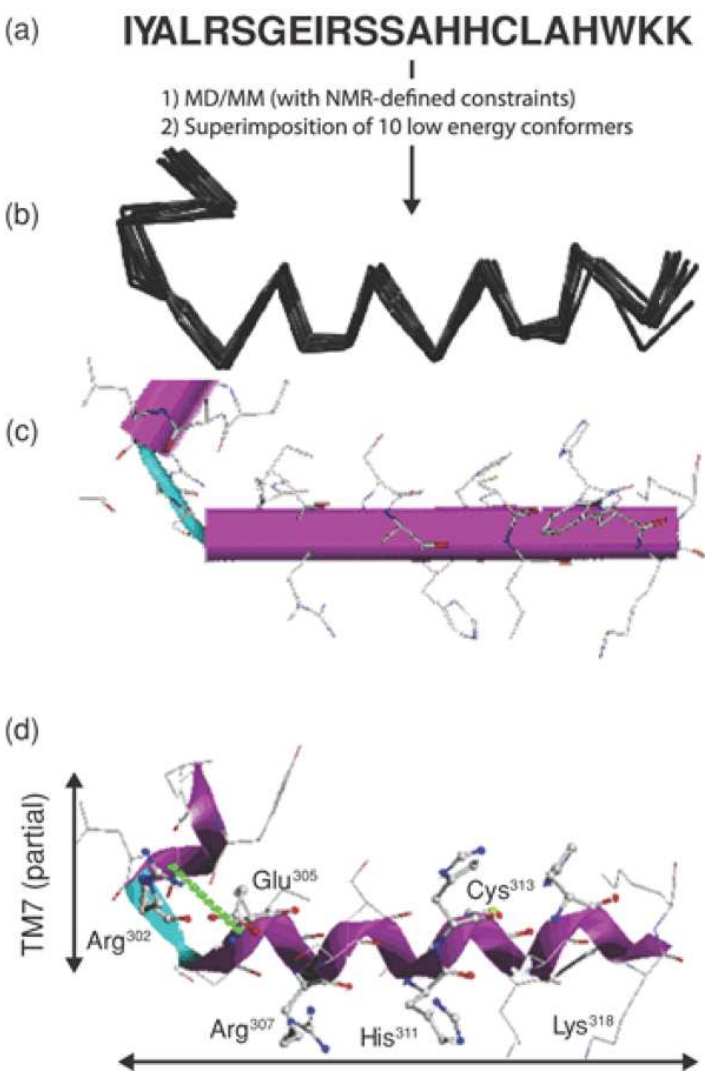

Fig. 3.7. Nuclear magnetic resonance NOE-constrained molecular dynamics/molecular mechanics structure calculation of (A) the polypeptides CB_2I298-K319; (B) the amino acid backbone superimposition of 10 low-energy conformers; (C) the cylinder representation with a turn at the fifth residue, arginine; (d) and the ribbon display of the two helical segments, showing a curve side chain of Arg302 forming a salt bridge (green line) with Glu305. (See black and white image.)

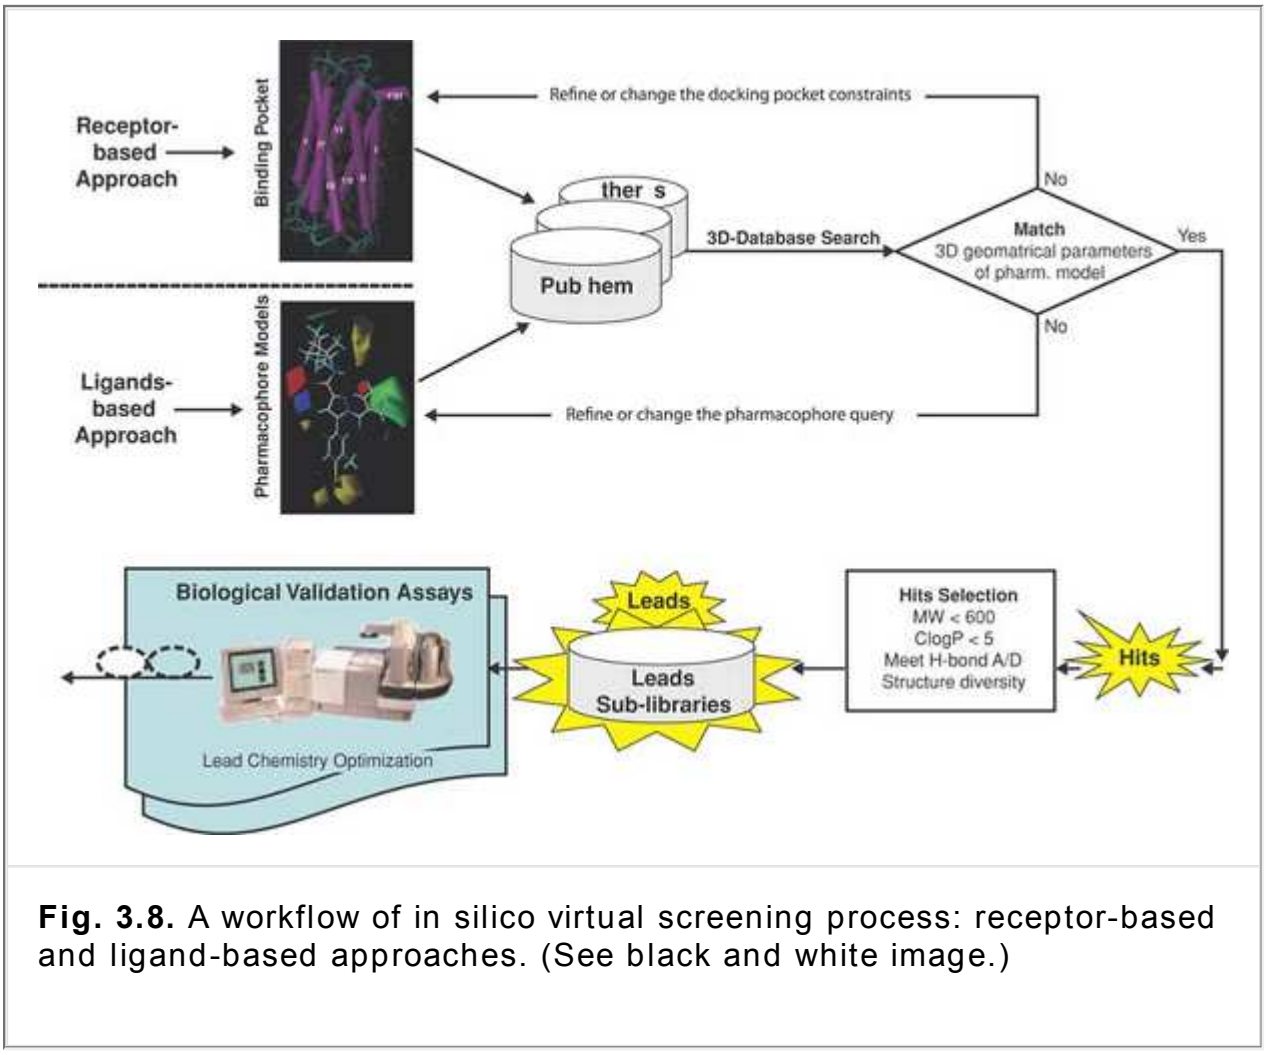

Fig. 3.8. A workflow of in silico virtual screening process: receptor-based and ligand-based approaches. (See black and white image.)

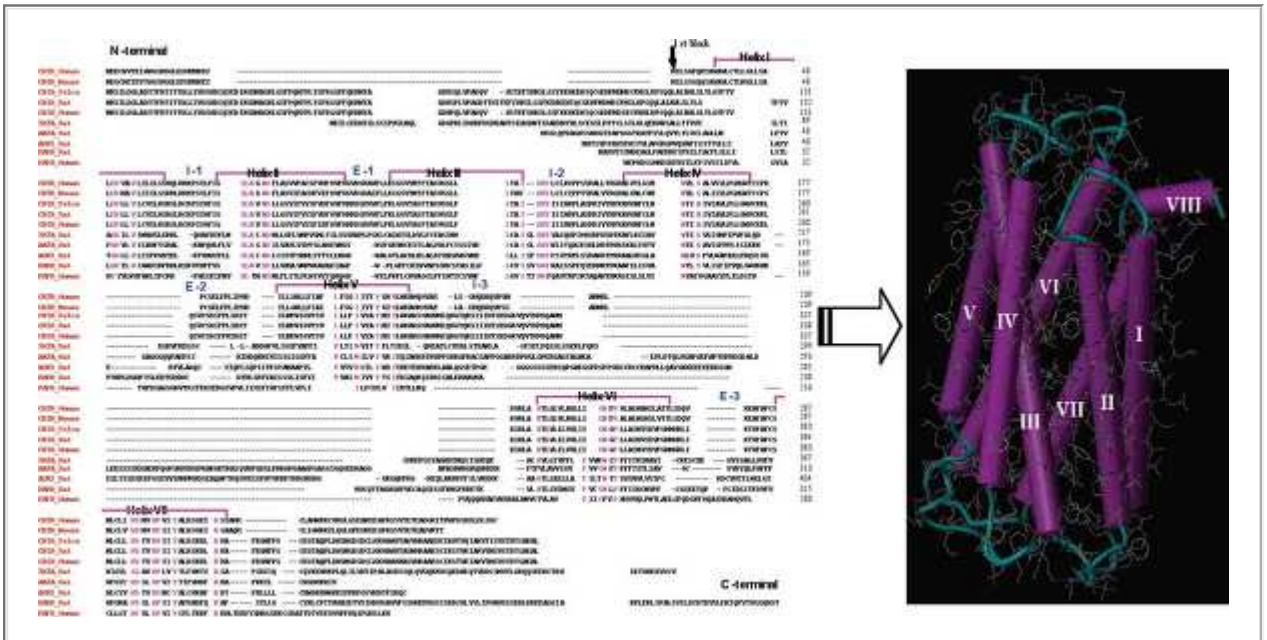

Fig. 3.9. Three-dimensional G protein–coupled CB_2 receptor structure (right) constructed by homology and multiple sequence alignment

method (left), including the seven transmembrane helices (cylinders, I–VII) and loop regions (ribbons). (From Xie XQ, Chen JZ, Billings EM. 3D structural model of the G protein–coupled cannabinoid CB2 receptor. Proteins: Structure, Function, and Genetics 2003;53:307–319; with permission.) (See black and white image.)

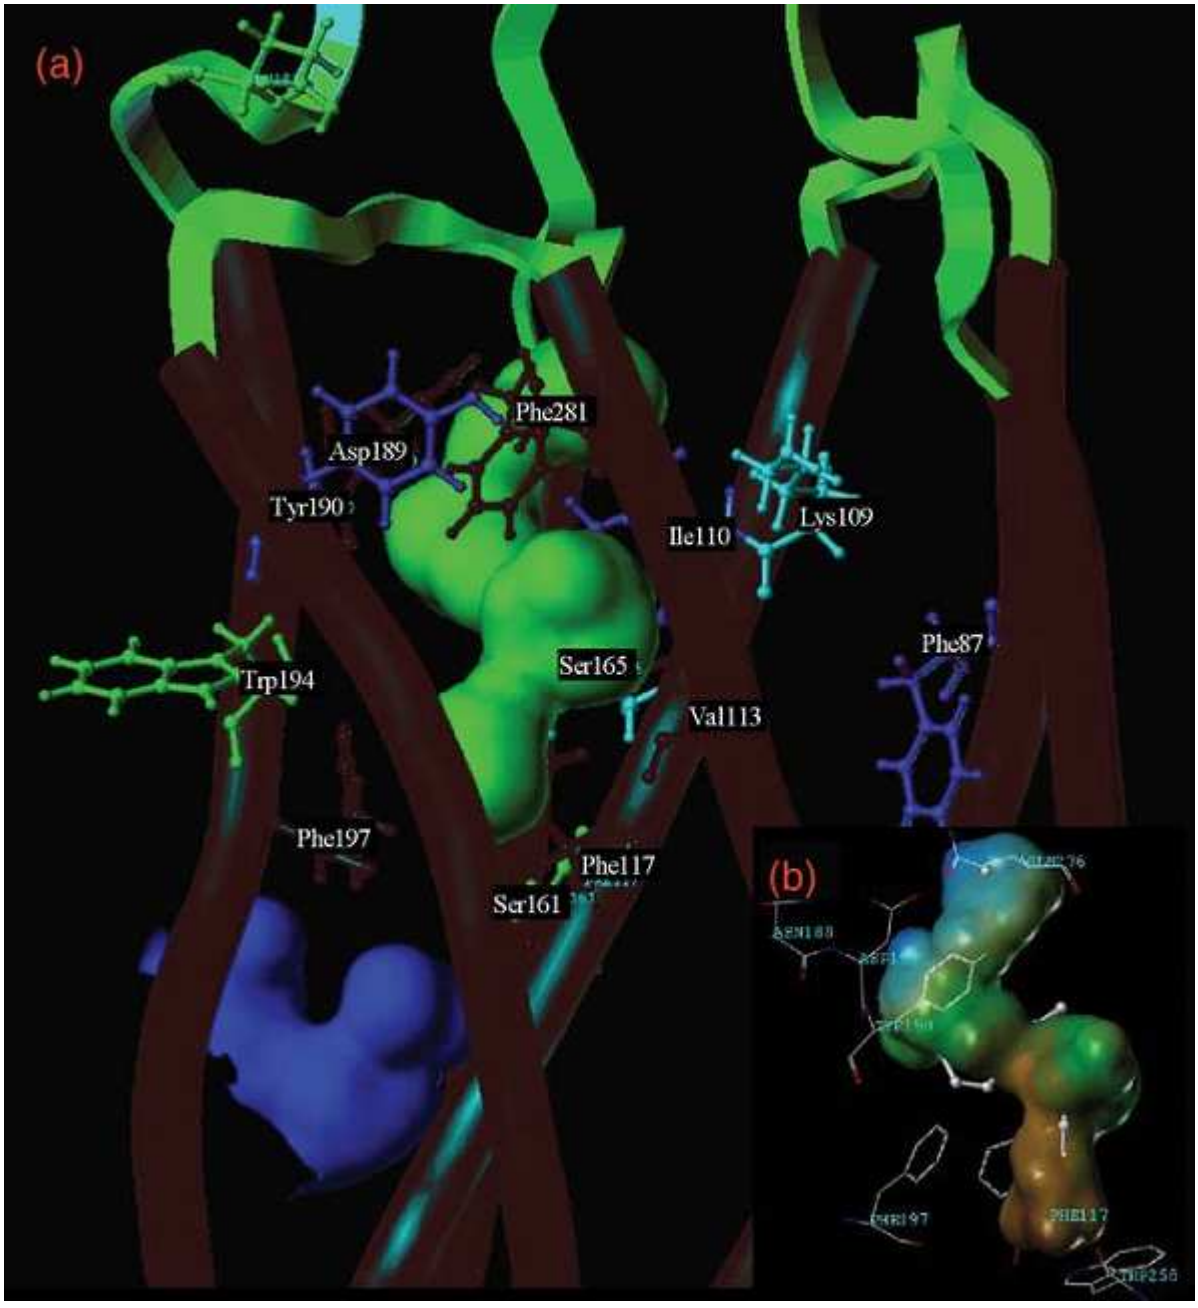

Fig. 3.10. MOLCAD-predicted CB_2-binding pocket surrounded by active amino acid residues, showing an amphipathic contour, hydrophilic center (blue), and hydrophobic cleft (brown). The site-directed mutagenesis–

detected binding residues are color-coded in terms of their distance to the pocket (magenta > yellow > green > blue) as the interaction weakens. (See black and white image.)

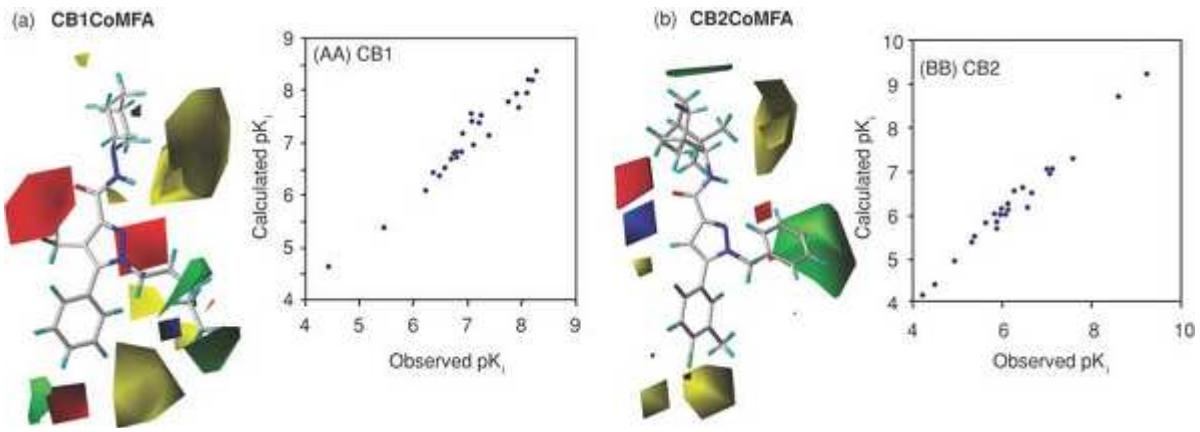

Fig. 3.11. CoMFA contour maps for arylpyrazole antagonists of cannabinoid receptor subtypes CB_1 (A) and CB_2 (B). Sterically favored areas (contribution level, 80%) are shown in green. Sterically unfavored areas (contribution level, 20%) are shown in yellow, and positive-potential favored areas (contribution level, 80%) are shown in blue. Positive-potential unfavored areas (contribution level, 20%) are shown in red. Plots of the corresponding CoMFA-calculated and experimental values of binding affinity (given as pK_i) of arylpyrazole compounds at CB_1 (AA) and CB2 (BB) receptor, respectively are shown as well. (Adapted with permission from Chen J, Han X, Lan R, et al. 3D-QSAR studies of arylpyrazole antagonists of cannabinoid receptor subtypes CB1 and CB2. A combined NMR and CoMFA approach. J Med Chem 2006;49:625–636; with permission.) (See black and white image.)

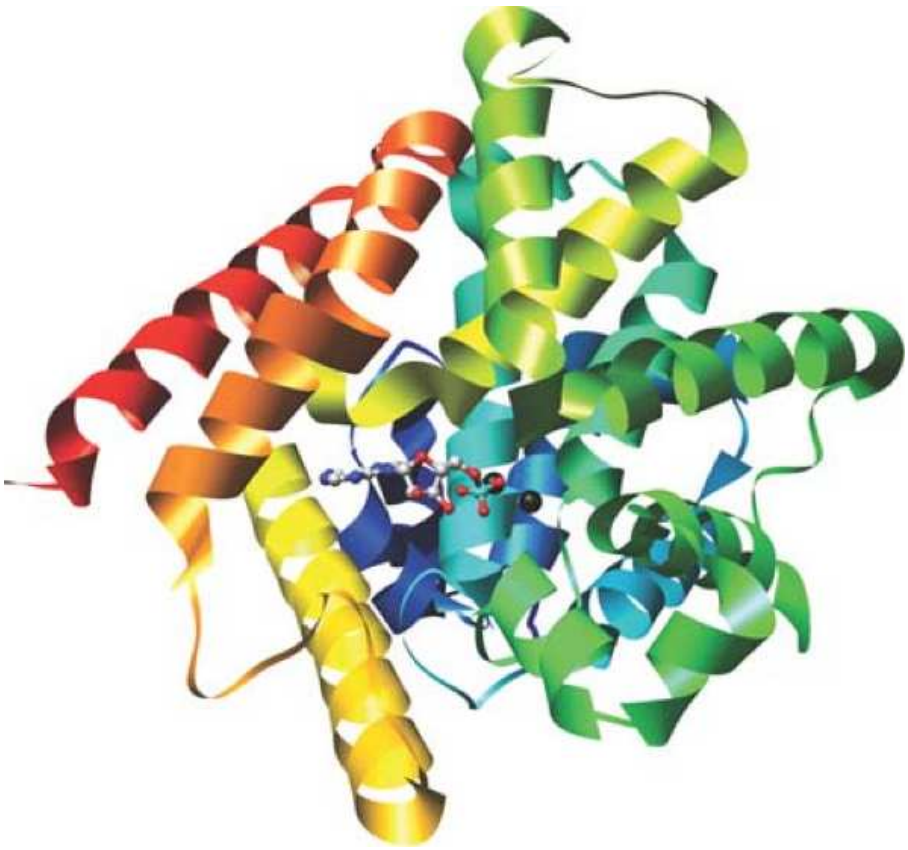

Fig. 17.4. Ribbon diagram of monomeric PDE4D2 (PDB 1PTW). 5′-AMP is shown as balls-and-sticks, whereas two divalent metal icons are shown as solid spheres. (From Manallack DT, Hughes RA, Thompson PE. The next generation of phosphodiesterase inhibitors: structural clues to ligand and substrate selectivity of phosphodiesterases. J Med Chem 2005;48:3449–6342; with permission.) (See black and white image.)

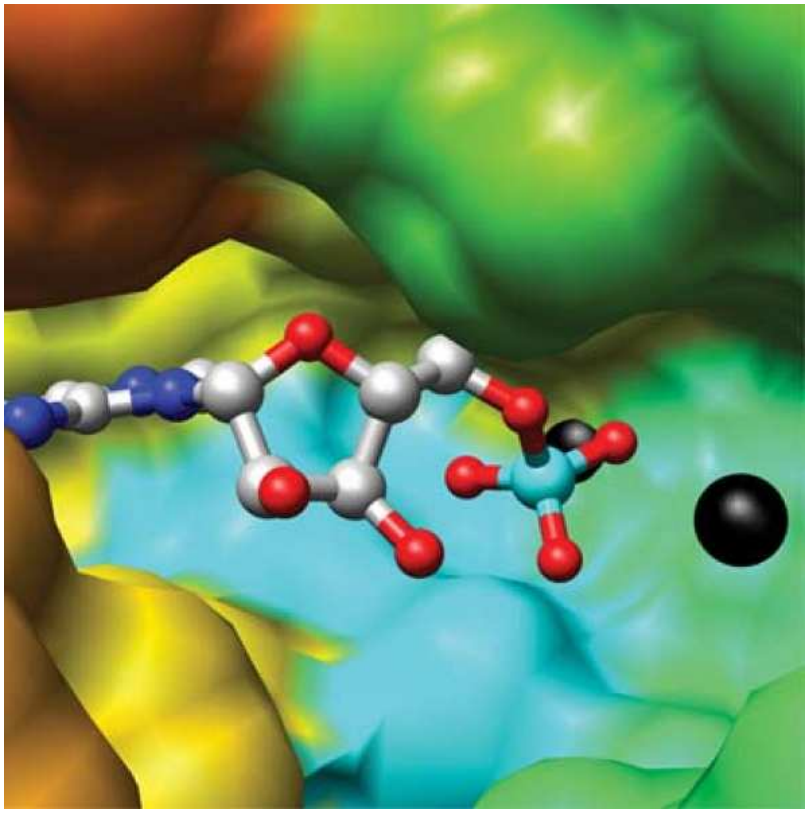

Fig. 17.5. Surface representation showing 5′-AMP in the nucleotide binding pocket of PDE4D2 (PDB 1PTW). 5′-AMP is shown as balls-and-sticks, while two divalent zinc icons are shown as solid spheres. (From Manallack DT, Hughes RA, Thompson PE. The next generation of phosphodiesterase inhibitors: structural clues to ligand and substrate selectivity of phosphodiesterases. J Med Chem 2005;48:3449–6342; with permission.) (See black and white image.)

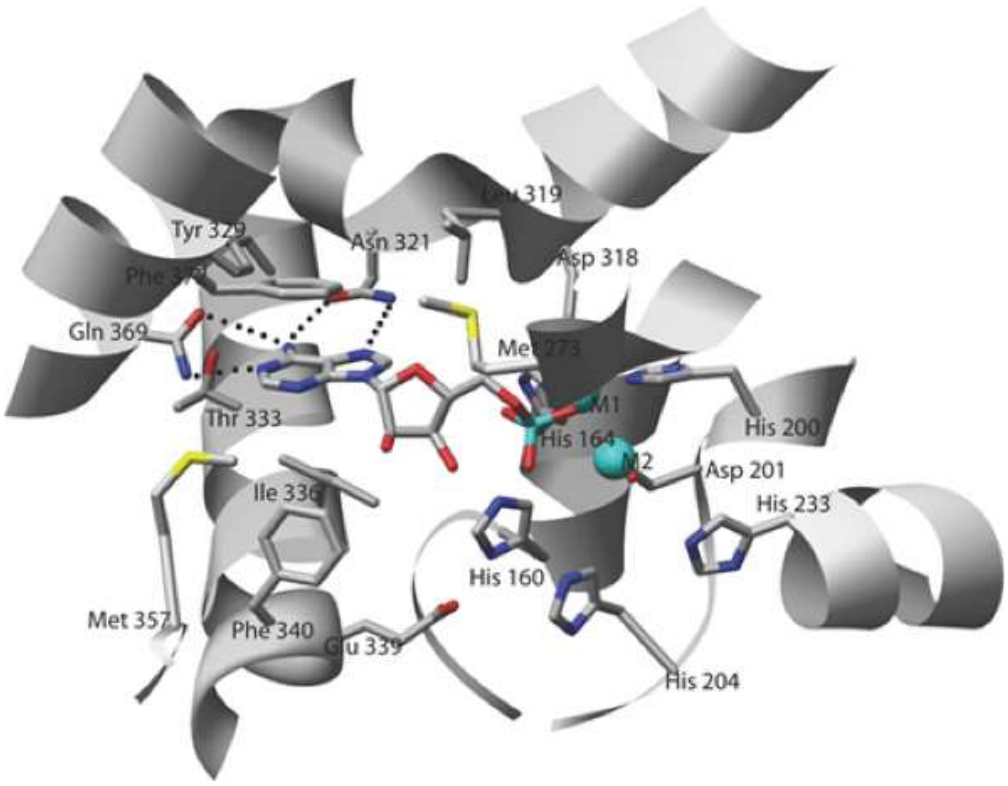

Fig. 17.7. Ribbon diagram of the active site of PDE4D2. The AMP phosphate group binds two divalent zinc icons and forms hydrogen bonds with His-160, Asp-201, and Asp-318. The adenine group of AMP adopts an anticonformation and orients toward the hydrophobic pocket made up of residues Tyr-159 (not shown), Leu-319, Asn-321, Thr-333, Ile-336, Gln-369, and Phe-372. It forms three hydrogen bonds with Gln-369 and Asn-321 and buttresses against Phe-372. The ribose of AMP has a C3′-endo puckering configuration and makes van der Waals contacts with residues His-160, Met-273, Asp-318, Leu-319, Ile-336, Phe-340, and Phe-372. (From Manallack DT, Hughes RA, Thompson PE. The next generation of phosphodiesterase inhibitors: structural clues to ligand and substrate selectivity of phosphodiesterases. J Med Chem 2005;48:3449–6342; with permission.) (See black and white image.)

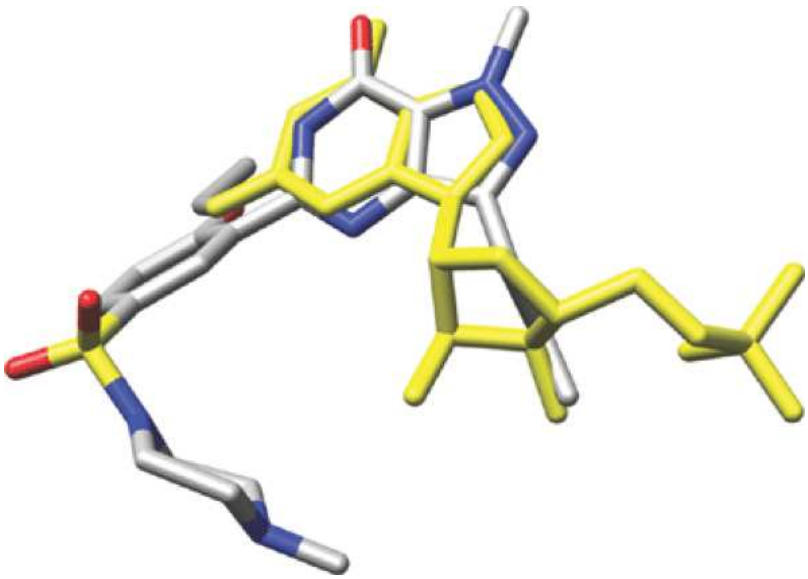

Fig. 17.9. Overlay of sildenafil with 5′-GMP in the active site of PDE5. (From Matot I, Gozal Y. Pulmonary responses to selective phosphodiesterase-5 and phosphodiesterase-3 inhibitors. Chest 2004;125:644–651; with permission.) (See black and white image.)

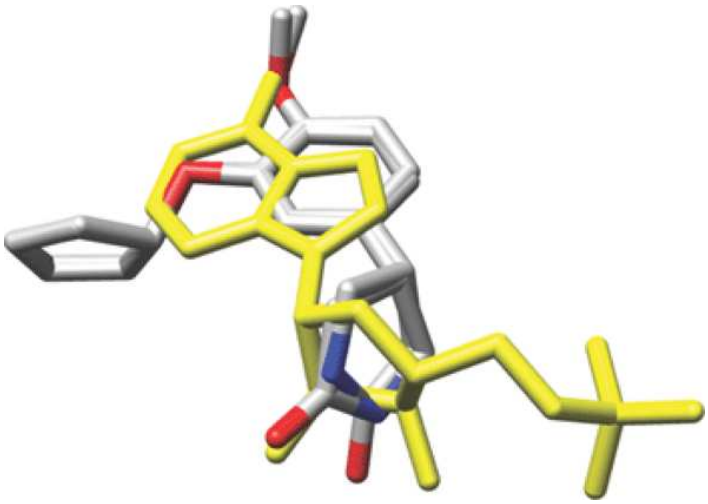

Fig. 17.11. Overlay of (R,S)-rolipram with 5′-AMP in the active site of PDE4D. (From Maurice DH, Palmer D, Tilley DG, et al. Cyclic nucleotide phosphodiesterase activity, expression, and targeting in cells of the cardiovascular system. Mol Pharmacol 2003;64:533–546; with permission.) (See black and white image.)

Historical Perspective of Medicinal Chemistry

John L. Neumeyer

> "The unprecedented increase in human life expectancy, which has almost doubled in a hundred years, is mainly due to drugs and to those who discovered them." (1)

History and Evolution of Medicinal Chemistry

Just as in all fields of science, the history of medicinal chemistry is comprised of the ideas, knowledge, and available tools that have advanced contemporary knowledge. The spectacular advances in medicinal chemistry over the years are no exception. Burger (1) stated that "the great advances of medicinal chemistry have been achieved by two types of investigators: those with the genius of prophetic logic, who have opened a new field by interpreting correctly a few well-placed experiments, whether they pertained to the design or the mechanism of action of drugs; and those who have varied patiently the chemical structures of physiologically active compounds until a useful drug could be evolved as a tool in medicine."

To place the development of medicinal chemical research into its proper perspective, one needs to examine the evolution of the ideas and concepts that have led to our present knowledge.

Drugs of Antiquity

The oldest records of the use of therapeutic plants and minerals are derived from the ancient civilizations of the Chinese, the Hindus, the Mayans of Central America, and the Mediterranean peoples of antiquity. The Emperor Shen Nung (2735 BC) compiled what may be called a pharmacopeia, including *ch'ang shang*, an antimalarial alkaloid, and *ma huang*, from which ephedrine was isolated. Chaulmoogra fruit was known to the indigenous American Indians, and the ipecacuanha root containing emetine was used in Brazil for the treatment of dysentery and diarrhea and is still used for the treatment of amebiasis. The early explorers found that the South American Indians also chewed cocoa leaves (containing cocaine) and used mushrooms (containing tryptamine) as hallucinogens. In ancient Greek apothecary shops could be found herbs such as opium, squill, hyoscyamus, and viper toxin and such metallic drugs as copper and zinc ores, iron sulfate, and cadmium oxide.

The Middle Ages

The basic studies of chemistry and physics shifted from the Greco-Roman to the Arabian alchemists between the thirteenth and sixteenth centuries. Paracelsus (1493–1541) glorified antimony and its salts in elixirs as cure-alls in the belief that chemicals could cure disease.

The Nineteenth Century Age of Innovation and Chemistry

The nineteenth century saw a great expansion in the knowledge of chemistry, which

greatly extended the herbal pharmacopeia that had previously been established. Building on the work of Lavoisier, chemists throughout Europe refined and extended the techniques of chemical analysis. The synthesis of acetic acid by Kolbe in 1845 and of methane by Berthelot in 1856 set the stage for organic chemistry. Pharmacognosy, the science that deals with medicinal products of plant, animal, or mineral origin in their crude state, was replaced by physiological chemistry. The emphasis was shifted from finding new medicaments from the vast world of plants to finding the active ingredients that accounted for their pharmacologic properties. The isolation of morphine by Sertürner in 1803, of emetine from ipecacuanha by Pelletier in 1816, and his purification of caffeine, quinine, and colchicine in 1820 all contributed to the increased use of “pure” substances as therapeutic agents. The nineteenth century also contributed to the use of digitalis by William Withering, the English physician and botanist, for the treatment of dropsy. Niemann isolated cocaine in 1860 and the active ingredient, physostigmine, from the calabar bean in 1864. As a result of these discoveries and the progress made in organic chemistry, the pharmaceutical industry came into being at the end of the nineteenth century.

The Twentieth Century and the Pharmaceutical Industry

Diseases of protozoal and spirochetal origin responded to synthetic chemotherapeutic agents. Interest in synthetic chemicals that could inhibit the rapid reproduction of pathogenic bacteria and enable the host organism to cope with invasive bacteria was dramatically increased when Domagk reported that the red dyestuff 2,4-diaminoazobenzene-4′-sulfonamide (Prontosil) dramatically cured dangerous, systemic Gram-positive bacterial infections in man and animals. The observation by Woods and Fildes in 1940 that the bacteriostatic action of sulfonamide-like drugs was antagonized by *p*-aminobenzoic acid was one of the early examples in which a balance of stimulatory and inhibitory properties depends on the structural analogies of chemicals.

Together with the discovery of penicillin by Fleming in 1929 and its subsequent examination by Florey and Chain in 1941, this led to a water soluble powder of much higher antibacterial potency and lower toxicity than

those of previously known synthetic chemotherapeutic agents. With the discovery of a variety of highly potent anti-infective agents, a significant change was introduced into medical practice.

Developments Leading to Various Medicinal Classes

Psychopharmacologic Agents and the Era of Brain Research

Psychiatrists have been using agents that are active in the central nervous system for hundreds of years. Stimulants and depressants were used to modify the mood and mental states of psychiatric patients. Amphetamine, sedatives, and hypnotics were used to stimulate or depress the mental states of patients. The synthesis of chlorpromazine by Charpentier ultimately caused a revolution in the treatment of schizophrenia, but who really discovered chlorpromazine? Charpentier, who first synthesized the molecule in 1950 at Rhone-Poulenc's research laboratory; Simon Courvoisier, who reported distinctive effects on animal behavior; Henri Laborit, a French military surgeon who first noticed distinctive psychotropic effects in man; or Pierre Deniker and Jean Delay, French psychiatrists who clearly outlined what has

now become its accepted use in psychiatry and without whose endorsement and prestige Rhone-Poulenc might never have developed it further as an antipsychotic. Because of the bitter disputes over the discovery of chlorpromazine, no Nobel Prize was ever awarded for what has been the single most important breakthrough in psychiatric treatment.

The discovery of the antidepressant effects of the antitubercular drug iproniazid led to the first-generation tricyclic antidepressant imipramine in 1957 and the monoamine oxidase inhibitor phenelzine. These were followed by present-day selective serotonin reuptake inhibitors, such as fluoxetine (Prozac). The antianxiety agents in the benzodiazepine class are examples of the serendipitous discovery of new drugs based on random screening of chemicals synthesized in the laboratory. The discovery of these drugs also was based on observations made by pharmacologists who recognized significant animal signs during general biologic screening of random chemicals. In 1946, F.M. Berger and, in 1957, L.O. Randall, working at Hoffmann LaRoche Laboratories, independently observed unusual and characteristic paralysis and relaxation of voluntary muscles in laboratory animals for different series of compounds. At this point, the treatment of ambulatory, anxious patients with meprobamate and of psychotic patients with one of the aminoalkyl-phenothiazine drugs was possible. There was a need for drugs of greater selectivity in the treatment of anxiety because of the side effects often encountered with phenothiazines. Leo Sternback, a chemist working in the research laboratory of Hoffman-LaRoche in New Jersey, decided to reinvestigate a relatively unexplored class of compounds that he had studied in the 1930s, when he was a postdoctoral fellow at the University of Cracow in Poland. He synthesized approximately 40 compounds in this series, all of which were disappointing in pharmacologic tests, after which the project was abandoned. In 1957, during a cleanup of the laboratory, one compound synthesized 2 years earlier had crystallized and was submitted for testing to L.O. Randall, a pharmacologist. Shortly thereafter, Randall reported that this compound was hypnotic and sedative and had antistrychnine effects similar to those of meprobamate. The compound was named chlordiazepoxide and marketed as Librium in 1960, just 3 years after the first pharmacologic observations by Randall. Structural modifications of benzodiazepine derivatives were undertaken, and a compound 5- to 10-fold more potent than chlordiazepoxide was synthesized in 1959 and marketed as diazepam (Valium) in 1963. The synthesis of many other experimental analogues soon followed, and by 1983, approximately 35 benzodiazepine drugs were available for therapy (see Chapter 22). Benzodiazepines are used in the pharmacotherapy of anxiety and related emotional disorders and in the treatment of sleep disorders, status epilepticus, and other convulsive states. They are used as centrally acting muscle relaxants, for premedication, and as inducing agents in anesthesiology.

Endocrine Therapy and Steroids

The first pure hormone to be isolated from an endocrine gland was epinephrine, which led to further molecular modifications in the area of sympathomimetic amines. Subsequently, norepinephrine was identified from sympathetic nerves. The development of chromatographic techniques allowed the isolation and characterization of a multitude of hormones from a single gland. In 1914, biochemist Edward Kendall isolated thyroxine (T_4) from the thyroid gland. He subsequently won the Nobel Prize in Physiology or Medicine in 1950 for his discovery of the activity of cortisone. Two of the hormones of the thyroid gland, T_4 and liothyronine (T_3,3,5,3′-triiodo-thyronine) have similar effects in the body, regulating metabolism, whereas

the two hormones from the posterior pituitary gland, vasopressin, which exerts pressor and antidiuretic activity, and oxytocin, which stimulates lactation and uterine motility, differ considerably both in their chemical structure and physiological activity (Fig. I.1).

Less than 50 years after the discovery of oxytocin in 1904 by Sir Henry Dale, who found that an extract from the human pituitary gland contracted the uterus of a pregnant cat, the biochemist du Vigneud synthesized the cyclic peptide hormone. His work resulted in the Nobel Prize in Chemistry in 1955.

A major achievement in drug discovery and development was the discovery of insulin in 1921 from animal sources. Frederick G. Bunting and Charles H. Best, working in the laboratory of John J.R. McLeod at the University of Toronto, isolated the polypeptide hormone and began testing it in dogs. By 1922, researchers, with the

help of James B. Collip and the pharmaceutical industry, were able to purify and produce animal-based insulin in large quantities. Insulin soon became a major product for Eli Lilly & Co. and Novo Nordisk, a Danish pharmaceutical company. In 1923, McLeod and Bunting were awarded the Nobel Prize in Medicine or Physiology, and after much controversy, they shared the prize with Collip and Best. For the next 60 years, cattle and pigs were the major sources of insulin. With the development of genetic engineering in the 1970s, new opportunities arose for making synthetic insulin that is chemically identical to human insulin. In 1978, the biotech company Genentech and the City of Hope National Medical Center produced human insulin in the laboratory using recombinant DNA technology. By 1982, Lilly's Humulin became the first genetically engineered drug to be approved by the U.S. Food and Drug Administration (FDA). At about the same time, Novo Nordisk began selling the first semisynthetic human insulin made by enzymatically converting porcine insulin. Novo Nordisk also was using recombinant technology to produce insulin. Recombinant insulin was a significant milestone in the development of genetically engineered drugs, and it combined the technologies of the biotech companies with the know-how and resources of the major pharmaceutical industries. Inhaled insulin was approved by the FDA in 2006. Many drugs are now available (see Chapter 32) to treat the more common type 2 diabetes, in which natural insulin production in the human needs to be increased. Insulin had been the only treatment for type 1 diabetes until 2005, when the FDA approved Amylin Pharmaceuticals' Symlin to control blood sugar levels in combination with the polypeptide hormone. The isolation and purification of several polypeptide hormones of the anterior pituitary and hypothalamic-releasing hormones now makes it possible to produce synthetic peptide agonists and antagonists that have important diagnostic and therapeutic applications.

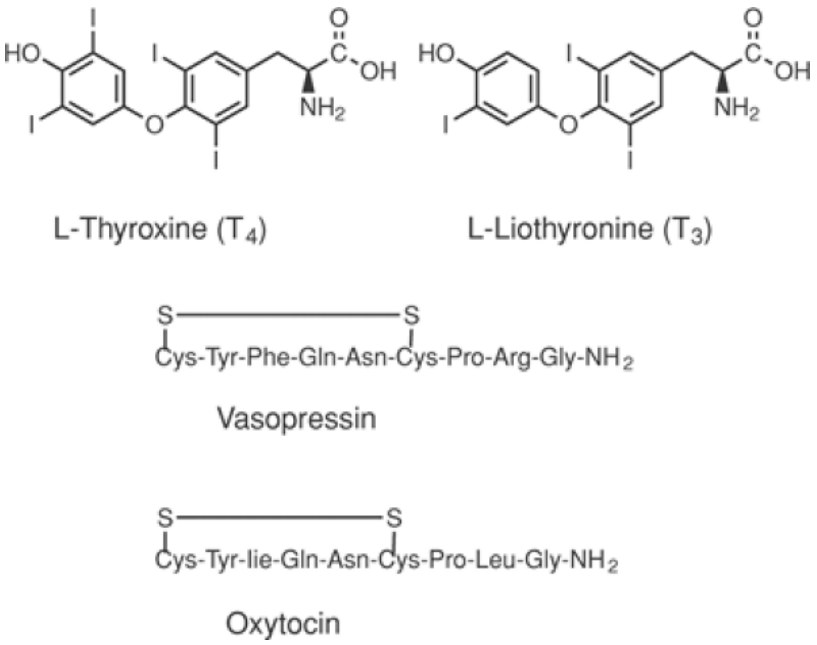

Fig. I.1. Hormones from the endocrine glands.

Extensive and remarkable advances in the endocrine field have been made through an understanding, development, and utilization of steroid hormones. The isolation and characterization of minute amounts of the active principles of the sex glands and from the adrenal cortex eventually led to their total synthesis. The various male and female sex hormones are used in the treatment of a variety of disorders associated with sexual development and the sexual cycles of males and females as well as in the selective therapy of malignant tumors of the breast and prostate gland. Synthetic modifications of the structure of the male and female hormones have furnished improved hormonal compounds, such as the anabolic agents (see Chapter 45). Since early days, women have ingested every manner of substance as birth control agents. In the early 1930s, Russell Marker found that for hundreds of years, Mexican women had been eating wild yams of the *Dioscorea* genus for contraception, apparently successfully. Marker determined that diosgenin is abundant in yams and has a structure similar to that of progesterone. Marker was able to convert diosgenin into progesterone, a substance known to stop ovulation in rabbits. Progesterone, however, is destroyed by the digestive system when ingested. In 1950, Carl Djerassi, a chemist working at the Syntex Laboratories in Mexico City, synthesized norethindrone, the first orally active contraceptive steroid, by a subtle modification of the structure of progesterone. Gregory Pincus, a biologist working at the Worcester Foundation for Experimental Biology in Massachusetts studied Djerassi's new steroid together with its double-bond isomer norethynodrel (Fig. I.2).

By 1956, clinical studies led by John Rock, a gynecologist, showed that progesterone, in combination with norethindrone, was an effective oral contraceptive. G.D. Searle was the first on the market with Enovid, a combination of mestranol and norethynodrel. In 2005. approximately 11 million American women, and approximately 100 million women worldwide, were using oral contraceptive pills. In 1993, the British weekly *The Economist* considered the pill to be one of the seven

wonders of the

modern world, bringing about major changes in the economic and social structure for women throughout the world.

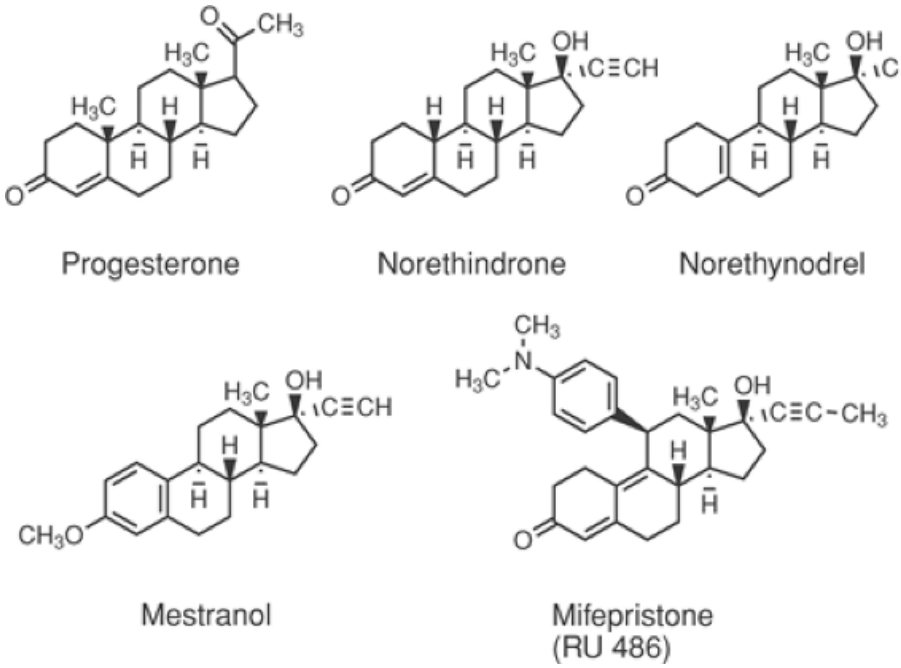

Fig. I.2. Steroidal agents.

In the early 1930s, chemists recognized the similarity of a large number of natural products, including the cortical steroids, such as hydrocortisone. The medicinal value of Kendall's Compound F and Reichstein's Compound M was quickly recognized. The 1950 Nobel Prize in Physiology or Medicine was awarded to Philip S. Hench, Edward C. Kendall, and Tadeus Reichstein “for their discovery relating to the hormones of the adrenal cortex, their structure and biological effects” (2).

An interesting development in the study of glucocorticoids led to the synthesis in 1980 of the “abortion pill,” RU-486, by Etienne-Emile Beaulieu, a consultant to the French pharmaceutical company Rousel-Uclaf. Researchers at that time were investigating glucocorticoid antagonists for the treatment of breast cancer, glaucoma, and Cushing's syndrome. In screening RU-486, researchers at Rousel-Uclaf found that it had both antiglucocorticoid activity as well as high affinity for progesterone receptors, where it could be used for fertility control. Also known as mifepristone (Mifeprex), RU-486 entered the French market in 1988. but sales were suspended by Rousel-Uclaf when antiabortion groups threatened to boycott the company. In 1994, the company donated the U.S. rights to the New York City–based Population Council, a nonprofit reproductive and population control research institution. Mifepristone is now administered in doctors' offices as a tablet in combination with misoprostol, a prostaglandin that causes uterine contractions to help expel the embryo. The combination of mifepristone and misoprostol is more than 90% effective. Plan B, also known as the “morning-after pill,” has been referred to as an emergency contraceptive. It contains norgestrel, the same

progestin that is in the pill. It should be taken within 3 days of unprotected sex and can reduce the risk of pregnancy by 89%.

Anesthetics and Analgesics

The first use of synthetic organic chemicals for the modulation of life processes occurred when nitrous oxide, ether, and chloroform were introduced in anesthesia during the 1840s. Horace Wells, a dentist in Hartford, Connecticut, administered nitrous oxide during a tooth extraction, and Crawford Long, a Georgia physician, employed ether as an anesthetic for excising a growth on a patient's neck. It was William Morton, a 27-year-old dentist, however, who gave the first successful public demonstration of surgical anesthesia on October 16, 1846, at the surgical amphitheater that is now called the Ether Dome at Massachusetts General Hospital. Morton attempted to patent his discovery but was unsuccessful, and he died penniless in 1868. Chloroform also was used as an anesthetic at St. Bartholomew's Hospital in London. In Paris, Pierre Fluorens tested both chloroform and ethyl chloride as anesthetics in animals.

The potent analgesic and euphoric properties of the extract of the opium poppy have been known for thousands of years. In the sixteenth century, the Swiss physician and alchemist Paracelsus (1493–1541) popularized the use of opium in Europe. At that time, an alcoholic solution of opium, known as laudanum, was the method of administration. Morphine was first isolated in pure crystalline form from opium in 1805 by the German apothecary Friedrich W. Sertürner, who named the compound “morphium,” after Morpheus, the Greek god of dreams. It took another 120 years before the structure of morphine was elucidated by Sir Robert Robinson at the University of Oxford. The chemistry of morphine and the other opium alkaloids obtained from *Papaver somniferum* have fascinated and occupied chemists for more than 200 years, resulting in many synthetic analgesics that are available today (see Chapter 24). (-)-Morphine was first synthesized by Marshall Gates at the University of Rochester in 1952. Although a number of highly effective, stereoselective synthetic pathways have been developed, it is unlikely that a commercial process can compete with its isolation from the poppy. Diacetylmorphine, known as heroin, is highly addictive and induces tolerance. The illicit worldwide production of opium now exceeds the pharmaceutical production by almost 10-fold. In the United States, some 800,000 people are chemically addicted to heroin, and a growing number are becoming addicted to oxycontin, a synthetic opiate also known as oxycodone. Another synthetic opiate, methadone, blocks the opiate receptors in the brain, curbing the craving for heroin or morphine. A series of studies in the 1960s at Rockefeller University by Vincent Dole and his wife, Marie Nyswander, found that methadone also could be a viable maintenance treatment to keep addicts from heroin. It is estimated that approximately 250,000 addicts are taking methadone in the United States. Unfortunately, it has not been widely recognized in the United States that opiate addiction is a medical condition for which there is no known cure. More than 80% of U.S. heroin addicts lack access to methadone treatment facilities, primarily because of the strong stigma against drug users and the medical distribution of methadone.

Only within the last 25 years have scientists begun to understand the effects of opioid analgesics at the molecular level. In 1954, Beckett and Casey at the University of London proposed that opiate effects were receptor mediated, but it was not until the early 1970s that the stereo-specific binding of opiates to specific receptors was demonstrated. The characterization and classification of three

different types of opioid receptors (μ, κ, and δ) by W.R. Martin formed the basis of our current understanding of opioid pharmacology. The demonstration of stereo-specific binding of radiolabeled ligands to opioid receptors led to the development of radioreceptor-binding assays for each of the opioid receptor types, a technique that has been of major importance in the identification of selective opioids as well as many other

receptors. In 1973, Avram Goldstein, Solomon Snyder, Ernst Simon, and Lars Terenius independently described saturable, stereospecific binding sites for opiate drugs in the mammalian nervous system. Shortly thereafter, John Hughes and Hans Kosterlitz, working at the University of Aberdeen in Scotland, described the isolation from pig brains of two pentapeptides that exhibited morphine-like actions on the guinea pig ileum. At about the same time, Goldstein reported the presence of peptide-like substances in the pituitary gland that showed opiate-like activity. Subsequent research revealed three distinct families of opiate peptides: the enkephalins, the endorphins, and the dynorphins.

Hypnotics and Anticonvulsants

Since antiquity, alcoholic beverages and potions containing laudanum, an alcoholic extract of opium, and various other plant products have been used to induce sleep. Bromides were used in the middle of the nineteenth century as a sedative-hypnotic, as was chloral hydrate, paraldehyde, urethane, and sulfenal. Von Merring, on the assumption that a structure having a carbon atom carrying two ethyl groups would have hypnotic properties, investigated diethyl acetyl urea, which proved to be a potent hypnotic. Further investigations led to 5,5-diethylbarbituric acid, a compound synthesized 20 years earlier, in 1864, by Adolph von Beyer. Phenobarbital was synthesized by the Bayer Pharmaceutical Company and introduced to the market under the name Luminol (Fig. I.3). The compound was effective as a hypnotic, but it also exhibited anticonvulsant properties. The success of phenobarbital led to the testing of more than 2,500 barbiturates, of which approximately 50 were used clinically, many of which are still in clinical use. Modification of the barbituric acid molecule also led to the development of the hydantoins. Phenytoin, also known as diphenylhydantoin or Dilantin, was first synthesized in 1908, but its anticonvulsant properties were not discovered until 1938. Because phenytoin was not a sedative at ordinary doses, it established that antiseizure drugs need not induce drowsiness and encouraged the search for drugs with selective antiseizure action (Fig. I.3).

Local Anesthetics

The local anesthetics can be traced back to the naturally occurring alkaloid cocaine isolated from *Erythroxylon coca*. A Viennese ophthalmologist, Carl Koller, had experimented with several hypnotics and analgesics for use as a local anesthetic in the eye. His friend, Sigmund Freud, suggested that they attempt to establish how the South American Indians allayed fatigue by chewing leaves of the coca bush. Cocaine had been isolated from the plant by the chemist Albert Niemann at Gothenburg University, Sweden, in 1860. Koller found that cocaine numbed the tongue; thus, he discovered a local anesthetic. He quickly realized that cocaine was an effective, nonirritating anesthetic for the eye, leading to the widespread use of cocaine in both Europe and the United States. Richard Willstatter in Munich determined the structure of both cocaine and atropine in 1898 and succeeded in synthesizing cocaine 3 years later. Although today cocaine is of greater historic than medicinal importance and is widely abused, few developments in the chemistry

of local anesthetics can disclaim a structural relationship to cocaine (Fig. I.4). Benzocaine, procaine, tetracaine, and lidocaine can all be considered structural analogues of cocaine, a classic example of how structural modification of a natural product can lead to useful therapeutic agents.

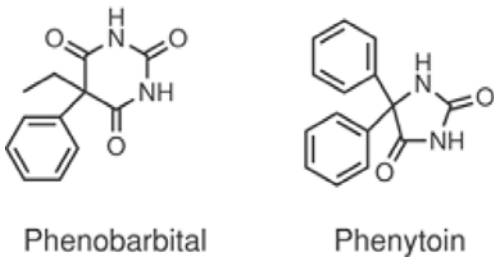

Fig. I.3. Examples of early an early hypnotic and anticonvulsant.

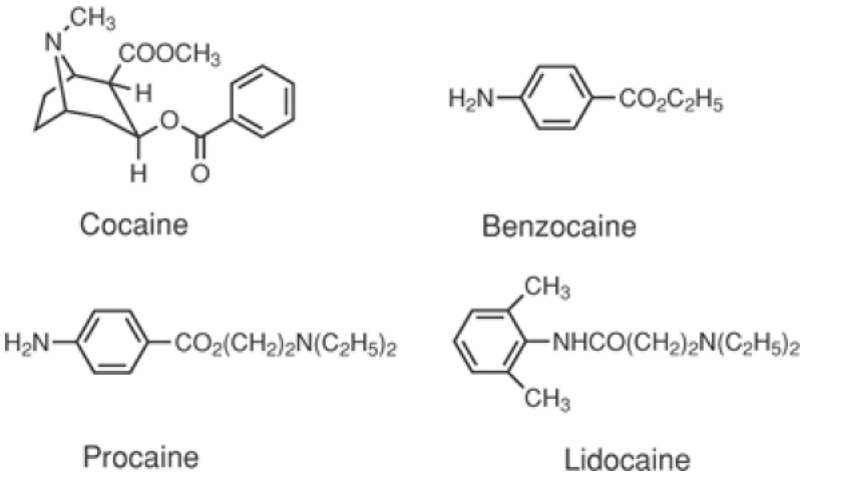

Fig. I.4. Synthetic local anesthetics development based on the structure of cocaine.

Drugs Affecting Renal and Cardiovascular Function

Included in the category are the diuretics, vasopressin, rennin and angiotensin drugs used in the treatment of myocardial ischemia, pharmacotherapy of congestive heart failure, antiarrythmic drugs, and drugs used in therapy for hypercholesterolemia. Use of the cardiac drug digoxin dates back to the folk-remedy foxglove, attributed to William Withering, who in 1775 discovered that the foxglove plant, *Digitalis purpurea*, was beneficial to those suffering from abnormal fluid buildup. The active principles of digitalis were isolated in 1841 by E. Humolle and T.

Quevenne in Paris. These active principles consisted mainly of digitoxin. The other glycosides of digitalis were subsequently isolated in 1869 by Nativelle and in 1875 by Schmiedberg. The correct structure of digitoxin was established more than 50 years later by Adolf Windaus at Gothenburg University. In 1929, Sydney Smith at Burroughs Welcome isolated and separated a new glycoside from *Digitalis purpurea*, known as digoxin. This is now the most widely used cardiac glycoside.

Today, dried foxglove leaves are processed to yield digoxin, much like the procedure used by Withering. It takes approximately 1,000 kg of dried foxglove leaves to make 1 kg of pure digoxin.

The group of drugs used in the therapy for hypercholesterolemia has received the greatest success and financial reward for the pharmaceutical industry during the last decade. Cholesterol-lowering drugs, known as statins, are one of the cornerstones in the prevention of both primary and secondary heart diseases. Drugs such as Merck's lovastatin (Mevacor) and Pfizer's Lipitor are a huge success. In 2004, Lipitor was the world's top-selling drug, with sales of more than $10 billion. As a class, cholesterol- and triglyceride-lowering drugs were the world's top category, with sales exceeding $30 billion.

The discovery of the statins can be credited to Akira Endo, a research scientist at Sankyo Pharmaceuticals in Japan (3). Endo's 1973 discovery of the first anticholesterol statin has almost been relegated to obscurity. The story of his research and the discovery of lovastatin are not typical but often escape attention. When Endo joined Sankyo after his university studies to investigate food ingredients, he searched for a fungus that produced an enzyme to make fruit juice less pulpy. The search was a success, and Endo's next assignment was to find an enzyme that would block the production of cholesterol, known as HMG-CoA reductase. With Endo's interest and background, he searched for fungi that would block this enzyme. After testing 6,000 fungal broths, he found such a fungus in 1973. A substance made by a mold, *Penicillium citrinum*, produced a potent inhibitor of the enzyme that helps the body to make cholesterol, and it was named compactin. The substance did not work in rats, but it did work in hens and dogs. Endo's bosses were unenthusiastic about his discovery and discouraged further research with this compound. With the collaboration of Akira Yamamoto, a physician treating patients with extremely high cholesterol because of a genetic defect, Endo prepared samples of his drug and had it administered to an 18-year-old woman by Yamamoto. Further testing in nine patients led to an average lowering of cholesterol of 27%.

In 1978, using a different fungus, Merck discovered a substance that was nearly identical to Endo's; this one was named lovastatin. Merck held the U.S. rights and, in 1987, started marketing it in the United States as Mevacor, the first FDA-approved statin. Sankyo eventually gave up compactin and pursued another statin, which they licensed to Bristol-Myers Squibb, and it was sold as Pravachol.

In 1985, Michael S. Brown and Joseph Goldstein won the Nobel Prize in Physiology or Medicine for their work in cholesterol metabolism. It was only in January of 2006 that Endo received the Japan Prize, considered by many to be equivalent to the Nobel Prize. There is no doubt that millions of people whose lives have been—and will be—extended through statin therapy owe their longevity to Akira Endo.

Anticancer Agents

Sulfur mustard gas was used as an offensive weapon by the Germans during World War I, and the related nitrogen mustards were manufactured by both sides in World War II. Later, investigations showed that the toxic gasses had destroyed the blood's white cells, which subsequently led to the discovery of drugs used in leukemia therapy. These compounds, although effective antitumor agents, were very toxic. 6-Mercaptopurine was really the first effective leukemia drug and was developed by George Hitchings and his technician, Gertrude Elion, who, working together at Burroughs Welcome Research Laboratories, shared the Nobel Prize in 1988 (Fig. I.5). By a process now termed “rational drug design,” Hitchings hypothesized that it might be possible to use antagonists to stop bacterial or tumor cell growth by interfering with nucleic acid biosynthesis in a way similar to how sulfonamides blocked cell growth.

Unlike many cancer drugs available today, cisplatin is an inorganic molecule with a simple structure (Fig. I.5). Cisplatin interferes with the growth of cancer cells by binding to DNA and interfering with the cells' repair mechanism, eventually causing cell death. It is used to treat many types of cancer, but primarily testicular, ovarian, bladder, lung, and stomach cancers. Cisplatin is now the gold standard against which new medicines are compared. It was first synthesized in 1845, and its structure was elucidated by Alfred Werner in 1893. It was not until the early 1960s, however, when Barnett Rosenberg, a professor of biophysics and chemistry at Michigan State University, observed the compound's effect in cell division, which prompted him to test cisplatin against tumors in mice. The compound was found to be effective and entered clinical trials in 1971. There is an important lesson to be learned from Rosenberg's development of cisplatin. As a biophysicist and chemist, Rosenberg realized that when he was confronted with interesting results for which he could not find explanations, he needed to enlist the help and expertise of researchers in microbiology, inorganic chemistry, molecular

biology, biochemistry, biophysics, physiology, and pharmacology. Such a multidisciplinary approach is the key to the discovery of modern medicines today. Although cisplatin is still an effective drug, researchers have found second-generation compounds, such as carboplatin, which has less toxicity and fewer side effects.

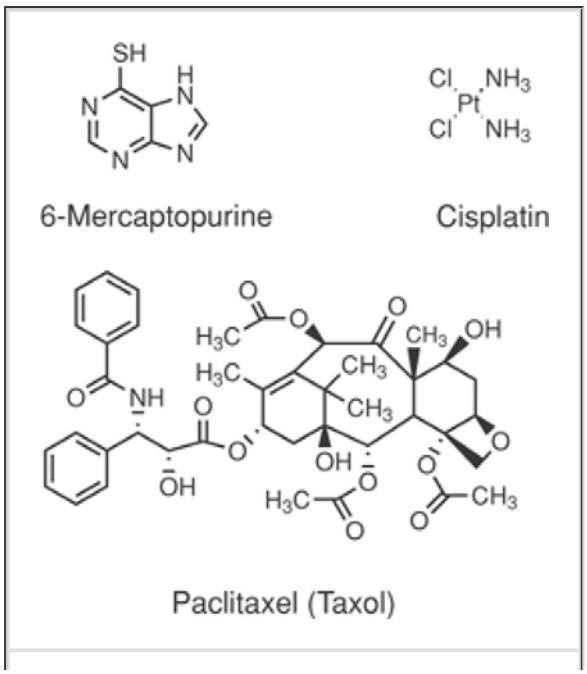

Fig. I.5. Anticancer drugs.

The third compound in this class of anticancer agents is Taxol, which was discovered in 1963 by Monroe E. Wall and Masukh C. Wani at Research Triangle Park in North Carolina (Fig. I.5). Taxol was isolated from extracts of the bark of the Pacific yew tree, *Taxus brevifolia.* The extracts showed potent anticancer activity. By 1967, Wall and his coworkers had isolated the active ingredients, and in 1971, they had established the structure of the compound. Susan Horwitz, working at the Albert Einstein College of Medicine in New York, studied the mechanism of how Taxol kills cancer cells. She discovered that Taxol works by stimulating the growth of microtubules and by stabilizing the cell structures so that the killer cells are unable to divide and multiply. It was not until 1993, however, that Taxol, generically called paclitaxel, was brought to the market by Bristol-Myers Squibb, but it soon became an effective drug for treating ovarian, breast, and certain forms of lung cancers. The product became a huge commercial success, with annual sales of approximately $1.6 billion in 2000.

Old Drugs as Targets for New Drugs

> Cannabis is used throughout the world for diverse purposes and has a long history characterized by usefulness, euphoria or evil, depending on one's point of view. To the agriculturist cannabis is a fiber crop; to the physician of a century ago it was a valuable medicine; to the physician of today it is an enigma; to the user, a euphoriant; to the police, a menace; to the trafficker, a source of profitable danger; to the convict or parolee and his family, a source of sorrow (4).

The plant *Cannabis sativa*, the source of marijuana, has a long history in folk medicine, where it has been used for such ills as menstrual pain and the muscle spasms that affect multiple sclerosis sufferers. As in so many other areas of drug research, progress was achieved through the understanding of the pharmacology and biogenesis of a naturally occurring drug only when the chemistry had been well established and researchers had at their disposal pure compounds of known composition and stereochemistry. Cannabis is no exception in this respect, with the last 50 years producing the necessary know-how in the chemistry of the cannabis constituents so that chemists could devise practical and novel synthetic schemes to provide the pharmacologists with pure substances. The isolation and determination of the structure of tetrahydrocannabinol (Δ^9-THC), the principal active ingredient, was determined in 1964 by Rafael Mechoulam at Hebrew University in Israel. Although cannabis and some of its structural analogs have been—and are still—used in medicine, during the last few years research has focused on the endocannabinoids and their receptors as targets for drug development. It was shown that Δ^9-THC exerts its effects by binding to receptors that are targets of naturally occurring molecules, termed endocannabinoids, that have been involved in controlling learning, memory, appetite, metabolism, blood pressure, emotions such as fear and anxiety, inflammation, bone growth, and cancer. It is no surprise then that drug researchers are focusing on developing compounds that either act as

agonists or antagonists of the endocannabinoids. In 1990, Lisa Matsuda and Tom Bonner at the National Institutes of Health cloned a Δ^9-THC receptor, now called CB_1, from a rat brain. Shortly thereafter, Mechoulam's group identified the first of these endogenous cannabinoids, called anandamide, and a few years later identified 2-arachidonylgyclerol. In 1993, the second cannabinoid receptor, CB_2, was cloned by Muna Abu-Shaar at the Medical Research Council in Cambridge, United Kingdom. The drug rimonabant, an endocannabinoid antagonist under development by the French pharmaceutical company Sanofi-Aventis, is the drug closest to clinical development. The drug binds to CB_1, but not CB_2, receptors and promotes weight loss. Efforts to develop other endocannabinoids as therapeutic agents are in full swing at many laboratories and include preclinical testing for epilepsy, pain, anxiety, and diarrhea. Thus, a new series of drugs may soon be on the market that are not centered on marijuana itself but, rather, are inspired by its active ingredient, Δ^9-THC, mimicking the endogenous substances acting in the brain or the periphery.

Molecular Imaging

Clinicians now have at their disposal a variety of diagnostic tools to help obtain information about the pathophysiological status of internal organs. The most widely used methods for noninvasive imaging are scintigraphy, radiography (x-ray and computed tomography), ultrasonography, positron-emission tomography (PET), single- photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI). Chemists continue to make important contributions to the preparation of radiopharmaceuticals and contrast agents. These optical, nuclear, and magnetic methods are increasingly empowered by new types of imaging agents. These modalities are now routinely being used to judge the effectiveness of new and old drugs to treat disease and to monitor the response to therapies.

The expanded use of the cyclotron in the late 1930s and of the nuclear reactor in the early 1940s made available a variety of radionuclides for potential applications in medicine. The field of nuclear medicine was founded with reactor-produced radioiodine for the diagnosis of thyroid dysfunction. Soon, other radioactive tracers, such as ^{18}F, ^{123}I, ^{131}I, ^{99m}Tc, and ^{11}C, became available. Together with more sensitive radiation detection instruments and cameras, this made it possible to study many organs of the body, such as the liver, kidney, lung, and brain. The

diagnostic value of these noninvasive techniques served to establish nuclear medicine and radiopharmaceutical chemistry as distinct specialties. A radiopharmaceutical is defined as any pharmaceutical that contains a radionuclide (5).

Historically, radioiodine has a special place in nuclear medicine. In 1938, Hertz, Roberts, and Evans first demonstrated the uptake of ^{128}I by the thyroid gland. With a longer half life (8 days), ^{131}I later became available and is now widely used. Although iodine has 24 known isotopes, ^{123}I, ^{131}I, and ^{125}I are the only ones currently used in medicine. At present, the most widely used PET radiopharmaceutical is the glucose analogue ^{18}F-FDG (2-fluoro-2-deoxy-D-glucose; half-life = 1.8 hours); it is routinely employed for functional studies of brain, heart, and tumor growth. The process is derived from the earlier animal studies quantifying regional glucose metabolism with [^{14}C]-2-dexoyglucose, which passes through the blood-brain barrier by the same carrier-facilitated transport system used for glucose. With the advancement in highly selective PET and SPECT ligands, the

potential of the noninvasive imaging procedures will achieve wider application both in pharmacologic research and in the diagnosis of central nervous system disorders.

The Next Wave in Drug Discovery

Genomics

Gleevec (imatinib) was discovered through the combined use of high-throughput screening and medicinal chemistry that resulted in the successful treatment of chronic myeloid leukemia. By molecular modifications, improved activity against the platelet-derived growth factor receptor (PDGFR) and tyrosine kinase as well as the loss of serine/threonine kinase inhibition were obtained. As a result of the success of Gleevec, scientists are modifying their drug discovery and development strategies to consider the patient's genes, without abandoning the more traditional drugs. It has been known for many years that genetics plays an important role in an individual's well-being. Attention is now being paid to manipulating the proteins that are produced in response to malfunctioning genes by inhibiting the out-of-control tyrosine kinase enzymes in the body that play such an important role in cell signaling events in growth and cell division. Using the knowledge obtained from the Human Genome Project, scientists with a knowledge of the sequencing of DNA and genes of various species have shown that some cancers are caused by genetic errors that direct the biosynthesis of dysfunctional proteins. Because proteins carry out the instructions from the genes located on the DNA, dysfunctional proteins, such as the kinases, deliver the wrong message to the cells, making them cancerous. The emphasis is now on inhibiting the proteins to slow the progression of the cancerous growth.

An emphasis in the pharmaceutical industry as well as in academia is to develop drug formulations that guarantee therapies will reach specific targets in the body. Vaccines based on a proprietary plasmid DNA that will activate skeletal muscles to manufacture desired proteins and antigens are being developed. Plasmid DNA vaccine technology represents a fundamentally new means of treatment that is of great importance for the future of drug targeting. Currently, the number of products coming out of biotechnology companies is increasing. Biotechnology drug discovery and drug development tools are used to create the more traditional small molecules. The promise of pharmacogenetics lies in the potential to identify sources of interindividual variability in drug responses that affect drug delivery and safety. Recent success stories in oncology demonstrate that the field of pharmacogenetics has progressed substantially. The knowledge created through pharmacogenetic trials can contribute to the development of patient-specific medicines as well as to improved decision making along the research and development value chain (6).

Combinatorial Chemistry and High-Throughput Screening

No discussion of the history and evolution of medicinal chemistry would be complete without briefly mentioning combinatorial chemistry and high-throughput screening. Combinatorial chemistry is one of the new technologies developed by academics and researchers in the pharmaceutical and biotechnology industries to reduce the time and cost associated with producing effective, marketable, and competitive new drugs. Chemists use combinatorial chemistry to create large populations of molecules that can be screened efficiently, generally using high-throughput screening. Thus, instead of synthesizing a single compound, combinatorial

chemistry exploits automation and miniaturization to synthesize large libraries of compounds. Combinatorial organic synthesis is not random but, rather, systematic and repetitive, using sets of chemical “building blocks” to form a diverse set of molecular entities.

Random screening has been a source of new drugs for several decades. Many of the drugs currently on the market were developed from leads identified through screening of natural products or compounds synthesized in the laboratory. In the late 1970s and 1980s, however, screening fell out of favor in the industry. Using traditional methods, the number of novel selective leads that were generated did not make this approach cost-effective. The last 25 years have seen an enormous advance in our understanding of critical cellular processes, leading to a more rationally designed approach in drug discovery. The availability of cloned genes for use in high-throughput screening to identify new molecules has led to a reexamination of the screening process. Targets now are often recombinant proteins (i.e., receptors) produced from cloned genes that are heterologously expressed in a number of ways. Combinatorial libraries complement the enormous numbers of synthetic libraries available from new and old synthetic programs. The development and

use of robotics and automation have made it possible to screen large numbers of compounds in a short period of time. It also should be emphasized that computerized data systems and analysis of the data have facilitated the handling of the information being generated, leading to the identification of new leads.

Summary

It is fair to say that more than 50% of the drugs in use today had their origin in a plant, animal, or mineral that had been used as cures for alleviating diseases occurring in humans. Examples of a number of discoveries of important drugs in use today are recounted as “case studies” in the drug discovery process and are described in more detail in the following chapters. The discoveries briefly described are, in large measure, a result of the increased sophistication brought to bear in the isolation, identification, structure determination, and synthesis of the active ingredients of the drugs used empirically hundreds of years ago.

The emergence of the pharmaceutical industry took place in conjunction with the advances in organic/medicinal/pharmaceutical chemistry, pharmacology, bacteriology, biochemistry, and medicine as distinct fields of science in the late nineteenth century. Current research efforts are now focused not only on discovering new, biologically active compounds using ever increasingly sophisticated technology but also on gaining a better understanding of how and where drugs exert their effects at the molecular level. One should not underestimate, however, that the discoveries in the twentieth and twenty-first centuries, and before, represent an amazing amount of insight, determination, and luck by researchers in chemistry, pharmacology, biology, and medicine. We owe gratitude and admiration to those earlier scientists who had the imagination and inspiration to develop drugs to cure so many illnesses.

Chapter 1
Drug Discovery from Natural Products

A. Douglas Kinghorn

Introduction

"Pharmacognosy" is one of the oldest established pharmaceutical sciences, and the term has been used for nearly two centuries. Initially, this term referred to the investigation of medicinal substances of plant, animal, or mineral origin in their crude or unprepared state, used in the form of teas, tinctures, poultices, and other types of formulation (1,2,3,4). By the middle of the twentieth century, however, the chemical components of such crude drugs began to be studied in more detail. Today, the subject of pharmacognosy is highly interdisciplinary, and it incorporates aspects of analytical chemistry, biochemistry, biosynthesis, biotechnology, ecology, ethnobotany, microbiology, molecular biology, organic chemistry, and taxonomy, among others (5). The term "pharmacognosy" is defined on the Web site of the American Society of Pharmacognosy (http://www.phcog.org) as "the study of the physical, chemical, biochemical, and biological properties of drugs, drug substances, or potential drugs or drug substances of natural origin, as well as the search for new drugs from natural sources."

There seems little doubt that humans have used natural drugs since before the advent of written history. In addition to their use as drugs, the constituents of plants have afforded poisons for darts and arrows used in hunting and euphoriants with psychoactive properties used in rituals. The actual documentation of drugs derived from natural products in the Western world appears to date back as far to the Sumerians and Akkadians in the third century BC as well as to the Egyptian *Ebers Papyrus* (approximately 1,600 BC). Other important contributions on the uses of drugs of natural origin were documented by Dioscorides (*De Materia Medica*) and Pliny the Elder in the first century AD and by Galen in the second century. Written records also exist from about the same time period regarding plants used in both Chinese traditional medicine and Ayurvedic medicine. Then, beginning approximately 500 years ago, information concerning medicinal plants began to be documented in herbals. In turn, the laboratory study of natural product drugs commenced approximately 200 years ago, with the purification of morphine from opium. This corresponds with the beginnings of organic chemistry as a scientific discipline. Additional drugs isolated from plant sources in the nineteenth century included atropine, caffeine, cocaine, nicotine, quinine, and strychnine, and in the twentieth century, digoxin, reserpine, paclitaxel, vincristine, and chemical precursors of the steroid hormones. Even as we enter the twenty-first century, approximately three-quarters of the world's population is reliant on primary health care from systems of traditional medicine, including the use of herbs. In recent years, a more profound understanding of the chemical and biological aspects of plants used in the traditional medicine of countries such as the People's Republic of China, India, Indonesia, and Japan, in addition to the medicinal plants used in Latin America and Africa. Many important scientific observations germane to natural product drug discovery have been made as a result (1,2,3,4).

By the mid-twentieth century, therapeutically useful alkaloids had been purified and derivatized from the ergot fungus, as uterotonic and sympatholytic agents. Then, the penicillins were isolated, along with further major structural classes of effective and potent antibacterials from terrestrial microbes, and these and later antibiotics revolutionized the treatment of infectious diseases. Of the types of organisms producing natural products, terrestrial microorganisms have been found to afford the largest number of compounds currently used as drugs for a wide range of human diseases, and these include antifungal agents, the "statin" cholesterol-lowering agents, immunosuppressive agents, and several anticancer agents (1,2,3,4).

At the beginning of the twenty-first century, there is much interest in the discovery and development of drugs from marine animals and plants. To date, however, marine organisms have had a relatively brief history as sources of drugs. Although the oceans occupy 70% of the surface of the earth, an intense effort to investigate the chemical structures and biological activities of marine fauna and flora has only been ongoing for approximately 30 years. Two established drugs based on marine-derived nucleoside model compounds are the antileukemic

agent cytosine arabinoside and the antiviral agent, adenine arabinoside (6).

The term “natural product” generally is taken to mean a compound that has no known primary biochemical role in the producing organism. Such small-molecular-weight organic molecules also may be referred to as “secondary metabolites,” and they tend to be biosynthesized by the producing organism in a biologically active chiral form to increase the chances of survival, such as by repelling predators or, in the case of terrestrial plants, serving as insect pollination attractants (1,2,3,4). There have been a number of studies to investigate the physicochemical parameters of natural products in recent years, and it has been concluded that “libraries,” or collections of these substances, tend to afford a higher degree of “drug-likeness” when compared to compounds in either synthetic or combinatorial “libraries” (7,8). This characteristic might well be expected, because natural products are

produced by living systems, where they are subject to transport and diffusion at the cellular level. Small-molecule natural products are capable of modulating protein–protein interactions and, thus, can affect cellular processes that may be modified in disease states. When compared to synthetic compounds, natural products tend to have more protonated amine and free hydroxy functionalities and more single bonds, with a greater number of fused rings containing more chiral centers. Natural products also differ from synthetic products in the average number of halogen, nitrogen, oxygen, and sulfur atoms, in addition to their steric complexity (9). It is considered that natural products and synthetic compounds occupy different regions of “chemical space”; hence, they each tend to contribute to the overall chemical diversity required in a drug discovery program (7,8). Fewer than 20% of the ring systems produced among natural products are represented in currently used drugs (8). Naturally occurring substances may serve either as drugs in their native or unmodified form or as “lead” compounds (prototype bioactive molecules) for subsequent semisynthetic or totally synthetic modification—for example, to improve biological efficacy or to enhance solubility (7,8,9,10).

In the present era of efficient drug design by chemical synthesis aided by computational and combinatorial techniques, and with other new drugs obtained increasingly through biotechnological processes, it might be expected that traditional natural products no longer have any significant role to play in this regard. Indeed, during the past decade, emphasis on the screening of natural products for new drugs by pharmaceutical companies has decreased, with greater reliance being placed on screening large “libraries” or collections of synthetic compounds (7,8,10). In a landmark review article, however, Newman et al. (11) from the U.S. National Cancer Institute pointed out that from 1982 to 2002, approximately 28% of the new chemical entities in Western medicine were either natural products per se or derived from natural products. Thus, of 1,031 new chemical entities over this 22-year period, 5% were unmodified natural products, and 23% were semisynthetic agents based on natural product lead compounds. An additional 14% of the synthetic compounds were designed based on knowledge of a natural product “pharmacophore” (the region of the molecule containing the essential organic functional groups that directly interact with the receptor active site and, therefore, confer the biologic activity of interest). Furthermore, in the thirteenth revision of the *World Health Organization Model List of Essential Medicines*, of approximately 300 drugs considered necessary for the practice of medicine, approximately 210 are small-molecular agents. Of these, more than 40 are unmodified natural products, 25 are semisynthetic drugs based on natural product prototypes, and more than 70 are either synthetic drugs based on natural product prototype molecules or synthetic mimics of natural products (12). The launch of new natural product drugs in the United States, Europe, and Japan has continued in the early years of the present decade of this new century, and such compounds introduced to the market recently have been reviewed by Butler (13).

Thus, the secondary metabolites of organisms generally are recognized to afford a source of small-organic molecules of outstanding chemical diversity that are highly relevant to the contemporary drug discovery process. Potent and selective leads are obtained from increasingly exotic organisms as collection efforts venture into increasingly inhospitable locales throughout the world, such as deep caves in terrestrial areas and thermal vents on the ocean floor. On occasion, a natural lead compound may help to elucidate a new mechanism of interaction with a biological target for a disease state under investigation. Natural products may serve to provide molecular inspiration in certain therapeutic areas for which there are only a limited number of

synthetic lead compounds. A widespread perception remains, however, that the resupply of the source organism of a secondary metabolite of interest may prove to be problematic and, consequently, will hinder the timely, more detailed biological evaluation of a compound that is available initially only in milligram quantities. In addition, natural product extracts have been regarded by some as being incompatible with the modern rapid screening techniques and the successful market development of a natural product–derived drug as being too time-consuming (7,8,13). A further consideration of the factors involved in the discovery of drugs from natural products will be presented in the next section. This will be followed by examples of natural products currently used in various therapeutic categories as well as a few selected representatives with future clinical potential.

Natural Products and Drug Discovery

Collection of Source Organisms

There are at least five recognized approaches to the choice of plants and other organisms for the laboratory investigation of their biological components: random screening; selection of specific taxonomic groups, such as families or genera; a chemotaxonomic approach in which restricted classes of secondary metabolites, such as alkaloids, are sought; an information-managed approach, which involves the target collection of species selected by database surveillance; and selection by an ethnomedical approach (e.g., by investigating remedies used in traditional medicine by “shamans” or medicine men or women) (14). In fact, if plant-derived natural products are taken specifically, it has been estimated that of 122 drugs of this type used worldwide from a total of 94 species, 72% can be traced to the original ethnobotanical uses that have been documented for their plant of origin (14). The need for increased research concerning natural product discovery involving ethnobotany should be regarded as urgent because to the accelerating loss in

developing countries of indigenous cultures and languages, inclusive of knowledge of traditional medical practice (15). It is common, however, for a given medicinal plant to be used ethnomedically in more than one disease context, which sometimes may obscure its therapeutic utility for a specific disease condition. Another manner in which drugs have been developed from terrestrial plants and fungi is through following up on observations of the causes of livestock poisoning, leading to new drugs and molecular tools for biomedical investigation (16). When the origin of plants with demonstrated inhibitory effects in experimental tumor systems was considered at the U.S. National Cancer Institute, medicinal or poisonous plants with uses as either anthelmintics or arrow and homicidal poisons were three- to fourfold more likely to be active in this regard than species screened at random (17).

Some shallow-water marine specimens may be collected simply by wading or snorkeling down to 20 feet below the water surface, but scuba diving permits the collection of organisms to depths of 120 feet. Deep-water collections of marine animals and plants have been made by dredging and trawling and through the use of manned and unmanned submersible vessels. Collection strategies for specimens from the ocean must take into account marine macroorganism–microorganism associations that may be involved in the biosynthesis of a particular secondary metabolite of interest (18). Thus, there seems to be a complex interplay between many marine host invertebrate animals and symbiotic microbes that inhabit them, and several bioactive compounds previously thought to be of animal origin may be produced by their associated microorganisms instead (19).

The process of collecting or surveying a large set of flora (or fauna) for the purpose of biological evaluation and isolation of lead compounds is called “biodiversity prospecting” (20). Many natural product collection programs are focused on tropical rain forests to take advantage of the inherent biological diversity (or “biodiversity”) evident there, with the hope of harnessing as broad a profile of chemical classes as possible among the secondary metabolites produced by the species to be obtained. To exemplify this, there may be more tree species in a relatively small area of a tropical rainforest than in the whole of the temperate regions of North America. A generally accepted explanation for the high biodiversity of secondary metabolites in humid forests in the tropics is that these molecules are biosynthesized (a process of chemical synthesis by the host organism) for ecological roles in response to a continuous growing season

under elevated temperatures, high humidity, and great competition resulting from the high species density present. Maximal biodiversity in the marine environment is found on the fringes of the ocean or sea bordering land, where intense competition for attachment space exists among sessile (nonmoving) organisms, such as algae, corals, sponges, and some other invertebrate animals space (21).

Great concern should be expressed about the continuing erosion of tropical rain forest species, which is accelerating as the twenty-first century begins (22). Approximately 25 “hot spots” of especially high biodiversity have been proposed that represent 44% of all vascular plant species and 35% of all species of vertebrates in approximately 1.4% of the earth's surface (23). At present, many of the endemic (or native) species to these biodiversity “hot spot” areas have been reported to be undergoing massive habitat loss and are threatened with extinction, especially in tropical regions (22,23).

Following the United Nations Convention on Biological Diversity, which was passed in Rio de Janeiro in 1992, biological or genetic materials are owned by the country of origin (20). A major present-day component of being able to gain access to the genetic resources of a given country for the purposes of drug discovery and other scientific study is the formulation of a Memorandum of Agreement, which itemizes access, previous informed consent (involving human subjects in cases where ethnomedical knowledge is divulged), intellectual property related to drug discovery, and equitable sharing of the financial benefits that may accrue from the project, such as patent royalties and licensing fees (20). When access to marine organisms is desired, the United National Convention on the Law of the Sea must be considered as well (24).

Once a formal “benefit sharing” agreement is on hand, the organism collection process can begin. Usually, 0.3 to 1 kg of each dried plant sample and approximately 1 kg wet weight of a marine organism are initially collected for preliminary screening studies (25). In the case of a large plant (tree or shrub), it is typical to collect up to four different organs or plant parts, because the secondary metabolite composition may vary considerably between the leaves, where photosynthesis occurs, and the storage or translocation organs, such as the roots and bark. Increasing evidence suggests that considerable variation in the profile of secondary metabolites occurs in the same plant organ when collected from different habitats, depending on local environmental conditions; thus, it may be worth reinvestigating even well-studied species in drug discovery projects (26). Taxa that are endemic to a particular country or region generally are of higher priority than pandemic weeds. It is very important not to remove all quantities of a desired species at the site of collection to conserve the native germplasm encountered. Also, rare or endangered species should not be collected; a listing of the latter is maintained, for example, by the *Red List of Threatened Species* of the International Union for Conservation of Nature and Natural Resources (http://www.redlist.org), covering terrestrial, marine, and freshwater organisms.

A crucial aspect of the organism collection process is to deposit voucher specimens representative of the species collected in a central repository, such as an herbarium or a museum, so that this material can be

accessed by other scientists. It is advisable to deposit specimens in more than one repository, including regional and national institutions of the country in which the organisms were collected. Collaboration with general and specialist taxonomists is very important, because without an accurate identification of a source organism, the value of subsequent isolation, structure elucidation, and biological evaluation studies will be greatly reduced.

Organisms for natural product drug discovery work may be classified into the Kingdoms Eubacteria (bacteria, cyanobacteria [or “blue-green algae”]), Archaea (halobacterians, methanogens), Protoctista (e.g., protozoa, diatoms, “algae” [including red algae, green algae]), Plantae (land plants [including mosses and liverworts, ferns, and seed plants]), Fungi (e.g., molds, yeasts, mushrooms), and Animalia (mesozoa [worm-like invertebrate marine parasites], sponges, jellyfish, corals, flatworms, roundworms, sea urchins, mollusks [snails, squid], segmented worms, arthropods [crabs, spiders, insects], fish, amphibians, birds, mammals) (20). Of these, the largest numbers of organisms are found for arthropods, inclusive of insects (~950,000 species), with only a relatively small proportion (5%) of the estimated 1.5 million fungi in the world having been identified. At present, with 300,000 to 500,000 known species,

plants are the second-largest group of classified organisms, representing approximately 15% of our biodiversity. Of the 28 major animal phyla, 26 are found in the sea, with eight of these exclusively so. More than 200,000 species of invertebrate animals and algal species have been found in the sea (5,18,20). During the last decade, a high proportion of the new natural product molecules was isolated from fungal sources (27). An area of investigation with great potential for expansion in the future will be microbes, particularly actinomycetes and cyanobacteria of marine origin, especially if techniques can be developed for their isolation and culturing in the laboratory (28). Along the same lines, endophytes (microorganisms that reside in the tissue of living plants) have been found to produce an array of biologically interesting new compounds and are worthy of more intensive investigation (29). Interestingly, in a survey regarding the origin of 30,000 structurally assigned lead compounds of natural origin, these compounds were derived from animals (13%), bacteria (33%), fungi (26%), and plants (27%) (9). A basic premise inherent in natural product drug discovery work is that the greater the degree of phylogenetic (taxonomic) diversity of the organisms sampled, the greater the resultant chemical diversity. Therefore, whereas natural product researchers tend to specialize in the types of organism on which they work, it is reasonable to envisage that the future investigation of all the major groups mentioned above will provide dividends in terms of affording new prototype biologically active compounds of use in drug discovery.

Preparation of Initial Extracts and Preliminary Biological Screening

Different laboratories tend to adopt different procedures for initial extraction of the source organisms being investigated, but typically, terrestrial plants undergo extraction initially with a polar solvent, such as methanol or ethanol, then subject this extract to a defatting (lipid-removing) partition with a nonpolar solvent, such as hexane or petroleum ether, and partition the residue between a semipolar organic solvent, such as chloroform or dichloromethane, and a polar aqueous solvent (26). Marine and aquatic organisms are commonly extracted fresh into methanol or a mixture of methanol and dichloromethane (25). A peculiarity of working on plant extracts is the need to remove a class of compounds known as “vegetable tannins” or “plant polyphenols” before subsequent biological evaluation, because these compounds act as interfering substances in enzyme inhibition assays as a result of precipitating proteins in a nonspecific manner. Several methods to remove plant polyphenols have been proposed, such as passage over polyvinylpyrrolidone and polyamide, on which they are retained. Alternatively, partial removal of these interfering substances may be effected by washing the final semipolar organic layer with an aqueous sodium chloride solution (25). It should be noted, however, that active interest remains in pursuing purified and structurally characterized vegetable tannins for their potential medicinal value (30,31). Caution also needs to be expressed in regard to common saturated and unsaturated fatty acids that might be present in natural product extracts, because these may interfere with various enzyme-inhibition and receptor-binding assays (32). Fatty acids and other lipids may largely be removed from more polar natural product extracts using the defatting solvent partition stage mentioned above.

Drug discovery from organisms is a “biology-driven” process, and as such, biological activity evaluation is at the heart of the drug discovery process from crude extracts prepared from organisms. So-called “high-throughput” screening (HTS) assays have become widely used for affording new leads. In this process, large numbers of crude extracts from organisms can be simultaneously evaluated in a cell- or noncell-based format, usually utilizing multiwell microtiter plates (33). Cell-based in vitro bioassays allow a considerable degree of biological relevance, and manipulation may take place so that a selected cell line may involve a genetically altered organism (34) or incorporate a reporter gene (20,33). In noncellular (cell-free) assays, natural product extracts and their purified constituents may be investigated for their effects on enzyme activity (30,32) or receptor-binding (35). Other homogenous and separation-based assays that are suitable for the screening of natural products have been reviewed (36). For maximum efficiency and speed, HTS may be automated through the use of robotics and may be rendered a more effective process through miniaturization.

Methods for Compound Structure Elucidation and Identification

Bioassay-directed fractionation is the process of isolating pure active constituents from some type of biomass (e.g., plants, microbes, marine invertebrates) using a decision tree that is dictated solely by bioactivity. A variety of chromatographic separation techniques are available for these purposes, including those based on adsorption on sorbents, such as silica gel, alumina, Sephadex, and more specialized solid phases, and methods involving partition chromatography inclusive of countercurrent chromatography. Recent improvements have been made in column technology, automation of high-performance liquid chromatography (HPLC; a technique often used for final compound purification), and compatibility with HTS methodology (13). Routine structure elucidation is performed using combinations of spectroscopic procedures, with particular emphasis on one- and two-dimensional ^{1}H- and ^{13}C-nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS). Considerable progress has been made in the development of cryogenic and microcoil NMR probe technology for the determination of structures in submilligram amounts of natural products (8). In addition, the automated processing of spectroscopic data for the structure elucidation of natural products is a practical proposition (37). Another significant advance is the use of “hyphenated” analytical techniques for rapid determination of the structure of natural products without the need for a separate isolation step, such as LC-NMR and LC-NMR-MS (8,13). The inclusion of an on-line solid-phase extraction cartridge is advantageous in the identification of natural product molecules in crude extracts using LC-NMR (38).

“Dereplication” is a process of determining whether an observed biological effect of an extract or specimen is caused by a known substance. This is applied during natural product drug discovery programs in an attempt to avoid the reisolation of compounds of previously determined structure. A step like this is essential to prioritize the resources available to a research program so that the costly stage of bioassay-directed fractionation on a promising lead crude extract can be devoted to the discovery of biologically active agents representing new chemotypes (39). This has been particularly necessary for many years in studies on anti-infective agents from actinomycetes and bacteria, and it is applied routinely to extracts from higher plants and marine invertebrates. Methods for dereplication must be sensitive, rapid, and reproducible, and the chemical methods employed generally contain a mass spectrometric component (39). For example, the eluant (effluent) from an HPLC separation of crude natural product extracts may be split into two portions so that the major part is plated out into a microtiter plate, with the wells then evaluated in an in vitro bioassay of interest. The fractions from the minor portion of the column eluant are introduced to a mass spectrometer, and the molecular weights of compounds in active fractions can be determined. This information may then be introduced into an appropriate natural product database, and tentative identities of the active compounds in the active wells can be determined (26,39).

“Metabolomics” is a recently developed approach in which the entire or “global” profile of secondary metabolites in a system (cell, tissue, or organism) is catalogued under a given set of conditions. Secondary metabolites may be investigated by a detection step, such as MS, after a separation step, such as gas chromatography, HPLC, or capillary electrophoresis (40). This type of technology has particular utility in systematic biology, genomics research, and biotechnology, and it should have value in future natural product drug discovery (40,41).

Compound Development

A major challenge in the overall natural product drug discovery process is to obtain larger amounts of a biologically active compound of interest for additional laboratory investigation and potential preclinical development. One strategy that can be adopted when a plant-derived, active compound is of interest is to recollect the species of origin. To maximize the likelihood that the recollected sample will contain the bioactive compound of previous interest, the plant recollection should be carried out in the same location as the initial collection, on the same plant part, and during the same time of the year (26). Some success has been achieved with the production of terrestrial plant and marine cyanobacterial secondary metabolites via plant tissue culture and aqu- aculture, respectively. For microbes of terrestrial origin, compound scale up often can be carried out through cultivation and large-scale fermentation.

Evaluation of crude extracts of organisms is not routinely carried out in animal models because of limitations of either test material or other project resources, but it is of great value to test in

vitro–active natural products in a pertinent in vivo method to obtain a preliminary indication regarding the worthiness of a lead compound for preclinical development. A number of "secondary discriminator" bioassays also provide an assessment of whether a given in vitro–active compound is likely to be active in vivo, and these require quite small amounts of test material. For example, the in vivo hollow-fiber assay was developed at the U.S. National Cancer Institute for the preliminary evaluation of potential anticancer agents, and it uses confluent cells of a tumor model of interest deposited in polyvinylidene fluoride fibers that are implanted in nude mice (26,42). It also is important for pure bioactive compounds to be evaluated mechanistically for their effects on a particular biological target, such as on a given stage of the life cycle of a pathogenic organism or a cancer cell. Needless to say, a pure natural product of novel structure with in vitro and in vivo activity against a particular biological target relevant to human disease acting through a previously unknown

mechanism of action is of great value in the drug discovery process.

Once a bioactive natural product lead is obtained in gram quantities, it is treated in the same manner as a synthetic drug lead and, thus, subjected to pharmaceutical development leading to preclinical and clinical trials. This includes lead optimization via medicinal chemistry, combinatorial chemistry, computational chemistry, as well as formulation, pharmacokinetics, and drug metabolism studies, as described elsewhere in this volume. Often, a lead natural product is obtained from its organism of origin along with several naturally occurring structural analogues, permitting a preliminary study of the structure–activity relationship to be conducted. This information may be supplemented with data obtained by microbial biotransformation or the production of semisynthetic analogues to allow researchers to glean some initial information about the pharmacophoric site(s) of the naturally occurring molecule (7,8,10).

"Combinatorial biosynthesis" is a contemporary approach with the ability not only to produce new natural product analogues but also to afford new drug candidates per se. This methodology involves the engineering of biosynthetic gene clusters in microorganisms. For example, the modification of bacterial polyketide synthases has led to production of some 200 new polyketides that do not occur naturally (43).

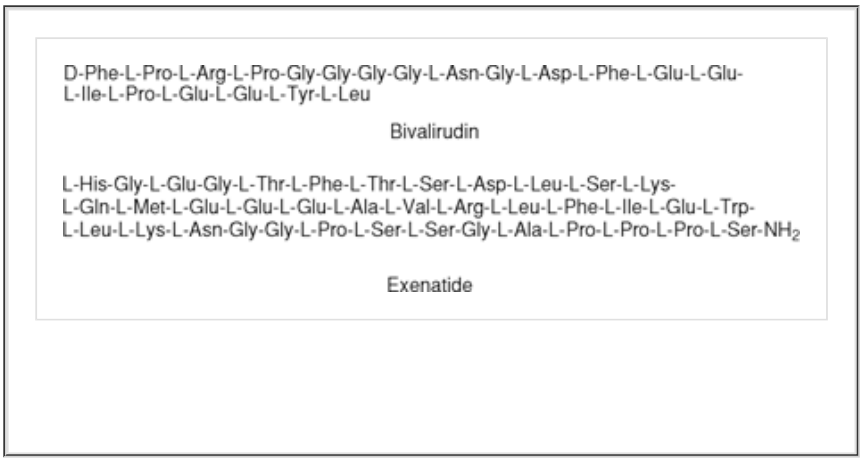
Selected Examples of Natural Product–Derived Drugs

In this section, examples are provided of both naturally occurring substances and synthetically modified compounds based on natural products with drug use. Many of the examples shown reflect considerable structural complexity, and the compounds introduced to the market have been obtained from organisms of very wide diversity. More detailed treatises with many more examples of natural product drugs also may be found (1,2,3,4). Several recent reviews have summarized newly introduced natural product drugs introduced to the market in recent years as well as substances on which clinical trials are being conducted (6,13,44,45).

Drugs for Cardiovascular and Metabolic Diseases

A very close relationship exists between natural product drugs and the treatment of cardiovascular and metabolic diseases. The powdered leaves of *Digitalis purpurea* have been used in Western medicine for more than 200 years, with the major active constituent being the cardiac (steroidal) glycoside digitoxin, which is still used for the treatment of congestive heart failure and atrial fibrillation. A more widely used drug today is digoxin, a constituent of *Digitalis lanata*, which has a rapid action and is more rapidly eliminated from the body than digitoxin. Deslanoside (deacetyllanatoside C) is a hydrolysis product of the *D. lanata* constituent lanatoside C and is used for rapid digitalization (1,2,3,4). The "statin" drugs used for lowering blood cholesterol levels are based on the lead compound mevastatin (formerly known as compactin), produced by cultures of *Penicillium citrinum*, and were discovered using a 3-hydroxy-3-methylglutaryl–coenzyme A reductase assay. Because hypercholesterolemia is regarded as one of the major risk factors for coronary heart disease, several semisynthetic and synthetic compounds modeled on the mevastatin structure (inclusive of the dihydroxycarboxylic acid side chain), including atorvastatin, fluvastatin, pravastatin, and simvastatin, now have extremely wide therapeutic use. Lovastatin is a natural product drug of this type, isolated from *Penicillium brevecompactin* and other organisms (2). There also is a history of the successful

production of cardiovascular agents from a terrestrial vertebrate—namely, the angiotensin-converting enzyme inhibitors, captopril and enalapril, which were derived from teprotide, a nonapeptide isolated from the pit viper, *Bothrops jararaca* (44).



Two more new drugs derived from a vertebrate and an invertebrate source, respectively, are bivalirudin and exenatide. Bivalirudin is a specific and reversible direct thrombin inhibitor that is administered by injection and is used to reduce the incidence of blood clotting in patients undergoing coronary angioplasty. This compound is a synthetic, 20-amino-acid peptide modeled on hirudin, a substance in the saliva of the leech, *Haementeria officinalis* (46,47). Exenatide is a synthetic version of a 39-amino-acid peptide (exenatide-4) produced in the salivary secretions of a lizard native to the southwestern United States and northern Mexico called the Gila monster, *Heloderma suspectum*, and it acts in the same manner as glucagon-like peptide-1 (GLP-1), a naturally occurring hormone. This drug also is administered by injection, and it enables improved glycemic control in patients with type 2 diabetes (44,48).

Central Nervous System Drugs

A comprehensive review has appeared regarding natural products (mostly of experimental value) that affect the central nervous system, inclusive of analgesics, antipsychotics, anti-Alzheimer's disease agents, antitussives, anxiolytics, and muscle relaxants, among other categories (49). The authors point out in this review that apart from the extensive past literature concerning plants and their constituents as hallucinogenic agents, this area of research on natural products is not well developed but is likely to be very productive in future.

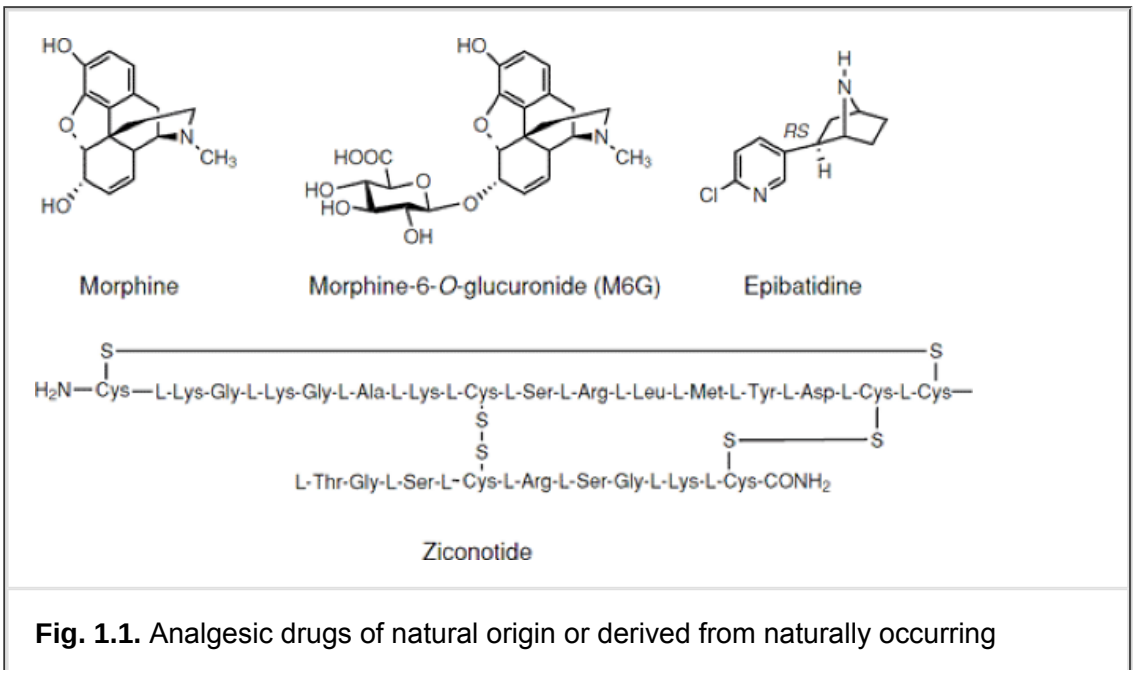


Fig. 1.1. Analgesic drugs of natural origin or derived from naturally occurring

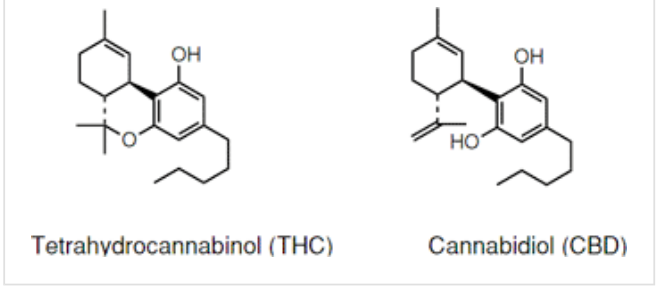
analgesics.

The morphinan isoquinoline alkaloid, (-)-morphine, is the most abundant and important constituent of the dried latex (milky exudate) of *Papaver somniferum* (opium poppy), and the prototype of the opioid analgesics, being selective for μ opioid receptors (Fig. 1.1). This compound may be considered to be the paramount natural product lead compound, with many thousands of derivatives synthesized in an attempt to obtain derivatives with strong analgesic potency but without any addictive tendencies (1,2,3,4). One derivative now in late clinical trials as a pain treatment is morphine-6-glucuronide (M6G) (Fig. 1.1), the major active metabolite of morphine, with fewer side effects than the parent compound (44,50). The pyridine alkaloid epibatidine (Fig. 1.1), isolated from a dendrobatid frog, *Epipedobates tricolor*, found in Ecuador, activates nicotinic receptors and has an analgesic activity 200-fold more potent than that of morphine. The drug potential of epibatidine is limited by its concomitant toxicity, but it is an important lead compound for the development of future new analgesic agents with less addictive liability than the opiate analgesics (51). A nonopioid analgesic, ziconotide, which is prescribed for the amelioration of chronic pain, has been introduced to the market recently (Fig. 1.1). This drug is a synthetic version of the peptide ω-conotoxin MVIIA. The conotoxin class is produced by the cone snail, *Conus magus*, and these compounds are peptides with 24- to 27-amino-acid residues. Ziconotide selectively binds to N-type voltage-sensitive neuronal channels, causing a blockage of neurotransmission and a potent analgesic effect (44,52). This is one of the first examples of a new natural product drug from a marine source.

(-)-Δ^9-*trans*-Tetrahydrocannabinol (THC) is the major psychoactive (euphoriant) constituent of marijuana, *Cannabis sativa*. The synthetic form of THC (dronabinol) was approved approximately 20 years ago to treat nausea and vomiting associated with cancer chemotherapy, and it has been used for a lesser amount of time to treat appetite loss in patients with HIV/AIDS (44). More recently, an approximately 1:1 mixture of THC and the structurally related marijuana constituent cannabidiol has been approved in Canada for the alleviation of neuropathic pain and spasticity for patients with multiple sclerosis and is administered in low doses as a buccal spray (53). Considerable interest exists in using cannabinoid derivatives based on THC for medicinal purposes, but it is necessary to minimize the central nervous system effects of these compounds.

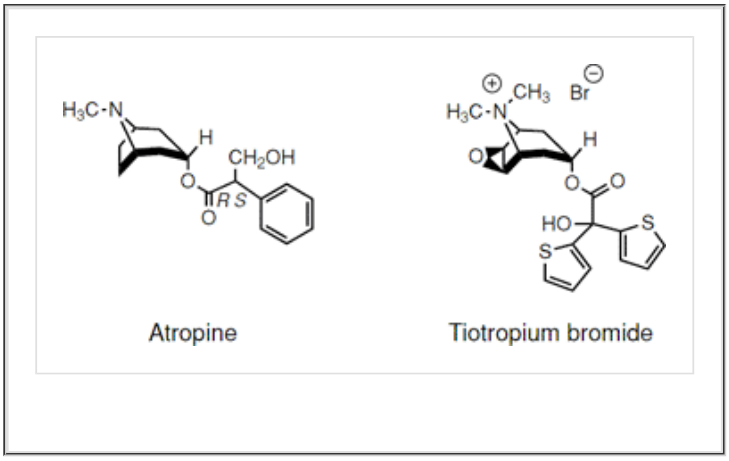


Another important natural product lead compound is the tropane alkaloid ester atropine [(±)-hyoscyamine], from the plant *Atropa belladonna* (deadly nightshade) Atropine has served as a prototype molecule for several anticholinergic and antispasmodic drugs. One recently introduced example of an anticholinergic compound modeled on atropine is tiotropium bromide, which is used for the maintenance treatment of bronchospasm associated with chronic obstructive pulmonary disease (54).

P.19

In the category of anti-Alzheimer's disease agents, galanthamine hydrobromide is a selective

acetylcholinesterase inhibitor that slows neurological degeneration by inhibiting this enzyme and by interacting with the nicotinic receptor (55). Galanthamine (also known as “galantamine”) is classified as an Amaryllidaceae alkaloid and has been obtained from several species in this family. Because commercial synthesis is not economic, it is obtained from the bulbs of *Leucojum aestivum* (snowflake) and *Galanthus* sp. (snowdrop) (1,2,3,4). some evidence indicates an ethnomedical basis for the current use of galanthamine (56).



Anti-infective Agents

Since the introduction of penicillin G (benzylpenicillin) to chemotherapy as an antibacterial agent in the 1940s, natural products have been the most important subcategory of anti-infective agents. As well as the discovery of additional penicillins more resistant to acid hydrolysis and to the β-lactamase enzyme, other classes of antibacterials that have been developed from natural product sources are the aminoglycosides, cephalosporins, glycopeptides, macrolides, rifamycins, and tetracyclines. Antifungals, such as griseofulvin and the polyenes, and avermectins, such as the antiparasitic drug ivermectin, also are of microbial origin (1,2,3,4). Of the approximately 90 drugs in this category that were introduced in Western countries (inclusive of Japan) from 1981 to 2002, almost 80% can be related to a microbial origin (11). In spite of this, relatively few major pharmaceutical companies are currently working on the discovery of new anti-infective agents from natural sources, both because of possible bacterial resistance against new agents and because of concerns in regard to regulation (44). Higher plants also have afforded important anti-infective agents, perhaps most significantly the quinoline alkaloid quinine, obtained from the bark of several *Cinchona* sp. found in South America, including *C. ledgeriana* and *C. succirubra*. Quinine continues to be used for the treatment of multidrug-resistant malaria and was the template molecule for the synthetic antimalarials chloroquine, primaquine, and mefloquine (1,2,3,4).

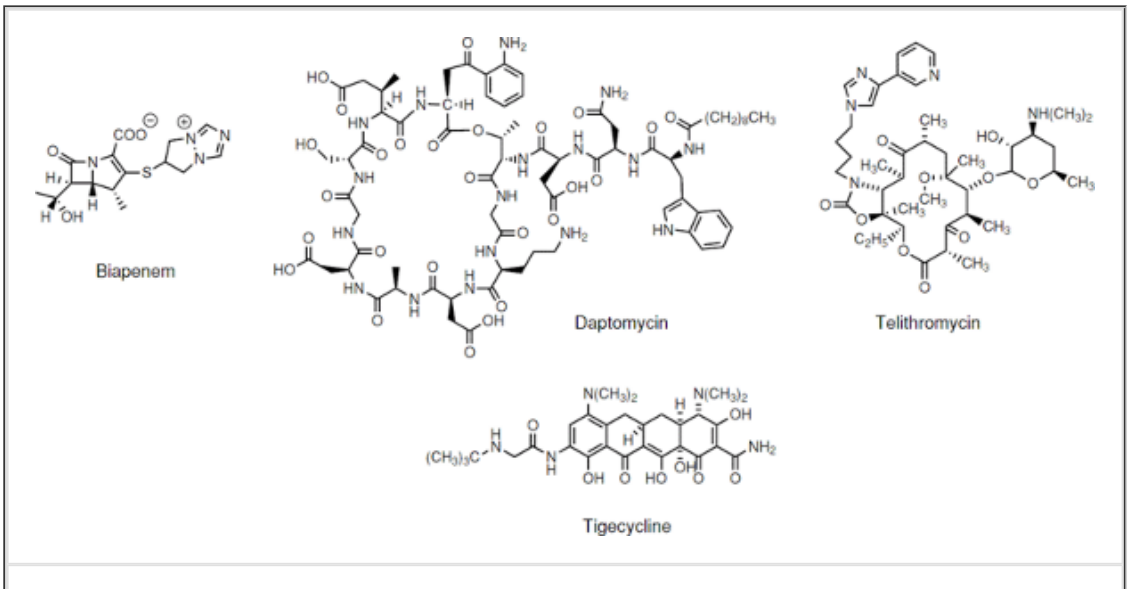


Fig. 1.2. Natural occurring anti-infective agents.

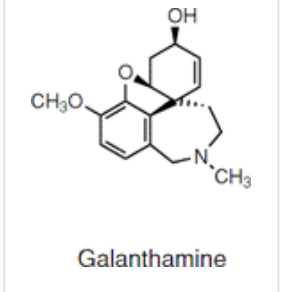
The following examples, shown in Figure 1.2, have been chosen to represent an array of different structural types of antibacterial agents recently introduced into therapy (44). Biapenem is a carbapenem (a group of β-lactam antibiotics in which the sulfur atom in the thiazolidine ring is replaced by a carbon atop) and is based on thienamycin, isolated from *Streptococcus cattleya*. It is a broad-spectrum antibacterial and is more stable to hydrolysis by human renal dihydropeptidase-1 (DHP-1) than other antibiotics in its structural class (57). Tigecycline is a member of the glycylcycline class of tetracycline antibacterials and is the 9-*tert*-butylglycylamido derivative of minocycline, a semisynthetic derivative of chlortetracycline from *Streptomyces aureofaciens*. This is a broad-spectrum antibiotic, with activity against methicillin-resistant *Staphylococcus aureus* (58,59). Daptomycin is the prototype member of the cyclic lipopeptide class of antibiotics,

and although isolated initially from *Streptomyces roseosporus*, it is now produced by semisynthesis. This compound binds to bacterial cell membranes, disrupting the membrane potential, and blocks the synthesis of DNA, RNA, and proteins. Daptomycin is bactericidal against Gram-positive organisms (inclusive of vancomycin-resistant *Enterococcus faecalis* and *E. faecium*) and is approved for the treatment of complicated skin and dermal infections (60,61). Telithromycin is a semisynthetic derivative of the 14-membered macrolide erythromycin A, from *Saccharopolyspora erythraea*, and is a macrolide of the ketolide class that lacks a cladinose sugar but has an extended alkyl–aryl unit attached to a cyclic carbamate unit. It binds to domains II and V of the 23S rRNA unit of the bacterial 50S ribosomal unit, leading to inhibition of the ribosome assembly and protein synthesis. This macrolide antibiotic is used to treat bacteria that infect the lungs and sinuses, including community-acquired pneumonia caused by *Streptomyces pneumoniae* (62,63).

Natural products have been a fruitful source of antifungal agents in the past, with the echinocandins being a recently introduced group of lipopeptides (44). Of these, two compounds are now approved drugs, including the acetate of caspofungin, which is a semisynthetic derivative of pneumocandin B_0, a fermentation product of *Glarea lozoyensis*. Caspofungin inhibits the synthesis of the fungal cell wall β(1,3)-D-glucan by noncompetitive inhibition of the enzyme β(1,3)-D-glucan synthase, producing both a fungistatic and a fungicidal effect (64). The compound is administered by slow intravenous infusion and is useful for treating infections by *Candida* and *Aspergillus* sp. (65).



Galanthamine

Malaria remains a parasitic scourge that is still extending in incidence. In 1972, the active principle from *Artemisia annua*, a plant used for centuries in Chinese traditional medicine to treat fevers and malaria, was established as a novel antimalarial chemotype. This compound, artemisinin ("qinghaosu" in Chinese), is a sesquiterpene lactone with an endoperoxide group that is essential for activity, and it reacts with the iron in heme in the malarial parasite, *Plasmodium falciparum* (Fig. 1.3). Because this compound is poorly soluble in water, a number

of derivatives have been produced with improved formulation, including arteether and artemether. Animal experiments have suggested that artemisinin derivatives are neurotoxic, but this may not be the case in patients with malaria (1,2,3,4). Artemisinin-based combination treatments, such as coartemether (artemether and lumefantrine), are now widely used for treating drug-resistant falciparum malaria (66). Coartemether also is known as Artemisinin Combination Therapy and is registered in approximately 75 countries. A second ether derivative of artemisinin, arteether, also has been developed and is registered in the Netherlands (67).

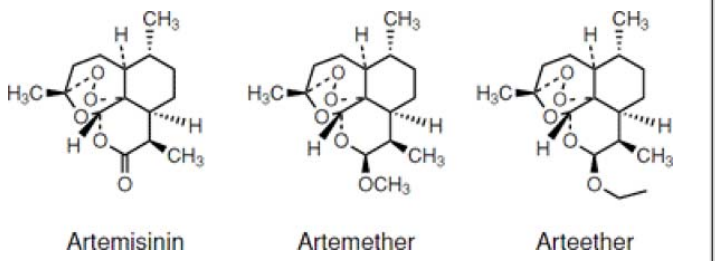


Fig. 1.3. Artemisins used for the treatment of malaria.

Anticancer Agents

For several decades, natural products have served as a very useful group of structurally diverse cancer chemotherapeutic agents, and many of our most important anticancer agents are of microbial or plant origin. Thus, the antitumor antibiotics include the anthracyclines (daunorubicin, doxorubicin, epirubicin, idarubucin, and valrubucin), bleomycin, dactinomycin (actinomycin D), mitomycin C, and mitoxantrone. Four main classes of plant-derived antitumor agents are used—namely, the vinca (*Catharanthus* sp.) bisindole alkaloids (vinblastine, vincristine, and vinorelbine), the semisynthetic epipodophyllotoxin derivatives (etoposide, teniposide, and etoposide phosphate), the taxanes (paclitaxel and docetaxel), and the camptothecin analogues (irinotecan and topotecan) (1,2,3,4).

The parent compounds, paclitaxel (originally called “taxol”) and camptothecin, were both discovered in the laboratory of the late Monroe E. Wall and Mansukh Wani at Research Triangle Institute in North Carolina (Fig. 1.4). Like some other natural product drugs, several years elapsed between the initial discovery of these substances and their ultimate clinical approval in either a chemically unmodified or modified form (68). One of the factors that served to delay the introduction of paclitaxel to the market was the need for the large-scale acquisition of this compound from a source other than from the bark of its original plant of origin, the Pacific yew, *Taxus brevifolia*, because this would involve destroying the slow-growing tree. Presently, paclitaxel and its semisynthetic analogue docetaxel are produced by partial synthesis. To enable this, the diterpenoid “building block,” 10-deacetylbaccatin III, is used as a starting material. This material can be isolated from the needles of the ornamental yew, *Taxus baccata*, a renewable botanical resource that can be cultivated in greenhouses (68).

P.21

P.22

The initial source plant of camptothecin, *Camptotheca acuminata*, is a rare species found in southern regions of the People's Republic of China. Today, camptothecin is produced commercially not only from cultivated *C. acuminata* trees in mainland China but also from the roots of *Nothapodytes nimmoniana* (formerly known as both *N. foetida* and *Mappia foetida*), which is found in the southern regions of the Indian subcontinent (69). Interestingly, these two antineoplastic agents are particularly important both because of the clinical effectiveness of their derivatives as cancer chemotherapeutic agents and because they are prominent lead

compounds for synthetic optimization. Numerous taxanes and camptothecin derivatives are now in clinical trials (43,44). Endophytic fungi also have been reported to produce paclitaxel (29) and camptothecin (70), so in the future, it may be possible to produce these important compounds by fermentation rather than by cultivation. Paclitaxel and camptothecin were each found to exhibit a unique mechanism of action for the inhibition of cancer cell growth: Paclitaxel promotes the polymerization of tubulin and the stabilization of microtubules, whereas camptothecin was the first inhibitor of the enzyme DNA topoisomerase I (68).

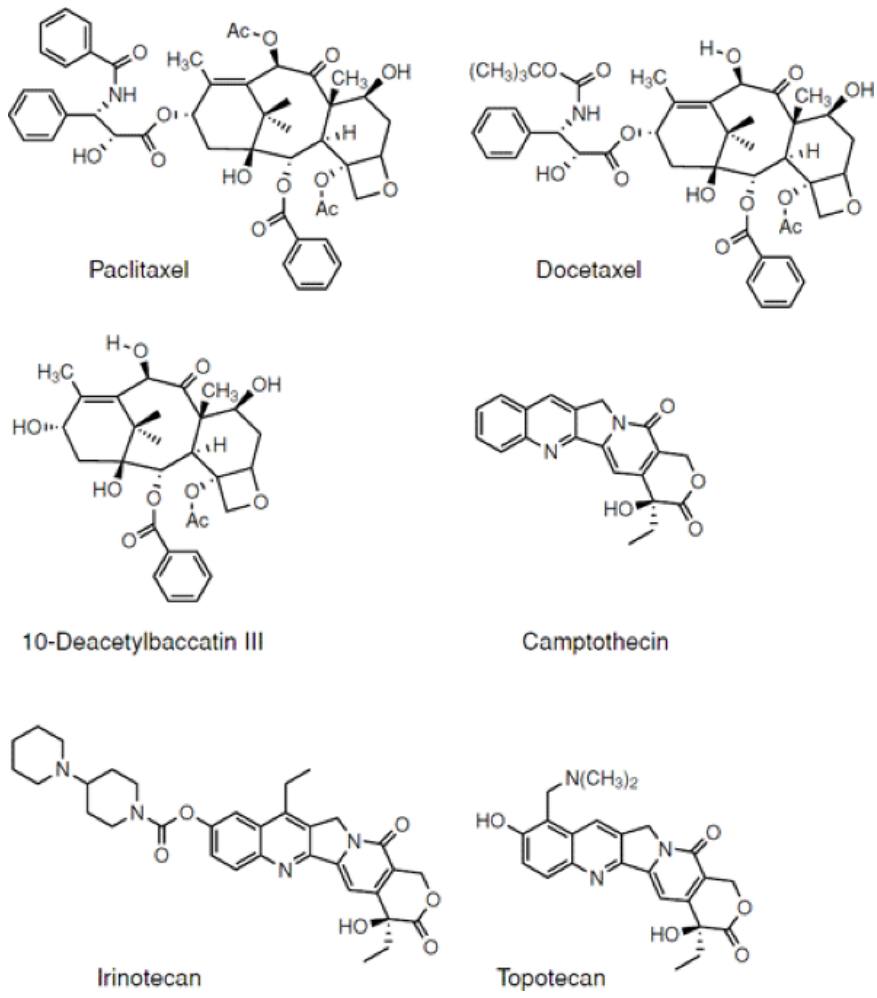

Fig. 1.4. Lead anticancer drugs paclitaxel and camptothecin and their respective derivatives.

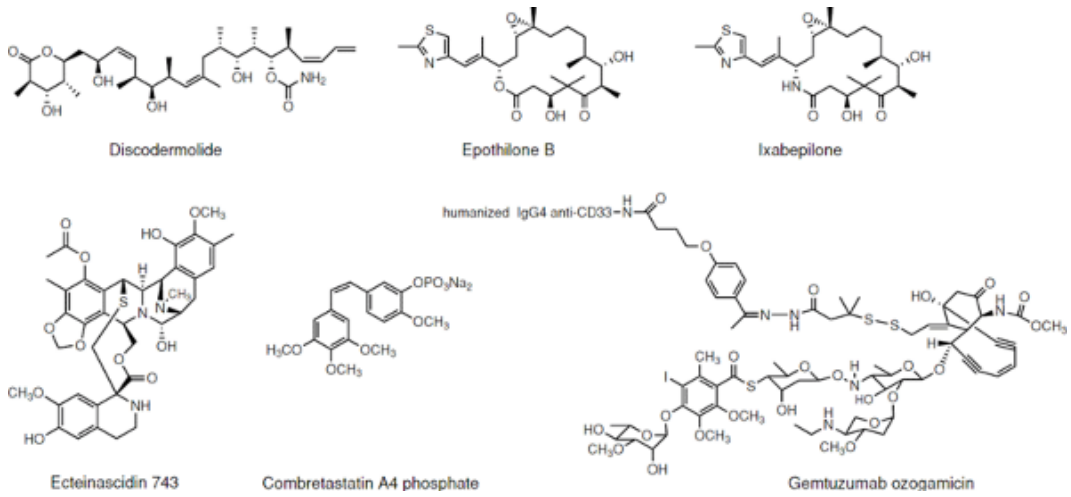

Fig. 1.5. Potential anticancer chemotherapeutic agents from marine, bacterial, plant, and fungal origin.

A large number of other new natural products of diverse origin have great potential for future therapeutic use as anticancer agents. Several other natural product molecules or their derivatives have been shown to have a action similar to that of paclitaxel against tubulin and are now either in clinical trials or preclinical development; these include dictyostatin-1, eleutherobin, laulimalide, and sarcodictyin, all of which are marine origin (6,43,44,71). Also included in this group are discodermolide, a polyketide lactone from the marine sponge, *Discodermia dissoluta*, which has now been synthesized (71,72), and several epothilones from the terrestrial myxobacterium *Sorangium cellulosum*, of which epothilone B and its semisynthetic derivative ixabepilone are representative (Fig. 1.5) (70,73). Two further examples of promising new anticancer agents are combretastatin A4 phosphate, a water-soluble prodrug of combretastatin A4 from the South African plant, *Combretum caffrum*, and ecteinascidin 743 (ET-743; trabectedin), biosynthesized from the marine tunicate, *Ecteinascidia turbinata*, but now produced by partial synthesis from a microbial metabolite (Fig. 1.5). Combretastatin A4 phosphate binds to tubulin and also affects tumor blood flow, and it is being evaluated along with other cytotoxic agents and radiotherapy (70,74). It binds to the minor groove of DNA, blocks cells in the G_2/M phase, and is being evaluated in patients with soft-tissue sarcoma (70,75). An example of a natural product derivative that has been recently introduced into cancer chemotherapy is gemtuzumab ozogamicin (Fig. 1.5). This is a conjugated molecule in which the highly active enediyne DNA-damaging agent component, calichaemicin γ1, produced by *Micromonospora echinospora*, is linked to a monoclonal antibody that binds specifically to the CD33 cell-surface antigen of acute myeloid leukemic cells, where the enediyne is released (8,76).

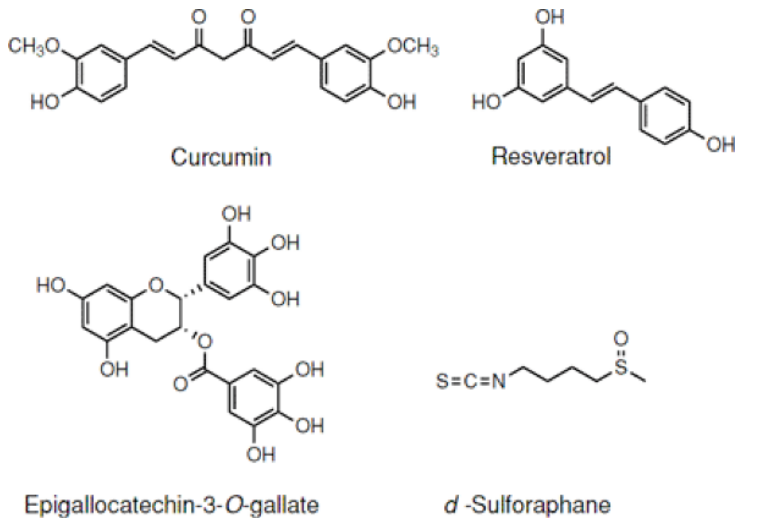

Fig. 1.6. Natural occurring chemopreventive agents.

Cancer chemoprevention is regarded as the use of synthetic or natural agents to inhibit, delay, or reverse the process of carcinogenesis through intervention before the appearance of invasive disease. This new approach toward the management of cancer has involved gaining a better understanding of the mechanism of action by cancer chemopreventive agents (77). Among the natural products that have been studied for this purpose, there has been a renewed interest in the effects of the phytochemical components of the diet, and some of these compounds have been found to block cancer initiation ("blocking agents") or to reverse tumor promotion and/or progression ("suppressing agents") (77). Members of many different structural types of plant secondary metabolites have been linked to potential cancer chemopreventive activity (78). Recently, approximately 35 foods of plant origin have been found to produce cancer chemopreventive agents, such as curcumin from turmeric, epigallocatechin 3-*O*-gallate from green tea, *trans*-resveratrol from grapes and certain red wines, and *d*-sulforaphane from broccoli (Fig. 1.6) (79).

Immunomodulators

The fungal-derived cyclic peptide cyclosporine (cyclosporin A) was found some years ago to be an immunosuppressive agent in organ and tissue transplant surgery. Another compound with this same type of use and that also acts by the inhibition of T-cell activation is the macrolide tacrolimus (FK-506), from *Streptomyces tsukubaensis* (2).

Two further natural product–derived immunosuppressants have been introduced recently, mycophenolate sodium and everolimus (Fig. 1.7) (44). The active principle of both mycophenolate sodium and an earlier introduced form, mycophenolate mofetil (a morpholinoethyl derivative), is mycophenolic acid, obtained from several *Penicillium* sp. This compound is a reversible inhibitor of inosine monophosphate dehydrogenase, which is involved in guanosine nucleotide synthesis (80).

Everolimus is an orally active, semisynthetic 40-*O*-(2-hydroxyethyl) derivative of rapamycin (also known as sirolimus) and was originally obtained from *Streptomyces hygroscopicus*. Everolimus is a proliferation inhibitor that blocks growth factor–mediated signal transduction and prevents organ rejection through a different mechanism than mycophenoliate mofetil (81).

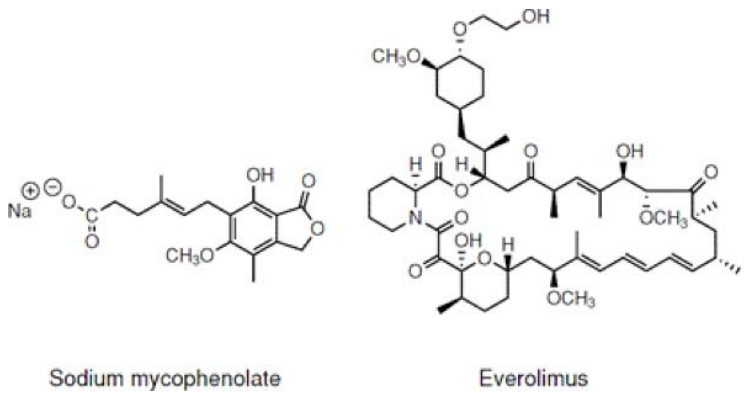

Fig. 1.7. Natural occurring immunosuppressants.

Botanical Dietary Supplements

The use of phytomedicines (herbal remedies) as prescription products has been well established in Germany and several other countries of Western Europe for approximately 25 years. Approximately 80% of physicians in Germany prescribe phytomedicines through the orthodox health care system. During the last decade, there has been a large influx of botanical products into community pharmacy practice and health food stores in the United States as a result of the Dietary Supplement Health and Education Act in 1994. Such products are regulated by the U.S. Food and Drug Administration as foods rather than drugs, and they must adhere to requirements in regard to product labeling and acceptable health claims (82). Currently, among the most popular botanical products used in the United States are those containing black cohosh, cranberry, echinacea, evening primrose, garlic, ginkgo, ginger, ginseng, green tea, milk thistle, saw palmetto, soy, St. John's wort, and valerian. These are purchased as either the crude powdered form in compressed tablets or capsules or as galenical preparations, such as extracts or tinctures, and they frequently are ingested in the form of a tea (82). In addition to the United States, a parallel increased interest in herbal remedies has occurred in Europe, Canada, and Australia, in part because of a greater awareness of complementary and alternative medicine. Many clinical trials focusing on these products have been conducted in Europe, and some are occurring in the United States under the sponsorship of the National Institutes of Health.

The recent widespread introduction of a large number of botanical dietary supplements has opened a new door in terms of research inquiry for natural product scientists in the United States. Not all of these products, however, have a well-documented efficacy (82). Three important needs in the scientific investigation of herbal remedies are the characterization of active principles (when these are not known), the development of rigorous and validated analytical methods for quality-control procedures, and the determination of potential toxicity and interactions with prescription medications (83). Unlike compounds approved as single-chemical drugs, it is accepted that combinations of plant secondary metabolites may be responsible for the physiological effects of herbal medicines. For example, both the terpene lactone (e.g., ginkgolide B) (Fig. 1.8) and flavonoid glycoside constituents of *Ginkgo biloba* leaves are regarded as being necessary for mediation of the symptoms of peripheral vascular disease, for which this phytomedicine is used in Europe (82). Moreover, an acetone-soluble extract of *G. biloba* containing standardized amounts of flavone glycosides (24%) and terpene lactones (6%) has been used in many clinical trials on this herb (82). If the “active principles” of an herbal remedy are known or can be discovered, these substances can act as reference standards, and their specified concentration levels can be quantified in chemical quality-control procedures, which are predominantly performed by HPLC. A number of official monographs for the standardization of botanical dietary supplements have been developed over the last decade in the United States (84). Other scientific challenges regarding herbal remedies are to establish more completely their dissolution, bioavailability, and shelf life. These products should be free of adulteration (the deliberate addition of nonauthentic plant material or of biologically active or

inactive compounds); free of other additives, such as herbicides, pesticides, heavy metals, and solvent residues; and free of microbial and biological contaminants (82,83,84).

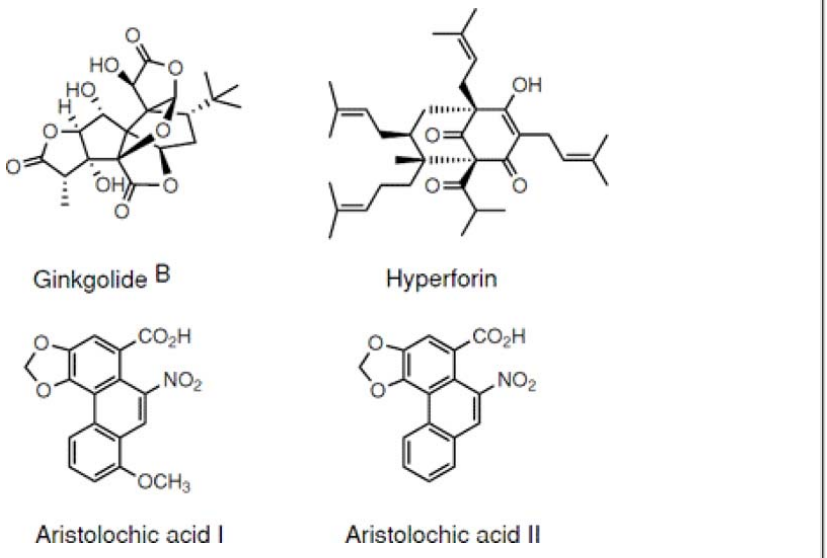

Fig. 1.8. Chemicals found in various phytomedicinal remedies.

Unfortunately, many herbal remedies may pose toxicity risks or be involved in harmful drug interactions. A drastic example of toxicity caused by a herbal product involves to the Chinese medicinal plant *Aristolochia fangchi*, which was

substituted in error for another Chinese plant in a weight-reducing regimen taken by a number of women in Belgium approximately 15 years ago. Several years later, this product was linked to the generation of severe renal disease, characterized as interstitial fibrosis with atrophy of the tubules, as well as the development of tumors. These toxic symptoms, also known as “Chinese herb nephropathy,” were attributed to the presence of the phenanthrene derivatives, aristolochic acids I and II (Fig. 1.8), produced by *A. fangchi*, which have been found experimentally to intercalate with DNA (85). The presence of high levels of the phloroglucinol derivative hyperforin (Fig. 1.8) in St. John's wort, *Hypericum perforatum*, products has been found to induce cytochrome P450 enzymes (particularly CYP34A), leading to decreased plasma concentrations of prescription drugs that are coadministered, such as alprazolam, cyclosporine, digoxin, indinavir, irinotecan, simvastatin, and warfarin, as well as oral contraceptives (86).

Future Prospects

The beginning years of the twenty-first century seem opportune for renewed efforts to be made in regard to the discovery of new secondary-metabolite, prototype biologically active compounds from animals, fungi, microorganisms, and plants of both terrestrial and marine origin. Although many pharmaceutical companies have reduced their investment in natural product research in favor of screening libraries of synthetic compounds and combinatorial chemistry, this has coincided with disappointing numbers of single-chemical entities being introduced as new drugs in recent years (8,11,13). Fortunately, many smaller “biotech” companies have actively taken up the challenge of contemporary natural product drug discovery from organisms (87). There continues to be a steady stream of new natural product–derived drugs introduced for the treatment of many common human diseases (e.g., cancer, cardiovascular diseases, neurological conditions) (13,43). There is ample potential, however, for much greater utilization of natural product–derived compounds in the treatment or prophylaxis of such major worldwide scourges as HIV/AIDS, tuberculosis, hepatitis C, and tropical diseases (inclusive of lymphatic filariasis, leishmaniasis, and schistosomiasis). The search for such agents should be enhanced by the availability of extensive libraries of taxonomically authenticated crude extracts of terrestrial and

marine origin as well as pure secondary metabolites from microorganisms, plants, and animals. In addition, this will be facilitated by recently developed techniques, such as biocatalysis, combinatorial biosynthesis, combinatorial and computational chemistry, metabolic engineering, and tissue culture. The high “drug-like” quality of natural product molecules stands as a constant, and it only remains for natural product chemists and biologists to investigate these substances in the most technically ingenious and expedient ways.

It should not be thought that, after approximately 200 years of investigation, the prospects of finding new drugs of natural origin are nearing exhaustion; much hope for success remains in this type of endeavor. For example, if one considers plants, less than 20% have been evaluated chemically or biologically. Moreover, of approximately 21,000 alkaloids, which are mainly of plant origin, approximately 75% have never been subjected to testing in a bioassay (87). The urgency of performing this type of work cannot be understated in view of the increasing erosion of natural resources that will accelerate as the twenty-first century progresses.

Chapter 2

Drug Design and Relationship of Functional Groups to Pharmacologic Activity

Medicinal chemistry is the discipline concerned with determining the influence of chemical structure on biological activity. As such, it is necessary for the medicinal chemist to understand not only the mechanism by which a drug exerts its effect but also the physicochemical properties of the molecule. The term “physicochemical properties” refers to the influence of the organic functional groups within a molecule on its acid-base properties, water solubility, partition coefficient, crystal structure, stereochemistry, and so on. All these properties influence the absorption, distribution, metabolism excretion, and toxicity of the molecule. To design better medicinal agents, the medicinal chemist needs to understand the relative contributions that each functional group makes to the overall physicochemical properties of the molecule. Studies of this type involve modification of the molecule in a systematic fashion and determination of how these changes affect biological activity. Such studies are referred to as studies of structure–activity relationships (SARs)—that is, what structural features of the molecule contributes to, or takes away from, the desired biological activity of the molecule of interest.

Because of the fundamental nature of the subject matter, this chapter includes numerous case studies throughout (as boxes) as well as at the end. In addition, a list of study questions at the end of—and unique to—this chapter provides further self-study material regarding the subject of drug design.

Introduction

Chemical compounds, usually derived from plants and other natural sources, have been used by humans for thousands of years to alleviate pain, diarrhea, infection, and various other maladies. Until the nineteenth century, these “remedies” were primarily crude preparations of plant material of unknown constitution. The revolution in synthetic organic chemistry during the nineteenth century produced a concerted effort toward identification of the structures of the active constituents of these naturally derived medicinals and synthesis of what were hoped to be more efficacious agents. By determining the molecular structures of the active components of these complex mixtures, it was thought that a better understanding of how these components worked could be elucidated.

Relationship Between Molecular Structure and Biological Activity

Early studies of the relationship between chemical structure and biological activity were conducted by Crum-Brown and Fraser (1) in 1869. They showed that many compounds containing tertiary amine groups became muscle relaxants when converted to quaternary ammonium compounds. Compounds with widely differing pharmacologic properties, such as strychnine (a convulsant), morphine (an analgesic), nicotine (deterrent, insecticide), and atropine (anticholinergic), could be converted to muscle relaxants with properties similar to those of tubocurarine when methylated (Fig. 2.1). Crum-Brown and Fraser therefore concluded that muscle-relaxant activity required a quaternary ammonium group

within the chemical structure. This initial hypothesis was later disproven by the discovery of the natural neurotransmitter and activator of muscle contraction, acetylcholine (Fig. 2.2). Even though Crum-Brown and Fraser's initial hypothesis concerning chemical structure and muscle relaxation was incorrect, it demonstrated the concept that molecular structure influences the biological activity of chemical compounds.

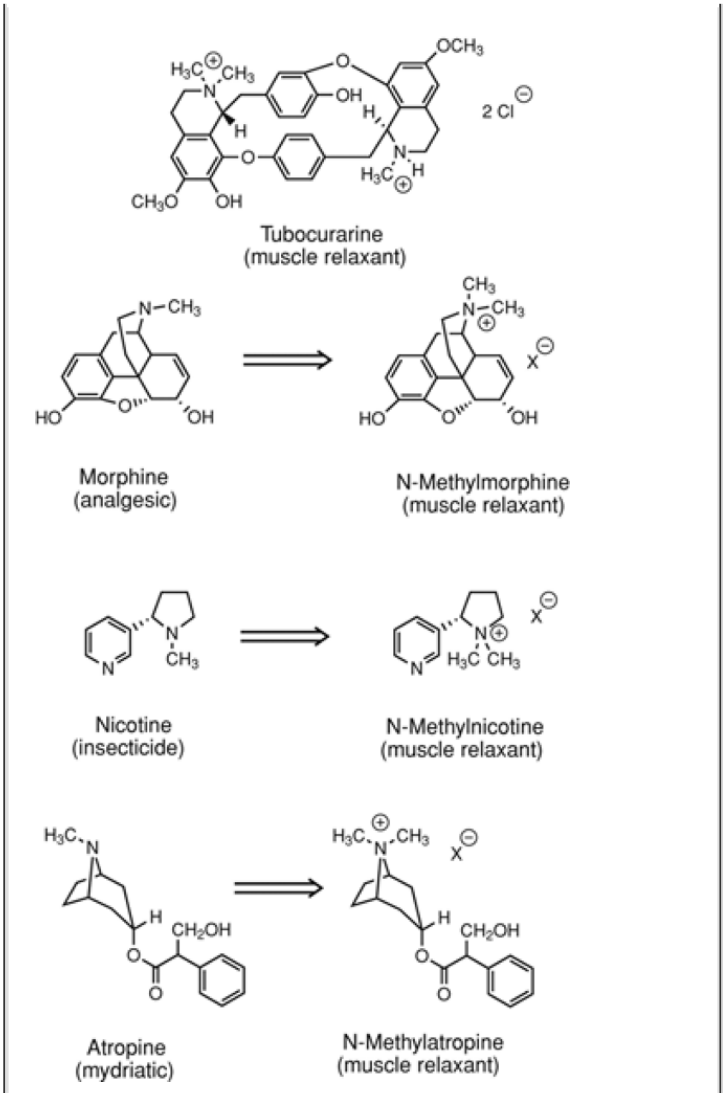

Fig. 2.1. Effects of methylation on biological activity.

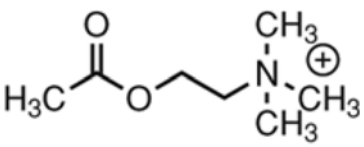

Fig. 2.2. Acetylcholine, a neurotransmitter and muscle relaxant.

With the discovery by Crum-Brown and Fraser that quaternary ammonium groups could produce compounds with muscle-relaxant properties, scientists began looking for other organic functional

groups that would produce specific biological responses. The thinking during this time was that specific chemical groups, or nuclei (rings), were responsible for specific biological effects. This lead to the postulate, which took some time to disprove, that “one chemical group gives one biological action” (2). Even after the discovery of acetylcholine by Loewi and Navrati (3), which effectively dispensed with Crum-Brown and Fraser's concept of all quaternary ammonium compounds being muscle relaxants, this was still considered to be dogma and took a long time to replace.

Selectivity of Drug Action and Drug Receptors

Although the structures of many drugs or xenobiotics, or at least the composition of functional groups, were known at the start of the twentieth century, how these compounds exerted their effects was still a mystery. Utilizing his observations regarding the staining behavior of microorganisms, Ehrlich (4) developed the concept of drug receptors. He postulated that certain “side chains” on the surfaces of cells were “complementary” to the dyes (or drug), thereby allowing the two substances to combine. In the case of antimicrobial compounds, this combining of the chemical to the “side chains” produced a toxic effect. This concept effectively was the first description of what later became known as the receptor hypothesis for explaining the biological action of chemical compounds. Ehrlich also discussed selectivity of drug action via the concept of a “magic bullet” for compounds that would eradicate disease states without producing undue harm to the organism being treated (i.e., the patient). This concept was later modified by Albert (5) and generally is referred to as “selective toxicity.” Utilizing this concept, Ehrlich developed organic arsenicals that were toxic to trypanosomes as a result of their irreversible reaction with mercapto groups (-SH) on vital proteins within the organism. The formation of As-S bonds resulted in death to the target organism. It was soon learned, however, that these compounds were toxic not only to the target organism but also to the host once certain blood levels of arsenic were achieved.

The “paradox” that resulted after the discovery of acetylcholine—how one chemical group can produce two different biological effects (i.e., muscle relaxation and muscle contraction)—was explained by Ing (6) using the actions of acetylcholine and tubocurarine as his examples. Ing hypothesized that both acetylcholine and tubocurarine act at the same receptor, but that one molecule fits to the receptor in a more complementary manner and “activates” it, causing muscle contraction. (Ing did not elaborate just how this activation occurred.) The blocking effect of the larger molecule, tubocurarine, could be explained by its occupation of part of the receptor, thereby preventing acetylcholine, the smaller molecule, from interacting with the receptor. With both molecules, the quaternary ammonium functional group is a common structural feature and interacts with the same region of the receptor. If one closely examines the structures of other compounds with opposing effects on the same pharmacologic system, this appears to be a common theme: Molecules that block the effects of natural neurotransmitters (antagonists) generally are larger in size than the native compound. Both agonists and antagonists share common structural features, however, thus providing support to the concept that the structure of a molecule, its composition and arrangement of chemical functional groups, determines the type of pharmacologic effect that it possesses (i.e., SAR). Thus, compounds that are muscle relaxants acting via the cholinergic nervous system will possess a quaternary ammonium or protonated tertiary ammonium group and will be larger than acetylcholine.

Structure–activity relationships are the underlying principle of medicinal chemistry. Similar molecules exert similar biological actions in a qualitative sense. A corollary to this is that structural elements (functional groups) within a molecule most often contribute in an additive manner to the physicochemical properties of a molecule and, therefore, to its biological action. One need only peruse the structures of drug molecules in a particular pharmacologic class to become convinced of this (e.g., histamine H_1 antagonists, histamine H_2 antagonists, and β-adrenergic antagonists). The objective of medicinal chemists in their quest for better medicinal agents (drugs) is to discover what functional groups within a specific structure are important for its pharmacologic activity and how can these groups be modified to produce more potent, selective, and safer compounds.

An example of how different functional groups can yield compounds with similar physicochemical properties is shown with sulfanilamide antibiotics. In Figure 2.3, the structures of sulfanilamide

and *p*-aminobenzoic acid (PABA) are shown. In 1940, Woods (7) demonstrated that PABA was capable of reversing the antibacterial action of sulfanilamide (and other sulfonamides antibacterials) and that both PABA and sulfanilamide had similar steric and electronic properties. Both compounds contain acidic functional groups, with PABA containing an aromatic carboxylic acid and sulfanilamide an aromatic sulfonamide. When ionized at physiological pH,

both compounds have a similar electronic configuration, and the distance between the ionized acid and the weakly basic amino group also is very similar. It should therefore be no surprise that sulfanilamide acts as an antagonist to PABA metabolism in bacteria.

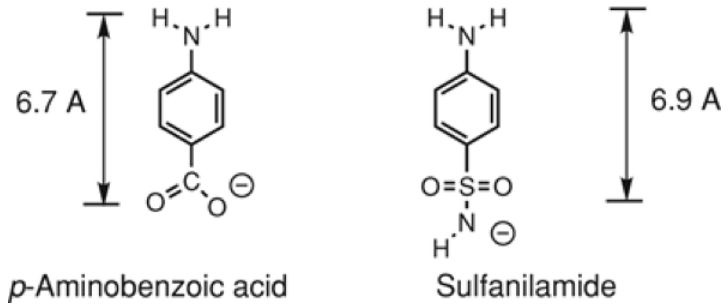

Fig. 2.3. Ionized forms of *p*-aminobenzoic acid (PABA) and sulfanilamide, with comparison of the distance between amine and ionized acids of each compound. Note how closely sulfanilamide resembles PABA.

Physicochemical Properties of Drugs

Acid-Base Properties

The human body is 70 to 75% water, which amounts to approximately 51 to 55 L of water for a 160-lb (73-kg) individual. For an average drug molecule with a molecular weight of 200 g/mol and a dose of 20 mg, this leads to a solution concentration of approximately 2×10^{-6} M. When considering the solution behavior of a drug within the body, we therefore are dealing with a dilute solution, for which the Brönsted-Lowry (8) acid-base theory is most appropriate for explaining and predicting acid-base behavior. This is a very important concept in medicinal chemistry, because the acid-base properties of drug molecules directly affect absorption, excretion, and compatibility with other drugs in solution. According to the Brönsted-Lowry Theory, an "acid" is any substance capable of yielding a proton (H^+), and a "base" is any substance capable of accepting a proton. When an acid gives up a proton to a base, it is converted to its "conjugate base." Similarly, when a base accepts, a proton it is converted to its "conjugate acid" (Eqs. 2.1 and 2.2):

Eq. 2.1 $CH_3COOH + H_2O \rightleftharpoons CH_3COO^{\ominus} + H_3O^{\oplus}$

Acid	Base	Conjugate base	Conjugate acid
(acetic acid)	(water)	(acetate)	(hydronium)

Eq. 2.2 $CH_3NH_2 + H_2O \rightleftharpoons CH_3NH_3^{\oplus} + {}^{\ominus}OH$

Base	Acid	Conjugate acid	Conjugate base
(methylamine)	(water)	(methylammonium)	(hydroxide)

Note that when an acid loses its proton, it is left with an extra pair of electrons that are no longer neutralized by the proton. This is the "ionized" form of the acid and is now more water

soluble because of the charge. Because the acid has lost its proton, it also often is referred to as having undergone “dissociation.” Many different organic functional groups behave as acids, and these are listed in Table 2.1. It is important that the student learn to recognize these functional groups and their relative acid strengths. This will help the student to predict absorption, distribution, excretion, and potential incompatibilities between drugs.

When a base is converted to its conjugate acid, it too becomes ionized. In this instance, however, it becomes positively charged because of the presence of the extra proton. Most basic drugs usually are derived from primary, secondary, and tertiary amines or imino amines, such as guanidines and amidines. Other organic functional groups that act as bases are shown in Table 2.2. Again, the student should become familiar with these functional groups and be able to readily recognize them by name and relative strengths.

Organic functional groups that cannot give up or accept a proton are considered to be “neutral” (or “nonelectrolytes”) with respect to their acid-base properties. Common functional groups of this type are shown in Table 2.3. In the case of quaternary ammonium compounds, the molecule is not electrically neutral, even though it is neither acidic nor basic. Additional reading on the acid-base behavior of the functional groups listed in Tables 2.1 through 2.3 can be found in Gennaro (9) and Lemke (10). Further review of organic functional groups and their acid-base properties can be found at http://www-home.cr.duq.edu/~harrold/.

A molecule may contain multiple functional groups and, therefore, possess both acidic and basic properties. For example, ciprofloxacin (Fig. 2.4), a fluoroquinolone antibiotic, contains a secondary alkylamine, two tertiary arylamines (aniline-like amines), and a carboxylic acid. The two arylamines are weakly basic and, therefore, do not contribute significantly to the acid-base properties of ciprofloxacin. Depending on the pH of the solution (or tissue), this molecule will either accept a proton (secondary alkylamine), yield a proton (carboxylic acid), or both. Thus, it is amphoteric (both acidic and basic) in its properties. Figure 2.5 shows the acid-base behavior of ciprofloxacin at two different locations of the gastrointestinal tract. Note that at a given pH (e.g., pH 1.0–3.5), only one of the functional groups (the alkylamine) is ionized. To be able to make this prediction, one has to understand the relative acid-base strength of acids and bases. Thus, one needs to know which acid or base within a molecule containing multiple functional groups is the strongest and which acid or base is the weakest. The concept of pK_a not only indicates the relative acid-base strength of organic functional groups but also allows one to calculate, for a given pH, exactly how much of the molecule is in the ionized and un-ionized form, which therefore allows prediction of relative water solubility, absorption, and excretion for a given compound.

Alkylcarboxylic acid (5-6)			Alkylcarboxylate
Arylcarboxylic acid (4-5)			Arylcarboxylate
Sulfonic acid (0-1)			Sulfonate

Acid strength usually increases as one moves down the table.

Table 2.1. Common Acidic Organic Functional Groups and Their Ionized (Conjugate Base) Forms

Relative Acid Strength (pK_a)

Strong acids and bases completely dissociate or accept a proton in aqueous solution to produce their respective conjugate bases and acids. For example, mineral acids, such as HCl, or bases, such as NaOH, undergo 100% dissociation in water, with the equilibrium shifted completely to the right side, as shown in Equations 2.3 and 2.4:

$$\text{Eq. 2.3} \qquad HCl + H_2O \rightleftharpoons Cl^{\ominus} + H_3O^{\oplus}$$

$$\text{Eq. 2.4} \qquad NaOH + H_2O \rightleftharpoons Na^{\oplus} + OH^{\ominus} + H_2O$$

Acids and bases of intermediate or weak strength, however, incompletely dissociate or accept a proton, and the equilibrium lies somewhere in between. The equilibrium is such that all possible species may exist. Note that in Equations 2.3 and 2.4, water is acting as a base in one instance and as an acid in the other. Water is amphoteric—that is, it may act as an acid or a base, depending on the conditions. Because we are always dealing with a dilute aqueous solution, the strongest base that can be present is OH^-, and the strongest acid is H_3O^+. This is known as the "leveling effect" of water. Thus, some organic functional groups that are considered to be acids or bases with respect to their chemical reactivity do not behave as such under physiological conditions in aqueous solution. For example, alkyl alcohols, such as ethyl alcohol, are not sufficiently acidic to undergo ionization to a significant extent in aqueous solution. Water is not sufficiently basic to remove the proton from the alcohol to form the ethoxide ion (Eq. 2.5). Therefore, under physiological conditions, alcohols may be considered to be neutral with respect to acid-base properties:

$$\text{Eq. 2.5} \qquad CH_3CH_2OH + H_2O \rightleftharpoons CH_3CH_2O^- + H_3O^{\oplus}$$

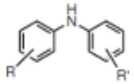
Arylamine (9-11)			Arylammonium
Aromatic amine (5-6)			Aromatic ammonium
Imine (3-4)			Iminium
Alkylamines (2^0 - 10-11) (1^0 - 9-10)			Alkylammonium
Amidine (10-11)			Amidinium
Guanidine (12-13)			Guanidinium

Table 2.2. Common Basic Organic Functional Groups and Their Ionized (Conjugate Acid) Forms

Predicting the Degree of Ionization of a Molecule

From general principles, it is possible to predict if a molecule is going to be ionized or un-ionized at a given pH simply by knowing if the functional groups on the molecule are acidic or basic. To be able to quantitatively predict the degree of ionization of a molecule, however, one must know the pK_a values of the acidic and basic functional groups that are present and the pH of the environment to which the compound will be exposed. The Henderson-Hassalbach equation (Eq. 2.6) can be used to calculate the percentage ionization of a compound at a given pH (this equation was used to calculate the major forms of ciprofloxacin in Fig. 2.5):

$$\text{Eq. 2.6} \qquad pK_a = pH + \log \frac{[\text{acid form}]}{[\text{base form}]}$$

			
Alkyl alcohol	Ether	Ester	Sulfonic acid ester
			


Amide	Diarylamine	Nitrile	Quaternary ammonium
			Amine oxide	Ketone & Aldehyde	Thioether	Sulfoxide Sulfone

Table 2.3. Common Organic Functional Groups That Are Considered Neutral Under Physiologic Conditions

The key to understanding the use of the Henderson-Hassalbach equation for calculating percentage ionization is to realize that this equation relates a constant, pK_a, to the ratio of acidic form to the basic form of the drug. Because pK_a is a constant for any given molecule, the ratio of acid to base will determine the pH of the solution. Conversely, a given pH determines the ratio of acid to base. A sample calculation is shown in Figure 2.6 for the sedative hypnotic amobarbital.

When dealing with a base, the student must recognize that the conjugate acid is the ionized form of the drug. Thus, as one should expect, a base behaves in a manner opposite to that of an acid. Figure 2.7 shows the calculated percentage ionization for the decongestant phenylpropanolamine. It is very important to recognize that for a base, the pK_a refers to the conjugate acid or ionized

form of the compound. To thoroughly comprehend this relationship, the student should calculate the percentage ionization of an acid and a base at different pH values.

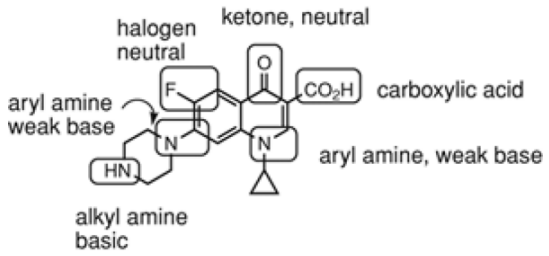


Fig. 2.4. Chemical structure of ciprofloxacin showing the various organic functional groups.

Water Solubility of Drugs

The solubility of a drug molecule in water greatly affects the routes of administration that are available as well as its absorption, distribution, and elimination. Two key concepts to keep in mind when considering the water (or fat) solubility of a molecule are the hydrogen bond–forming potential of the functional groups in the molecule and the ionization of functional groups.

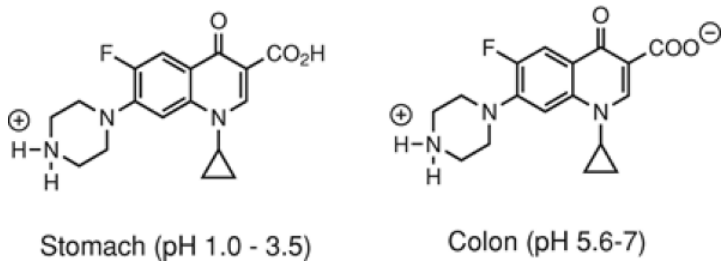

Fig. 2.5. Predominate forms of ciprofloxacin at two different locations within the gastrointestinal tract.

Hydrogen Bonds

Each functional group capable of donating or accepting a hydrogen bond will contribute to the overall water solubility of the compound and increase the hydrophilic (water-loving) nature of

the molecule. Conversely, functional

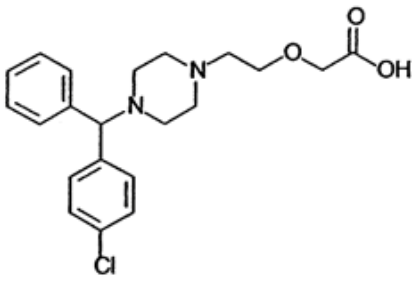
P.32

groups that cannot form hydrogen bonds will not enhance hydrophilicity and will actually contribute to the hydrophobicity (water-hating) nature of the molecule. Hydrogen bonds are a special case of what generally are referred to as dipole–dipole bonds. Dipoles result from unequal sharing of electrons between atoms within a covalent bond. This unequal sharing of electrons results when two atoms involved in a covalent bond have significantly different electronegativities. As a result, partial ionic character develops between the two atoms, producing a permanent dipole—that is, one end of the covalent bond has higher electron density than the other. When two molecules containing dipoles approach one another, they align such that the negative end of one dipole is electrostatically attracted to the positive end of the other. When the positive end of the dipole is a hydrogen atom,

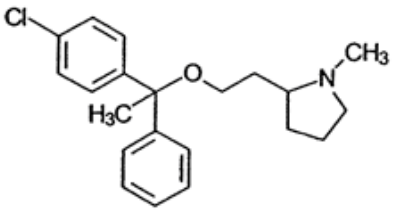
P.33

this interaction is referred to as a “hydrogen bond” (or H-bond). Thus, for a hydrogen bond to occur, at least one dipole must contain an electropositive hydrogen. The hydrogen atom must be involved in a covalent bond with an electronegative atom, such as oxygen (O), nitrogen (N), sulfur (S) or selenium (Se). Of these four elements, only oxygen and nitrogen contribute significantly to the dipole, and we will therefore concern ourselves only with the hydrogen-bonding capability of OH and NH groups. (This is only in reference to functional groups that “donate” hydrogen bonds.)

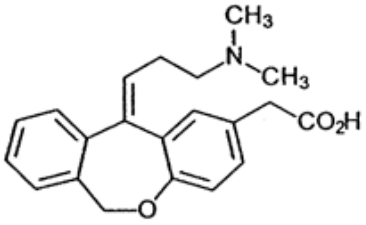
Absorption/Acid-Base Case



Cetirizine (Zyrtec)



Clemastine (Tavist)



Olopatadine (Patanol)

A long-distance truck driver comes into the pharmacy complaining of seasonal allergies. He asks you to recommend an agent that will act as an antihistamine but that will not cause drowsiness. He regularly takes TUMS for indigestion because of the bad food that he eats while on the road.

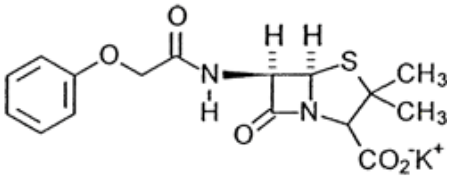
1. Identify the functional groups present in Zyrtec and Tavist, and evaluate the effect of each functional group on the ability of the drug to cross lipophilic membranes (e.g., blood-brain barrier). Based on your assessment of each agent's ability to cross the blood-brain barrier (and, therefore, potentially cause drowsiness), provide a rationale for whether the truck driver should be taking Zyrtec or Tavist.
2. Patanol is sold as an

aqueous solution of the hydrochloride salt. Modify the structure above to show the appropriate salt form of this agent. This agent is applied to the eye to relieve itching associated with allergies. Describe why this agent is soluble in water and what properties make it able to be absorbed into the membranes that surround the eye.

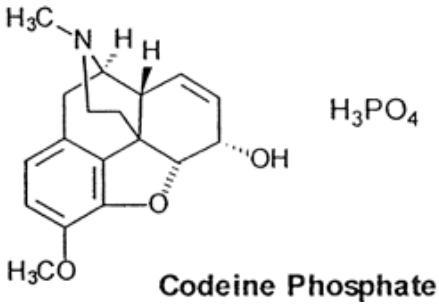
3. Consider the structural features of Zyrtec and Tavist. In which compartment (stomach [pH 1] or intestine [pH 6–7]) will each of these two drugs be best absorbed?
4. TUMS neutralizes stomach acid to pH 3.5. Based on your answer to question 3, determine whether the truck driver will get the full antihistaminergic effect if he takes his antihistamine at the same time that he takes his TUMS. Provide a rationale for your answer.

Acid-Base Chemistry/Compatibility Cases

The IV technician in the hospital pharmacy gets an order for a patient that includes the two drugs drawn below. She is unsure if she can mix the two drugs together in the same IV bag and is not certain how water soluble the agents are.

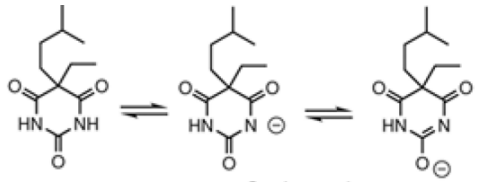


Penicillin V Potassium



Codeine Phosphate

1. Penicillin V potassium is drawn in its salt form, whereas codeine phosphate is not. Modify the structure above to show the salt form of codeine phosphate. Determine the acid-base character of the functional groups in the two molecules drawn above as well as the salt form of codeine phosphate.
2. As originally drawn above, which of these two agents is more water soluble? Provide a rationale for your selection that includes appropriate structural properties. Is the salt form of codeine phosphate more or less water soluble than the free base form of the drug? Provide a rationale for your answer based on the structural properties of the salt form of codeine phosphate.
3. What is the chemical consequence of mixing aqueous solutions of each drug in the same IV bag? Provide a rationale that includes an acid-base assessment.



Acid form
pK_a 8.0

Conjugate base

Question: At a pH of 7.4, what is the percent ionization of amobarbital?

Answer:

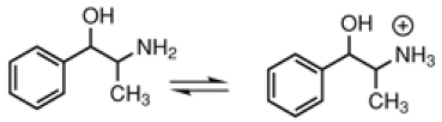
$$8.0 = 7.4 + \log \frac{[\text{acid}]}{[\text{base}]}$$

$$0.6 = \log \frac{[\text{acid}]}{[\text{base}]}$$

$$10^{0.6} = \frac{[\text{acid}]}{[\text{base}]} = \frac{3.98}{1}$$

$$\% \text{ acid form} = \frac{3.98 \times 100}{4.98} = 79.9\%$$

Fig. 2.6. Calculation of percentage ionization of amobarbital. Calculation indicates that 80% of the molecules are in the acid (or protonated) form, leaving 20% in the conjugate base (ionized) form.



Base form

Conjugate acid form
pK_a 9.4

Question: What is the % ionization of phenylpropanolamine at pH 7.4?

Answer:

$$9.4 = 7.4 + \log \frac{[\text{acid}]}{[\text{base}]}$$

$$2.0 = \log \frac{[\text{acid}]}{[\text{base}]}$$

$$10^2 = \frac{[\text{acid}]}{[\text{base}]} = \frac{100}{1}$$

$$\% \text{ ionization} = \frac{100 \times 100}{101} = 99\%$$

Fig. 2.7. Calculation of percentage ionization of phenylpropanolamine. Calculation indicates that 99% of the molecules are in the acid form, which is the same as the percentage ionization.

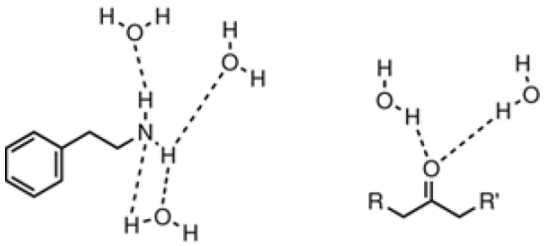


Fig. 2.8. Examples of hydrogen-bonding between water and hypothetical drug molecules.

Even though the energy involved for each hydrogen bond is small (1–10 kcal/mol/bond), it is the additive nature of multiple hydrogen bonds that contributes to water solubility. We will see in Chapter 4 that this same bonding interaction also is important in drug–receptor interactions. Figure 2.8 shows several possible hydrogen bond types that may occur with different organic functional groups and water. As a general rule, the more hydrogen bonds that are possible, the greater the water solubility of the molecule. Table 2.4 lists several common organic functional groups and the number of potential hydrogen bonds for each. Note that this table does not take into account the possibility of intramolecular hydrogen bonds that could form. Each intramolecular hydrogen bond decreases water solubility (and increases lipid solubility), because one less interaction with solvent occurs.

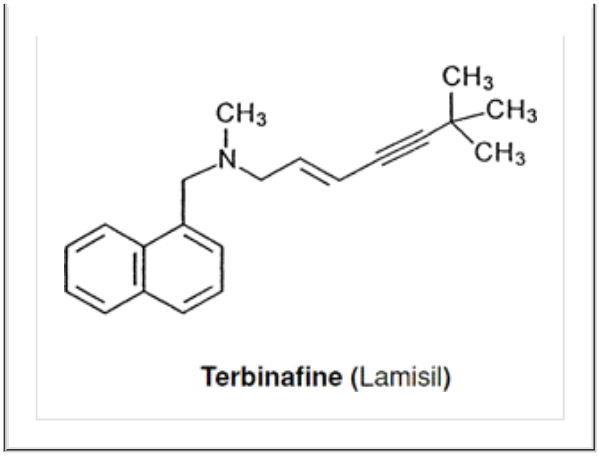
Table 2.4. Common Organic Functional Groups and Their Hydrogen-Bonding Potential

Absorption/Binding Interactions Case

A 24-year-old man comes into the pharmacy and asks you to recommend a treatment for the itching and burning he has recently noticed on both feet. He indicates that he would prefer a cream rather than a spray or a powder. Your recommendation to this patient is to use Lamisil®, a very effective topical antifungal agent that is sold over-the-counter.



Terbinafine (Lamisil)

1. Identify the structural characteristics and the corresponding properties that make terbinafine an agent that can be utilized topically.
2. The biological target of drug action for terbinafine is squalene epoxidase. Consider each of the structural features of this antifungal agent, and describe the type of interactions that the drug will have with the target for drug action. Which amino acids are likely to be present in the active site of this enzyme?

Ionization

In addition to the hydrogen-bonding capability of a molecule, another type of bonding interaction plays an important role in determining water solubility: ion–dipole interaction. This type of interaction comes into play when one deals with organic salts. Ion–dipole interactions develop between either a cation or anion and a formal dipole, such as water. A cation, having a deficiency in electron density, will be attracted to regions of high electron density. When dealing with water, this would be the two lone pairs of electrons associated with the oxygen atom. An anion will associate with regions of low electron density or the positive end of the dipole. In the case of water as solvent, this would be the hydrogen atoms (Fig. 2.9).

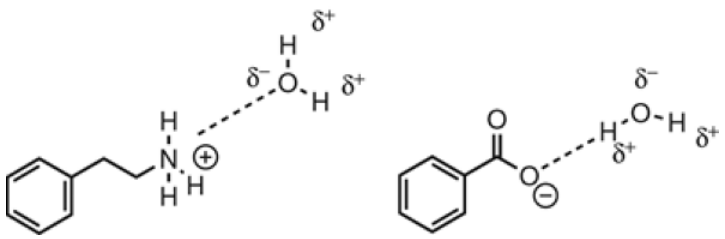


Fig. 2.9. Examples of ion–dipole interactions.

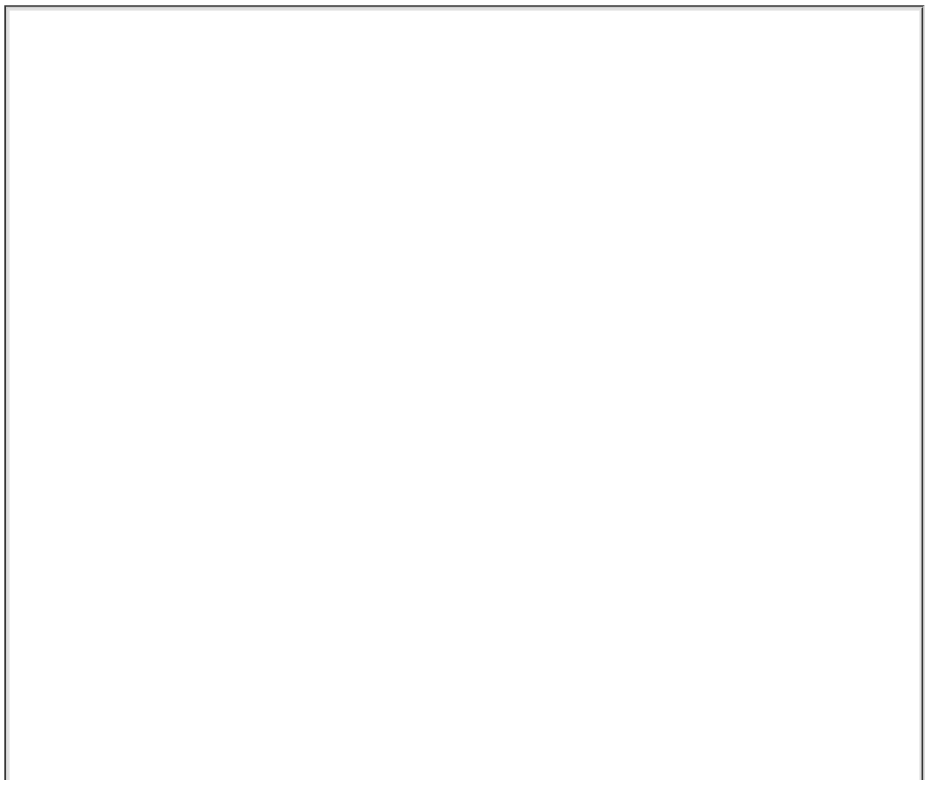
P.34

Not all organic salts are necessarily very water soluble. To associate with enough water molecules to become soluble, the salt must be highly dissociable; in other words, the cation and anion must be able to separate and interact with water molecules. Highly dissociable salts are those formed from strong acids with strong bases (e.g., sodium chloride), weak acids with strong

bases (e.g., sodium phenobarbital), or strong acids with weak bases (e.g., atropine sulfate). Examples of strong acids (strong acids are 100% ionized in water [i.e., no ionization constants or pK_a values of <1]) include the hydrohalic acids (hydrochloric, hydrobromic, and hydrofluoric), sulfuric, nitric, and perchloric acid. All other acids are partially ionized with pK_a values from 1–14 and are therefore considered to be moderate or weak acids, such as phosphoric, tartaric and acetic acids. Sodium hydroxide, potassium hydroxide, and calcium hydroxide are strong bases, because they are 100% ionized, whereas the other bases, such as amines, are moderate or weak bases. The magnitude of the pK_a values is a measure of acid or base strength. Thus, the salt of a carboxylic acid and of an alkylamine is a salt of a weak acid and weak base, respectively, and therefore does not dissociate appreciably and may or may not be very water soluble, depending on their molecular weights: Low-molecular-weight salts generally are water soluble, and high-molecular-weight salts are water insoluble. Some examples of common organic salts used in pharmaceutical preparations are provided in Figure 2.10.

When dealing with the water solubility of ionized molecules, one also must consider the possibility of intramolecular ionic interactions. Compounds with ionizable functional groups that produce opposite charges have the potential to interact with each other rather than with water molecules. When this occurs, such compounds often become very insoluble in water. A classic example is the amino acid tyrosine (Fig. 2.11). Tyrosine contains three very polar functional groups, with two of these groups (the alkylamine and carboxylic acid) capable of being ionized, depending on the pH of the solution. The phenolic hydroxyl also is ionizable (pK_a 9–10), but it does not contribute much to the ionization of tyrosine under the conditions most often encountered in pharmaceutical formulations or physiologic conditions (<1% at pH 7). Because of the presence of three very polar functional groups (two of them being ionizable), one would therefore expect tyrosine to be very soluble in water, yet its solubility is only 0.45 g/1,000 mL. Because the basic alkylamine (pK_a 9.1 for the conjugate acid) and the carboxylic acid (pK_a 2.2) can react with one another to form a zwitterionic molecule, the two charged groups are sufficiently close to allow a strong ion–ion interaction to form, thereby keeping each of these groups from forming ion–dipole interactions with the surrounding water molecules. The lack of interaction of the ions with the water dipoles results in a molecule that is very insoluble (Fig. 2.12). Not all zwitterions or multiply charged molecules show this behavior; only those containing ionized functional groups that are close enough to interact to form an ion–ion interaction will be poorly soluble. Generally, the greater the separation between charges, the more highly water soluble one would expect the molecule will be. This is only true, however, to up to a certain number of carbon atoms. This will be discussed in more detail below.



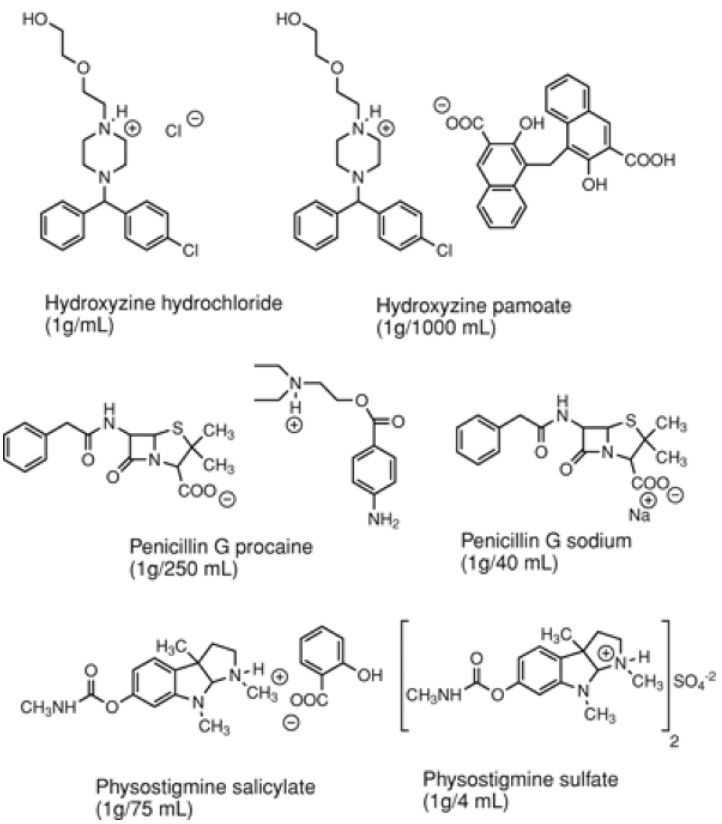


Fig. 2.10. Water solubilities of different salt forms of selective drugs.

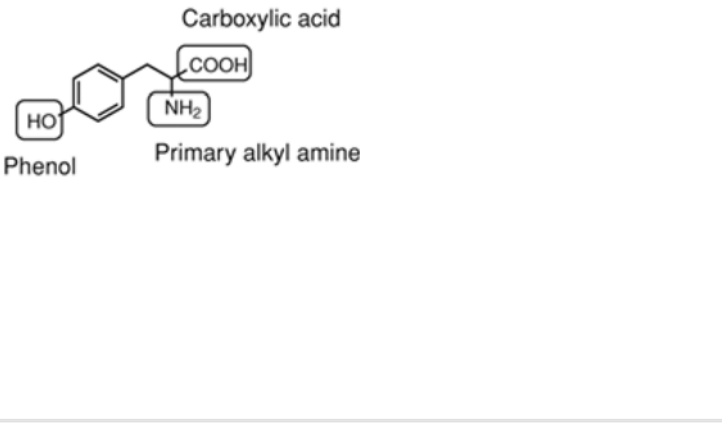

Fig. 2.11. Organic functional groups in tyrosine (see text for pK_a values).

Predicting Water Solubility: Empiric Approach

Lemke (10) has developed an empiric approach to predicting the water solubility of molecules based on the carbon-solubilizing potential of several organic functional groups. If the solubilizing potential of the functional groups exceeds the total number of carbon atoms present, then the molecule is considered to be water

soluble. Otherwise, it is considered to be water insoluble. Functional groups that can interact

either through intramolecular hydrogen or ion–ion interactions will decrease the solubilizing potential of each group. It is difficult to quantitate how much such interactions will take away from water solubility, but recognizing these interactions will allow one to explain anomalous results.

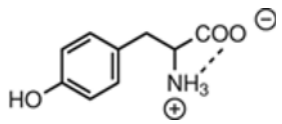

Fig. 2.12. Zwitterionic form of tyrosine showing ion–ion bond.

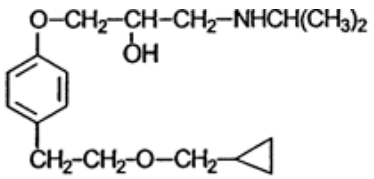
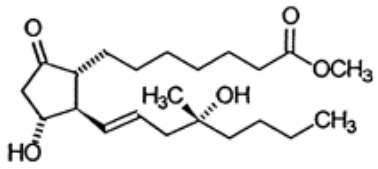
Binding Interactions

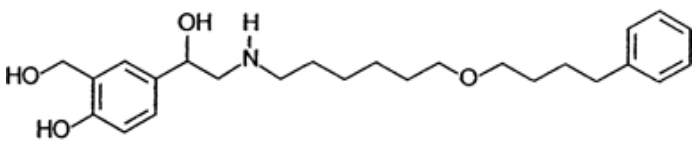
Each of these drug molecules interacts with a different biological target and elicits a unique pharmacologic response. For each of the three molecules, list the types of binding interactions that are possible with a target for drug action. For each type of binding interaction, provide one example of an amino acid that could participate in that interaction.



Betaxolol
(Betoptic)



Misoprostol (Cytotec)



Salmeterol (Serevent)

Example: Binding Interaction: Van der Waals

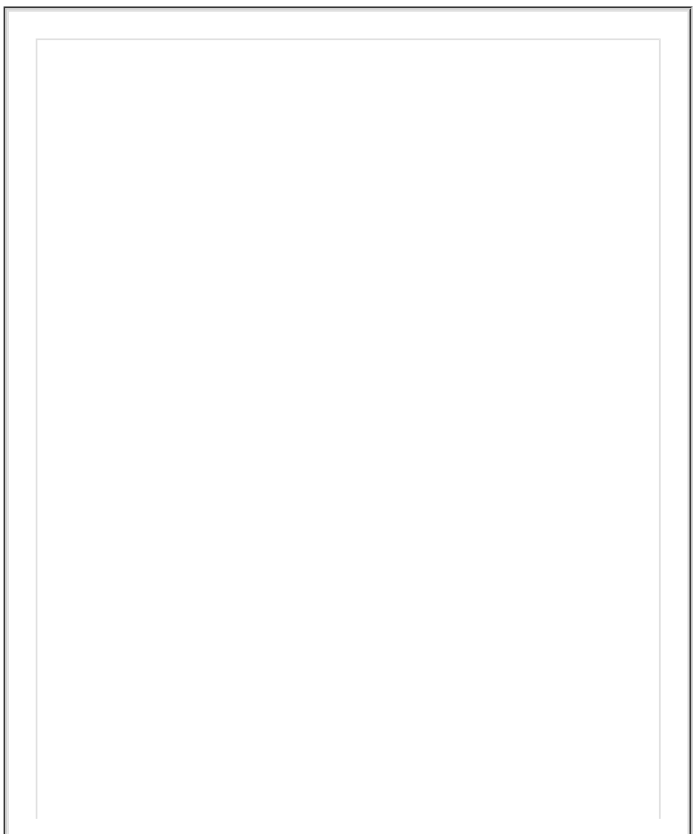
Amino Acid: leucine

Table 2.5 shows the water-solubilizing potential for several organic functional groups that are common to many drugs. Because most drug molecules contain more than one functional group (i.e., are polyfunctional), the second column in the table will be used most often. A couple of examples for predicting water solubility will be used to demonstrate Lemke's method. Anileridine (Fig. 2.13) is a narcotic analgesic containing three organic functional groups that contribute to water solubility: an aromatic amine (very weak base), a tertiary alkylamine (weak base), and an ester (neutral). There are a total of 21 carbon atoms in the molecule, with a solubilizing potential from

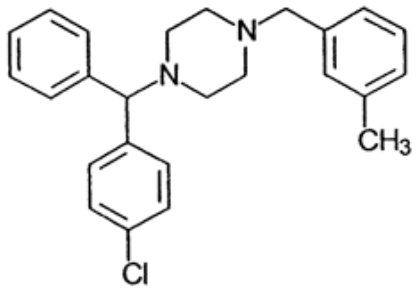
the three functional groups of nine carbon atoms. Because the solubilizing potential of the functional groups is less than the total number of carbons that are present, the prediction would be that anileridine is insoluble in water. This is, indeed, the case: Its solubility is reported in the U.S. Pharmacopeia (USP) as 1 g/10,000 mL, or 0.01%. When the hydrochloride salt of anileridine is considered, however, not only do the three functional groups contribute a solubilizing potential of nine carbon atoms, the positive charge of the alkylammonium also contributes to its solubility. Lemke (10) estimates that each charge on a molecule (cationic or anionic) contributes a solubilizing potential of 20 to 30 carbon atoms. Thus, the solubilizing potential for these groups in anileridine hydrochloride is 29 to 39 carbon atoms, which is more than the total number of carbon atoms in the molecule. The compound should therefore be soluble in water, and it is (to the extent of 0.2 g/ml, or 20%). Problem 6 at the end of this chapter provides more opportunity to utilize this approach to predict water solubility for several compounds. Solubility data for these compounds can be found in the USP. The student should be able to rationalize any discrepancies between their results and the USP data.

Water/Lipid Solubility Case

When you look at any drug molecule, there are a number of functional groups present that contribute to the properties of that drug molecule. Identify the types of functional groups in each molecule and to which physical properties (water/lipid solubility) each contributes.

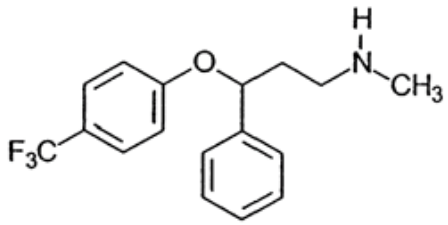


1. Structural Feature Physical Property



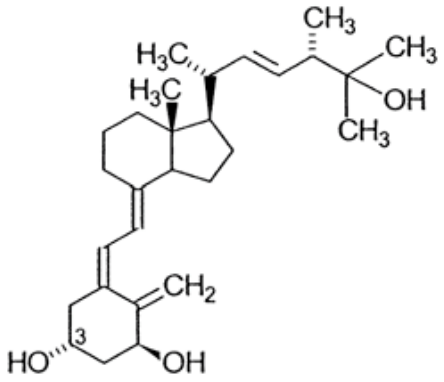
Meclizine
(Antivert)

2. Structural Feature Physical Property



Fluoxetine
(Prozac)

3. Structural Feature Physical Property



1, 25-dihydroxy Vit D_2

Table 2.5. Water-solubilizing Potential of Organic Functional Groups in a Mono- or Polyfunctional Molecule

Functional Group	Monofunction Molecule	Polyfunctional Molecule
Alcohol	5 to 6 carbons	3 to 4 carbons
Phenol	6 to 7 carbons	3 to 4 carbons
Ether	4 to 5 carbons	2 carbons
Aldehyde	4 to 5 carbons	2 carbons
Ketone	5 to 6 carbons	2 carbons
Amine	6 to 7 carbons	3 carbons
Carboxylic acid	5 to 6 carbons	3 carbons
Ester	6 carbons	3 carbons
Amide	6 carbons	2 to 3 carbons
Urea, carbonate, carbamate		2 carbons

Water solubility is defined as greater than 1% solubility (9).

Predicting Water Solubility: Analytical Approach

Another method for predicting water solubility involves calculating an approximate logP, or log of the partition coefficient for a molecule. This approach is based on an approximation method developed by Cates (11) and discussed in Lemke (10). In this approach, one sums the hydrophobic or hydrophilic properties of each functional group present in the molecule. Before we can calculate logP values, we must first digress to a brief explanation of the concept of partition coefficient.

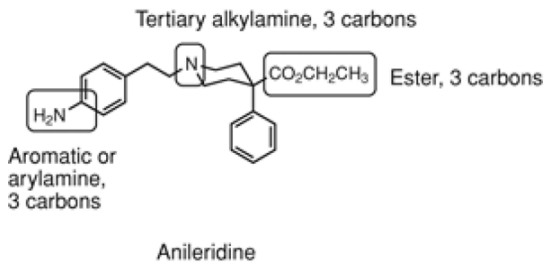


Fig. 2.13. Identification of functional groups in anileridine.

In its simplest form, the partition coefficient, P, refers to the ratio of the concentrations of drug in octanol to that in water. Octanol is used to mimic the amphiphilic nature of lipid, because it has a polar head group (primary alcohol) and a long hydrocarbon chain, or tail, such as that of fatty acids, which make up part of a lipid membrane. Because P is logarithmically related to free energy (12), it generally is expressed as logP and, therefore, is the sum of the hydrophobic and hydrophilic characteristics of the organic functional groups making up the structure of the molecule. Thus, logP is a measure of the solubility characteristics of the entire molecule. Because each organic functional group contained within the molecule contributes to the overall hydrophobic/hydrophilic nature of the molecule, a hydrophobic/hydrophilic value (the hydrophobic substituent constant, π) can be assigned to each organic functional group. Equation 2.7 defines this relationship:

$$\text{Eq. 2.7} \qquad \text{LogP} = \Sigma\pi \text{ (fragments)}$$

When calculating logP from hydrophobic substituent constants, the sum is usually referred to as $\text{logP}_{\text{calc}}$ or ClogP to distinguish it from an experimentally determined value ($\text{logP}_{\text{meas}}$ or MlogP). Over the years, extensive tables of π values have been compiled for organic functional groups and molecular fragments (12,13,14,15). Table 2.6 is a highly abbreviated summary of π values from Lemke (10), based largely on the manuscript by Cates (11). Using the values in this table, it is possible to obtain a fairly reasonable estimate for the water solubility of many organic compounds.

As an example, we will once again use the narcotic analgesic anileridine to demonstrate the calculation of logP. This compound has a total of 21 carbon atoms, some aliphatic and some aromatic. We need to separate these, because aromatic carbon atoms, because of delocalized π orbitals for the sp^2 hybridized atoms, are more polar than aliphatic carbons. The compound also contains one tertiary alkylamine, one aromatic amine, and one ester. Note that when dealing with esters and amides, the oxygen, nitrogen, and ester/amide carbon are counted in this π value. The remaining aliphatic carbons are then counted. Figure 2.14 summarizes the logP calculation for anileridine. The calculation gives a ClogP value for anileridine of +5.8. Water solubility as defined by the USP is solubility of greater than 3.3%, which equates to an approximate logP of +0.5. Values less than +0.5 are therefore considered to be water soluble, and those greater than +0.5 are considered to be water insoluble. According to our calculation, anileridine would be predicted to be insoluble in

water. This calculation agrees with the more empiric procedure discussed earlier.

Binding Interactions/Solubility Case

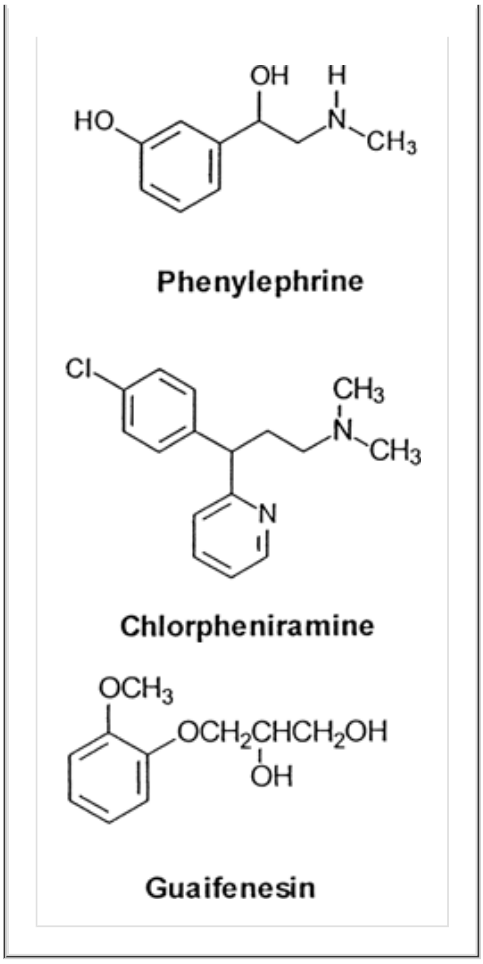
JK presents a prescription for her 6-month-old daughter for Donatussin Drops. She wants to know if this medication will have an effect on her daughter's alertness.

Components of Donatussin:

Phenylephrine (decongestant)

Chlorpheniramine (antihistamine)

Guaifenesin (expectorant)



1. Identify the structural features/functional groups of phenylephrine and guaifenesin that contribute to improved water solubility (medication given as drops). List the type(s) of interactions that these groups have with water, and draw an example of these interactions (with appropriate labels) below.
2. Evaluate each of the three molecules, and determine if each molecule contains any functional groups that will allow the drug to cross the blood-brain barrier and have an effect on this child's alertness (create a list of relevant functional groups for each molecule). Based on your evaluation, which agent is likely to have the most significant effect? Identify what property is necessary for these agents to cross this biological membrane.
3. Identify the binding interactions that chlorpheniramine and guaifenesin could have with their respective targets for drug action. Be sure to identify which functional groups will participate in each of these binding interactions.

Other sample calculations are shown in Figure 2.15, and several problems are provided at the end of this chapter. In Figure 2.15, MlogP values (when available) and ClogP values obtained from the ClogP 4.0 program MaclogP (16) are included for comparison purposes. Even though the π values from Table 2.6 are not as extensive as those in the computer program, there is good general agreement with most of these compounds regarding their solubility (or insolubility) in water. In addition, other programs besides ClogP are available to predict logP values; some of these programs are available on the Internet. One must keep in mind that because of the assumptions made in these programs, they may not produce results in total agreement with measured values or other prediction programs. At this time, it generally is agreed that the ClogP values calculated from ClogP 4.0 (16) are the most accurate. Other programs for calculating logP values

such as Molinspiration (17) and Interactive Analysis (18), use different methods and assumptions and, therefore, do not always agree with ClogP predictions or experimentally determined values. This is not to say the latter two programs do not give accurate results. Often, one or all of the programs will agree with measured values, and with other molecules, none of the programs agree, especially as the number of hydrogen-bond acceptors and hydrogen-bond donor group increase.

Table 2.6. Hydrophilic-lipophilic Values (π V) for Organic Fragments (10)

Fragments	π Value
C (aliphatic)	+0.5
Phenyl	+2.0
Cl	+0.5
O_2NO (nitrate ester)	+0.2
IMHB (intramolecular hydrogen bond)	+0.65

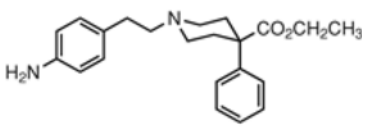
O_2N (aromatic)	–0.28



Fragments	π
2 amines	-2.0
9 aliphatic carbons	+3.5
2 phenyl rings	+4.0
1 ester	-0.7
logP	+4.8

Fig. 2.14. Calculation of logP for anileridine.

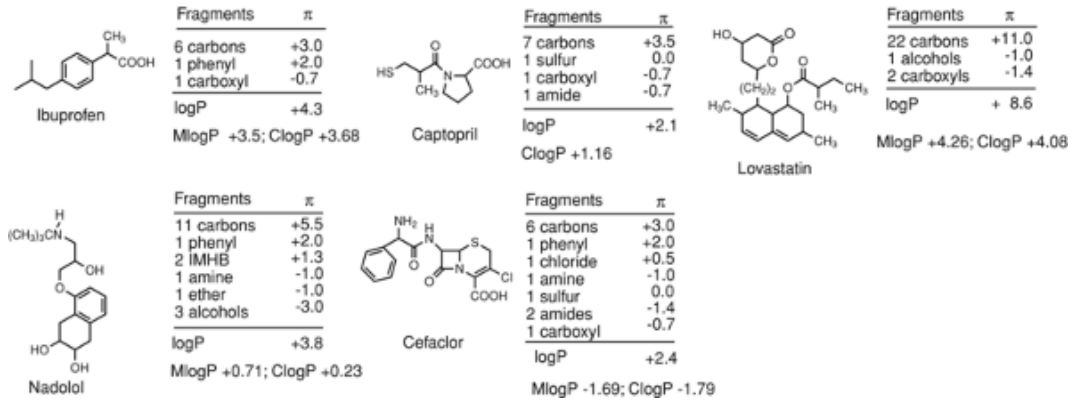


Fig. 2.15. ClogP calculations for selected compounds.

Predicting the percentage ionization or water solubility of a molecule should not be viewed as an exercise in arithmetic but also as a way to understand the solution behavior of molecules, especially when dealing with admixtures and differences among molecules in their pharmacokinetics. The ionization state of a molecule influences its water solubility as well as its ability to traverse membranes and, therefore, its ability to be absorbed. Serum protein binding (and, therefore, the amount of free drug available for receptor binding) also is greatly influenced by the ionization state and the hydrophilic/hydrophobic nature of the molecule.

Questions We Can Now Answer about Any Drug Molecule

Based on your knowledge of acid-base chemistry, from where will this drug primarily be absorbed?

What is the solubility of the drug in the stomach, plasma, or an aqueous IV?

What are the possible interactions that the drug could have with its respective target for drug action?

What is the compatibility of the drug if mixed with other drugs?

How should this drug be delivered? Is it stable in stomach acid?

Stereochemistry and Drug Action

Stereoisomers are compounds containing the same number and kinds of atoms, the same arrangement of bonds, but different three-dimensional structures; in other words, they only differ in the three-dimensional arrangements of atoms in space. Stereoisomers are subdivided into two types, enantiomers and diastereoisomers. Enantiomers are compounds for which the three-dimensional arrangement of atoms is such that they are nonsuperimposable mirror images. Diastereoisomers are all stereoisomeric compounds that are not enantiomers. Thus, the term “diastereoisomer” includes compounds containing double bonds (geometric isomers) as well as ring systems. Unlike enantiomers, diastereoisomers exhibit different physicochemical properties, including, but not limited to, melting point, boiling point, solubility, and chromatographic

behavior. These differences in physicochemical properties allow the separation of diastereoisomers from mixtures utilizing standard chemical separation techniques, such as column chromatography or crystallization. Enantiomers cannot be separated using such techniques unless a chiral environment is provided or they are converted to diastereoisomers

(e.g., salt formation with another enantiomer). Examples of enantiomers and diastereoisomers are provided in Figure 2.16.

Learning the Lingo: Drug Molecule Evaluation

Analysis of Individual Functional Groups:

- Name of functional group
- Shape of functional group
- Hydrophobic vs. hydrophilic character
- Polar vs. nonpolar character
- Acidic vs. basic (pK_a) character
- Binding interactions
- Chemical/enzymatic stability

Analysis of the Whole Drug Molecule:

- Looking for functional group balance: water solubility and absorption
- Ionization issues: effect on solubility and absorption
- Drug combinations: acid-base interactions
- Drug interactions with biological target: good fit or not?
- Stability and bioavailability: route of administration

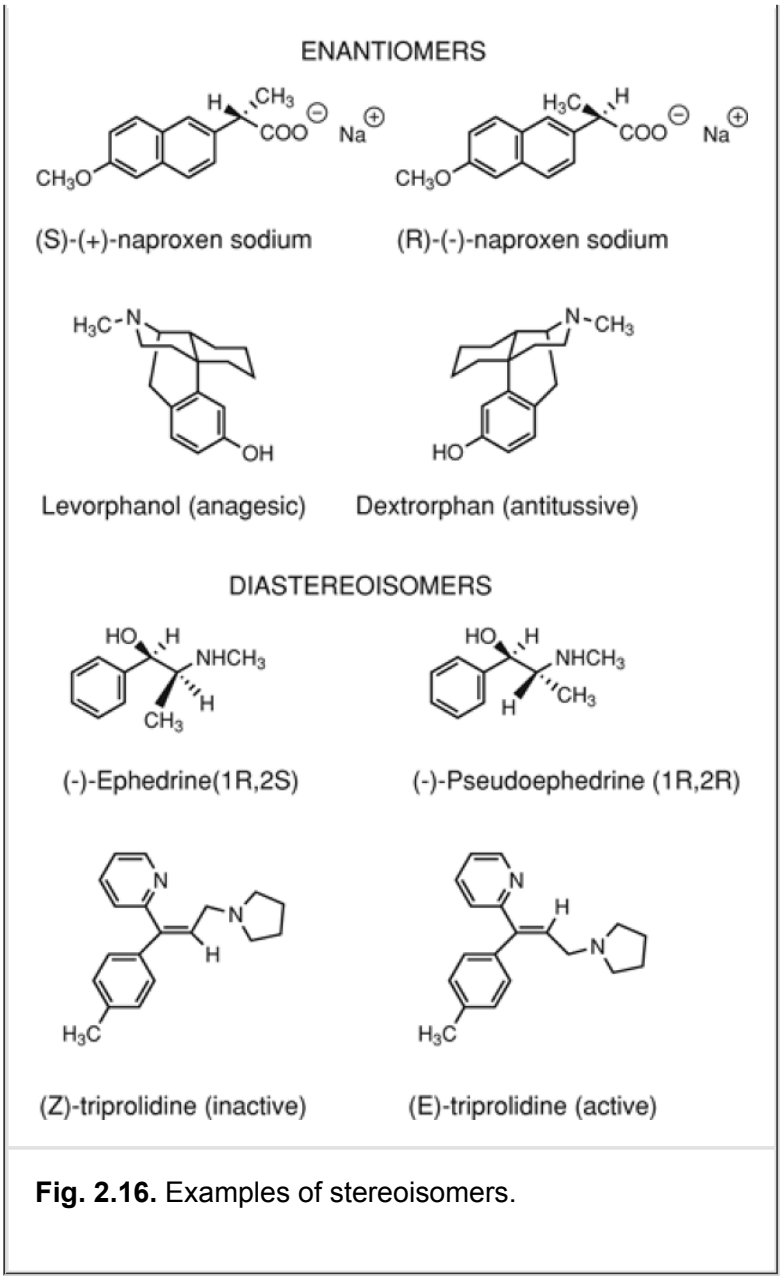

Fig. 2.16. Examples of stereoisomers.

The physicochemical properties of a drug molecule are dependent not only on what functional groups are present in the molecule but also on the spatial arrangement of these groups. This becomes an especially important factor when a molecule is subjected to an asymmetric environment, such as the human body. Because proteins and other biological macromolecules are asymmetric in nature, how a particular drug molecule interacts with these macromolecules is determined by the three-dimensional orientation of the organic functional groups that are present. If crucial functional groups are not occupying the proper spatial region surrounding the molecule, then productive bonding interactions with the biological macromolecule (or receptor) will not be possible, potentially negating the desired pharmacologic effect. If, however, these functional groups are in the proper three-dimensional orientation, the drug can produce a very strong interaction with its receptor. It therefore is very important for the medicinal chemist developing a new molecular entity for therapeutic use to understand not only what functional groups are responsible for the drug's activity but also what three-dimensional orientation of these groups is needed.

Approximately one in every four drugs currently on the market can be considered to be an isomeric mixture, yet for many of these compounds, the biological activity may reside in only one isomer (or at least predominate in one isomer). The majority of these isomeric mixtures are what are referred to as “racemic mixtures” (or “racemates”). These are compounds, usually synthetic, that contain equal amounts of both possible enantiomers, or optical isomers.

Enantiomers also are referred to as chiral compounds, antipodes, or enantiomorphs. When introduced into an asymmetric, or chiral, environment, such as the human body, enantiomers will display different physicochemical properties, producing significant differences in their pharmacokinetic and pharmacodynamic behavior. Such differences can result in adverse side effects or toxicity, because one or more of the isomers may exhibit significant differences in absorption (especially active transport), serum protein binding, and metabolism. With the latter, one isomer may be converted into a toxic substance or may influence the metabolism of another drug. To discuss further the influence of stereochemistry on drug action, some of the basic concepts of stereochemistry need to be reviewed.

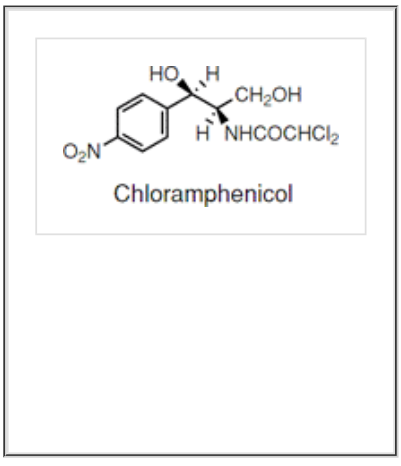
Stereochemical Definitions

Designation of Absolute Configuration

At first, enantiomers were distinguished by their ability to rotate the plane of polarized light. Isomers rotating light to the right, or in a clockwise direction, were designated as dextrorotatory, and this was indicated by a (+)-sign before the chemical name (e.g. (+)-amphetamine or dextroamphetamine). The opposite designation, levorotatory or (–)-, was given to compounds that rotated the plane of polarized light to the left, or in a counterclockwise direction. The letters d- and *l*- were formerly used to indicate (+)- and (–)-, respectively. A racemate (racemic mixture)—that is, a 1:1 mixture of enantiomers—is indicated by a (±)- before the compound name. The student should be aware that this method of nomenclature is based on a physical property of the molecule and does not provide any information concerning the absolute configuration or three-dimensional arrangement of atoms around the chiral center. Because rotation of the plane of polarized light is a physical property, both the magnitude and direction of rotation can vary, depending on the conditions. Thus, temperature, solvent, and concentration of the substance are three

P.40

factors that need to be considered when reporting optical rotations. A good example of this is the antibiotic chloramphenicol. There are two chiral centers in this molecule, resulting in four possible stereoisomers. The isomer shown here is dextrorotatory when its optical rotation is measured in ethanol but levorotatory when measured in ethyl acetate. Obviously, the simple measurement of a physical property, such as rotation of the plane of polarized light, is not sufficient for assignment of the absolute configuration of a molecule.



Chloramphenicol

In the late nineteenth century, Fisher and Rosanoff developed a system of nomenclature based on the structure of glyceraldehyde (Fig. 2.17). Because at this time no methods were known for determining the absolute three-dimensional arrangement of atoms in space, the two isomers of glyceraldehyde were arbitrarily assigned the designation of D-(+)- and L-(–). It was not until the 1950s that the absolute configurations were determined, and it was found that Fisher had fortuitously guessed correctly. Assignments of configuration to other molecules were done based on their relationship to D- or L-glyceraldehyde via synthesis or chemical degradation, irrespective of the observed direction of rotation of the plane of polarized light. Thus, via chemical degradation, it was possible to determine that (+)-glucose, (–)-2–deoxyribose, and (–)-

fructose had the same terminal configuration as D-(+)-glyceraldehyde and, therefore, were given the D-absolute configuration. Amino acids were assigned based on their relationship to D-(+)- and L-(–)-serine (Fig. 2.17). Unfortunately, this system becomes very cumbersome with molecules containing more than one chiral center.

In 1956, a new system of nomenclature was introduced by Cahn et al. (19) and has since become known as the Sequence Rule or CIP system. With this system, atoms attached to a chiral center are ranked according to their atomic number. Highest priority is given to the atom with the highest atomic number, and subsequent atoms are ranked accordingly, from highest to lowest. When a decision cannot be made regarding priority—for example, two atoms with the same atomic number attached to the chiral center—the process continues to the next atom until a decision can be made. The molecule is then viewed from the side opposite the lowest-priority atom, and the priority sequence from highest to lowest is determined. If the sequence is to the right, or clockwise, the chiral center is designated as the (R)-absolute configuration. The designation is (S) when the priority sequence is to the left, or counterclockwise. An example of this is seen in the neurotransmitter norepinephrine.

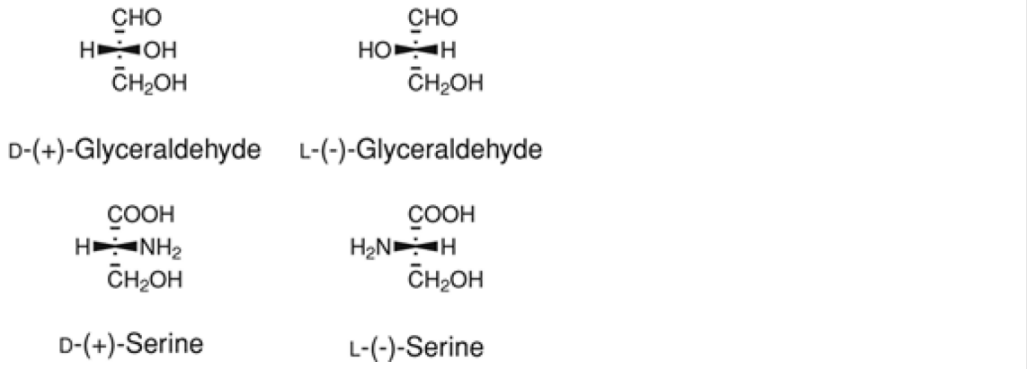


Fig. 2.17. Relationship of optical isomers of serine to D- and L-glyceraldehyde.

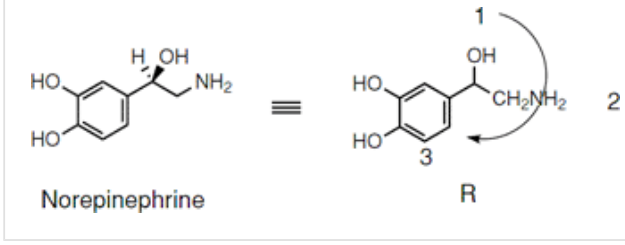
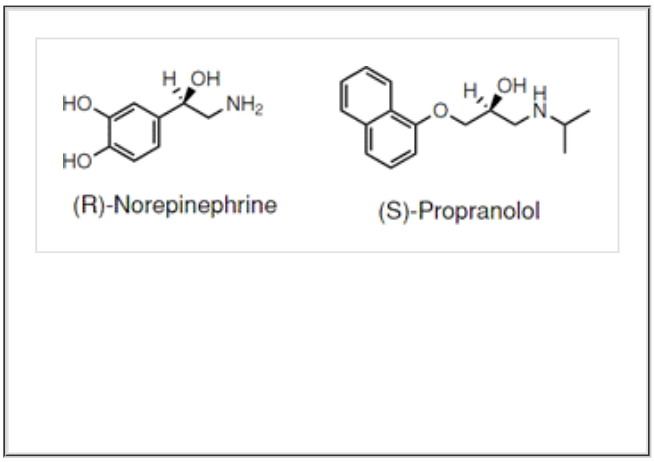


Degradation studies demonstrated that (–)-norepinephrine is related to D-(–)-mandelic acid; therefore, it was given the D-designation using the Fisher system. With the CIP system, norepinephrine is assigned the (R)-absolute configuration.

The student should note that the CIP system of nomenclature uses a set of arbitrary rules and, therefore, should be viewed as a system that keeps track of absolute configuration only. In many instances, two molecules may have different absolute configurations as designated by the CIP system but the same relative orientation of the functional groups relevant for biological activity. A case in point is the absolute configuration of the nonselective β-adrenergic antagonist propranolol as compared to norepinephrine. Because of the ether oxygen, the priority

sequence of the functional groups about the chiral center results in the assignment of the (S)-absolute configuration for the more active enantiomer of propranolol. Close inspection of both (R)-norepinephrine and (S)-propranolol, however, shows that the hydroxy group, basic amine, and aromatic rings of both compounds occupy the same regions in three-dimensional space.



Stereochemistry and Biological Activity

Easson-Stedman Hypothesis

In 1886, Piutti (20) reported different physiologic actions for the enantiomers of asparagine, with (+)-asparagine having a sweet taste and (–)-asparagine a bland one. This was one of the earliest observations that enantiomers can exhibit differences in biological action.

P.41

In 1933, Easson and Stedman (21) reasoned that differences in biological activity between enantiomers resulted from selective reactivity of one enantiomer with its receptor. They postulated that such interactions require a minimum of a three-point fit to the receptor. This is demonstrated in Figure 2.18 for two hypothetical enantiomers. In Figure 2.18, the letters A, B, and C represent hypothetical functional groups that can interact with complementary sites on the hypothetical receptor surface, represented by A′, B′, and C′. Only one enantiomer is capable of attaining the correct orientation to enable all three functional groups to fit their respective sites on the receptor surface. The lack of achieving the same interactions by the other enantiomer explains its reduced biological activity, because it is unable to properly fit into the receptor and, therefore, cannot “trigger” the appropriate change in the receptor conformation. The Easson-Stedman Hypothesis states that the more potent enantiomer must be involved in a minimum of three intermolecular interactions with the receptor surface and that the less potent enantiomer only interacts with two sites. This can be illustrated by looking at the differences in vasopressor activity of (R)-(–)-epinephrine, (S)-(+)-epinephrine and the achiral N-methyldopamine (Fig. 2.19). With (R)-(–)-epinephrine, the three points of interaction with the receptor site are the substituted aromatic ring, β-hydroxyl group, and the protonated secondary ammonium group. All three functional groups interact with their complementary binding sites on the receptor surface, producing the necessary interactions that stimulate the receptor. With (S)-(+)-epinephrine, only two interactions are possible (the protonated secondary ammonium and the substituted aromatic ring). The β-hydroxyl group occupies the wrong region of space and, therefore, cannot interact properly with the receptor. N-methyldopamine can achieve the same interactions with the receptor as (S)-(+)-epinephrine; therefore, it is not surprising that its vasopressor response is the same as that of (S)-(+)-epinephrine and less than that of (R)-(–)-epinephrine.

(R)-(-)-Epinephrine (S)-(+)-Epinephrine N-Methyldopamine

Fig. 2.19. Drug receptor interaction of (R)-(–)-epinephrine, (S)-(+)-epinephrine, and N-methyldopamine.

Not all stereoselectivity seen with enantiomers can be attributed to differences in reactivity at the receptor site. Differences in biological activity also can result from differences in the ability of each enantiomer to reach the receptor site. Because the biological system encountered by the drug is asymmetric, each enantiomer may experience selective penetration of membranes, metabolism, and absorption at sites of loss (e.g., adipose tissue) or excretion. Figure 2.20 shows the selective phases that enantiomers may encounter before reaching the receptor. Not all of these processes may be encountered by a particular enantiomer, but such processes may

provide enough of an influence to cause one enantiomer to produce a significantly better pharmacologic effect than the other. Conversely, such processes also may contribute to untoward effects of a particular enantiomer. The student

must continually keep in mind that not all pharmacologic effects of a drug are necessarily beneficial to the patient, and differences in pharmacologic action among stereoisomers provide excellent examples of this concept.

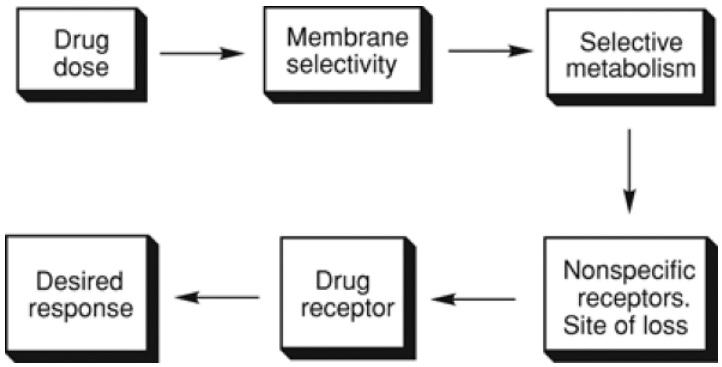

Fig. 2.20. Selective phases to which optical isomers may be subjected before biological response.

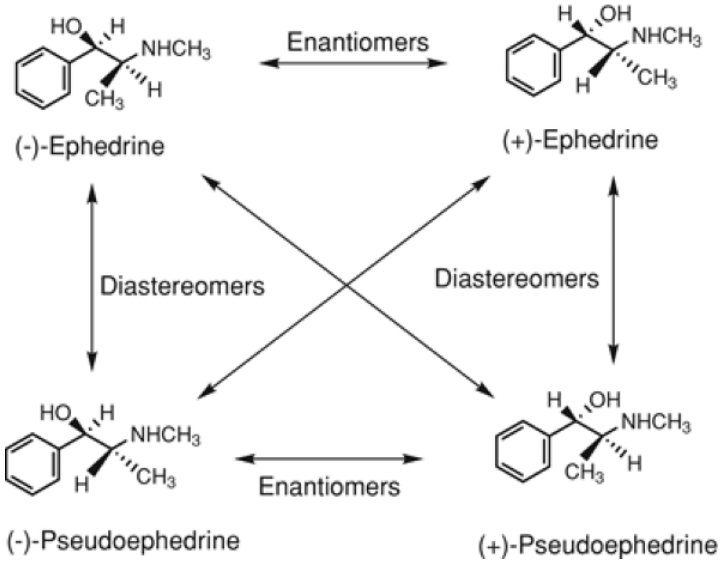

Fig. 2.21. Relationship between the diastereomers of ephedrine and pseudoephedrine.

Diastereomers

As mentioned earlier, diastereoisomers are compounds that are nonsuperimposable, nonmirror-image isomers. Such compounds can result from the presence of more than one chiral center in the molecule, double bonds, or ring systems. These isomers have different physicochemical properties; thus, differences in biological activity between such isomers often can be attributed

to these properties.

Compounds containing more than one chiral center probably are the most common type of diastereoisomer used as drugs. The classic example of compounds of this type is the diastereoisomers ephedrine and pseudoephedrine (Fig. 2.21). When a molecule contains two chiral centers, there can be as many as four possible stereoisomers consisting of two sets of enantiomeric pairs. For each enantiomeric pair, there is inversion of both chiral centers, whereas the difference between diastereomers is inversion of only one chiral center (Problem 9 at the end of this chapter helps to illustrate this point).

Figure 2.22 shows several examples of other compounds that contain two or more chiral centers and, therefore, are diastereoisomeric (see Problem 10 at the end of this chapter).

Restricted bond rotation caused by carbon–carbon double bonds (alkenes or olefins) and similar systems, such as imines (C==N), can produce stereoisomers. These also are referred to as geometric isomers, although they more properly are classified as diastereoisomers. In compounds of this type, substituents can be oriented on the same side or on opposite sides of the double bond. The alkene 2-butene is a simple example of this.

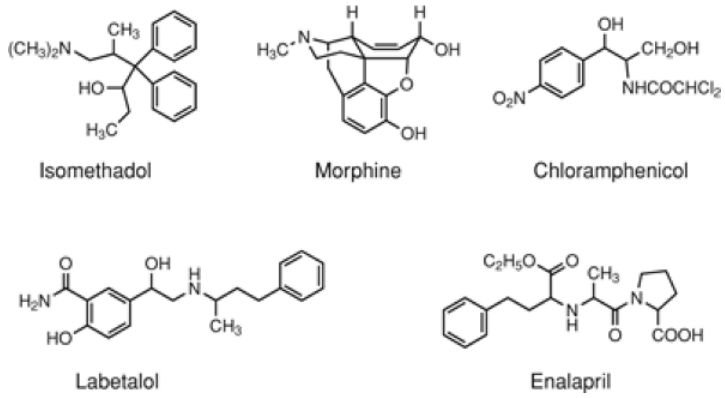

Fig. 2.22. Examples of chiral drugs with two or more asymmetric centers.

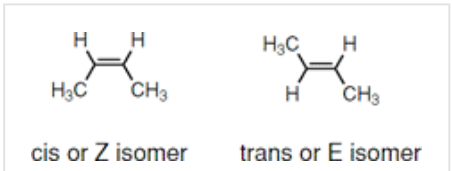

With 2-butene, it is readily apparent that the methyl groups may be on the same side or on opposite sides of the double bond. When they are on the same side, the molecule is defined as the *cis*- or *Z*-isomer (from the German *zusammen*, meaning “together”); when they are on opposite sides, the designation is *trans*- or *E*- (from the German *entgegen*, meaning “opposite”). With simple compounds, such as 2-butene, it is easy to determine which groups in the molecule are *cis* or *trans* to one another. This becomes more difficult to determine, however, with more complex structures, in which it is less obvious which substituents should be referred to when naming the compound. In 1968, Blackwood et al. (22) proposed a system for the assignment of

"absolute" configuration with respect to double bonds. Using the CIP sequence rules, each of the two substituents attached to the carbon atoms comprising the double bond are assigned a priority of 1 or 2, depending on the atomic number of the atom attached to the double bond. When two substituents of higher priority are on the same side of the double bond, this isomer is given the designation of *cis* or *Z*. When the substituents are on opposite sides, the designation is *trans* or *E*. The histamine H_1-receptor antagonist triprolidine (Fig. 2.23) is a good example for

demonstrating how this nomenclature system works. The *E*-isomer of triprolidine is more active both in vitro and in vivo, indicating that the distance between the pyridine and pyrrolidine rings is critical for binding to the receptor.

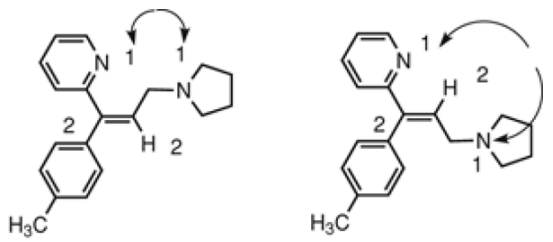

Fig. 2.23. Geometric isomers of triprolidine.

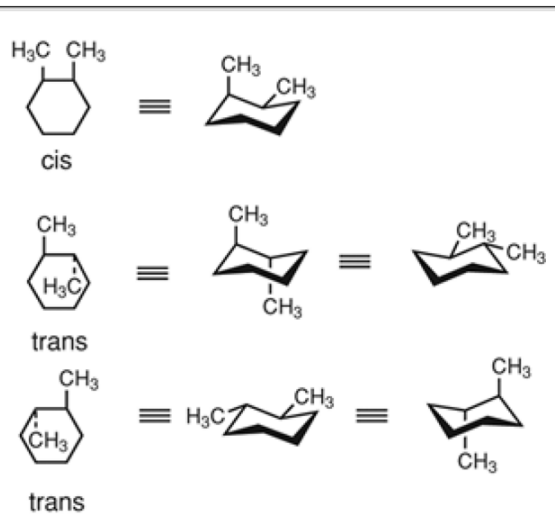

Fig. 2.24. Diastereomers of 1,2-dimethylcyclohexane.

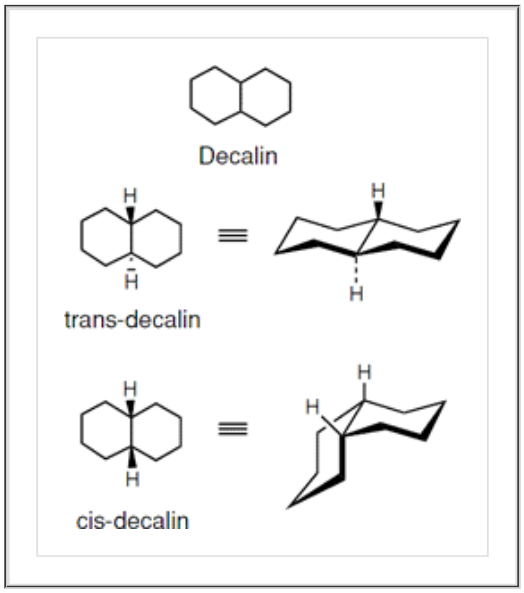
Diastereoisomers (as well as enantiomers) also can be found in cyclic compounds. For example, the cyclic alkane 1,2-dimethylcyclohexane can exist as *cis/trans*-diastereoisomers, and the *trans* isomer also can exist as an enantiomeric pair. In Figure 2.24, each of the *trans*-enantiomorphs are depicted in the two possible chair conformations for the cyclohexane ring. Cyclohexane rings can exhibit significant conformational freedom that allows for the possibility of conformational isomers. Isomers of this type will be discussed in the next section. When two or more rings share a common bond (e.g., decalin), rotation around the bonds is even more restricted, preventing ring "flipping" (through conformational rigidity) from occurring, thereby

producing diastereoisomers and enantiomers.



In the case of the two-ring system of decalin, the rings can join together at the common bond in either the *trans* or *cis* configuration as shown. Steroids, a class of medicinally important compounds consisting of four fused rings (three cyclohexanes and one cyclopentane), exhibit significantly different biological activity when the first two cyclohexane rings are fused into different configurations, referred to as the 5α- or 5β-isomers (Fig. 2.25). The β-designation indicates that the substituent in the 5-position is below the "plane" of the ring system; the β-designation refers to the substituent being above this plane. What appears to be a very minor change in orientation for the substituent results in a very drastic change in the three-dimensional shape of the molecule and in its biological activity. Figure 2.25 shows the diastereoisomers 5α-cholestane and 5β-cholestane as examples. The chemistry and pharmacology of steroids will be discussed in more detail in Chapters 32 (Adrenocorticoids), 45 (Estrogens and Progestins), and 46 (Androgens).

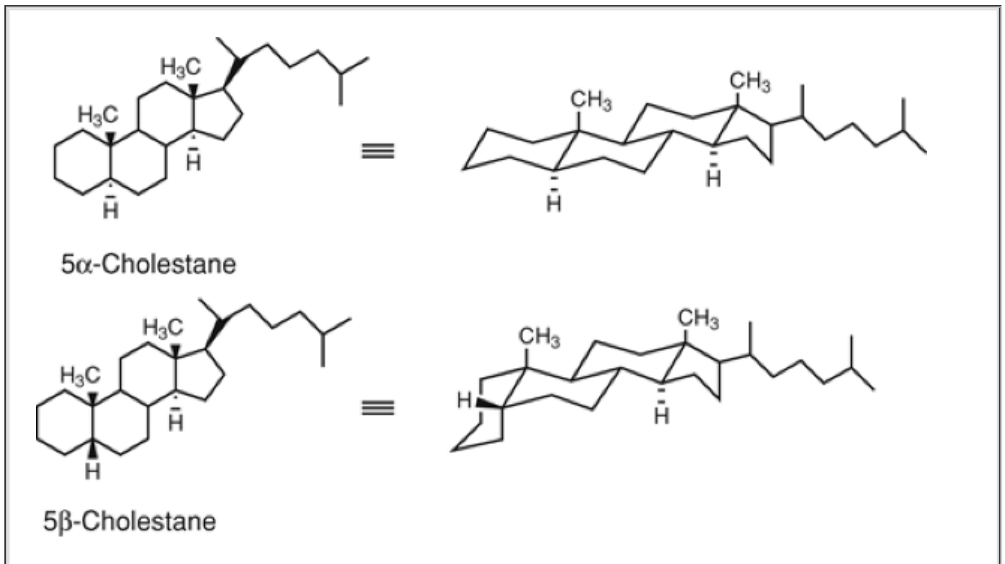


Fig. 2.25. The 5α and 5β conformations of the steroid nucleus cholestane.

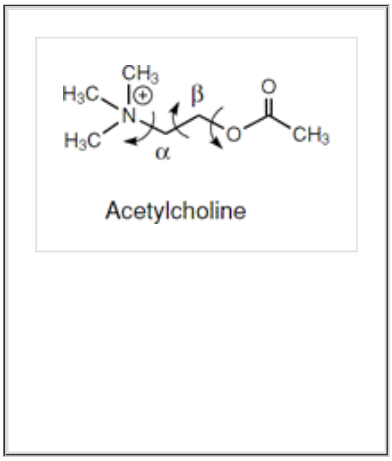
Conformational Isomerism

With conformational isomerism, we are dealing with a dynamic process—that is, isomerization takes place via rotation about one or more single bonds. Such bond rotation results in

nonidentical spatial arrangement of atoms in a molecule. Changes in spatial orientation of atoms because of bond rotation results in different conformations (or rotamers), whereas conversion of one enantiomer into another (or diastereoisomer) requires the breaking of bonds, which has a much higher energy requirement than rotation around a single bond. The neurotransmitter acetylcholine can be used to demonstrate the concept of conformational isomers.



Each single bond within the acetylcholine molecule is capable of undergoing rotation, and at room temperature, such rotations readily occur. Even though rotation around single bonds was shown by Kemp and Pitzer (23) in 1936 not to be free but, rather, to have an energy

P.44

barrier, this barrier is sufficiently low that at room temperature, acetylcholine exists in many interconvertible conformations (see Chapter 12). Close observation reveals that rotation around the central Cα–Cβ bond produces the greatest spatial rearrangement of atoms compared to rotation around any other bond within the molecule. In fact, several rotatable bonds in acetylcholine produce redundant structures, because all of the atoms attached to one end of some bonds are identical, resulting in no change in spatial arrangement of atoms (e.g., methyl groups). When viewed along the Cα–Cβ bond, acetylcholine can be depicted in the sawhorse or Newman projections, as shown in Figure 2.26. When the ester and trimethylammonium group are 180° apart, the molecule is said to be in the anti, or staggered, conformation (or conformer or rotamer). This conformation allows maximum separation of the functional groups and, therefore, considered to be the most stable conformation energetically. Other conformations possibly are more stable if factors other than steric interactions come into play (e.g., intramolecular hydrogen bonds). Rotation of one end of the Cα–Cβ bond by 120° or 240° results in the two gauche, or skew, conformations shown in Figure 2.26. These are considered to be less stable than the anticonformer, although some studies suggest that an electrostatic attraction between the electron-poor trimethylammonium and electron-rich ester oxygen stabilizes this conformation. Rotation by 60°, 180°, and 240° produce conformations in which all of the atoms overlap, or what are referred to as eclipsed conformations. These are the least stable conformers.

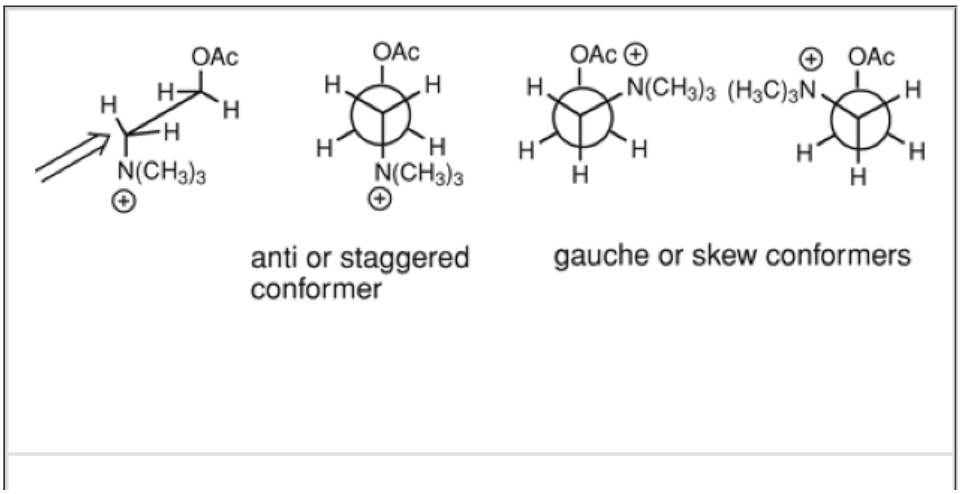


Fig. 2.26. Anti and gauche conformations of acetylcholine.

An interesting observation can be made with the two gauche conformers shown in Figure 2.26. These conformers are not distinct molecules, and they only exist for a transient period of time at room temperature. If these could be “frozen” into the conformations shown, however, they would be nonsuperimposable mirror images or enantiomers. Thus, a compound that is achiral, such as acetylcholine, can exhibit prochirality if certain conformational isomers can be formed. It is quite possible that such a situation could exist when acetylcholine binds to one of its receptors. Studies have suggested that the gauche conformation is the form that binds to the nicotinic receptor. whereas the anti form, which is achiral, binds to the muscarinic receptor.

Drug Design: Discovery and Structural Modification of Lead Compounds

Natural Product Screening

Perhaps the most difficult aspect of drug discovery for the medicinal chemist is that of lead discovery. Until the late nineteenth century, the development of new chemical entities for medicinal purposes was achieved primarily through the use of natural products, generally derived from plant sources (see Chapter 1). As the colonial powers of Europe discovered new lands in the Western Hemisphere and colonized Asia, the Europeans learned from the indigenous peoples of the newly discovered lands of remedies for many ailments derived from herbs. Salicylic acid was isolated from the bark of willow trees after learning that Native Americans brewed the bark to treat inflammatory ailments. Further development of this lead compound by the Bayer Corporation of Germany resulted in acetylsalicylic acid, or aspirin, the first nonsteroidal anti-inflammatory agent. South American natives used a tea obtained by brewing Cinchona bark to treat chills and fever. Further study in Europe led to the isolation of quinine and quinidine, which subsequently were used to treat malaria and cardiac arrhythmias, respectively. Following leads such as these, chemists of the late nineteenth and early twentieth centuries began to seek new medicinals from plant sources and to assay them for many types of pharmacologic actions. This approach to drug discovery often is referred to as “natural product screening.” With this approach, compounds were isolated from natural sources based on information obtained from indigenous peoples in many parts of the world. Until the mid-1970s, this was one of the major approaches to obtaining new chemical entities as leads for new drugs. Unfortunately, this approach declined in favor of what were then considered to be more rational approaches to drug design developed during that period (see below). Recently, however, because heightened awareness of the fragility of ecosystems, especially the rainforests, there has been a resurgence of screening products from plants before they become extinct. A new field of pharmacology, called “ethnopharmacology,” has emerged as a result. Ethnopharmacology is the term used for the discipline of identifying potential natural product sources with medicinal products based on native lore.

Compounds isolated from natural sources usually are tested in bioassays for the ailment that the plant material has been described to treat. Sometimes, this may require several bioassays, because the plant has been reported to be effective against several ailments. Often, the treatment of different ailments requires different methods of preparation (e.g., brewing, chewing, or direct application to wounds) or different parts of the same plant (e.g., roots, stem, leaves, flowers, or sap). Each method of administration or part of the plant may involve one or more different chemical compounds to produce the

desired outcome. One can readily see that isolation of active constituents from plants that may be useful as medicinals is not a simple process. A number of variables may influence the amount of active compound or compounds and, ultimately, the pharmacologic activity of the extract.

Drug Discovery via Random Screening of Synthetic Organic

Compounds

This approach to discovering new chemical structures for a particular biological action began in the 1930s, after the discovery of the sulfonamide class of antibacterials. Thousands of compounds and their synthetic intermediates were assayed in search of new structures that possessed antibacterial activity. All compounds available to the investigator (natural products, synthetic compounds), regardless of structure, were tested in the assays available at the time. This approach also was applied in the 1960s and 1970s in an effort to find agents that were effective against cancer. Some groups did not limit themselves to a particular biological activity but, rather, tested compounds in a wide variety of assays. This approach was a precursor to what is now referred to as high-throughput screening assays, which involve the bioassay of thousands of compounds in hundreds to thousands of bioassays simultaneously. This only became possible with the advent of computer-controlled robotic systems for the assays and combinatorial chemistry techniques. These will be discussed further below.

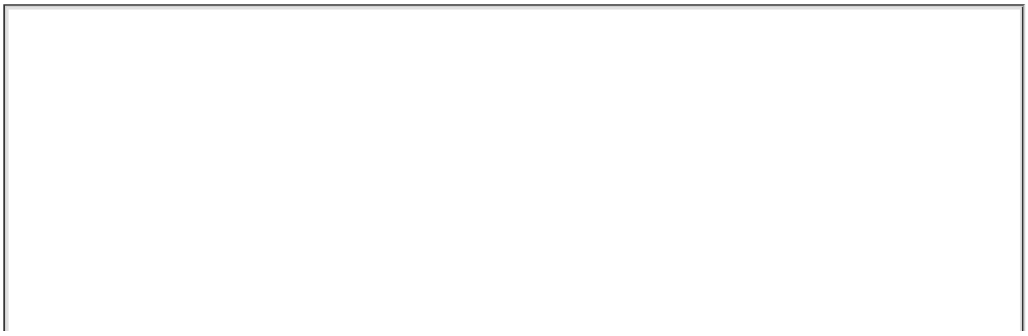
What is crucial for random screening to be successful is a good bioassay system for the pharmacologic action of interest. Unfortunately, this means of lead discovery is very inefficient, because no rational approach is taken to what compounds are to be tested to find new lead structures. Random screening eventually gave way to dedicated screening and rational design techniques.

Drug Discovery via Targeted Dedicated Screening and Rational Drug Design

This approach is more or less random in nature and involves greater knowledge of the therapeutic targets and some actual design based on physicochemical properties. Testing usually is done with one or two models (e.g., specific receptor systems or enzymes) based on the therapeutic target. The design aspect often involves molecular modeling and the use of quantitative SARs to better define the physicochemical properties that are crucial for biological activity. The drawback of these approaches is that they are better for developing a lead compound than for discovering a lead compound.

Drug Discovery via Drug Metabolism Studies

New compounds have been “discovered” by investigating the metabolism of compounds that already are clinical candidates or, in rare instances, are already on the market. Metabolites of known compounds are isolated and then assayed for biological effects either on the same target system or with a broader screen of several other target systems. The latter will be more useful if the metabolite being studied is a chemical structure that has been radically altered from the parent molecule through some unusual rearrangement reaction. More often, the metabolite is not radically different from the parent molecule and, therefore, would be expected to have similar pharmacologic effects. The advantage is that a metabolite may possess better pharmacokinetic properties, such as a longer duration of action, better absorption orally, or less toxicity with fewer side effects (e.g., terfenadine and its antihistaminic metabolite, fexofenadine). The sulfonamide antibacterial agents were discovered in this way. The azo dye Prontosil was found to have only antibacterial action in vivo, but it was soon discovered that this compound required metabolic reduction of the diazo group to produce 4-aminobenzene sulfonamide (Fig. 2.27). The sulfonamide mimics the physicochemical properties of PABA, a crucial component in microbial metabolism. This results in the sulfonamide acting as a competitive inhibitor of the enzyme that uses PABA as a substrate.



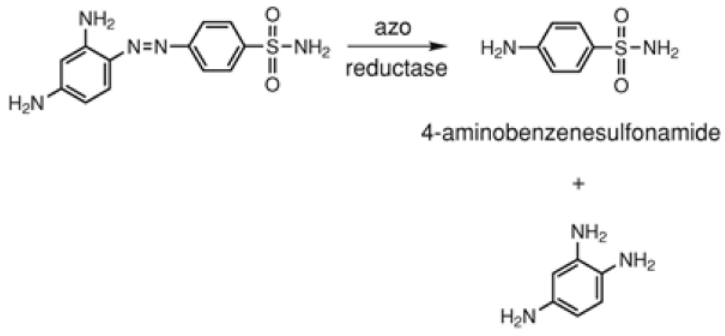


Fig. 2.27. Metabolic conversion of prontosil to 4-aminobenzenesulfonamide.

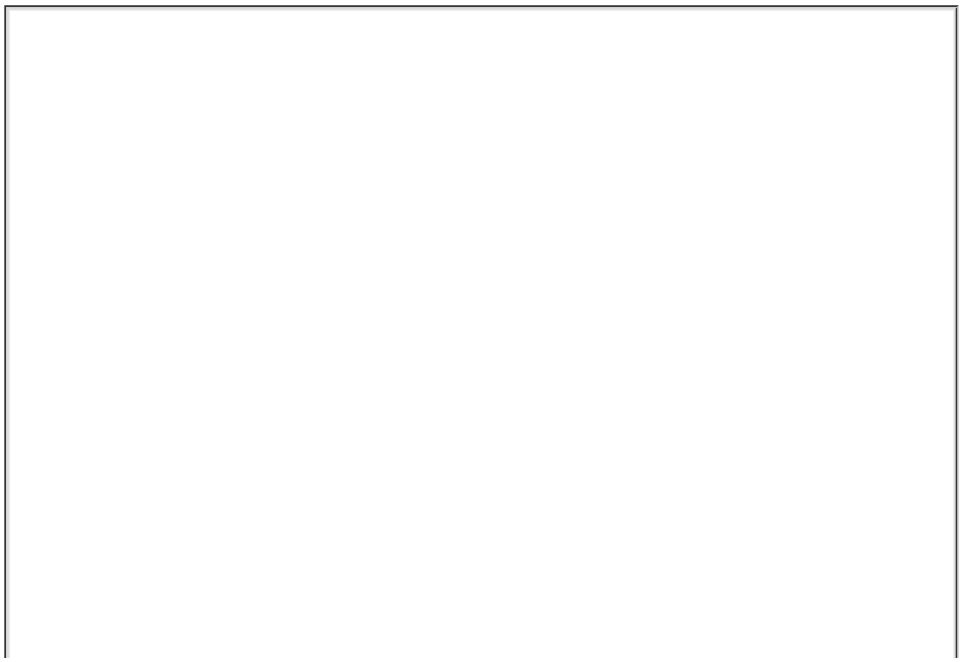
Drug Discovery from the Observation of Side Effects

An astute clinician or pharmacologist may detect a side effect in a patient or animal model that could lead, on further development, to a new therapeutic use for a particular chemical structure. Further development may even lead to an entirely new chemical class. Discovery of new lead compounds via exploitation of side-effect profiles of existing agents has occurred several times and will be discussed below.

One of the more interesting cases of drug development is that of the phenothiazine antipsychotics (see Chapter 22). These compounds can be traced back to the first histamine H_1-receptor antagonists developed in the 1930s. In 1937, Bovet (24) was the first to recognize that it should be possible to antagonize the effects of histamine and, thereby, treat allergic reactions. He tested compounds that were known to act on the autonomic nervous system and, eventually, discovered that benzodioxanes (Fig. 2.28) were capable of significant antagonism

of the effects of histamine. During an attempt to improve the antihistaminic action of the benzodioxanes, it was discovered that ethanolamines also provided significant antihistaminic activity. Further development of this class ended up generating two different classes of antihistamines. One approach led to the development of the diphenhydramine class of antihistamines and is represented by the first clinically useful H_1-receptor antagonist developed in the United States, diphenhydramine (Fig. 2.28). The other approach led to the ethylenediamine class, represented by tripelennamine (Fig. 2.28) (see Chapter 37).



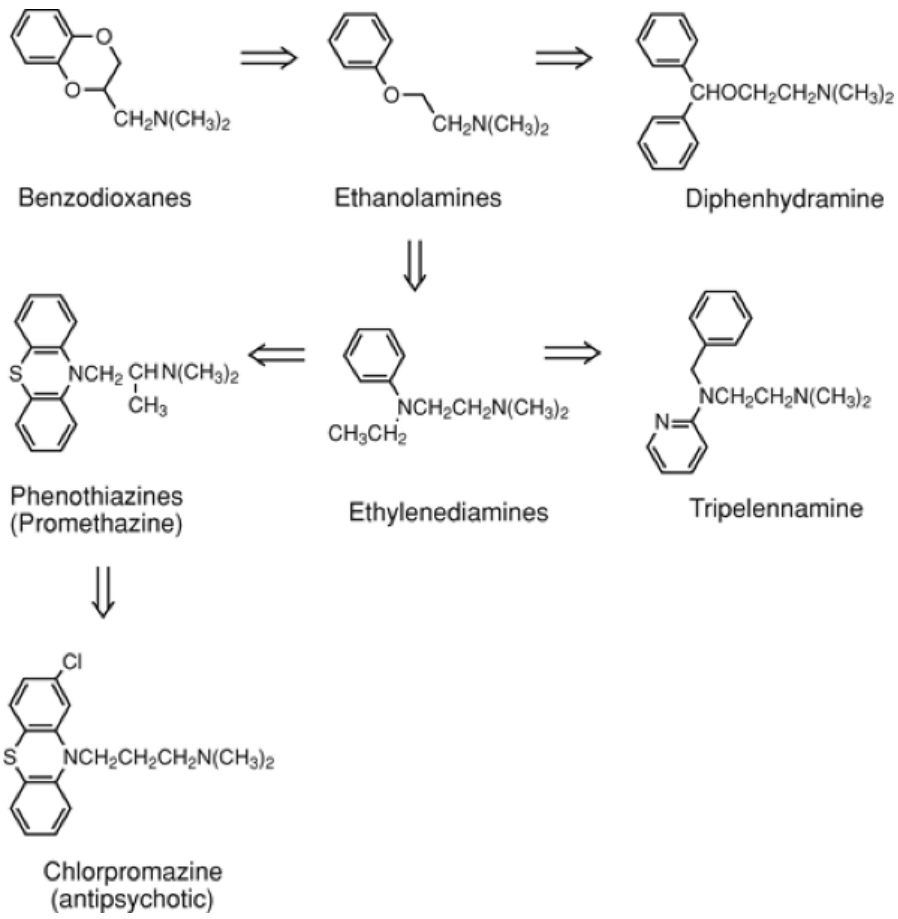


Fig. 2.28. Development of phenothiazine-type antipsychotic drugs.

Incorporation of the aromatic rings of the ethylenediamines into the tricyclic phenothiazine structure produced compounds (e.g., promethazine) with good antihistaminic action and relatively strong sedative properties (see Chapter 37). At first, these compounds were found to be useful as antihistamines, but their very strong sedative properties also lead to their use as potentiating agents for anesthesia (25). Further development to increase the sedative properties of the phenothiazines resulted in the development of chlorpromazine in 1950 (26).

Chlorpromazine was found to produce a tendency for sleep, but unlike the previous phenothiazines, it also produced a disinterest in patients regarding their surroundings and, with patients suffering psychiatric disorders, an ameliorative effect on the psychosis as well as a relief of anxiety and agitation. These observations suggested that chlorpromazine had potential for the treatment of psychiatric disorders. Thus, what started out as an attempt to improve antihistaminic activity ultimately resulted in an entirely new class of chemical entity useful in an unrelated disorder (27).

Another example of how new chemical entities can be derived from compounds with unrelated biological effects is that of the development of the potassium channel agonist diazoxide (Fig. 2.29). This compound was developed as a result of the observation that the thiazide diuretics, such as chlorothiazide, not only had a diuretic component, because of inhibition of sodium absorption in the distal convoluted tubule, but also a direct effect on the renal vasculature. Structural modification to enhance this direct effect led to the development of diazoxide and related potassium channel agonists for the treatment of hypertension (see Chapter 29).

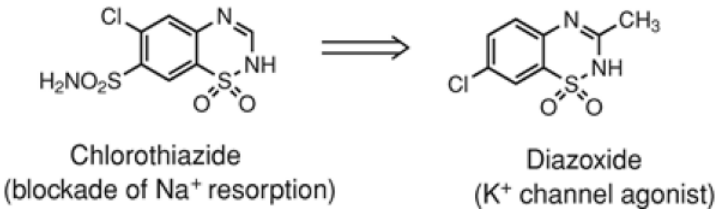

Fig. 2.29. Structural similarity of chlorothiazide (a diuretic), and diazoxide (an antihypertensive that acts via opening of K^+ channels).

P.47

Refinement of the Lead Structure

Determination of the Pharmacophore

Once a lead compound has been discovered for a particular therapeutic use, the next step is to determine the pharmacophore for this compound. The pharmacophore of a drug molecule is that portion of the molecule containing the essential organic functional groups that directly interact with the receptor active site and, therefore, confers on the molecule the biological activity of interest. Because drug–receptor interactions can be very specific, the pharmacophore may constitute a small portion of the molecule. It has been found on several occasions that what seem to be very complex molecules can be reduced to simpler structures with retention of the desired biological action. An example of this is the narcotic analgesic morphine, which is a tetracyclic compound with five chiral centers. Not only would simplification of the structure possibly provide molecules with fewer side effects, a reduction in the number of chiral centers would greatly simplify the synthesis of morphine derivatives and, thereby, decrease cost. Figure 2.30 shows how the morphine structure has been simplified in the search for compounds with fewer deleterious side effects, such as respiratory depression and addiction potential. Within each class are analogues that are less potent, equipotent, and many times more potent than morphine. It can be readily seen from the figure that the pharmacophore of morphine must consist of a tertiary alkylamine that is at least four atoms away from an aromatic ring. A more detailed discussion of the chemistry and pharmacology of morphine can be found in Chapter 24.

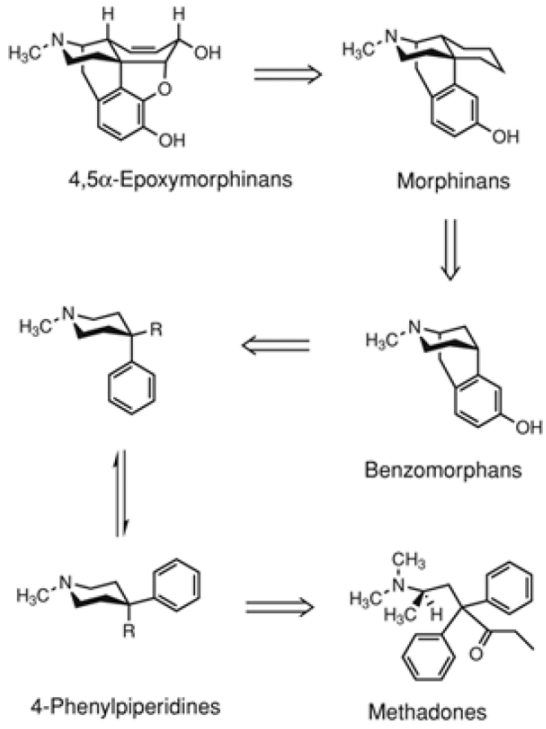

Fig. 2.30. Morphine pharmacophore and its relationship to analgesic derivatives.

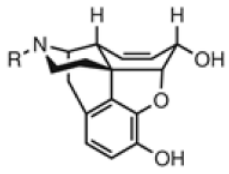
Alterations in Alkyl Chains: Chain Length, Branching, and Rings

Alterations in alkyl chains, such as increasing or decreasing chain length (homologation), branching, and changing ring size, can have profound effects on the potency and pharmacologic activity of the molecule. Simply changing the length of an alkyl chain by one CH_2 unit or branching the chain will alter the lipophilic character of the molecule and, therefore, its properties of absorption, distribution, and excretion. If the alkyl chain is directly involved in the receptor interaction, then chain length and branching can alter the binding characteristics. Molecules that are conformationally flexible may become less flexible if branching is introduced at a key position of an alkyl chain. Changes in conformation will affect the spatial relationship of functional groups in the molecule, thereby influencing receptor binding. Changes as small as one CH_2 unit may seem trivial at first, but in many instances, such small changes are important aspects in the design of analogues.

An example in which simply increasing hydrocarbon chain length has significant effects not only on potency but also on the agonistic or antagonistic action of a molecule is provided by a series of N-alkyl morphine analogues (Fig. 2.31). In this series, going from R==CH_3 (morphine) to R==$CH_2CH_2CH_3$ (N-propylnormorphine) produces a pronounced decrease in agonist activity and an increase in antagonist activity. When R== $CH_2CH_2CH_2CH_3$ (N-butylnormorphine), the compound is totally devoid of agonist or antagonist activity (i.e., the compound is inactive), but further increases in chain length (R==$CH_2CH_2CH_2CH_2CH_3$ and R==CH_2CH_2 $CH_2CH_2CH_2CH_3$) produce compounds with increasing potency as agonists. When R is β-phenylethyl, the compound is a full agonist, with a potency approximately 14-fold that of morphine (28,29).

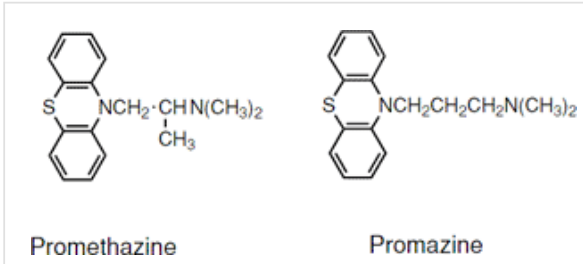


R	Pharmacological activity
$-CH_3$	Analgesic (morphine)
$-CH_2CH_3$	Opioid agonist activity decreased
$-CH_2CH_2CH_3$	Opioid antagonist activity increased
$-CH_2CH_2CH_2CH_3$	Inactive as opioid agonist or antagonist
$-CH_2CH_2CH_2CH_2CH_3$	Opioid antagonist activity increased
$-CH_2CH_2CH_2CH_2CH_2CH_3$	
$-CH_2CH_2-C_6H_5$	14X potency of morphine

Fig. 2.31. Effect of alkyl chain length on activity of morphine.

P.48

Branching of alkyl chains also can produce drastic changes in potency and pharmacologic activity. If the mechanism of action is closely related to the lipophilicity of the molecule, then branching of a hydrocarbon chain will result in a less lipophilic compound and significantly altered biological effect. This decrease in lipophilicity as the result of hydrocarbon chain branching results from the chain becoming more compact and, therefore, produces less disruption of the hydrogen-bonding network of water. If the hydrocarbon chain is directly involved in receptor interactions, then branching can produce major changes in pharmacologic activity. For example, consider the phenothiazines promethazine and promazine:



The primary pharmacologic activity of promethazine is that of an antihistamine, whereas promazine is an antipsychotic. The only difference between the two is the alkylamine side chain. In the case of promethazine, it contains a isopropylamine side chain, whereas promazine has a *n*-propylamine. In this case, the small change of one carbon atom from a branched to a linear hydrocarbon radically alters the pharmacologic activity.

Position isomers of substituents on aromatic rings also may possess different pharmacologic properties. Substituents on aromatic rings can alter the electron distribution throughout the ring, which in turn can affect how the ring interacts with the receptor. Ring substituents also may

influence the conformation of a flexible molecule, especially if they are located ortho to flexible side chains and can participate in steric or electronic intramolecular interactions (e.g., hydrogen, ion–dipole, or ion–ion bonds). Ring substituents influence the conformations of adjacent substituents via steric interactions and may significantly affect receptor interactions. Aromatic methoxy groups ortho to two other substituents take on a conformation perpendicular to the plane of the aromatic ring in hallucinogenic phenylalkylamines (Fig. 2.32) and can explain the lack of hallucinogenic activity in these compounds (30).

Functional Group Modification: Isosterism and Bioisosterism

Isosterism

When a lead compound is first discovered for a particular disease state, it often lacks the required potency and pharmacokinetic properties suitable for making it a viable clinical candidate. These may include undesirable side effects, physicochemical properties, other factors that affect oral bioavailability (see Chapter 9), and adverse metabolic or excretion properties. These undesirable properties could be the result of specific functional groups in the molecule. The medicinal chemist therefore must modify the compound to reduce or eliminate these undesirable features without losing the desired biological activity. Replacement or modification of functional groups with other groups having similar properties is known as “isosteric replacement,” or “bioisosteric replacement.”

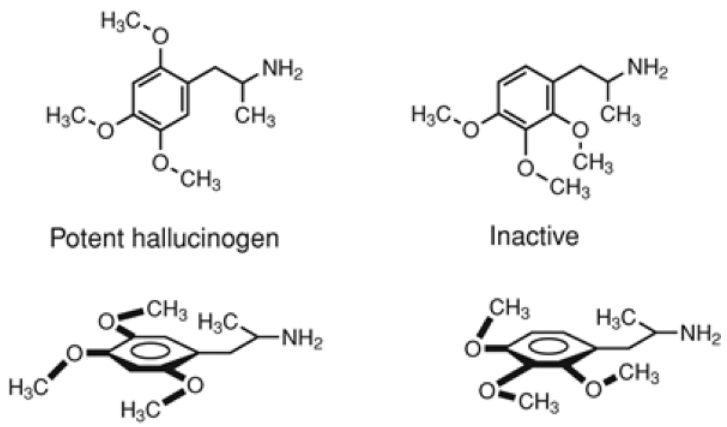


Fig. 2.32. Effect of positional isomers on structural conformation and biological activity.

In 1919, Langmuir (31,32) first developed the concept of chemical isosterism to describe the similarities in physical properties among atoms, functional groups, radicals, and molecules. The similarities among atoms described by Langmuir primarily resulted from the fact that these atoms contained the same number of

valence electrons and came from the same columns within the periodic table. This concept was limited to elements in adjacent rows and columns, inorganic molecules, ions, and small organic molecules, such as diazomethane and ketene. Table 2.7 shows a comparison of the physical properties of N_2O and CO_2 to illustrate Langmuir's concept.

To account for similarities between groups with the same number of valence electrons but different numbers of atoms, Grimm (33) developed his hydride displacement law. This is not a “law” in the strict sense but, rather, more an illustration of similar physical properties among closely related functional groups. Table 2.8 presents an example of hydride displacement. Descending diagonally from left to right in the table, hydrogen atoms are progressively added to maintain the same number of valence electrons for each group of atoms within a column. Within each column, the groups are considered to be “pseudoatoms” with respect to one another. Thus,

NH_2 is considered to be isosteric to OH, and so on. This early view of isosterism did not consider the actual location, motion, and resonance of electrons within the orbitals of these functional group replacements. Careful observation of this table reveals that some groups do share similar physicochemical properties, but others have very different properties, despite having the same number of valence electrons. For example, OH and NH_2 share similar hydrogen-bonding properties and, therefore, should be interchangeable if that is the only criterion necessary. The NH_2 group is basic, however, whereas the OH is neutral. Hence, at physiological pH, the NH_2 group would be in its protonated, or conjugate acid, form and give the molecule a positive charge. If OH is being substituted by NH_2, the additional positive charge could have a significant effect on the overall physicochemical properties of the molecule in which it is being introduced. The difference in physicochemical properties of the CH_3 group relative to the OH and NH_2 groups is even greater. In addition to basicity and acidity, this "law" fails to take into account other important physicochemical parameters, such as electronegativity, polarizability, bond angles, size, shape of molecular orbitals, electron density, and partition coefficients, all of which contribute significantly to the overall physicochemical properties of a molecule.

Table 2.7. Comparison of Physical Properties of N_2O and CO_2

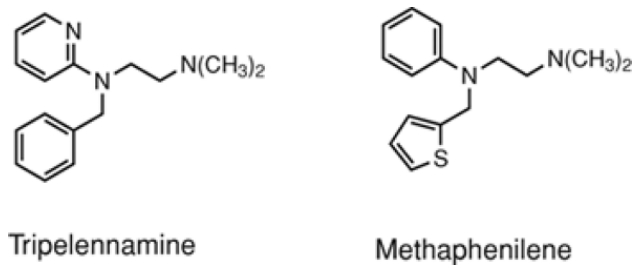
Property	N_2O	CO_2
Viscosity at 20°C	148×10^{-6}	148×10^{-6}
Density of liquid at 10°C	0.856	0.858
Refractive index of liquid, D line 16°C	1.193	1.190
Dielectric constant of liquid at 0°C	1.593	1.582
Solubility in alcohol at 15°C	3.250	3.130

Table 2.8. Grimm's Hydride Displacement "Law"

C	N	O	F	Ne
	CH	NH	OH	FH
		CH_2	NH_2	OH_2
			CH_3	NH_3

Instead of considering only partial structures, Hinsberg (34) applied the concept of isosterism to entire molecules. He developed the concept of "ring equivalents"—that is, groups that can be exchanged for one another in aromatic ring systems without drastic changes in physicochemical properties relative to the parent structure. Benzene, thiophene, and pyridine illustrate this concept (Fig. 2.33). A –CH==CH- group in benzene is replaced by the divalent sulfur, -S-, in thiophene, and a –CH== is replaced by the trivalent –N== to give pyridine. The physical properties of benzene and thiophene are very similar. For example, the boiling point of benzene

is 81.1°C, and that of thiophene is 84.4°C (at 760 mm Hg). Pyridine, however, deviates, with a boiling point of 115 to 116°C. Hinsberg therefore concluded that divalent sulfur (-S- or thioether) must resemble –C==C- in shape, and these groups were considered to be isosteric. Note that hydrogen atoms are ignored in this comparison. Today, this isosteric relationship is seen in many drugs (e.g., H_1-receptor antagonists) (Fig. 2.33).



Tripelennamine Methaphenilene

Fig. 2.33. Isosteric substitution of thiophene for benzene and benzene for pyridine.

Bioisosterism

It is difficult to relate biological properties to physicochemical properties of individual atoms, functional groups, or entire molecules, because many physicochemical parameters are involved simultaneously and, therefore, are difficult to quantitate. Simple relationships as described above often do not hold up across the many types of biological systems seen with medicinal agents. That is, what may work as an isosteric replacement in one biological system (or a given drug receptor, enzyme, etc.) may not work in another system. Because of this, it was necessary to introduce the term “bioisosterism” to describe functional groups related in structure and having similar biological effects. Friedman (35) introduced the term bioisosterism and defined it as follows: “Bioisosteres are (functional) groups or molecules that have chemical and physical similarities producing broadly similar biological properties.” Recently, Burger (36) expanded this definition to take into account biochemical views of biological activity: “Bioisosteres are compounds or groups that possess near equal molecular shapes and volumes, approximately the same distribution of electrons, and which exhibit similar physical properties such as hydrophobicity. Bioisosteric compounds affect the same biochemically associated systems as agonist or antagonists and thereby produce biological properties that are related to each other.” The key point is that the same pharmacologic target is influenced by bioisoteres as agonists or antagonists. What may work as a bioisosteric group in one biological system may not have similar effects on another.

Classical and Nonclassical Bioisosteres

Bioisosteric groups can be subdivided into two categories: classical and nonclassical bioisosteres. Functional groups that satisfy the original conditions of Langmuir and Grimm are referred to as classical bioisosteres. Nonclassical bioisosteres do not obey steric and electronic definitions of classical bioisoteres and do not necessarily have the same number of atoms as the substituent they replace. A wider set of compounds and functional groups are encompassed by nonclassical bioisoteres that produce, at the molecular level, qualitatively similar agonistic or antagonistic responses. In animals, many hormones, neurotransmitters, and so on with very similar structures and biological actions can be classified as bioisosteres. An example would be the insulins isolated from various mammalian species. Even though these insulins may differ by several amino acid residues, they

still produce the same biological effects. (If this did not occur, the use of insulin to treat

diabetes would have had to wait another 60 years for recombinant DNA technology to allow production of human insulin.)

Monovalent bioisosteres

F, H
OH, NH

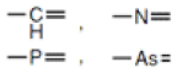
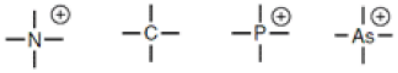
Trivalent atoms or groups:



Tetrasubstituted atoms:



Ring equivalents:

Table 2.9. Classical Bioisosteres (Groups Within the Row Can Replace Each Other)

What may be a successful bioisosteric replacement for a given molecule interacting with a particular receptor quite often has no effect or abolishes biological activity in another. Thus, the use of bioisosteric replacement (classical or nonclassical) in drug design is highly dependent on the biological system being investigated. No hard-and-fast rules exist to determine what bioisosteric replacement is going to work with a given molecule, although as the following tables and examples demonstrate, some generalizations are possible. The medicinal chemist, however, must still rely on experience and intuition to decide the best approach to use when applying this strategy.

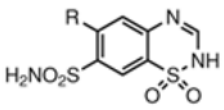
Each category of bioisostere can be further subdivided as shown below, and examples are provided in Table 2.9:

I.	Classical bioisosteres
	A. Monovalent atoms and groups
	B. Divalent atoms and groups
	C. Trivalent atoms and groups
	D. Tetrasubstituted atoms

	E. Ring equivalents
II.	Nonclassical bioisoteres
	A. Exchangeable groups
	B. Rings versus noncyclic structure

Classical Bioisoteres

Substitution of hydrogen by fluorine is one of the most common monovalent isosteric replacements. Sterically, hydrogen and fluorine are quite similar, with their van der Waal's radii being 1.2 and 1.35 Å, respectively. Because fluorine is the most electronegative element in the periodic table, any differences in biological activity resulting from replacement of hydrogen with fluorine can be attributed to this property.



R =	Cl	Br	CF_3
σ	+0.23	+0.23	+0.54
π	+0.71	+0.86	+0.88
E_s	-0.97	-1.16	-2.40

Fig. 2.34. Isosteric replacement of chlorine in thiazide diuretics. Comparison of physicochemical properties of the substituents.

A classic example of hydrogen replacement by fluorine is development of the antineoplastic agent 5-fluorouracil from uracil. Another example is shown in Figure 2.34, in which the chlorine of chlorothiazide has been replaced with bromine or a trifluoromethyl group. For each of the substitutions, the electronic (σ, where σ^+ is electron withdrawing and σ^- is electron donating) and hydrophobic (π) properties of each group are maintained relatively constant, but the size of each group varies significantly, as indicated by the Taft steric parameter (E_s).

Figure 2.35 shows an example of classical isosteric substitution of an amino group for a hydroxyl group in folic acid. The amino group is capable of mimicking the tautomeric forms of folic acid and providing the appropriate hydrogen bonds to the enzyme active site.

A tetravalent bioisosteric replacement study was done by Grisar et al. (37) with a series of α-tocopherol analogues (Fig. 2.36). α-Tocopherol has been shown to scavenge

lipoperoxyl and superoxide radicals and to accumulate in heart tissue. This is thought to be part of its mechanism of action for reducing cardiac damage resulting from myocardial infarction. All of the bioisosteric analogues were found to produce similar biological activity.

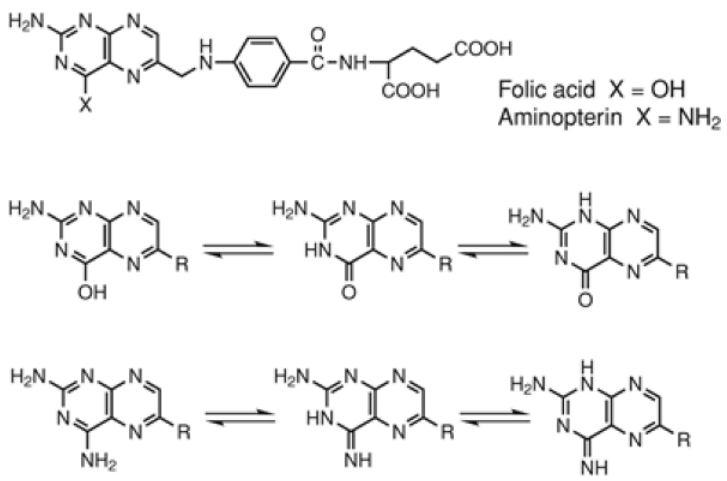


Fig. 2.35. Isosteric replacement of OH by NH_2 in folic acid and possible tautomers of folic acid and aminopterin.

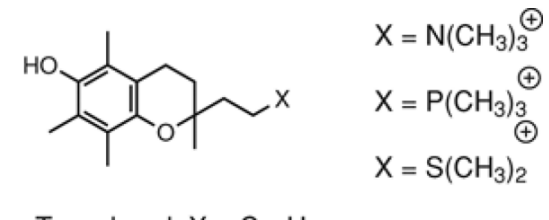

Fig. 2.36. Tetravalent bioisosteres of α-tocopherol.

Nonclassical Bioisoteres

As mentioned earlier, nonclassical bioisosteres are replacements of functional groups not defined by classical definitions. Some of these groups, however, mimic spatial arrangements, electronic properties, or some other physicochemical property of the molecule or functional group critical for biological activity. One example is the use of a double bond to position essential functional groups into a particular spatial configuration critical for activity. This is shown in Figure 2.37 with the naturally occurring hormone estradiol and the synthetic analogue diethylstilbestrol. The *trans* isomer of diethylstilbestrol has approximately the same potency as estradiol, whereas the *cis* isomer is only one-fourteenth as active. In the *trans* configuration, the phenolic hydroxy groups mimic the correct orientation of the phenol and alcohol in estradiol (38,39). This is not possible with the *cis* isomer, and more flexible analogues (Fig. 2.37) have little or no activity (40,41).

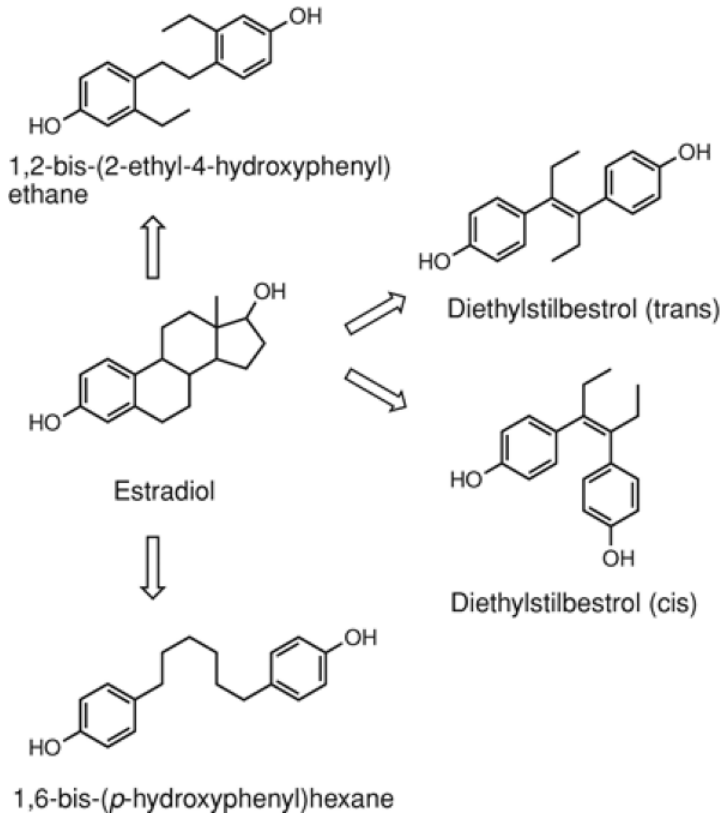

Fig. 2.37. Noncyclic analogs of estradiol.

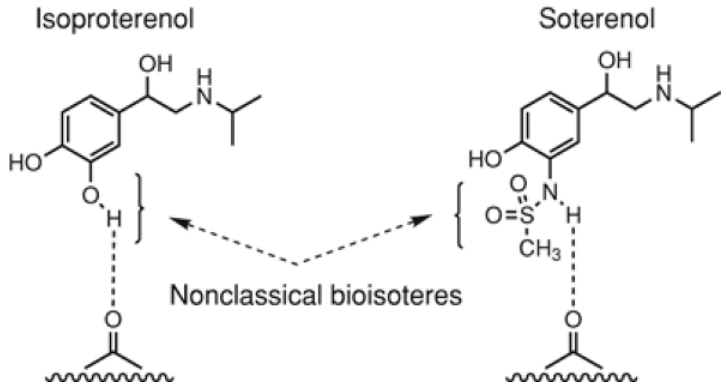

Fig. 2.38. Bioisosteric replacement of m-OH of isoproterenol with a sulfonamido group and similar hydrogen-bonding capacity to a possible drug receptor.

Another example of a nonclassical replacement is that of a sulfonamide group for a phenol in catecholamines (Fig. 2.38). With this example, steric factors appear to have less influence on receptor binding than acidity and hydrogen-bonding potential of the functional group on the aromatic ring. Both the phenolic hydroxyl of isoproterenol and the acidic proton of the arylsulfonamide have nearly the same pK_a (~10) (42). Both groups are weakly acidic and capable of losing a proton and interacting with the receptor as anions or participating as hydrogen-bond donors at the receptor, as shown in Figure 2.38. Because the replacement is not susceptible to metabolism by catechol O-methyltransferase, it also has the added advantages of

increasing the duration of action and making the compound orally active. Other examples of successful bioisosteric replacements are shown in Table 2.10, and a more detailed description of the role of bioisosterism can be found in the review by Patani and LaVoie (43).

Summary

Medicinal chemistry involves the discovery of new chemical entities for the treatment of disease and the systematic study of the SARs of these compounds. Such studies provide the basis for development of better medicinal agents from lead compounds found via random screening, systematic screening, and rational design. The role of the medicinal chemist is to increase the potency and duration of action of newly discovered compounds and to decrease adverse side effects. Without a thorough understanding of the physicochemical properties of the organic functional groups that comprise any given structure, this task would be impossible.

For the pharmacist, it is also important to understand the physicochemical properties of the medicinal agents that he or she is dispensing. Such knowledge will help the practicing pharmacist not only to better understand the clinical properties of these compounds but also to anticipate the properties of new agents that appear on the

market. An understanding of the chemical properties of the molecule will allow the pharmacist to anticipate formulation problems (especially IV admixtures) as well as potential adverse interactions with other drugs as the result of serum protein binding and metabolism.

Table 2.10. Nonclassical Bioisosteric Replacements

Problems

The following problems are provided for additional study:

1. Calculate the percentage ionization of amobarbital at pH 2.0, 5.5, and 8.0. What trend is seen?
2. Calculate the percentage ionization of phenylpropanolamine at pH 2.0, 5.5, and 8.0. Compare these results with those obtained in Problem 1.
3. Calculate the percentage ionization of sulfacetamide in the stomach, duodenum, and ileum. Draw the structure of the predominate form of the drug in each tissue.
4. Referring to Figure 2.15, redraw each compound in its ionized form.
5. For the organic functional groups listed in Table 2.4, name each functional group, and

redraw them, showing all potential hydrogen bonds with water.

6. Using the empiric method of Lemke, predict the water solubility for each of the following molecules (*Note:* Water solubility is defined as >1% solubility):

Aspirin	Carphenazine maleate
Chlordiazepoxide	Codeine
Codeine phosphate	Cyproheptadine hydrochloride
Haloperidol	Phenytoin

7. Calculate the logP value for each of the following:

Aspirin	Carphenazine
Codeine	Cyproheptadine
Haloperidol	Chlordiazepoxide
Phenytoin	

8. Using the Merck Index, find the chemical structures for the following empirical formulae. List as many physicochemical properties as possible for each compound, and compare them within each group of isomers:

$$C_4H_{10}O_2 \quad C_5H_8O$$
$$C_5H_{11}O_2 \quad C_7H_7NO_2 \quad C_8H_8O_2$$
$$C_{12}H_{17}NO_3$$
$$C_{20}H_{30}O_2$$

9. Using the Cahn-Ingold-Prelog rules, assign the absolute configuration to each chiral center of ephedrine and pseudoephedrine (Fig. 2.21).

10. For the compounds shown in Figure 2.22, indicate, using an*, where the chiral centers are in each molecule.

11. Draw each possible stereoisomer for chloramphenicol and enalapril. Assign the absolute stereochemistry to each chiral center.

12. I. Draw the Newman projection along the CH_3-N bond of acetylcholine in the staggered conformation. Rotate the bond 120° and 240°. Are these rotameters conformational isomers? Explain why or why not.

    II. Repeat the above exercise with the N1–C2 bond of acetylcholine.

13. Draw the three most stable rotameters of norepinephrine. Of these rotameters, is there the possibility of an intramolecular interaction that would stabilize what normally would be

considered an unstable rotameter? Explain.

Chapter 3

Molecular Modeling and In Silico Drug Design

Xiang-Qun (Sean) Xie

Introduction

Molecular modeling allows scientists to use computers to visualize molecules, to discover new lead compounds for drugs, or to refine existing drugs in silico. It enables computational chemists to rigorously study molecular behavior in ways that are not possible in the laboratory. “Molecular modeling” is a term for which the definition has evolved along with the capabilities of computer hardware and algorithms. The term referred to software capable of displaying and manipulating simple structures of molecules. As computers became faster and algorithms more accurate, the term grew to include algorithms for calculating the structures of small molecules, such as the pioneering work of Hendrickson (1). Modern molecular modeling software is used to study small molecules, proteins, lipids, DNA, and nonbiological work. One goal of molecular modeling is to develop a sufficiently accurate model of the system so that the physical experiments may not be necessary.

As we learn about physical chemistry, we extend that understanding to new systems of interest, but the transition from simple molecules to more complicated systems is limited by our human abilities. We can imagine a butane molecule and imagine both how and why different conformers are preferred. When we tackle pentane or combinations of functional groups, however, it becomes difficult to simultaneously consider the relative effects of electrostatics, steric interactions, and bulk properties, such as solubilities. Fortunately, we can construct models in software that allow us to properly treat all of these interactions. The scientific field of molecular modeling or, more generally, computational chemistry is the practice of simulation of molecular systems with sufficient detail to address a question of interest.

Furthermore, computational chemistry has advanced from the classical quantum mechanical ab initio calculations to semiempirical molecular orbital calculations and molecular mechanics empirical force fields. The tremendous development of the new generation of simulation techniques (e.g., molecular dynamics, Monte Carlo, docking, and virtual screening) and advanced computer hardware provides high computing power and various molecular modeling or computational chemistry approaches. Actually, the term “molecular modeling” has expanded over the last decades from a tool to visualize three-dimensional (3D) molecular structures (Fig. 3.1) and to simulate, predict, and analyze the properties and behaviors of molecules on an atomic level to a data-mining and *in silico* drug design platform to organize many compounds and their properties into databases and to perform virtual drug screening via 3D database searches for novel drug compounds.

The diverse molecular modeling packages have converged to offer a core of similar capabilities for manipulating molecules. They differ in their user interfaces and level of sophistication. Several newly emerged programs have specialized functions for fields such as virtual drug screening, virtual combinatorial chemistry, de novo drug design, chemical synthesis pathway prediction, and toxicology (absorption, distribution, metabolism, and excretion [ADME]) prediction as reviewed in literature (2,3,4,5,6,7,8,9,10). Various computer molecular modeling software programs are available for computational chemistry (described later); however, several pitfalls are associated with computational chemistry. Software packages are marketed to simplify our work by providing extensive default choices, which simplifies a calculation. The default parameters sometimes are incapable of providing a meaningful result. It is the user's responsibility to determine the appropriate methods and parameters for the quality of the result needed. A second pitfall is overinterpreting of the results while ignoring the experimental data. Little effort is made in most packages to provide error analysis and data integrity tests. A good application of computational chemistry techniques ensures that a level of accuracy appropriate to the question is used and balances the amount of computer time necessary with the importance of the result. An appreciation of molecular modeling and its pitfalls requires an understanding of the fundamentals presented in this chapter.

In this chapter, we shall discuss the basis and common applications of molecular modeling methods so that readers may appreciate its usefulness and be wary of its shortcomings. The cost for an improved understanding of what computational chemistry techniques can accomplish is an investment of time to understand the mathematical basis for representing atoms and molecules in software. Once the reader is equipped with a basic appreciation of the molecular model, the different methods and applications available to the practitioner make more sense. A brief review of the physical principles is provided to help medicinal chemists to recall the mathematical basis underlying the subsequent computational techniques. The techniques described in this chapter include molecular mechanics, molecular dynamics simulations, Monte Carlo techniques, ligand docking, and virtual screening methods. This chapter also covers the modern computer-aided drug design approaches, including ligand-based design and receptor-based design, along with the practical aspects of these techniques and applications.

Computational Chemistry Approaches

Molecular modeling or, more generally, computational chemistry is the scientific field of simulation of molecular systems. An effective simulation must include enough of the underlying physical and quantum chemistry to capture the behavior of the system of interest. This chapter, however, tends to focus on computational chemistry techniques and applications to meet its objectives.

Basically, computational methods can be thermodynamically rigorous by considering the components of the free energy of the system ($\Delta G = \Delta H - T\Delta S$). Once it can be estimated, the free energy of a system can be used to assess many interesting aspects of the system. In drug design, the free energy may be used to assess whether a modification to a drug increases or decreases target binding. In developing formulations, it can be used to estimate the relative stability of different compounds. In synthesis, it may be used to determine if the system is at equilibrium or how fast and to what extent it is likely to undergo a reaction. The central, descriptive role of the free energy, ΔG, makes it a worthwhile target for computational methods. In addition, the enthalpy (ΔH) of a system may be estimated as the energy required for assembling the constituents into a particular configuration. Consequently, the energy of the system is a function of the type and number of atoms and their positions. Molecular modeling software is designed to calculate this efficiently. To date, four levels of theory have matured and found widespread use in molecular modeling: ab initio, density functionals, semiempirical methods, and empirical force fields. For example, the configurational energy of the butane molecule in Figure 3.2 (black line) could be calculated by each of these methods. The first three are quantum mechanical methods and are based on different solutions to Schrödinger equation. Empirical force fields are an example of molecular mechanics approaches and are based on simple functions that are fit to experimental data. These implicitly include quantum effects and, consequently, are much faster to compute.

An understanding of the different levels of theory is important in the design of a computational study. In general, the more detailed the description (i.e., a higher level of theory), the more accurate and generally useful the results. On the other hand, the more detailed the description, the longer the calculation takes. For example, quantum mechanical methods offer some of the most detailed and robust expressions for the energy. They are lengthy calculations for small systems (10–100 atoms) and intractable for larger ones. Empirical force fields were developed to capture much of the behavior of systems but are much faster. A typical empirical force field calculation can be 10^4-fold faster than a quantum mechanical model. Because the available computing resources place a practical limit on our studies, it is appropriate to match the level of theory to the question. To be effective, the level of theory must contain terms necessary to reproduce the effect under study. For example, to study electron rearrangement, it must contain explicit terms for electrons. Although this seems obvious, molecular modeling software packages often make it easy for the casual user to use the wrong tool, which can result

in misleading findings. Therefore, each of the four levels of theory will be covered later.

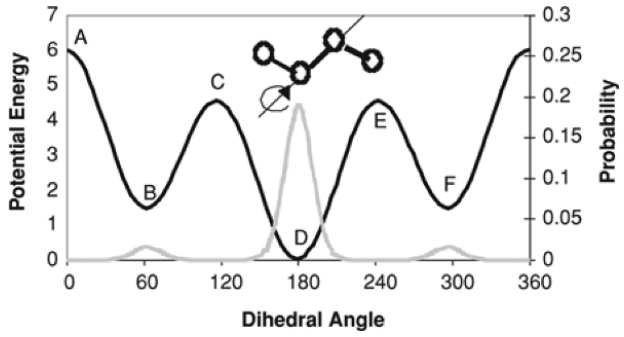

Fig. 3.2. Potential energy surface of a dihedral angle in butane.

Molecular Behavior: Computing the Energy of a Model system

The energy of a set of molecules plays a central role in computational chemistry, so it figures prominently in this chapter. If an algorithm can estimate the energy of the system, then many important properties may be derived from it. In an ideal world with infinitely fast computers, the energy would be computed from first principles (ab initio) using our most precise level of quantum theory. On today's computers, however, this level of theory could take days or months to calculate—even for a simple system. So, in practice, various approximations must be introduced that reduce the calculation time while adding an acceptably small effect on the result. As long as we are aware of the approximations and the errors they introduce, we are free to take this more expedient route. When designing a study, a computational chemist must carefully select the appropriate level of theory to derive meaningful results in a reasonable amount of time.

Four levels of theory (or accuracy) will be introduced in later sections to compute the energy of a system, ranging from empirical force fields to quantum chemistry. Fortunately, all of these methods are used to quantify the physicochemistry concepts with which we have become familiar. For example, consider the familiar conformations of butane. The central dihedral angle of butane and its associated energy are shown in Figure 3.2. The *trans* conformation (D in Fig. 3.2) is the lowest energy, because it reduces the steric interaction between the terminal methyl groups. For any given rotation about this central angle, the associated energy may be computed using any of the four levels of theory introduced in the next section.

Small molecules are comprised of bonded atoms and, typically, adopt the most favorable conformation. This one-dimensional potential energy surface (Fig. 3.2, black line) represents the excess conformational energy for the dihedral angle formed by the

four carbons in butane, for example. Butane has the *trans* (180°) configuration (D in Fig. 3.2) as its favorable, low-energy state. The *cis* (0°) position (A in Fig. 3.2) is the relative maximum. The gauche (60° and 300°) positions (B and F, respectively, in Fig. 3.2) are local minima. The probability of a given state also is shown in Fig. 3.2 (gray line).

Prediction of a molecule's behavior demands that we consider more than the energy of a single configuration. For example, if we wish to predict what conformation a butane molecule is most likely to adopt, we must consider the energy of its current state as well as the energy of the states it might adopt. If we only compute the energy of the butane molecule in its gauche conformation (B or F in Fig. 3.2), we would not observe that it would be more stable in the *trans* conformation. We can use the energy profile for butane in Figure 3.2 to determine how likely a given conformation is populated (gray line in Fig. 3.2). Similarly, if we are interested in how a drug binds to its target, we should consider all of the binding sites—not just one. To increase the utility of the study, we should consider the energy of the nearly infinite number of states it could adopt. Several methods, including molecular mechanics, molecular dynamics, and Monte Carlo methods, will be introduced later to address the possible states.

Quantum Mechanics: Energies Derived from Theory

Generally, molecular modeling methods can be categorized as molecular mechanics and quantum mechanics (molecular orbital) methods. Quantum mechanics is basically molecular orbital calculation and offers the most detailed description of a molecule's chemical behavior. An example of molecular orbitals of HOMO and LUMO calculation is illustrated in Figure 3.3. The surface type of HOMO is the highest-occupied molecular orbitals, and LUMO represent the lowest-unoccupied molecular orbitals. The shapes and symmetries of HOMO and LUMO are crucial in predicting the reactivity of a species and the stereochemical and regiochemical outcome of a chemical reaction. Several molecular properties (Table 3.1) are only accessible with these methods, because they explicitly require a description of the molecule's electronic structure. It is important to understand their foundation as well as their relative accuracy and generality.

Quantum mechanics is based on the extended Schrödinger equation to describe the motion of the nucleus and electrons on the potential energy surface:

$$H\Psi = E\Psi = (U + K)\,\Psi \qquad \textbf{Eq. 3.1}$$

where H is the Hamiltonian for the system, Ψ (pronounced “p-sigh”) is the wavefunction, and E is the energy. Simply put, the Hamiltonian is an “operator,” a mathematical construct that operates on the molecular orbital, Ψ, to determine the energy. The total energy E

contains the potential energy (U) energy and kinetic energy (K) components. The wavefunction Ψ describes the distribution of the electrons around the molecule (e.g., *s, p, d, f, ...* orbitals and their complex shape). Hamiltonian H is shorthand notation for operations necessary to add up the total energy of the system. So, quantum mechanical methods are the most rigorous methods in use for describing the energy, and they include quantum effects explicitly. Typically, three quantum mechanical calculations are used for molecular modeling: ab initio, density functionals, and semiempirical methods.

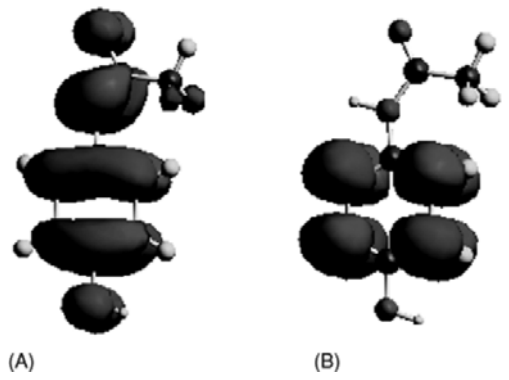

Fig. 3.3. Graphic visualization of molecular orbital surface HOMO/LUMO calculation for the drug molecule acetaminophen. (See color plate.)

Table 3.1. Summary of Molecular Modeling Methodologies and Their Capabilities

		Quantum mechanical Calculations		
	Empirical Force Fields Calculations	**Ab initio**	**Density Functional Theory**	**Semiempirical**
Basic principle	Hamiltonian equation		Schrödinger's equation	
Level of computing	Atoms		Electrons, nuclei orbital	
Parameterization	By atom type and charge	None		
Geometry optimization	Yes	Yes	Yes	Yes

Molecular dynamics	Yes	No	No	Limited
Vibration spectra	Yes	Yes	Yes	Yes
Heat formation Δ*H* (enthalpy)	Relative	Yes	Yes	Yes
Binding energy Δ*G* (free energy)	Yes	No	Yes (but not accurate)	Yes

Ab Initio Methods

Ab initio methods (11), derived "from the beginning" premises of quantum theory, is one of the quantum mechanical calculations based on the Hartree-Fock self-consistent field theory with one-electron molecular orbital. This method that uses no experimental data is based on variation theory to seek the nuclear geometry of the molecule or hydrogen-bonded complex with lowest energy.

Hartree and Fock simplified calculations by combining the electrons into an averaged field. This allowed the Hamiltonian to be calculated for each electron independently using a new term for its interaction with the overall electron cloud. So, low-energy conformations, especially for global conformation searches, require very large amounts of computer time, both because atomic Cartesian coordinates are allowed to vary and because the nuclear configuration of minimum energy is sought. This involves a global search in 3(*N 2* 1) dimensions, where *N* is the number of atoms in the molecule or assemblage of molecules. Basically, the ab initio method is initially introduced only as satisfactory for modeling small molecules (11), whereas more computational work has been reported using ab initio method as the high computing horsepower and capability lately become available. Many properties of molecules may be determined following a successful determination of the molecular orbitals and their occupancy, such as dipole moments, magnetic susceptibility, chemical shielding, spin–spin coupling constants, and electron affinities. Several versions of ab initio methods are available. Commercial software packages tend to have more sophisticated user interfaces, such as Gaussian series (12). It requires no a priori assumptions about the structure and only needs the atomic positions. Unlike experimental methods of structural analysis, no basis exists for estimating the error associated with a particular calculation; however, calculations are performed at successively more accurate levels, each of which requires more computer time. In addition,

academic versions at low cost and with a variety of methods under development are available, including GAMESS (13,14) (http://www.msg.ameslab.gov/GAMESS) and GAMESS-UK (15) (http://www.cfs.dl.ac.uk/gamess-uk/).

Density Functional Theory

Basically, density functional theory (DFT) is similar to the ab initio method, but it is not based on a wavefunction. Instead, the energy is computed as a functional of the electron density (16). The DFT methods were developed that are much faster than Gaussian-style programs. Currently, many functional approximations are in use.

The most common implementation of DFT is through the Kohn-Sham method (sometimes called the Kohn-Sham theory) (17). Within the framework of Kohn-Sham DFT, the many-body complex of interacting electrons in a static external potential is reduced to a tractable problem of noninteracting electrons moving in an effective potential. The effective potential includes the external potential and the effects of the Coulomb interactions between the electrons (e.g., the exchange and correlation interactions). DFT was not considered to be accurate enough, however, for calculations in quantum chemistry until the 1990s, when the approximations used in the DFT theory were greatly refined to better model the exchange and correlation interactions. DFT is now a leading method for calculations of electronic structure. Nevertheless, despite the improvements in DFT, difficulties remain in using DFT to properly describe intermolecular interactions, especially van der Waals forces (dispersion).

Density functional theory is a successful approach for the description of ground-state properties of metals, semiconductors, and insulators. It also has become an attractive method to calculate complex materials, such as proteins and carbon nanotubes. For example, DFT calculation has been used to compute anion-binding properties of 2,6-diamidopyridine dipyrromethane hybrid macrocycles (18), to predict drug resistance of HIV-1 reverse transcriptase to nevirapine through point mutations (19), and to analyze the β_2-adrenergic G protein–coupled receptor (20). A free DFT software program also is available (http://dft.physics.cornell.edu/). The detailed techniques and potential applications of DFT as well as drug design were described in a recent review (21).

Semiempirical Molecular Orbital Methods

Semiempirical calculations are based on the same or related quantum mechanical principles above but make approximations or assumptions for the majority of the electron–electron interactions to simplify the computations or to include some empirical parameters based on experimental data (22). Three types of semiempirical methods, which differ in their approach to approximation, have been used extensively for conformational calculations on medium-size biological molecules, including the CNDO (complete neglect of differential overlap) (23), MNDO (Modified Neglect of Differential Overlap; a part of the MOPAC program) (24), and PCILO (Perturbation Configuration Integration Using Localized Orbital) (25). Both CNDO and MNDO simplify the computations by neglecting (or partially neglecting) the differentials in the energy calculations for the valence electrons, and both treat the inner-shell electron as a core that screens the nuclear charge. In PCILO calculations, the molecular orbitals are not expanded in the usual LCAO (linear combination of atomic orbitals) form but, rather, in pairwise hybrids. It uses perturbation theory rather than variation theory to obtain the wavefunctions and to calculate the energy. The PCILO method is too computationally intensive for macromolecules. The global searching problem can be severe for even small molecules with a significant number of variable torsion angles.

$$E = \sum_{Bond} \frac{1}{2} k_r (rb - br_0)^2 + \sum_{Angle} \frac{1}{2} k_\theta (\theta - \theta_0)^2 + \sum_{Dihedral} \frac{1}{2} k_\phi [1 + \cos(n\phi + \delta)] + \sum_{Coulomb} \frac{q_i q_j}{\varepsilon r_{ij}} + \sum_{vdw} \varepsilon \left[\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}} \right]$$

Fig. 3.4. A generic empirical force field equation.

The MOPAC program (Molecular Orbital PACkag) (26) is one of the popular quantum mechanical semiempirical methods. The AM1 (Austin Model 1), developed by Michael Dewar (26), is a generalization of the modified neglect of differential diatomic overlap (MNDO) approximation. Often, AM1 is implemented in the MOPAC, and MOPAC(AM1) has been widely used to minimize molecular conformations, to calculate electronic configuration, and to predict such properties as electron distribution and partial charges. The semiempirical methods are dramatically (100- to 1,000-fold) faster and are suitable for many applications. The results of AM1 calculations often are used as the starting points for parameterizations (e.g., atomic charges) of force fields in molecular dynamics simulations (27,28) and CoMFA quantitative structure–activity relationship (QSAR) modeling studies (29).

Molecular Mechanics: Energies Approximated from Experimental Data

Molecular mechanics is based on simple empirical approximations of atomic and molecular interactions. The Hamiltonian in molecular mechanics classically describes the energy of the whole system as the sum of the inter- and intramolecular interactions. Simply put, the energy of a molecular system is evaluated two atoms at a time, without quantum mechanics. The generic molecular mechanics potential energy function is given in Figure 3.4 and further breaks down the pairwise interactions into bonded interactions (or internal coordinates) and nonbonded interactions. Atoms that are connected via one to three bonds are treated with internal coordinates. The nonbonded terms include an electrostatic and van der Waals component. This type of potential energy function sometimes is referred to as an empirical force field, because the energetic terms have simple forms and parameters that are derived from experimental data and ab initio calculations.

It is on this expression that the whole field of molecular mechanics, conformational calculations, and molecular dynamics

simulations rest. A “force field” therefore just includes an analytical energy function and its associated set of numerical parameters. In other words, the force field is an empirical fit to the potential energy of a molecular system. It defines the coordinates to be used

P.59

(the bond lengths, *b*, and angles, θ, φ); the functional mathematical forms ranging from simple quadratic to Morse functions, Fourier expansions, Leonard-Jones potentials, and so on; and the parameters adjusted in the empirical fit of the potential energy surface. Simply said, the force field is the description of the potential energy of a molecule as a function of its position (or coordinates) of all the atoms, as described below.

Bonded Interactions

The bonded interactions or internal coordinates (short-range energy terms) are used to better approximate the interaction of adjacent atoms. The bond, angle, and dihedral terms are used to treat atoms that are separated by one, two, and three bonds. To better illustrate the bonded energy terms, we can consider that the calculation of internal energies in molecular mechanics is simply based on the Newtonian laws of classical mechanics (30,31,32). Molecules are treated as if they consist of an assembly of soft rubber balls (or atoms) and springs (or bonds), as shown below. Each ball (or atom) is the junction point between springs (or chemical bonds), which have, at their equilibrium state, bond length (b_0), bond angle (θ_0) and torsion angle (φ_0), with appropriate values of stretching (k_b), bending (k_θ) and twisting (k_φ) force constants, respectively (Fig. 3.5).

Principally, for small deviations from the equilibrium values, Hooke's Law is applied:

Eq. 3.2 $$f = kx$$

where the force, *f*, on the spring (or bond) needed to stretch an ideal spring is proportional to its elongation *x*, and where *k* is the force constant or spring constant of the spring. The extension of Hooke's Law to a molecular system is illustrated in Figure 3.5 with respect to bond stretching, bond angle bending, and torsion angle. Hooke's Law can approximate the bond vibration:

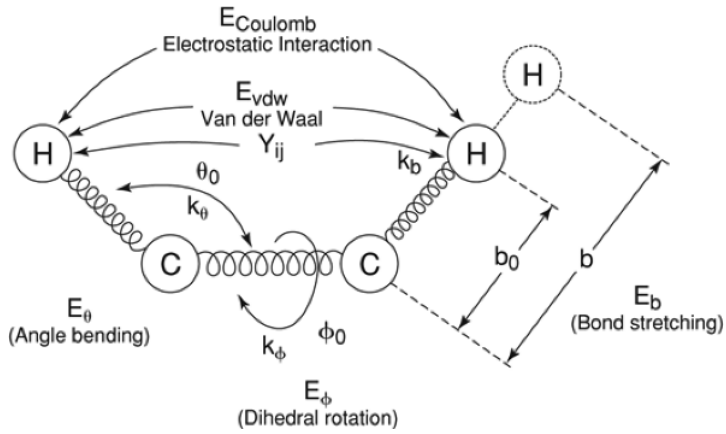

Fig. 3.5. Graphic representation of the bonded and nonbonded interactions and the corresponding energy terms.

Eq. 3.3

$$E_{\text{Bond Vibration}} = \frac{1}{2}k_b(b-b_0)^2 + \frac{1}{2}k_\theta(\theta-\theta_0)^2 + \frac{1}{2}k_\phi(1-\cos(n\phi+\delta))$$

where k_b, k_Θ, and k_φ are the bond and angle force constants. These three parameters are specific to the type atoms and the bond order (e.g., –C–C–, –C==C–, and –C–N). The values for the parameters are derived from x-ray crystallographic structures and infrared spectra. The squared term in Hooke's Law results in both compression (negative displacement) and expansion (positive displacement) of the bond from its equilibrium value increasing the energy.

The “bond term” is symmetric about the equilibrium bond length, and we know this is an approximation. It actually takes more energy to compress the bond than to stretch it. If necessary, we can use a Morse function that takes more time to compute but does a better job. In general, as long as the bond length is not too far from the equilibrium, the approximation is a good one (Fig. 3.5):

Eq. 3.4 $$E_{\text{bond}} = \frac{1}{2}k_b(b-b_0)^2$$

The “angle term” uses a similar term to increase the energy when the bond angle bends or deviates from its equilibrium value (Fig. 3.5):

Eq. 3.5 $$E_{\text{angle}} = \frac{1}{2}k_\theta(\theta-\theta_0)$$

The energy of the dihedral angles must be periodic, because, for example, dihedral angles across single bonds are free to rotate. This term's potential energy surface is the same as the butane central dihedral angle (Fig. 3.2) and is treated as a sum of cosine terms (Fig. 3.6):

Eq. 3.6 $$E_{\text{dihedral}} = k_\phi(1+\cos(n\phi+\delta))$$

P.60

where k_φ is the dihedral force constant, *n* determines the periodicity of the term, and δ adjusts phase for each term. The parameters for this term are adjusted to reproduce infrared and crystallographic data.

Nonbonded Interactions

The nonbonded interactions (long-range energy terms; i.e., the electrostatic and van der Waals terms) are applied to nearly all

pairs of atoms. They are not computed for pairs of atoms treated by the internal coordinates, because the bond, angle, and dihedral terms provide a better approximation of their interaction. The nonbonded terms usually are smaller in magnitude individually, but they can have a dominant effect because of the large number. The number of atom pairs is $N(N-1)/2$, where N is the number of atoms in the system. A typical model of a protein (without solvent) might have 5,000 atoms, with 25,000,000 atom-pair interactions and 15,000 internal coordinate terms to calculate. It is no surprise that the nonbonded interactions usually take more than 90% of the computer time for a simulation. Several methods exist for reducing the number of interactions that need to be calculated, but each introduces artifacts. Recently, the Ewalds method has gained general acceptance as a way to include all interactions within an acceptable amount of computation (33) using some mathematical cleverness and periodic boundary conditions. The nonbonded terms usually include electrostatic interactions and van der Waals interaction, which are almost the same for all force field programs and are expressed as coulombic interactions as well as Lennard-Jones type potentials, respectively. All of them are a function of the distance between atom pairs, r_{ij} (nonbond cutoff distances) (Fig. 3.5).

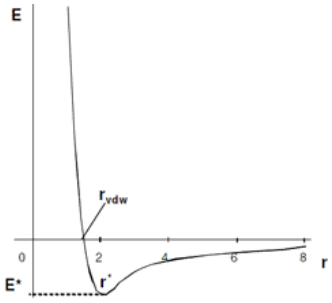
Electrostatic interactions between atoms (e.g., atoms i and j), either within a molecule or between adjacent molecules, are calculated using Coulomb's Law by means of an atomic point-charge model. Each atom is assigned a charge to represent both formal and partial charges that arise because of unequal sharing of electrons. The partial charges frequently are derived from quantum mechanical calculations that are described in the previous section. Although the form of Coulomb's Law is simple, it captures the underlying physics. The magnitude of the interaction is proportional to the atoms' charges (q_i and q_j) and inversely proportional to their separation (r_{ij}) and the dielectric constant (ε):

Eq. 3.7

$$E_{\text{Coulomb}} = \frac{q_i q_j}{\varepsilon r_{ij}}$$

The dielectric constant ε is a bulk property of the environment of a system. The dielectric of a vacuum is one, which implies that no polarization of the environment exists. If a solvent, such as water or methanol, is explicitly included in the system, then a dielectric of one is used, because the orientation of the solvent molecules will polarize in the presence of the electric field. If water is the solvent, it is possible to use continuum models and, thus, reduce the amount of computation required. This does add artifacts to the simulation. These artifacts are fairly well characterized, however, and the computation time is dramatically reduced. In some case, two different dielectric constants were used to mimic the different biological environments. For example, in a membrane protein structural modeling, the dielectric constant was set to a value of five for simulating the hydrophobic transmembrane environment and the dielectric constant to 80 for mimicking the hydrophilic loop environment in the two phases of computer simulations (34).

Van der Waal term describes a more complex interaction between nonbonded atoms. Atoms (e.g., atoms i and j) are attracted to each other by weak dispersion forces (also called London forces) linked to small oscillating dipoles created by electron cloud fluctuation. Atoms also are repelled by each other because of the Pauli exclusion principle, which states that no two electrons may share the same quantum numbers. The van der Waals interaction between two atoms (e.g., atoms i and j) arises from a balance between repulsive and attractive forces. At a large distance, a net attraction or dispersion force exists between all (even neutral) atoms because of the concerted oscillation of their electrons, and the forces become stronger linearly as $1/r$ to the sixth power increases. At close range, however, the electrons and nuclei strongly repel each other, and the forces of repulsion become more repulsive linearly as $1/r$ to the 12th power increases. The attractive interaction usually is longer range than the repulsion, but as the distance become short, the repulsive interaction becomes dominant. This gives rise to a minimum in the energy. Positioning of the atoms at the optimal distances stabilizes the system. Both the value of energy at the minimum (E^*) and the optimal separation of atoms (r^*, or the sum of Van der Waals radii of the atoms) depend on chemical type of these atoms. The van der Waals interaction most often is modeled using the Lennard-Jones 6-12 potential, which expresses the interaction energy using the atom-type dependent constants A_{ij} and B_{ij}. Experimental data for the energy of interaction can be fit with a Lennard-Jones, or 6-12, function:



Eq. 3.8

$$E_{\text{vdw}} = \varepsilon\left[\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}}\right]$$

where r_{ij} is the distance between the atoms (i and j), The constant A_{ij} and B_{ij} values may be determined by a variety

of experimental methods, such as nonbonding distances in crystals and gas-phase scattering measurements.

Force fields

The above internal coordinates and nonbonded interaction terms comprise the force field equations in molecular mechanics to calculate the potential energy of a molecular system. The basic form of empirical force fields has been varied as part of efforts to improve their treatment of various biological systems. Extensive work has been done on the systematic improvement of the both the form and the parameters used (35). However, this consensus form is common to AMBER (36), CHARMM (37), and CVFF (38), three popular classical empirical force fields.

Amber (Assisted Model Building and Energy Refinement)

The AMBER force field was developed by Peter Kollman and coworkers (39) at the University of California, San Francisco. In addition to the common terms of generic force fields, AMBER has a hydrogen-bond energy term that augments the electrostatic description of the hydrogen bond and estimates the relative contribution of energy from hydrogen-bonding. AMBER defines the atomic partial charges by using a charge-fitting scheme that replicates the electrostatic potential at a distance out from the nucleus, with only the atom centers having charge. An extended version of AMBER (40) has been parameterized and widely used

for proteins and DNA. AMBER also is the name for the molecular dynamics simulation package that implements these force fields. Further development of both the force fields and software is now coordinated by David A. Case at the Scripps Research Institute.

Charmm (Chemistry at HARvard Macromolecular Mechanics)

The CHARMM force field, originally developed at Harvard, has been widely used for both small molecules and macromolecules (37). This force field has two additional energy terms, including the improper term that accounts for the out-of-plane bending with the out of plan angle ($\omega - \omega_0$) and the force constant (k_ω) as well as the cross-term (Urey-Bradley component) that accounts for angle bending using 1,3-nonbonded interactions with the respective force constant (k_u) and the distance (U) between the 1,3-atoms in the harmonic potential. In addition, CHARMM uses different protocols to develop the partial atomic charges by beginning with the Mullikin charges and then strategically places a water molecule near any polar group. The extended CHARMM development project involves a network of developers in the United States and elsewhere working with Martin Karplus and his group at Harvard to develop and maintain the CHARMM program.

Cvff (Consistent Valence Force field)

The CVFF is the original force field provided with the Discover program (41) and is a generalized valence force field (42). Valence charge and atom-type parameters are provided for amino acids, water, and a variety of other functional groups. The force field expression consists of additional energy terms (i.e., the cross-terms that account for interactions between the four internal coordinates). The cross-terms represent the coupling between the adjacent bond–bond, the angle–angle term, the bond–angle term, the valence angle–torsion angle, and improper torsions. Such cross-terms are important for accurately reproducing experimental properties (e.g., vibrational frequencies) but can cause problems during the initial refinement of strongly distorted structures (derivatives > 100 kcal/mol/Å). So, both cross-terms and the Morse potential should be used only with the reasonably optimized structures.

Other force fields

In addition to the classical force fields above, many other force fields have been developed for small drug molecules or macromolecules. The MM2, MM3, and MM4 force fields were developed by Norman L. Allinger for a broad range of chemicals, and CFF is a family of force fields adapted to a broad variety of organic compounds, polymers, metals, and so on. The MMFF force field was developed at Merck for a broad range of chemicals. ReaxFF is a reactive force field, developed by William Goddard and coworkers, is fast, transferable, and the computational method of choice for atomistic-scale dynamics simulations of chemical reactions.

These programs are organized quite differently. The most popular commercial packages offer mature, sophisticated user interfaces, with easier point-and-click interfaces for many functions. The academic versions typically offer more advanced features and methods that are still under development. Their user interfaces are improving but lack robust point-and-click interfaces. Each offers advantages and disadvantages that must be considered before selecting one program and spending the time to learn it.

The advantages of empirical force field methods lie in their ability to treat thousands of atoms and their direct connection with statistical thermodynamics. Many biological systems, such as enzymes, proteins, and DNA and their complexes, are within the range of molecular mechanics. Scoring functions and simulations based on empirical force fields have successfully analyzed binding modes, folding mechanisms, and allosteric effects. The simulations may be analyzed with statistical thermodynamics methods to estimate the free energy of binding or folding. Trajectories of atoms may be used to derive diffusion constants or to compare with nuclear magnetic resonance (NMR) estimates of atomic motion. The flexibility of empirical force field methods must be balanced with the time required to develop parameters for a new system. Proteins, nucleotides, and carbohydrates parameter sets continue to evolve but have been useful for more than 10 years. Novel lead compounds often will require parameterization to achieve meaningful results.

Molecular Mechanics Energy Minimization

Molecular mechanics is an approach of energy minimization that finds stable, low-energy conformations by changing the geometry of a structure or identifying a point in the configuration space at which the net force on each atom vanishes. In other words, it is to find the coordinates where the first derivatives of the potential energy function equals zero. Such a conformation represents one of many different conformations that a molecule might assume at a temperature of 0°K. The potential energy function (or force field) is evaluated by a certain algorithm or minimizer (e.g., steepest descent or conjugate gradient) that moves the atoms in the molecule to a nearest local minimum (not necessarily the global minimum), whereas the selection of different minimization algorithms is important for various molecule systems, as discussed below.

Steepest Descent

Steepest descent method (32) is an optimization algorithm that approaches a local minimum of a function by taking steps proportional to the negative of the gradient (or the approximate gradient) of the function at the current point. Simply put, steepest descent uses the gradient to determine the direction and move down in one dimension parallel to the net force. Steepest descent will lead directly to the nearest local minimum by following a path that is determined by moving from the previous value to a new value (at some constant times) in the directions in which the energy is decreasing (Fig. 3.6). If the new movement decreases the energy, the new structure is accepted, and the process is repeated. If, on the other hand, the energy increases, the previous structure is restored. This algorithm converges fast in a steep place for correcting “bad” initial geometry, especially when systems are far from harmonic. It has poor convergence properties, however, and often jitters around the minimum area, because the gradient approaches zero near the minimum.

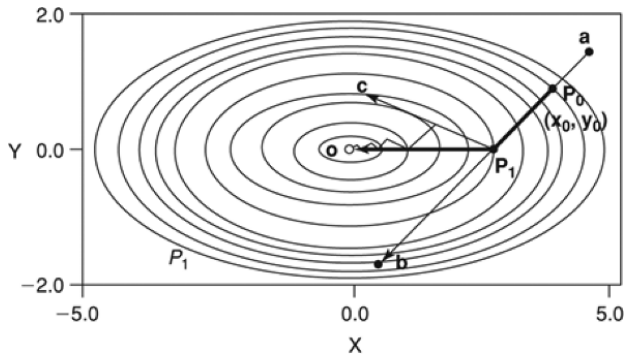


Fig. 3.6. Steepest descent algorithm (thin line): The derivative vector from the initial point P_0 (x_0,y_0) defines the line search direction. The derivative vector does not point directly toward the minimum (O). The negative gradient of the potential energy (the force) points into the direction ($P_0 \rightarrow b$, $P_1 \rightarrow c$) of the steepest descent of the energy hypersurface and is always oriented perpendicular to energy isosurfaces. Conjugate gradients algorithm (thick line): The search direction ($a \rightarrow P_1 \rightarrow$ O) is in one dimension for the minimum. The energy point P_1 takes the direction $P_1 \rightarrow$ O instead of the direction $P_1 \rightarrow c$. The direction $P_1 \rightarrow c$ of gradient conjugates to the direction $P_0 \rightarrow b$.

Conjugate Gradient

The conjugate gradient method (32,43) improves the step efficiency by minimizing only along directions that are mutually conjugate so that movement along one direction will not counteract progress made in earlier iterations. The conjugate gradient method takes the next search direction to be a linear combination of the current gradient and the previous ones (Fig. 3.6). Conjugate gradients require fewer energy evaluations and gradient calculations, and further convergence characterizations are better than with steepest descent. Conjugate gradient is the method of choice for large systems in which storing and manipulating a large second derivative matrix is impartial, such as the Newton-Raphson method.

Newton-Raphson Procedure

The Newton-Raphson procedure (32) is a powerful, convergent minimization procedure, but it requires the second derivative matrix to be available. The Newton-Raphson procedure is based on the assumption that the energy is quadratically dependent—in other words, that it behaves like a classical spring. Then, the new coordinates in each iteration can be found by the calculation of the matrix of the second derivative with respect to the coordinates and the first derivatives. The advantage of the Newton-Raphson procedure that the minimization could converge in one or two steps. The major drawback is that this method requires the calculation of the second derivatives. The minimization can then become unstable when a structure is far from the minimum (or the energy surface is anharmonic).

Criteria for Evaluating Convergence in Minimization Processes

Geometric optimization is an iterative procedure of computing the energy of a structure and then making incremental changes to reduce the energy. Minimization of a molecule involves two steps. First, an equation describing the energy of the system as a function of its coordinates must be defined and evaluated for a given conformation. Second, the conformation is adjusted to lower the value of the potential function. Minimization provides information complementary to that obtained from molecular dynamics. A minimum energy conformation can be found but may require thousands of iterations, depending on the nature of the algorithm, the form of the potential function, and the size of the molecule.

The efficiency of the minimization is judged by both the time to evaluate the target function and the number of structural adjustments (iterations) needed to converge on the minimum.

Zero Derivatives

Mathematically, a minimum is reached by the point at which the derivatives of the function are zero, as in Equation 3.9:

$$\textbf{Eq. 3.9} \qquad \frac{\partial E}{\partial x} \longrightarrow 0, \frac{\partial E}{\partial y} \longrightarrow 0, \frac{\partial E}{\partial z} \longrightarrow 0$$

Several points may exist, however, where the net atomic forces are zero. The point of the lowest energy, or the global minimum, which usually is the conformation of interest, sometimes may not be found from a single starting point of energy minimization. Therefore, thorough conformation sampling (e.g., dynamics simulation) is critical to minimization studies. In theory, convergence occurs at a minimum point where all derivatives are zero and the second derivative matrix is positive-definite. In practice, however, it can be difficult to judge whether it is close enough to the true global minimum. To solve this problem, different algorithms and methods are chosen and combined to search for the global minimum.

Some minimization algorithms assume that the energy surface is approximately harmonic or, for nonharmonic surfaces, that the shape of the nonharmonic surface becomes harmonic in the limit as you converge on the minimum. The derivatives are proportional to the coordinates for the molecular energy surfaces where the force field is harmonic. The derivatives include the information regarding how far away you are from the minimum. The magnitude of the derivatives also is the most rigorous way to characterize the convergence to a minimization. In general, a minimization is converged when the derivatives are equal (or nearly equal) to zero.

Evaluation of the Atomic Derivatives

In molecular minimization, the results of minimization in terms of the atomic derivatives may be summarized either as an average, a root mean square, or the largest value of derivatives as the following. An average derivative is an average of the absolute value of the derivatives, because the distribution of derivatives is symmetric about zero. A root-mean-square derivative (RMS) weights larger derivatives more; therefore, it is less likely that a few large derivatives escape from the detection, which can occur with simple average derivatives. In most studies, the maximum derivative is used to evaluate the minimization convergence. There cannot be ambiguity about the quality of the minimum if all derivatives are less than a given value. For instance, minimizing until maximum derivative of 1.0 kcal/mol/Å normally is sufficient for relaxing overlapped atoms before a dynamics run. The acceptable maximum derivative, however, must be less than 0.001 kcal/mol if a normal mode of minimization analysis is performed.

Strategies for Selecting Minimization Algorithms

Numerous algorithms are available for geometric optimization, such as steepest descent, conjugate gradients, and Newton-Raphson, as discussed above. The proper selection of a minimization algorithm means selecting the most efficient one with good convergence. The choice of the algorithms depends on two factors, the size of the system and the current state of optimization. For example, when the derivatives are well above 100 kcal/mol/Å, it is likely that the structure is outside the quadratic region of the potential energy surface. So, the algorithms (conjugate gradients and Newton-Raphson) that assume the energy surface is quadratic can be unstable in this situation. Typically, two minimization algorithms are combined to achieve the good convergence effectively.

As a general rule for selecting minimization algorithms, when the derivative is larger than 10 kcal/mol/Å, the steepest descents algorithm should be used, and when derivative is less than 10 kcal/mol/Å, the conjugate gradients algorithm is used if the molecule is larger than 200 atoms and the Newton-Raphson algorithm if less than 200 atoms. The steepest descent algorithm often is the best minimizer to use for the first 10 to 100 steps, after which the conjugate gradients minimizer can be used to complete the minimization. The molecular structures built from default bond and angle geometry normally are heavily distorted structures. It is recommended to use the steepest descents with no Morse function and no cross-term options to minimize the structure near a minimum (e.g., maximum derivative <1 kcal/mol). Then, the conjugate gradients algorithm can be used with or without the Morse potential and cross-term as needed to do minimization. The Newton-Raphson minimizer is usually restricted to small molecules, because it requires analytically calculating the second derivatives. The advantage of this minimizer is its quadratic convergence close to the minimum. The Newton-Raphson method can give extremely good convergence to a much tighter criterion after running conjugate gradients to a near minimum.

As we described above, molecular mechanics is an approach of minimum-energy configuration calculations based on the certain force field and one or more minimization algorithms or minimizers. A common limitation of classical molecular mechanics minimization algorithms is that the molecules tend to locate at a local minimum close to the starting configuration and not necessarily at the global minimum, because the minimizers are specifically designed to ignore configurations if the energy increases. So, such minimazation algorithms do not push a system over barriers but, rather, down into the nearest valley. This problem can be solved using dynamics simulations in which kinetic energy gets over the local barrier, as described in the next section.

Molecular Dynamics Simulation

Exploring Molecular Dynamics

Molecular dynamics has been used to compute the dynamics of the molecular system, including time-averaged structural and energetic properties, structural fluctuations, and conformational transitions. The subsequent use of molecular mechanics energy minimizations revealed groups of conformations. In comparison, molecular mechanics, or empirical potential energy functions (Fig. 3.4), ignores the time evolution of the system and, instead, focuses on finding particular geometries and their associated energies or other static properties (31).

The dynamics of a system may be simplified as the movements of each of its atoms. If the velocities and the forces acting on atoms can be quantified, then their movement may be simulated. During the molecular dynamics process, the initial condition is specified by the analytical expression for the potential energy of a molecular system that includes coordinates, energies, and a set of velocities for each atom. Then, a force is applied on each atom, which is described by Newton's equation of motion (Eq. 3.10):

$$\textbf{Eq. 3.10} \qquad F = ma$$

where F is the force on an atom, m is the atom's mass, and a is the acceleration. Because the negative of the first derivative of the potential energy (E) with respect to the coordinates (r) gives the force on each atom, Newton's equation (Eq. 3.10) can be used to describe the motion of a particular molecule:

$$\textbf{Eq. 3.11} \qquad F = ma = -\frac{dE}{dr} = -m\frac{d^2r}{dt^2}$$

where t is the time and r represents the Cartesian coordinates of the atom. The forces are obtained from the energy expression by calculation of the analytical derivatives. The forces are applied for a small time step (~10^{-15} seconds), and the acceleration is calculated from Newton's Law (Eq. 3.11). Then, the velocity and position of each atom is updated to a new velocity and position using an integration algorithm, and the forces and accelerations are calculated once again at the new atomic positions. Next, this process is repeated to produce a trajectory. The positions of each atom in the system are recorded in the dynamics history file. The structures are retreated and then minimized with molecular mechanics and analyzed later. Above all, the solution of Eq. 3.11 using an empirical fit to the potential energy surface is known as molecular dynamics simulation.

It is then possible to approximate the movement of an atom a short time into the future, Δt, using a Taylor expansion:

$$\textbf{Eq. 3.12} \qquad \vec{r}(t + \Delta t) = \vec{r}(t) + \vec{v}\Delta t + \vec{a}\frac{\Delta t^2}{2} + \ldots$$

This expression states that the position of an atom at some time in the future, $\vec{r}(t + \Delta t)$, may be found from its initial position ($\vec{r}$), velocity ($\vec{v}$) and acceleration ($\vec{a}$). The new position is now in terms of known quantities, because molecular dynamics calculations keep track of atomic positions and velocities at each step. Keeping

this in mind, two important factors need to be considered in using dynamics simulation, simulation temperature and sampling time steps, in order to make sure that all conformers are sampled during the simulation.

Temperature and Time Steps in Dynamics Simulation

It is unique that molecular dynamics can simulate the molecular motion at high temperature. The simulation of molecular motion at high temperature increases the probability of overcoming energy barriers, giving the possibility of sampling all possible minimum conformations without being trapped in a local energy minimum. however, the temperature is expressed in terms of the atomic velocities, which are proportional to the kinetic energy of a system (31,42). The temperature setting is discussed in the given molecular dynamics simulation protocol below.

In addition, the molecular dynamics simulation requires using a value of time step Δt that is small enough to correctly simulate the fastest atomic motions. Choosing the proper simulation time step is very important to make sure all conformers are sampled during calculation. The C-H bonds vibrate with a period of about 10^{-14} seconds. To simulate these motions, the time step must be roughly one-tenth of that, or 10 to 15 seconds (1 femtosecond [fs]). Simulations become unstable with values much larger than this 1-fs time step. Simulations are also unstable when forces are applied for a longer time interval (Δt) than that for which they are really valid. For example, if the attractive force of a carbon acting on a hydrogen (in a C-H bond) is applied for too long a time interval or for a large time step, the hydrogen will have been repositioned too close to the carbon. During the next time step, a very strong repulsive force will lead to the hydrogen being repositioned well beyond its typical bond length. This oscillatory process will continue until the energy of the bond is no longer conserved and the molecular dynamics indicates an error condition. A typical molecular dynamics simulation protocol is given below.

Molecular Dynamics Simulation Protocol

As discussed above, in molecular dynamics, Newtonian equations of motion are solved numerically for all atoms as a function of time. A statistical average with time is obtained by applying initial velocities (i.e., kinetic energy), which allows the system to pass the energy barriers and sample all the local minima. An energy calculation, however, has to be carried out for each of a very large number of configurations. Only molecular mechanics can provide the necessary computational speed. So, molecular mechanics and molecular dynamics often are used together to achieve the target conformers with lowest energy configurations.

P.65

Several molecular dynamics simulation approaches are available, including regular simulation, constrained simulation, and simulated annealing techniques. In addition, the simulated annealing dynamics simulation also was popular in computational chemistry studies of proteins and drug molecules (34,44,45). A common experimental protocol has been widely used in molecular dynamics simulation as following (34,46,47):

1. *Build the target protein model.* The initial 3D protein structures can be constructed from an NMR or x-ray crystallographic structure or homology-predicted structure. For example, one can incorporate the NMR experimental data into the target structure by applying the distance constraints and/or dihedral constraints with a square-well potential and a force constant of 50 kcal/mol/Å. If it is to simulate the ligand–protein complex, the ligand should be placed into the putative binding site.
2. *Set up the simulation environment.* One can choose the simulation environment by selecting the proper dielectric constant or by adding counterions and immersing the protein into a periodic box of water, even in lipid bilayers.
3. *Perform energy minimization to relax the initial molecule.* It is important to remove any high-energy artifacts from the construction process to avoid the fault simulation.
4. *Heat up the system, and equilibrate at the selected temperature (e.g., 1,000K).* Typically, dynamics simulation will equilibrate at the temperature for 1 to 25 picoseconds (ps) to allow the total energy and core structures to be stabilized.
5. *Begin the molecular dynamics simulation at the desired temperature.* Typically, dynamics simulation is performed over a period of time 200 ps, with the sampling time step of 1 fs and the trajectories recorded every 1 ps. The dynamics sampling period is selected based on the target protein size and the available computer capacity (20–50 ps for large proteins and 200–300 ps for small molecules). With the time step of 1 fs, a total of 200,000 conformations or frames are sampled during the simulation. To reduce the volume of the output data to a more manageable level, conformer structures were recorded at 1-ps intervals, thus reducing the number of structures to 200 frames.
6. *Retrieve and energy-minimize the sampled conformers.* The 200 conformers recorded during the dynamics run were retrieved and energy-minimized with a two-step minimization, using the steepest descent method for the first 100 iterations and then the conjugate gradient method until the maximum derivative was less than 0.001 kcal/mol.

Furthermore, the molecular dynamics study also may be postprocessed in several ways. First, the study may attempt to locate the lowest-energy binding modes. In this case, the trajectories of the atoms may be sampled at 1-ps intervals and the resulting structures then subjected to energy minimization. The resulting structures could be ranked according to their energy and used to evaluate the expected binding mode. A second use would be to track the interatomic distances between residues of interest. A third use is to derive quantities, such as the free energy of binding, correlation functions, diffusion constants, or a potential of mean force. The full power of statistical thermodynamics may be applied to a simulation, because the time averaged quantities may be used to approximate the free energy.

An example of structure calculation of a G-protein- coupled receptor (GPCR) juxtamembrane domain is given here to illustrate the molecular dynamics simulation. The fourth cytoplasmic domain, the so-called C-terminal juxtamembrane segment, has been identified in numerous G protein–coupled receptors and exhibits unique functional characteristics. Xie and Chen (48) applied the molecular dynamics/molecular mechanics simulation with NMR-defined constraints to study the 3D structural conformations of a synthetic peptide

P.66

CB_2I298-K319 fragment of G protein–coupled CB_2 receptor (Fig. 3.7)

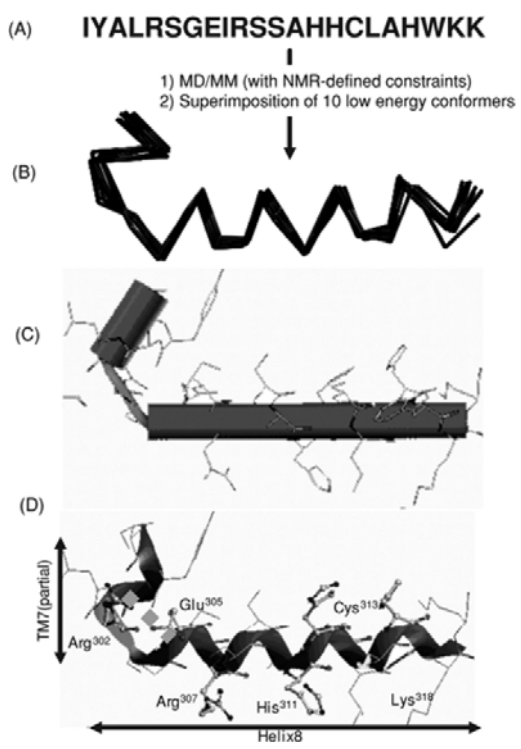

Fig. 3.7. NMR NOE-constrained MD/MM structure calculation of the polypeptides CB2I298-K319 (A), the backbone superimposition of 10 low energy conformers (B), the cylinder representation with a turn at the fifth residue arginine (C), and the ribbon display of the two helical segments (D), showing a curve side chain of Arg302 forming a salt bridge (green line) with Glu305. (See color plate.)

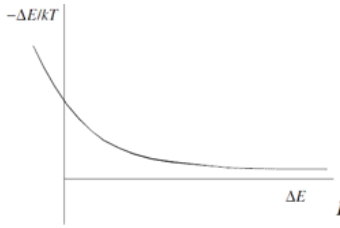
The initial structure was built by using SYBYL program and minimized to relieve any overly strained coordinates. Molecular dynamics simulation was carried out under the Kollman All Atom force field and Kollman charges for 200 ps with time steps of 1 fs at 1,000K. The NMR-determined Nuclear Overhauser Effect (NOE) distance constraints, with three boundaries of 1.8 to 2.8 Å (strong), 1.8 to 3.3 Å (medium), or 1.8 to 5.0 Å (weak), were applied during the dynamics simulation with a square-well potential and a force constant of 50 kcal/mol/Å. The distance restraints will be linearly released in 10 ps of dynamics. A total of 200,000 conformations or frames were sampled during the simulation with 1-fs time steps, and the sampled conformer structures were recorded at 1-ps intervals. The 200 frames recorded during the dynamics run were retrieved and minimized with a two-step minimization, using the steepest descent method for the first 100 iterations and then the conjugate gradient method until the maximum derivative was less than 0.001 kcal/mol. The superposition of the backbones of the 10 low-energy peptide conformers of the target peptide is illustrated in Fig. 3.7B. The calculated structures show two helical portions, the short helix segment and a long helix domain, which are assigned to the partial segment of transmembrane seven (TM7) and the cytoplasmic domain (Helix8), respectively, as displayed in cylinder representation in Fig. 3.7C with a turn at the fifth residue, arginine. In addition, the CB_2I298-K319 peptide fragment shows a curve side chain of Arg^{302} forming a salt bridge with Glu^{305}(Fig. 3.7D), which attributes to the specificity of the signal transduction activation by the C-terminal juxtamembrane region for the CB_2 receptor (48).

Monte Carlo simulation

Unlike the molecular dynamics techniques that evaluate forces to determine incremental atomic motions, Monte Carlo simulation simply imposes relatively large motions on the system and determines whether the altered structure is energetically feasible at the temperature simulated. Because Monte Carlo simulation samples conformation space by jumping abruptly from conformation to conformation rather than evolving smoothly through time, it cannot provide time-dependent quantities. It may, however, be much better than molecular dynamics in estimating average thermodynamics properties for which the sampling of many system configurations is important. Monte Carlo techniques (49,50) are stochastic methods in which a statistical ensemble of configurations are generated and the average structural features and thermodynamics properties are obtained by weighted averages. Monte Carlo makes use of Boltzmann probabilities, but not forces. The probability $P(x)$ of a configuration is calculated as the Eq. 13:



Eq. 3.13

where the E is the energy of the configuration, k is the Boltzmann constant, and T is the temperature. The factor $e^{-E/kT}$ is the Boltzmann factor. The energy is calculated for each conformer or configuration generated, and a structural thermodynamics

average is obtained according to the Boltzmann distribution. Unlike energy minimizations, Monte Carlo does not find an energy minimum but, rather, samples an ensemble of states, just as the actual molecular system does, with higher-energy states being sampled as temperature increases. As opposed to molecular dynamics techniques, in which the equations of motion are integrated numerically and the small time steps are necessary, in Monte Carlo simulation one can take larger time steps, which are then optimized independently. Monte Carlo calculations have been applied to a wide variety of biological problems, especially the study of solvent around peptides and proteins (51) and protein folding (52).

Virtual Drug Screening Techniques and Applications

Traditional molecular modeling methods discussed in the previous sections deal with a single or fewer number of molecules for structural properties at high resolution. Modern computational chemistry or cheminformatics tends to deal with massive amount of molecules or compounds for their biological behaviors at lower resolution. This is accomplished by using high-throughput virtual screening techniques, or 3D database search methods. The techniques are similar, however, in their attempt to improve their quality and generality by including as many of the principles of computational chemistry as possible. For example, scoring functions generally are based on simplified empirical force fields. Parameters for the scoring functions are increasingly derived from quantum mechanical calculations for improving the overall accuracy. Molecular dynamics or Monte Carlo sampling schemes are designed to explore as much of the relevant regions of conformation spaces as possible. In short, screening techniques attempt to incorporate as much of the molecular modeling methods discussed above as possible and still get the study completed within an acceptable amount of time.

Actually, the virtual screening and 3D database search techniques have been increasingly used in the pharmaceutical industry as lead generation, selection, and optimization are becoming a key bottleneck in drug discovery. The real-time experimental high-throughput drug screening (HTS) is the process to accelerate drug discovery by biologically screening large libraries of compounds

(drug candidates) against targets (receptor or enzymes) using 96-, 384-, or 1,536-well microplate (250 µL at 1–10µM) at a rate of thousands of compounds per week. At screening rates of 500,000 compounds per week, however, a cost of $1 per well is still difficult for many companies or academic institutes to afford on a weekly basis (53). The costs of robotic equipment, compound purchasing, assay development, and radioactive material disposals also the main issues challenging the HTS method development and applications. Most importantly, the data show that only 1 in 100,000 HTS actives reaches the stage of becoming a drug candidate, which often also fails later because of the lack of good permeability, solubility, or ADME properties. In this regard, computational chemistry and a knowledge-based in silico design approach can play an important role in drug screening. It can be carried out as a “prescreen” or “virtual screen” before committing to the costly experimental testing of large numbers of compounds. The in silico methods will not only expedite the discovery of new leads but also generate a structurally diverse set of molecules or sublibraries of compounds that merit more detailed study.

Thus, the pressure to identify good leads and, therefore, drug candidates at an ever-increasing pace has led to the rapid advancement of molecular database or cheminformatics that manages information about small molecules, including the storage, display, and searching of chemical structures and their physical and biological properties. In general, four computer virtual screening techniques are available, which are related to each other in terms of the available structural information for the compounds and their targets: docking receptor–based design, ligand-based design, combinatorial computational chemistry, and de novo design techniques (2,3,4,5,6,7,8,9,10).

Table 3.2. Available Software Programs for Pharmacophore Identification and Ligand-Based Design

Software	Pharmacophore Identification Programs and Resources
GALAHALD	Genetic Algorithm with Linear Assignment for Hypermolecular Alignment of Datasets (GALAHAD), Tripos, Inc. http://www.tripos.com/data/SYBYL/GALAHAD_9-7-05.pdf
DISCO and DISCOtech	DIStance COmparison for multiple pharmacophores generations, Based on clique detection. The conformational search is separated. Tripos, Inc. www.tripos.com/data/SYBYL/DISCOTech_072505.pdf
GASP	Genetic Algorithm Similarity Program. A flexible genetic algorithm. The pharmacophoric features are defined by the SYBYL package. Tripos, Inc. www.tripos.com/data/SYBYL/GASP_072505.pdf
Catalyst	An integrated environment for database management and querying tasks for drug discovery. Accelrys, Inc. http://www.accelrys.com/products/catalyst/
HipHop	HipHop matches the chemical features of compounds without considering activity. The resulting hypotheses can be used to iteratively search chemical databases Accelrys, Inc. http://www.accelrys.com/products/catalyst/catalystproducts/cathypo.htm
HypoGen	HYpothesis GENerator uses ligand activity values and incorporates them into the scoring function. The conformational search is separated. Accelrys, Inc. www.accelrys.com/products/catalyst/catalystproducts/cathypo.html
PHASE	PHASE applys a novel, tree-based partitioning algorithm to exhaustively identify spatial arrangements of functional groups that are common and essential to the

	biologic activity of a set of high affinity ligands. Schrodinger Inc. http://www.schrodinger.com/
MOE/pharmcophore modeling	Molecular Operating Environment (MOE). MOE's pharmacophore modeling module is to generate and use 3D geometric information to search for novel active compounds, particularly when no receptor geometry is available. Chemical Computing Group:http://www.chemcomp.com/software.htm
FlexS	Flexible Shape-Based Screening of Ligands http://www.biosolveit.de/FlexS/
MPHIL	Mapping Pharmacophores in Ligands. Relaxed MCS approach. A rigid alignment, based on clique detection and genetic algorithm. (141)
RAPID	Randomized Pharmacophore Identification. A rigid alignment based on mapping triangles of 3D atom coordinates. (142)
SCAMPI	Statistical classification of activities of molecules for pharmacophore identification. Handles large heterogeneous data sets. A random conformational search is combined. (144) Glaxo Wellcome, Inc. www.gsk.com/index.htm

In Silico Drug Design Programs and Resources

Various virtual screening techniques have been developed as a result of the temptation to predict the geometries of

biomolecular complex and to discover novel ligands as leads for drug design. Choices of various programs depend on the target goals and purposes of the performed computational chemistry, the capacity of computer facilities, and the availability of software programs.

The software programs used for ligand-based approach deal with the purpose of ligand pharmacophore identifications and 3D database search programs. The available pharmacophore identification programs are summarized in Table 3.2. New pharmacophore-generation programs, such as GALAHAD (Genetic Algorithm with Linear Assignment for Hypermolecular Alignment of Datasets) (54), are emerging with improved computational ability and capacity. GALAHAD assumes shared pharmacophore/shape, explores "all" of conformational space, and generates multiple partial-match constraints (or pharmacophore) for 3D database search. GALAHAD is an improvement over GASP in its multiobjective scoring capability and ability to deal with large numbers of molecules, and it is an improvement over DISCO in the simplicity of its interface and higher-quality molecular alignments. Other commonly used ligand-based virtual screening programs are UMOE (55), FlexS (56) and Catalyst (57,58), which are based on active ligand pharmacophore models, and ROCS (59), which is based on active ligand shape.

Most software programs, however, involve a large number of docking tools and score functions that have been developed for receptor-based virtual screening, as summarized in Table 3.3. The commonly used DOCK program (60) models receptor sphere centers to ligand atoms via either rigid or flexible docking to be scored by evaluation of empirical force field energy, using AMBER (61). Similarly, AUTODOCK (62) uses a simulated annealing or genetic algorithm and AMBER scoring method. FlexX (63), however, applies the fragment-based incremental buildup strategy and scores the docked ligands by an empirical algorithm based on the Bohm function (64). This strategy basically counts hydrogen bonds, salt bridges, aromatic-ring interactions, and hydrophobic interactions, and it effectively reduces the number of conformational possibilities (65,66). GOLD (67) applies a genetic algorithm for generating ligand-docked poses, and the results are scored by an empirical function based on interaction possibilities derived from atom–atom contact probabilities in the Cambridge Structural Database (CSD) (68). Other programs, including GLIDE(69), LigandFit (70), FFLD (71), Eudock (72), and ICM-DISCO (73), also are widely used for *in silico* drug screening.

In reviewing these drug available molecular docking programs used for in silico screening platforms (Table 3.3), their algorithms and advantages have been addressed in the literature (4). For example, DOCK (60) and Flexidock/UNITY (55) allow users to dock the ligand as flexible structures onto the target enzyme or receptor using the directed tweak algorithm (55). These methods are very time-consuming, however, because such "on-the-fly" conformational

searches must be repeated for each pharmacophoric search query. The time will increase several-fold when van der Waals bump-check is included (74). For example, ChemDBS-3D/Chemical Design (75), Catalyst/MSI (57,76), and Merck Flexibase databases (77) use the method to generate a number of energetically reasonable representative conformations for each structure at the time of compound registration and stores these conformers in the database. This latter approach requires a sufficient coverage of the available conformational space such that at least one conformation of each active compound is sufficiently close to the active conformation to be considered a hit by a database query. FOUNDATION (78) and 3D search (79) have database queries consisting of pharmacophore models supplemented by steric constraints defined from protein crystallographic coordinates. Only a single conformation of a ligand is considered, however, and FOUNDATION only examines a single orientation of a ligand. The LUDI (80) software package has been applied to 3D database mining, but is restricted to single conformations of small, rigid molecules. Other programs, such as CLIX (81) and FLOG (82), essentially use the DOCK approach, although in FLOG, multiple conformations of each compound are explicitly stored in a database. So, many choices for docking programs are available either commercially or free for academics (Table 3.3).

In Silico Design and Virtual Screening Techniques

Several computational chemistry approaches are based on the availabilities of the target protein structures and known active ligands.

DOCK Receptor-Based Approach

When receptor and ligand structures are both known, the docking receptor-based approach is the most ideal situation (6,83,84,85). The ligand can be docked into the known receptor site and molecular mechanics used to simulate receptor–ligand interactions and dynamics. One can address highly specific receptor–ligand interactions using these techniques, but even here, there can be surprises in the form of alternative modes of binding and conformational changes in the receptor structure. It is frequently necessary (or of more interest) to study the binding of thousands of compounds at low resolution rather than fewer compounds at high resolution. This often is the case when searching for lead compounds. The GRID approach (86) maps the binding site by superimposing a grid and calculating the electrostatics, hydrogen-bonding sites, or lipophilicity at each grid point. Among the docking-related programs discussed above, classical DOCK program uses a similar approach (60) for scoring and also provides other tools for scoring compounds, attempting alternate orientations, and performing geometry optimization to include the flexibility of the ligand. A grid-based approach dramatically reduces the amount of computer time required. Each ligand's interaction is computed with the limited number of grid points and not all of the target's atoms. Several common programs, including AUTODOCK, Glide, LUDI, LigandFit, and FlexX/CSCores, also have been widely used in ligand docking and lead

screening studies (6) (Table 3.3).

Ligand-Based Approach

When the receptor structure is unknown but the ligand structures are known, a ligand-based approach is used (7,87,88,89,90). This situation represents the most common case. An extension of the QSAR approach is taken to study the active ligands, also known as pharmacophore-based drug design. The pharmacophore refers to an ensemble of steric and electronic features (or 3D arrangement of the functional groups) that enables a molecule to exhibit a specific biological activity. The ligand-based approach is basically an indirect method of pharmacophore identifications. In general, pharmacophore-based virtual screening techniques depend on the application of descriptors of molecular structure and properties (2,91,92), including structure- or descriptor-based queries (or similarity search in two-dimensional (2D) and 3D substructures or pharmacophore models), fingerprint queries (or binary bit string-search based on Tanimoto coefficient, 2D/3D pharmacophore fingerprints), and clustering and partitioning (or intermolecular distances in chemical reference spaces and reference frame). The details descriptions of these techniques have been reviewed in literature (2,7,87) and summarized in Table 3.2.

Combinatorial-Based Approach

When receptor and ligand structures are both unknown, virtual combinatorial chemistry approaches are used. In this case, computational chemistry is used both to generate structures and in parallel to perform chemical similarity and diversity search analysis before and after combinatorial chemistry-based experimental HTS. For example, the combinatorial chemistry software package from Accelrys and Tripos companies provides the unique features to preanalyze and select diverse building blocks for the target libraries to help discover small molecule drug therapies. This promises a maximum range of drug-like compounds and increases the potential of finding active leads for the targets. The developments of combinatorial chemistry library have been described in the literature (93,94,95).

De Novo Design-Based Approach

When receptor structure is known and ligand structures are unknown, de novo design-techniques are used (10,96,97). In this situation, there is available information about the target receptor, or a similar receptor, but no existing leads that can interact with the active receptor sites. One can use recently developed de novo design- techniques to propose new ligands, which are complementary to the active site. These techniques use 3D searching of large databases to identify small molecule fragments that can interact with specific sites in the receptor, bridging fragments with the correct size and geometry, or framework structures that can support functional groups at favorable orientations. For example, programs such as GROW (98) or LEGEND (99)

use “seed” structures through de novo design of a compound to fit the binding site and add functional groups to optimize the use of possible binding sites. These tools have been most effective when used to support rather than to automate drug design efforts (10).

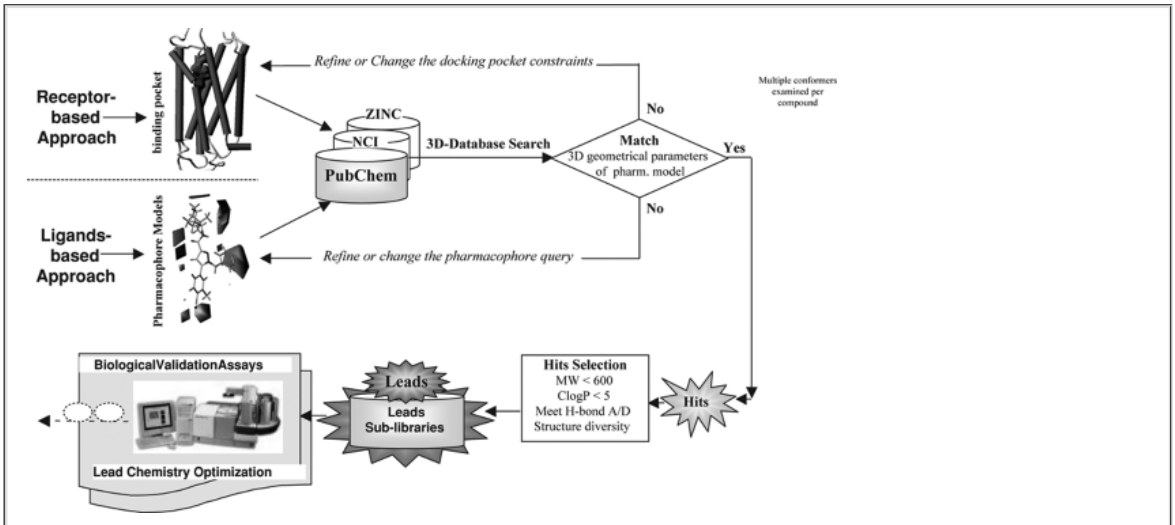

Fig. 3.8. A workflow of in silico virtual screening process: receptor-based and ligand-based approaches. (See color plate.)

Practical Aspects of Virtual Screening Applications

Given the recent advances in supercomputer clusters/CPU horsepower for new compute-intensive algorithms as well as the availability of public and proprietary databases, in silico drug design and virtual screening methods have been advanced to search large compound databases or hypothetical virtual libraries *in silico* by computer analysis and selection of a limited number of candidate molecules likely to be active against a biological target. The general methods of *in silico* design or virtual screening can be illustrated practically as in Fig. 3.8: protein structure-based compound screening or docking receptor-based design (100,101), and chemical-similarity searching based on small molecules or ligand-based design(102).

Basically, the virtual screening experimental protocol (Fig. 3.8) could be described as follows:

1. Build virtual compound database.

2. Generate the database search query, either ligand pharmacophore hypotheses or receptor-binding pockets.
3. Refine and modify the query through training databases.
4. Search the target compound databases for novel leads with new chemical scaffolds and better binding activities
5. Carry out the hit selection based on defined criteria.
6. Bio-validate the hit leads via HTS experiments and functional assays.
7. Conduct lead optimization virtually and experimentally to improve the novel lead bioactivity.

Build Virtual Compound Libraries

The first step of virtual screening is to build virtual compound collections that can be used for in silico virtual screening. Pharmaceutical companies treat the databases of compounds they have synthesized or purchased as a valued corporate asset. The National Institutes of Health (NIH) recently constructed a public compound library, PubChem, that consists of more than 11 million compounds (http://pubchem.ncbi.nlm.nih.gov/). In general, two major compound libraries are needed in virtual screening.

Construct known compound training databases

A training database is recommended to be constructed for the purposes of optimizing the query hypotheses to improve the hit accuracy in database search. Such a training database usually contains a thousand compounds typically, consisting of 980 random molecules and 20 known active ligands. For example, users can examine and refine the hypothetic pharmacophore (or query) against the test database in terms of hit precision rate, false-negative rate, and false-positive rate. The process is very

important. it also helps to evaluate the qualities of pharmacophore queries and molecular alignments generated or the binding pocket defined in the target protein before searches in the large target database.

Construct target compound databases

The 3D target virtual compound database can be constructed through single molecular entry or systematically importing from other public or commercial compound catalog sources (in either SFD, MOL2, or Smiles formats) (Table 3.4). For example, compound library catalogs can be converted from the 2D data format into a 3D searchable compound database by the CONCORD program (103) or Daylight Rubicon program (104) using artificial intelligence and geometry optimization. In addition, structurally diverse sublibrary or target-specific libraries also can be constructed from the large virtual libraries of millions of compounds. For example, the NIH PubChem database consists of approximately 11 million compounds. It will be reasonable to create one or several sublibraries from the PubChem database and then evaluate them by using software programs, such as Tripos' Diverse Solution (105), Selectors (106), or the TimTec's Diversity program (107). The diverse sublibraries are created to represent the parent libraries with the same diversities but much smaller datasets (usually ~10–20% compounds). The sublibraries are created mainly for the purpose of enhancing the computer screening. Although the virtual screening is much faster than the experimental HTS, especially with the high-horsepower computational facilities now available, it will still take a month to search through a 3D database with millions of compounds.

Table 3.4. Available Chemical and Drug Compound Databases

Database Name	No. of Compounds	Company/Web site

In addition, a quality-control procedure is required to ensure the 2D to 3D structure-converting accuracy and data integrity as well as further data portability. This includes randomly selecting the converted compounds

P.72

and examining them for the molecular structure (bond types/lengths, bond angles, atom types/charges, and carbon chirality), 3D molecular geometry (quick energy minimization, if needed), the compound catalog numbers versus their original numbers and the reference source, and the data export features to ensure portability of the data for sharing.

Build 3D Structure of the Target Protein

Knowledge of the 3D structure of a target protein is often a prerequisite for the receptor-based virtual screening and building a reliable 3D protein structure is a first important step for a successful receptor-based design. In general, protein structures are mainly derived from x-ray, NMR, or homology models. The experimental sources of 3D structures are available from Cambridge Structural Database (CSD) (~250,000 x-ray structures) and the Brookhaven Protein Data Bank (PDB; ~17,000 structures of proteins defined by x-ray, NMR, and computations). Several reviews of x-ray crystallography provide excellent overviews of ligand-free and ligand-bound protein crystallographic data for drug design (108). The x-ray crystallographic method, however, is limited by the available pure crystals of the target proteins, particularly for large membrane proteins. The GPCR membrane proteins do not generally crystallize in a form suitable for x-ray crystallography. In addition, the crystal protein conformation sometimes may be distorted by crystal packing force and may not be exactly relevant to its in vivo counterpart. Because of the difficulties in crystallizing membrane-bound protein for x-ray crystallography, the only GPCR that has been crystallized with high resolution x-ray is rhodopsin (109).

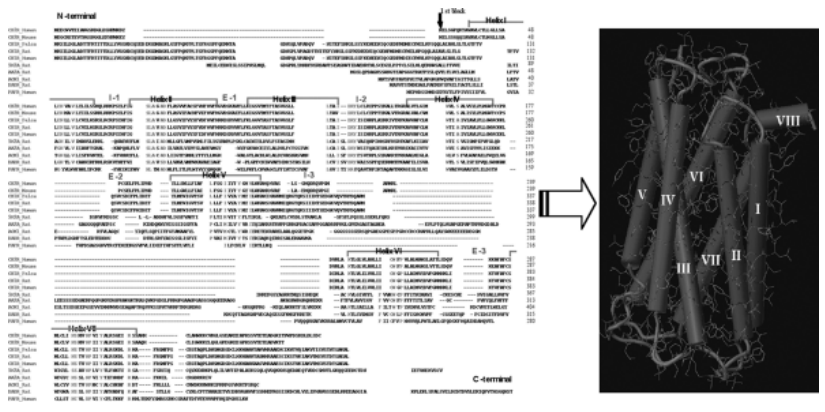

Fig. 3.9. Three-dimensional G protein–coupled CB2 receptor structure (right) constructed by homology and multiple sequence alignment method (left), including the seven transmembrane helices (cylinders, I–VII) and loop regions (ribbons) (See color plate.) (From Xie XQ, Chen JZ, Billings EM. 3D structural model of the G protein–coupled

cannabinoid CB_2 receptor. Proteins: Structure, Function, and Genetics 2003;53:307–319; with permission.)

The NMR structures of target proteins generally are determined in a solution or membrane-like environment, which is similar to the physiological state of most systems. Often, however, the NMR-determined protein structures are studied at low pH, whereas the resulting structures sometimes can show significant pH-dependent variation and the protein backbone may display considerable motion and unfolding at different pH values (110).

Computer homology modeling provides an alternative way to predict 3D protein structure. The homology-generated models usually are refined further by incorporating experimental constraints measured by x-ray and NMR. Actually, if the sequence identity between the target protein and template is sufficiently high (>50%), the *in silico* design and virtual screening results using homology-predicted 3D models have been shown to be similar to those when x-ray structures are used (111). The homology-predicted 3D models have proven to be successful in docking receptor-based studies or receptor-based virtual screening. An example in Figure 3.9 is given here to illustrate that the computer homology and multiple sequence alignment techniques were used to build a 3D receptor structure (34,48). Xie et. al. constructed the 3D structural model of cannabinoid receptor CB2 by using multiple sequence alignment of 10 homologous GPCRs (34). Alignments were analyzed with mutation scores, pairwise hydrophobicity profiles, and Kyte-Doolittle plots. The 3D model of the transmembrane segment was generated by mapping the CB2 sequence onto the homologous residues of the x-ray crystallographic data of rhodopsin structure. The extra- and intracellular loop regions of the CB2 were generated by searching for homologous C_α backbone

sequences of published structures in the Brookhaven Protein Databank (PDB). Residue side chains were positioned through a combination of rotamer library searches, simulated annealing and minimization.

Other successful homology models have been used in docking applications and have successfully resulted in the discovery of novel hits, include retinoic acid receptor (112), thyroid hormone receptor (113), CK2 kinase (114), SARS (severe acute respiratory syndrome) protease (115), CDK4 kinase (116), and SrC sH_2 (117) for the application of de novo design methods (117).

Predict the Binding Sites of the Target Proteins

After determination of the 3D target protein structure, identification of the target binding site is the next important step, which often depends on whether the ligand–receptor complex is known. Accordingly, binding sites generally are referred to as cavities or grooves (i.e., the depression in the protein surface). If the ligand–target complex structures are available through x-ray or NMR, identification of the binding site is straightforward. The experimental site-directed mutagenesis results will also be very informative to characterize the residues implicated in ligand binding or function.

Often, however, limited mutageneses data are available about the binding sites, and little is known about the protein or the protein complex, which requires using computational techniques to detect these surface features to predict the potential binding sites. Several geometry-based computational methods are available, including SiteID (118), LIGSITE (119), APROPOS (Automatic PROtein Pocket Search) (120), and PASS (Putative Active Site with Spheres) (121). Other programs, such as GRID (86), van der Waals–FFT (122), and XSITE (123), were used to search for complementarities between the ligand functional groups and site functionality and to identify the physicochemical properties of the different cavities to identify the site of interests.

In the 3D protein structure construction and binding site prediction above, drug binding pocket(s) should be mapped out for 3D database search using the docking program. An example is given here to illustrate the computer prediction of the protein binding pockets. Xie et al. (34) applied the MOLCAD solvent-accessible channel surfaces calculation (124) to predict the binding site of the cannabinoid CB2 receptor, as shown in Figure 3.10. The result was confirmed by Tripos SiteID program (118). The predicted binding site also is correlated well with known site mutagenesis data (except Phe87), as shown in Fig. 3.10. The data also showed an amphipathic binding contour (Fig. 3.10): The hydrophilic center (blue) is framed by polar residues, whereas the hydrophobic cleft (brown) is surrounded by aromatic residues. The computational chemistry approach offers an alternative avenue for understanding the receptor–ligand interactions in terms of hydrogen-bonding, hydrophobic centers, charged centers, and steric interactions that are defined in the pharmacophoric feature identification process and for assisting the in silico virtual screening.

Derive Active Pharmacophore Models

For a ligand-based design approach, generating reliable pharmacophore hypotheses is a prerequisite for the 3D pharmacophore database search. Several approaches are available for generating pharmacophore models, including programs to derive the active pharmacophore models or “virtual receptor” (e.g., 3D QSAR/CoMFA (125) and AAA [Active Analog Approach] (126)) and programs to generate hypothetical pharmacophore queries (e.g., DISCO (127) and GALLAHAD (54)) for database searches of the new chemical scaffolds that match the target pharmacophores. An example of the pharmacophore generations is given below.

The CoFMA (Comparative Molecular Field Analysis) is superior to classical QSAR in mapping out 3D QSAR models. The CoMFA program (128) provides tools to postulate a biological active conformation and to establish a set of alignment rules (129) to superimpose the molecules under consideration. It will generate a grid or lattice as a box of points around the molecules and calculate the electrostatic and steric fields that each molecule exerts on a probe atom positioned at each lattice point. Then, a statistical analysis of the data using partial least squares statistics is made to derive a linear correlation (3D QSAR) between the calculated values and the input biological data. Subsequently, it validates the predictability of the derived model by using cross-validation (r^2). Finally, active ligand CoMFA models are established that can be used to guide novel ligand design and to predict the biological activities. CoMFA analysis has been used to study the pharmacophoric requirements of cannabinoid antagonists (125) (Fig. 3.11), to study the effect of shape on binding of steroids to carrier proteins (130), to deduce active site geometries of angiotensin-converting enzyme (131), and to analyze a set of muscarinic agonists (132).

The DISCO (DIStance Comparison) program (133) often is used to generate multiple pharmacophore models by identifying common pharmacophoric features (e.g., H-bond donor atoms, H-bond acceptor atoms, charged centers, and centers of mass of hydrophobic rings) for a given set of active compounds, producing optimally aligned structures, and extracting the key features of the pharmacophores. Then, these pharmacophore hypotheses can be compared, refined, and used to guide lead generation and optimization and in performing 3D searches of databases for new leads. DISCO has been used in pharmacophore generation during studies of muscarinic M3 receptor antagonists (134), muscarinic agonists (135), and melatonin analogues (136).

Other pharmacophore identification approaches (7) include GALAHAD (54), GASP (137), HipHop (138), HypoGen (139), PHASE (140), MPHIL (141), RAPID (142), MOE (143), and SCAMPI (144), as well as AAA (126) and ensemble distance geometry (145).

P.74

The generated various pharmacophore models will be used as hypothetic queries in the database search for lead discovery

To achieve a successful database search, one must ensure the quality of the derived pharmacophore models by considering the following issues while composing a 3D database query:

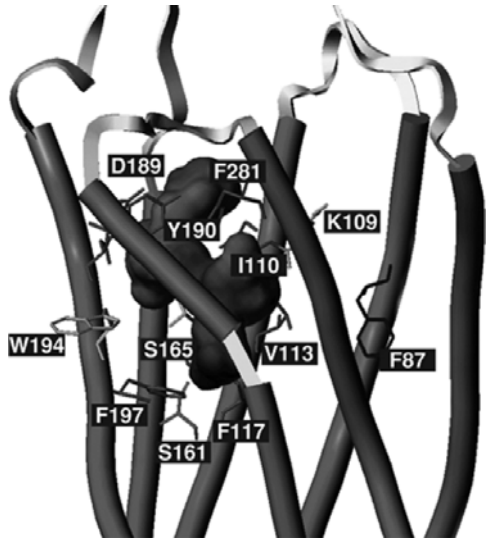

Fig. 3.10. MOLCAD-predicted CB_2-binding pocket surrounded by active amino acid residues, showing an amphipathic contour, hydrophilic center (blue), and hydrophobic cleft (brown). The site-directed mutagenesis–detected binding residues are color-coded in terms of their distance to the pocket (magenta > yellow > green > blue) as the interaction weakens. (See color plate.)

1. Which functional groups or set of topological constraints should be chosen?
2. What average distance should separate the pharmacophoric features, or by what average angle should the features be arranged?
3. Which type of geometric relationships should be imposed, and what are their tolerances (e.g., interatomic distances, angular relationships between two pendant substituents, and the angle of a lone pair to the plane of a phenyl ring)?

These factors often have influence on the false-positive or false-negative hits during the database search, as discussed later.

3D Database Search Protocol

The basic rationales of 3D database search methods are the same for either ligand-based or receptor-based approaches, as reviewed in literatures (2,6,53), whereas the search protocols may need to be changed as different approaches are used. In general, the docking receptor-based virtual screening techniques are based on the active defined receptor binding pockets as queries, whereas the ligand pharmacophore-based search is based on the active ligand pharmacophore models or shapes as database queries. Although 3D structures of target proteins are becoming increasingly available as search templates, small molecule virtual screening still dominates the field. This is particularly true for the receptors lacking 3D structures, except for

P.75

rhodopsin. In light of page limitations, we will illustrate the ligand pharmacophore database search and use the UNITY program as an example.

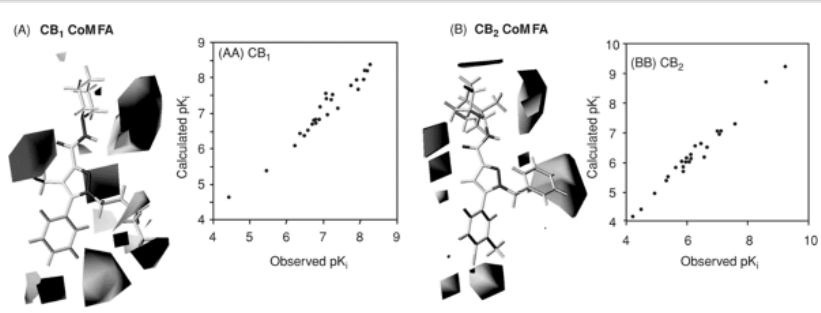

Fig. 3.11. CoMFA contour maps for arylpyrazole antagonists of cannabinoid receptor subtypes CB_1 (A) and CB_2

(B). Sterically favored areas (contribution level, 80%) are shown in green. Sterically unfavored areas (contribution level, 20%) are shown in yellow, and positive-potential favored areas (contribution level, 80%) are shown in blue. Positive-potential unfavored areas (contribution level, 20%) are shown in red. Plots of the corresponding CoMFA-calculated and experimental values of binding affinity (given as pK_i) of arylpyrazole compounds at CB_1 (AA) and CB_2 (BB) receptor, respectively are shown as well. (See color plate.) (Adapted with permission from Chen J, Han X, Lan R, et al. 3D-QSAR studies of arylpyrazole antagonists of cannabinoid receptor subtypes CB_1 and CB_2. A combined NMR and CoMFA approach. J Med Chem 2006;49:625–636; with permission.)

For a ligand-based search, a typical search query consists of the following types of information: a 2D pattern (representing important groups in the molecule; e.g., CC(C = O)N defines the backbone of an amino acid), 3D geometric features (e.g., name = hbond; atoms = 1,2,3; distance = 1.57; angle = 120.0; dihedral = 180.0), and 3D constraints (define the relationship between geometric features and excluded volumes). The common database search protocol is given here as an illustration:

1. A 2D similarity search is first carried out to find specific fragments in the database (e.g., CC(C==O)N for an amino acid). With the defined pharmacophore patterns, we will search the database using sub-/superstructure search, similarity search, Tanimoto coefficient (146), Tversky search (147), and so on. The search returned hit list will be grouped into a molecular spreadsheet for further studies. The 2D database searches usually are carried out as initial screening, followed by 3D searches.
2. A 3D geometric search is then performed to look for relationships between features in a molecule. The initial 2D pattern search takes into account only the composition of the molecule, such as atom types and bond types. The 3D portion is only concerned with the geometric relations between the features (e.g., distance, angle, exclusive van der Waals volume, overlapping van der Waals volume, and constraints). A 3D search makes use of the coordinates stored in the database for determining whether constraints are satisfied.
3. A flexible 3D search is subsequently conducted by altering the geometry of the molecule to determine any possibly satisfied geometric constraints without having to save every possible conformation in the database. The conformational flexibility can be explored by determining the geometries at search time without having to save every possible conformation, which is considered to be a unique feature for the UNITY database compared with other 3D databases (134,148).
4. The next step is database search hit evaluation and selection. Compounds that have at least one conformation satisfying the geometric requirements and possess functional groups residing within the respective tolerance spheres of the pharmacophoric features are considered to be "hits" (i.e., potential candidates for biological testing). A number of additional criteria are used in the selection of compounds for biological evaluation and experimental validations to achieve maximum efficiency in the discovery of lead compounds.

   The hit selection strategy is initially established on the basis of Lipinski's rules (149). Hit selection criteria for a good lead compound have the following properties: simple chemical structure, easy synthesis, calculated logP (ClogP) of less than 5 (or measured logP <4.15), small molecule (molecular

   weight, <500 daltons), nonpeptidic, and chemical structure diversity. In addition, other drug-likeness parameters (e.g., ADME) also will be considered as hit selection. For example, the VolSurf program is used to predict ADME properties based on precalculated models, to compute unique ADME-relevant descriptors, and to create QSAR models of bioactivity (150), as discussed later.
5. No method is generally accepted to rank the hits of molecules obtained from pharmacophore-based database searches nor proper score functions are available, as for the docking receptor–based approach. Greenidge et al. (151) have reported use of the overall superimposition of functional groups of the molecules to the appropriate features of the pharmacophore to evaluate the hits (i.e., the better the superimposition, the higher the score of the fit). Van Drie (152) presented the DANTE approach, in which ranking candidate pharmacophores were used to evaluate the hit selection. For the FlexS/UNITY hits ranking approach (148), the evaluation of this potential is based on three values: strain energy of the hit, root mean square (RMS) of the hit features from their queries, and number of rotatable bonds in the hit (entropic term). The actual ranking could also be done by means of the simple scoring function:

$$\text{Score} = R_{\text{energy}} + \sqrt{R_{\text{bonds}} \times R_{\text{rms}}},$$

   where R_{energy}, R_{bonds}, and R_{rms} are the ranks of the hits by energy, number of rotatable bonds, and RMS, respectively. Interested readers are encouraged to find these more detailed discussions in UNITY program (148) and the literature (7,87,152).
6. Often, one runs into the problem of too many hits (false positive) or too few hits (false negative) during a database search. One commonly used approach is to examine the following hypothesis by creating a training database (e.g., containing 980 random molecules plus 20 known active ligands) (90). The derived pharmacophore queries are examined and refined against the training database by carrying out the following investigations:
   a. *The influences of the numbers of pharmacophoric features and their tolerances on hit rates.* One should create a pharmacophore with different combinations of features and tolerances and examine those against the training database to find a reasonable balance between the number of pharmacophoric features and their tolerances to maximize the number of true positives and minimize the number of false positives. For example, if some ambiguity or uncertainty exists regarding whether an OH group is a hydrogen-bond donor or acceptor, two possible alternative hydrogen-bonding networks will be investigated in the defined pharmacophores.
   b. *The effects of pharmacophore tolerances versus weights on hit rates.* One could examine several variants of a pharmacophore model, such as one with the same feature tolerances but different feature weights (weight is a measure of its proposed importance to the pharmacophore as a whole) and another with the same feature weights but different feature tolerances to determine how altering tolerances and weights would affect hit rates, particularly how many known ligands structures are retrieved.

c. *The effect of the receptor excluded volumes (REVs).* In addition, the ligand-generated REVs as additional search constraints can be combined with pharmacophoric features (numbers and tolerances) to reduce the number of false positives. In the actual experiments, one may consider several variants in the pharmacophoric search, such as the positions of the REVs and their scales according to the sizes of atoms delineating the putative binding cavity, the effects of the REV scale (volume radii to 25 and 50%) on the size of hit list or hit rates, and the effects of the REV radii on database search time (e.g., whether it significantly slows the search). Such studies will reveal unfavorable steric interactions between ligand and receptor, and uncover true positive hits at a given van der Waals scaling factor.

There are emerging examples of successful in silico design and virtual screening reports. The 3D pharmacophore database search methods have been successfully used to identify micromolar inhibitors of *Pneumocystis carinii* dihydrofolate reductase (82), to generate leads for muscarinic M3 receptor antagonists (134), and to search for novel protein kinase C agonists in the National Cancer Institute 3D database (153), HIV protease inhibitors (154), dopamine transporter inhibitors (90), thyroid hormone–receptor antagonists (151), and 5HT-2c agonists (155). The 3D pharmacophore database search to discover novel activities of existing compounds has emerged as a new tool for drug discovery in recent years, because in most cases, target receptor structures are unknown but the ligands are known.

The recent advances in virtual screening have revealed its particular efficiencies in discovering new and active lead compounds. For example, Doman et al. (156) reported a 1,700-fold higher hit rate of the virtual screening method over random HTS for the inhibitors of protein tyrosine phosphatase 1B (PTP1B), with a median inhibitory concentration (IC50) for enzymes of less than 100 μM. In their studies, the HTS bioassay showed that 400,000 compounds in the library generated a hit rate of 85 compounds (0.021%), whereas the *in silico* screening methods search of 235,000 compounds from the

Advanced Chemical Development (ACD) database (157) against the x-ray crystallographic structure of PTP1B gave a hit rate of 127 compounds (31.8%). Paiva et. al. (158) also demonstrated their studies between HTS and virtual screening on the Merck chemical collection against the tuberculosis target dihydrodipicolinate reductase, showing a hit rate of 0.2% for HTS and 6% for docking screening under the same threshold activity (IC50 <100 μM). Other successful virtual screening work includes 3D pharmacophoric searching in the discovery of VLA-4 integrin antagonists with submicromolar potency (159), 2D fingerprints QSAR (161), and flexible docking for discovery of novel carbonic anhydrase inhibitors (160). Clearly, computer modeling and 3D database virtual screening approaches have become an important drug discovery approach; many are carried out as "prescreening" before the beginning of costly experimental testing of large numbers of compounds.

Calculations of ADME and Physicochemical Properties

As described previously, virtual screening and in silico design will accelerate the discovery of active lead compounds with new chemical scaffolds. The *in silico* prediction of physicochemical and ADME (absorption distribution metabolism elimination) properties, however, also are very critical for lead development. Actually, pharmacokinetics and toxicity have been identified as important causes of costly late-stage failures in drug development. The recently developed in silico approaches will increase model productivity in fine-tuned lead optimization to improve compound design and lead optimization.

The pharmacokinetic and metabolic behaviors in the body often are linked to the physical properties of a compound, as summarized by Lipinski et al. (149). Those authors analyzed a subset of 2,245 drugs from the World Drug Index by studies of QSAR structure permeability as a function of hydrophobicity, molecular size, and hydrogen-bonding capacity to better understand the common molecular features of orally available drugs. The results showed that a good oral drug absorption or permeation is more likely to occur when the molecular weight is less than 500 daltons, the ClogP (calculated octanol–water partition coefficient) is less than five, the number of hydrogen-bond donors is less than five (the sum of O-H and N-H groups), and the number of hydrogen-bond acceptors is less than 10 (the sum of N and O atoms).

Their computational results have been referred to as the "Rule of Five," and it had a major impact on drug discovery in the pharmaceutical industry. The Rule of Five was implemented early on in the drug discovery process for all the drug discovery stages, particularly medicinal chemistry design, to avoid a designed compound with potential absorption and permeability failure. In addition to oral drug absorption, blood-brain barrier (BBB) permeability is very important in medicinal chemistry design and virtual screening. A similar rule system (or "Rule of Two") was proposed by Norinder and Haeberlein (162) to evaluate the good permeability of a compound to cross the BBB: That is, the sum of nitrogen and oxygen (N + O) atoms must be less than or equal to five, and subtracting (N + O) from logP must yield a positive number. A lead compound satisfying these two rules is likely to have positive brain/blood concentration ratio. In summary, both the Rule of Five and the Rule of Two have provided a good starting point for computational and medicinal chemists in designing novel drug molecules. In the following sections, we will discuss the ADME prediction, logP, and solubility prediction methods.

ADME Prediction

In Silico ADME Prediction

Nearly 40% of drug candidates fail in clinical trials because of poor ADME. Today, it is widely accepted that ADME prediction plays a critical role in new drug development and that focusing on promising compounds will dramatically reduce the amount of wasted time and resources in the overall development process. Generally, two approaches exist for ADME prediction.

Structural Approach (Molecular Modeling)

The structural approach for ADME prediction is based on the 3D structure of the target protein as determined by x-ray, NMR, or homology modeling of related human protein. Quantum mechanical methods are used to assess the potential for interaction between the small molecules under consideration and the protein involved in the ADME processes. The structural approach can provide concrete and logic interpretation and enables us to understand the QSAR mechanism of drug–receptor interactions in systems. This method is limited, however, by the available 3D protein structures and long computation time. This approach has been used successfully for predicting cytochrome P450 drug metabolism (163) and p-glycoprotein substrates (164).

Data-Based Approach (Data Mining)

Multivariate statistical analyses are performed to search for the correlation between a given property and a set of molecular and structural descriptors of the molecules, including fragment descriptors, topological descriptors, and global physicochemical

descriptors. Such a QSAR model was used to predict the property of unknown molecules. Although they are empirical methods, data-based approaches are useful for the prediction of complex physicochemical and biological phenomena. These approaches have been used successfully for predicting human intestinal absorption (165) and oral bioavailability (166). Because of the limited scope of this chapter, interested readers may turn to several reviews in the literature (167,168) regarding the subject of ADME prediction.

To illustrate the basic principle of the ADME prediction method, we give an example of computational protocol for prediction of percentage human intestinal absorption (%HIA) (165). First, the GRID program (169)

P.78

is used to create the 3D MIF (Molecular Interaction Fields) maps, which are a 3D matrix containing attractive and repulsive forces between a chemical probe and a target molecule. The VolSurf program (150,170) is then used to compress the information in the 3D maps into a few quantitative, numerical descriptors by multivariate analysis, including principal component analysis and partial least squares. Subsequently correlation between %HIA with the VolSurf descriptors will be established based on the "Training" database set. Furthermore, the HIA model will be used to calculate the %HIA for external compounds with unknown or imprecise human intestinal absorption values. Finally, once the model is created, the computational procedure will be fully automated and fast. Thus, the established protocol can be used a tool for fast virtual screening of lead compounds. Interested readers can find more detailed discussions on this subject in the literatures (165).

The ADME prediction method has been used to predict BBB permeation. As we know, the BBB separates the brain and central nervous system from the bloodstream. The BBB permeation remains a challenge in drug design. Crivori et al. (171) collected 40 agents containing a number of related, but chemically diverse, compounds, which are either high brain-penetrating (BBB+), have a moderate permeation BBB(±), or have little if any ability to cross the BBB (BBB-) (Fig. 3.12). The 3D structure of the compounds was built, and the GRID program was used to calculate the 3D molecular interaction fields. Molecular descriptors were calculated using the VolSurf program. Chemometric tools (principal component analysis and discriminant partial least squares) were used to correlate the data and to build a BBB permeation model. The calculated model is in good agreement with the known molecular factors influencing BBB permeation and predicts more than 90% of the BBB permeation data. The fully automatic and fast computational procedure provides a new tool for virtual screening. Recent review articles have provided detailed descriptions of the techniques and methodologies (170,172,173). Many computational programs are available for performing ADME prediction; popular commercial programs include VolSurf (150), ADME/Tox (174), ACD PhysChem (175), and ADMET (176).

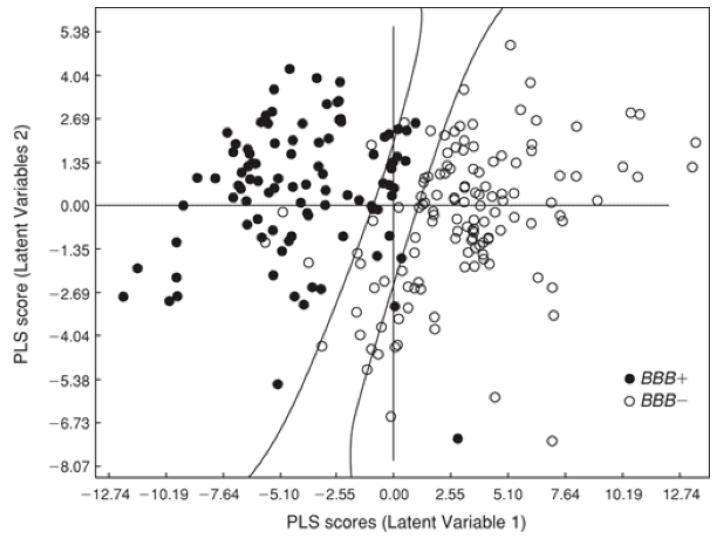

Fig. 3.12. Discriminant partial-least-squares score plot for the global model of blood-brain barrier (BBB) permeability prediction. The model offers a good discrimination and evaluation of a compound's ability to cross the BBB: good permeability, BBB+ (black circles); poor permeability, BBB– (open circles). The model assigned a correct BBB profile to more than 90% of the compounds. A confidence interval is built in the t1-t2 space, where BBB prediction can be borderline and doubtful. (From Crivori P, Cruciani G, Carrupt PA, et al. Predicting blood-brain barrier permeation from three-dimensional molecular structure. J Med Chem 2000;43:2204–2216; with permission.)

In Silico Prediction of Partition Coefficient logP

The octanol-water partition coefficient, or logP, measures the partition of a compound to between 1-*n*-octanol and water, which in turn is a model for the propensity of a compound to cross membrane barriers via passive diffusion. Basically, logP is the log ratio of the concentrations of the chemicals in the two solvents, logP = log [O]/[W], where O is octanol and W is water. In addition, logP is a measure of the hydrophobicity and hydrophilicity of a chemical. Because the hydrophobic parameter is related to absorption, bioavailability, ligand–receptor

P.79

interactions, metabolism, and toxicity, logP has become a valuable parameter in many QSAR approaches that have been developed for pharmaceutical, environmental, biochemical, and toxicological sciences. In virtual screening and in silico drug design, logP values often are used to select the lead compounds. For example, Lipinski et. al. (149) has concluded that poor oral drug absorption of permeation are more likely to occur when the ClogP or logP is greater than five.

The value of logP can be measured experimentally or in silico predicted from structural data. Being more accurate than the prediction, measurement of this property is always recommended, but the experimental techniques are very time-consuming. So, it is important to be able to calculate reliable logP values of compounds that are not available for experimental determinations. A

large number of different calculation methods have been derived for prediction of chemical logP values. The logP prediction methods can be distinguished into five major classes (177,178), including fragment-based, atomic contribution–based, molecular properties–based, solvatochromic parameters–based, and π-substituent–based methods.

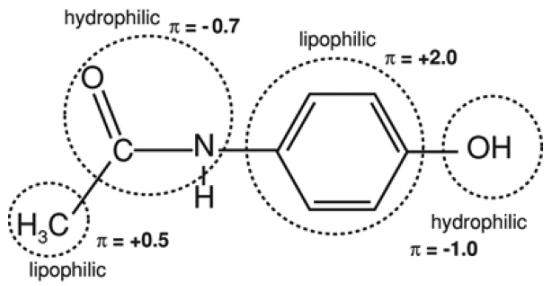
Fragment-Based Method

The fragment-based methods of calculating logP was pioneered by Rekker (179) and further developed by Leo (177) into a widely used ClogP program. Briefly, the method is based on the assumption of the additive nature of hydrophobicity values from different molecular fragments, and the parameter values are calibrated by statistical analysis of a large experimental database. To estimate the logP value of a novel molecule, the chemical structure is first decomposed into smaller fragments that can be recognized by the ClogP program. The logP value of the molecule is simply the incremental sum of parameter values from the composite fragments and, in some cases, additional correction factors by employing the following general equation (180) shown in Figure 3.13,

$$\mathrm{CLogP} = \Sigma fn + \Sigma Fm$$

where *f* denotes atomic or fragmental increments and *F* denotes correction factors. The simplified version of the logP calculation shown above was the basis of the hydrophilic–lipophilic values for organic fragments, as illustrated in Fig. 3.13. The main advantage of a fragment-based method is that it tends to be very accurate, because the correction factors play a crucial role in the success of the calculations. On the other hand, the approach suffers from two major problems. The first is that the molecular decomposition process often is very tricky. The second—and more serious—concerns missing parameter values when a given structure cannot be decomposed to structures for which fragment values are available.

The ClogP calculation methods have been widely used for predicting drug logP values in virtual screening studies. For example, ClogP was used to estimate the logP for the molecule of o-methylacetanilide (ClogP = 0.90) that is close to the experimental value (logP = 0.86) (181). The fragment-based logP prediction software programs include ClogP (177), ACD/logP (180), kLogP (182), and AB/logP (183).



Fragment name	Number	π -value	Calc. LogP
Aliphatic carbon	1	0.5	0.5
Phenyl	1	2.0	2.0
Amide	1	-0.7	-0.7
Hydroxyl	1	-1.0	-1.0
Sum LogP			0.80

Fig. 3.13. LogP calculation gives LogP = 0.80 for acetaminophen (or Tylenol) based on the simplified fragment method (experimentally measured logP = 0.49).

Other Methods

The other LogP prediction methods include the π-substituent method, atomic contribution method, molecular properties method, and solvatochromic method. The atomic contribution method is similar to the fragment-based methods but uses atomic fragments instead of chemical group fragments (178). The contributions of each atom type and correction factor are derived by multivariate regression analysis of 1,853 organic compound with known experimental logP values. This method provides good estimation results, comparable to those of fragment-based approaches. The available software programs are MOLCAD (184), PrologP (185), SMIlogP (186), and XlogP (178). The π-substituent method (187,188) calculates logP by the replacement of a hydrogen atom on a parent compound of known logP with a π value of the given substituent based on the following equation (177): $\log P_{(Y\text{-}R\text{-}X)} = \log P_{(H\text{-}R\text{-}H)} + \pi_{(Y)} + \pi_{(X)}$. For example, the logP value of 3-cyanophenol is calculated to be 1.71, which is comparable with the experimental value of 1.70 (181). The molecular properties–based method (189) computes logP values as a function of different calculated molecular properties, including van der Waals molecular volume (*V*) and each functional group (*N*): $\log P = a_1 V + a_2 N$. (Where a_1 and a_2 are coefficients determined by linear regression). The logP value is then determined by the oxygen- or nitrogen-containing functional groups in the molecule and correlates with hydrogen-bonding acceptor basicity. The software programs QlogP and BlogP have been used for studies of benzodiazepine γ-secretase inhibitors (190), Src tyrosine kinase inhibitor (191),

and the enzymatic hydrolysis of noncongener carboxylic esters (192). The solvatochromic approach (193) is, in essence, a molecular properties methodology but with more parameters, including a solute volume (*V*), solute polarity/polarizability (π*), solute hydrogen-bond acceptor strength (β_H), solute hydrogen-bond donor strength (α_H), and the intercept (*e*): $\log P = aV + b\pi^* + c\beta_H + d\alpha_H + e$. The regression coefficients *a*, *b*, *c*, and *d*, reflect the relative contributions of each solute parameter to log P. The solvatochromic method has been used for predicting the oral absorption potential of peptides (194). Interested readers are encouraged to find more detailed discussions in literatures (195).

In Silico Prediction of Solubility LogS

Another important physicochemical parameter of a drug molecule is the aqueous solubility, often expressed as log units of molar solubility (mol/L), or logS. Aqueous solubility is a key property for all chemical compounds considered as drug lead molecules.

Especially in drug discovery research, knowledge of a compound's aqueous solubility can lead to an understanding of its pharmacokinetics as well as an appropriate means of drug formulation. The solubility of organic compounds in water is related to the logP values discussed above and has become increasingly important for studies regarding the oral absorption of pharmaceuticals and the toxicity of chemical compounds.

Several computer programs have been developed for solubility prediction, as described in reviews (196,197,198,199,200,201,202,203,204,205). In this chapter, we only describe the commonly used prediction approaches based on logP values. Probably the best-known solubility model that includes crystal forces is the general solubility equation (GSE) (206): $\log(S_0) = -0.01(MP - 25°C) - \log P + 0.05$, where S_0 is the intrinsic aqueous solubility in the units of mol/L, logP is the octanol–water partition coefficient, and MP is the melting point (°C). The requirement of a measured melting point, however, has greatly limited use of the GSE in the pharmaceutical industry, because melting point measurements are no longer routine in modern medicinal chemistry. An extension from the GSE equation (e.g., ACD/solubility DB program) was made to use the pH-dependent solubility predictions of compounds with several functional groups (207): logS = *a*logD + *b*MW + *c*MV +*d*BP+ *e*Hbond +*f*Polariz +hnd$_{20}$ + $i\sum$Frg + j, where logS is solubility (mol/L), logD is the octanol–water partition coefficient for partially dissociated compounds, MW is the molecular weight, MV is McGowan molecular volume, BP is boiling point at 760 torr, Hbond is hydrogen-bond parameter, Polariz is polarizability, nd$_{20}$ is refraction index, ∑Frg is the sum of fragmental increments, and j is the intercept. The regression coefficients a, b, c, and d reflect the relative contributions of each solute parameter to log P, and the interested readers can find the detailed description of various LogS value prediction methods in the recent literature (200,204,205).

In Silico Prediction of pK$_a$

Another important drug physicochemical phenomenon is the ionization of Brønsted acids and bases in aqueous solution that plays a central role in much of chemistry and biochemistry and that also affects drug in vitro stability and in vivo metabolism activity. The extent of ionization can be represented by the pK$_a$ or ionization constant, which often is used in predicting drug–drug interaction because of the change of acid or base properties. For example, given a weak acid HA, its dissociation in water is subject to the chemical equilibrium:

$$HA \rightleftharpoons H^+ + A^-$$

The pK$_a$ or ionization constant is defined as the negative logarithm of the equilibrium coefficient neutral and charged forms of HA concentration:

$$pK_a = -\log_{10} k_a = -\log_{10}\left[\frac{[H^+][A^-]}{[HA]}\right]$$

Often, pKa values are obtained through experimental measurement of associated and dissociated HA concentrations. Other situations exist, however, in which accurate measurements are difficult. Hence, theoretical prediction models were developed to calculate pK$_a$ values in a variety of chemical systems by various computational techniques, including the classical method by Hammett (208) and Taft (209), the atom type-based pK$_a$ prediction method (210), and the quantum chemistry–based pK$_a$ prediction (211). The latter two methods, however, are more commonly used.

Prediction of pK$_a$ by atom typing is a simple but surprisingly effective method. Typically, the two most influential factors governing pK$_a$ are the atomic species undergoing protonation or deprotonation and the very local steric and electronic affects (210). Among many commercial programs, ACD/pK$_a$ (212) allows rapid and automatic calculation of acid-base ionization constants (pK$_a$) for large sets of compounds at once. For example, the ACD/pK$_a$ program was used to predict the pK$_a$ of the drug atropine as 10.3 (experimental value of 9.9) (210). Another pK$_a$ calculation is based on quantum chemistry, including density functional computations (211) on a series of aliphatic carboxylic acids, substituted benzoic acids, phenols, anilinium ions, and pyridinium ions (213). Comparison with accurate experimental values indicates that average unsigned errors of generally less than 0.2 pK$_a$ units can be achieved in the calculation of relative pK$_a$ values.

Summary

Computational chemistry provides an array of valuable tools for in silico drug design and virtual screening, and it continues to expand its role in modern drug discovery. Computer molecular modeling, molecular graphic representations, and easy-to-access structural

databases have become essential day-to-day components on the desktop of the medicinal chemist. In particular, virtual screening and in silico drug design techniques have become one of the important processes for medicinal chemists to conduct their rational design of novel scaffold compounds and can even predict their bioactivities before being synthesized. Furthermore, commercial software continues to expand on the core user interface, and new algorithms from both industry and academia are quickly incorporated into the high-end packages. Public domain packages are becoming more stable and offering functionality that rivals some of the commercial offerings. Computers continue to double in speed every year and a half as well as terabyte in data disk storage capacity as computational chemistry and cheminformatics become more sophisticated and intuitive.

In addition, emerging new techniques, such as computational enzymology as well as genomic and proteomic search engines, promise to extend the range of molecular modeling tools. The quality of the methods also is improving as greater computer power facilitates greater sampling, longer simulations, and improved statistics. Quantum mechanical calculations are improving the quality of empirical force field parameters and speeding the development of new parameters, such as those currently under development in carbohydrate chemistry for adjuvant studies and lipid bilayer simulations. All of these elements make molecular modeling an integral part of drug design, which is a synthetic, multidisciplinary research process rather than a linear process. As new insights regarding molecular interactions appear, new methods must be developed and incorporated. The extensibility of computational chemistry will ensure that it continues to play a vital role in visualizing and organizing our understanding of molecular interactions and designing novel drugs.

Chapter 4

Receptors and Drug Action

Timothy J. Maher

David A. Johnson

Introduction

The human body is an example of an exquisitely designed, extremely complex machine that functions day-in and day-out to allow for survival of the organism in response to a never-ending onslaught of external challenges. When one considers the enormous variety of environmental stressors to which the body is continually subjected, it is not surprising to anticipate the existence of a multitude of checks and balances associated with its physiological and biochemical systems. These systems, including endocrine, nervous, and enzymatic, typically function in concert to adapt to changing environmental conditions. Some systems are designed to respond quickly (i.e., within milliseconds) and for a short time; others are designed to act more slowly but usually have significantly longer durations (i.e., months to years). Together, these systems support the organism's survival. Often, however, malfunctioning of the control of such systems leads to disease and, potentially, the eventual demise of the individual.

The use of specific chemical compounds to treat disease dates back to early humans. Many primitive cultures used plants and other natural sources in an attempt to mitigate the influences of evil spirits and other factors rooted in superstition, which were believed to be the foundations of such illnesses. Over the centuries, a number of serendipitous observations involving the ability of largely botanical preparations to alter disease processes laid the foundation for the modern, more systematic approach to the discovery of medicinals for therapeutic use. The collaboration of chemical and biological scientists continue this quest for the “magic bullet” to treat those diseases that challenge the individual's well-being.

Historical Perspectives

For years, it had been known that some drugs were capable of producing their effects by acting at specific sites within the body. Claude Bernard was the first to demonstrate this in the mid-1800s, with his classical experiments involving curare (1). He showed that this neuromuscular blocking agent, which was used as an arrow poison by the South American natives, was capable of preventing skeletal muscle contraction following nerve stimulation, but was without effect when the muscle was stimulated directly. This work demonstrated for the first time a localized site of action for a drug and, most importantly, suggested that a gap, or synapse, existed between the nerve and the muscle. From these findings, he also postulated that some chemical substance normally communicated the information between the nerve and the target tissue—in this case, the muscle. These findings established the foundations for what is known today as “chemical neurotransmission,” a process frequently disrupted by diseases and, likewise, the target of many therapeutic agents.

Investigations by J.N. Langley (2) in the early 1900s established the initial foundations for the interaction of drugs with specific cellular components, later to be identified and termed “receptors.” Before this time, many leading experts believed that most drugs acted nonselectively on virtually all the cells in the body to produce their biological responses, with a response resulting from their general physical characteristics (e.g., lipid solubility) and not related to specific structural features of the compound. Langley noted that compounds like pilocarpine, which act to mimic the parasympathetic division of the autonomic nervous system, were very selective and also extremely potent. Additionally, a compound like atropine was capable of blocking, in a rather selective fashion, the effects of pilocarpine and parasympathetic nervous system stimulation. Importantly, he concluded that these two compounds interacted with the same component of the cell.

Paul Ehrlich (3), a noted microbiologist during the late 19th and early 20th centuries, is credited with coining the term “receptive substance,” or “receptor.” His observations that various organic compounds appeared to produce their antimicrobial effects with a high degree of selectivity led him to speculate that drugs produced their effects via binding to such a receptive substance. The interaction of the drug with the receptor was analogous to a “lock” and “key.” Thus, certain organic compounds would fit properly into the receptor and activate it, leading to a high degree of specificity. Although such a situation might be considered to be ideal for drug therapy, few drugs actually interact only with their intended receptors. The frequency of side effects not associated with a simple extension of their desired pharmacological actions indicates that drug molecules also can combine with other receptors or nonreceptor entities on or within cells to produce a host of other—and often undesirable—effects.

Some drugs produce their desired effects without interaction with a specific receptor. For instance, osmotic diuretics produce their pharmacological effects simply by creating an osmotic gradient in the renal tubules and, thereby, foster the elimination of water in the urine. This is purely the result of a physical characteristic of the drug. Similarly, antacids produce their beneficial effects by chemically neutralizing the hydrochloric acid found in the gastrointestinal tract. No absorption of the drug is even required for its effects to be realized. Often, the

failure of a drug to be absorbed and, thus, only act locally at the desired biological site constitutes a tremendous advantage regarding the safety of that compound. Unfortunately, from a practical standpoint, most pharmacological agents require absorption following administration to reach the intended target; thus, side effects typically are a serious consideration.

More sophisticated mechanisms also can be involved in the nonreceptor actions of therapeutic agents. For instance, the antineoplastic agent mechlorethamine, a nitrogen mustard, produces its beneficial (pharmacologic) and adverse (toxicologic) effects via interaction with many cellular components in both cancerous and normal cells. Via its conversion to a highly reactive electrophilic ethyleniminium ion intermediate, this agent reacts with nucleophilic cellular components, such as amino, hydroxyl, sulfhydryl, phosphate, carboxyl, and imidazole groups. In particular, by alkylating the N-7 position of guanine in DNA, this agent produces miscoding (cytosine normally base pairs with guanine in DNA; however, thymine now substitutes for cytosine) and the eventual death of the cell (4). When one realizes that all replicating cells contain an N-7 nitrogen in guanine in their DNA, it is easy to see why mechlorethamine produces nonselective destruction of cells throughout the body. Thus, no specific receptor is involved in the actions of this class of pharmacological agent.

Affinity—The Role of Chemical Bonding

During the early 1900s, A.V. Hill used nicotine and curare in isolated muscle preparations and noted the effects of temperature in his experiments (1). He concluded that the ability of a drug to produce an effect must result from specific chemical interactions between the drug and specific sites. He also noted that the effects of many drugs were reversible, because washing the isolated tissue often restored the sensitivity of the tissue to nerve stimulation. These studies set the foundation for our understandings of the chemical interactions between drugs and receptors.

When a drug interacts with a receptor, a number of chemical attractive forces are believed to be responsible for the initial interaction. Compounds that are attracted to a receptor macromolecule are said to have affinity for that receptor and may be classified as agonists or antagonists. Additionally, compounds with affinity also are referred to as ligands. Agonists are those compounds that have affinity for the receptor and are capable of producing a biological response as a result of its interaction with the receptor (5). As will be noted later, the ability to produce a response is termed “efficacy,” or “intrinsic activity.” Drugs that are capable of interacting with the receptor but not of activating it to produce a response are classified as antagonists. This class of drug is said to have affinity, but it lacks intrinsic activity. The affinity of a compound for a receptor is dependent on its proper three-dimensional characteristics, such as its size, stereochemical orientation of its functional groups, and its physical and electrochemical properties (e.g., ionic and dipole interactions).

Assuming that a compound has been distributed to the general vicinity of a receptor, based on its physical characteristics, the binding of the drug to the receptor will then initially depend on the types of chemical bonds that can be established between the drug and its receptor. The overall strengths of these bonds will vary (Fig. 4.1) and will determine the degree of affinity between the drug and the receptor.

Covalent Bond

The strongest of bonds involved in drug–receptor interactions is the covalent bond, in which two atoms, one from the ligand and one from the receptor, share a pair of electrons. Because of the significant strength of the covalent bond (50–150 kcal/mol), covalent bonding often produces a situation in which the ligand is irreversibly bound by the receptor and, thus, leads to the receptor's eventual destruction via endocytosis and chemical destruction. Full recovery of cellular function therefore requires the synthesis of new receptors.

An example of an irreversible covalent bond formation between drug and receptor involves the long-lasting blockade of α-adrenoceptors by phenoxybenzamine (see Chapter 13). Once phenoxybenzamine is converted to a highly reactive carbonium ion intermediate, this haloalkylamine can covalently link, via alkylation with amino, sulfhydryl or carboxyl groups at the α-adrenoceptor. The receptor is thus rendered irreversibly nonfunctional and, eventually, destroyed. The synthesis of new receptor requires a number of days, thus accounting for the extremely prolonged duration of the block associated with this agent. As will be discussed below, this property of phenoxybenzamine to irreversibly bind the α-adrenoceptor was critical for the demonstration of spare receptors (6,7). Because other receptors and cellular components also contain molecular groups that are likewise capable of interacting with the activated phenoxybenzamine intermediate, it is not surprising to find that receptors that mediate the actions of other

neurotransmitters (e.g., acetylcholine, serotonin, and histamine) also are subject to alkylation and blockade, demonstrating the lack of selectivity of phenoxybenzamine.

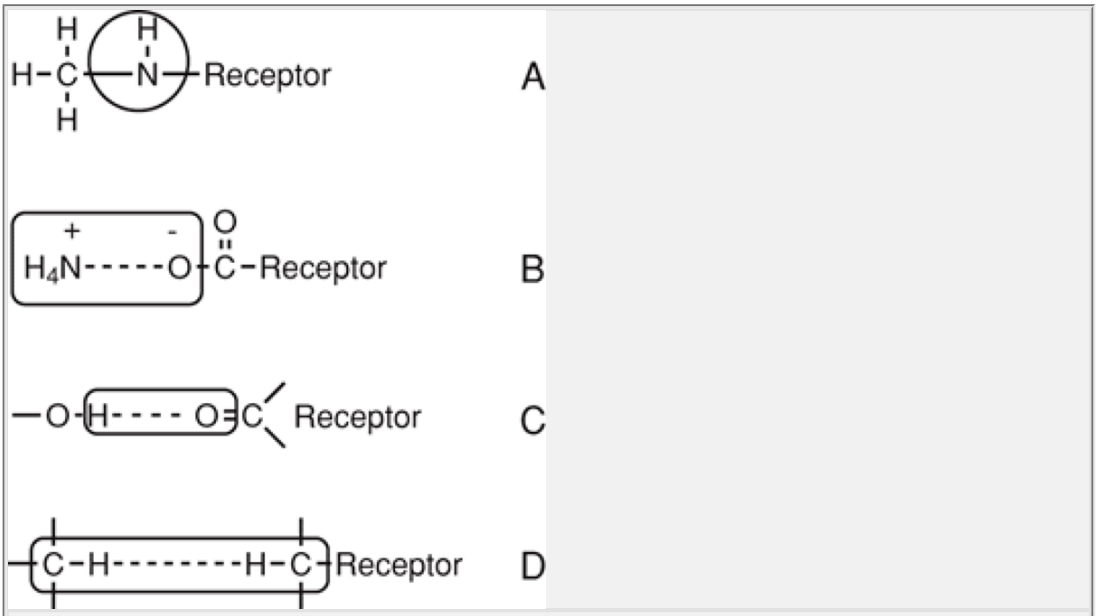

Fig. 4.1. Various drug–receptor bonds. (A) Covalent. (B) Ionic. (C) Hydrogen. (D) Hyrdophobic.

Another important example of a class of compounds that produces its effects via a covalent bond to its receptor are the organophosphate acetylcholinesterase inhibitors. Examples of such agents include the insecticides parathion and malathion and the nerve-gas agents sarin, soman, and tabun. These compounds are capable of alkylating the active site of this enzyme that normally is responsible for metabolizing acetylcholine, the neurotransmitter found at the neuromuscular junction and within many sites of the autonomic and central nervous systems. Reaction of the enzyme with its normal substrate acetylcholine leads to a readily hydrolyzable acetylated enzyme, which rapidly regenerates the active enzyme. Covalent bonding by the organophosphates, however, results in phosphorylation of a serine within the active site of the enzyme, which is extremely stable and essentially irreversible. Recovery of enzymatic function in the tissue requires the synthesis of new enzyme molecules.

Ionic Bond

When two ions of opposite charge are attracted to each other through electrostatic forces, an ionic bond is formed. The strength of this type of bond varies between 5 and 10 kcal/mol, and it decreases proportionally to the square of the distance between the two atoms. The ability of a drug to bind to a receptor via ionic interactions therefore increases significantly as the drug molecule diffuses closer to the receptor. Additionally, the strength associated with the ionic bond is strong enough to support an initial transient interaction between the receptor and the drug, but unlike the covalent bond, the ionic bond is not so strong as to prevent dissociation of the drug receptor complex.

The tendency of an atom to participate in ionic bonding is determined by its degree of electronegativity. Hydrogen, as a standard, has an electronegativity value of 2.1 (Linus Pauling Units). Fluorine and chlorine atoms as well as hydroxyl, sulfhydryl, and carboxyl groups form strong ionic bonds because of a stronger attraction for electrons compared with that of hydrogen. On the other hand, alkyl groups do not participate in ionic bonds because of a weaker tendency to attract electrons compared with that of hydrogen.

Hydrogen Bond

Hydrogen that is linked via a covalent bond to a strongly electronegative atom, such as oxygen, nitrogen, or sulfur, develops a relative positive charge and will be attracted to another atom possessing a relative negative charge via what is termed “hydrogen bonding.” A water molecule that behaves as an electronic dipole (i.e., the hydrogens are relatively positive because of the attraction of electrons by the oxygen) can easily bond to other water molecule through hydrogen bonding. At 2 to 5 kcal/mol, a single hydrogen bond is relatively weak and would not be expected to support a drug–receptor interaction alone, but when multiple hydrogen bonds are formed between drugs and receptors, as typically is the case, a significant amount of stability is conferred on the drug–receptor interaction. Thus, hydrogen bonding most likely is an essential requirement for many drug–receptor interactions.

Hydrophobic Interactions

Hydrophobic interactions between nonpolar organic molecules also can contribute to the binding forces that attract a ligand to its receptor. Theorists have suggested that for these forces to operate, a momentary dipolar structure needs to exist to allow such association. This induced dipolar structure may result

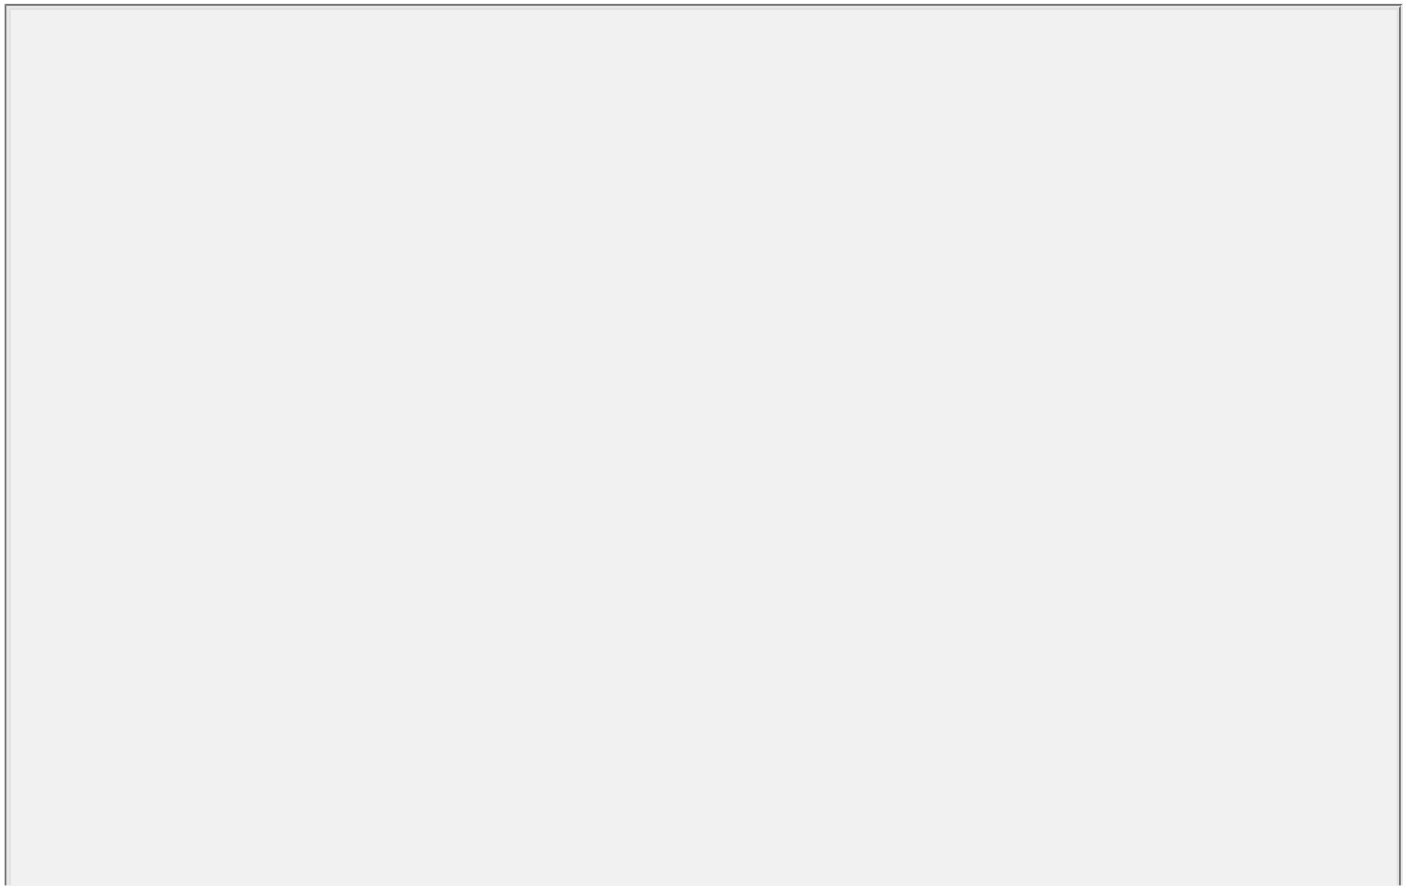
from a temporary imbalance of charge distribution within molecules. These forces are very weak (0.5–1 kcal/mol) and decrease proportionally to the seventh power of the interatomic distance. These bonds, also referred to as van der Waals forces or London forces, require that the two nonpolar molecules come in close proximity to one another.

Affinity—The Role of Conformation

Most therapeutically useful drugs bind only transiently to their intended receptor. The combination of a variety of bonds, including ionic, hydrogen and van der Waals attractive forces, can contribute to the binding of a drug to the receptor. The critical portion of the structure of the drug that is believed to bind to the receptor is termed the “pharmacophore.” Once the drug has bound, a biological response may result (e.g., especially if an agonist). Either following or during the process of binding to the receptor, a conformational change may occur in the receptor that initiates the activation of the biological response and changes the attractive environment between the drug and the receptor. This conformational change in the receptor also may allow the dissociation of the drug–receptor complex. This simple explanation of the interaction of a drug with a receptor producing a biological response is commonly referred to as the “occupancy theory,” and it predicts that the response is directly related to the number of receptors bound by an agonist.

Another theory of drug–receptor interactions, termed the “rate theory,” suggests that the number of drug–receptor interactions per unit time determines the intensity of the response. Thus, drugs that associate with and then rapidly dissociate from the receptor, thus allowing other drug molecules to subsequently interact with the receptor, would be expected to produce the most robust responses. The “induced-fit theory” suggests that as the drug approaches the receptor, a conformational change occurs in the receptor to allow effective binding (Fig. 4.2). According to this theory, the receptor does not normally exist in the proper conformation for drug binding. Following dissociation of the drug, the receptor can then

revert to its original configuration. In this theory, an antagonist can induce a conformational change in the receptor; however, the change is not the proper change required for a biological response to be elicited. Combining the induced-fit and rate theories yields the “macromolecular pertubation theory,” which suggests that two types of conformational changes exist and that the rate of their existence determines the observed biological response. Agonists produce the specific pertubation required for a biological response, whereas antagonists produce a nonspecific pertubation, which fails to yield a biological response. This theory can partially account for the activity of partial agonists. Finally, the “activation-aggregation theory” indicates that receptors are always in a dynamic equilibrium between active and inactive states. Agonists function by shifting the equilibrium toward the activated state, whereas antagonists prevent the activated state. This theory can account for the activity of inverse agonists, which produce neither a typical agonist response nor an antagonist response (i.e., blocking the receptor) but, rather, produce biological responses opposite to those of the agonist.



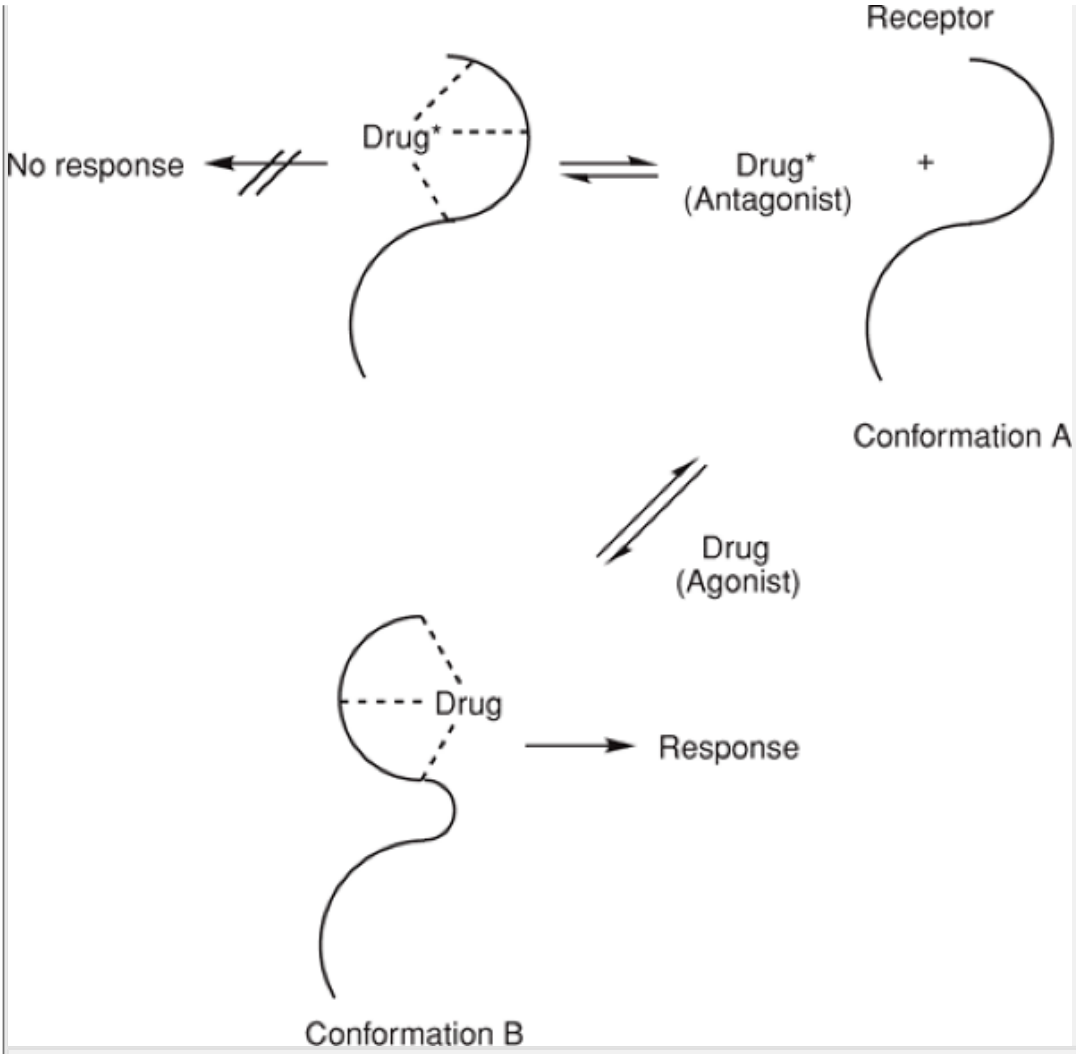


Fig. 4.2. Diagrammatic representation of drug-induced fit theory, in which an agonist (Drug) or antagonist (Drug*) interacts with two different conformations of the receptor.

Affinity—The Role of Stereochemistry

Very specific three-dimensional requirements must be satisfied for a compound to effectively act as an agonist. To elegantly demonstrate the specificity of a drug for its receptor, the unique three-dimensional characteristics of chiral compounds can be used as an example. As early as 1901, Pasteur (8) noted the significance of asymmetric compounds in biological systems. Since that time, much has been learned from chiral compounds regarding three-dimensional binding requirements of receptors. For instance, although the individual enantiomers (i.e., nonsuperimposable mirror images) of norephedrine (2-amino-3-phenyl-1-propanol) (Fig. 4.3) have identical molecular weights, melting points, lipid solubility, and empirical formulae, these compounds have significantly different α-adrenoceptor agonistic activities. The 1R,2S enantiomer (levo) is approximately 100-fold more potent than the 1S,2R enantiomer (dextro) both in vivo and in vitro (9,10). (Because there are two chiral centers, there also is another set of stereoisomers called diastereomers, 1S,2S and 1R,2R, that have an even different pharmacological profile.) Thus, the greater efficacy of the 1R,2S enantiomer most likely is dependent on its ability to bind and activate the receptor as a result of its preferential fit into the receptor.

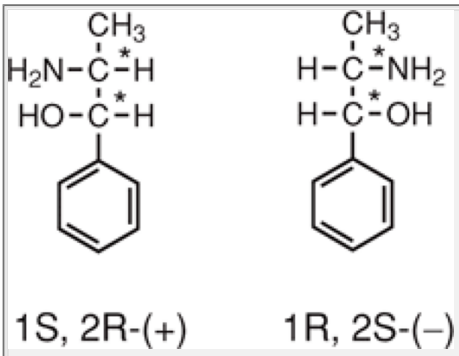

Fig. 4.3. Projection formulae of 2-amino-3-phenyl-1-propanol stereoisomers. (From Maher TJ, Johnson DA. Review of chirality and its importance in pharmacology. Drug Dev Res 1991;24:149–156; with permission.)

Because labetalol, an adrenoceptor-blocking agent structurally related to epinephrine, has two asymmetric centers, four diastereomers exist (Fig. 4.4). The formulation available for use as a mixed α- and β-adrenoceptor blocker contains equal amounts of each diastereomer. The R,R isomer accounts for much of the β-adrenoceptor blocking activity, whereas the S,R isomer has the greatest effect on α-adrenoceptors. The S,S isomer has some α-adrenoceptor blocking activity but no activity at β-adrenoceptors. The R,S isomer is essentially devoid of activity at both α- and β-adrenoceptors.

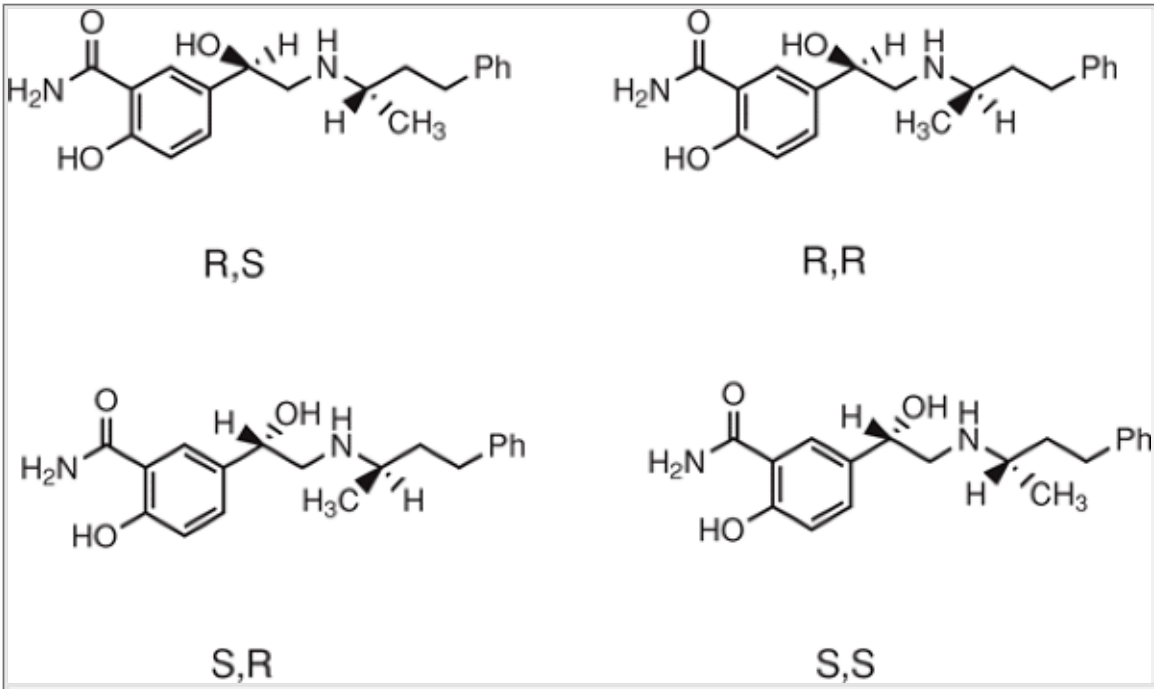

Fig. 4.4. Diastereomers of labetalol.

Many synthetically prepared therapeutic agents are a mixture of two enantiomers (racemates), with one

enantiomer, termed the “eutomer,” being largely responsible for the desired pharmacological effect (11). The other enantiomer, termed the “distomer,” may be inactive or even contribute more significantly to the toxicity of the therapeutic agent. Thus, in the future, knowledge of chirality should play a significant role in the advances gained in receptor theory as well as in therapeutics.

Receptor Binding and Drug Discovery

The discovery of pharmacological agents by modern pharmaceutical companies and universities often involves the use of receptor–ligand binding techniques. Following the synthesis of a series of new chemically related compounds, which may constitute hundreds to thousands of compounds, the determination of the desired biological activity was once a rather daunting task. Before the advent of receptor–ligand binding techniques, the initial screening of these compounds involved individually injecting each agent into experimental animals or incubating each agent with isolated tissues (e.g., intestine, heart, and skeletal muscle), which are techniques that require a large investment of resources, including personnel, time, animals, and money. Today, receptor–ligand binding techniques are used to narrow large numbers of compounds down to those that display the greatest affinity for a receptor, thereby significantly decreasing the time and cost associated with identifying "lead" compounds. One danger associated with such an initial screening approach, however, is the failure to recognize potentially useful compounds that might require biotransformation before exerting a biological effect, such as a pro-drug. Additionally, it should be remembered that ligand binding based on the affinity of a drug for a receptor does not differentiate agonists from antagonists. Despite these potential pitfalls associated with receptor–ligand binding techniques, modern drug discovery relies heavily on these approaches.

Dose–Response Relationships

A.J. Clark generally is given credit for being the first to apply the law of mass action principles to the concept of drug–receptor interactions, thus providing further evidence for the dose–effect phenomenon (12). This concept, as applied by Clark, states that the greater the number of agonist molecules at the site of the receptors, the greater the response (i.e., a direct relationship); however, these principles of the law of mass action in receptor–drug interactions have been questioned. The law of mass action applies to compounds dissolved in fluids that are allowed to diffuse freely. Now that much is known about the anchoring of most receptors to, or within, cell membranes where receptor–drug interactions are thought to occur, this environment would actually constitute a solid–liquid interface. Thus, the law of mass action as applied to compounds dissolved in fluids where they are allowed to diffuse freely might not be completely applicable.

Equation 4.1 illustrates the interaction of a drug ([D]) with a receptor ([R]), which results in a drug–receptor complex ([DR]) and a biological response. The interaction between most therapeutically useful drugs and its receptor generally is reversible:

$$\textbf{Eq. 4.1} \qquad [D] + [R] \rightleftharpoons [DR] \rightarrow \text{Biological Response}$$

Following administration of a drug, one can monitor the biological responses produced. Plotting the dose or concentration of the drug versus the effect produced (% response) yields a rectangular hyperbolic function, as illustrated in Figure 4.5a. This type of function is mathematically difficult to accurately extrapolate quantitative information from because of the constantly changing slope of the curve. When the effect produced is plotted against the log of the drug concentration or the dose administered, however, a sigmoidal function results, as illustrated in Figure 4.5b. This function possesses a relatively linear portion of the curve about its central point, thereby making quantitative extrapolations more accurate.

Dose–response curves typically are plotted to determine both quantitative and qualitative parameters of potency and efficacy. Potency is inversely related to the dose required to produce a given response (typically half-maximum), and efficacy is the ability of a drug to produce a full response (100% maximum). In Figure 4.6, Drug X is equally efficacious to Drug Y, but Drug X is more potent than Drug Y. That is to say, both Drug X and Drug Y can produce a 100% response, but with Drug X reaching that response at a lower dose. Visual inspection of such dose–response curves allows easy qualitative interpretations (e.g., in a series of curves): Those positioned to the left are more potent than those positioned to the right. Additionally illustrated in Figure 4.6, Drug Z is more potent than Drug Y, and Drug Z is equipotent to Drug X. However, comparisons of efficacy are visually apparent, because the greater the maximum response (i.e., efficacy), the higher the maximum point on the dose–response curve. Thus, in Figure 4.6, Drug X and Drug Y are of equal efficacy, and Drug X and Drug Y are of greater efficacy than Drug Z.

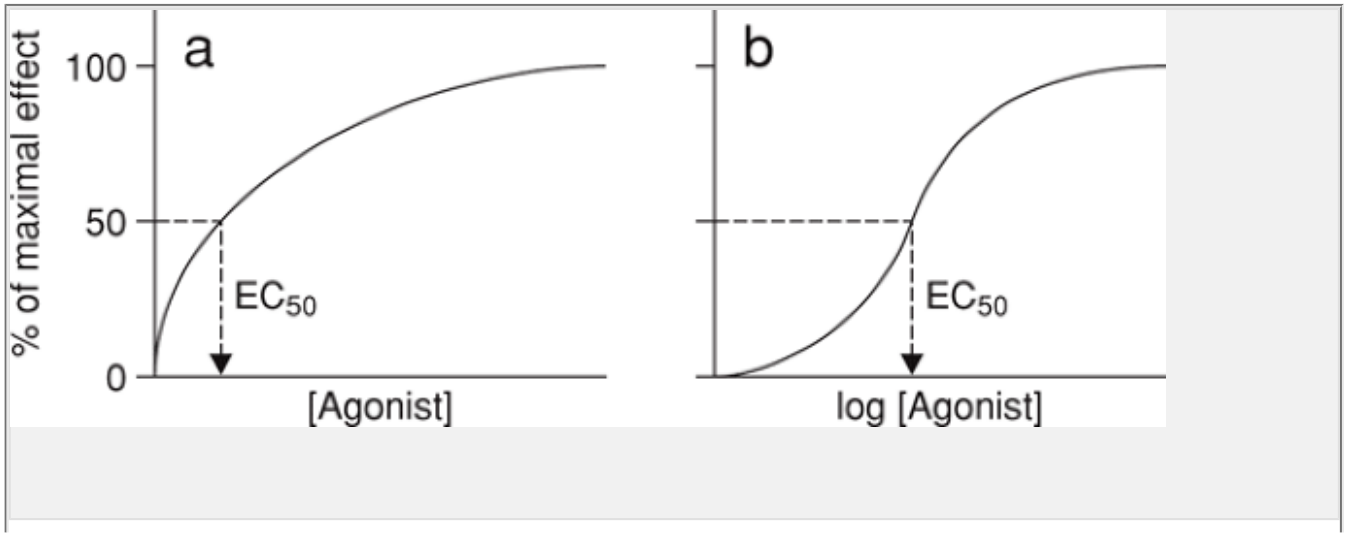

Fig. 4.5. Plot of (a) dose or concentration and (b) log of the dose or concentration of a drug versus the effect produced.

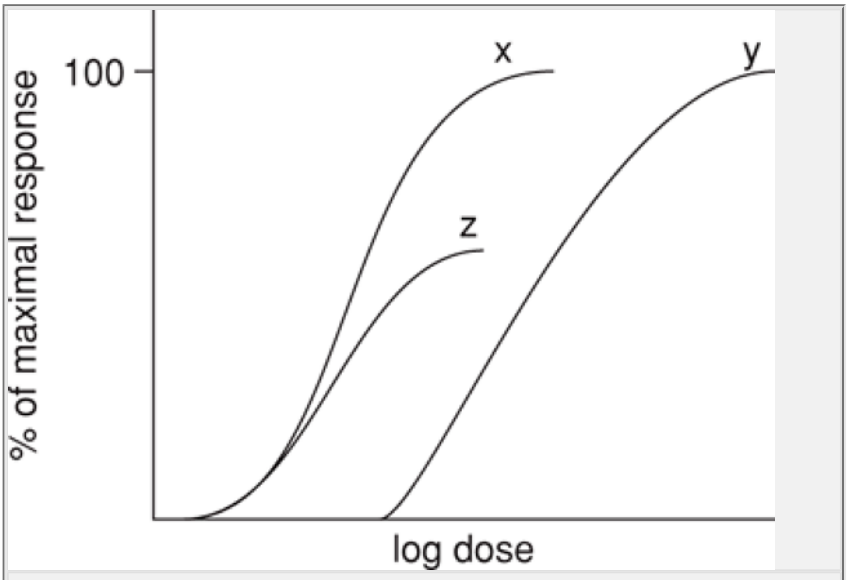

Fig. 4.6. Dose–response relationship.

Presynaptic and Postsynaptic Receptor Locations

When an action potential arrives at the nerve cell's axon, a depolarization-induced exocytosis of neurotransmitter from its storage sites in the presynaptic terminal occurs. Through this process, the action potential continues the flow of information to the target site, typically the postsynaptic cell. The neurotransmitter is believed to diffuse across the extracellular fluid filled space known as the synapse and to interact with postsynaptic receptors. The released neurotransmitter, however, also may be capable of interacting with presynaptic receptors located on the neurons that just released the neurotransmitter. The function of these receptors typically involve the regulation of nerve transmission and are termed “autoreceptors,” because the neurotransmitters that activate them function to control their own release.

An exquisite example of both receptor locations and the action of autoreceptors in the control of neurotransmission is observed in norepinephrine-containing postganglionic neurons of the sympathetic nervous system (Fig. 4.7) (13). Norepinephrine, which is capable of stimulating both α- and β-adrenoceptors, initially is released and is present at low concentration in the synapse. Low concentrations of this agent are capable of preferentially stimulating β-adrenoceptors located presynaptically, which function to increase the release of more neurotransmitter and, thereby, to magnify the intended response. Additionally, the epinephrine released from the adrenal medulla during sympathetic stimulation also is thought to play an important role in facilitating neuronal norepinephrine release. This is an example of a positive-feedback system, which allows a rapid rise in the concentration of the neurotransmitter and, thus, the intended signal. Following this initial period of robust norepinephrine release, very high norepinephrine concentrations result in the synaptic cleft, which then is capable of stimulating other presynaptic autoreceptors, this time terminating the additional release of neurotransmitter. This negative-feedback system allows the signal to be terminated very quickly.

Together, the presynaptic facilitatory β-adrenoceptor–mediated mechanism and the presynaptic inhibitory α-adrenoceptor–mediated mechanism allow a rapid, robust, and well-controlled signal to be delivered. If one were to design a system that was to respond quickly to stressors, such as the sympathetic nervous system is believed to be designed to do, then a system that turns on rapidly and can be terminated quickly would be ideal and, presumably, an evolutionary advantage. Additionally, many other neurotransmitter autoreceptors have been identified, such as in the serotoninergic, dopaminergic, and histaminergic transmitter systems. Examples even exist whereby a neurotransmitter can interact with a presynaptic receptor to influence the release of a different neurotransmitter. For instance, norepinephrine released from neurons in the gastrointestinal tract can function to decrease acetylcholine release. This is termed a heteroreceptor.

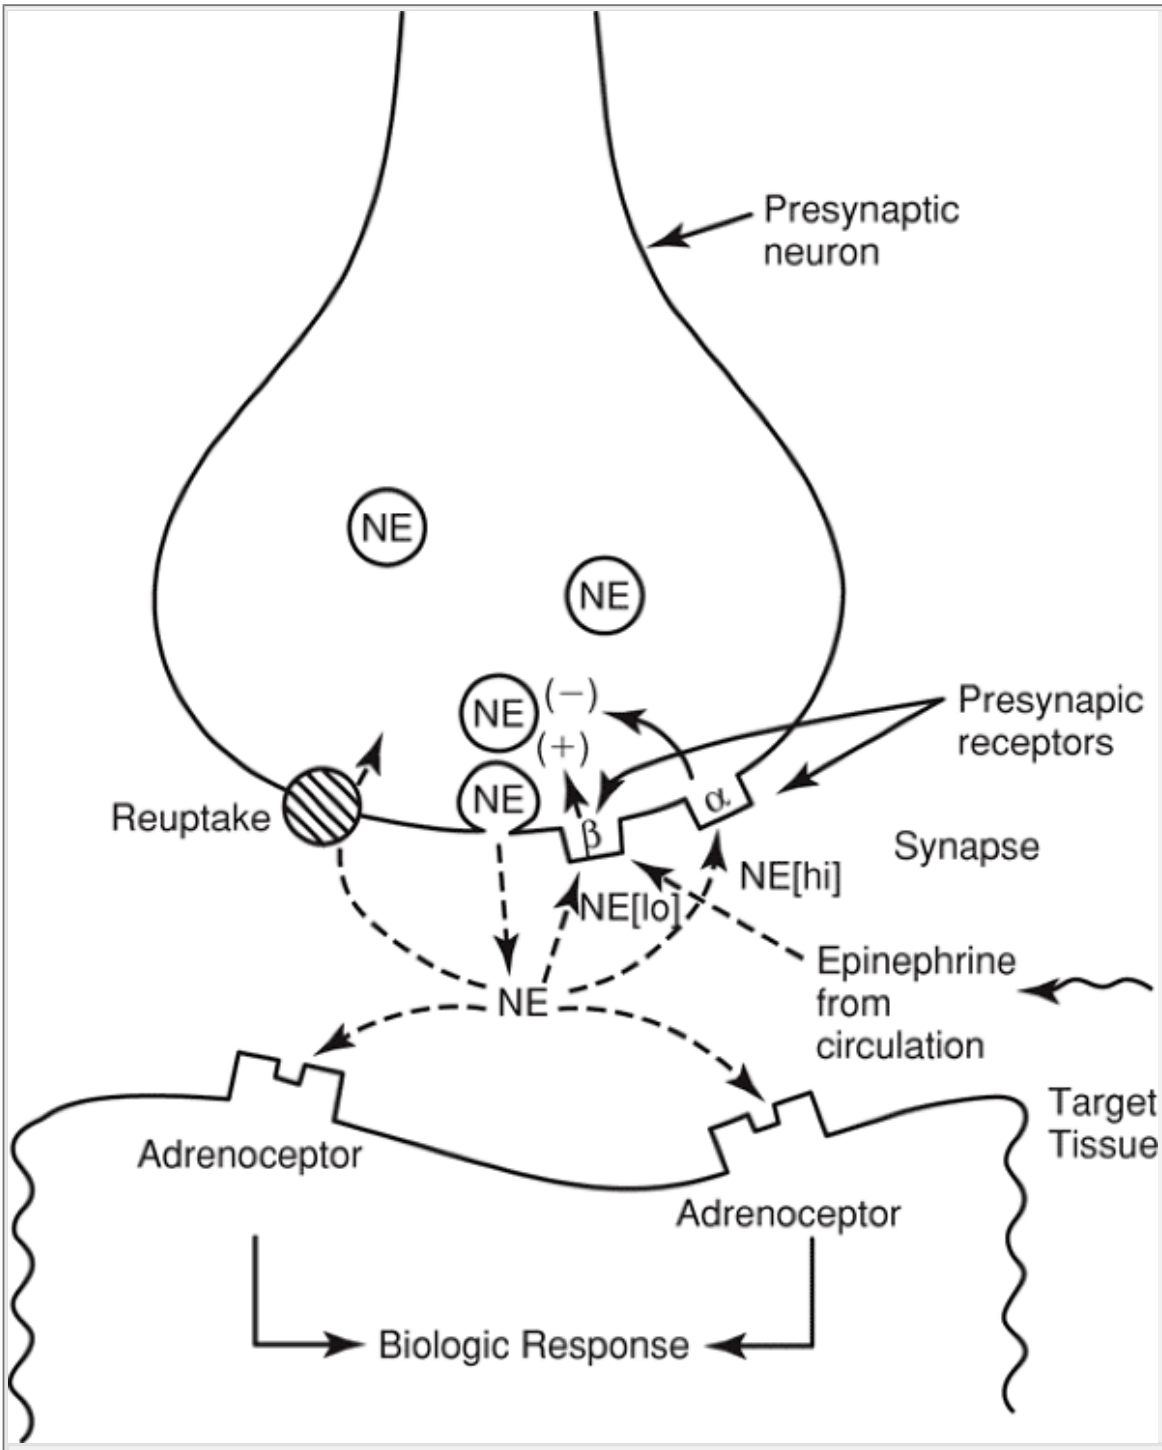

Fig. 4.7. Autoreceptor control of neurotransmission as observed in norepinephrine-containing postganglionic neurons of the sympathetic nervous system. NE, norepinephrine; NE[lo], low norepinephrine concentration; NE[hi], high norepinephrine concentration, α, α-adrenoceptor; β, β-adrenoceptor; (–), inhibit; (+), stimulate.

Drug Receptors and the Biological Response

There are four major families of receptors that drugs, which mimic, modify, or antagonize endogenous neurotransmitters, hormones, or autocoids, are capable of interacting with in the body (Fig. 4.8). Some receptors allow a rapid response to a released neurotransmitter/hormone

or an administered drug. These responses generally are important for the immediate response to a significant homeostatic challenge to the individual. Both ion channel and G protein–coupled receptors tend to be rapid responders, with some catalytic receptors also characterized this way. These responses tend

to be short-lived. On the other hand, many catalytic and just about all cytoplasmic/nuclear receptors tend to respond much more slowly, on the order of hours to days, and these responses are much longer in duration than the rapid-responding receptors.

Chapter 1, Drug–Receptor Interactions. In: Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004, pp. 3–16, with permission.)

Signal Transduction

Signal transduction is a communication process by which a cell converts an extracellular signal or stimulus by transmitting this signal across the cell membrane to the interior of the cell. Proteins on the cell's extracellular surface function as receptors for specific molecules, ligands, or agonists (first messengers). The binding of the ligand to the receptor initiates an interlinked series of processes, termed “signal transduction,” that involve a sequence of biochemical reactions inside the cell, which are carried out by enzymes, proteins, and ions (especially calcium) that are linked through second messengers, such as cyclic AMP (cAMP) or inositol 1,4,5-trisphosphate (IP_3). This signal is relayed via a second messenger that results in specific cellular responses or changes in gene expression in the nucleus (Fig. 4.9). Such processes take place in as little as a millisecond or as long as a few seconds. Slower processes rarely are referred to as signal transduction.

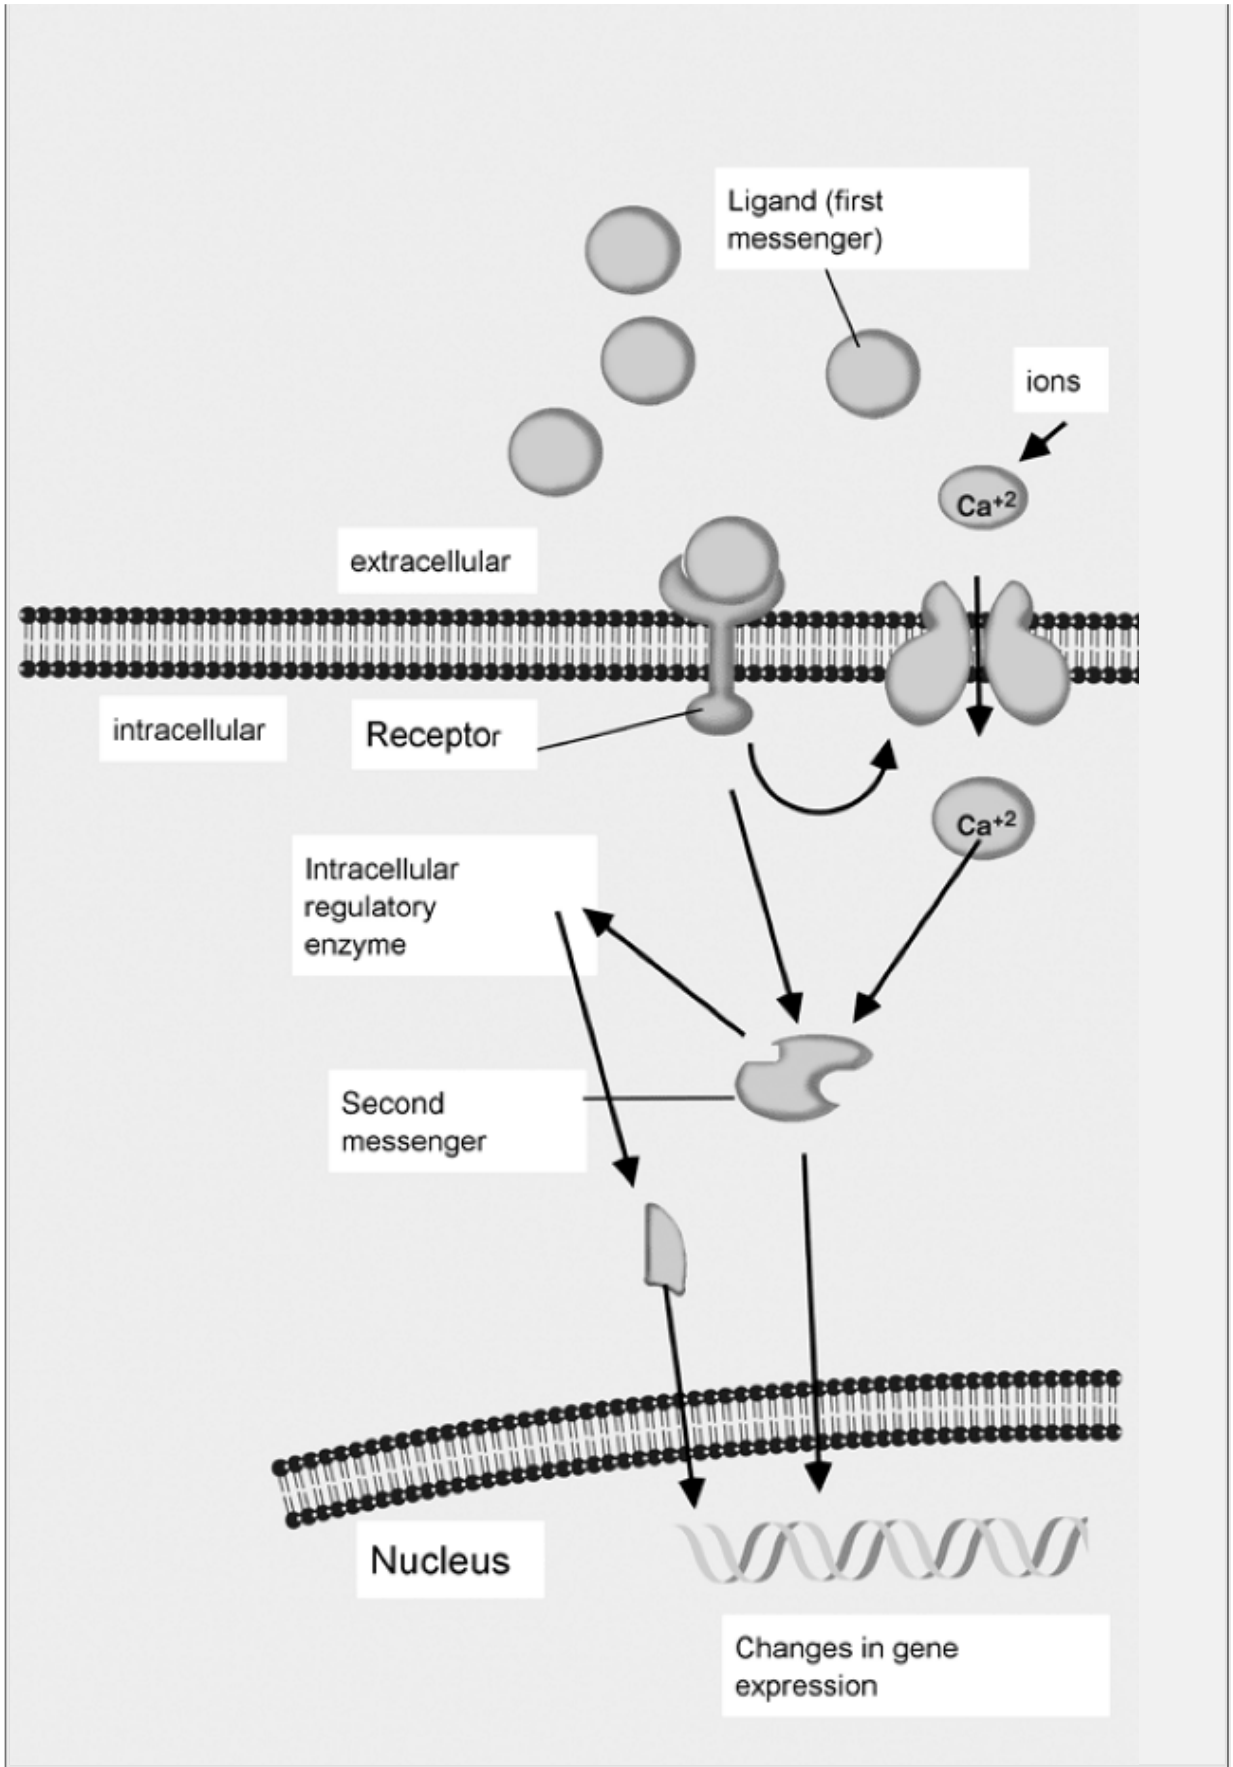

Fig. 4.9. Overview of signal transduction in cellular regulation and gene expression via second messengers.

The process of signal transduction serves several critical roles. First, it enables extracellular molecules to affect cellular function without entering the intracellular environment. This “long distance” communication is accomplished by the binding of a ligand (agonist) to the receptor protein and stabilizing the

receptor structure in an active conformation. The active receptor conformation can then facilitate the flow of ions through a membrane

channel by the removal of steric or electronic hindrances (opening of channel gates). For those receptors that produce signals via activation of intracellular metabolic pathways, the active state or conformation changes the intracellular molecular environment in such a way as to activate, directly or indirectly, intracellular regulatory enzymes. Second, several different signals may affect one another by facilitating or inhibiting the activation of regulatory enzymatic proteins via common or opposing metabolic pathways. Thus, signal transduction mechanisms can interact in such a way as to yield an integrated response to multiple stimuli. Third, via the activation of enzymes and the production of second messengers (e.g., cAMP, diacylglycerol [DAG], ad IP3), an initially weak signal can be amplified, and its duration prolonged, to produce a robust cellular response. This amplification can occur through several mechanisms. The kinetic time frame for enzyme activation and the presence of key metabolites may be much longer than the time of receptor activation itself. Thus, a brief activation of a small number of receptors may result in a magnified response by the cell. Amplification also can occur via a molecular "cascade," in which one initial signal can trigger a multitude of intracellular reactions that lead to an enhanced cellular response. Outcomes of signal transduction may include one or more of the following: 1) a change in cell membrane polarity in electrically excitable tissues, such as nerves and muscles, which then results in the facilitation or inhibition of an action potential, thus affecting the excitability of the tissue; 2) the activation of cytosolic metabolic cascades, resulting in alterations of cellular morphology or function; and 3) gene activation, leading to the synthesis of new proteins that may then modify cellular structures and physiology.

Transmembrane Ion Channels

Ligand-Gated Ion Channels

The most rapid cellular responses to receptor activation are mediated via ligand-gated ion channels (LGICs) (Fig. 4.8A). The main component of this signal transduction pathway is a plasma membrane–spanning protein composed of multiple peptide subunits, each of which contains four membrane-spanning domains. The nicotinic acetylcholine receptor is, perhaps, the best characterized LGIC. The nicotinic receptor is composed of five distinct subunits, two α and, depending on the receptor subtype, various combinations of additional α, β, γ, and δ subunits. The binding of an acetylcholine molecule to the binding site on each of two α subunits induces a conformational change in the receptor, opening a sodium-selective ion channel through the center of the protein (14). The result is depolarization of the surrounding plasma membrane. Other neurotransmitter-activated LGICs include γ-aminobutyric acid, glycine, glutamate, and some serotonin receptors (15). These receptors share a similar structural conformation and function to the nicotinic receptor, except for the specificity of the ligand-binding site and selectivity of the channel for particular ions. The primary reason for the rapidity (milliseconds) of the cellular response with LGICs is that the transduction of the signal requires the activation of a single molecule. Therefore, this transduction mechanism is especially suited for physiological processes necessitating an immediate response, such as the stimulation of nerves and muscles.

Voltage-Gated and Second Messenger–Gated Channels

Other ion channels are controlled by either voltage changes or second messenger molecules. An example of a voltage-gated channel includes the sodium channels responsible for impulse conduction in sensory nerve fibers that transmit information about pain and temperature. Following administration, the local anesthetic lidocaine enters the nerve cell via diffusion in its unprotonated form. Once inside the nerve cell, lidocaine is protonated, and in this charged form, it is capable of blocking the sodium channel from the intracellular side. Some second messenger molecules (e.g., cAMP and IP_3; discussed below) generated following the activation of G protein–coupled receptors can influence the degree of channel opening or closing. The most common channels influenced by these second messengers include those for calcium and potassium.

Transmembrane G Protein–Coupled Receptors

The G protein–coupled receptors (GPCRs) are a class of large membrane-bound proteins, which share a well-conserved structure and transduce their signal via the activation of an intracellular guanine nucleotide–binding protein (G protein). This family of proteins has seven hydrophobic (heptahelical) domains that span the plasma membrane; therefore, it sometimes is referred to as having a serpentine structure (Fig. 4.8B). The extracellular region of the protein is composed of the amino terminus and several loops, which comprise the ligand-binding site. Smaller ligands tend to bind deep within the extracellular loops, close to the plasma membrane, whereas larger molecules have binding sites that are more superficial. The carboxy end of the receptor is located in the area of the protein that protrudes into the cytoplasm. The intracellular side of the receptor also includes the binding site for the G protein, which usually binds to the third loop between the sixth and seventh transmembrane regions of the protein. Close to the carboxy terminus are serine and threonine residues, which are targets for ATP-dependent phosphorylation. Following prolonged activation, phosphorylation of these residues is hypothesized to occur via a negative-feedback regulatory metabolic pathway, which facilitates the binding of modulating molecules that subsequently impair the coupling of G proteins to the receptor. The result is receptor desensitization.

More than 100 different GPCRs bind to a variety of ligands encompassing biogenic amines, such as acetylcholine, norepinephrine, and serotonin; amino acid neurotransmitters, such as glutamate and glycine; and peptide hormones, such as angiotensin II and somatostatin.

P.93

There are multiple GPCR types for a single ligand. The result is the possibility that a single ligand can activate a variety of transduction pathways and produce a multiplicity of cellular responses. Thus, a receptor is defined not just by which ligand binds to it but also by how the signal is transduced and the physiological response that results. As an example, at least nine different adrenergic receptor subtypes exist (16). Norepinephrine can bind to the β_1 receptor, which is coupled to a G protein (designated G_s). Following receptor stimulation of G_s, there is activation of the enzyme adenylyl cyclase, thus leading ultimately to an increase in heart rate and force of contraction. Norepinephrine binding to α_1-receptors, on the other hand, results in the binding to a different G-protein (G_q), which activates the production of the second messengers IP_3 and DAG, which then initiate a cascade of intracellular events leading to smooth muscle contraction. Therefore, a single ligand can induce a wide range of responses as a consequence of coupling to different G proteins. Which G protein is activated depends on factors such as the presence and availability of individual G proteins within a particular cell type, kinetic issues (e.g., the binding affinity of the G protein for the receptor protein), and finally, the affinity of the activated G-protein subunits for signal transduction enzymes.

G Proteins

G proteins are heterotrimeric in structure with the subunits (in decreasing size) designated as α, β, and γ. At least 13 types of G proteins have been identified, which are divided among four families, G_s, G_i, G_q, and G_{12}. Individual G proteins transduce the receptor activation signal via one of a number of second messenger systems discussed below. The best-understood second messenger systems associated with each G protein family are summarized in Table 4.1.

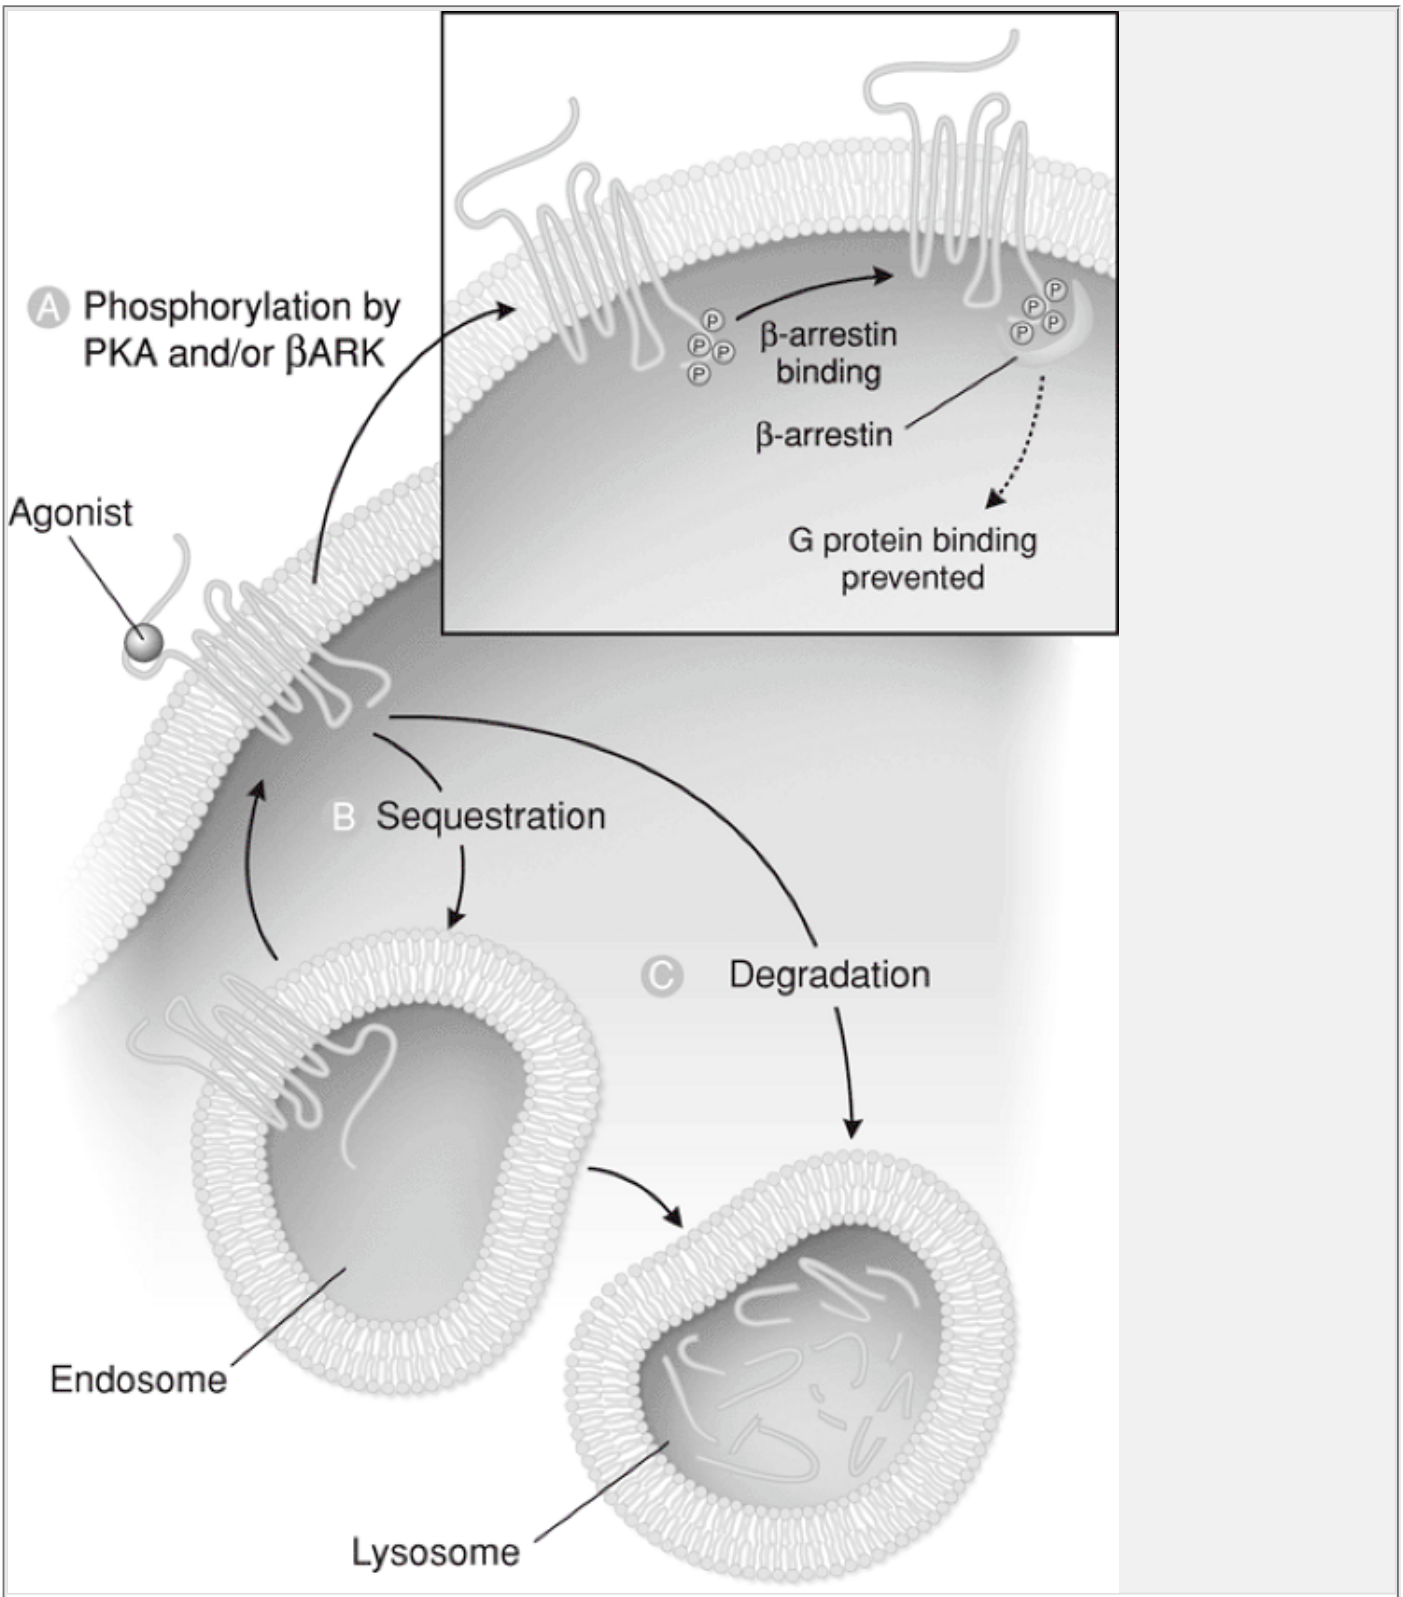
The characteristics of the α subunit are what determine the designation of the G protein. Receptor activation leads to a conformational change in the associated G protein, triggering the release of bound GDP from the α subunit, which is then replaced by a molecule of GTP. With the binding of GTP, the α-subunit GTP complex dissociates from the $\alpha\beta$ subunits and binds to a particular target enzyme, resulting in its activation or inhibition. Within a short period of time, the α subunit catalyzes the dephosphorylation of the associated GTP molecule to GDP, resulting in the reassociation of the α subunit with the $\alpha\beta$ subunits and, thus, the return of the G protein to the inactivated state (Fig. 4.10). Variations on this scheme include the activation of proteins such as G protein–gated ion channels by dissociated $\alpha\beta$ subunits and the ability of receptor proteins to activate more than a single G protein. The simultaneous activation of more than one type of GPCR results in the initiation of multiple signals, which can then interact with one another (a phenomenon commonly referred to as cross-talk).

P.94

This interaction can be of several types: If both receptors use a common signal transduction pathway, the activation can result in an additive response by the cell. Conversely, if simultaneous receptor activation triggers opposing signal transduction pathways, the outcome will be an attenuated cellular response. Other types of interactions may include the desensitization or activation of other receptor proteins or second messenger pathways. The final outcome of the activation of multiple signals is an integrated response by the cell.

Table 4.1. G-Protein Transducers and Second Messengers

G-Protein Transducer Family	Second Messenger System
G_s	Stimulates adenylyl cyclase activity and Ca^{2+} channels
G_i	Inhibits adenylyl cyclase activity and activates K^+ channels
G_q	Stimulate phospholipase C activity
G_{12}	Modulate sodium/hydrogen ion exchanger



A Phosphorylation by PKA and/or βARK
β-arrestin binding
β-arrestin
G protein binding prevented
Agonist
B Sequestration
C Degradation
Endosome
Lysosome

Fig. 4.10. β-Adrenoceptor regulation. Following repeated stimulation of the β-adrenoceptor by an agonist, phosphorylation of amino acids on the intracellular C-terminal domain by protein kinase A (PKA) and/or β-adrenergic receptor kinase (βARK) may (A) prevent subsequent G-protein binding, (B) enhance removal of the receptor from the membrane via sequestration into endosomes, or (C) enhance degradation via lysosomal internalization and cleavage.

(From Simon JB, Golan DE, Tashjian A, Armstrong E, et al., eds. Chapter 1, Drug–Receptor Interactions. In: Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004, pp. 3–16, with permission.)

Second Messenger Pathways

As discussed above, in response to receptor activation, G proteins activate plasma membrane-bound enzymes, which then trigger a metabolic cascade that results in a cellular response (17). The products of these enzymatic actions are termed “second messengers,” because they mobilize other enzymatic and structural proteins, which then produce the cellular response. The enzymes that catalyze the synthesis of second messengers generally fall into two categories: those that convert the purine triphosphates ATP and GTP into their respective cyclic monophosphates, and enzymes that synthesize second messengers from plasma membrane phospholipids. The most thoroughly studied second messenger system is controlled by a family of 10 plasma membrane-bound isoenzymes of adenylyl cyclase, which catalyze the conversion of ATP to cAMP (Fig. 4.11). Adenylyl cyclase is activated by the G_s family of G proteins and inhibited by the G_i family. Following synthesis, cAMP activates cAMP-dependent protein kinases by triggering the dissociation of regulatory subunits from catalytic subunits. The catalytic subunits then activate other target proteins via phosphorylation, which then trigger the cellular response. The magnitude of the cellular response is proportional to the concentration of cAMP. Degradation of cAMP occurs via phosphodiesterases or by reducing cAMP concentration via active transport out of the cell. The result is termination of the signal.

A similar, although less ubiquitous, second messenger pathway is associated with guanylyl cyclase. Guanylyl cyclase is activated in response to catalytic receptors selective for ligands including atrial natriuretic factor and nitric oxide. When stimulated, guanylyl cyclase then catalyzes the synthesis of cyclic GMP (cGMP) from GTP. Cyclic GMP subsequently activates cGMP-dependent protein kinases, which then activate other proteins. The actions of cGMP are terminated by enzymatic degradation of the second messenger or the dephosphorylation of substrates. One effect of this second messenger pathway is the relaxation of smooth muscle via the dephosphorylation of myosin light chains.

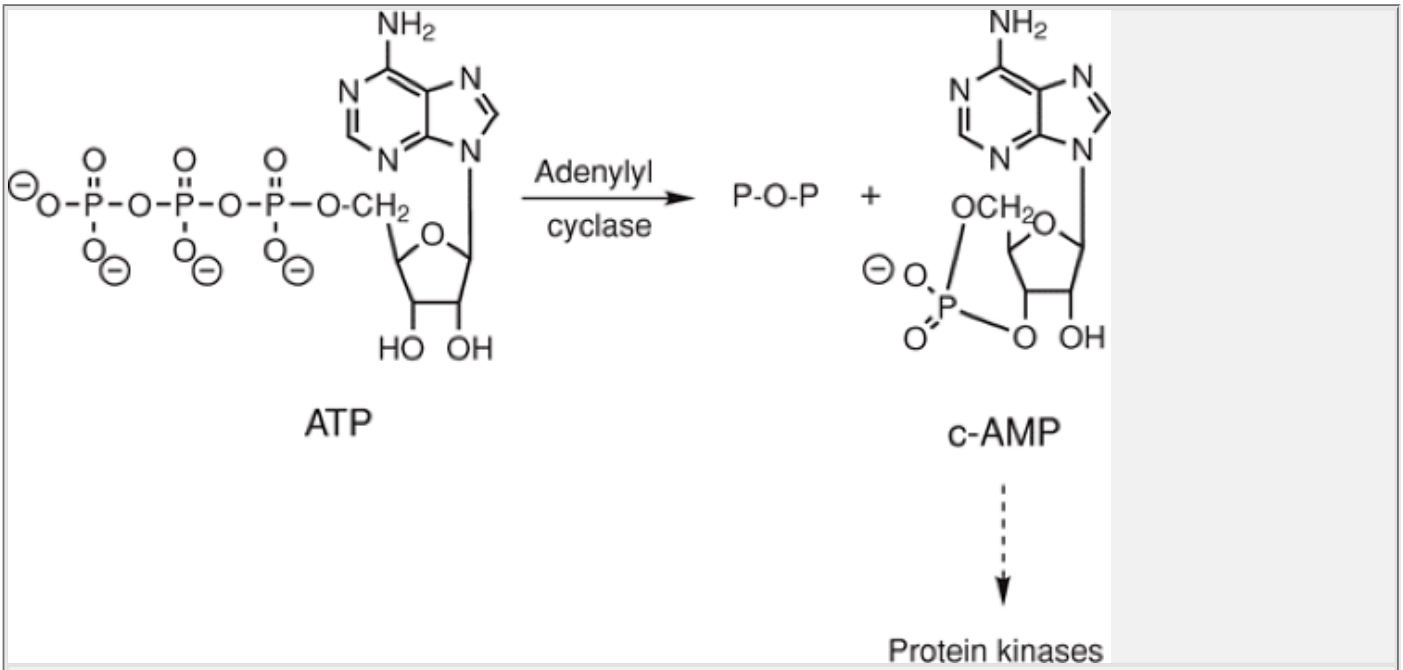


Fig. 4.11. Conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (c-AMP) catalyzed by adenylyl cyclase.

The generation of second messengers from plasma membrane phospholipids is mediated primarily by G-protein activation of phospholipase C (PLC) (18).

There are three families of PLC, designated PLC-β, PLC-γ, and PLC-δ. Phospholipase C-β can be activated by the α subunit of the G_q family of G proteins or the βγ subunits of other G proteins. Phospholipase C-γ is activated via tyrosine kinase receptors, but the mechanism for PLC-δ is not yet understood. On activation, PLC hydrolyzes phosphatidyl inositol-4,5-bisphosphate to DAG and IP_3 (Fig. 4.12). The water–soluble IP_3 diffuses into the cytoplasm, where it triggers the release of calcium from intracellular

stores. Intracellular calcium then binds to the protein calmodulin and also to protein kinase C, both of which then stimulate, via protein phosphorylation, a broad range of enzymes and other proteins, including specific kinases. The other product of PLC, DAG, is lipid soluble and remains in the plasma membrane, where it facilitates the activation of protein kinase C by calcium. The signal is terminated via inactivation of IP_3 by dephosphorylation, whereas DAG is inactivated by phosphorylation to phosphatidic acid or deacetylation to fatty acids. The concentration of intracellular calcium is reduced by sequestration within cytoplasmic organelles or transport out of the cell. Activation of phospholipase D hydrolyzes phosphatidylcholine to phosphatidic acid, which can then be metabolized to DAG via phosphatidate phosphohydrolase. This pathway prolongs the duration of elevated levels of DAG. Phospholipase A_2 is activated by increased concentrations of intracellular calcium and metabolizes phosphatidylcholine to arachidonic acid. Arachidonic acid then functions as a substrate for the synthesis of autocoids, including prostaglandins, thromboxane A_2, and leukotrienes.

Chapter 1, Drug–Receptor Interactions. In: Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004, pp. 3–16, with permission.)

Transmembrane Catalytic Receptors

Catalytic receptors are a class of plasma membrane-bound receptors that are characterized by a monomer with a ligand-binding site in the extracellular domain, a single membrane-spanning domain, and an intracellular domain with enzymatic activity (Fig. 4.8C). This family of receptors is activated predominately by peptide hormones, such as insulin, epidermal growth factor, platelet-derived growth factor, and atrial natriuretic factor. The catalytic portion of the receptor functions as a protein kinase, targeting primarily tyrosine residues; however, the receptor for atrial natriuretic factor, rather than having kinase activity, activates guanylyl cyclase and metabolizes GTP to cGMP (19). Receptor activation occurs by ligand binding, which then triggers dimerization of receptor proteins via the cross-phosphorylation of tyrosine residues. The dimeric protein is the active form of the catalytic receptor. One consequence of activation via dimerization is that the intracellular signal can be maintained even after the ligand has dissociated from the binding site. The phosphorylation of intracellular proteins by this receptor type results in effects such as the opening of ion channels, changes in cytoplasmic function, or initiation of genomic expression. Other catalytic receptors, activated by transforming growth factor-β, use serine/threonine kinases in regulating cellular growth and differentiation.

Enzyme-Coupled Receptors

Enzyme-coupled receptors are similar in their function to catalytic receptors, except rather than inherent catalytic activity, enzyme-coupled receptors bind to separate enzymatic proteins (Fig. 4.8C). This class of receptor binds cytokines, including growth hormone, erythropoietin, and interferon. Like catalytic receptors, enzyme-coupled receptors are activated via dimerization following ligand binding. Kinase activity is accomplished by separate, noncovalently bound protein kinases of the Janus-kinase (JAK) family. Following dimerization, JAKs are activated and phosphorylate receptor tyrosine residues. The phosphorylated receptor then binds other molecules, termed “signal transducers and activators of transcription” (STATS), which are phosphorylated by the JAKs and, subsequently, dissociate into the cytoplasm. The STATS then translocate to the nucleus, where they initiate gene transcription.

Intracellular Cytoplasmic/Nuclear Receptors

Cytoplasmic/nuclear receptors differ from those described above in that they are not associated with the plasma membrane but, rather, are located within the cytoplasm or are bound to the surface of the nucleus (Fig. 4.8D). These receptors are composed of a single polypeptide with three functional domains. The amino terminal contains a binding site for a modulator protein, heat shock protein-90, which is associated with the receptor in the absence of agonist. In the middle of the receptor peptide is a binding site for DNA, and the carboxy terminus contains the ligand-binding site. Cytoplasmic/nuclear receptors are activated by lipid-soluble ligands, which passively diffuse through the plasma membrane (20). Agonists include nitric oxide, steroid hormones, and vitamin D. Ligand binding activates the receptor by inducing the dissociation of heat shock protein-90. The receptor then translocates to the nucleus and binds to a DNA response element, which then initiates translation of the target gene. The response to this type of signal transduction is relatively slow, requiring 30 minutes to several hours following protein binding. Moreover, the duration of the response can last long after the concentration of the ligand has fallen to zero. The duration of the response is related to turnover rate of the synthesized protein; however, it also may be affected by a ligand with extremely high binding affinity, possibly resulting in prolonged receptor activation.

Receptor Subtypes

Careful examination of the effects of a series of sympathomimetics by Ahlquist (21) led him to postulate the existence of at least two types of adrenoceptors, which he termed α and β. Realizing that adrenoceptor agonists were capable of causing either relaxation or contraction of isolated smooth muscles, he noted that although a compound like norepinephrine had potent excitatory actions but weak inhibitory actions, another catecholamine, isoproterenol, had potent inhibitory actions but weak excitatory actions. When a series of related compounds were tested for potency in various tissues, it was demonstrated that for the α-adrenoceptor,

the order of potency was epinephrine ≥ norepinephrine >>> isoproterenol, and for the β-adrenoceptor, the order of potency was isoproterenol > epinephrine

≥ norepinephrine. Following the findings of Ahlquist, others used specific antagonists that had become available to further support this designation of receptor subtypes. Additionally, with the development of highly selective antagonists and procedures for cloning and determining the amino acid sequence of proteins, the classification of receptors into subtypes has expanded at a tremendous rate (22). For example, the α-adrenoceptor noted above can be subclassed as α_{1A}, α_{1B}, α_{1C}, α_{1D}, α_{2A}, α_{2B}, and α_{2C} based on cloning experiments (Table 4.2).

Table 4.2. Adrenoceptor Families

Receptor Type	Subtype	Transduction Mechanism	Tissue Function
α_1	1A	Activates $G_{q/11}$	Smooth muscle and myocardial contraction
α_1	1B	Activates $G_{q/11}$	Smooth muscle contraction
α_1	1D	Activates $G_{q/11}$	Smooth muscle contraction
α_2	2A	Activates $G_{i/o}$	Hypotension, sedation, analgesia, anesthesia
α_2	2B	Activates $G_{i/o}$	Vasoconstriction
α_2	2C	Activates $G_{i/o}$	Not established
β_1	—	Activates G_s	Increases heart rate and force of contraction
β_2	—	Activates G_s	Smooth muscle relaxation
β_3	—	Activates or inhibits adenylyl cyclase	Lipolysis, cardioinhibition

The therapeutic significance of such distinctions is not yet known, however, because of a lack of selective agonists or antagonists. Some therapeutic distinction can be made between α_1 and α_2 adrenoceptors in a general way, in that α_1 vasoconstriction antagonism by prazosin and central nervous system α_2-adrenoceptor stimulation by clonidine are useful in the treatment of hypertension. Similarly, β-adrenoceptor antagonists are available that antagonize β_1-adrenoceptors with some selectivity. Thus, the use of metoprolol, a selective β_1-antagonist, is effective and relatively safe in hypertensive patients with compromised airway function, whereas the use of a nonselective (β_1 and β_2) antagonist, such as propranolol, would be clearly contraindicated in such a patient.

A summary of the most important receptor subtypes from a therapeutic standpoint is presented in Table 4.3. The reader should realize that this is a simplification of what currently is known about the various receptor subtypes. For instance, within the general category of serotonin receptors, at least 13 subtypes can be identified from cloning experiments. The lack of selective agonists and antagonists to characterize the pharmacology of each of these subtypes, however, has hindered our understanding of their individual functions and importance from a therapeutic standpoint. Our ability to eventually develop drugs that selectively manipulate such receptor subtypes has enormous therapeutic implications.

Spare Receptors

Biological systems often have built-in safety factors to enhance the efficiency of receptor-stimulus coupling and, thereby, assure the desired neurotransmission. In many tissues containing α-adrenoceptors, only a small percentage of the available receptors need to be occupied to produce a maximum response. This depends on the particular tissue being studied and the agonist used. Therefore, 100% occupancy of the available receptors is not always required, because spare receptors (or a receptor reserve) are present. Studies using phenoxybenzamine, which alkylates the α-adrenoceptor and, therefore, irreversibly inactivates the receptor, indicate that only 5 to 10% of the available receptors need to be activated to elicit a maximum response to a full, or strong, agonist, such as norepinephrine or phenylephrine (6,7,23). To obtain a maximum response to a partial agonist like ephedrine, however, nearly 100% of the receptors need to be occupied. The explanation behind this difference may involve a less than ideal receptor–drug interaction for partial agonists. A partial agonist may function as an antagonist if it interferes with the ability of a full agonist to bind to its receptor and produce a response. In the absence of a full agonist, however, the partial agonist only displays agonistic activity.

Dynamic Nature of Receptors

As is characteristic of most individual components of living systems, receptors are not static but, rather, are constantly in a state of dynamic adaptation. One could envision these protein molecules floating within the fluid mosaic of the biological membrane awaiting interaction with normal physiological signals. The

function of such receptors, once stimulated, involves attempts to respond to perturbations of the normal physiology of the cell or organism. The role in maintaining homeostasis within the organism requires constant adaptation of receptor number and/or sensitivity in response to the changing environment in the vicinity of the receptor. One approach to controlling receptor activation is by regulating the concentration of neurotransmitter at the receptor binding

site. This is accomplished by the modulation of release via activation of presynaptic receptors, as described above. Altering the rate of synthesis, degradation, or efficiency of the enzymes that create or degrade neurotransmitter molecules also is used to regulate neurotransmitter concentrations at the receptor.

Table 4.3. Survey of Receptor Subtypes

Receptor Class	Subtype	Selective Agonist	Selective Antagonist	Effector	Cloned
Adrenoceptors	α_1	Phenylephrine	Prazosin	IP_3/DAG	Yes
	α_2	Clonidine	Yohimbine	↓cAMP	Yes
	β_1	Dobutamine	Atenolol	↑cAMP	Yes
	β_2	Terbutaline	Butoxamine	↑cAMP	Yes
Dopamine receptors	D_1	Fenoldopam	Dihydroxidine	↑cAMP	Yes
	D_2	Bromocriptine	(–) Sulpiride	↓cAMP	Yes
Excitatory amino acid receptors	NMDA	NMDA	D-AP5	$\downarrow Na^+/Ca^{2+}$	Yes
	AMPA	AMPA	CNQX	$\uparrow Na^+$	Yes
	Kainate	Kainate	?	$\uparrow Na^+/K^+$	Yes
GABA receptors	$GABA_A$	Muscimol	Bicuculline	$\uparrow Cl^-$	Yes
	$GABA_B$	Baclofen	Saclofen	↓cAMP	Yes
Histamine receptors	H_1	2-(m-Fluorophenyl) Histamine	Mepyramine	IP_3/DAG	Yes
	H_2	Dimapril	Ranitidine	↑cAMP	Yes
Muscarinic receptors	M_1	Oxotremorine	Pirenzepine	IP_3/DAG	Yes
	M_2	Oxotremorine	AF-DX116	↓cAMP	Yes
Nicotinic receptors	N_{muscle}	?	Decamethonium	$\uparrow Na^+/Ca^{2+}$	Yes
	$N_{neuronal}$	?	Hexamethonium	$\uparrow Na^+/Ca^{2+}$	Yes
Opioid receptors	Mu	Sufentanil	CTAP	↓cAMP	Yes
	Delta	[D-Ala^2]deltorphin	Naltrindole	↓cAMP	Yes
	Kappa	Dynorphin	Nor-binaltorphimine	↓cAMP	Yes
Serotonin receptors (5-HT)	5-HT_{1A}	8-OH-DPAT	Spiperone	↓cAMP	Yes
	5-HT_{2A}	α-Methyl-5-HT	Ketanserin	IP_3/DAG	Yes

?, no known selective compounds available; cloned, receptor subtype has been cloned and the amino acid structure is known. Chemical abbreviations used: AF-DX116, 11-([2-{(diethylamino)methyl}-1-piperidinyl]acetyl)-5-11-dihydro-6H-pyridol[2,3-b] [1,4] benzodiazepine-6-one; AMPA, D,L-α-amino-3-hydroxy-5-methyl-4-isoxalone propionic acid; cAMP, cyclic adenosine 3′,5′-monophosphate; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; CTAP, D-Phe-Cys-Tyr-DTrp-Arg-Thr-Pen-Thr-NH2; DAG, diacyl glycerol; D-AP5, D-amino-5-phosphonopentanoate; GABA, γ-aminobutyric acid; 5-HT, 5-hydroxytryptamine, serotonin; IP_3, inositol 1,4,5-triphosphate; NMDA, N-methyl-D-aspartate; 8-OH-DPAT, 8-hydroxy-2-(di-n-propylamino)tetralin.

A second mechanism for modulating the cellular response to receptor activation is to alter receptor number and/or sensitivity. The process is best understood

for GPCR but also has been characterized for ion channel receptors, such as the nicotinic receptor. The alteration in the availability or functional capacity of a given receptor constitutes an adaptive mechanism whereby the cell or organism is protected from agonist overload. For example, the chronic administration of a β-adrenoceptor agonist, such as isoproterenol, is known to produce a desensitization of the β-adrenoceptors in the heart (24). During the period of overstimulation, the receptor becomes desensitized to further activation via phosphorylation by G protein–coupled kinases, such as protein kinase A or β-adrenoceptor kinase, at serine and threonine residues on the C-terminal domain that interferes with G_S binding (Fig. 4.10). Desensitization also may occur at other receptors with analogous phosphorylation sites (heterologous desensitization). A more prolonged or powerful overstimulation typically results in a decrease in receptor number and is termed "downregulation." In these GPCRs, downregulation initiated by phosphorylation of amino acids near the intracellular C-terminal domain results in binding to β-arrestins that facilitate their internalization via a clathrin-dependent pathway. Following internalization, the receptor may either be recycled back into the plasma membrane via endosomes or degraded by lysosomes. Reduced receptor numbers also can be accomplished via changes in the transcription and/or translation of genes that code for the receptor. Changes in receptor number or efficiency of receptors that lead to diminished responses and, thus, the efficacy of a drug with repeated or long-term use is an example of pharmacodynamic tolerance. As a general principle, the body will always attempt to maintain homeostasis, whether perturbed by environmental challenges, disease processes, or even the administration of drugs. Actually, the body sees the administration of drugs as a pertubation of homeostasis and, usually, attempts to overcome the effects of the drug by invoking receptor adaptations. Often, however, with appropriate dosing schedules, drugs can be used with little observed receptor adaptation such that the desired pharmacological effect continues to be observed.

In a similar fashion to the example described above, chronic administration of the β-adrenoceptor antagonist propranolol leads to a state of receptor supersensitivity or upregulation. The cells within the tissue, such as the heart, sense an alteration in the normal rate of basal β-adrenoceptor stimulation and, thus, respond by either

increasing the number or the affinity of the receptors for their natural agonists, norepinephrine and epinephrine. Additionally, an enhanced efficiency of the interaction between the receptor and its transducing systems also may account for a portion of the observed supersensitivity. The knowledge that such a receptor adaptation occurs has paramount practical therapeutic implications, because abrupt withdrawal of this class of agents may precipitate acute myocardial infarction. Thus, this practice should be scrupulously avoided.

Some pathophysiological states are characterized by perturbations in receptor dynamics. Prinzmetal's angina is thought to be characterized by an imbalance between vasodilatory β_2-adrenoceptor function and vasoconstrictor α_1-adrenoceptor function. In this disease state, the excessive alpha vasoconstriction of coronary arteries leads to myocardial ischemia and pain. The inadvertent use of a β-adrenoceptor antagonist, which is safely employed in typical angina pectoris to prevent β-adrenoceptor vasodilation, may leave unopposed alpha vasoconstrictor inputs and actually precipitate anginal pain. Thus, an understanding of the role that receptors play in physiology, pathophysiology, and pharmacology is essential for optimal therapeutic interventions.

Future Directions

Our understanding about the nature and role of receptors has increased tremendously since the early work of Langley and Ehrlich. Today, with the advances made in the field of molecular biology, it is possible to clone individual receptor subtypes (Table 4.3) and determine their function in cell culture. By modifying the amino acid structure at those sites believed to be involved in agonist binding, a better appreciation for the interaction of drugs currently available—and the rational design of those awaiting discovery—may be realized. Additionally, as we begin to be able to determine the structure of receptor subtypes through cloning techniques, we hopefully will better understand those disease processes that result from, or lead to, receptor adaptations or dysfunction.

Footnotes

*This enzyme is known by two names, *adenylate cyclase* (EC 4.6.1.1)- its official name from the International Union of Biochemistry and Molecular Biology Nomenclature Committee or its alternative name, adenylyl cyclase.

**This enzyme is known by two names, *guanylate cyclase* (EC 4.6.1.2)- its official name from the International Union of Biochemistry and Molecular Biology Nomenclature Committee or its alternative name, guanylyl cyclase.

Chapter 5

Drug Discovery Through Enzyme Inhibition

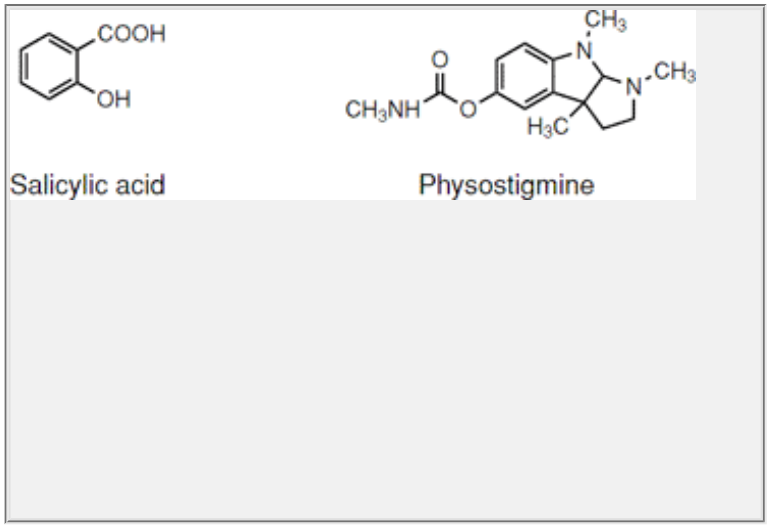
Stephen Kerr

Overview of Enzymes as Catalytic Receptors

A Perspective

The concept of using small molecules that specifically target one or more enzymatic systems in the body is not new. Historically, compounds that were extracted from natural products have been used as medicinal agents (see Chapter 1). Subsequently, they have been shown to have their therapeutic effect by targeting certain systemic enzymes (1). A classic example is the bark of the willow tree, known since ancient days to have antipyretic and analgesic effects. Its active ingredient, salicin, a glycoside, is metabolized in vivo to salicylic acid, which is a known inhibitor of cyclooxygenase, a key enzyme in the formation of prostaglandins, which are mediators of pain and fever. Similarly, physostigmine, isolated from the West African Calabar bean, was used as a treatment for glaucoma in the mid-1800s.

Physostigmine's mechanism of action was only later determined to be inhibition of acetylcholinesterase (1).



Inhibition of acetylcholinesterase in the eye leads to improved drainage and, thus, a decrease in the intraocular pressure giving relief to glaucoma patients. It was only in the 20th century, with the concept of the “magic bullet” having selective toxicity, introduced by Ehrlich as a rational approach to chemotherapy (1), that the concept of rational design and discovery of enzyme inhibitors followed. The discovery in 1935 of the antibacterial activity of the azo dye prontosil by Domagk (2), and the subsequent explanation in 1940 by Woods (3) of its metabolic reduction to sulfanilamide, an antimetabolite of *p*-aminobenzoic acid, finally paved the way for the rational design of enzyme inhibitors (Fig. 5.1). *p*-Aminobenzoic acid is an essential metabolite used in the bacterial synthesis of folic acid. Sulfanilamide, by its structural resemblance to *p*-aminobenzoic acid, competes for and selectively inhibits the bacterial enzyme dihydropteroate synthase (Fig. 5.2). In the absence of dihydropteroic acid, the bacteria are unable to synthesize tetrahydrofolic acid, an essential cofactor in one-carbon transfers that is involved in the de novo synthesis of purines and in the synthesis of thymidylate. This concept of designing drugs as antimetabolites, or structural analogues of essential metabolites, became the hallmark for the development of enzyme inhibitors. This was especially important in cancer therapy during the early days of rational drug design (4). As mechanisms of enzymes became better understood, the inhibitor design strategy grew more sophisticated, resulting in more potent and selective inhibitors being developed. The present-day focus on drug design through enzyme inhibition makes use of the antimetabolite theory as well as detailed kinetic and mechanistic information about the enzymatic pathways. These strategies use sophisticated assays, enzyme crystal structures and active site environments, site-directed mutagenesis experiments of catalytic residues of enzymes, and molecular docking experiments employing computers. It must be mentioned, however, that in the drug design process, designing a potent inhibitor of an enzyme is only the first step in the long and difficult process of drug development. Other factors, including pharmacokinetic profile of the inhibitor, toxicities and side effects, and animal and preclinical studies, must all be satisfactorily completed or addressed before the inhibitor can even enter clinical studies as a new drug candidate. Hence, even though an enormous amount of data exist regarding enzyme inhibitors, only a selected few turn out to be marketable drugs (Table

5.1). In succeeding paragraphs, an overview of enzymes as catalytic receptors and general concepts of enzyme inhibitors and their rational design into drugs will be discussed with selected examples.

Overview

Enzymes are biological catalysts. By interacting with substrates, they act as receptors and catalyze chemical reactions involved in the biosynthesis of many cellular products. Enzymes derive their name from Greek, in which the term means “in yeast” and was used mainly to distinguish the whole microorganism, such as yeast (“organized ferments”), from that of extracts of the whole microorganisms (“unorganized ferments”). The implication was that enzymes were unorganized ferments in yeast. Although the vast majority of enzymes are proteins, certain nucleic acids (RNAs) also possess enzymatic activity (i.e., ribozymes). Enzymes are the most efficient catalysts known in nature, because they have the ability to enhance reaction rates by enormous factors. Like all catalysts, enzymes have the ability to lower the activation energy of reactions, and the tremendous catalytic power they posses results from their inherent ability to provide stabilization to the reacting molecules at their activated complex states. A preliminary enquiry shows that enzymatic rates for reactions in aqueous solutions are limited

by the diffusion rate constant so that the second-order rate constant of an enzyme (k_{cat}/K_m) is approximately 10^9 $M^{-1}s^{-1}$ (diffusion rate constant of water (5)). This implies that every collision of a reactant molecule (substrate) with the enzyme leads to product formation. Because for many enzymes K_m (the Michaelis or apparent substrate–enzyme dissociation constant) values are in the micro- or submicromolar range (10^{-4} M), one can compute the k_{cat} (the catalytic or first-order rate constant) value to be approximately 10^5/s. Estimates (6) for uncatalyzed reactions in water have ranged from 10^{-1} to 10^{-20}/s; thus, the rate enhancements for enzyme-catalyzed reactions over the noncatalyzed reaction (also referred to as the proficiency of an enzyme) can range from 10^6 to over 10^{25}—truly remarkable proficiencies. Moreover, enzymes display great specificity toward particular chemical bonds (bond specificity; e.g., peptidases for peptide bonds) or functional groups (group specificity; e.g., esterases for esters), or they display absolute specificity toward a single molecule (e.g., carbonic anhydrase, which catalyses the hydration of carbon dioxide). Furthermore, this specificity and catalytic proficiency is carried out, in most cases, at ambient temperatures and normal pressures in aqueous solutions. It is no wonder then that enzymes have intrigued scientists for many centuries.

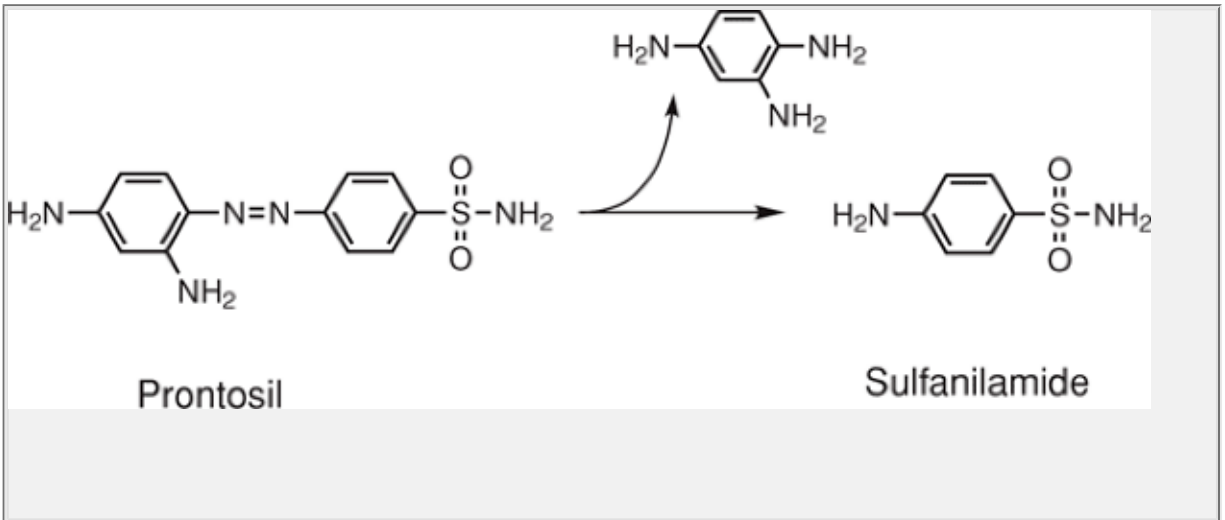


Fig. 5.1. Metabolic reduction of prontosil to sulfanilamide.

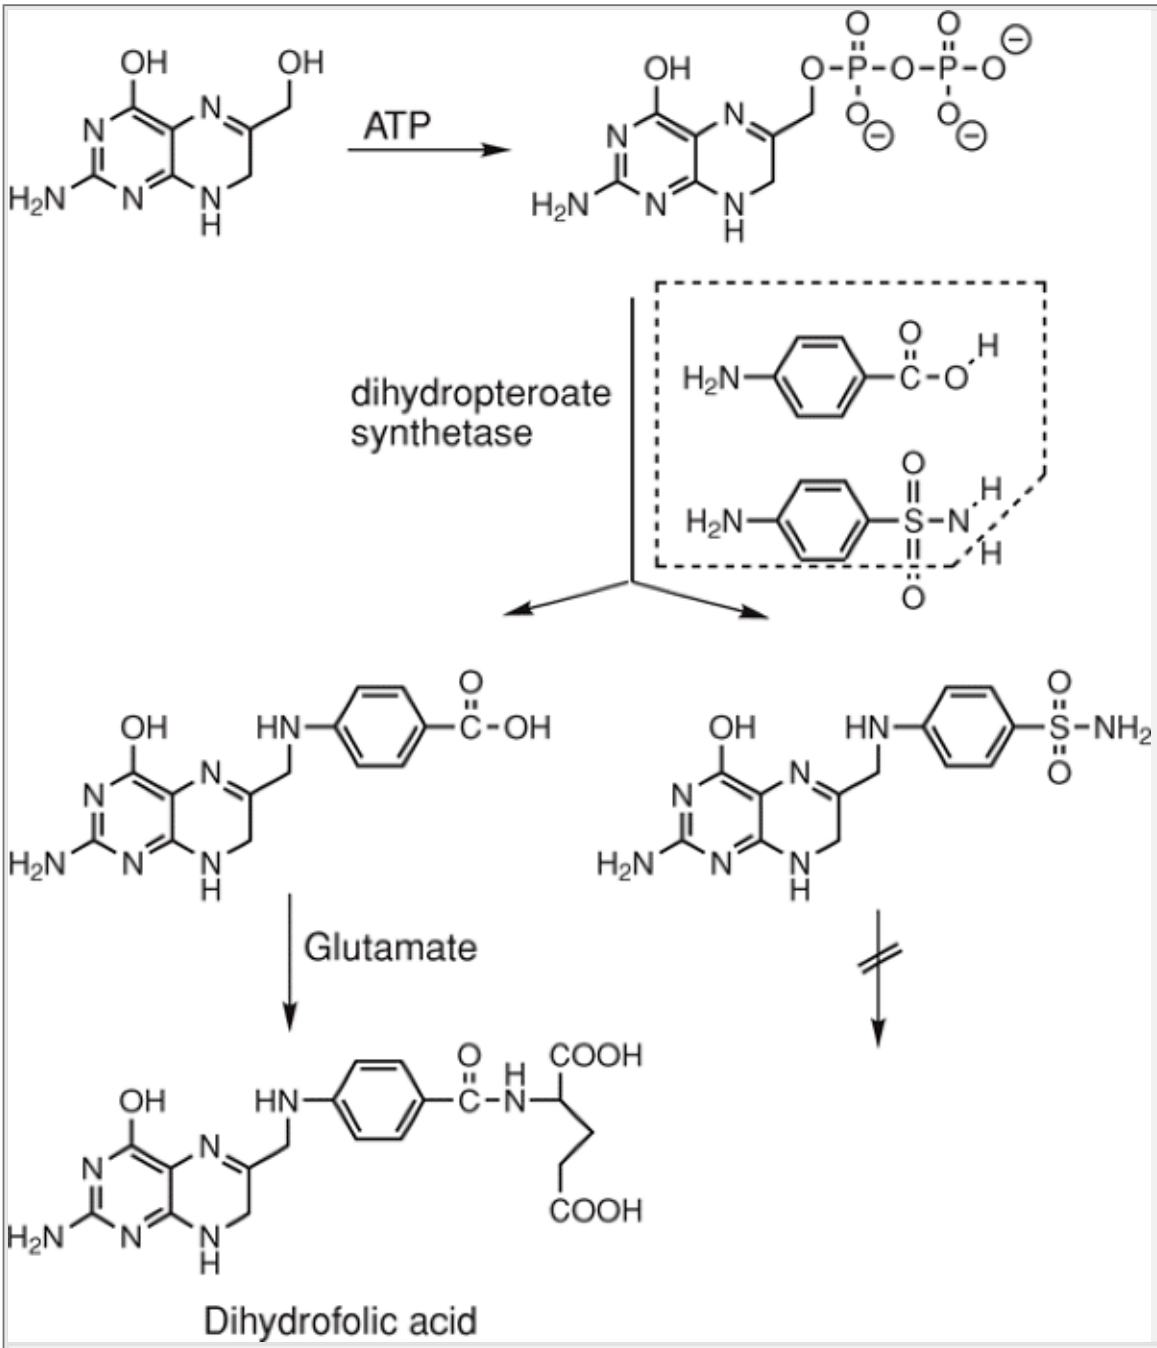

Fig. 5.2. Metabolic pathway leading to dihydrofolic acid and its inhibition by sulfanilamide. This figure shows the structural resemblance to *p*-aminobenzoic acid.

Enzymes have been classified on the type of reaction catalyzed, and six major classes (families) of enzymes, numbered from 1 to 6, have been assigned by the Enzyme Commission (EC) of the International Union of Biochemistry and Molecular Biology (7). These classes are as follows: 1, oxidoreductases (e.g., dehydrogenases); 2, transferases (group transfer enzymes; e.g., kinases); 3, hydrolases (hydrolytic reactions; e.g., esterases); 4, lyases (formation or removal of double bonds; e.g., hydratase—addition of water across a double bond); 5, isomerases (e.g., mutarotation of glucose by mutases); and 6, ligases (joining of two substrates at the expense of energy, also referred to as synthetases). All presently discovered enzymes are identified by the prefix EC followed by an Arabic numeral based on the major class of reaction catalyzed, as indicated above. Furthermore, this is followed by a series of three more Arabic numerals, which indicate the subclass (functionality), sub-sub class (specific bond type), and serial number of the enzyme in that class, respectively. For example, the enzyme, acetylcholinesterase has been given the following assignment, EC 3.1.1.7. As can been seen in this example, the numeral 3 indicates that this enzyme belongs to the family of hydrolases, the first 1 indicates that the nature of the bond being hydrolyzed is an ester, the second 1 indicates that specific ester bond is a carboxylic acid ester, and the last number is the serial number of this enzyme in this sub-subclass.

Many enzymes make use of cofactors, which enable them to carry out the catalysis. These small molecules (including ions) are intimately bound to the enzyme and are essential to the functioning of the enzyme. As macromolecular receptors, enzymes have the inherent ability to bind ligands (substrates). In

effecting the transformation of these substrates to products (catalyzing the chemical reaction), enzymes use all the necessary tools in the chemical bonding arsenal to hold these substrates extremely tightly as the transformation occurs. Because all chemical reactions require bond breakage and formation, the substrate must go through a transition state, or an “activated complex,” which is a destabilizing event, because bonds are being polarized and there is partial charge development. It is the inherent ability of the enzyme to greatly stabilize such activated complexes that give them their role in nature and allows their phenomenal catalytic power.

Pauling (8) first proposed the stabilization theory of the activated complex by enzymes. He concluded that the active site of the enzyme is complementary to the

P.101

P.102

structure of the activated complex so that the binding of the enzyme to the activated complex is extremely tight. The ability to stabilize such complexes and correspondingly reduce the activation energy of the reaction and, thus, enhance the reaction rate is caused by many factors, both noncovalent as well as covalent (9). Noncovalent influences include entropic effects, such as proximity and orientation; restricted motion, where enzymes, by their evolvement, have the inherent ability to bring reacting molecules closer together and in the correct orientation for bonds to form; desolvation effects, to strip solvent (water) molecules from the reactants; transition state electrostatic stabilization, to stabilize the partial charges being developed in the activated complex; induced-fit effects, in which the flexibility of the enzyme can accommodate the substrate, intermediate, and/or product; strain and distortion effects, to increase the reactivity of compounds; and many other such ancillary effects. Moreover, covalent influences (effects) also play a vital role in the enzyme's catalytic role. “Covalent effects” imply a covalent bond being made by the enzyme (or its cofactor) to the substrate being transformed. These covalent effects would include general acid-base catalysis, in which amino acid residues partake in the overall reaction through proton donation (general acid) or proton abstraction (general base), as well as nucleophilic and electrophilic catalysis, in which there is bond formation with an amino acid side-chain residue (or cofactor) to the substrate.

Table 5.1. A Partial Listing of Enzyme Inhibitor Drugs Presently Used as Drugs

Inhibitor (Drug)	Enzyme Inhibited	Use	Organism
Caspofungin	1,3-β-Glucan synthase	Antifungal	Fungal
Trilostane	3 (or 17)β-Hydroxysteroid dehydrogenase	Breast cancer	Human
Sildenafil	3',5'-Cyclic GMP phosphodiesterase	Erectile dysfunction	Human
Theophylline	3',5'-Cyclic nucleotide phosphodiesterase	Asthma	Human
Nitisinone	4-Hydroxyphenylpyruvate dioxygenase	Tyrosinemia	Human
Finasteride	Steroid 5α-reductase	Benign prostatic hyperplasia	Human
Pyridostigmine	Acetylcholinesterase	Myasthenia gravis	Human
Pentostatin	Adenosine deaminase	Cancer	Human
Cycloserine	Alanine racemase	Tuberculosis	Bacterial
Fomepizole	Alcohol dehydrogenase	Alcoholism	Human
Disulfiram	Aldehyde dehydrogenase	Alcoholism	Human
Acarbose	α-Amylase	Diabetes	Human
Miglitol	α-Glucosidase	Diabetes	Human
Ethambutol	Arabinosyltransferase	Tuberculosis	Bacterial
Zileuton	Arachidonate 5-lipoxygenase	Inflammation	Human
Carbidopa	Aromatic L-amino acid decarboxylase	Parkinson's disease	Human
Clavulinic acid	β-Lactamase	In combination with penicillins	Bacterial
Acetazolamide	Carbonate dehydratase (carbonic anhydrase)	Glaucoma	Human
Entacapone	Catechol O-methyltransferase	Parkinson's disease	Human
Miglustat	Ceramide glucosyltransferase	Gaucher's disease	Human
Methotrexate	Dihydrofolate reductase	Cancer	Human
Trimethoprim	Dihydrofolate reductase	Antibacterial	Bacterial
Sulfamethoxazole	Dihydropteroate synthase	Antibacterial	Bacterial
Topotecan	DNA topoisomerase	Cancer	Human

Ciprofloxacin	DNA gyrase	Antibacterial	Bacterial
Acyclovir	DNA-directed DNA polymerase	Antiviral (anti-HSV)	Viral
Rifampin	DNA-directed RNA polymerase	Antibacterial	Bacterial
Bacitracin	Dolichyl phosphatase	Antibacterial	Bacterial
Isoniazid	Fatty acid enoyl reductase	Tuberculosis	Bacterial
Oseltamivir	Viral neuraminidase	Anti-influenza	Viral
Fondaparinux	Factor Xa	Thrombosis	Human
Alendronate	Farnesyl-diphosphate farnesyltransferase	Osteoporosis	Human
Pyrazinamide	Mycobacterial fatty acid synthase	Tuberculosis	Bacterial
Valproic acid	Histone acetyltransferase	Seizures	Human
Nelfinavir	HIV protease	AIDS (Anti-HIV)	Viral
Esomeprazole	H^+/K^+-ATPase	Gastroesophageal reflux disease	Human
Atorvastatin	HMG-CoA reductase	Hyperlipidemia	Human
Mycophenolate	IMP dehydrogenase	Immune suppression	Human
Propylthiouracil	Iodide peroxidase	Hyperthyroid	Human
Cilastatin	Renal dehydropeptidase	In combination with imipenam	Human
Eflornithine	Ornithine decarboxylase	Trypanosomes	Parasitic
Allopurinol	Xanthine oxidase	Gout	Human
Captopril	Peptidyl-dipeptidase A (angiotensin-converting enzyme)	Hypertension	Human
Pemetrexed	Phosphoribosylglycinamide formyltransferase	Cancer	Human
Aprotinin	Plasma kallikrein	Thrombosis	Human
Aminocaproic acid	Plasmin	Thrombosis	Human
Etodolac	Prostaglandin-endoperoxide synthase (cyclooxygenase)	Inflammation	Human
Bortezomib	Proteasome endopeptidase complex	Myeloma	Human
Imatinib	Protein-tyrosine kinase	Cancer	Human
Gemcitabine	Ribonuleoside-diphosphate reductase	Cancer	Human
Ribavirin	IMP dehydrogenase	Anti-viral (Broad spectrum)	Viral
Azidothymidine	HIV reverse transcriptase	AIDS (Anti- HIV)	Viral
Lamuvidine	Reverse transcriptase	AIDS, Hepatitis B	Viral
Penicillin	Serine-type D-Ala—Ala carboxypeptidase	Antibiotic	Bacterial
Digitoxin	Na^+/K^+-ATPase	Congestive Heart Failure	Human
Terbinafine	Squalene monooxygenase	Antifungal	Fungal
Itraconazole	Sterol 14α-demethylase	Antifungal	Fungal
Lepirudin	Thombin	Thrombosis	Human
Floxuridine	Thymidylate synthase	Cancer	Human
Orlistat	Tricylglycerol lipase	Obesity	Human
Metyrosine	Tyrosine 3-monooxygenase	Pheochromocytoma	Human
Fosfomycin	UDP-N-acetylglucosamine 1-carboxyvinyltransferase	Antibacterial	Bacterial
Aminoglutethimide	Monooxygenase	Breast cancer	Human
Acetohydroxamic	Urease	Gastritis	Bacterial
Dicumarol	Vitamin K–epoxide reductase	Thrombosis	Human

(Adapted from Robertson J. Mechanistic basis of enzyme-targeted drugs. Biochemistry 2005;44:5561–5771; with permission.)

It should be mentioned here that “covalent catalysis” has traditionally implied a group transfer reaction between one substrate and another being facilitated through an enzyme-residue intermediate (e.g., the enzyme sucrose phosphorylase transfers a glucose residue from sucrose to phosphate giving the products glucose-1-phosphate and fructose through an enzyme-glucosyl intermediate). Many amino acid side-chain residues (i.e., acidic and basic amino acids, e.g.,

Asp, Glu, His, Lys, Arg, Tyr, and Cys) as well as nucleophilic amino acid residues allow such covalent effects. Recent analysis of enzyme rate enhancements has postulated that noncovalent effects allow an increase of as many as 11 orders of magnitude over the noncatalyzed reaction, whereas for those enzymes with rate enhancements exceeding 11 orders of magnitude (over noncatalyzed reactions) it is covalent catalysis in the transition state that accounts for this exceptional increase in rate enhancement (10).

Noncovalent effects like proximity and orientation may be explained on the basis that enzymes have the inherent ability to affect the order of reactions by the "effective concentration" principle—for example, to change a second-order reaction to a first-order one by bringing the reacting molecules closer to each other so that there is a lower amount of entropic loss for the reacting substrates. In the example shown in Figure 5.3, which is taken from physical-organic chemical studies (11), one can consider the hydrolysis of a nitrophenyl ester by an amine in two scenarios: reaction (i), with two individual molecules reacting (i.e., amine and ester), versus reaction (ii), with a single molecule having an "in-built" amine on the ester molecule. If the reaction rate constants are compared (one needs to keep in mind that we are comparing a first-order rate constant for (ii), with a second-order rate constant for (i), which may not be a true comparison, because mechanisms are likely to be different), however, one finds that the first-order rate reaction (reaction (ii)) has a rate enhancement over the reaction (i) by a factor of ~5,000 M attributed to the fact that reaction (i) needs to give up more degrees of freedom (as compared to reaction (ii)) to react (i.e., form productive collision complexes, leading to product formation). This proximity effect indicates that by using such a system (bringing the reacting centers closer to each other), one can effectively increase the concentration of the reactants by this factor, resulting in a faster reaction. This enhancement factor of 5,000 M (i.e., effectively changing a second-order reaction to that of a first-order one) has been termed the "effective concentration," because this is an unrealistic increase in the concentration of the reactants, which gives rise to the higher rate constant (i.e., it is impossible to make a solution of 5,000 M of the reactants).

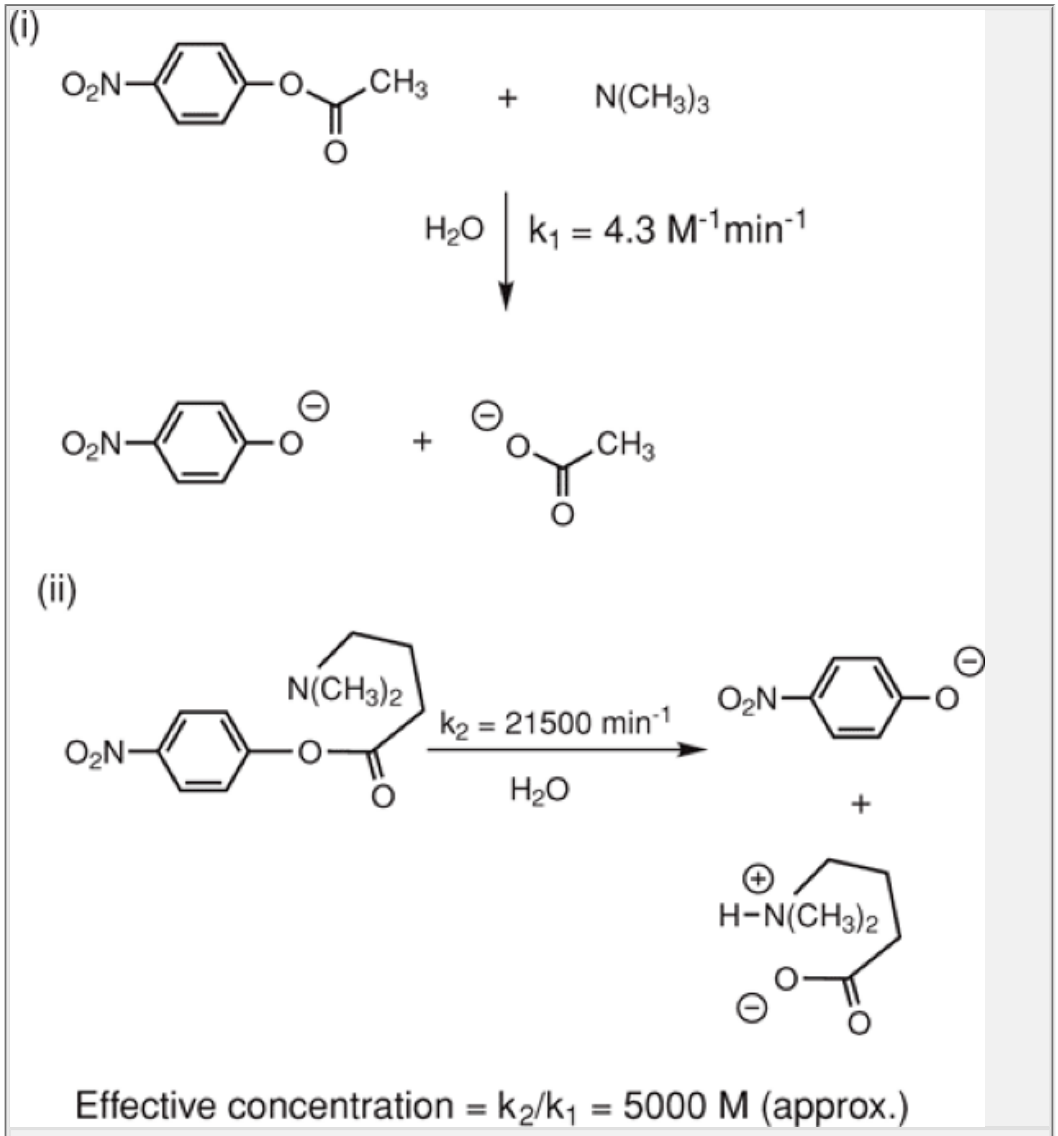

Fig. 5.3. Concept of proximity and effective concentration.

The next example, which is shown in Figure 5.4, illustrates that besides the proximity factor, one also can use "orientation" effects to bring about an increase

in the reaction rate constant (12). For example, as shown in Fig. 5.4, one may use alkyl groups to sterically hinder rotation about single bonds, effectively freezing the molecule in a particular conformation to provide maximum orbital overlap for bonding. Thus, using a “dimethyl lock” system in molecule II, which restricts rotation, ensures that lactonization for molecule II is faster by a factor of 4×10^4 than molecule I. Both of these effects,

proximity and orientation, are thought to be part of an enzyme's arsenal of tools in allowing enzymes to lower the activation energy for reactions. Other noncovalent effects, such as desolvation of the reactant molecules, also can be effectively achieved by enzymes. Enzymes have the capacity, by lining their exterior and/or interior surfaces with appropriately situated hydrophobic amino acids, to effectively strip away water molecules from substrates as they enter into the active site of the enzyme through such channels. Thus, no further expense of energy is required to desolvate the substrate before the reaction.

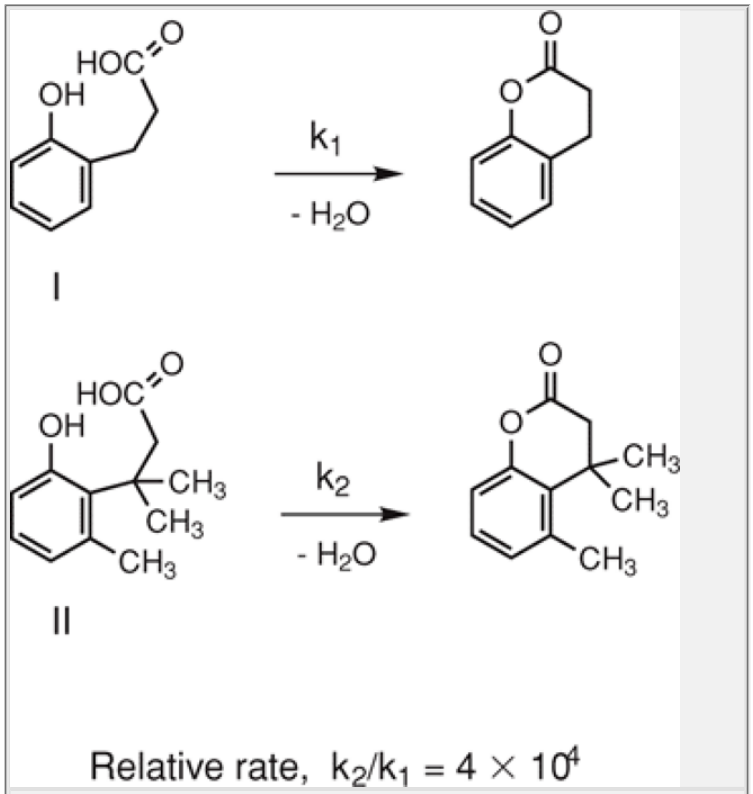

Fig. 5.4. Concept of orientation.

As mentioned previously, enzymes also use covalent chemistry as a means to effect catalysis. Indeed, it has been recently postulated that covalent chemistry plays a far greater role in enzyme catalysis than previously thought (10). Nucleophilic catalysis by hydrolytic enzymes, such as the serine proteases or esterases, are classic examples of covalent effects in enzyme catalysis. In such systems, for example, as in the case of the serine protease chymotrypsin, which hydrolyzes peptide bonds containing aromatic amino acids (e.g., phenylalanine and tyrosine), the covalent effects occur at the level of general acid, general base, and nucleophilic covalent catalysis. Figure 5.5 illustrates an accepted mechanism for such enzymes. It should be noted that all serine proteases contain a “catalytic triad” of the amino acids, designated as Ser-195, His-57, and Asp-102 (numerals represent the amino acid position in the protein primary structure), which are present in the active sites of these proteases. The catalysis is effected by making the hydroxyl functionality of the serine residue more nucleophilic for attack at the carbonyl center of the peptide bond. One should recall that in general, hydroxyl groups have pK_a values in the range of greater than 14 and, as such, are not acidic and unable to ionize at physiological pH. Because of catalytic triad, however, the proton from the serine hydroxyl group is transferred to the aspartate residue through the histidine residue in a “charge relay system” such that the serine hydroxyl group is made into the highly nucleophilic alkoxide ion. This is achieved by the aspartate residue acting as a general base to pick up the proton from histidine, which also can abstract a proton from the serine-hydroxyl group (see I in Fig. 5.5). Thus, histidine behaves as a tautomeric catalyst in this enzyme (i.e., acts as both a general acid and a general base) and, in essence, relays the proton from serine to aspartate. The serine (as its alkoxide) is now a much more powerful nucleophile and can attack the peptidyl carbonyl group to generate a “tetrahedral oxy-anion intermediate” (see II in Fig. 5.5), which collapses to liberate a new amino terminus of the

peptide and the acylated serine enzyme (see III in Fig. 5.5). The next part of the reaction involves a water molecule (which also is made more nucleophilic by a similar mechanism; see III in Fig. 5.5) that goes on to hydrolyze, through a tetrahedral intermediate (see IV in Fig. 5.5), the serine-acyl bond to liberate the

new carboxyl terminus of the peptide (R_1COOH) and the free enzyme, which can be recycled for another round of catalysis.

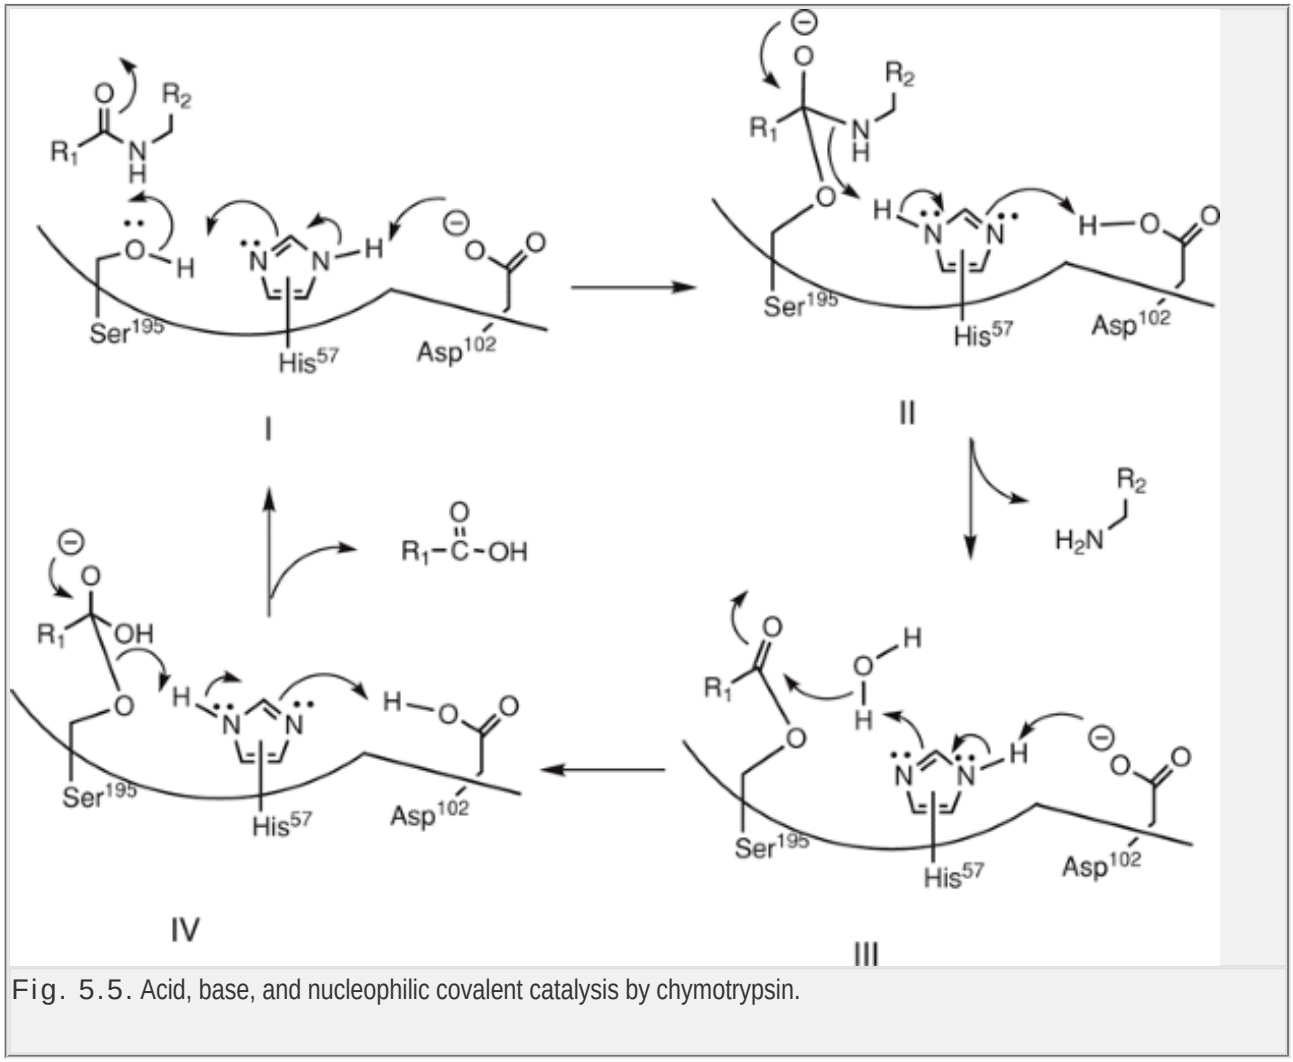

Fig. 5.5. Acid, base, and nucleophilic covalent catalysis by chymotrypsin.

Knowledge of the mechanisms and interactions, both noncovalent and covalent, that allow enzymes to function as such efficient catalysts provides the medicinal chemist with insights to design molecules that achieve selective inhibition of the enzyme. Such knowledge also paves the way to the design and discovery of drugs.

General Concepts of Enzyme Inhibition

The body is composed of thousands of different enzymes, many of them acting in concert to maintain homeostasis. Although disease states may arise from the malfunctioning of a particular enzyme, or the introduction of a foreign enzyme through infection by microorganisms, inhibiting a specific enzyme to alleviate a disease state is a challenging process. Most bodily functions occur through a cascade of enzymatic systems, and it becomes extremely difficult to design a drug molecule that can selectively inhibit an enzyme and result in a therapeutic benefit. To address the problem, however, the basic mechanism of enzyme action needs to be understand. Once knowledge of a particular enzymatic pathway is determined and the mechanism and kinetics are worked out, the challenge is then to design a suitable inhibitor that is selectively used by the enzyme causing its inhibition.

As outlined above, enzymes (E) represent the best-known chemical catalysts, because they are uniquely designed to carry out specific chemical reactions in a highly efficient manner (5). They initially act by binding a substrate (S) to form an enzyme–substrate complex [E·S], which undergoes specific chemistry (catalysis) to give the enzyme–product complex [E·P], followed by dissociation of product (P) and free enzyme (E). Equation 5.1 represents a simplified version of this scenario:

$$\textbf{Eq. 5.1}\quad \mathrm{E} + \mathrm{S} \; K_\mathrm{d}\ (\text{or } K_\mathrm{m}) \rightleftharpoons [\mathrm{E{\cdot}S}] \; k_\mathrm{cat} \rightleftharpoons [\mathrm{E{\cdot}P}] \rightleftharpoons \mathrm{E} + \mathrm{P}$$

where K_d is the enzyme–substrate dissociation constant and k_{cat} represents the rate constant for the catalytic step (chemical modification step or slowest step in the overall pathway). If the binding step of E + S to form [E·S] is relatively fast as compared to the catalytic step and one assumes steady-state conditions, then K_m, the Michaelis constant (the substrate concentration at half-maximum velocity [V_{max}/2]), may be equated to the K_d, as shown in Equation

5.2): where v = velocity of the reaction

Eq. 5.2 Michaelis-Menten equation: $$v = \frac{V_{max}[S]}{K_m + [S]}$$

Lineweaver-Burk equation: $$\frac{1}{v} = \frac{K_m}{V_{max}} \cdot \frac{1}{[S]} + \frac{1}{V_{max}}$$

Lineweaver-Burk equation: $$\frac{1}{v} = \frac{K_m}{V_{max}} \cdot \frac{1}{[S]} + \frac{1}{V_{max}}$$

The rate of the reaction can then be derived in terms of K_m and V_{max} (or $k_{cat} = V_{max}/[E]$). From the knowledge of the dissociation constant ($K_{m(d)}$) and the rate constant for catalysis (k_{cat}), it is then possible to compare inhibitors and the dissociation constant for the inhibitors, K_i, in relation to the natural substrates and the effect on the catalytic rates. These kinetic parameters, k_{cat} and $K_{m(d)}$ (or K_i) can then give an indication as to the affinity (K_i versus $K_{m(d)}$) and specificity (k_{cat}/K_i or $k_{cat}/K_{m(d)}$) of the inhibitor for a particular enzyme. Equation 5.3 represents the general scheme of reversible inhibition, and Figure 5.6 illustrates graphically and mathematically the relationship of the velocity of the enzyme reaction to the substrate [S] and inhibitor [I] concentration as well as the kinetic parameters K_m, k_i, and V_{max} (or $k_{cat} = V_{max}/[E]$):

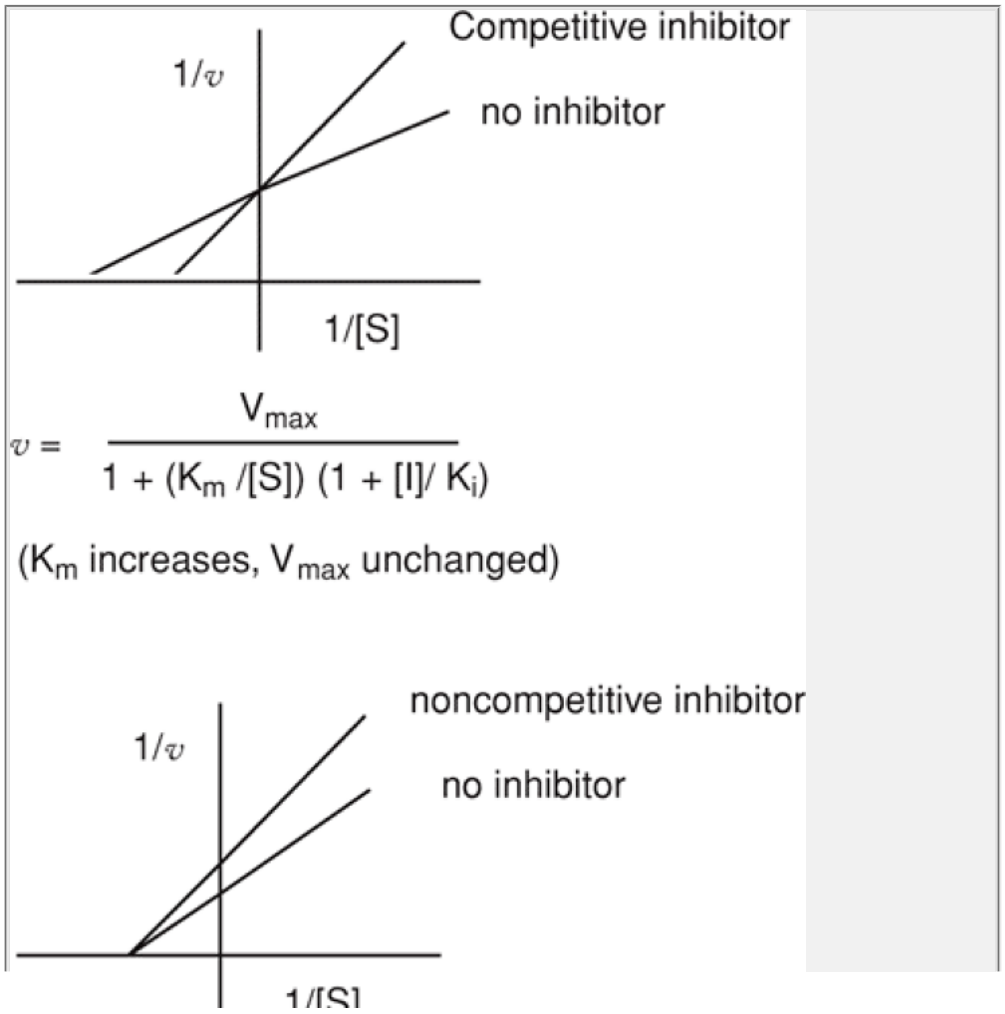
Eq. 5.3(a) Competitive Inhibition

$$E + S \; K_m \rightleftharpoons [E \cdot S] \rightleftharpoons E + P$$
$$E + I \; K_i \rightleftharpoons [E \cdot I] \rightarrow P$$

Eq. 5.3(b) Noncompetitive Inhibition

$$E + S \overset{K_m}{\rightleftharpoons} [E \cdot S] \; \diagdown\!\!\diagup \; + I$$

$$E + I \overset{K_i}{\rightleftharpoons} [E \cdot I] \; \diagup\!\!\diagdown \; \begin{matrix} [E \cdot S \cdot I] \\ + S \end{matrix}$$



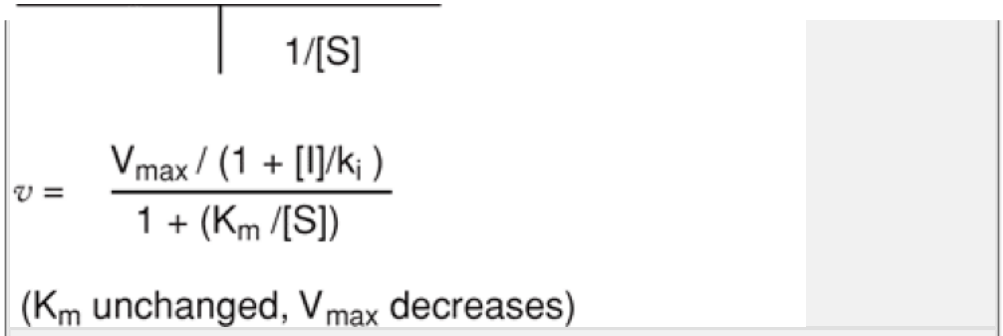


Fig. 5.6. Graphic representation of competitive and noncompetitive enzyme inhibition.

Inhibition of enzymes may be broadly classified under two categories—reversible and irreversible inhibitors—as shown in Equation 5.4:

Eq. 5.4 $$E + I \underset{}{\overset{K_i}{\rightleftharpoons}} [E{\cdot}I] \text{ (reversible inhibition)}$$
$$E + I \underset{}{\overset{K_i}{\rightleftharpoons}} [E{-}I] \text{ (irreversible inhibition)}$$

In the presence of inhibitor, the enzyme–substrate complex, [E·S], is replaced by the enzyme–inhibitor complex, [E·I], which may block or retard the formation of product. In the presence of a reversible inhibitor, the enzyme is tied up and the reaction retarded or stopped; however, the enzyme can be subsequently regenerated from the enzyme–inhibitor complex, [E·I], to react again with substrate and produce product (see Eq. 5.3). On the other hand, irreversible inhibition implies that the enzyme cannot be regenerated, and the only way for catalysis to proceed would be if new molecules of the enzyme are generated from gene transcription and translation. Irreversible inhibition is commonly associated with covalent bond formation between inhibitor and enzyme [E—I], which *cannot* be easily broken and often is defined as a time-dependent loss of enzyme activity. Reversible inhibition, on the other hand, does not necessarily imply noncovalent bond formation. In many instances, reversible inhibition can occur through covalent bond formation, but these bonds can be hydrolyzed to regenerate free enzyme and inhibitor. Thus, for a reversible enzyme inhibitor, there is no time-dependent loss of activity, and enzyme activity can always be recovered. There are instances when reversible inhibition tends to look kinetically like irreversible inhibition. This scenario results whenever there is a tight binding of a reversible inhibitor to the enzyme; consequently, the dissociation of the enzyme from this enzyme–inhibitor complex is extremely slow. Kinetically, it is extremely difficult to distinguish this type of inhibition from an irreversible inhibitor, because over time, the enzyme does tend to look like it loses its activity and, for all practical purposes, the enzyme behaves as if it were irreversibly tied up. To differentiate between tight-binding reversible and irreversible inhibitors, one can dialyze the enzyme–inhibitor complex. In case of the reversible inhibitor, on dialysis, the inhibitor will be removed from the enzyme, resulting in recovery of the enzyme activity; however, this is not so with the irreversible one.

Reversible Enzyme Inhibition

Reversible enzyme inhibition may be classified under two main headings, competitive and noncompetitive, with both following Michaelis-Menten kinetics. Competitive inhibition, by definition, requires that the inhibitor competes with the substrate for binding to the enzyme at the active site, and this binding is mutually exclusive. That is, if the inhibitor binds to the enzyme, the substrate will not be able to bind, and vice versa. Competitive inhibition also, however, suggests that the inhibition can be reversed in the presence of saturating amounts of substrate, because in this case, all enzyme active sites will be occupied by substrate-displacing inhibitor. In contrast, noncompetitive inhibition implies independent binding (i.e., both inhibitor and substrate may bind to the enzyme at different sites). Because binding of the inhibitor to the enzyme is at a site other than the active site, noncompetitive inhibition cannot be reversed by increasing the concentration of substrate. Graphing the kinetics of inhibition (Fig. 5.6), the Lineweaver-Burk plot of $1/V$ versus $1/[S]$ shows distinguishing characteristics between the two types of inhibition. In competitive inhibition, there is no change in the maximum velocity of the reaction (V_{max}; the intercept on the *y*-axis remains constant in the presence of inhibitor). However, the slope of the curve (K_m/V_{max}) is different with the inhibitor present, and K_m changes because of the presence of the competitive inhibitor (Fig. 5.6, competitive inhibition). In the case of noncompetitive inhibition, only the V_{max} of the reaction decreases, while the K_m remains unchanged (intercept on the *x*-axis unchanged with inhibitor, Fig. 5.6, noncompetitive inhibition).

Most of the rationally designed and clinically useful reversible inhibitors are competitive inhibitors. Table 5.1 gives a listing of several currently approved drugs that act as enzyme inhibitors. The majority of enzyme inhibitors generally bear some structural resemblance to the natural substrate of the enzyme. The design of such inhibitors would thus seem to be a logical and rational task which is uniquely suited to the medicinal chemist who can use the principles of bio-isosteric modification of natural enzyme substrates and metabolites, or modification of “lead” structures and structure activity relationships, to create selective and potent inhibitors. There are pitfalls in this endeavor, however, because even the most rationally designed drug must still overcome transport and other cellular barriers before exerting its effects. In the case of the noncompetitive inhibitors, the design is not as straightforward. These inhibitors can have widely differing structures, which in many instances bear no resemblance to the natural substrate. In general, inhibitors of the noncompetitive type have

been obtained primarily through random screening of chemically novel molecules followed by further synthetic manipulation of the pharmacophore to optimize their inhibitory effects.

Examples of Reversible Inhibitors

The design of enzyme inhibitors has included random screening of synthetic chemical agents, natural products, and combinatorial libraries followed by molecular optimization or structure–activity relationships of so-called "lead" structures as well as bio-isosteric analogues of the enzyme substrates themselves. Drugs (e.g., finasteride) also have been developed for one indication but, based on observed side effects, have lead to other uses.

The rational approach in the design of enzyme inhibitors is greatly aided if the enzymatic reaction is characterized in

terms of its kinetic mechanism. Such a characterization would include the knowledge of the kinetic parameters (rate constants and dissociation constants) of individual steps in the overall reaction pathway as well as the characterization of (any) intermediates involved in these individual steps. Examples of such "rational" inhibitors include both reversible and irreversible inhibitors of enzymes.

Uses of Finasteride

Finasteride (Proscar) an inhibitor of steroid 5α-reductase, an enzyme involved in the catalytic reduction of testosterone to dihydrotestosterone, was originally developed as an agent to treat prostate hyperplasia. In addition to this original use, finasteride also currently is indicated as an agent (Propecia) to stimulate hair growth for treatment of male pattern baldness. This benefit was recognized as a useful side effect during clinical trials of finasteride as an antiprostate agent.

Antimetabolites

Antimetabolites are agents that interfere with the functioning of an essential metabolite and that most often are designed as structural analogues of the natural metabolite. As described earlier, the mechanism of action of sulfanilamide is that of a competitive inhibitor of *p*-aminobenzoic acid. In the case of the sulfanilamide, however, the mechanism was only determined after the bacterial inhibitory action was noted. This often is the case when a drug is discovered to have a certain therapeutic effect and, later, this effect is "rationalized" as being caused by an enzyme-inhibitory action (1). Other classic examples of a competitive inhibitor acting as an antimetabolite include a number of nucleoside analogues used as antiviral and anticancer agents. These agents again bear structural resemblance to natural nucleosides, which in their triphosphate form are substrates for nucleic acid polymerases involved in the synthesis of nucleic acids. Nucleic acid polymerases catalyze the condensation of the free 3′-hydroxy end of a nucleic acid with an incoming 5′-triphosphate derivative of a nucleoside (dNTP), resulting in a 3,′5′-phospho- diester linkage. Hence, nucleoside analogues, to compete with the natural substrate in the synthesis of nucleic acid, must be converted intracellularly to their mono-, di-, and finally, triphosphate derivative before exerting their inhibitory effects on nucleic acid synthesis. Certain drug design strategies incorporate a "masked" phosphate group on the nucleoside such that once absorbed, they enter into the systemic circulation as the monophosphate (13). The majority of these analogues are designed such that they lack the 3′-hydroxy group and are dideoxy derivatives of the natural substrate. These analogues thus ensure that once they are incorporated into nucleic acid, further extension of the nucleic acid is prevented because of the lack of a 3′-hydroxy group.

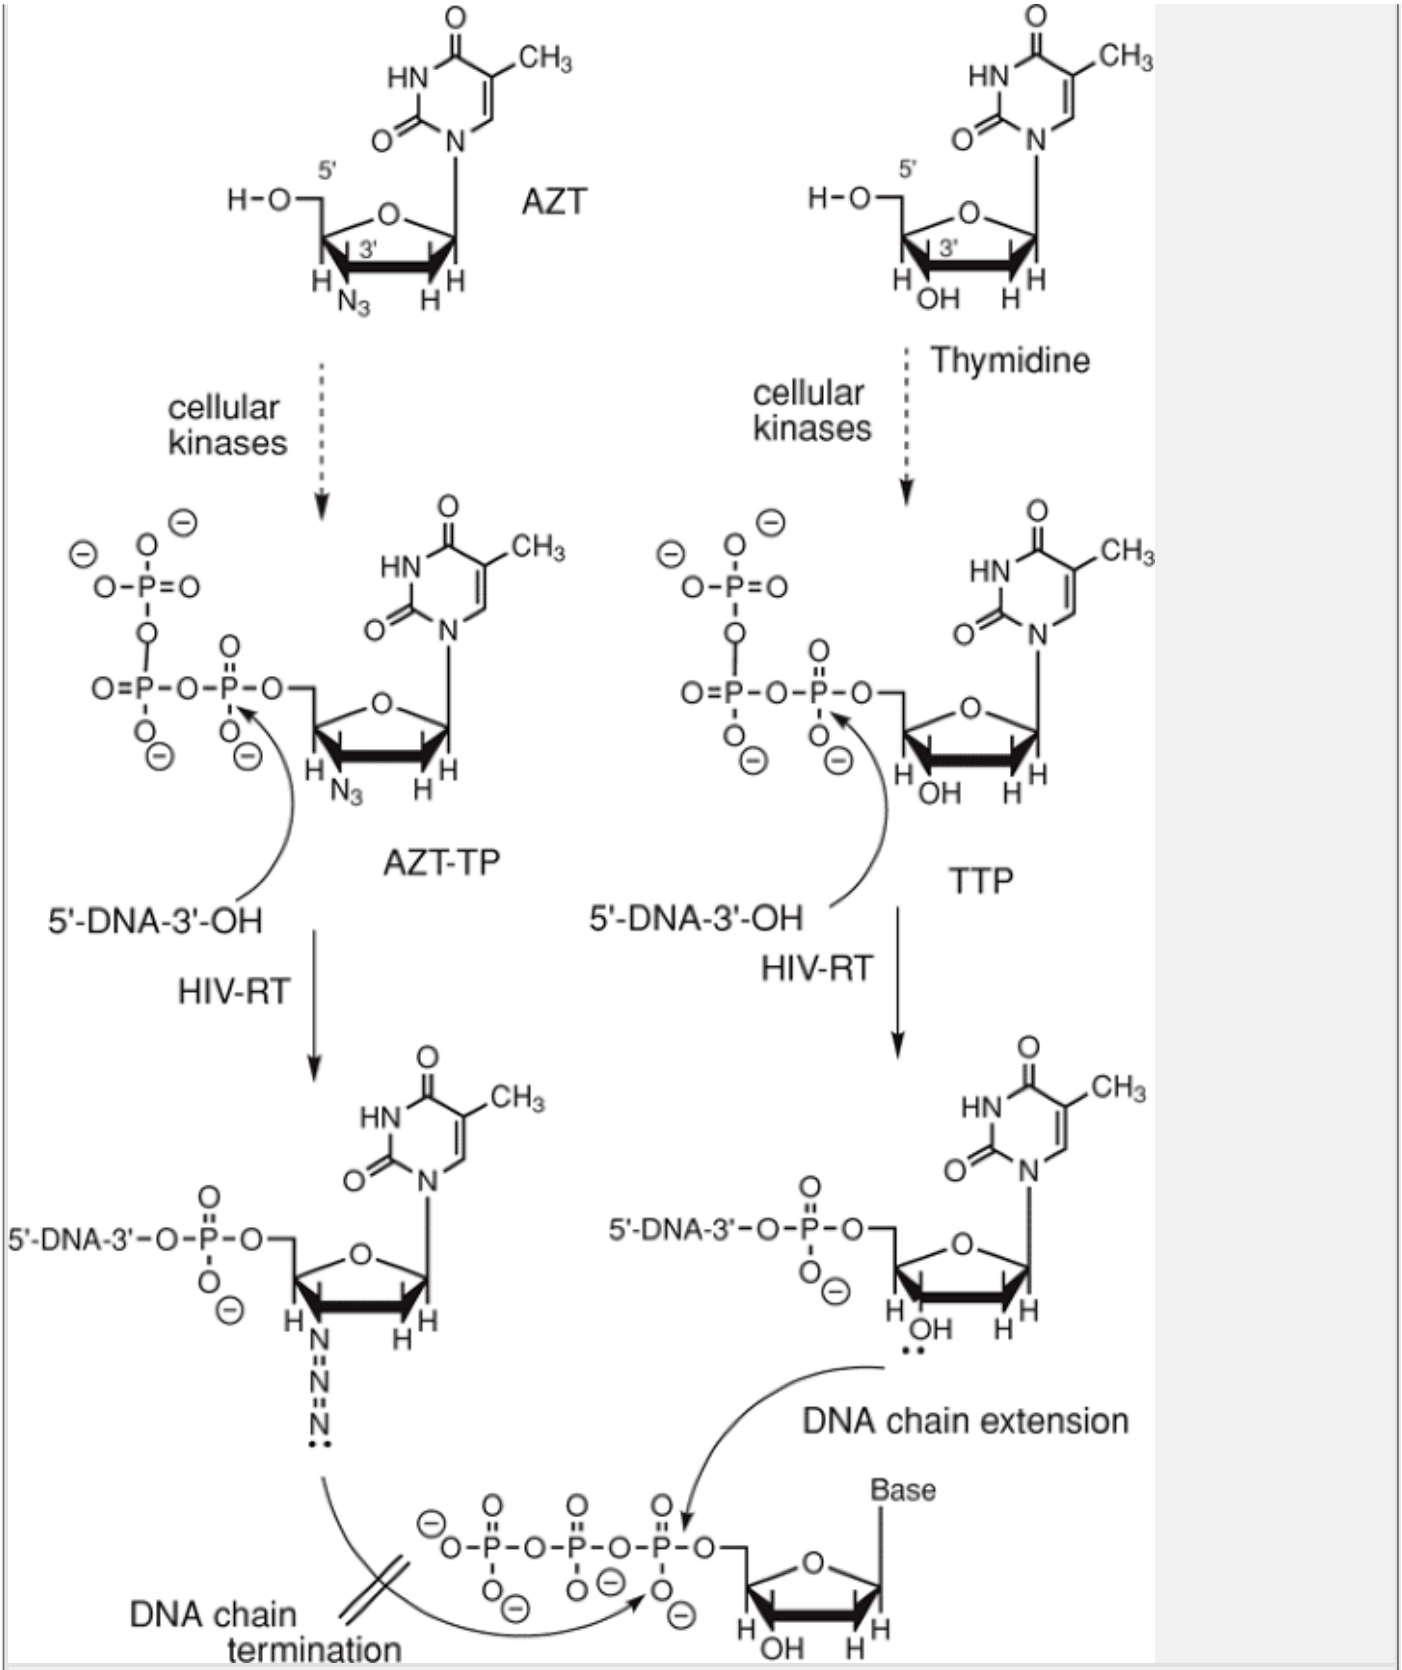

Fig. 5.7. Activation, incorporation, and chain-terminating action of azidothymidine (AZT), a thymidine analogue, as a reversible inhibitor of human immunodeficiency virus–reverse transcriptase (HIV-RT).

Inhibition of HIV-reverse transcriptase

Azidothymidine (AZT)

The advent of AIDS stimulated a great interest in designing inhibitors against the essential viral polymerase—HIV-reverse transcriptase (HIV-RT). AZT is a potent inhibitor of HIV-RT (14), the retroviral polymerase that catalyzes the formation of proviral DNA from viral RNA. Structurally, AZT is similar to the natural nucleoside thymidine but has an azide group ($-N_3$) rather than a hydroxy group (–OH) at the 3′-position of the sugar deoxyribose (Fig. 5.7). AZT is activated intracellularly to its triphosphate and competes with thymidine triphosphate for uptake by HIV-RT into DNA (15). Once incorporated, further chain extension of the DNA is prevented, because there is no 3′-hydroxyl group to continue the DNA synthesis. In this fashion, AZT is an effective chain terminator of viral DNA synthesis.

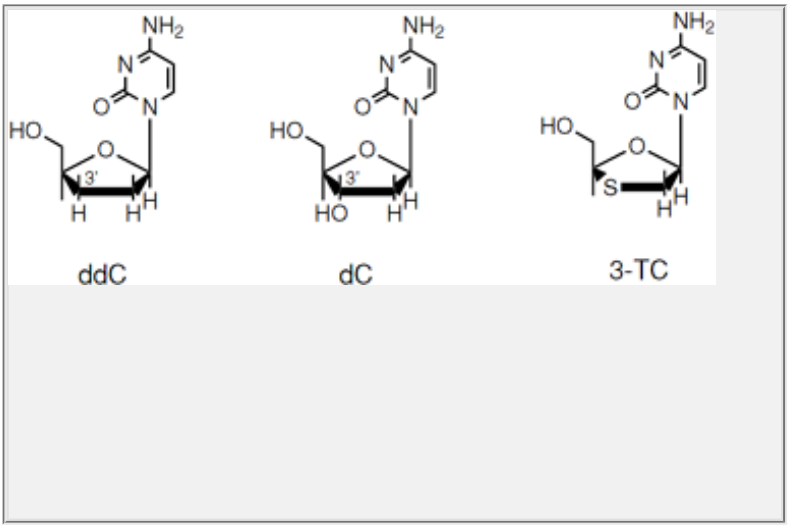
Dideoxycytidine (ddC [Zalcitabine®]) and 3-thiacytidine (3-TC [Lamivudine®])

2,′3′-Dideoxycytidine is another antiretroviral agent used against HIV-RT. In this case, ddC resembles the natural metabolite, deoxycytidine (dC),

and as in the case of AZT, it is a 3′-deoxy analogue of dC, where the 3′-OH group of dC is replaced by a hydrogen atom. Similarly, 3-TC is another anti-HIV agent that resembles dC. In this example, however, rather than replacing the 3′-hydroxyl functionality as in ddC, the 3′-carbon position of the sugar has been substituted by a sulfur atom.

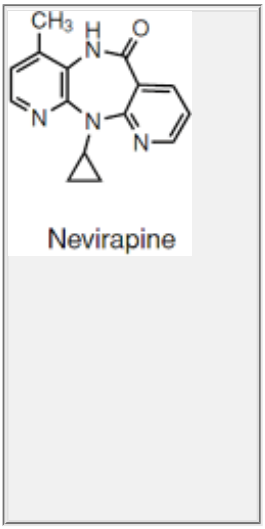
Historical Development of AZT

Interestingly, AZT was originally synthesized as an anticancer agent to inhibit cellular DNA synthesis, but it was found to be too toxic. Subsequently, in the mid-1980s, during a random screening of nucleoside agents for potential inhibitory effects against HIV-RT, AZT was found to have selectivity for the HIV-RT (7). As such, its effects on host cell polymerases result in its dose-limiting bone marrow toxicity.



Nevirapine

An example of a potent noncompetitive inhibitor of HIV-RT is the drug nevirapine, a benzodiazepine analogue (16), which is extremely tight-binding to the enzyme, having a K_i in the nanomolar range. As can be seen in the structure of nevirapine, the drug bears no resemblance to any of the natural nucleotide substrates and was discovered through a random screening program. X-ray crystallographic studies of HIV-RT complexed with nevirapine have shown it binding in a hydrophobic pocket at a site adjacent to and slightly overlapping the nucleotide-binding site of HIV-RT (17). Kinetic studies with the enzyme have revealed an extremely slow binding rate for the drug; however, once bound, the polymerization rate for the reaction is effectively reduced (18).



A drawback for nevirapine, however, is that the virus can develop resistance very rapidly, through mutation of the amino acid residues in the binding pocket (19). Thus, its usefulness is limited to combination therapy with other antiretroviral agents rather than single-drug therapy.

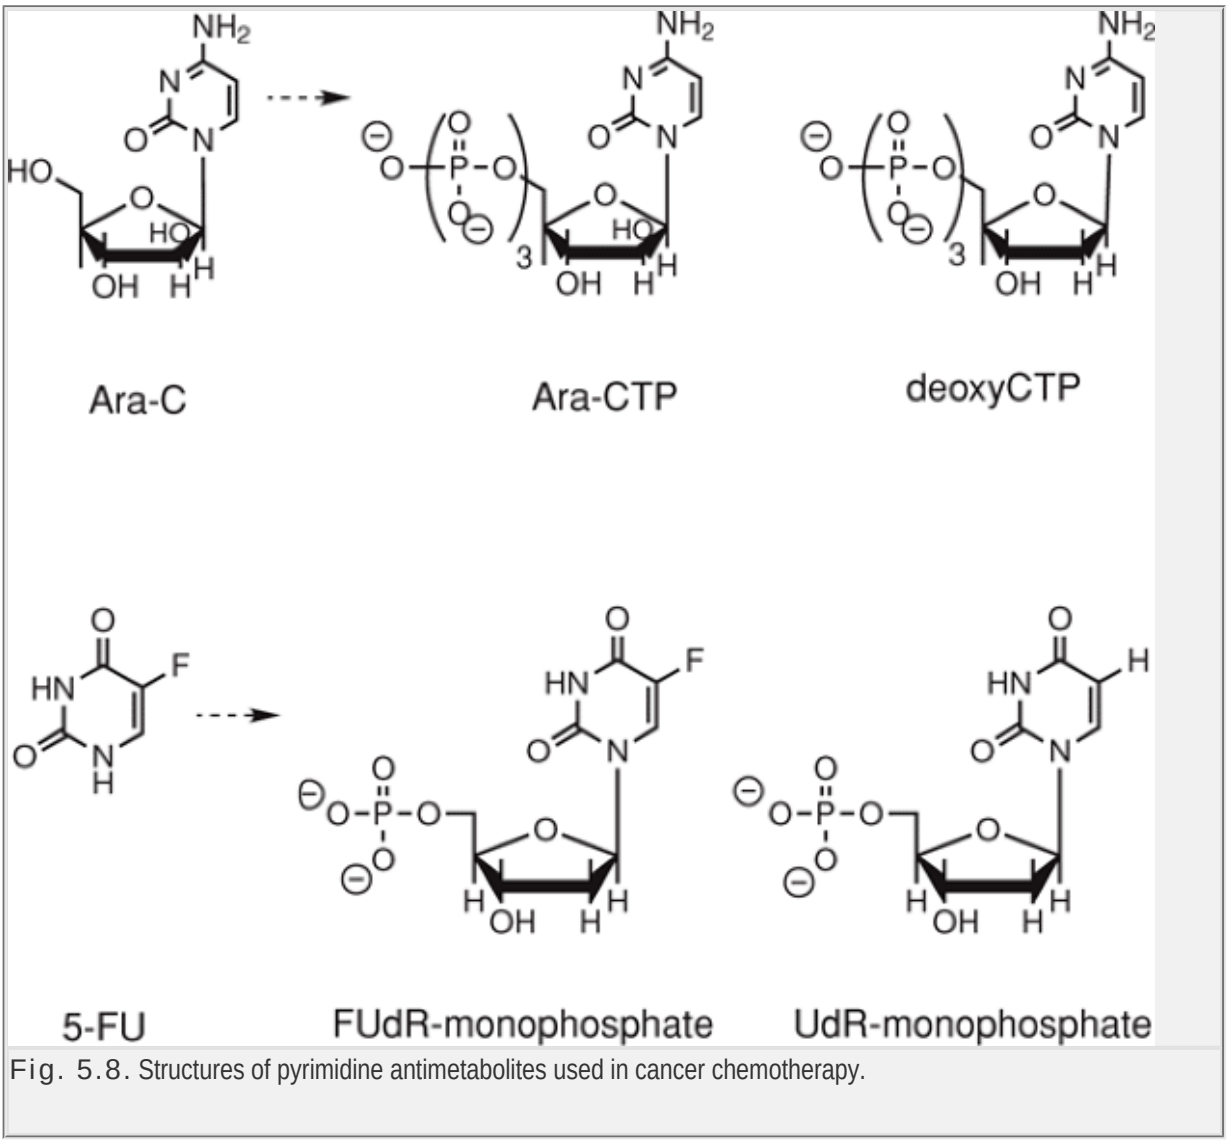


Fig. 5.8. Structures of pyrimidine antimetabolites used in cancer chemotherapy.

Reversible inhibitors used in cancer therapy

The design of several anticancer agents have been based on the antimetabolite theory. Because cancer results in overproliferation and uncontrolled cell

growth, drugs designed against cancer have been based on inhibiting DNA synthesis in the cell. Thus, these drugs have been targeted against those enzymes, including nucleic acid polymerases, thymidylate synthase, and dihydrofolate reductase (DHFR), that play a role in DNA synthesis. Examples of drugs that have been designed against nucleic acid polymerases include cytosine arabinoside (Ara-C) and 5-fluorouracil (5-FU) (Fig. 5.8). Cytosine arabinoside is first converted to its triphosphate, and as such, it functions as an antimetabolite of deoxycytidine triphosphate (deoxy CTP) to inhibit DNA polymerase. As can be seen from its structure, Ara-C is the arabino isomer of cytidine. That is, the 2′-hydroxyl functionality in Ara-C is in the arabino configuration rather than the ribo configuration of cytidine. Because of this stereochemical change in the placement of the 2′-hydroxyl function, Ara-C tends to resemble deoxycytidine rather than cytidine. In this way, Ara-C inhibits DNA polymerases by competing with deoxycytidine. 5-FU is an analogue of the pyrimidine base uracil, where the hydrogen at the 5-position in uracil has been substituted by an isosteric fluorine (F) atom. This makes 5-FU look very similar to uracil. 5-FU, after conversion to 5-fluorodeoxyuridine monophosphate (FdUMP), is an inhibitor of thymidylate synthase, the enzyme involved in the de novo synthesis of thymidylate. In this case, FdUMP is an antimetabolite of deoxyuridine monophosphate.

Methotrexate is a potent inhibitor of DHFR, the enzyme responsible for the reduction of folic acid to dihydro- and tetrahydrofolic acid, precursors to one-carbon donation in purine and pyrimidine de novo synthesis. Methotrexate is

an analogue of folic acid where the 4-hydroxyl group (–OH) on the pteridine ring of folic acid has been replaced by an amino ($–NH_2$) functionality and the nitrogen atom at the 10-position is methylated (Fig. 5.9). These substitutions led to methotrexate having an affinity for DHFR orders of magnitude greater than that for the natural metabolite, folic acid, and allows it to be an extremely potent inhibitor.

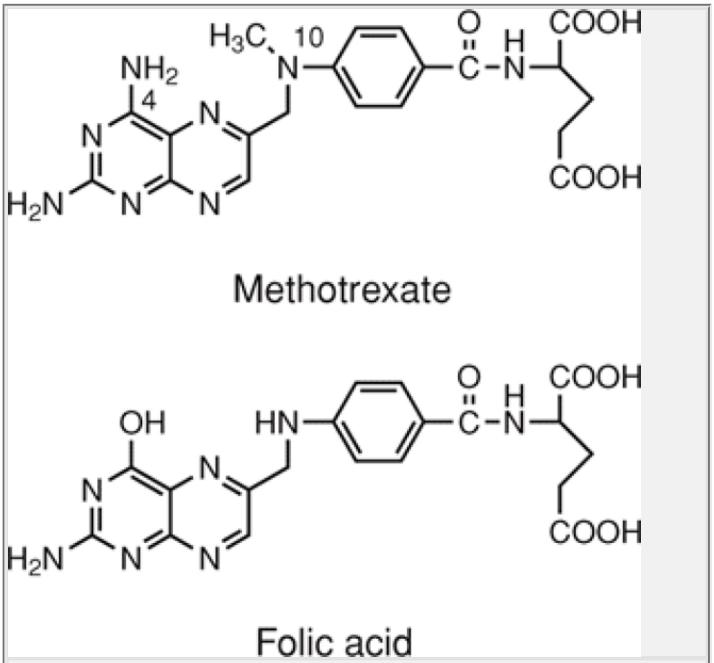

Fig. 5.9. Methotrexate, the antimetabolite of folic acid.

Inhibition of Acetylcholinesterase

Acetylcholinesterase (AChE) is the enzyme that catalyzes the catabolism of the neurotransmitter acetylcholine to acetate and choline (see Chapter 12). Thus, inhibition of AChE would lead to increased concentrations of acetylcholine and a prolonged action of the neurotransmitter. Inhibitors of AChE have found use in cases of myasthenia gravis, glaucoma, and Alzheimer's disease. To appreciate the design of these inhibitors, it is useful to first understand the mechanism of action of AChE. AChE has an anionic site that can bind the positively charged quaternary ammonium group of the choline functionality and an active esteratic site that contains a nucleophilic serine residue involved in the hydrolysis of the ester bond (Fig. 5.10). The mechanism involves the attack of the nucleophilic serine hydroxy group on the carbonyl group of acetylcholine to form a tetrahedral intermediate that breaks down, resulting in the release of choline and an intermediate, acetylated serine that subsequently hydrolyzes to release AChE.

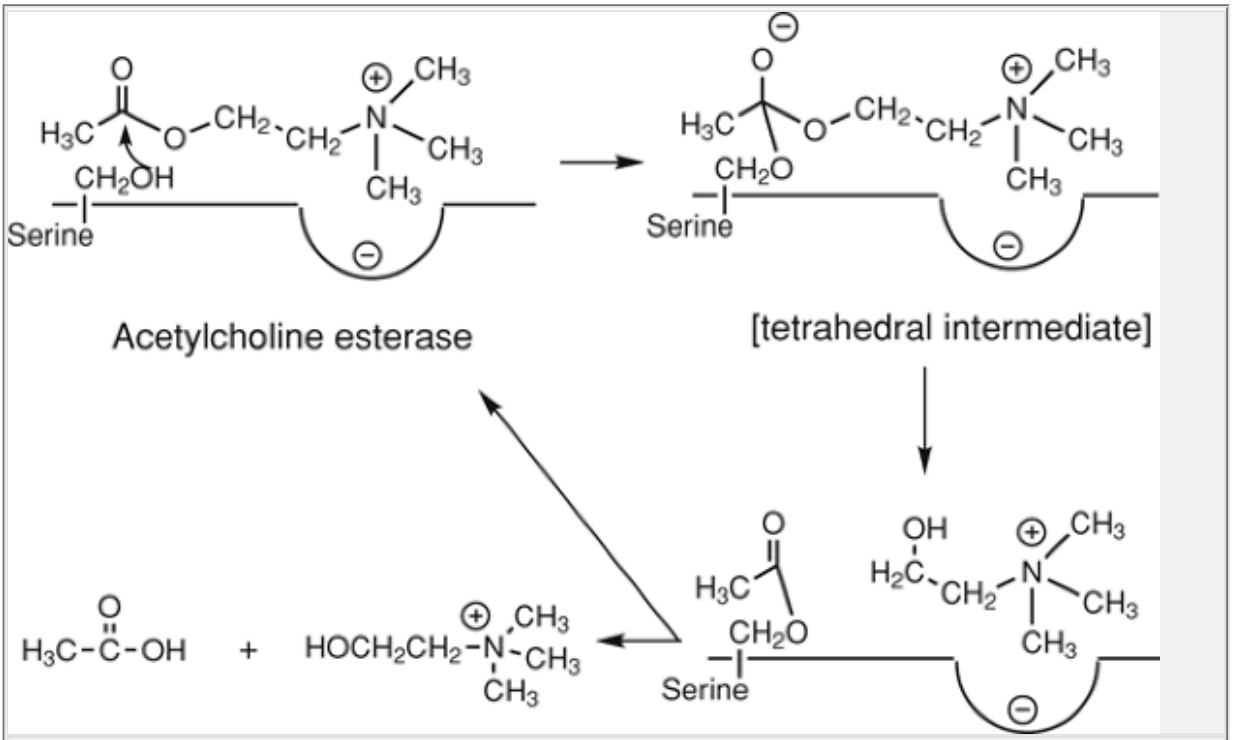

Fig. 5.10. Mechanism of hydrolysis of acetylcholine by acetylcholine esterase.

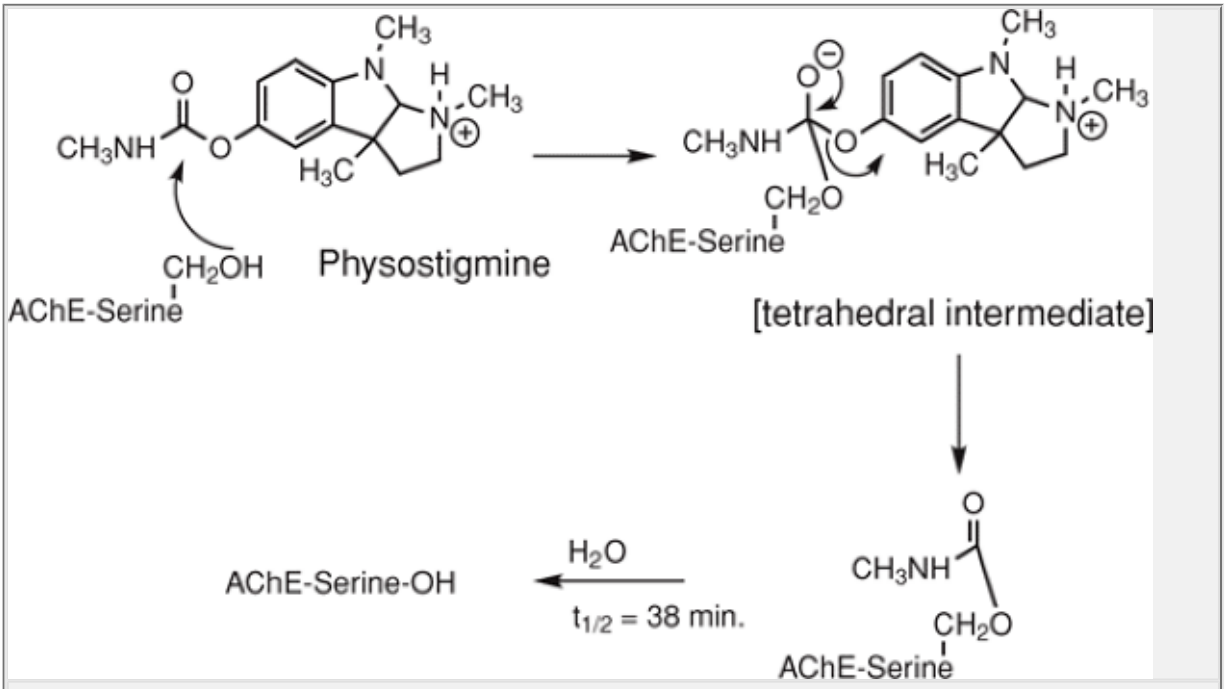

Fig. 5.11. Mechanism of inhibition of acetylcholine esterase by physostigmine.

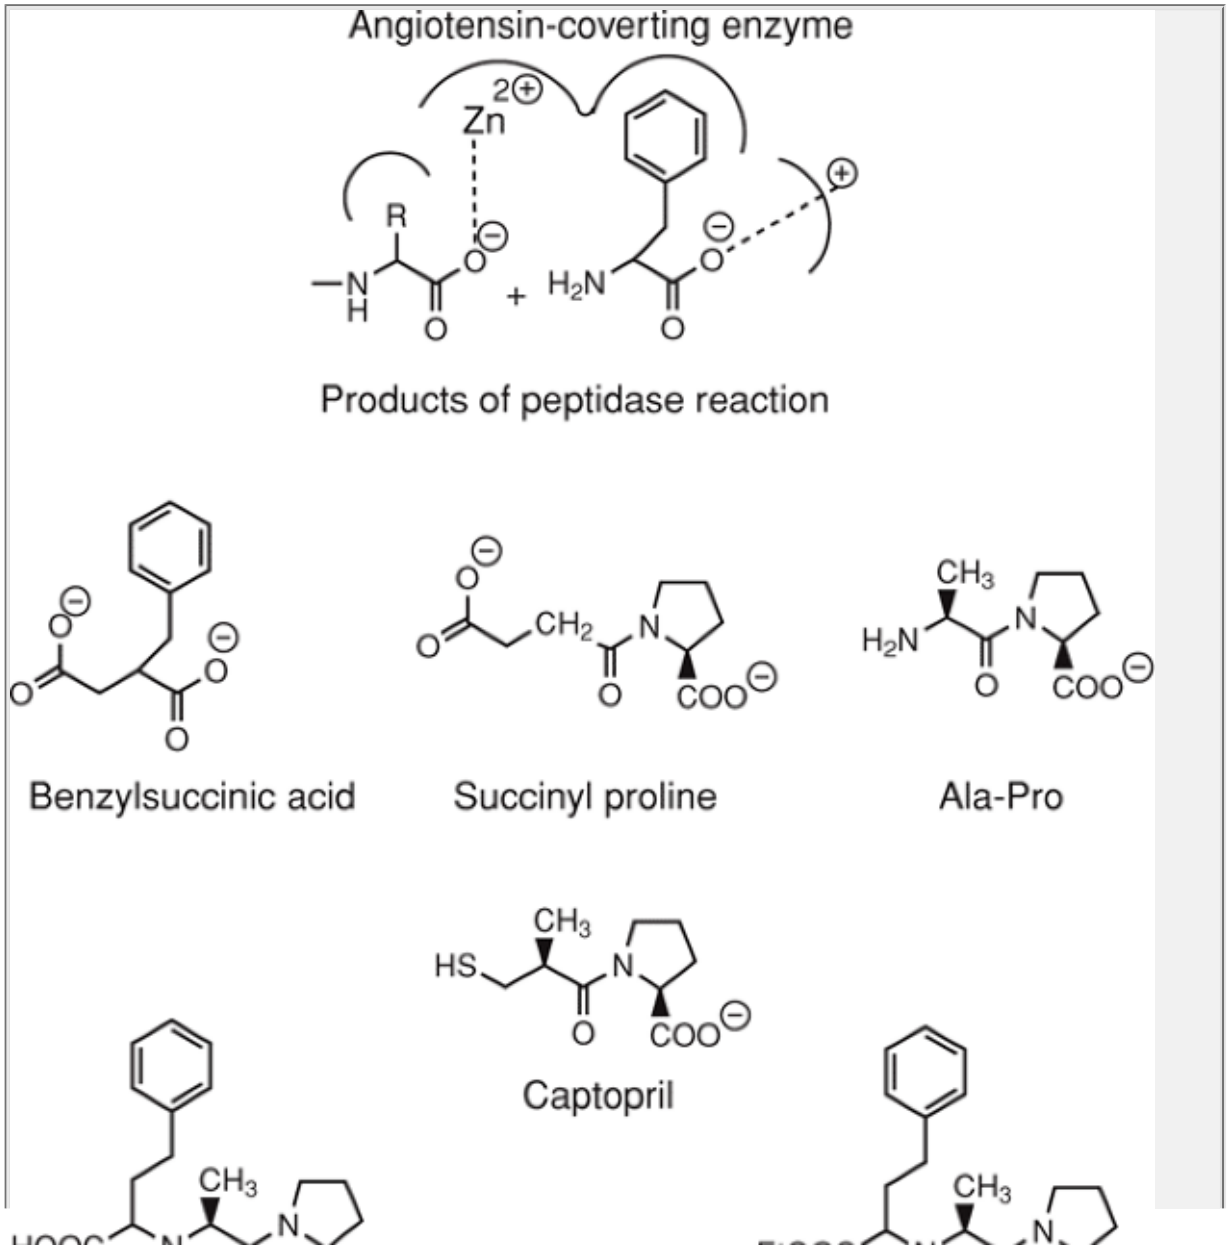
Physostigmine has been used in the treatment of glaucoma. It is an alkaloid with a carbamate moiety that resembles the ester linkage of acetylcholine. Being an alkaloid, it is protonated at physiological pH and, thus, can bind to the anionic site of AChE. Following the mechanism of AChE, the serine residue of the enzyme can attack the carbonyl group of physostigmine, and in the process, the serine is carbamylated (Fig. 5.11). This carbamyl serine intermediate is more stable, to enzymatic than is acetylated SER and subsequent hydrolysis by water occurs extremely slowly. The carbamylated enzyme is only slowly regenerated, with a half-life of 38 minutes—more than seven orders of magnitude slower than that for the natural substrate, acetylcholine. This is an example of a reversible inhibitor involved in covalent bond formation with the enzyme that ultimately gets hydrolyzed.

Inhibitors of Angiotensin-Converting Enzyme

Angiotensin-converting enzyme (ACE) is a carboxypeptidase having a zinc ion as a cofactor and is involved in the renin-angiotensin cascade of blood pressure control (20). The design of the antihypertensive drug captopril, a clinically important and potent reversible inhibitor of ACE, is an example of one of the early endeavors and successes of a rationally designed enzyme inhibitor (21) (see Chapter 28). The design of captopril was based on several factors. These included the knowledge that ACE was similar in its enzymatic mechanism to carboxypeptidase A, except that ACE cleaved off a dipeptide whereas carboxypeptidase A cleaved single amino acid residues from the carboxyl end of the protein; the discovery of L-benzylsuccinic acid as a potent inhibitor of carboxypeptidase A; and, studies of a potent pentapeptide inhibitor of ACE, $BPP_{5\alpha}$ (Glu-Lys-Trp-Ala-Pro), from the venom of the Brazilian viper (*Bothrops jararaca*), which showed that the N-terminal peptide fragments, including tetra-, tri-, and dipeptide fragments (Ala-Pro) of $BPP_{5\alpha}$, retained

some inhibitory activity. Benzylsuccinic acid has been described as a biproduct inhibitor of carboxypeptidase A, wherein its design was based on the combination of the products of the peptidase reaction (i.e., the two peptide fragments, one with a free carboxyl end that coordinates the zinc ion of the protease and the other with a free amino terminus) (Fig. 5.12) (22). In the case of benzylsuccinic acid, the amino ($–NH_2$) functionality is replaced by the isosteric methylene ($–CH_2–$) group. Using the above concepts, it was rationalized that succinyl amino acids could similarly behave as a biproduct inhibitors of ACE. Starting with a succinyl-proline moiety, the structural activity developmental effort finally resulted in captopril with the substitution of the stronger zinc coordinating mercapto functionality in place of the carboxylic residue (of succinic acid) and a stereospecific R methyl group on the succinyl function to represent the methyl group on the natural L-Ala residue in Ala-Pro (the dipeptide fragment that had previously shown inhibitory activity). Captopril soon became highly successful in the clinic as an antihypertensive agent and, in combination with diuretics, has proved to be the treatment of choice in controlling hypertension.



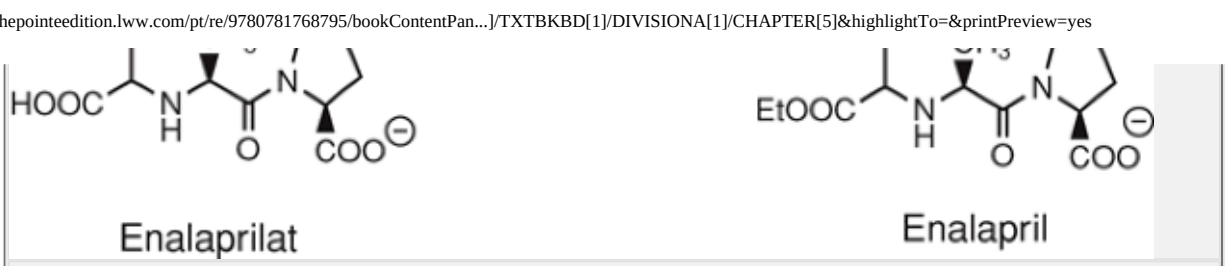


Fig. 5.12. Angiotensin-converting enzyme (ACE) inhibitors and efforts that led to their development.

Following on the heels of captopril was another byproduct ACE inhibitor, enalaprilat. Enalaprilat incorporated a phenylethyl moiety with the S-configuration and made use of a hydrophobic binding pocket in ACE that was overlooked during the design of captopril (23). Recalling that the tripeptide fragment of $BPP_{5\alpha}$ (Trp-Ala-Pro) contained the aromatic tryptophan residue and showed weak inhibitory properties suggested the benefit of an aromatic binding site.

Substituting the tryptophan residue with a phenyl group allowed the design of enalaprilat, which retained the carboxylic group as the coordinating ligand for zinc and resulted in a 20-fold increase in potency over captopril. However, enalaprilat, a diacid, was poorly absorbed from the gastrointestinal tract; thus, a pro-drug ethyl ester of enalaprilat, called enalapril, was developed. Enalapril had superior pharmacokinetics to enalaprilat and was rapidly metabolized to the active drug.

Transition-State Analogues

Transition-state analogues are compounds that resemble the substrate portion of the hypothetical transition state of an enzymatic reaction. All chemical reactions progressing from substrate to product must cross an energy barrier and proceed through a transition state or activated high-energy complex. This energy barrier is described as the activation energy. In the case of enzyme-catalyzed reactions, it is accepted that the enzyme reduces this energy barrier as compared to the nonenzyme catalyzed reaction. Factors contributing to this reduced energy barrier are several and include stabilization of the transition state and intermediate forms of the reaction during the course of transition from substrate to product as well as conformational effects of distortion of the substrate while traversing towards the product (5). In 1948, Pauling (8) initially suggested that compounds resembling the transition state of an enzymecatalyzed reaction would be effective inhibitors of the enzyme, because the substrate transition state should have the greatest affinity for the enzyme. Later, Wolfenden (24) proposed that thermodynamically, it is possible to relate the hypothetical equilibrium dissociation constants between substrate and its transition state of an enzyme-catalyzed reaction with that of the nonenzyme- catalyzed one. Using such an analysis, he showed that the ratio of the hypothetical transition state dissociation constants of nonenzyme-catalyzed reaction to that of the enzyme-catalyzed one is equal to the ratio of the first-order rate constants of formation of transition state for enzyme-catalyzed reaction to noncatalyzed reaction. Because the ratio of the enzyme-catalyzed rate constant to that of the noncatalyzed one ranges from 10^7 to 10^{10}, it follows that the substrate transition state would bind the enzyme 10^7- to 10^{10}-fold more tightly than the substrate itself (25). Hence, transition-state analogues that resemble the substrate would be extremely tight-binding compounds. To design a transition-state inhibitor, knowledge of the enzyme chemistry and its mechanism is a basic requirement. It must be understood, however, that these substrate transition states are, by nature, unstable transient species existing for no longer than a few picoseconds. Nevertheless, experimental evidence

has shown that even crudely designed transition-state inhibitors resembling the substrate are extremely potent inhibitors (25).

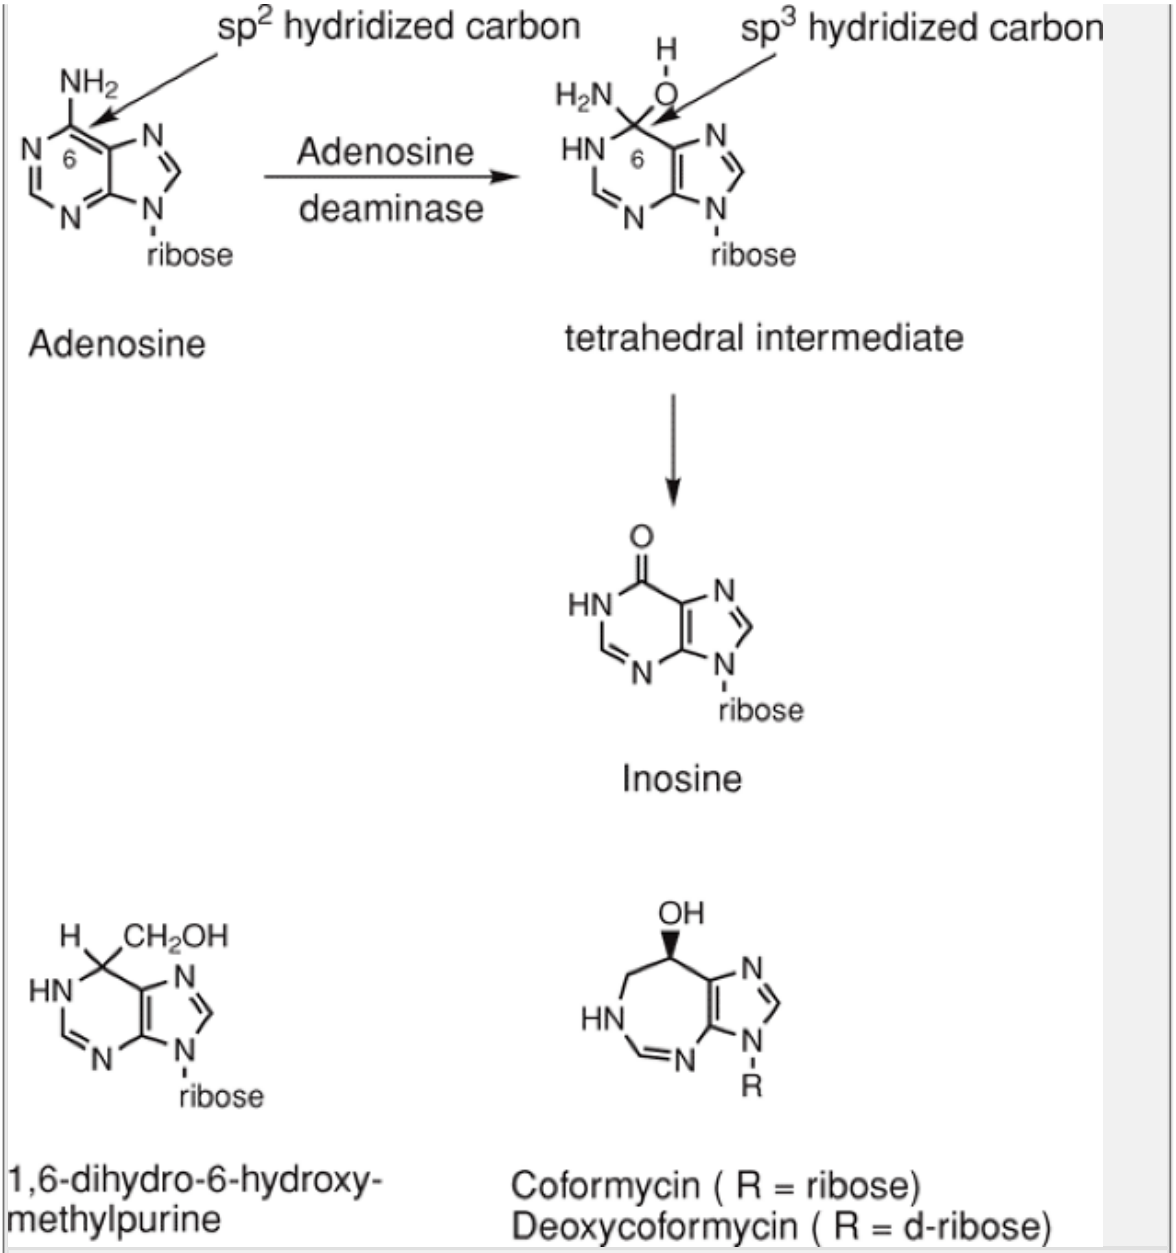

Fig. 5.13. Mechanism and transition-state inhibitors of adenosine deaminase.

Transition-state inhibitor of adenosine deaminase

Adenosine deaminase is the enzyme that hydrolyzes adenosine (or deoxyadenosine) to inosine (or deoxyinosine) and is important for purine metabolism. High levels of adenosine are toxic to B cells of the immune system and can result in an immunocompromised state. Also, people who lack the gene for adenosine deaminase have the genetic condition of severe combined immunodeficiency and are extremely susceptible to opportunistic infections. Many cancer and antiviral agents also are degraded by this enzyme; hence, there is a role for the development of inhibitors of this enzyme (26). The mechanism proposed for adenosine deaminase is a nucleophilic attack of water at the 6-position of the purine base to form a tetrahedral intermediate (Fig. 5.13). The transition state presumably resembles this intermediate.

During the course of the deaminase reaction, the hybridization of the G-carbon changes from an sp^2-hybridized state to an sp^3 state. Subsequently, there is a loss of ammonia to give the product inosine. To develop a transition-state inhibitor for this enzyme, one would have to factor in this change in the hybridization of the substrate molecule; thus, molecules having an sp^3-hybridized carbon at this position and resembling the substrate would potentially be candidates for transition-state inhibitors. The compound 1,6-dihydro-6-hydroxymethylpurine has such geometry, and its potent inhibitory properties of adenosine deaminase (K_i< 1 μM, as compared to a K_m for adenosine of 31 μM) has been rationalized as being a transition-state inhibitor (27). Two compounds that nature has provided, coformycin and its deoxyribose analogue, deoxycoformycin (Fig. 5.13), are extremely potent inhibitors of adenosine deaminase (K_i = 0.002 nM). Both of these compounds contain a seven-member ring structure, which through its flexibility is presumed to resemble the

hypothesized distorted sp^2–sp^3 transition state that forms during the addition of water to adenosine (28).

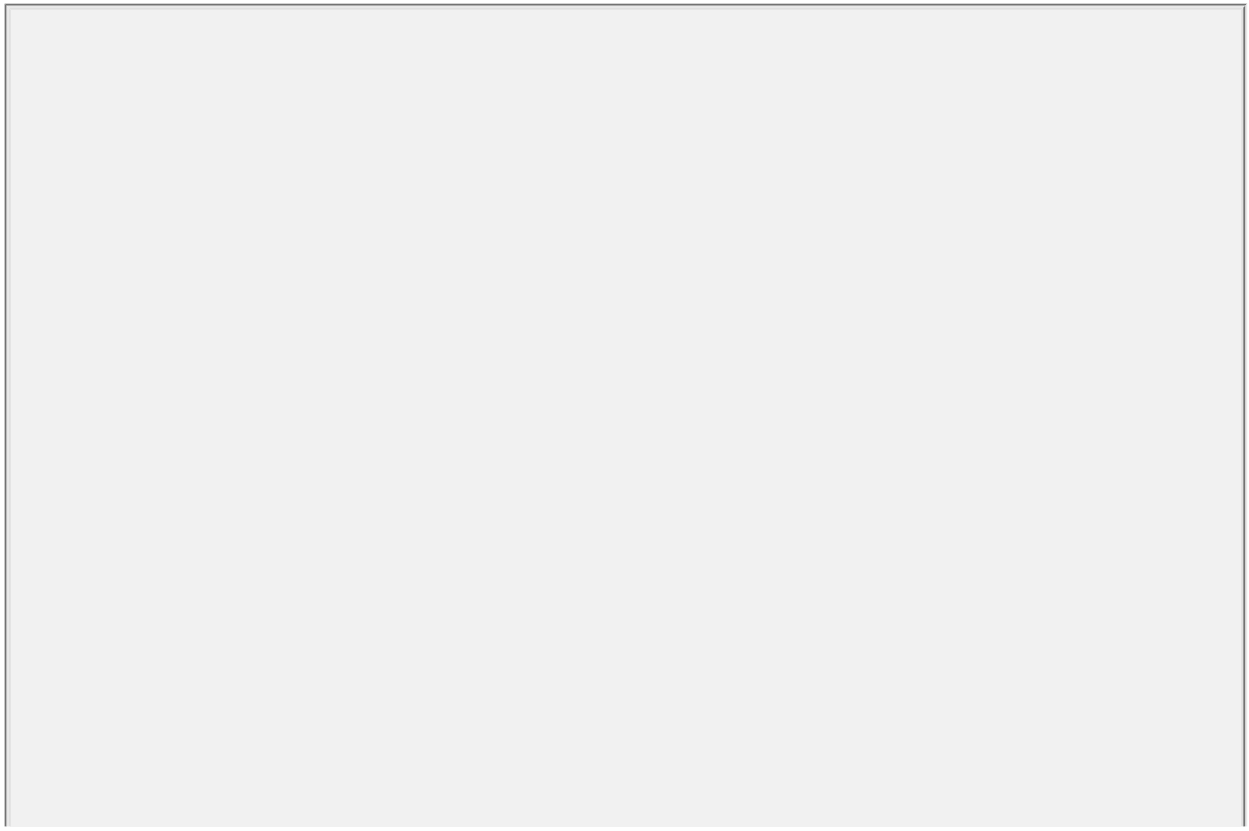
Irreversible Enzyme Inhibition

As previously described, irreversible enzyme inhibition is defined as "time-dependent inactivation of the enzyme," which implies that the enzyme has, in some way or form, been permanently modified, because it can no longer carry out its function. This modification is the result of a covalent bond being formed with the inhibitor and some amino acid residue in the protein. Furthermore, this bond is extremely stable and, for all practical purposes, is not hydrolyzed to give back the enzyme in its original state or structure. In most examples of irreversible inhibition, a new enzyme must be generated through gene transcription and translation for the enzyme to continue its normal catalytic action. Basically, there are two types of irreversible enzyme inhibitors, the affinity labels or active site–directed irreversible inhibitors and the mechanism-based irreversible enzyme inactivators.

Affinity Labels and Active Site–Directed Irreversible Inhibitors

The affinity labels are those chemical entities that are inherently reactive and can target any nucleophilic residue in the enzyme, especially those residing in and around the catalytic center of the protein. These agents generally resemble the substrate so that they may bind in the active site of the enzyme. In most examples, these agents also contain an electrophilic functional group, which includes groups such as halo-methyl ketones ($X\text{-}CH_2C{=}O$, where X = halide), sulfonyl fluorides (SO_2F), nitrogen mustards ($(ClCH_2CH_2)_2NH$), diazoketones ($COCHN_2$), and other such reactive groups, that can "label," or alkylate, a nucleophilic amino acid residue in the enzyme. They generally tend to be indiscriminate in their action and have little therapeutic value, because they are nonselective and, thus, inherently toxic. They have been used mainly as biochemical tools to probe active sites of enzyme to discern the types of amino acid residues both in and around the catalytic center of an enzyme. The classic example of an affinity label is TPCK (tosyl-phenylalanyl-chloromethyl-ketone), an irreversible inhibitor of the serine protease chymotrypsin (29). Because TPCK resembles the amino acid phenylalanine, it can bind to the active site of the chymotrypsin, the selectivity of which is for such hydrophobic amino acid residues (Phe and Tyr). During the course of normal peptide hydrolysis, the reactive chloromethyl-ketone

labels the nucleophilic histidine residue present as part of the catalytic triad (Ser-His-Asp) in the active site of the protease (Fig. 5.14). Another similarly designed affinity label is TLCK (tosyl-lysyl-chloromethyl-ketone), the specificity of which is for the protease trypsin. Trypsin cleaves peptide bonds adjacent to the basic amino acids, lysine and arginine. It was found that TLCK was a specific inhibitor of trypsin but had no activity for chymotrypsin. On the other hand, TPCK, although extremely specific for chymotrypsin, showed no activity for trypsin.



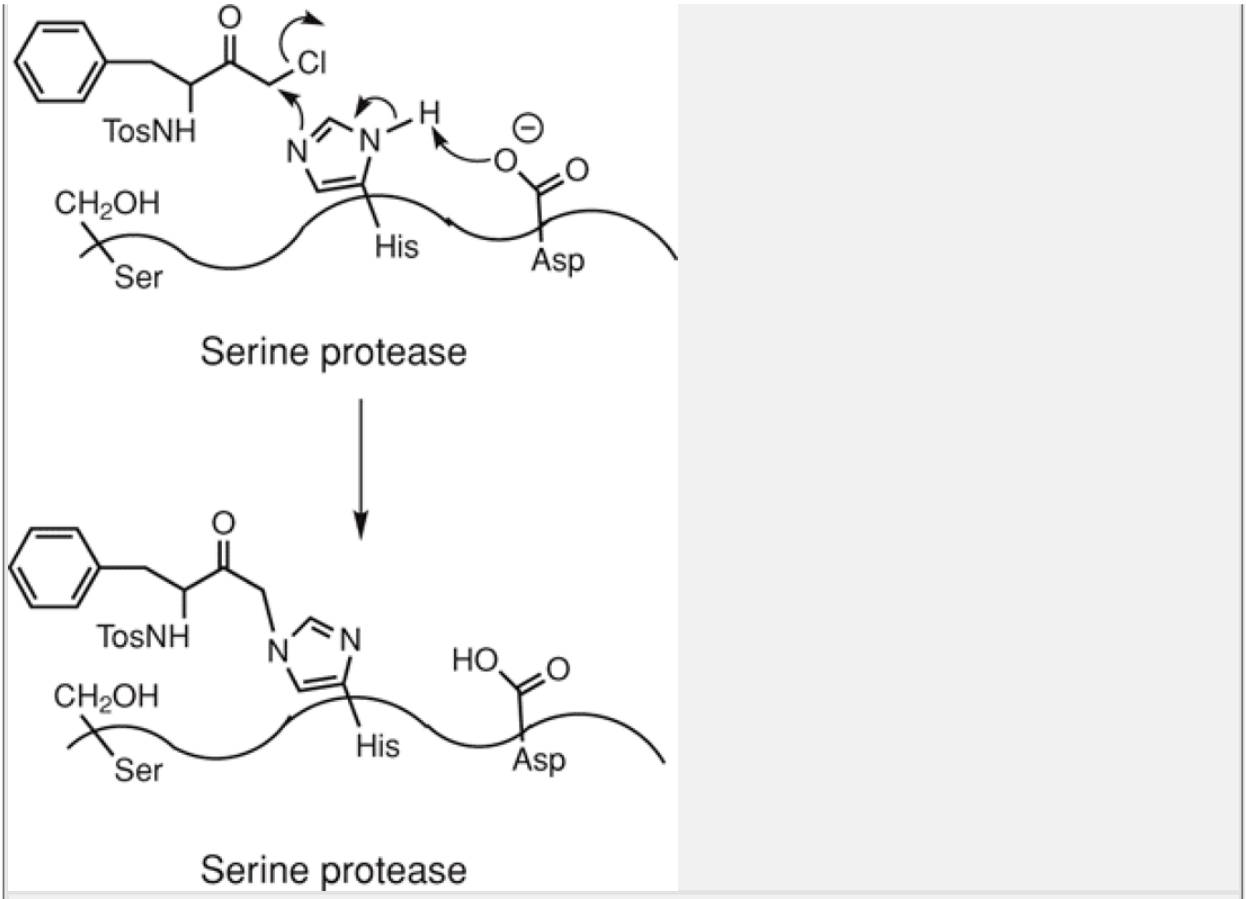


Fig. 5.14. Mechanism of affinity label of serine protease with TPCK (tosyl-phenylalanyl-chloromethyl-ketone).

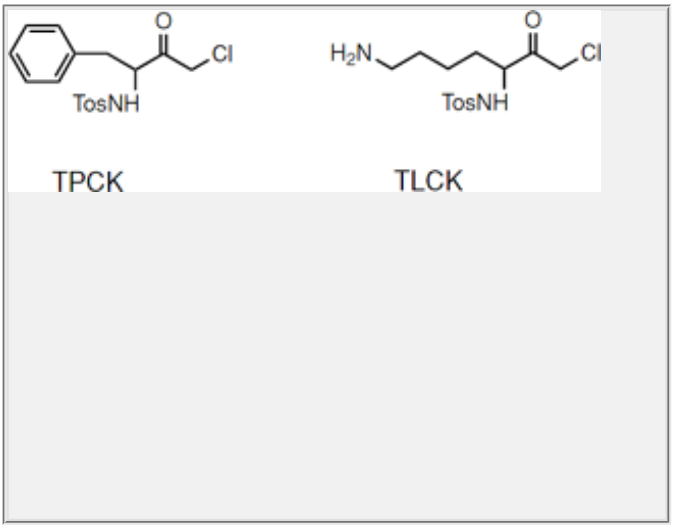

Because of the inherent reactivity and nonselectivity of these affinity labels and their limited utility in drug therapy, the late B.R. Baker (30) extended this concept to design inhibitors that would have greater selectivity and specificity and, thus, be potential drug candidates. He designed several analogues, termed active site–directed irreversible inhibitors, targeted toward thymidylate synthase, a key enzyme involved in the de novo metabolism of thymidylate. These analogues contained a substrate-binding region linked to a reactive group, such as a halomethyl ketone, by a tether whose chain length could be manipulated. The substrate portion of the analogue ensures both affinity and rapid binding to the enzyme active site. Once bound, areas in and around the binding site and on the surface of the enzyme could be probed for nucleophilic amino acid residues. By manipulating the length of the tether, ideal inhibitors could then be designed such that any suitably located, sufficiently nucleophilic amino acid residue on the surface of the enzyme could potentially be alkylated by the halomethyl ketone (Fig. 5.15). Once alkylated, the tether “bridges” the active site with the labeled amino acid residue, thus “tying up” and preventing further catalysis by the enzyme.

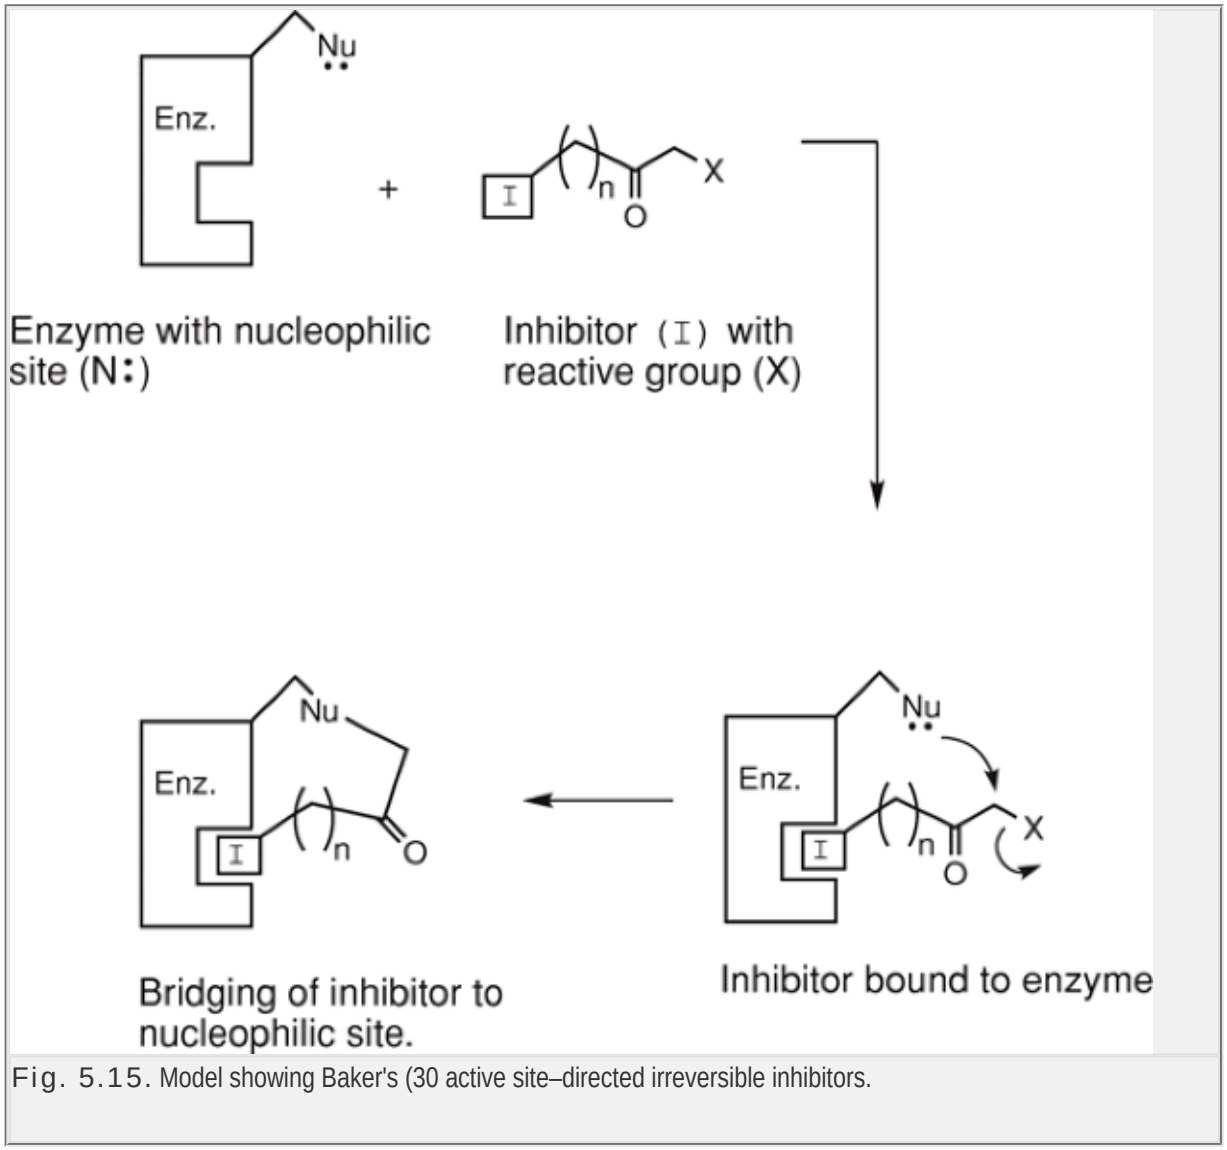

Fig. 5.15. Model showing Baker's (30 active site–directed irreversible inhibitors.

Mechanism-Based Irreversible Enzyme Inactivators

Overview

The mechanism-based irreversible inhibitors also have been termed as suicide substrates," "k_{cat} inhibitors," "Trojan horse inhibitors," or "latent alkylating agents." These inhibitors are inherently unreactive but, on normal catalytic processing by the enzyme, are activated into highly reactive moieties (31,32,33). These reactive functionalities can then irreversibly alkylate a nucleophilic amino acid residue or cofactor in the enzyme and, in essence, cause the enzyme's death ("suicide"). Basically, these inhibitors have a latent reactive functionality that only becomes apparent after binding and acted on by the normal catalytic machinery of the enzyme. This type of inhibitor design differs from the preceding one in that these inhibitors have one more level of built-in selectivity. The kinetic scheme for such inhibition is shown in Equation 5.5, in which enzyme, E, binds with substrate (inhibitor), S, to give an [E–S] complex with dissociation constant of K_i:

$$\textbf{Eq. 5.5} \quad \begin{array}{l} \mathrm{E + S} \underset{}{\overset{K_i}{\rightleftharpoons}} [\mathrm{E{\cdot}S}] \xrightarrow{k_{cat}} [\mathrm{E{\cdot}S^*}] \xrightarrow{k_{inact}} [\mathrm{E{-}S}] \\ \qquad\qquad\quad \downarrow k_{diff} \\ \qquad\qquad\quad \mathrm{E + S^*} + \mathrm{Nu:} \rightarrow [\mathrm{Nu{-}S}] \end{array}$$

Next, the [E–S] complex is converted into a highly activated complex [E–S*] by the catalytic machinery (k_{cat}) of the enzyme, which can then go on to alkylate the enzyme, [E-S]. Note that it is possible for the reactive species [S*]

to diffuse (dissociate) from the enzyme and react with some other target (nucleophilic species)—that is, the system is "leaky." If this happens, however, the

inhibitor cannot be classified as a “true” suicide substrate, because specificity is lost.

Several requirements need to be met by these inhibitors for them to be classified as suicide substrates. These include the following: 1) Inactivation should be time dependent (reaction should be irreversible), 2) kinetics should be first order, 3) the enzyme should show saturation phenomenon, (4) the substrate should be able to protect the enzyme, and 5) stoichiometry of the reaction should be 1:1 (one active site to one inhibitor).

Examples of suicide substrates

During the past three decades, besides the rational design of hundreds of molecules that have been synthesized and tested as suicide substrates, it also has come to light that nature itself has known about this mechanistic mode of enzyme inhibition and provided us with several extremely potent mechanism-based suicide inactivators. Below are a few selected examples to demonstrate the mode of action of these inhibitors.

Halo enol lactones

Halo enol lactones are an example of suicide inhibitors for serine proteases. These analogues were developed by Katzenellenbogen and coworkers at the University of Illinois (34). On normal catalytic processing by the serine hydroxyl functionality, they give rise to a reactive halo-methyl ketone, which subsequently alkylates a nearby nucleophilic residue on the enzyme (Fig. 5.16). Other suicide inactivators for the serine proteases have been designed by various researchers (32).

Clauvulinic acid

Clavulanic acid is a potent inhibitor of bacterial β-lactamase (35). This enzyme is a serine protease and can hydrolyze β-lactams, such as the penicillin antibiotics. It is the principal enzyme responsible for penicillin-resistant bacteria. Clavulanic acid itself is a β-lactam and, if given in combination with penicillin, is preferentially taken up by β-lactamase and hydrolyzed. During the process of hydrolysis, however, the molecule undergoes a cleavage, leading to the formation of a “Michael acceptor,” which subsequently alkylates a nucleophilic residue on β-lactamase, causing irreversible inhibition (Fig. 5.17). Such combinations of a β-lactamase inhibitor and a penicillin have resulted in clinically useful agents [clavulanic acid plus amoxicillin (Augmentin)].

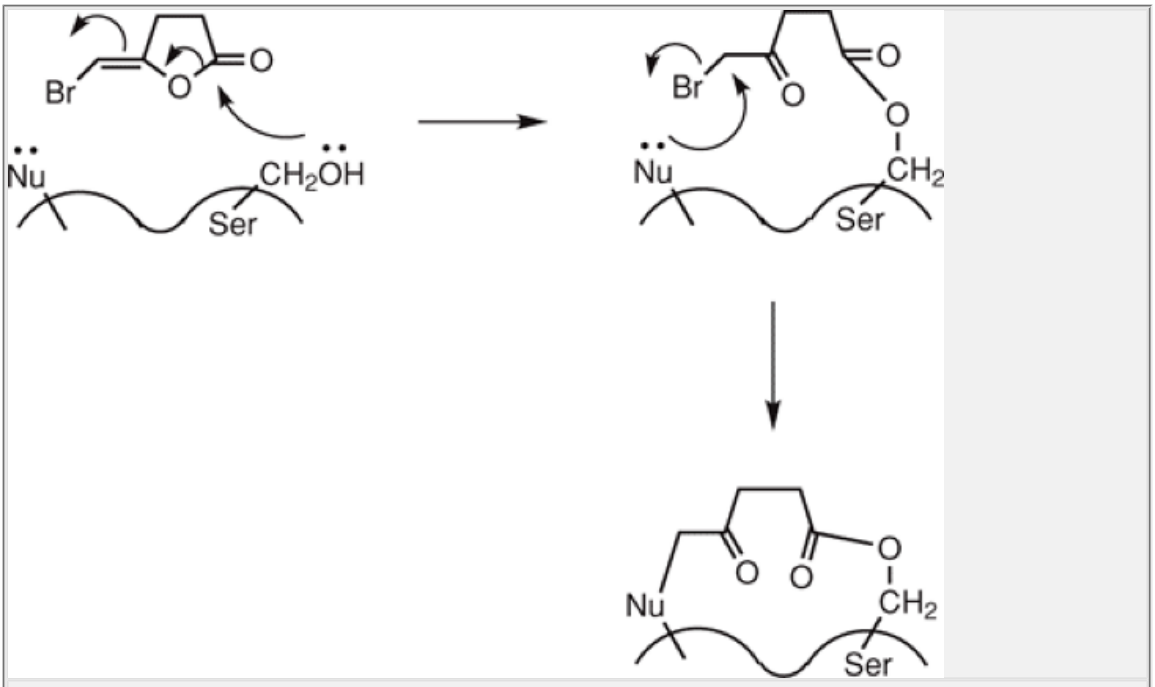

Fig. 5.16. Mechanism-based inhibition of serine proteases by Katzenellenbogen's halo enol lactone.

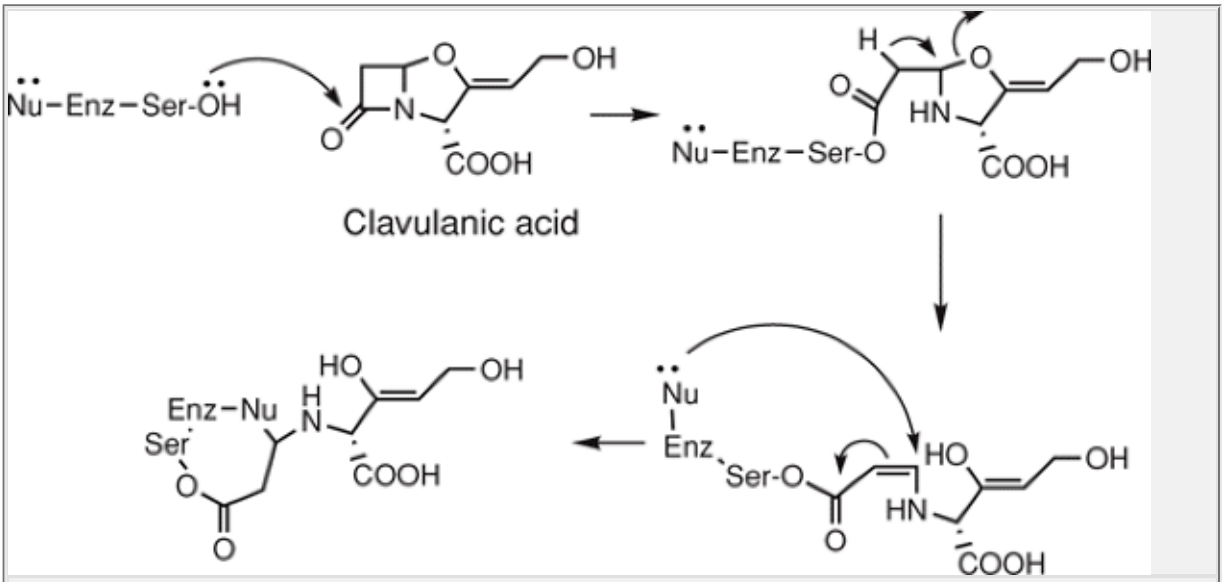

Fig. 5.17. Mechanism-based inhibition of β-lactamases by clavulinic acid.

Gabaculin

Gabaculin, a naturally occurring neurotoxin, is a potent mechanism-based inhibitor of the enzyme γ-ainobutyric acid transaminase (GABA-T) with an interesting mechanism of action (36). GABA-T is a pyridoxal phosphate (PLP)–dependent enzyme involved in the catabolism (transamination) (Fig. 5.18) of the excitatory neurotransmitter, GABA, to succinate semialdehyde and pyridoxamine. As part of the normal catalytic mechanism of PLP-dependent enzymes, the amino group of gabaculin first forms a Schiff base with the aldehyde of PLP (Fig. 5.18). Next, this adduct undergoes an aromatization reaction, resulting in an extremely stable covalent bond with the cofactor, PLP. Hence, in this case, rather than an enzymatic nucleophilic residue being alkylated, the cofactor is "tied up," resulting in the inhibition.

Finasteride

Finasteride is a clinically useful agent in the treatment of prostate hyperplasia and male pattern baldness. It is a potent inhibitor of human steroid-5α-reductase, the enzyme responsible for the reduction of testosterone to dihydrotestosterone (Fig. 5.19). (see Chapter 45) The inhibitory action of finasteride has been attributed both to its similarity in structure to testosterone, which allows it to bind to the enzyme and be reduced to dihydrofinasteride in place of testosterone, as well as to its ability to act as a mechanism-based inhibitor, during which it can tie up the cofactor, NADPH, by forming a covalent NADP-dihydrofinasteride adduct (Fig. 5.19) (see Chapter 45). This adduct very slowly releases dihydrofinasteride with a half-life of one month (37).

Conclusion

This chapter has attempted to give the reader an overview of enzyme catalysis and the various ways in

which enzymes can act as catalytic receptors. Based on these properties and mechanisms of enzyme action, the essentials of drug design and discovery through enzyme inhibition with a few choice examples have been outlined. The reader is referred to suggested reading material for more detailed explanations and insights regarding the rationale and design strategies of enzyme inhibitors. In conclusion, drug design by enzyme inhibition is a continually developing enterprise. There will always be the need to discover more selective and more potent inhibitors in an effort to increase the therapeutic benefit to patients. This chapter has tried to give a brief insight into this fascinating area of medicinal chemistry and the various types of enzyme inhibitors that can be rationally designed.

Chapter 6

Pharmaceutical Biotechnology—From Nucleic Acids to Personalized Medicine

Ronald E. Reid

Robert D. Sindelar

Introduction

Pharmaceutical biotechnology is advancing with unprecedented methodology and achievements. The early 1980s saw the products of modern pharmaceutical biotechnology come to the marketplace as the U.S. FDA approved recombinant DNA–produced insulin in 1982 and second-generation home pregnancy test kits containing monoclonal antibodies were developed. In an article entitled “Biotechnology: are you ready for it?”, appearing as the cover story in the May 1990 issue of *Drug Topics*, Conlan (7) suggested that “pharmacists will skillfully ride the coming biotechnology drug wave into the 21st century, where they'll reign as the unchallenged drug therapy experts, designing, dispensing, counseling, and monitoring medicines in the brave new world of genetic engineering.” Although a decade later this vision has yet to be fulfilled in its entirety, this is certainly an attractive scenario and represents an exciting opportunity for pharmacists (8). Pharmaceutical biotechnology generates basic scientific knowledge, useful therapeutic and diagnostic products, and promising methodologies for future research and clinical applications. There is little doubt that the techniques of biotechnology have led to the development and marketing of new and novel therapies residing on pharmacists' shelves today, improved methods of manufacturing pharmaceuticals, and significant contributions to our better understanding of disease etiology, pathophysiology, and biochemistry. Advances in biotechnology will have an increasing impact on pharmacy practice in the first decade of the 21st century and well into the future. Genomics, transcriptomics, proteomics, metabolomics, and enviromics—the core technologies of pharmaceutical biotechnology—are currently making major contributions to drug therapy in three areas (9):

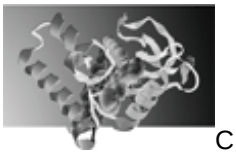
- Identification of new genes.
- Identification of drug targets.
- Development of “personalized medicine.”

The human species is a product of millions of years of evolution. The living organism that has evolved is supported by complex chemical machinery that senses and responds to environmental signals, nourishes and protects the trillions of cells that are the basic unit of the living organism, determines and regulates cellular function, and finally, assures that cellular multiplication and organism reproduction will occur. Disruptions of this chemical machinery are the sources of disease and disability, and a detailed understanding of these mechanisms at the molecular level is critical to understanding disease pathology and developing an effective defense or aggressive therapy against disease and disability. Much information about the human condition to date arises from studies of simpler organisms like the bacteriophage and viruses, bacteria, yeasts, nematodes, fruit flies, and the more complex mouse. Through such studies, we seek understanding to be able to detect the damage potential of a particular internal or external environment, repair damage that has already occurred, or sustain the body in the presence of damage.

Current dogma places biochemical information and its transfer as the basis of the function of a living organism, regulating the nervous, immune, digestive, and reproductive systems. This information flow originates at the deoxyribonucleic acid (DNA) molecule and proceeds to ribonucleic acid (RNA), which is then translated into protein (10). Proteins are the main components of the functional organization of the cell and are critical to the relationship

between the organism's DNA structure, or genotype, and the organism's functional organization, or phenotype. Therefore, intervention in the regulatory system to detect or repair disease or to sustain the organism in the event of disease may occur at any level between the genotype and the phenotype. Genetic intervention has many levels, from direct tinkering with the genes (the information source) to manipulating the many processes involved in the transcription and translation of the genetic information into proteins. Protein function may be altered through direct manipulation of proteins or through altering the many events occurring between protein production and the physical response noted by the organism. Regardless of the particular approach taken in any

isolated instance, our understanding about the molecular mechanisms of the chemical-mediated information transfer will be the basis for rationalizing any therapeutic initiative. It is highly likely that any approach to disease therapy will use a mixture of techniques, only a few of which will involve the direct manipulation of genes in the form of gene replacement therapy. Further development of the knowledge of molecular processes involved in this information transfer and how it is related to disease may help us to make better use of the current therapeutic technologies and allow us to treat the individual patient rather than the disease symptoms (11).



Clinical Significance

The biotechnology industry has grown explosively over the past 30 years, with estimated 2005 revenues from human therapeutic and diagnostic products for the top 16 biotechnology companies reaching approximately $35.5 billion—more than twice the revenues for the entire industry five years ago (1). The nearly 375 publicly traded biotechnology and drug companies around the world have marketed more than 100 U.S. Food and Drug Administration (FDA)–approved biopharmaceuticals and vaccines (2). This is an impressive number, because only 39 products were approved by 1996.

Improved manufacturing of pharmaceuticals was the first major contribution of biotechnology to pharmaceutical care in the 1980s. Biotechnology-produced human insulin, growth hormone, and erythropoietin—all replacements of highly specific, endogenous molecules—were major advances in therapy. Since the late 1980s, however, pharmaceutical biotechnology also has helped to identify new compounds with new mechanisms of action. Significant contributions to our understanding about the mechanism of disease at the molecular level continue to be made by biotechnology researchers and will translate into newer, better pharmaceuticals. The impact of biotechnology on pharmaceutical care is expected to increase exponentially as advances in technology continue to yield novel medicinal agents, such as the colony-stimulating factors, tissue-type plasminogen activator, new vaccines, DNase, fusion protein drugs (e.g., leukin diftitox), and specific monoclonal antibodies, including trastuzumab. Products of biotechnology are playing a critical role in the discovery and design as well as in the production of treatments for life-threatening diseases, such as cancer, AIDS, and cardiovascular disease.

Pharmaceutical care using biotechnology-derived products requires (3,4):

- An understanding of how the handling and stability of biopharmaceuticals differs from those of other drugs that pharmacists dispense.
- A preparation of the product for patient use, including reconstitution or compounding, if required.
- Patient education regarding their disease, benefits of the prescribed biopharmaceutical, potential side effects or drug interactions to be aware of, and the techniques to self-administer the biotechnology drug.
- Patient counseling about the reimbursement issues involving an expensive product.
- Monitoring of the patient for compliance.

The evolution of biotechnology medicine is gaining momentum. The techniques of pharmaceutical biotechnology will make it possible to prevent, cure, and treat more diseases than possible today; to anticipate and prevent disease symptoms; to eliminate the contamination risks of infectious pathogens found in human blood–derived biopharmaceuticals; to target drug therapy toward the underlying cause of diseases, not just the treatment of disease symptoms; to produce replacement human proteins on a large scale; and to develop more precise and effective medicines with fewer side effects (2). Key areas of future growth for biotechnology in the 21st century will include pharmacogenomics/pharmacogenetics; recombinant-based therapies, such as vaccines delivered by novel administrative routes; genetic modification of the patient; and cloning of human tissues and organs. The field has matured sufficiently with the first generic versions of original biotech drugs, called “Biogenerics” or “Follow-On Biologics,” nearing regulatory approval (5,6). It will be interesting to view the impact of the breath of future biotechnological advances on the practice of pharmacy.

The clinician of the future will have the tools to routinely screen for the genetic implications of new drugs, improving a patient's response to drug treatment and making therapeutics a true science. Although many of the first biotechnology-derived therapeutics were initially used in acutely ill, hospitalized patients, the products of today's pharmaceutical biotechnology increasingly have an impact on the chronic disease patient populations constituting much of ambulatory care practice.

The Chemical Basis of Pharmaceutical Biotechnology

Pharmaceutical biotechnology is defined, at its most basic level, as the manipulation of nucleic acids in the production of therapeutic and diagnostic agents. Both DNA and RNA are the fundamental genetic material;

therefore, an understanding of the molecular composition of the genetic material and the structure and functional nature of the gene is basic knowledge on which to build the science of pharmaceutical biotechnology.

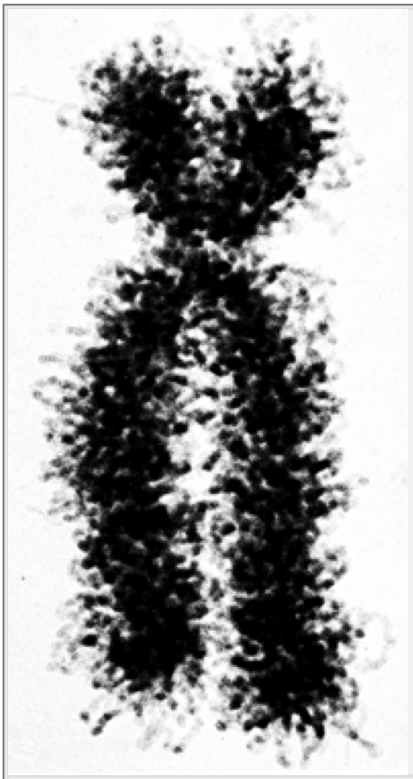


Fig. 6.1. Sister chromatids of a mitotic pair. The sister chromosomes are produced by the previous replication event and are still joined together at this stage of mitosis. Each of the chromosomes consists of a fiber with a diameter of approximately 30 nm. The DNA is 5- to 10-fold more condensed in chromosomes than it is at interphase. (Adapted from Lewin B. Genes IV, 4th Ed. Oxford: Oxford University Press and Cell Press, 1990; with permission.)

Nucleic Acids: DNA and RNA

The eukaryotic chromosome makes a brief appearance when the cell is actively dividing and can be seen as a pair of chromatids (daughter chromosomes produced during replication of DNA before mitosis) (Fig. 6.1). The individual chromosome can be divided along its length into many clear striations of dark bands and light interband regions (Fig. 6.2). The dark bands are dense clumps of protein and DNA; the interbands are regions with a lower density of protein and DNA. The reasons for this highly regular banding are not known. Each of these bands and interbands of the chromosome is composed of a well-defined mixture of protein and DNA called chromatin.

The main protein component of chromatin is histones, which are basic proteins associated with the DNA in the form of structures called nucleosomes (Fig. 6.3) (12). The DNA can be stored in very small, compact forms called condensed DNA, which is 10^4- to 10^6-fold less in volume than uncondensed DNA. The main force that must be overcome in the condensation process is charge repulsion because of the negatively charged phosphates in the polyanion. This repulsion may be overcome by DNA interaction with multivalent organic and inorganic cations. The histones, which are the major components of the nucleosome, are cationic organic proteins that interact with DNA in the compact nucleosome structure.

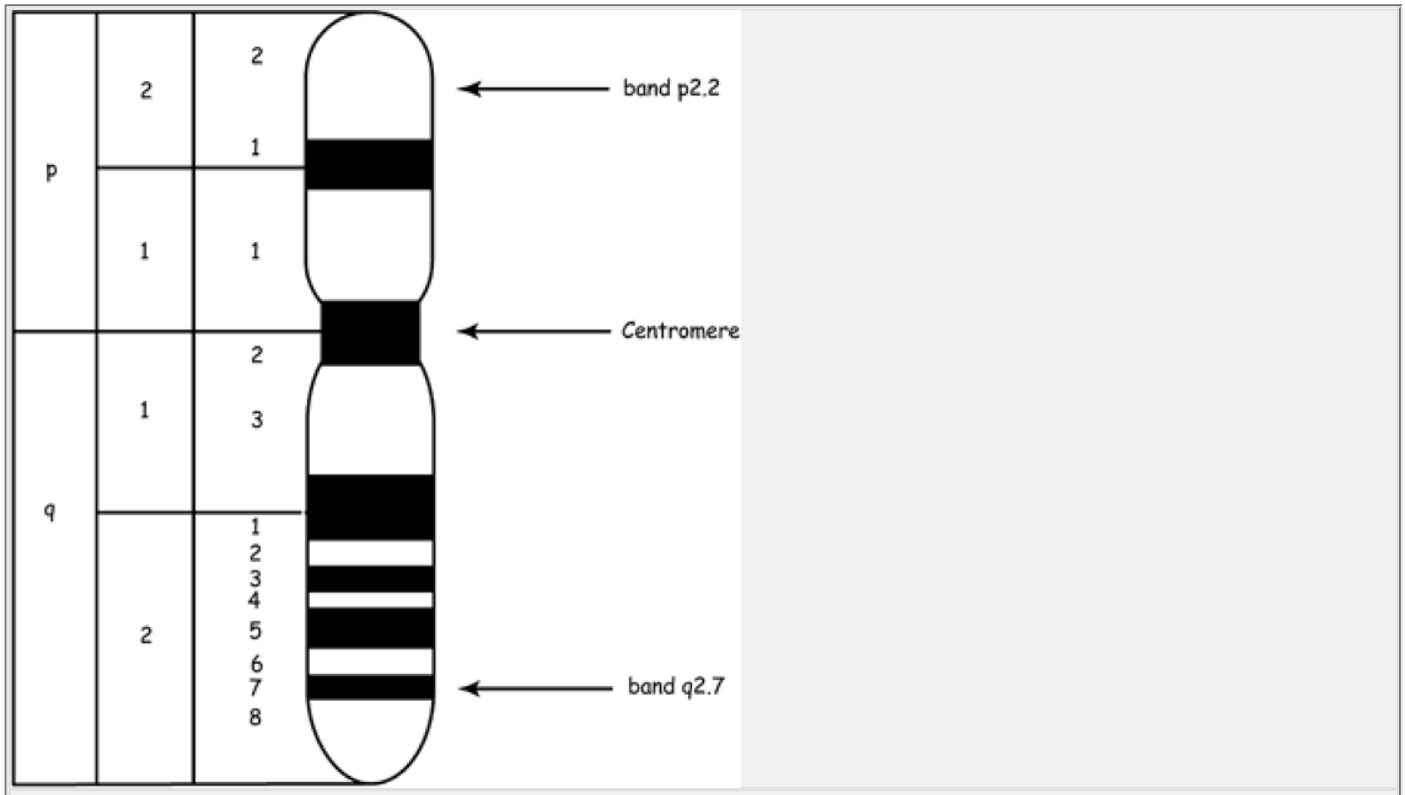

Fig. 6.2. The human X chromosome can be divided into distinct regions by its banding pattern. (Adapted from Lewin B. Genes IV, 4th Ed. Oxford: Oxford University Press and Cell Press, 1990; with permission.)

The nucleosome consists of a 200-base-pair (bp) DNA strand making two left-handed coils around an octamer of histone proteins consisting of two copies each of histones H2A, H2B, H3, and H4, and a single copy of the histone H1 (Fig. 6.3).

Separation of the protein spools from chromatin leaves a very long, string-like DNA molecule. The DNA is

composed of purine bases (adenine [A] and guanine [G]), pyrimidine bases (cytosine [C] and thymine [T] or uracil [U], in the case of RNA), deoxyribose sugars (ribose sugars in the case of RNA), and phosphates (Fig. 6.4). The bases combine with the 1′ position of the ribose to form a nucleoside. The DNA structural unit, a nucleotide, is a 3′- or 5′-monophosphate ester of a nucleoside. Nucleotides are covalently linked through phosphate esters to form the DNA polymer chain. Each nucleotide is linked to one neighbor by a 5′,3′-phosphodiester bond and to the other neighbor by a 3′,5-phosphodiester bond (Fig. 6.5). All the 3′- and 5′-hydroxyl groups in the DNA molecule are involved in phosphodiester bonds except the first and last nucleotides in the chain. The first nucleotide in the chain has a 5′-phosphate nonbonded to a nucleotide, and the last nucleotide in the chain has a free 3′-hydroxyl group (Fig. 6.5). The DNA sugar-phosphate backbone chain has polarity, meaning it has a 5′ end and a 3′ end.

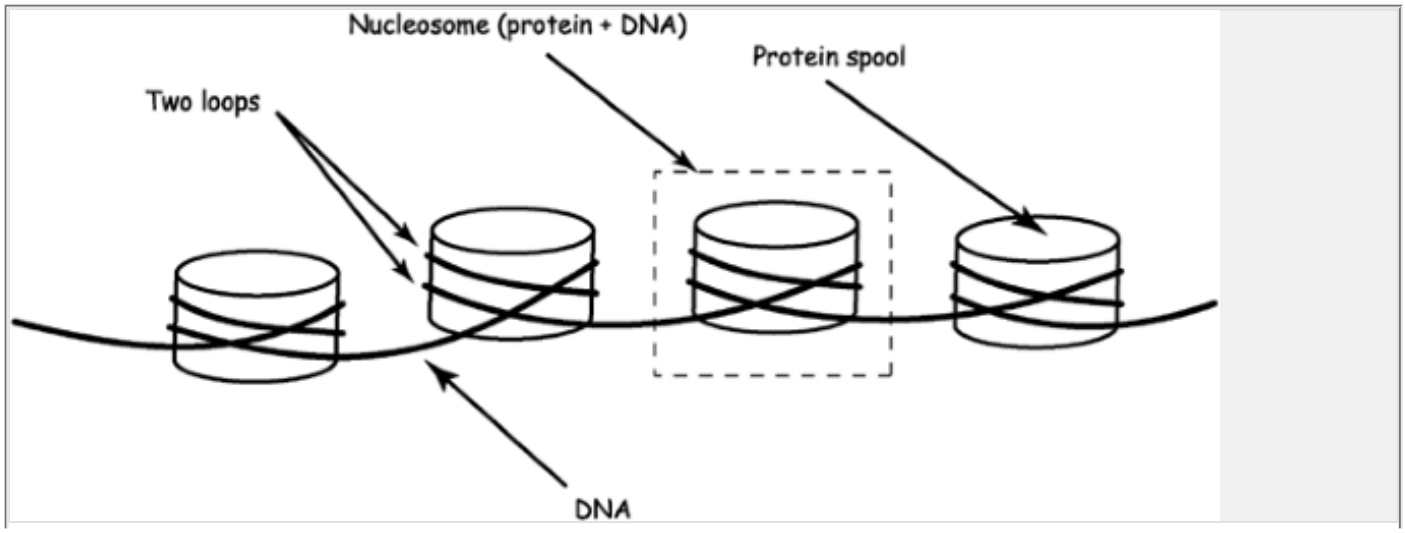

Fig. 6.3. A DNA thread making two left-handed coils around each of a series of protein spools. A single spool consists of an octamer of histone proteins, two each of H2A, H2B, H3, and H4. The ninth histone protein, H1, may be located in the linker region between spools immediately adjacent to the spool. The DNA and histones make up the nucleosome. (From Calladine CR, Drew HR. Understanding DNA: The Molecule and How It Works, 2nd Ed. New York: Academic Press, 1997; with permission.)

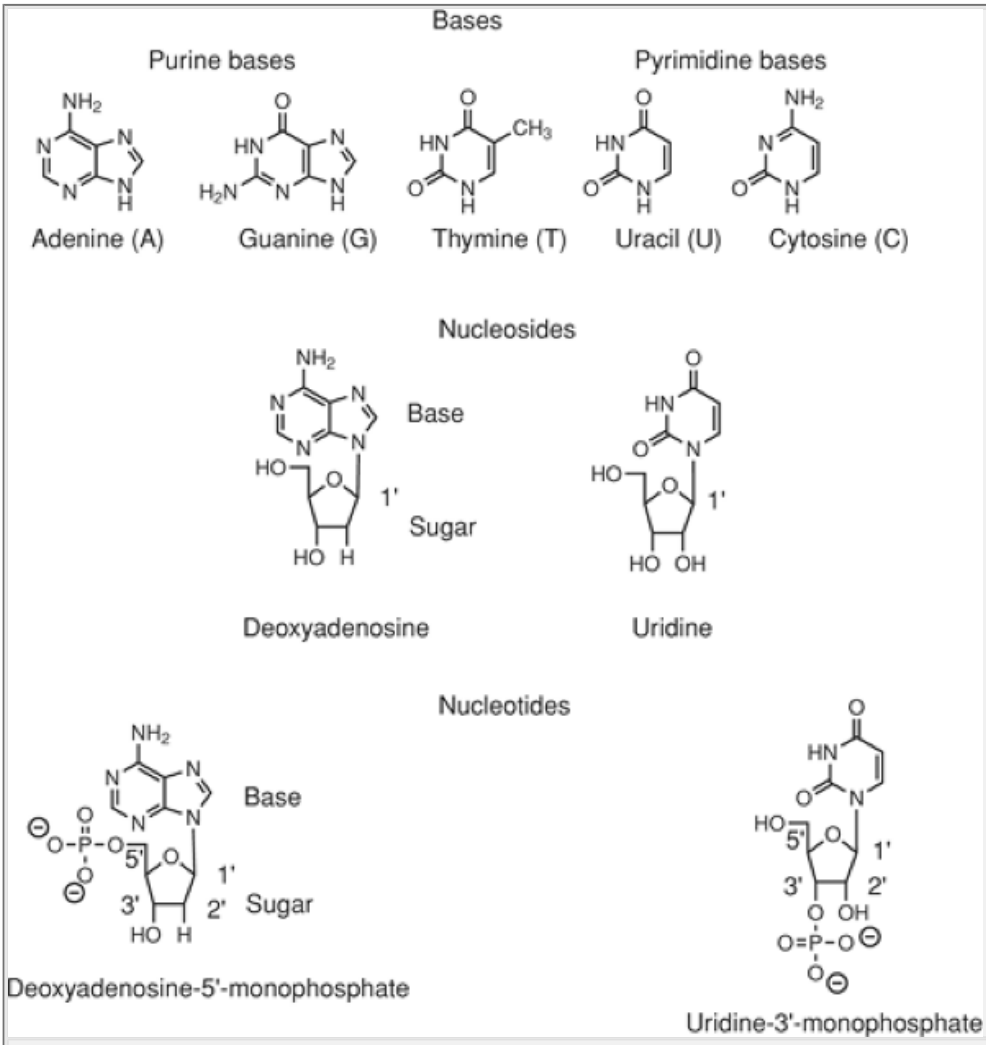

Fig. 6.4. Chemical structure of the purines and pyrimidine bases as well as representative nucleosides and nucleotides.

The structure of deoxyribonucleic acid was determined in 1953 by Watson and Crick to consist of two antiparallel strands of deoxyribonucleic acid coiled around a common axis in a “double helix” (Fig. 6.6). The purine and pyrimidine bases are on the inside of the helix, whereas the phosphate and deoxyribose units are on the outside. The planes of the bases are perpendicular to the axis of the helix. The planes of the sugars are at approximately 70° to those of the bases. The helix diameter is 20 Å; adjacent bases are separated by 3.4 Å along the

helical axis and related by a rotation of 36°. Hence, the helical structure repeats after 10 residues on each chain—that is, at intervals of 34 Å along the axis. The two chains are held together by hydrogen bonds between base pairs. Adenine is always paired with thymine, and guanine is always paired with cytosine, thus providing a specific interaction between the two DNA strands such that the nucleotide sequence of the strand can be exploited as a method of transmitting information (i.e., the amino acid sequence coded for by the nucleotide sequence in the nucleic acid).

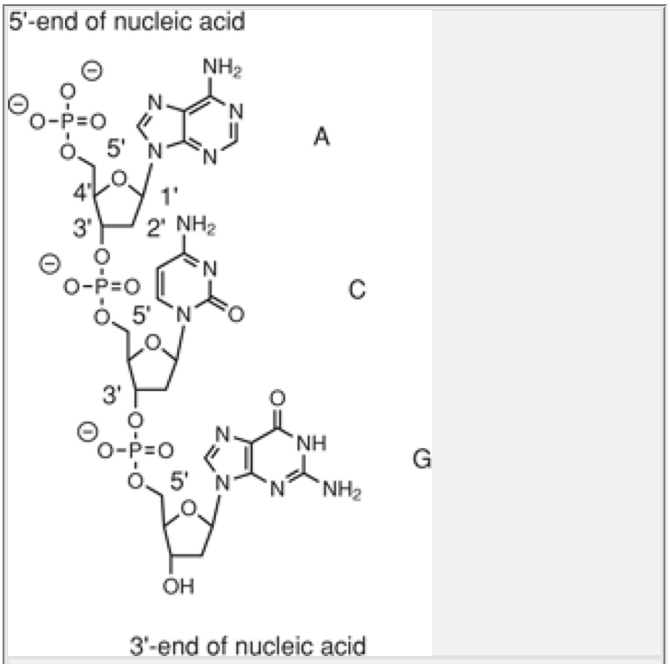

Fig. 6.5. Chemical structure of a DNA fragment ACG.

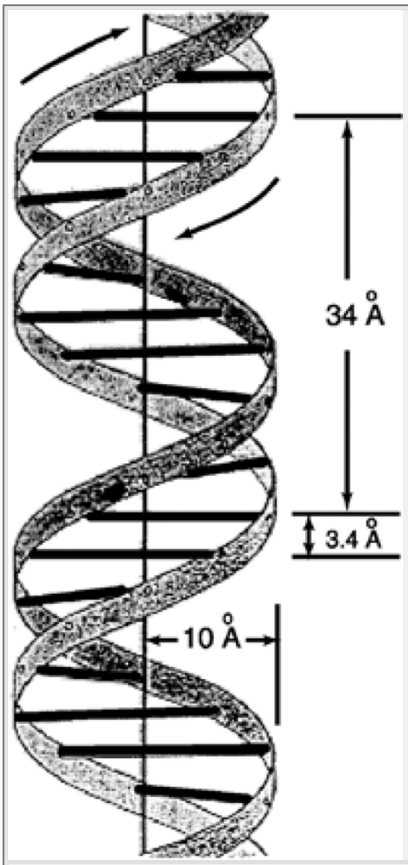

Fig. 6.6. Schematic representation of the Watson and Crick double helix model of DNA. The radius of the double helix is 10 Å, the vertical rise per base pair is 3.4 Å, and one complete turn of the double helix traverses 10 base pairs of 34 Å.

The double helix stability is determined by a longitudinal interaction of neighboring bases, called base stacking, which results from complex interactions of π-electron orbitals of the planar bases, dipole, dipole-induced dipole, London dispersion forces, and hydrophobic interactions. The stability of base stacking is of the order purine-purine > purine-pyrimidine > pyrimidine-pyrimidine. The G/C pairs are more stable than A/T pairs, because they have three hydrogen bonds as opposed to two (Fig. 6.7). Therefore, stacked dimers high in G/C content are energetically preferred to those rich in A/T content (13).

Nucleic acids are water soluble because of the polyanionic character of the molecule. It is possible to obtain viscous aqueous solutions of DNA up to 1% (w/v). The long, thin DNA structure means that the molecule is very susceptible to cleavage by shearing or sonication in solution, which results in a reduction in solution viscosity. The nucleic acids are precipitated from aqueous solution by the addition of alcohol.

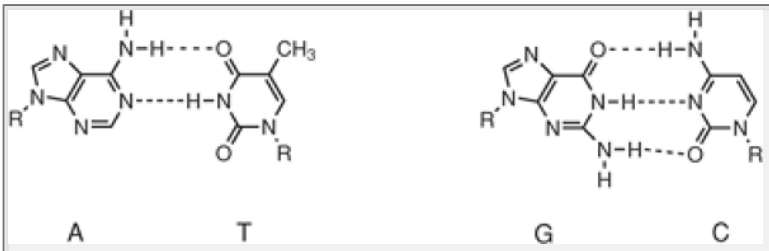

Fig. 6.7. Watson and Crick base pairing in double-stranded DNA. The purine A pairs with the pyrimidine T, and the purine G pairs with the pyrimide C.

Strong acid at high temperatures will result in complete hydrolysis of nucleic acids into their constituent bases, sugars, and phosphate. Milder acidic conditions (pH 3–4) at 37°C will result in hydrolysis of the most susceptible bonds, those being the glycosyl bonds linking the purine bases, A and G, to the sugar molecules, resulting in depurination of the nucleic acid. Depyrimidation is less frequently seen but also may occur.

Heterocyclic molecules containing nitrogen tautomerize to yield a mixture of molecular species in solution, because the hydrogens attached to nitrogen in the ring systems are able to migrate to other nitrogens or keto oxygens in the same molecule (Fig. 6.8).

Because correct base pairing is critical to information transfer in the replication, transcription, and translation of DNA structure, base tautomerization could be a disaster for living systems. Fortunately, the keto and amine structures are the predominant tautomeric structures, with less than 0.1% in the imino and enol tautomeric states. Increasing pH of the nucleic acid environment, however, will shift the keto/enol tautomeric equilibrium to the enol form due to ionization of the enolic hydroxyl group, with the net result being disruption of the hydrogen bonding in DNA and denaturation of the double-stranded molecule. The double helix structure of DNA also can be denatured through heat or relatively high concentrations of chemical agents, such as urea and formamide, that also disrupt the critical hydrogen bond system.

Helical regions of RNA are similarly denatured by alkali; however, hydrolysis of RNA is the predominant reaction occurring in alkali. The hydrolysis is assisted by the 2′-OH group on the ribose sugar (Fig. 6.9). The DNA is not as susceptible to the alkaline hydrolysis, because the 2′-OH group is missing.

The spectroscopic properties of DNA provide a wealth of information concerning concentration, structure, stability, and purity of a particular DNA preparation. Nucleic acids absorb ultraviolet (UV) light at λ_{max} = 260 nm because of the conjugated aromatic ring systems of the bases. The absorption intensity is greatest for single-stranded DNA (ssDNA) and RNA and least for double-stranded DNA (dsDNA) (Fig. 6.10). The hydrophobic environment of the stacked bases in dsDNA is responsible

for the lower intensity of UV absorption of this molecule at 260 nm. The ssDNA is said to be hyperchromic relative to dsDNA; thus, dsDNA undergoes a hyperchromic shift during denaturation to ssDNA.

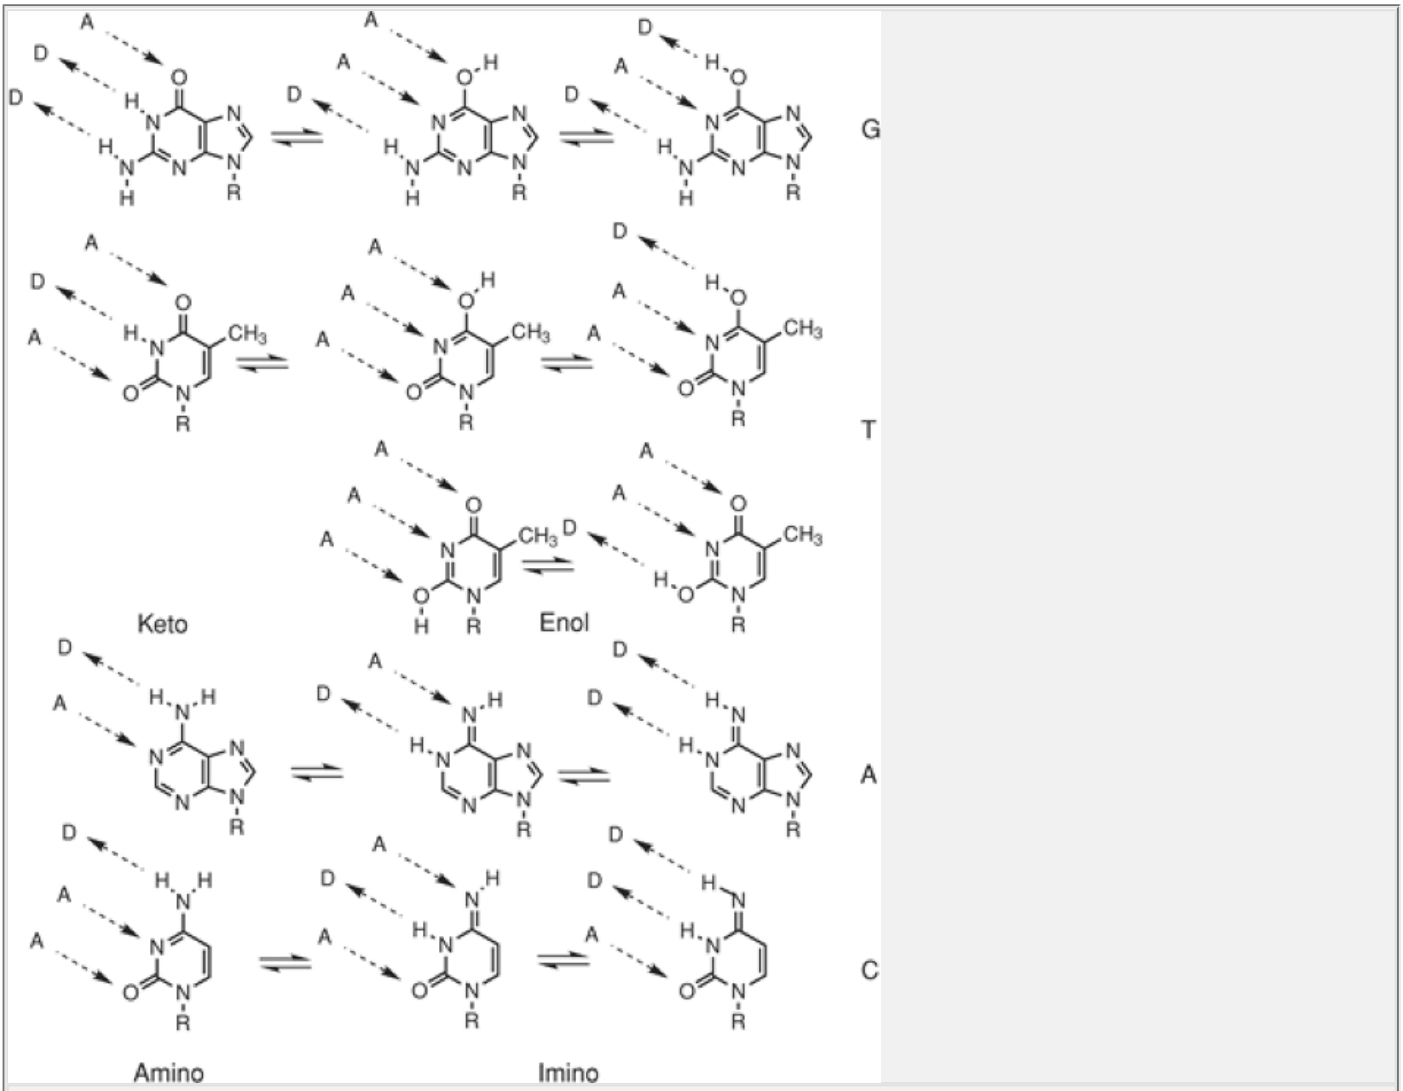

Fig. 6.8. Keto-enol and amino-imino tautomerism in nucleoside bases. Arrows denote A and D, which symbolize acceptor and donor sites for hydrogen bond formation. Note that in the enol forms, G becomes equivalent to A, and U becomes equivalent to C. In the imino forms, A is equivalent to U or G, and C is equivalent to U. The situation changes if the imino or enol groups rotate, giving rise to a diversity of hydrogen-bonding possibilities.

The extinction coefficient of a nucleic acid is not suitable for determination of the concentration of the nucleic acid, because it is dependent on the length of the molecule. The extinction coefficient is instead expressed in terms of concentration, where a 1 mg/ml solution of dsDNA has an A_{260nm} (absorbance at 260 nm) of 20. Similar concentrations of ssDNA or RNA have an A_{260nm} of approximately 25. This value is approximate for ssDNA and RNA, both because the absorbance of purines is greater than pyrimidines at 260 nm and because the ratio of purines to pyrimidines in ssDNA and RNA will vary (whereas the same ratio is one in dsDNA). Additionally, the A_{260nm} is dependent on base stacking, which also is variable in ssDNA and RNA but constant in dsDNA.

The spectroscopic properties of a DNA solution can be used to determine the approximate purity of the preparation as well. Because the shape and λ_{max} of the UV absorption spectra will vary depending on the environment of the bases, one can use the ratio of A_{260nm}/A_{280nm} to estimate the RNA and protein content of a dsDNA preparation. Pure dsDNA has a ratio of 1.8, and pure RNA has a ratio of 2.0. Because protein has a λ_{max} of around 280 nm, the A_{260nm}/A_{280nm} of a protein solution will always be less than one. Therefore, a sample of dsDNA with a A_{260nm}/A_{280nm} greater than 1.8 suggests RNA contamination, whereas a ratio less than 1.8 suggests protein contamination.

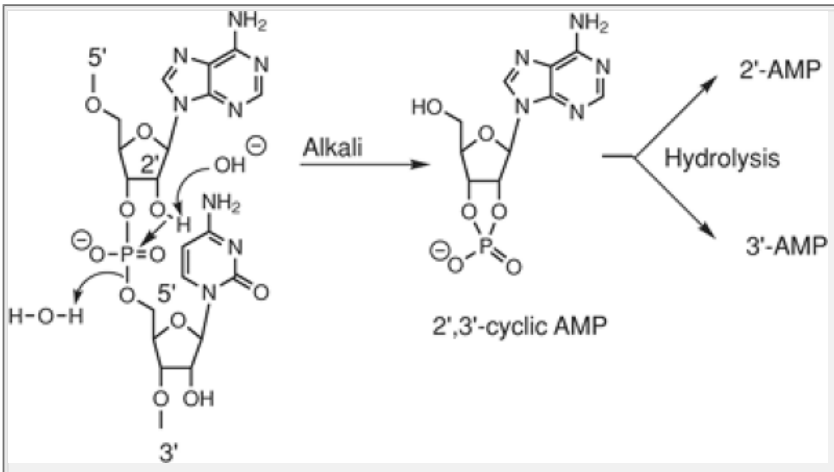

Fig. 6.9. Alkaline hydrolysis of RNA to produce the intermediate 2′, 3′-cyclic nucleotide monophosphate which undergoes further hydrolysis to 2′ and 3′ nucleotide monophosphates.

The stability of dsDNA can be determined through a temperature denaturation study. Native dsDNA will denature to ssDNA as the temperature of the solution is increased. This is a reversible process, and the ssDNA will anneal to dsDNA on slowly cooling the denatured solution. This behavior can be followed spectroscopically (Fig. 6.11) by noting the increase in A_{260nm} with temperature, indicating the hyperchromic shift as the dsDNA denatures to ssDNA. The midpoint of the sigmoid curve is termed the "melting temperature" of the dsDNA (T_m). Stability of different dsDNA molecules can be demonstrated by comparing the T_m values of the solutions (Fig. 6.11).

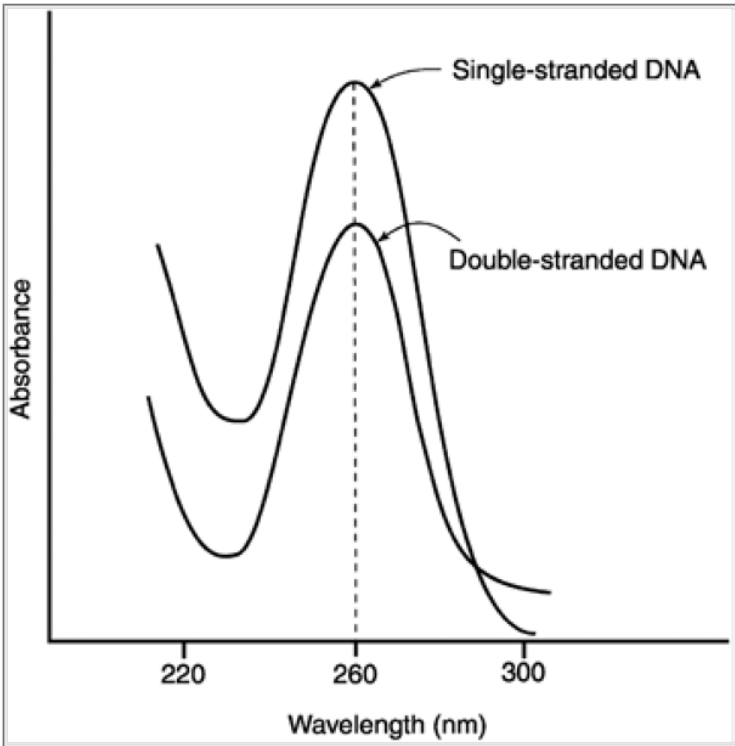

Fig. 6.10. Hyperchromic shift between double-stranded and single-stranded DNA. Single-stranded DNA has a higher ultraviolet absorbance at 260 nm than does double-stranded DNA.

Replication

Replication of prokaryotic and eukaryotic DNA proceeds from the origin (single origins in prokaryotes and multiple origins in eukaryotes), which is a region

high in A and T residues that make opening of the double helix easier because of fewer base-pairing hydrogen bonds

between A/T compared to G/C. Because each strand of the DNA carries the same information, replication produces two daughter strands built from the parent strands acting as templates.

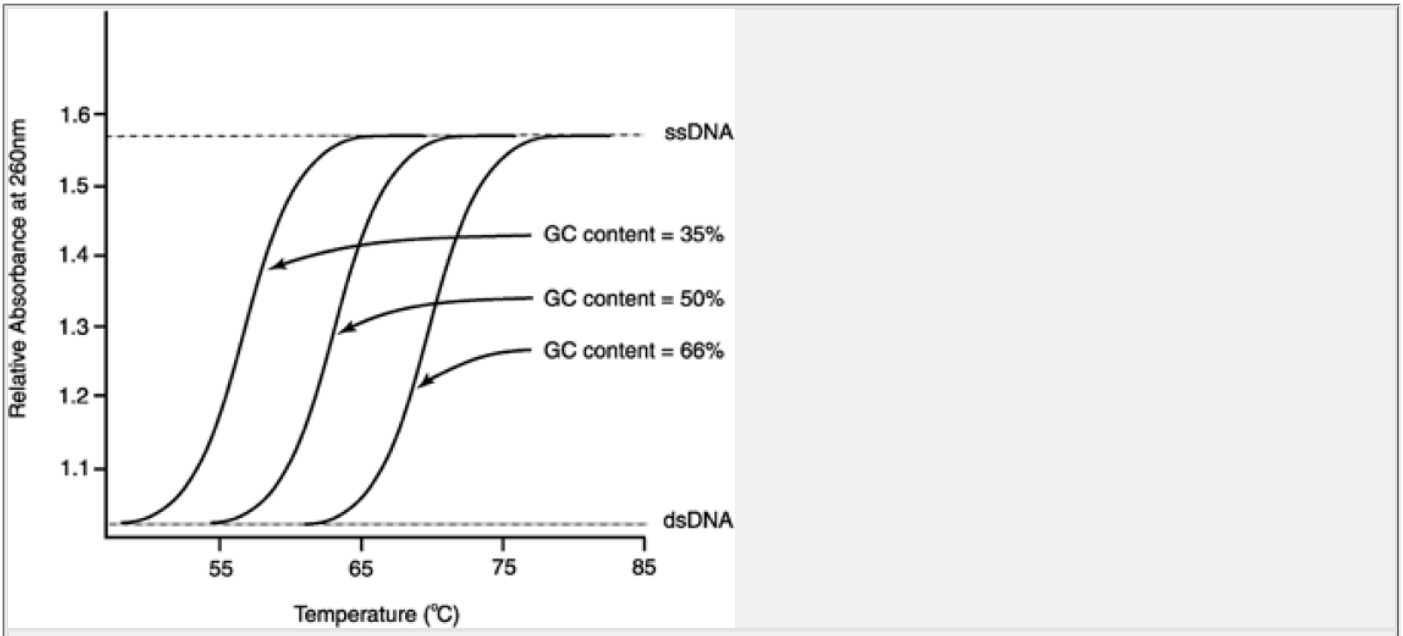

Fig. 6.11. Stability of double-stranded DNA (dsDNA) based on the GC content of the nucleic acid. The melting temperature is detected by a hyperchromic shift that occurs during the temperature-induced melting of dsDNA to single-stranded DNA and is shown to increase as the GC content of dsDNA increases.

The process of replication takes place at the replication fork, where the parent strands are unwound and the daughter strands are synthesized in the 5′ → 3′ direction (reading the parent template in the 3′ → 5′ direction) (Fig. 6.12). Both daughter strands are synthesized at the same time. One is synthesized as a continuous strand called the leading strand. The other, called the lagging strand, must be made in the reverse direction to the leading strand starting at the replicating fork and proceeding 5′ → 3′ back to the origin, resulting in the necessity of synthesizing blocks of nucleic acids (100–200 nucleotides in eukaryotes and 1,000–2,000 nucleotides in prokaryotes) known as Okazaki fragments. These fragments are subsequently joined into a continuous daughter strand by a DNA ligase. The DNA polymerase responsible for adding deoxynucleoside triphosphates to the growing strands requires short strands of nucleic acids as primers to start the synthetic process. These primer fragments are short RNA strands that are replaced with DNA by a proofreading exonuclease associated with the polymerase. The use of RNA primers assures the fidelity of DNA replication at the 5′ end of the newly synthesized strands, because the increased mobility of the “unanchored” base at the 5′ end of a DNA strand can never appear as a “correct” residue and, therefore, cannot be proofread. A short RNA strand, however, is recognized as low-fidelity material and replaced with DNA. The polymerases responsible for DNA replication are different in prokaryotes and eukaryotes. The DNA polymerase (pol) III synthesizes both the leading and lagging strands in prokaryotes but DNA pol I replaces the RNA primers in the lagging strand with DNA. Eukaryotic polymerases are more complex. The DNA pol α starts both the lagging and leading strands in eukaryotes but is replaced by DNA pol δ on the leading strand and DNA pol ε on the lagging strand.

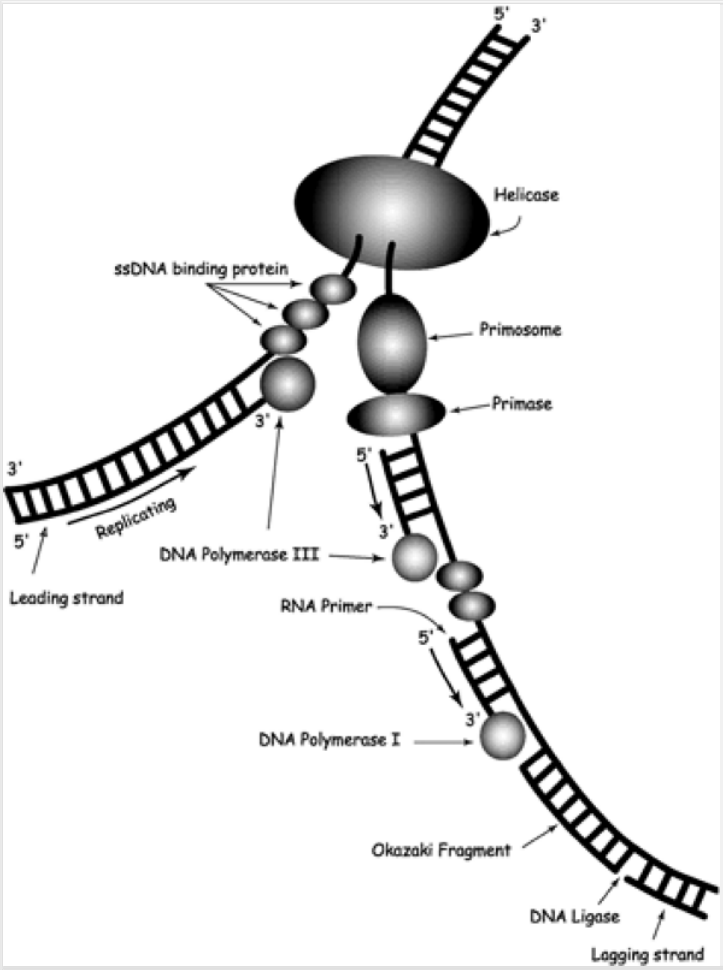

Fig. 6.12. Schematic representation of DNA replication. Helicase is responsible for unwinding the double-stranded DNA, and the single-stranded DNA is stabilized by single-stranded DNA–binding proteins. The leading strand is synthesized continuously by DNA polymerase III. A primase responsible for making the RNA primers that are used by DNA polymerase III to synthesize the initial fragments in the lagging strand, which are then elongated by DNA polymerase I to make the Okazaki fragments that are finally ligated by DNA ligase to complete the lagging strand. Transcription

It is impossible for DNA to act as a direct template in the ordering of amino acids in protein synthesis, because almost all DNA is located in the nucleus and protein synthesis occurs in the cytoplasm. The genetic information in DNA is transcribed to the intermediate RNA molecule that moves to the cytoplasm, where it directs the synthesis of the gene product on the ribosomes. The RNA differs chemically from the DNA in that the sugar molecule is ribose and thymine in DNA is replaced by uracil in RNA. Structurally, RNA is predominantly a single-stranded molecule with short, double helical regions providing some three-dimensional structure.

There are several types of RNA molecules in the cell, three of which play major roles in the message transcription and protein synthesis. Messenger RNA (mRNA) is transcribed from a particular DNA sequence and carries the specific message from DNA in the nucleus to the cytoplasm. The molecule is very unstable, with a relatively short half-life of only a few minutes. Transfer RNAs (tRNAs) are relatively small molecules of approximately 80 nucleotides in length. These molecules are covalently linked to specific amino acids, and they carry the anticodon triplet that recognizes a particular complementary trinucleotide sequence of mRNA specific for the amino acid that it carries. The tRNA is involved in protein synthesis and is metabolically unstable, being degraded once it has transferred its amino acid to the growing protein chain. Ribosomal RNA (rRNA) is a metabolically stable complex of ribonucleic acids and proteins. The rRNA provides the site of mRNA and tRNA interaction at which proteins are synthesized in the cytoplasm. Although several differences exist in the mechanism of transcription

between prokaryotes and eukaryotes, the more complex eukaryotic system will be described here.

Transcription is carried out by RNA polymerases, of which there are three types in the eukaryote. RNA pol I catalyzes the synthesis of rRNAs, RNA pol II is responsible for the synthesis of mRNA, and RNA pol III synthesizes tRNA. All three polymerases are large enzymes containing 12 or more subunits.

Like prokaryotic RNA polymerase, each eukaryotic enzyme copies DNA from the 3′ end, thus catalyzing mRNA formation in the 5′ ⇒ 3′ direction and synthesizing RNA complementary to the antisense DNA template strand. The reaction requires the precursor nucleotides ATP, GTP, CTP, and UTP and does not require a primer for transcription initiation. Unlike the prokaryotic bacterial polymerases, the eukaryotic RNA polymerases require the presence of additional initiation proteins before they are able to bind to promoters and initiate transcription. The five stages of eukaryotic transcription include initiation, elongation and termination, capping, polyadenylation, and splicing.

Initiation

Eukaryotes have different RNA polymerase–binding promoter sequences than prokaryotes. The TATA consensus sequence of the eukaryotic promoter region is located 25 to 35 bp upstream from the transcription start site (Fig. 6.13). The low activity of basal promoters is greatly increased by the presence of other elements located upstream from the promoter called upstream regulatory elements. These elements are located 40 to 200 bp upstream of the promoter sequence and include the SP1 box, the CCAAT box, and the hormone response elements. Transcription from many eukaryotic promoters can be stimulated by control elements, called enhancers, located many thousands of base pairs away from the transcription start site and usually 100 to 200 bp in length.

The length of DNA between the enhancer and the promoter region loops out to allow the transcription factors bound to the enhancer to interact with the general transcription factors, other regulatory proteins, or the RNA polymerase itself to bring about initiation of polymerization. The RNA pol II requires a number of other proteins or protein complexes, called general transcription factors, to initiate transcription (Fig. 6.14). All these have the generic name of TFII (for transcription factor for RNA pol II). The first event in initiation is binding of TFIID to the TATA box. The key subunit of TFIID is TBP (TATA box-binding protein). After TFIID binding, TFIIA binds, followed by TFIIB and then RNA pol II already complexed with TFIIF, followed in turn by TFIIE, TFIIH, and TFIIJ. This final complex contains at least 40 polypeptides and is called the transcription initiation complex.

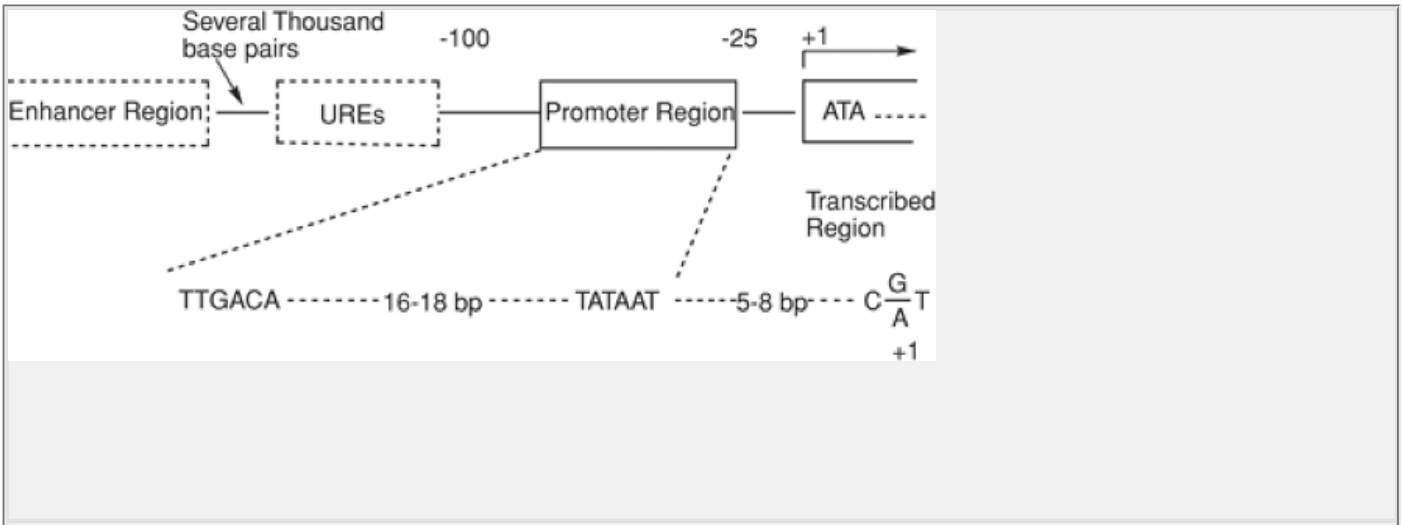

Fig. 6.13. Schematic representation of the eukaryotic transcription unit showing the relationship between the promoter, upstream regulatory elements, and enhancer region. Note that transcription usually starts with a purine base in the 1 position. (Adapted from Turner PC, McLennan AG, Bates AD, White MRH. Instant Notes in Molecular Biology. New York: BIOS Scientific Publishers Ltd, Springer-Verlag, 1997; with permission.)

Elongation and termination

The RNA polymerase moves along the DNA template until a terminator sequence is reached. The RNA pol II does not terminate at specific sites but, rather, stops at varying distances downstream of the gene. Eukaryotic termination of transcription is not as well understood as that of prokaryotic transcription. The RNA molecule made from a protein-coding gene by RNA pol II in eukaryotes is called pre-mRNA. The pre-mRNA from a eukaryotic protein-coding gene is extensively processed en route to creating mRNA ready for translation.

Capping

At the end of polymerization, the 5′ end of the pre-mRNA molecule is modified by addition of a N-7-methyl guanine molecule (Fig. 6.15). The 5′ terminal phosphate is removed by a phosphatase, and the resulting diphosphate 5′ end reacts with the α-phosphate of GTP to form an unusual 5′,5′-triphosphate link (Cap 0). The 5′-cap also may be methylated by S-adenosylmethionine on the 2′-OH of the ribose sugar of the adjacent nucleotide (Cap 1) or on both ribose sugars in the 2 and 3 positions (Cap 2) (Fig. 6.15). This cap structure protects the 5′ end of the primary transcript against attack by ribonucleases

that have specificity for 3′,5′-phosphodiester bonds and so cannot hydrolyze the 5′,5′ bond in the cap structure. The cap structure also plays a role in the initiation step of protein synthesis in eukaryotes. Only RNA transcripts from eukaryotic protein-coding genes become capped; prokaryotic mRNA and eukaryotic rRNA and tRNA are uncapped.

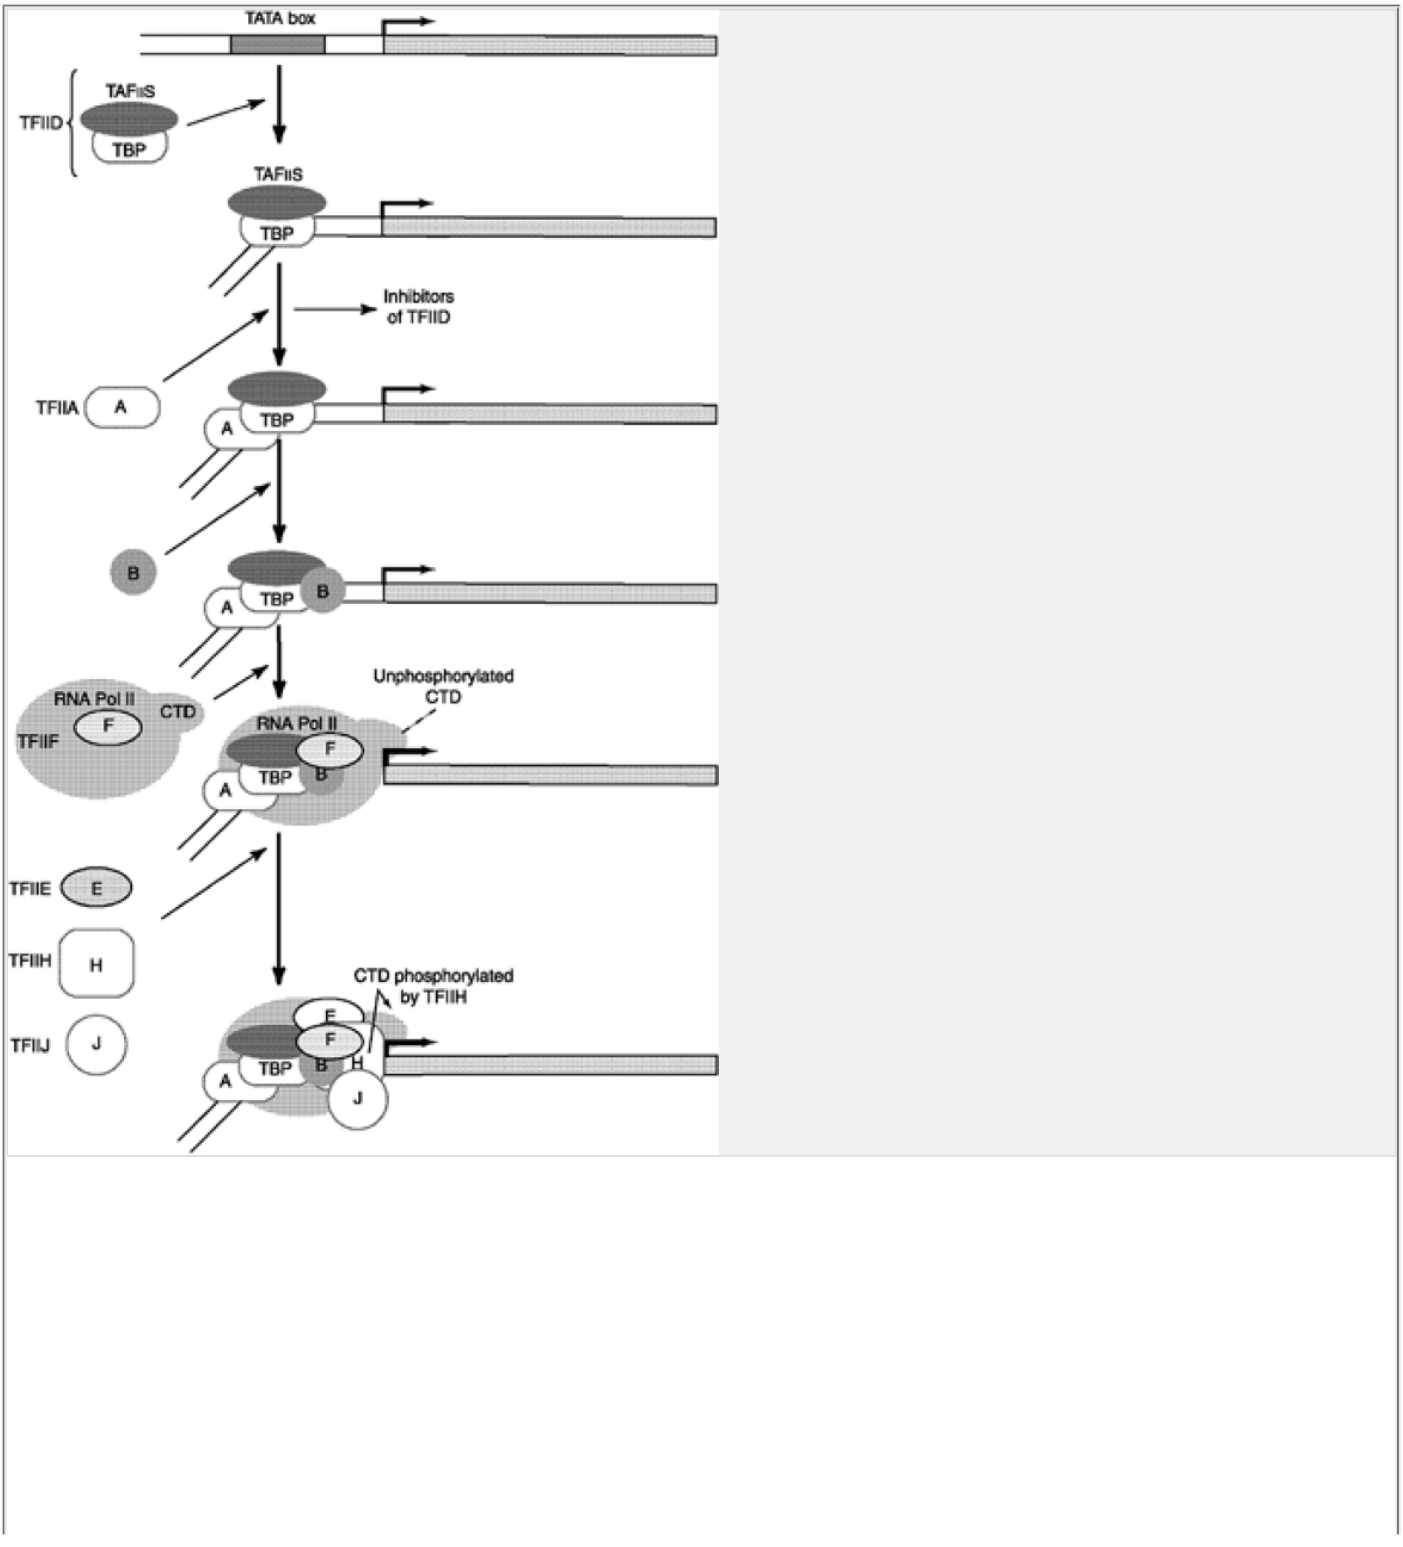

Fig. 6.14. Schematic representation of the assembly of the RNA polymerase II transcription initiation complex at a TATA box promoter. The transcription factors are labeled TFIIA, TFIIB, TFIIE, TFIIF, TFIIH, and TFIIJ. The TFIID is a complex of TATA-binding protein (TBP) and multiple accessory factors called TBP-associated factors of TFIIA. The TFIID binds to the TATA box, and this binding is enhanced by TFIIA, which appears to stop some inhibitory factors from binding to TFIID, thus preventing further assembly of the complex. The TFIIB binds to the complex and acts as a bridge for binding the RNA polymerase, which attaches itself to the complex along with TFIIF. When RNA polymerase II binding occurs, the transcription factors TFIIE, TFIIH and TFIIJ, which are required for transcription, bind in a defined sequence. The carboxyl-terminal domain (CTD) of RNA polymerase II is phosphorylated by TFIIH, thus allowing the polymerase to leave the promoter region. (Adapted from Turner PC, McLennan AG, Bates AD, White MRH. Instant Notes in Molecular Biology. New York: BIOS Scientific Publishers Ltd, Springer-Verlag, 1997; with permission.)

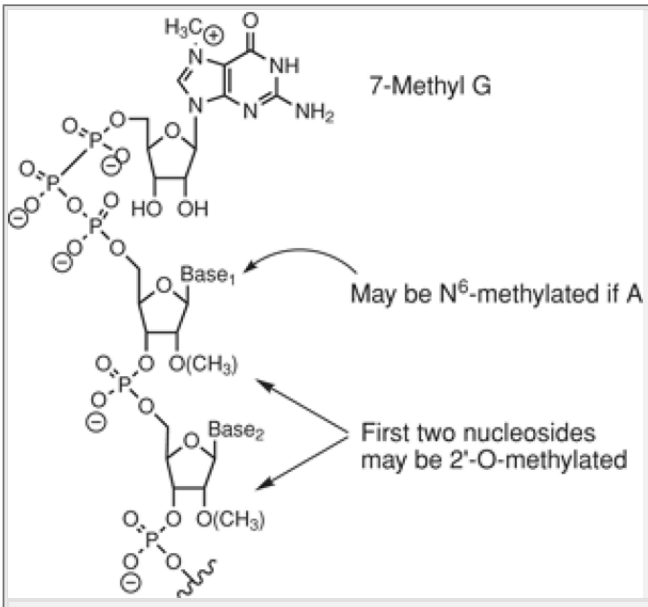

Fig. 6.15. Chemical structure of the 5′-cap of mRNA. Cap 0 consists of the 7-methylguanosine triphosphate attached to the 5′ end of the mRNA. Cap 1 consists of the 7-methylguanosine and 2′-O-methylation of the 5′ base. Cap 2 consists of the 7-methylguanosine and the 2′-O-methylation of the first two bases in the sequence.

Polyadenylation

The 3′ end of the pre-mRNA is generated by cleavage by nucleases followed by the addition of a run, or tail, of 100 to 200 adenosine nucleotides, resulting in what is called the poly(A) tail. Cleavage and polyadenylation require specific sequences in the DNA and its pre-mRNA transcript that are part of the transcription termination signal (Fig. 6.16). A 5′-AAUAAA-3′ sequence followed by a 5′-PyA-3′ (Py = pyrmidine) within the next 11 to 20 nucleotides and a GU-rich sequence further downstream collectively make up the requirements for a polyadenylation site. The poly(A) tail is thought to help stabilize the molecule, because a poly(A)-binding protein interacts with the tail, reducing the pre-mRNA's sensitivity to 3′-nuclease activity. In addition, the poly(A) tail may have a role to play in the translation of mature RNA in the cytoplasm.

Splicing

The next step in pre-mRNA processing is the precise cutting out of the intron sequences and joining the ends of neighboring exons to produce a functional mRNA molecule, a process termed “RNA splicing.” The exon–intron boundaries are marked by specific sequences. Introns are sequences that interrupt those sequences that will eventually become adjacent regions in mature RNA. Exons become the protein-coding regions of mRNA. The exon–intron boundary at the 5′ splice site always starts the intron with a GU sequence (Fig. 6.17a). The boundary at the 3′ splice site always ends the intron with an AG sequence. Each sequence at

the 5′ and 3′ splice sites lie within a larger consensus sequence. The intron also has a stretch of 10 pyrimidines near the 3′ splice site and an internal branch site containing an important adenosine residue located approximately 20 to 50 nucleotides upstream of the 3′ splice site. Splicing takes place in a two-step reaction (Fig. 6.17b). First, the bond in front of the G at the 5′ splice site is attacked by the 2′ hydroxyl group of the A residue at the branch point sequence, creating a tailed, circular molecule called the lariat and a free exon. In the second step, cleavage of the 3′ splice site occurs after G of the AG sequence as the two exons are joined together.

Translation

Protein synthesis occurs when the triplet genetic code carried by mRNA is translated into a protein sequence on the ribosome. As mentioned earlier, tRNA carries a specific amino acid attached to its 3′ terminus based on the anticodon present in its structure. The anticodon complements the triplet codon sequence in mRNA. A triplet is the minimum number of nucleotides necessary to provide a unique sequence for each of the 20 amino acids. With a triplet code, there is a possibility of 64 different combinations, of which 61 actually code for amino acids (Table 6.1). The remaining three codons are nonsense or stop codons. Eighteen of the 20 common amino acids are coded for by more than one codon, meaning the code is degenerate or redundant. Two amino acids, Met (AUG) and Trp (UGG), each have one unique codon. From a fixed start point on the mRNA (start codon, AUG), which establishes the open reading frame, each group of three bases in the coding region of the mRNA represents a codon that is recognized by a complementary triplet on the end of a particular tRNA molecule. One triplet on an mRNA molecule is directly followed by the next one without any additional bases between them, indicating that the code is commaless and nonoverlapping. Because each triplet is independent of any other and there are no gaps between codons, any reading frame can be divided up in three ways. Once the start codon is found, the reading frame is fixed, and the protein sequence begins.

There are four stages in the protein synthesis in both prokaryotes and eukaryotes:

- *Initiation*—assembly of the ribosome on an mRNA molecule.
- *Elongation*—repeated cycles of amino acid addition.

Termination—recognition of the stop codon, release of the new protein chain, and breakdown of the synthetic complex.

- *Posttranslational modification*—usually include protein cleavage by carboxy or amino peptidases, and chemical modification such as acetylation, sulfonylation, phosphorylation, hydroxylation, and/or addition of polysaccharides.

Table 6.1. The Genetic Code

First Position	Second Position				Third Position

	Val	Ala	Glu	Gly	G
	GUG	GCG	GAG	GGG	

There are distinct differences in detail between the mechanism in prokaryotes and eukaryotes, most of which occur in the initiation stage.

Genes

Manipulation of genes is one of the major technologies in pharmaceutical biotechnology, so it is rather important to have an understanding of the techniques

used in gene manipulation. A gene is not equated with the gene product. We have seen how several changes may occur to the gene product during the production process, and the final product seldom corresponds to a direct decoding of a linear nucleic acid chain. A gene is defined as the segment of DNA involved in producing a polypeptide chain; it includes regions preceding (the leader or 5′-untranslated region) and following (the trailer or 3′-untranslated region) the coding region as well as intervening sequences (introns) between individual coding segments (exons) (14). The details of cell function that are attainable using the current tools of molecular biology will find exceptions to the above definition.

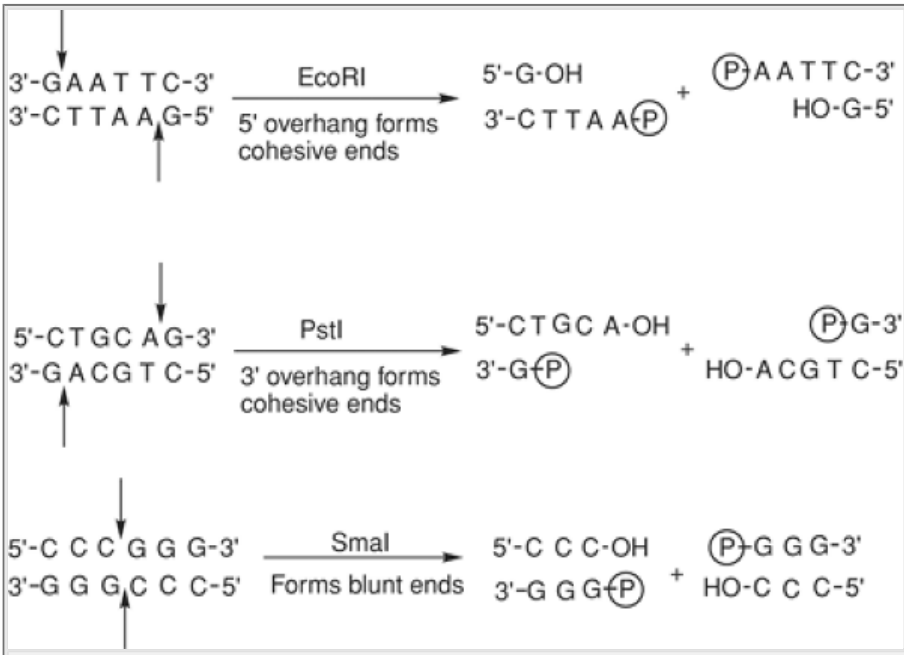

Fig. 6.18. Actions of restriction endonucleases *Eco*RI, *Pst*I, and *Sma*I at their recognition sequences. Note that *Eco*RI and *Pst*I enzymes produce “sticky ends,” with overlapping sequences, whereas *Sma*I produces “blunt ends,” or nonoverlapping sequences.

Cloning and the Preparation of DNA Libraries

Studies on the nature of DNA, genes and chromosomes ground to a near halt in the early 1960s, because DNA was just too large a molecule to work with and attempts to break it up into manageable pieces were thwarted by the inability to put the pieces back together in the correct order. The discovery in the early 1970s of bacterial enzymes capable of cleaving nucleic acids at specific, palindromic (symmetrical) base sequences was a major breakthrough in nucleic acid chemistry (Figs. 6.18 and 6.19). The second discovery in molecular biology that advanced genetic analysis was the use of bacterial plasmids as vehicles (vectors) to amplify gene fragments produced by restriction enzymes. Plasmids are small, circular, extrachromosomal nucleic acid molecules in bacteria that replicate independently within the bacterial cell. Restriction enzymes are used to produce relatively small DNA fragments that are inserted into bacterial plasmid vectors, forming recombinant DNA molecules (rDNA). The rDNA vectors are inserted into bacterial hosts, where the plasmid replicates with the bacteria, producing a large number of identical rDNA molecules known as clones, thus completing the process know as DNA cloning.

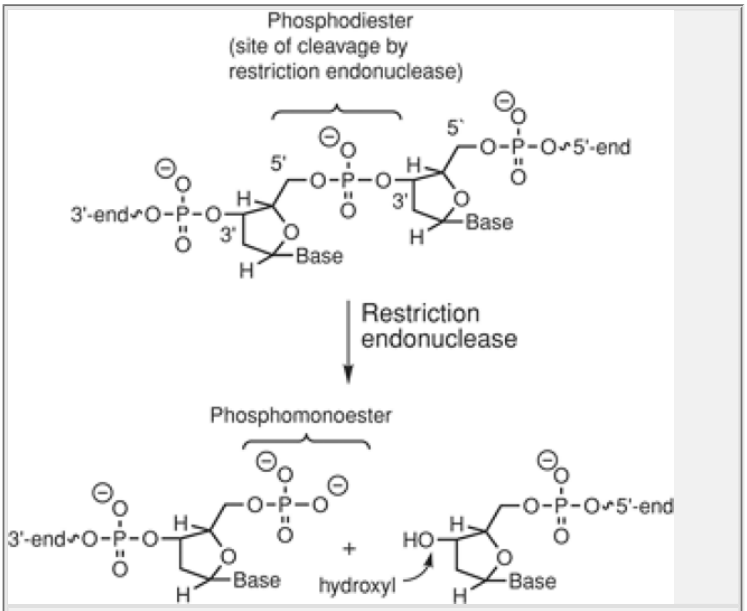

Fig. 6.19. Cleavage by restriction endonuclease.

Two sources of DNA are used to prepare fragments or libraries of DNA fragments. Genomic DNA isolated from the species of interest is digested with restriction enzymes, and the fragments are inserted into plasmids to produce a genomic DNA (gDNA) library. Alternatively, one can use mRNA fragments from restriction enzyme digests of mRNA from a cell or tissue and prepare DNA copies of the mRNA fragments using reverse transcription. The DNA fragment copies are complementary to the mRNA and are called complementary DNA (cDNA) fragments, thus producing a cDNA library. The two types of DNA libraries provide different genetic information. The gDNA library would have the gene regulatory sequences along with the introns in the gene coding sequence, whereas the cDNA would be missing these and other nontranscribed features of the gene sequence.

Finding a Gene in the Library

A well-prepared gene library has a high probability of containing a particular gene sequence. Library screening is

the process through which one or more clones containing the gene of interest can be identified (15). If one wishes to screen for a particular gene, sufficient knowledge of that gene sequence must be available to allow synthesis of oligonucleotide fragments complementary to the gene or parts of it. These fragments can be radiolabeled or fluorescently labeled and used as nucleic acid probes to screen the library by hybridization. Assuming the library was made by ligating the gene fragments to bacterial vectors and inserting the vectors into *Escherichia coli*, the library is spread on several agar plates, and the bacteria are allowed to grow to form colonies such that each colony arises from a single bacteria carrying a single vector with a single gene fragment (Fig. 6.20).

After the colonies have grown to a size visible to the naked eye, nitrocellulose filters are carefully laid onto the surface of the agar plates to make an exact replica of the plate by blotting up a small amount of each colony on the plate (Fig. 6.20). The bacteria on the filter are lysed by soaking the filter in sodium dodecyl sulfate and a protease. The DNA is denatured using alkali (NaOH), and the ssDNA is bonded to the filter by baking. The filter is then incubated in a solution of radiolabeled or fluorescently labeled nucleic acid probe complementary to a portion of the gene of interest and allowed to hybridize to the ssDNA on the filter. The filters are carefully washed to remove the nonspecifically bound probe, and the specifically bound probes are located on the filter by exposing the filter to x-ray film (autoradiography) or laser excitation (fluorescence). The bacterial colony that specifically bound the probe likely contains a fragment of the gene in question. This colony will show up on the autoradiogram as a dark spot or a fluorescent band, and its position on the original agar plate can be located by comparing the nitrocellulose filter to the agar plate. Once located, the colony can be picked off the original plate and grown in culture to provide a large sample of the bacteria carrying the vector with the gene fragment.

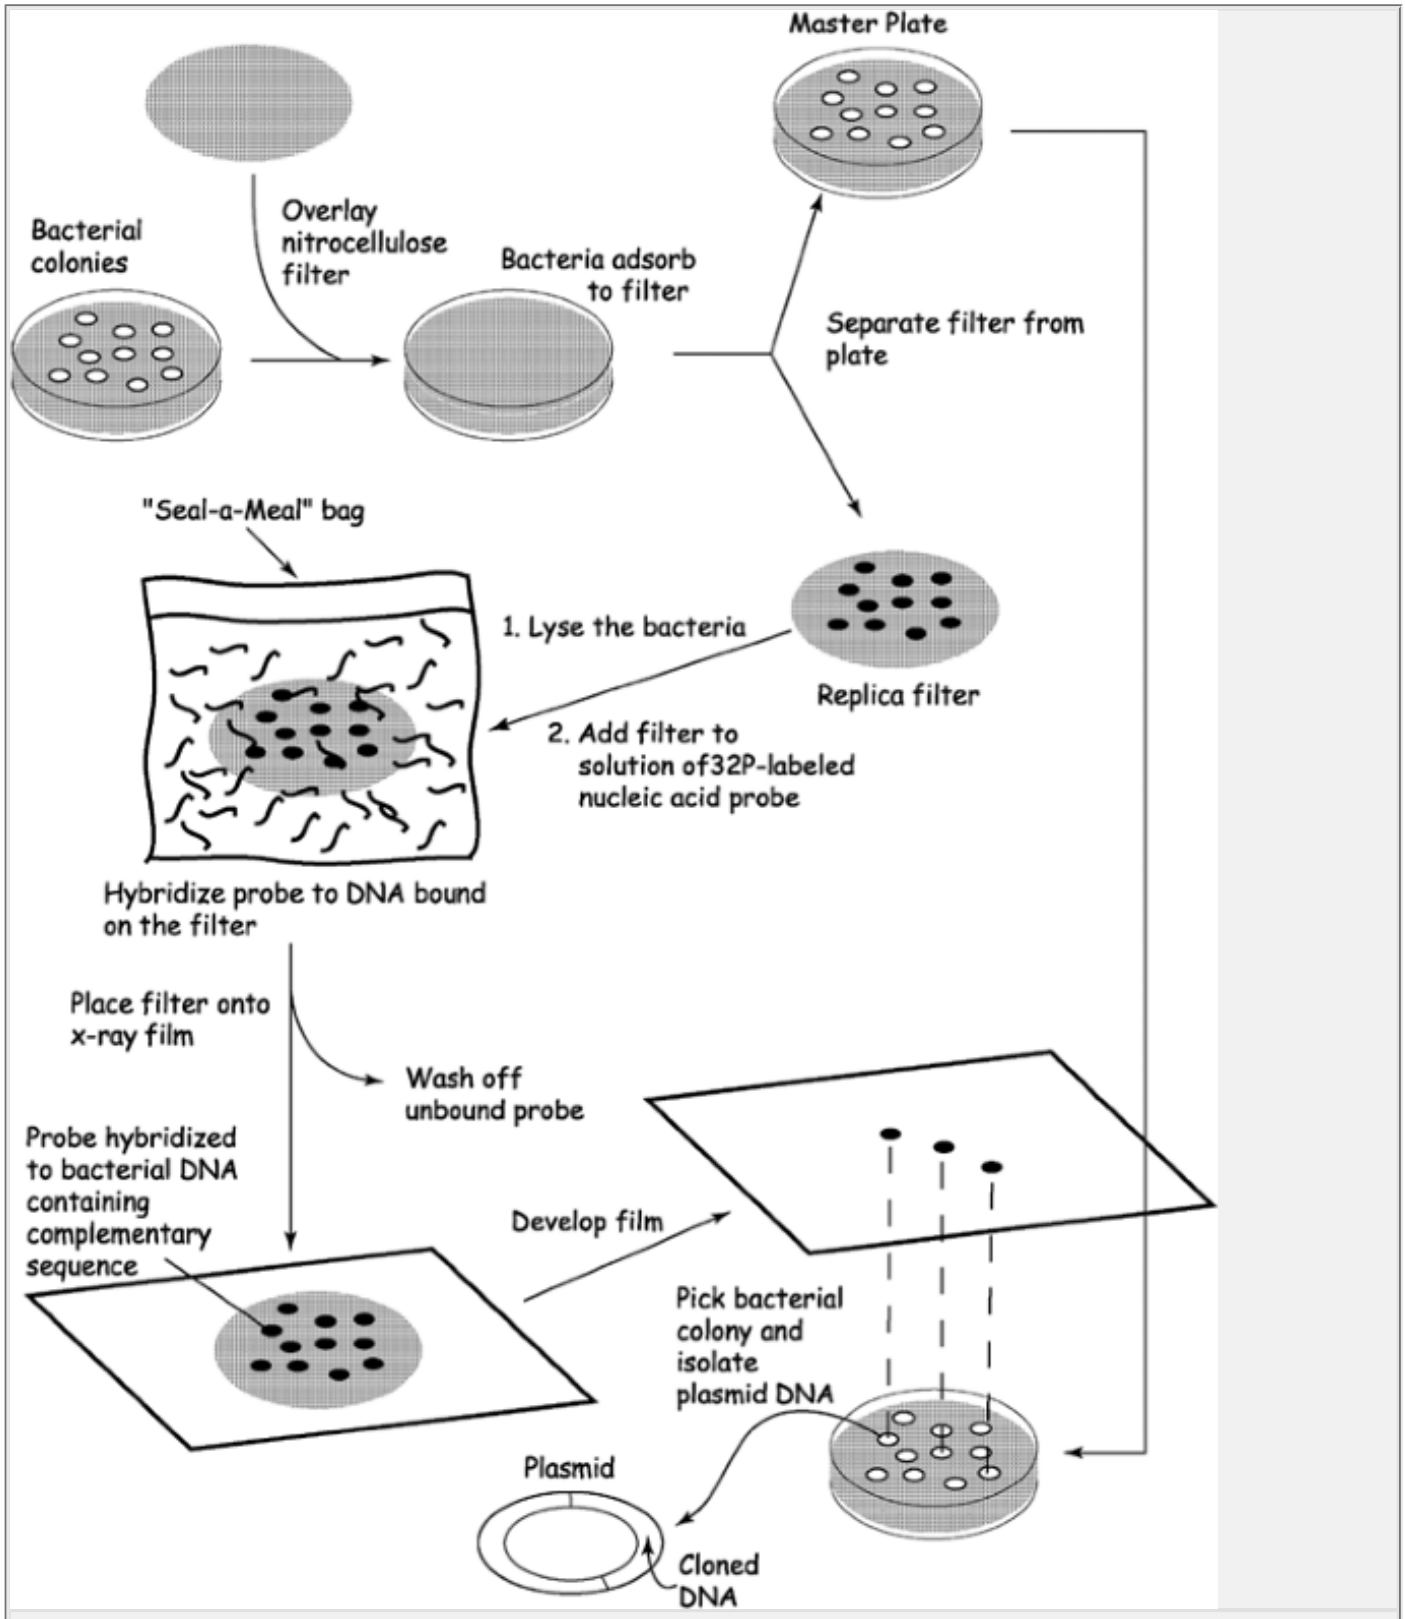

Fig. 6.20. Screening a library with a nucleic acid probe to find a clone of the pattern of bacterial colonies. (Adapted from Watson JD, Gilman M, Witkowski J, et al. Recombinant DNA, 2nd Ed. New York: Scientific American Books, W.H. Freeman and Company, 1992; with permission.)

Characterizing the Cloned Gene Fragment

Once the gene fragment has been cloned, the next step is characterization. Five techniques are critical to this characterization: size determination using agarose gel electrophoresis, restriction enzyme mapping to further reduce the size of the fragments, sequencing the fragments, synthesizing primers and

probes used in the amplification and identification of the fragments, and amplification of the fragments through the polymerase chain reaction (PCR).

Agarose Gel Electrophoresis

The size of DNA fragments generally is determined by agarose gel electrophoresis. The dsDNA samples are placed in wells in the surface of the gel in separate lanes, and when an electric current is applied to an agarose gel in the presence of a buffer that will conduct electricity, the dsDNA fragments will travel through the gel toward the anode (positive electrode) at a rate dependent on the size of the linear molecule. Small fragments will travel faster than larger fragments, separating the mixture of DNA fragments according to size. The fragments generally are viewed by staining the gel with ethidium bromide, a chemical that intercalates into dsDNA. The molecular weight of fragments may be roughly determined by running a standard sample of DNA fragments with known molecular weights in a lane on the same gel as the unknown fragments.

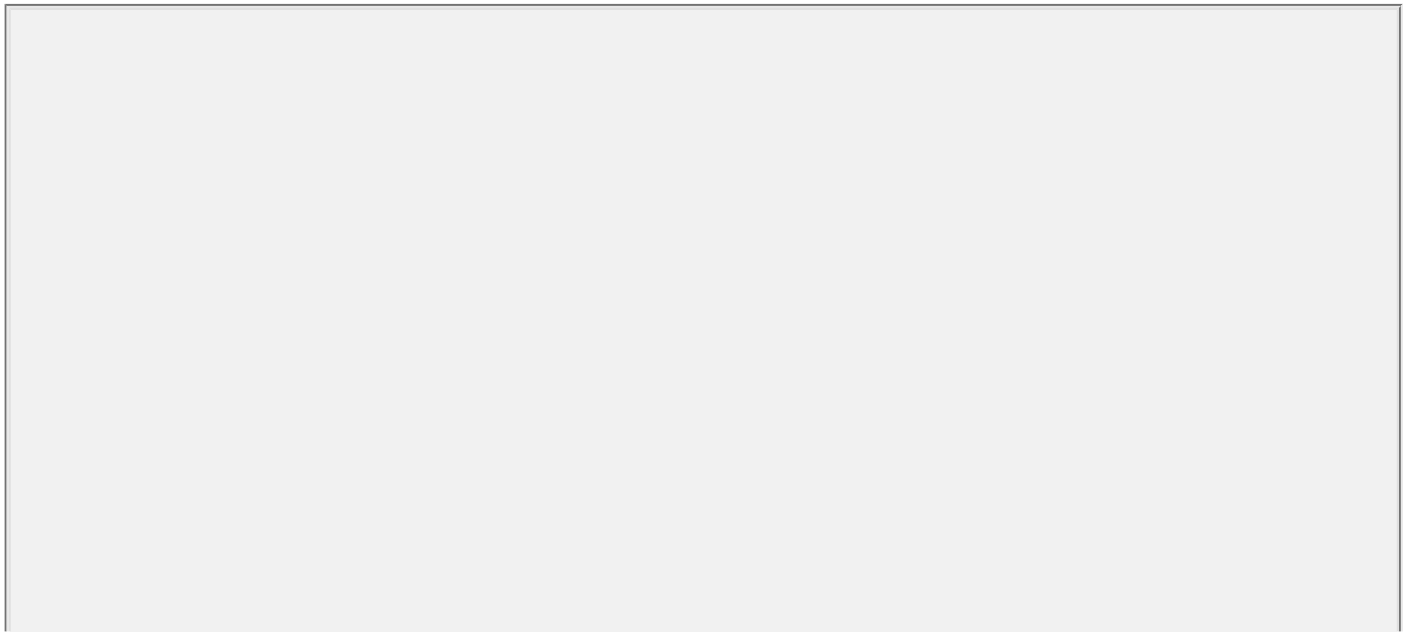
Restriction Mapping and Southern Blotting

A DNA fragment isolated by the cloning technique described above may be characterized further by restriction enzyme mapping. This procedure consists of isolating the DNA fragment from the cloning vector and digesting it with one or more restriction enzymes, then separating the fragments on gel electrophoresis and staining them with ethidium bromide.

The number and size of the restriction fragments provide valuable information about the original DNA fragment. The individual restriction fragments may be

extracted from the gels and the nucleotide sequence determined by Sanger's dideoxy method (see below) (16). When the nucleotide sequences of the restriction fragments are determined, overlapping fragments may be found and the fragments reassembled to determine the sequence of the original fragment. If examination of the sequence indicates the presence of a start and stop codon, an open reading frame exists in the sequence, and it is possible that the sequence codes for an expressed gene. Further studies are necessary, however, to determine if the sequence is expressed in the cell from which the original DNA fragment was isolated.

It also is possible to analyze DNA fragments by hybridization with particular radiolabeled or fluorescently labeled probes using a technique called Southern blotting (Fig. 6.21). The DNA solutions that have been digested with restriction enzymes are placed in wells at the top of the gel, and electrophoresis separates the fragments, which are then denatured with alkali and blotted onto nitrocellulose paper to make an exact replica of the gel. This is done by placing the agarose gel on a sponge in a tray of buffer. The nitrocellulose filter is placed over the gel and covered with a large stack of paper towels that act as a wick pulling the buffer through the gel and filter. The DNA fragments are carried from the gel to the filter, where they stick. The filter is removed and hybridized with a radioactively labeled probe that specifically tags the sequence of interest through hybridization. The stringency with which the hybridization and washing is carried out is critical and is determined by temperature and salt concentration in the hybridization buffer, with high temperature and low salt being the most stringent conditions. If the conditions are not too stringent, then the probe may bind to too many nonhomologous sequences to be useful. Unbound probe is removed by washing, and the filter is placed on an x-ray film, where the bound probe appears as a band. A similar technique using RNA fragments is called Northern blotting.



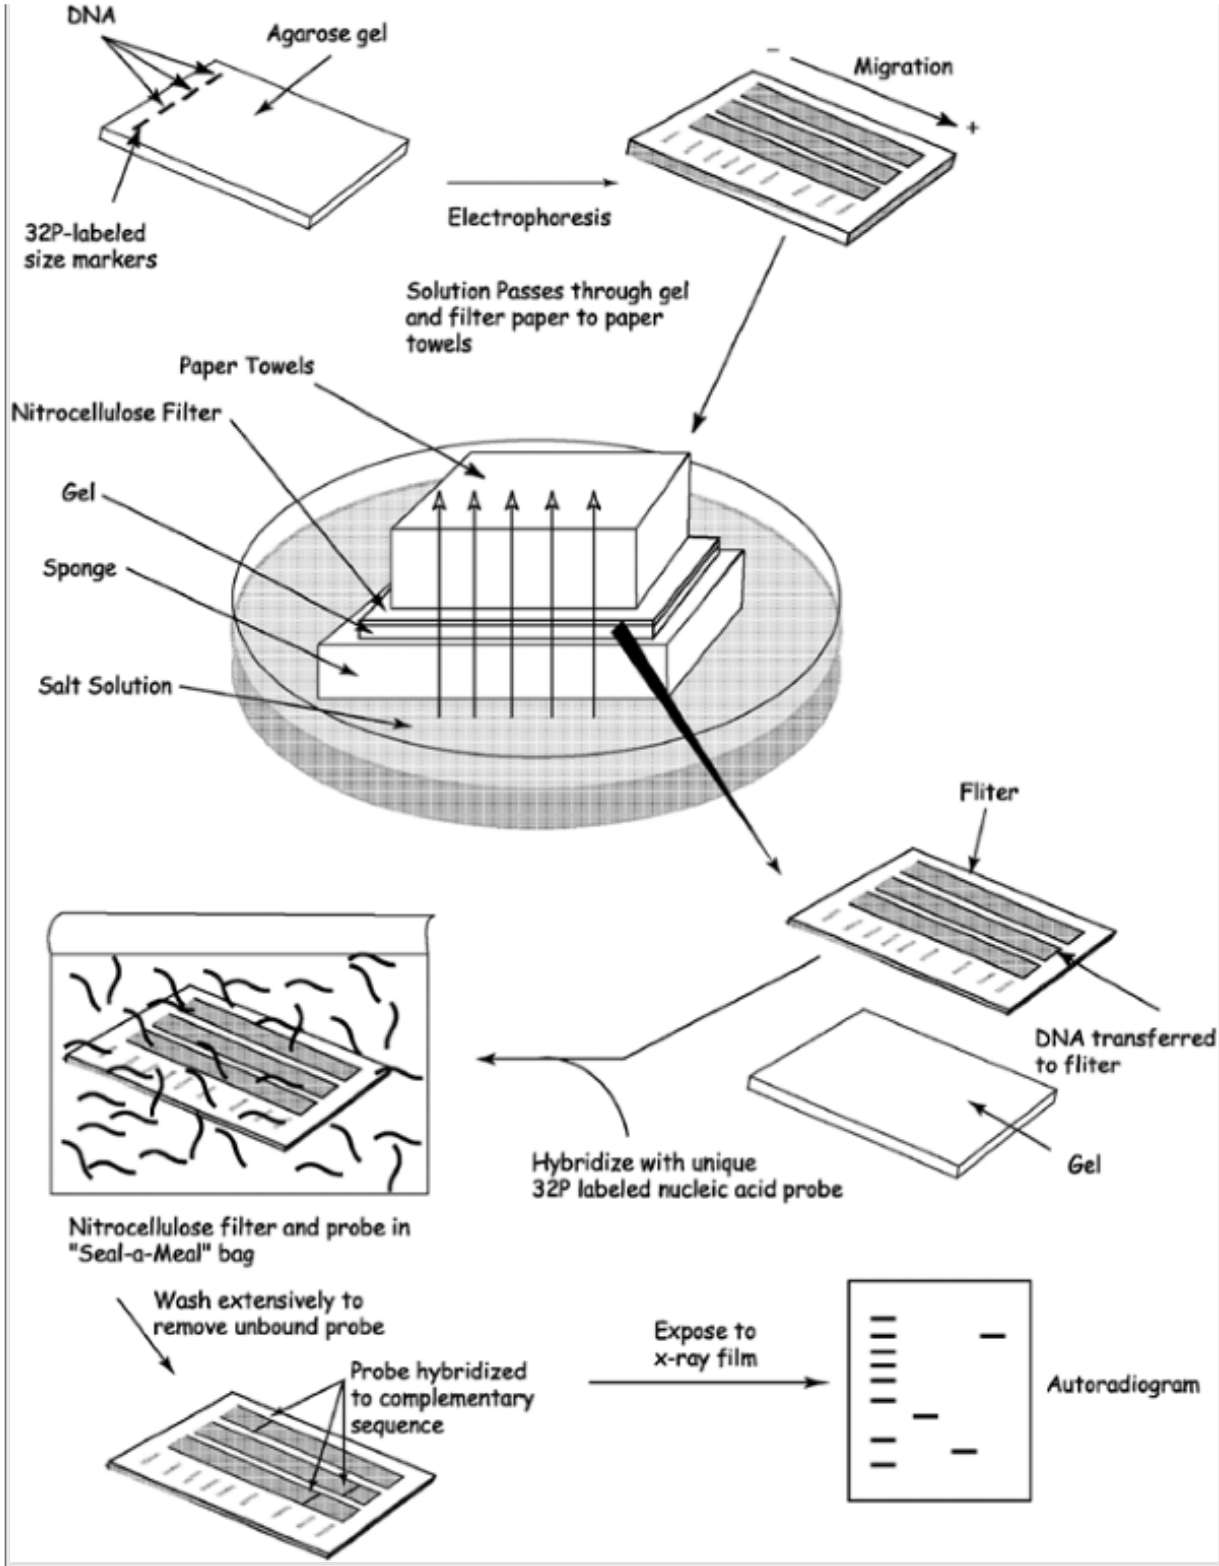


Fig. 6.21. Analyzing DNA by gel electrophoresis and Southern blotting. (Adapted from Watson JD, Gilman M, Witkowski J, et al. Recombinant DNA, 2nd Ed. New York: Scientific American Books, W.H. Freeman and Company, 1992; with permission.)

Sequencing DNA Fragments

The two major methods of nucleic acid sequencing are the Maxam and Gilbert chemical method (17) and Sanger's dideoxy method (16). The dideoxy method of Sanger is largely the method of choice to sequence DNA fragments. It capitalizes on the use of DNA polymerase to catalyze the synthesis of a copy of the DNA fragment that one wishes to sequence. The method relies on the fact that when 2′,3′-dideoxynucleotide triphosphates (ddNTPs) are incorporated into growing nucleic acid chains, the growth ceases, because the dideoxynucleotide does not have a 3′-hydroxyl group on which to add the next nucleotide in the

chain. The method consists of four reagent vials, each containing the ssDNA template fragment to be sequenced, DNA polymerase, a short radiolabeled oligonucleotide primer that hybridizes to the 3′ end of the template fragment, and the four nucleotide triphosphates (dATP, dGTP, dCTP, and dTTP). Each vial contains one of the four ddNTPs (either ddATP, ddGTP, ddCTP, or ddTTP), and the vial is labeled according to which ddNTP is present (Fig. 6.22). The ratio of the ddNTP to the normal dNTPs in the vial is carefully controlled such that the polymerase-catalyzed synthesis of the fragment will go to completion but a small, yet detectable, portion of the synthesis will be terminated each time a ddNTP is attached to the growing fragment. The reaction is initiated by the addition of the polymerase to the vials. When the synthesis is complete, a sample from each vial is applied to wells at the top of a polyacrylamide gel, and the gel is developed to separate the DNA fragments in each vial by size (Fig. 6.22). All fragments that arise in each of the vials as a result of termination of the synthesis at the incorporation of a ddNTP can be visualized on the gel by autoradiography, because the primer is radiolabeled (usually with a ^{32}P phosphate at the 5′- end) and all fragments will contain the primer sequence. The nucleotide sequence of the complementary strand of the fragment that acted as template in the DNA polymerase–catalyzed reaction can be read from the bottom of the gel starting with the sequence of the 5′ end primer and adding nucleotides based on the lane in which the next largest fragment occurs (Fig. 6.22). The smallest visible fragment will be

the primer, and the largest visible fragment will be the complete fragment, both of which will appear in all the vials. The intermediate fragment sizes will be different in each lane depending on the sequence of the template and which ddNTP was present.

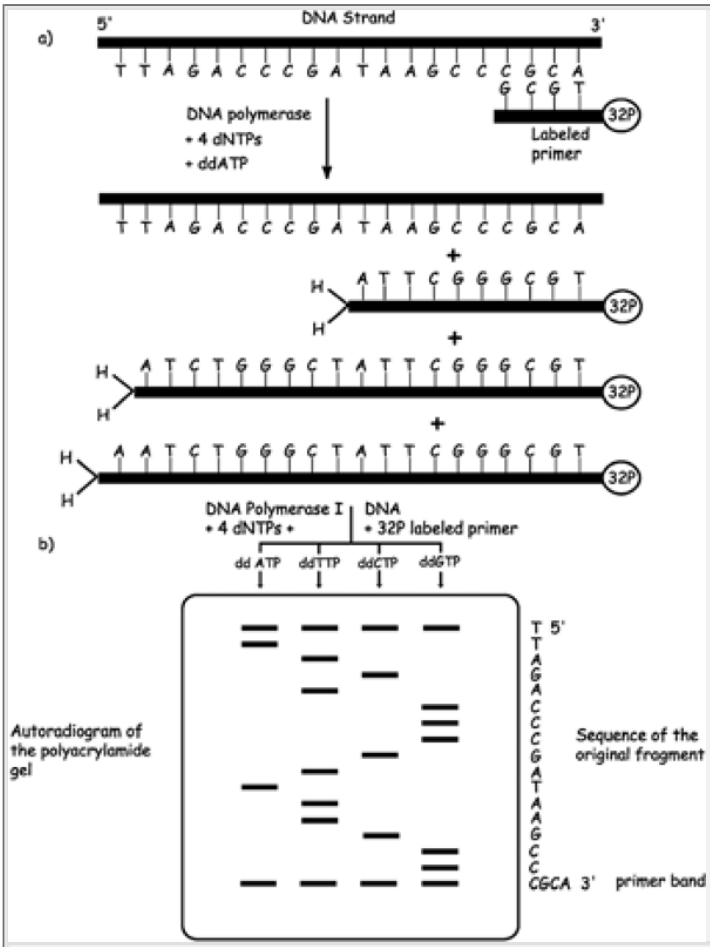

Fig. 6.22. The Sanger DNA-sequencing procedure. (a) The Sanger dideoxynucleotide sequencing reaction with ^{32}P-labeled primers. (b) Acrylamide gel separation of the labeled fragments. (Adapted from Watson JD, Gilman M, Witkowski J, et al. Recombinant DNA, 2nd Ed. New York: Scientific American Books, W.H. Freeman and Company, 1992; with permission.)

This technique has been modified to use fluorescently labeled ddNTPs such that each NTP has a specific fluorescent label. The consequence of this change in protocol is that there is no need to use one reaction for each ddNTP. The sequencing reaction can be done in one vial, the separation of sequencing fragments run in one lane, and the terminal dNTP for each fragment identified by the color of the fluorescent label. After the gel is run, the lanes are scanned with an excitation laser, and the fluorescence detected is fed to a computer that records the data and provides a printout of the nucleic acid sequence.

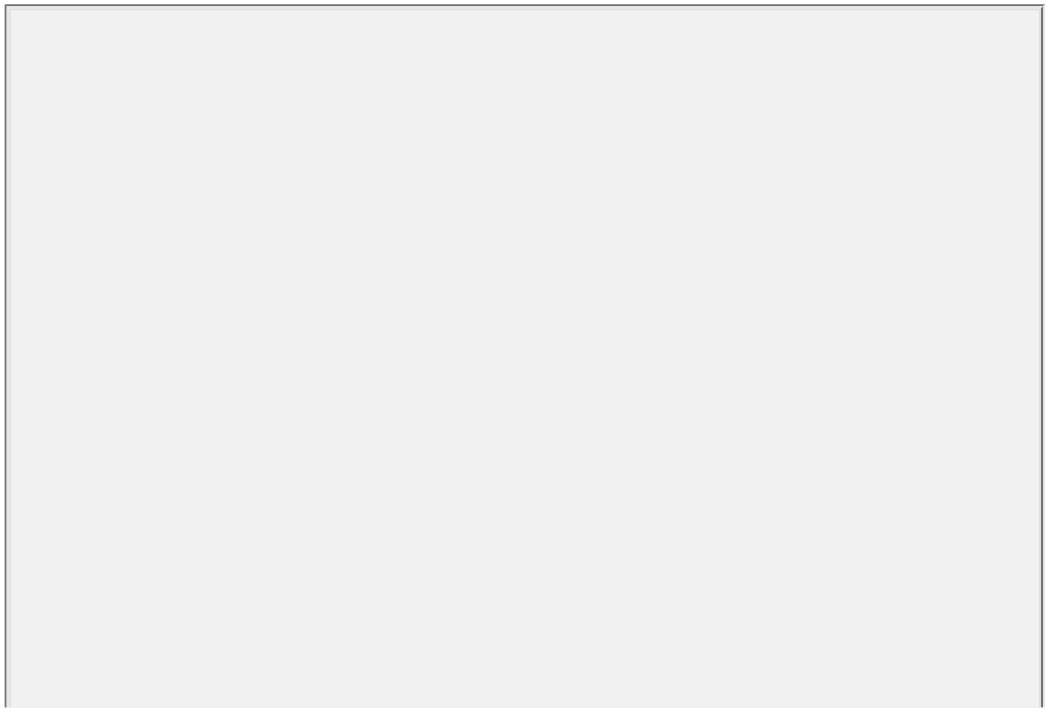
Synthesizing Oligonucleotides

The need for short oligonucleotides of known sequence has grown tremendously with the need for radiolabeled and fluorescently labeled probes to isolate and characterize nucleic acids as well as the need for primers of the DNA polymerase–catalyzed synthesis of nucleic acids. It is now possible to synthesize an entire gene by enzymatically linking chemically synthesized oligonucleotide fragments making up the gene sequence. The phosphite triester (18) and the phosphotriester methods (19) are convenient solid-phase automated techniques for the synthesis of oligonucleotides. The solid-phase technique synthesizes the nucleic acid in the 3′ → 5′ direction by attaching the 3′-hydroxyl group of a 5′-O-dimethoxytrityl–protected deoxyribonucleoside to an insoluble solid support that may be polystyrene resin, silica gel, glass beads, polyamide, or cellulose paper. The subsequent 5′-protected nucleosides are coupled as 3′-phospho or phosphite triesters to the 5′-deprotected nucleic acid attached to the solid support. The 6-amino group of adenine and the 4-amino group of cytosine are protected as benzoyl amides, and the 2-amino group of guanine is protected by the isobutyryl amide.

The basic steps in the phosphite triester method are as follows (Fig. 6.23) (18):

- Removal of the 5′-O-dimethoxytrityl group from the deoxyribonucleoside attached to the solid support is carried out by treatment of the reaction mixture with 3% dichloroacetic acid in dichloromethane.
- The free 5′-OH group is coupled with excess 5′-O-dimethoxytrityl deoxyribounceloside-3′-phosphoramidite using tetrazole as an acid catalyst.

- The new 3′,5′-phosphite triester linking the two nucleotides is converted to the more stable phosphotriester by iodine-catalyzed oxidation.
- Any 5′-OH groups that failed to react are capped by acetylation with acetic anhydride.
- The 5′-O-dimethoxytrityl protecting group is removed by treatment of the reaction mixture with 3% dichloroacetic acid in dichloromethane.
- The sequence of deprotection, coupling, oxidation, and capping is repeated until the oligodeoxyribonucleotide of desired length is obtained.
- The final product is deprotected, removed from the solid support, and purified.



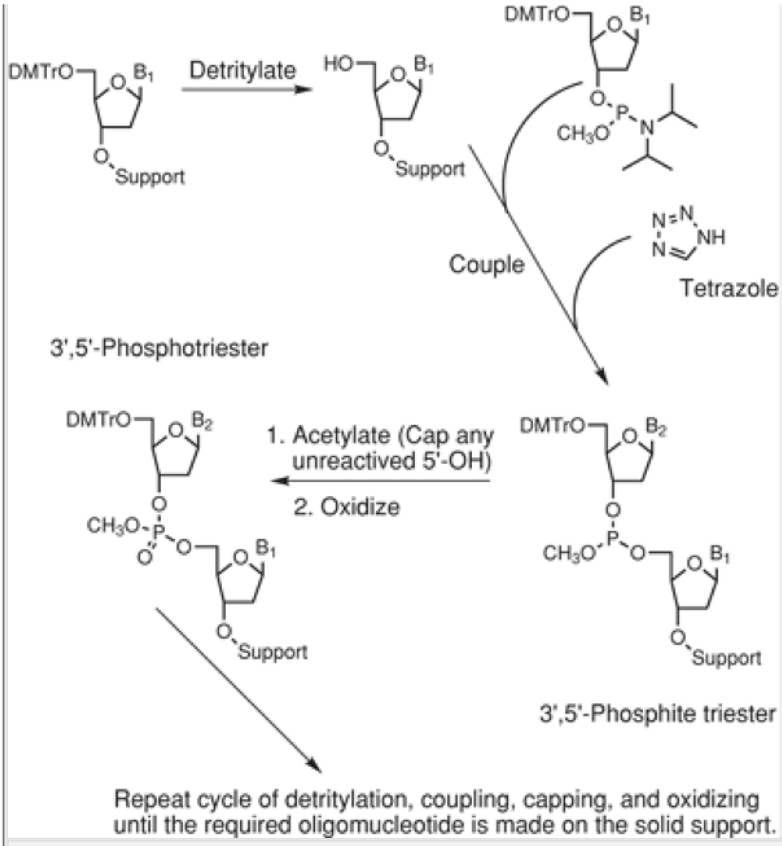


Fig. 6.23. Solid-phase phosphate triester method of oligodeoxyri- bonucleotide synthesis.

Polymerase Chain Reaction

The problem of working with small quantities of nucleic acids isolated from cell and tissue sources was solved, to a certain extent, with the development of cloning techniques that would amplify a DNA fragment as part of a replicating vector in bacteria. The PCR was the second development that tremendously increased the ease with which a fragment of DNA could be amplified without the need for the complications of cloning (20). There was not even a need to isolate the fragment to be amplified. The only requirement was for DNA polymerase oligonucleotide primers at the boundaries of the fragment to be amplified.

The dsDNA fragment is targeted for amplification by designing oligonucleotide primers that anneal to the 3′ ends of the double-stranded fragment (Fig. 6.24). A DNA polymerase uses the oligonucleotides as primers to size the two strands from the 3′ ends, producing two new dsDNA strands carrying the DNA fragment bounded by the two primers. A series of cycles of denaturation, annealing primers, and DNA polymerization results in greatly amplified quantities of the fragment of interest (Fig. 6.24). The original technique used a DNA polymerase from *E. coli* that was heat sensitive and, hence, had to be replaced at every cycle of the reaction. The finding that thermophilic bacteria made DNA polymerases were resistant to the high temperatures used in the denaturation step of the polymerase cycle provided a source for the polymerase enzyme that would not have to be replaced each cycle, and the reaction could be automated without interruption. The most common temperature resistant enzyme used is *Taq* polymerase isolated from *Thermus aquaticus*. This enzyme survives a 1- to 2-minute exposure to 95°C temperature but lacks a 3′ → 5′ proofreading exonuclease activity, so it may introduce errors during DNA replication. Other enzymes with better features have been isolated and are being used in place of the *Taq* polymerase. The technique has many different applications in molecular biology and is really a cornerstone in the research on genetic structure/function relationships.

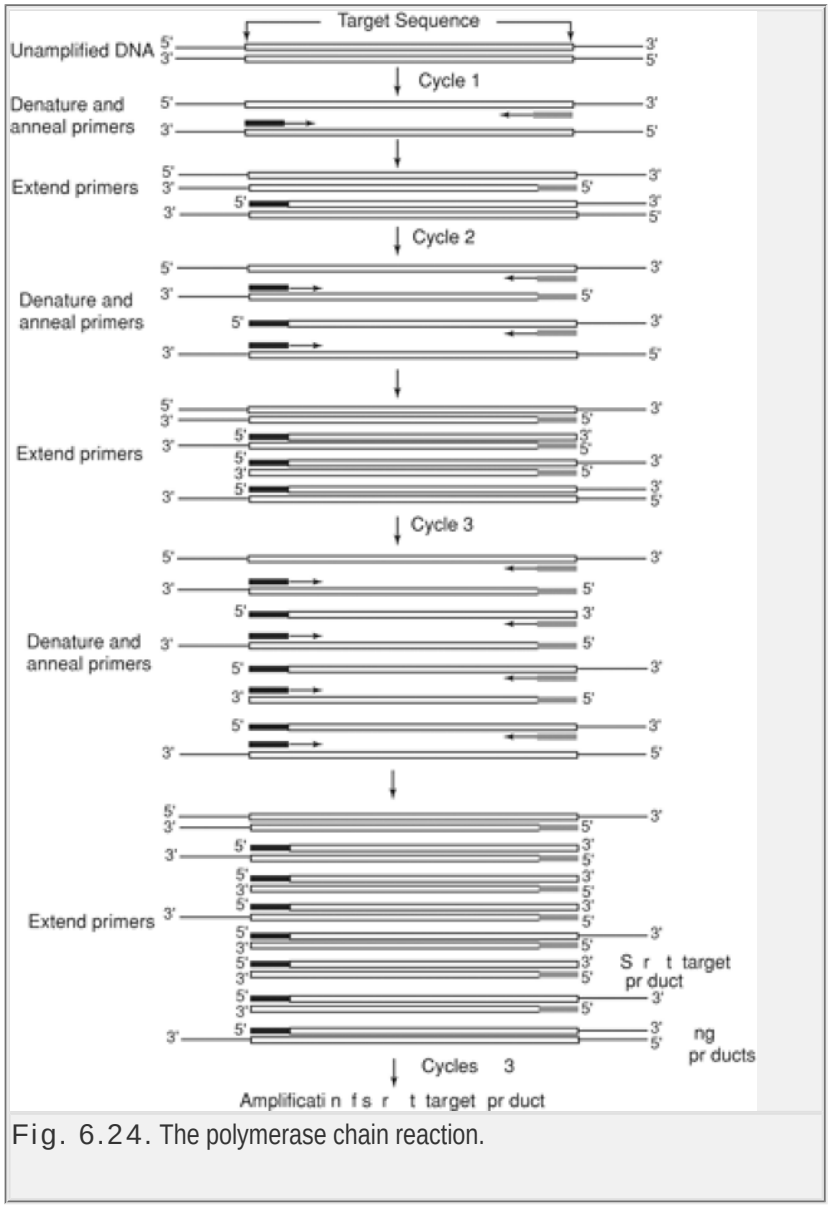

Fig. 6.24. The polymerase chain reaction.

Protein Synthesis through Recombinant DNA

Useful reviews detailing the process of rDNA are available (4,5,6,7,8,13,14,15,16). Applicable sections in any biochemistry or molecular biology textbook (21,22,23,24) provide more detailed reviews. Several reviews of rDNA technology have been written for practicing pharmacists (4,25,26,27,28). A general summary of the typical rDNA production of a protein follows and is schematically presented in Figure 6.25.

Once the gene coding for the desired protein has been identified and isolated (Fig. 6.25), the genetic material is introduced into cells using restriction endonucleases and a vector to enable DNA replication and to produce protein. The discovery of restriction endonuclease enzymes that recognize explicit sequences of bases in dsDNA and precisely hydrolyze the phosphodiester bonds of the nucleic acids at specific sites along the DNA strands offered a way of isolating predictable fragments of any DNA molecule. This family of "scissors-like" enzymes is used to provide the DNA fragment coding for the protein of interest by "cutting" or "clipping" the DNA (Figs. 6.18 and 6.19). The bacterial enzymes, numbering greater than 100 variations isolated

(see Table 6.2 for representative examples), have led to the powerful techniques of DNA sequencing and rDNA technology. Most restriction endonucleases create two single-strand breaks, one in each strand generating a 5′-phosphomonoester and 3′-hydroxyl group from each cleavage. The breaks are not necessarily opposite one another, as can be seen in Table 6.2 (e.g., *Asu*II, *Bal*I, and *Eco*RV). For instance, Eco RI causes breaks that are not opposite one another, creating sticky (or cohesive or complementary) ends to the DNA strands. The DNA fragments can be isolated, purified, and identified.

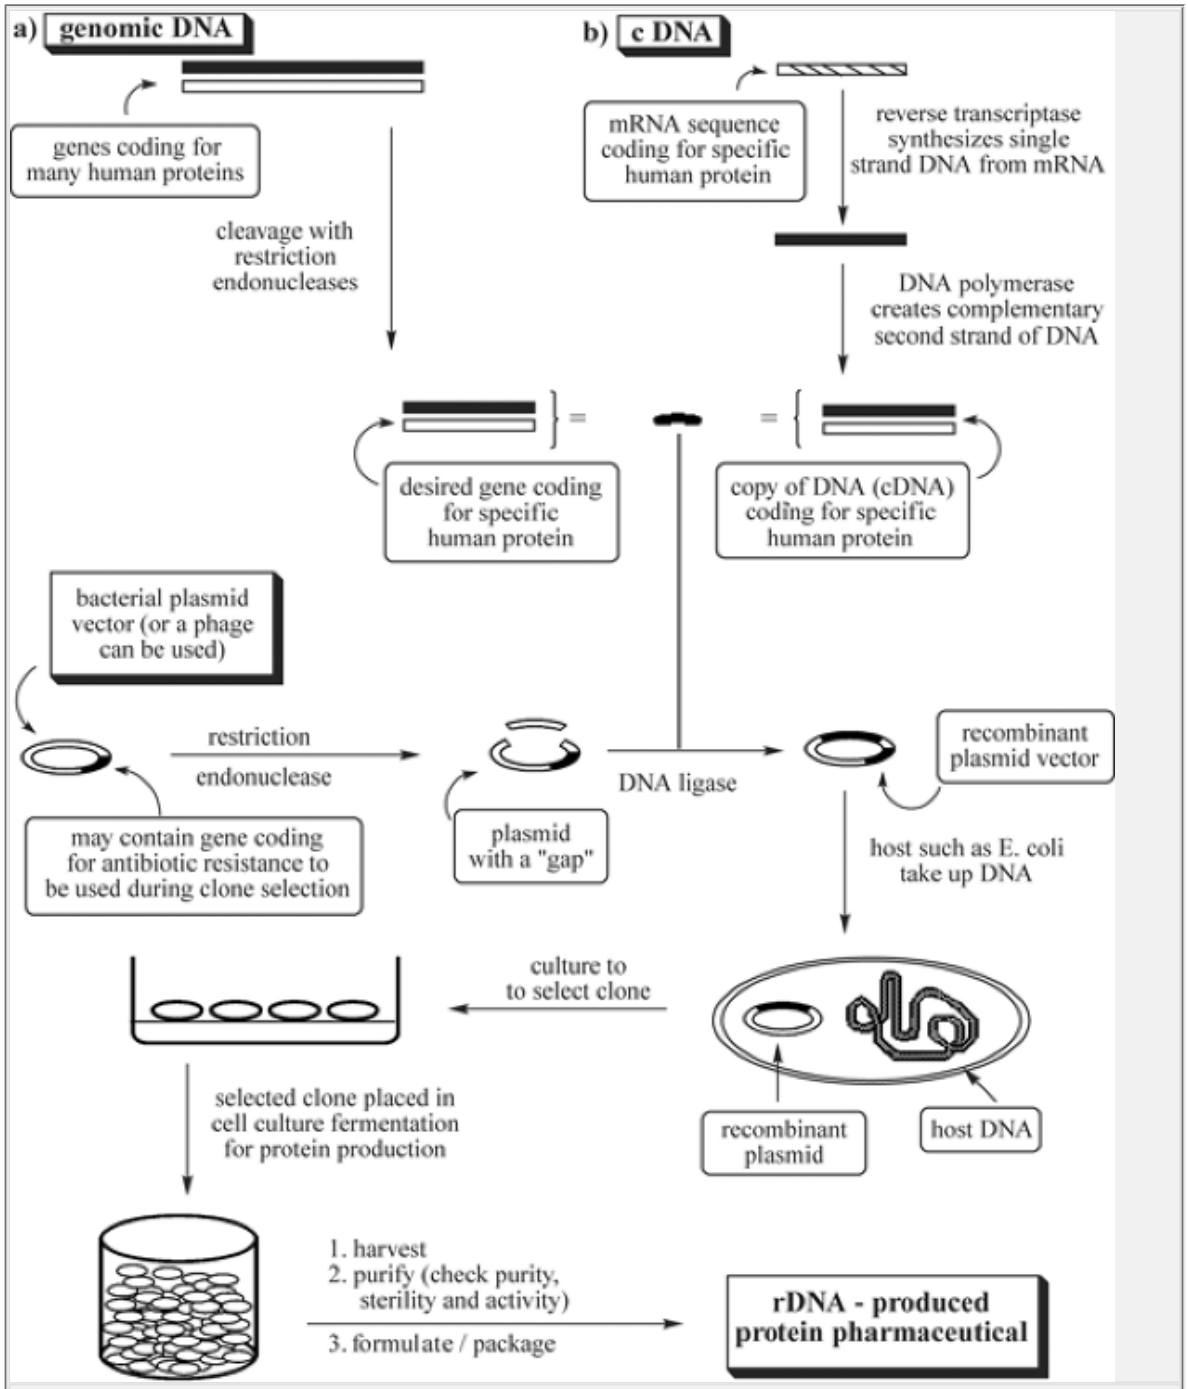

Fig. 6.25. Summary of typical rDNA production of a protein from either (a) genomic DNA or (b) cDNA.

A cloning vector is a carrier molecule, the vehicle that is used to insert foreign DNA into a host cell. Typically, vectors are genetic elements that can be replicated in a host cell separately from that cell's chromosomes. Bacterial plasmids, or circular DNA of only a few thousand base pairs outside of the nucleus that replicate freely within the cell, are ideal for carrying the gene into the host organism. In the first such rDNA experiments in early 1973, Cohen et al. (29) used the small *E. coli* plasmid pSC101 containing only a single Eco RI recognition site as the vector to insert foreign plasmid DNA into *E. coli*. Other vectors include the constructed plasmids pBR322 and pUC18 and bacteriophages. Bacteriophages are bacterial viruses modified to accept large pieces (7–20 kb) of exogenous DNA without altering their ability to infect and replicate inside the bacteria (30). Large genomic libraries have been created by fragmenting all

of the embryonic or sperm cell DNA of an organism, inserting them into bacteriophage lambda, and screening with DNA probes to identify the gene sequences.

Table 6.2. Some Representative Examples of Restriction Endonucleases (15,39)

Restriction Endonucleases	Source	Recognition Sequence[a]	Cleavage Products	
*Alu*I	*Arthrobacter*	5′- TT/CGAA-3′	-TT-	-CGAA-

[a]Illustrates the position where the DNA strands are cleaved.

The DNA fragments coding for the desired protein can be cloned from genomic DNA or cDNA as described previously. The piece of DNA coding for the protein of interest is then inserted into the vector that carries the code to synthesize the protein in the host. The plasmid or bacteriophage DNA is opened with a restriction enzyme, and the exogenous gene is pasted into it by an enzyme called DNA ligase with the assistance of special sections of DNA called linkers. The DNA ligase seals the single-strand breaks in dsDNA. Also, promoter or enhancer DNA sequences are added to increase plasmid replication and increase protein synthesis by the gene. A promoter is a short DNA sequence that amplifies the expression of protein by the adjacent target gene. An enhancer is a viral DNA sequence that dramatically increases the level of transcription of adjacent DNA. A gene providing antibiotic resistance (as a selection tool) also may be placed in a plasmid that is inserted into a bacterial host. This gene confers a particular antibiotic resistance on the clone and may be used in the clone selection later in the rDNA process. This vector is now an rDNA molecule consisting of the gene, linker, promoter/enhancer, and vector DNA.

The vector containing the code for the target protein is then inserted into the host. Host cells are typically bacteria (e.g., *E. coli*), eukaryotic yeast (e.g., *Saccharomyces cerevisiae* [baker's yeast]), or mammalian cell lines. Examples of mammalian cell lines include CHO (Chinese hamster ovary), VERO (African green monkey kidney), and BHK (baby hamster kidney). The choice of host system is influenced primarily by the type of protein to be expressed and by the key differences among the various host cells (31). Bacterial and yeast cells are more easily cultured in large fermenters. Overall protein yields generally are much lower in mammalian cells, but in some cases, this may be the only system that produces some mammalian proteins. Another difference is that yeast and mammalian cells do not form toxins, whereas Gram-negative bacteria produce endotoxins. Finally, an important distinction is that posttranslational modification reactions, such as glycosylation, do not occur in bacteria.

The host cells containing the vector are grown in small-scale culture to select only for the correct clone that contains the desired gene and is able to express the best yields of the protein (32). The selected cloned cells (or cell bank cells) are used as inoculum first for a small-scale cell culture/fermentation, which is then followed by larger fermentations in bioreactors. The medium is carefully controlled to enhance cell reproduction and protein synthesis. The host cells divide, and the vectors within the hosts multiply. The host produces its natural proteins along with the desired protein, which may be secreted into the growth medium. The protein of interest can then be isolated from the fermentation, purified, and formulated to give a potential rDNA-produced pharmaceutical.

Protein Isolation and Purification

The isolation and purification of the final protein product from the complex mixture of cells, cellular debris, medium nutrients, and other host metabolites is a challenging task (31,32). The structure, purity, potency, and stability of the recombinant protein must be considered. Often, sophisticated filtrations, phase separations, precipitation, and complex multiple-column chromatographic procedures are required to obtain the desired protein. Although isolation of the recombinant protein, produced in culture in relatively large amounts, generally is easier than isolating the native protein, ensuring the stability and retention of the bioactive three-dimensional structure (correct protein folding) of any biopharmaceutical is

a more arduous task. In addition, recombinant proteins from bacterial hosts require removal of endotoxins, whereas viral particles may need to be removed from mammalian cell culture products (33). A discussion of these techniques is beyond the scope of this chapter, however. Useful reviews on the extraction and purification (31,32,34) and the analysis and chromatography (35,36,37,38,39) of biotechnology products are available as a resource for further

information.

Therapeutic Application of Recombinant DNA

Overview

The techniques made available by advances in biotechnology that have provided new medicinal agents fall into several broad areas. First, rDNA technology, the ability to manipulate the genetic information inherent within the nucleus of living cells, provides the ability to take identified gene sequences from one organism and place them functionally into another to permit the production of protein medicines. Second, hybridoma techniques permit the production of monoclonal antibodies (MAbs), which are ultrasensitive hybrid immune system–derived proteins designed to recognize specific antigens. The MAbs are used as diagnostic agents for laboratory and home kits and for site-directed therapeutics. Additionally, the development of technologies to study DNA–DNA and DNA–RNA interactions has led to the formation of RNA and DNA probes (antisense technology) for a variety of research purposes with potential uses as diagnostics and therapeutics. Tools of modern pharmaceutical biotechnology also include PCR, genomics, proteomics, gene therapy, transgenics, glycobiology, and a host of other evolving techniques (Table 6.3).

Recombinant DNA Technology

The revolution in biology and genetics that has occurred over the past 30 years, affecting both the basic research and its practical aspects, has been fueled by rDNA technology. Sometimes also referred to as genetic engineering, gene cloning, or in vitro genetic manipulation, rDNA technology provides the ability to introduce genetic material from any source into cells (bacterial, fungal, plant, or animal) or even whole plants and animals (40). A general understanding of the technologies involved should readily help the pharmacist better gain insight regarding and comprehension of a biotechnology drug's use, stability, handling, side effects, and potential toxicity—in other words, how these agents differ from traditional drugs. Also, such an understanding should readily demonstrate the impact that rDNA technology is having on both current and future pharmacy practice.

General Properties of Biotechnology-Produced Medicinal Agents

Although a majority of traditional medicinal agents are relatively small organic molecules, rDNA and hybridoma technologies have made it possible to produce large quantities of highly pure, therapeutically useful proteins. The rDNA-derived proteins and MAbs are not dissimilar to the other protein pharmaceuticals or biopharmaceuticals that pharmacists have dispensed in the past. As polymers of amino acids joined by peptide bonds, the properties of

these proteins differ generally from those of small organic molecule pharmaceuticals. An overview of the general properties of biotechnology-produced medicinal agents actually is a review of the general physicochemical properties of proteins. Therefore, to study the stability, handling, storage, route of administration, and metabolism of biotechnology-produced pharmaceuticals, it is valuable to understand the chemical nature of proteins. Chapter 7 of this text and other publications (41,42,43,44,45,46,47,48) review the physical biochemistry of protein drugs; related chapters in any biochemistry textbook also review this topic.

Stability of Biotech Pharmaceuticals

Several detailed reviews on the stability of proteins and protein pharmaceuticals written for pharmaceutical scientists are available (43,45,46,47,48,49,50). A brief overview of these resources follows and provides additional information. The instability of proteins, including protein pharmaceuticals, can be separated into two distinct classes. Chemical instability results from bond formation or cleavage yielding a modification of the protein and a new chemical entity. Physical instability involves a change to the secondary or higher-order structure of the protein rather than a covalent bond-breaking modification.

Chemical Instability

A variety of reactions give rise to the chemical instability of proteins, including hydrolysis, oxidation, racemization, β-elimination, and disulfide exchange (Fig. 6.26). Each of these changes may cause a loss of biological activity.

Proteolytic hydrolysis of peptide bonds results in fragmentation of the protein chain. It is well established that in dilute acids, aspartic acid (Asp) residues in proteins are hydrolyzed at a rate at least 100-fold faster than that of other peptide bonds because of the mechanism of the reaction. An additional hydrolysis reaction is the deamidation of the neutral residue of asparagine (Asn) and glutamine (Gln) side-chain linkages, forming the ionizable carboxylic acid residues aspartic acid (Asp) and glutamic acid (Glu) (Fig. 6.26a). This conversion may be considered primary sequence isomerization.

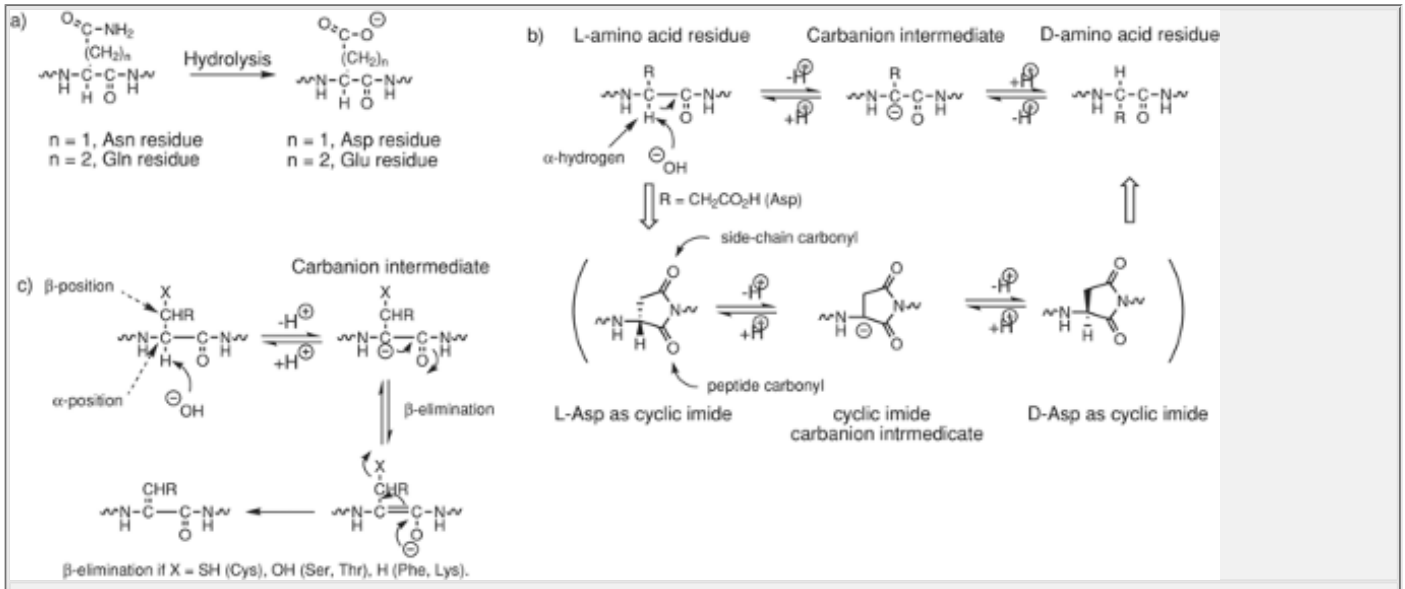

Fig. 6.26. Chemical instability of protein biopharmaceuticals. (a) Hydrolysis. (b) Base-catalyzed racemization. (c) β-Elimination.

Oxidative degradative reactions can occur to the side chains of sulfur-containing methionine (Met) and cysteine (Cys) residues and the aromatic amino acid residues histidine (His), tryptophan (Trp), and tyrosine (Tyr) in proteins during their isolation and storage. The weakly nucleophilic thioether group of Met (R-S-CH_3) can be oxidized at low pH by hydrogen peroxide as well as by oxygen in the air to the sulfoxide (R-SO-CH_3) and the sulfone (R-SO_2-CH_3). The thiol (sulfhydryl, R-SH) group of Cys can be successively oxidized to the corresponding sulfenic acid (R-SOH), disulfide (R-SS-R), sulfinic acid (R-SO_2H), and finally, sulfonic acid (R-SO_3H). A number of factors, including pH, influence the rate of this oxidation. Oxidation of His, Trp, and Tyr residues is believed to occur with a variety of oxidizing agents, resulting in the cleavage of the aromatic rings.

Base-catalyzed racemization reactions may occur in any of the amino acids except achiral glycine (Gly) to yield residues in proteins with mixtures of L- and D-configurations. The α-methine hydrogen is removed to form a carbanion intermediate (Fig. 6.26b). The degree of stabilization of this intermediate controls the rate of this reaction. Racemization generally alters the proteins' physicochemical properties and biological activity. Also, racemization generates

nonmetabolizable D-configuration forms of the amino acids. Generally, most amino acid residues are relatively stable to racemization, with a notable exception. Aspartate residues in proteins racemize at 10^5-fold faster rate than when free, in contrast to the two- to fourfold increase for the other residues. The facilitated rate of racemization for Asp residues is believed to result from the formation of a stabilized cyclic imide.

Proteins containing cysteine (Cys), serine (Ser), threonine (Thr), phenylalanine (Phe), and lysine (Lys) are prone to β-elimination reactions under alkaline conditions (Fig. 6.26c). The reaction proceeds through the same carbanion intermediate as racemization. The reaction is influenced by a number of additional factors, including temperature and the presence of metal ions.

The interrelationships of disulfide bonds and free sulfhydryl groups in proteins are important factors influencing the chemical and biological properties of protein pharmaceuticals. Disulfide exchange can result in incorrect pairings and major changes in the higher-order structure (secondary and above) of proteins. The exchange may occur in neutral, acidic, and alkaline media.

Physical Instability

Generally not encountered in most small organic molecules, physical instability is a consequence of the polymeric nature of proteins. Proteins adopt secondary,

tertiary, and quaternary structures, which influence their three-dimensional shape and, therefore, their biological activity. Any change to the higher-order structure of a protein may alter both. Physical instability includes denaturation, adsorption to surfaces, and noncovalent self-aggregation (soluble and precipitation). The most widely studied aspect of protein instability is denaturation. Noncovalent aggregation, however, is one of the primary mechanisms of protein degradation (43).

A protein, in principle, can be folded into a virtually infinite number of conformations. The combination of spatial arrangements and noncovalent intramolecular interactions of nearby amino acid residues providing the lowest-energy conformation is the most stable secondary structure. Longer-distance interactions cause the globular nature of proteins (tertiary structure), including their ability to fold so that hydrophilic amino acid side chains are directed toward the exterior surface of the protein exposed to an aqueous environment. In general, all molecules of any protein species adopt the same conformation, or native state. Denaturation occurs by disrupting the weaker noncovalent interactions that hold a protein together in its secondary and tertiary structures. Temperature, pH, and the addition of organic solvents and solutes may cause denaturation. The process can be reversible or irreversible. In general, denaturation affects the protein by decreasing aqueous solubility, altering three-dimensional molecular shape, increasing susceptibility to enzymatic hydrolysis, and causing the loss of the native protein's biological activity.

Handling and Storage of Biotechnology-Produced Products

The preparation and administration of drugs of recombinant or hybridoma origin are dissimilar to the other nonprotein pharmaceuticals that pharmacists have been dispensing in the past. Proteins generally have more limited shelf stability. The average shelf life for a biotechnology product is 12 to 18 months, compared with more than 36 months for a small molecule drug. Although each individual biotechnology drug may be different, several generalizations can be made.

Proper storage of the lyophilized and the reconstituted drug is essential. Most of these drugs are expensive, so special care must be taken not to inactivate the therapeutic protein during storage and handling. The human proteins have limited chemical and physical stability, which is shortened on reconstitution. Expiration dating ranges from 2 hours to 30 days. The self-association of either native state or misfolded protein subunits may readily occur under certain conditions. This can lead to aggregation and precipitation and results in a loss of biological activity. Self-association mechanisms depend on the conditions of formulation and may occur as a result of hydrophobic interactions.

Many of the biotechnology-produced drugs are stored refrigerated, but not frozen (2–8°C). In general, temperature extremes must be avoided. One example is the rDNA-produced, blood clot–dissolving drug alteplase. A recombinant version of a naturally occurring human tissue-type plasminogen activator, lyophilized alteplase is stable at room temperature for several years if protected from light (51). Freezing or exposure to excessive heat decreases the physical stability of the protein. Anything that causes denaturation or self-aggregation, even though labile peptide bonds are not broken, may inactivate the protein. Some pharmacy facilities may need to increase cold storage capacity to accommodate biotech storage needs. If the patient must travel any distance home after receiving the medication, the pharmacist should help package the biotechnology product according to the manufacturer's directions. This may mean supplying a reusable cooler for the patient's use. Because the protein drug should not be frozen, the cooler should contain an ice pack rather than dry ice.

Some rDNA-derived pharmaceuticals, particularly the cytokines (e.g., the interferons, interleukin-2, and colony-stimulating factors), require human serum albumin in their formulation to prevent adhesion of the protein drug to the glass surface of the vial, which results in loss of protein (51,52,53). The amount of

human serum albumin added varies with the biotech product. The vials should not be shaken to prevent foaming of the albumin, which causes protein loss or inactivation of the biotechnology-derived proteins. Care must be exercised in reconstituting protein pharmaceuticals. The diluent used for reconstitution of biotechnology drugs varies with the product and is specified by the manufacturer. Diluents can include normal saline, bacteriostatic water, and 5% dextrose. Several reviews of biotechnology drugs written for pharmacists contain additional information on the subjects of handling and storage (4,26,52,54,55,56,57).

Biotechnology Drug Delivery

Protein-based pharmaceuticals, whether produced by biotechnology or isolated from traditional sources, present challenges to drug delivery because of the unique demands imposed by their physicochemical and biological properties. Although a detailed discussion of this topic is beyond the scope of this chapter, a brief overview follows. Useful reviews also are available for further information (46,58,59,60,61,62).

Delivery of large-molecular-weight, biotechnology-produced drugs into the body is difficult because of the poor absorption of these compounds, the acid lability of peptide bonds, and the rapid enzymatic degradation of these drugs in the body. In addition, protein pharmaceuticals are susceptible to physical instability, complex feedback control mechanisms, and peculiar dose–response relationships.

Given the limitations of today's technology, the strongly acidic environment of the stomach, the peptidases in the gastrointestinal tract, and the barrier to absorption presented by gastrointestinal mucosal cells preclude successful oral administration of most protein drugs. Therefore, administration

of all the biotechnology-produced protein drugs currently is parenteral (by intravenous, subcutaneous, or intramuscular injections) to provide a better therapeutic profile. Manufacturers supply most of these drugs as sterile solutions without a preservative. In such cases, it is recommended that only one dose be prepared from each vial to prevent bacterial contamination. Novel solutions to overcome delivery problems associated with biotechnology protein products are being explored. Oral drug delivery approaches in development for various biotechnology-derived drugs include conjugated systems (e.g., with polyethylene glycol), liposomes, microspheres, erythrocytes as carriers, and viruses as drug carriers (45). Specialized delivery methods being examined include transdermal systems, pulmonary delivery, intranasal sprays, buccal administration, ocular delivery systems, rectal administration, iontophoresis, phonophoresis, metered pumps, protein pro-drugs, lymphatic uptake, coadministration of peptidase inhibitors, and penetration enhancers.

Some Pharmacokinetic Considerations of Biotechnology-Produced Proteins

The processes of adsorption into, distribution within, metabolism by, and excretion from the body (i.e., ADME) of biotechnology-produced pharmaceuticals are important factors affecting the time course of their pharmacologic effect. To deliver quality pharmaceutical care with biotech products, a pharmacist must be able to apply pharmacokinetic principles to establish and maintain a nontoxic, therapeutic effect. The pharmacokinetics of these protein drugs differ in some pharmacokinetic aspects from those of the small molecule organic agents with which we are most familiar. Although a lengthy discussion of this topic is beyond the scope of this chapter, a brief overview of metabolism follows. Useful reviews also are available for further information (63,64).

The plasma half-life of most administered proteins is relatively short, because they are susceptible to a wide variety of metabolic reactions. Rapid hydrolytic degradation of peptide bonds by both nonspecific enzymes and highly structurally selective aminopeptidases, carboxypeptidases, deamidases, and proteinases occurs at the site of administration, while crossing the vascular endothelia, at the site of action, in the liver, in the blood, in the kidney, and in fact, in most tissues and fluids of the body. Overall, the metabolic products of most proteins are not considered to be a safety issue. They generally are broken down into amino acids and reincorporated into new, endogenously biosynthesized proteins.

Metabolic oxidation reactions may occur to the side chains of sulfur-containing residues, similar to that observed for in vitro chemical instability. Methionine can be oxidized to the sulfoxide, whereas metabolic oxidation of cysteine residues forms a disulfide. Metabolic reductive cleavage of disulfide bridges in proteins may occur, yielding free sulfhydryl groups.

Adverse Effects

Overview

An important consideration in the pharmaceutical care of a patient being administered a biotechnology-produced medicinal agent is the potential for adverse reactions. Many of the protein agents are biotechnology-derived versions of endogenous human proteins normally present, on stimulus, in minute quantities near their specific site of action. Therefore, the same protein administered in much larger quantities may cause adverse effects not commonly observed at normal physiologic concentrations (63,64,65). Careful monitoring of patients administered biotechnology-produced drugs is critical for the health care team.

Immunogenicity

The immune system may respond to an antigen, such as a protein pharmaceutical, by triggering the production of antibodies. Biotechnology-derived proteins may possess a different set of antigenic determinants (i.e., regions of a protein recognized by an antibody) because of structural differences between the recombinant protein and the natural human protein (43,62,63). Factors that can contribute to this immunogenicity include lack of or incorrect glycosylation, amino acid modifications, and amino acid additions and deletions. A number of recombinant proteins produced with bacterial vectors contain an N-terminal methionine in addition to the natural human amino acid sequence. Bacterial vector-derived recombinant protein preparations also may contain small amounts of immunoreactive bacterial polypeptides as possible contaminants. Additionally, immunogenicity may result from proteins that are misfolded, denatured, or aggregated.

Recombinant DNA-Produced Medicinal Agents

Recombinant DNA technology provides a powerful tool for new pharmaceutical product development and production. Table 6.4 lists the rDNA-produced drugs and vaccines approved by the U.S. FDA through the year 2000. The biotech products include hormones, enzymes, cytokines, hematopoietic growth factors, other growth factors, blood clotting factors and anticoagulants, and vaccines.

Hormones

Insulin

Biotechnology has provided hormone replacement therapy with the introduction of human insulin (66,67,68), the first U.S. FDA–approved rDNA drug in 1982, for the treatment of insulin-dependent diabetes. The human insulin molecule has the structural characteristics of a large protein yet is only the size of a polypeptide, totaling 51 amino acid residues. Two disulfide bonds (cysteine [Cys] A7 to Cys B7 and Cys A20 to Cys B19) link two

polypeptide chains, with the A-chain consisting of 21 amino acids and the B-chain 30 residues. An additional disulfide loop is found in the A-chain between Cys A6 and Cys A11 (Fig. 7.17 and Fig. 32.1). Insulin formulation development focused on modifying the time-action profile (onset, peak plasma concentration, and duration of action) through the use of various levels of zinc and protamine. Also, the chemical stability of insulin was improved by moving from acidic to neutral formulations.

Table 6.4. Drugs and Vaccines of Recombinant DNA Origin Approved by the U.S. Food and Drug Administration

Class	Generic Name	Indication
Hormone	Insulin (human)	Insulin-dependent diabetes mellitus
	Insulin (human) lispro	Insulin-dependent diabetes mellitus
	Insulin (human) aspart	Insulin-dependent diabetes mellitus
	Insulin (human) glargine	Insulin-dependent diabetes mellitus
	Glucagon	Treatment of hypoglycemia, diagnostic aid
	Somatrem	hGH deficiency in children
	Somatropin	hGH deficiency in children
		Growth failure in children because of chronic renal insufficiency
		Turner's syndrome
		hGH deficiency in adults
		Children with Prader-Willi syndrome
	Pegvisomant	Treatment of acromegaly
	Follitropin alpha	Infertility
	Follitropin beta	Infertility

	Thyrotropin alfa	Detection and treatment of thyroid cancer
	Teriparatide	Treatment of osteoporosis in postmenopausal women
Enzyme	Alteplase	Acute myocardial infarction
		Acute myocardial embolism
		Ischemic stroke
	Retavase	Acute myocardial infarction
	Tenecteplase	Acute myocardial infarction
	Dornase alpha	Cystic fibrosis
	Imiglucerase	Treatment of Gaucher disease
Cytokine	Interferon-α_{2a}	Hairy cell leukemia
		AIDS-related Kaposi's sarcoma
		Chronic myelogenous leukemia
		Hepatitis C
	Interferon-α_{2b}	Hairy cell leukemia
		Genital warts
		AIDS-related Kaposi's sarcoma
		Hepatitis B
		Hepatitis C
		Malignant melanoma
		Follicular lymphoma
	Peginterferon α_{2a}	Chronic hepatitis C
	Interferon alfacon-1	Treatment of chronic hepatitis C viral infection
	Interferon-β_{1a}	Relapsing multiple sclerosis
	Interferon-β_{1b}	Relapsing, remitting multiple sclerosis
	Interferon-γ_{1b}	Management of chronic granulomatous disease
	Aldesleukin	Renal cell carcinoma
		Metastatic melanoma
	Denileukin diftitox	Persistent or recurrent cutaneous T-cell lymphoma
	Oprrelvekin	Prevention of severe chemotherapy-induced thrombocytopenia
	Anakinra	Moderate to severe active rheumatoid arthritis
	Etanercept	Moderate to severe active rheumatoid arthritis
Hematopoietic growth factor	Epoetin alpha	Anemia related to AZT therapy in HIV-infected patients
		Anemia associated with chronic renal failure
		Anemia caused by chemotherapy in patients with nonmyeloid malignancies
		Prevention of anemia associated with surgical blood loss
		Anemia in children—chronic renal failure undergoing dialysis
	Darbepoetin alfa	Treatment of anemia
	Filgrastim	Decrease incidence of infection—patients with nonmyeloid malignancies receiving myelosuppressive drugs
		Autologous or allogeneic bone marrow transplantation
		Chronic severe neutropenia
	Sargramostim	Myeloid recovery in patients after autologous bone marrow transplantation
		Neutropenia—result of chemotherapy for acute myelogenous leukemia

		Allogeneic bone marrow transplantation
		Support for peripheral blood progenitor cell mobilization and transplantation
Other growth factors	Becaplermin	Lower extremity diabetic neuropathic ulcers
Blood clotting factor	Recombinant factor VIII	Hemophilia B
	Recombinant factor IX	Hemophilia A
Anticoagulant	Lepirudin	Heparin-inducer thrombocytopenia type II
Vaccine	Hepatitis B vaccine	Prevention of hepatitis B
	Lyme disease vaccine	Prevention of Lyme disease

Before the availability of rDNA-produced human insulin, porcine and bovine insulin were the most commonly used pharmaceutical preparations. Both porcine and bovine insulin differ in primary structure from human insulin, with alanine (Ala) replacing threonine (Thr) at the C-terminal of the B-chain (B30). Bovine insulin also differs from human insulin by Ala replacing Thr at A8 and valine (Val) substituting for isoleucine (Ile) at A10 (Table 32.8). These subtle differences can result in immunologic responses to the nonhuman insulins, requiring a modification of the therapeutic regimen. The biotechnology solution has several advantages over insulin derived from animal sources:

- It should have potentially fewer serious immune reactions.
- It is pyrogen-free.
- It is not contaminated with other peptide hormones, such as glucagon, somatostatin, and proinsulin, as found in isolated products.
- It can be produced in larger amounts.

The first successful attempts to tailor a protein hormone for therapy by rDNA techniques has yielded interesting insulin analogues (66,67,68).

Human insulin rDNA origin is available commercially as Humulin, Novolin, and as several analogues. The Humulin and Novolin products are produced using genetically modified strains of two different microorganisms. Humulin is prepared using recombinant *E. coli* bacteria. The pharmaceutical preparation is reported to contain less than 4 ppm of immunoreactive bacterial polypeptides that act as possible contaminants. Baker's yeast (*S. cerevisiae*) serves as the recombinant organism for the production of Novolin. Before 1986, Humulin was produced by chemically joining together the separately rDNA-derived A-chain and B-chain. Today, the product is prepared by enzymatically cleaving the connecting peptide in recombinant proinsulin.

Studies in animals, healthy adults, and patients with type I diabetes mellitus have shown human insulin to have pharmacologic effects identical to those of purified porcine insulin. A comparable pharmacokinetic profile also has been shown. Human insulin, however, administered intramuscularly or intravenously, may have a slightly faster onset and slightly shorter duration of action when compared with purified porcine insulin in patients with diabetes. The usual precautions concerning toxic potentials observed with insulin of animal origin should be followed with rDNA human insulin. As would be expected, the recombinant product has been shown to be less immunogenic than animal insulins.

Insulin remains the only treatment option for type I diabetes and is still widely used to treat patients with type II diabetes who do not respond adequately to other pharmacotherapies. Recombinant DNA technology has lead recently to the development of insulin analogues that have greater utility in certain situations and may more closely resemble the normal diurnal pattern of insulin secretion (Table 32.10). The newly engineered analogues have specific amino acid sequence modifications that improve absorption properties and biological profiles (69). Insulin lispro (Humalog) has a more rapid onset and shorter duration of action than regular human insulin. Unlike regular insulin that must be injected 30 to 60 minutes before a meal, recombinant insulin lispro is effective when injected 15 minutes before a meal. The analogue differs from natural human insulin, because the B-chain amino acids B28 proline and B29 lysine are exchanged. Insulin aspart (Novolog), which is homologous with human insulin except for the single amino acid substitution of aspartic acid for proline at B28, is effective when injected 5 to 10 minutes before a meal. Insulin glargine (Lantus) is the newest rDNA-derived human insulin analogue. An ultra-long-acting agent, insulin glargine differs from human insulin in that the amino acid asparagine at residue A21 is replaced by glycine, and two arginines are added to the C-terminus of the B chain. When administered subcutaneously, insulin glargine has a duration of action up to 24 to 48 hours. This change in action profile resulted from structural modifications that enhanced the products basicity, thus causing the product to precipitate at neutral pH postinjection and, therefore, increasing its duration of action.

Glucagon (Glucagen)

Like insulin, glucagon is a hormone normally biosynthesized as a high-molecular-mass protein from which the mature peptide hormone is released by selective proteolytic cleavage. The single-chain, 29-amino-acid polypeptide has an overall catabolic effect that tends to oppose the actions of insulin. Interestingly, the amino acid sequence of human, bovine, and porcine glucagon are identical. Glucagon of rDNA origin is now available (67). Replacing the bovine product with the rDNA-derived drug would eliminate the risk of acquiring bovine spongiform encephalopathy from glucagon therapy.

Growth Hormones

The introduction of rDNA human growth hormone (hGH) (70), previously isolated from cadaver pituitaries, greatly improved the long-term treatment of children who have growth failure caused by a lack of adequate endogenous hGH. The major, circulating form of human pituitary hGH is a globular protein of 191 amino acids in

a single polypeptide chain with a molecular weight of 22,000 daltons. Pituitary hGH is a roughly spherical protein with a hydrophobic interior. It is nonglycosylated. Degradation pathways of hGH include typical proteolysis reactions; deamidation of Asn and Gln residues; oxidation of Met, Trp, His, and Tyr residues; disulfide exchange; and aggregation.

Table 6.5. Commercially Available rDNA hGH

Drug	Trade Name	Chemical Nature
Somatrem	Protropin	hGH + N terminal methionone
Somatoprotin	GenoTropin	hGH
	Humatrope	hGH
	Norditropin	hGH
	Nutropin	hGH
	Nutropin Depot	hGH-long acting
	Saizen	hGH
	Serostim	hGH
Pegvisomant	Somavert	hGH + polyethylene glycol

Somatrem, first introduced in 1985, contains the identical 191-amino-acid sequence found in the pituitary-derived hGH plus the addition of a methionine amino acid at the N-terminus of the peptide chain (resulting in a 192-amino-acid protein; also known as Met-rhGH) (Table 6.5). Somatropin products contain the 191-amino-acid sequence identical to that of hGH of pituitary origin. Marketed somatropin products are shown in Table 6.5. Actions of rDNA-derived hGHs include an increase in the linear growth of the patient, increased skeletal growth, increased protein synthesis, reduction in body fat stores, and increased organ growth (Table 6.4). Clearance and bioavailability do not appear to be clinically or statistically different from those for somatrem and somatropin. Although the direct clinical comparison of the efficacy of the two forms of hGH have yet to be performed, separate controlled studies of growth hormone–deficient patients were similar. Recombinant hGHs are safe and effective therapies with relatively few side effects. A long-acting dosage form of somatotropin is approval for use in children with Prader-Willi syndrome, a rare genetic disorder that causes short stature; an involuntary, continuous urge to eat that is lifelong and may be life threatening; low muscle tone; and cognitive disorders. The formulation was designed to reduce the frequency of injections to once or twice a month by encapsulating the agent in biodegradable microspheres.

Gonadotropins—Follitropin Alpha (Gonal-F) and Follitropin Beta (Fillistim)

The gonadotropins are a family of protein hormones that include follicle-stimulating hormone (FSH) and primarily target their actions to the gonads. Follicle-stimulating hormone is synthesized and released by the pituitary gland. The hormone enhances spermatogenesis in males and stimulates follicular growth in females, and it is a 34-kDa glycoprotein (approximately 14% carbohydrate) containing two polypeptide subunits, an α- and a β-chain. Follitropin alpha and follitropin beta are human FSH preparations produced by rDNA technology (71). Gonadotropin preparations are used for infertility treatments in men and women. The production of rhFSH in a CHO cell line has proved to be particularly challenging. Follitropin alpha was the first heterodimeric glycoprotein to be produced by rDNA technology. Before the product of rDNA origin was available for infertility treatment, FSH was isolated from urine at less than 5% purity.

Thyrotropin

Thyroid-stimulating hormone (thyrotropin) is a glycoprotein (molecular weight, 28,000–30,000 daltons) secreted by the anterior lobe of the pituitary gland that is necessary for the growth and function of the thyroid. A recombinant thyrotropin α useful for the detection and treatment of cancer was approved by the U. S. FDA in November 1998.

Enzymes

Tissue-Type Plasminogen Activator

The fibrinolytic system is activated in response to the presence of an intracellular thrombus or clot. The process of clot dissolution is initiated by the conversion of plasminogen to plasmin. Plasminogen activation is catalyzed by two endogenous highly specific serine proteases, urokinase-type plasminogen activator and tissue-type plasminogen activator (t-PA) (see Chapter 31).

The mature human t-PA is a glycoprotein consisting of a single chain of 527 amino acids. Its molecular weight is approximately 70,000 daltons. Human t-PA contains 35 cysteines assigned to 17 disulfide bonds (Fig. 31.22). A serine protease domain of approximately 260 residues is located at the carboxy-terminal end of this protein. A fibronectin “finger” domain, two kringle domains, and an epidermal growth factor domain also are present. The t-PA protease domain is approximately 35 to 40% homologous with typical serine protease, such as bovine trypsin and chymotrypsin.

Mammalian cells produce two t-PA variants of N-linked glycosylation, type 1 (at asparagines 117, 184, and 448) and type 2 (only as asparagines 117 and 448). The rate of fibrin-dependent plasminogen activation is two- to threefold faster for type 2 compared with type 1. The cDNA obtained from a human melanoma cell line was expressed in CHO cells to achieve glycosylation and a protein identical to the natural protein. Protein engineering studies have produced variant t-PA molecules with modified pharmacokinetics, affinity for fibrin, catalytic activity, and side effects.

Three rDNA thrombolytic agents are approved in the United States (31,72,73,74) (Table 6.6 and Fig. 31.22). The first is alteplase, an enzyme equivalent to human t-PA. It is supplied as vials of a white to off-white, lyophilized powder for injection. The powder should be stored at a

room temperature of 15 to 30°C or refrigerated at 2 to 8°C. The expiration date is 2 years after manufacture. Reconstituted solutions (diluent supplied) contain no preservatives and should be stored at 2 to 30°C for no more than 8 hours.

Table 6.6. Commercially Available rDNA Tissue-Type Plasminogen Activators

Generic Name	Trade Name	Chemical Nature
Alteplase	Activase	Human t-PA (527 amino acids)
Reteplase	Retavase	Modified human t-PA (355 amino acids)
Tenecteplase	TNKase, TNK-tPA	Modified human t-PA (527 amino acids)

Alteplase is indicated for the treatment of acute myocardial infarction (administered as a bolus), acute massive pulmonary embolism (administered by intravenous infusion), and ischemic stroke (Table 6.4). The mechanism of action of t-PA is unlike that of streptokinase and urokinase. It is the first fibrin-selective thrombolytic agent preferentially activating fibrinogen bound to fibrin. Thus, the thrombolytic effect is localized to a blood clot and avoids systemic activation of fibrinogen, preventing bleeding elsewhere in the body. Plasma t-PA concentrations are proportional to the rate of infusion. Alteplase is rapidly cleared from circulating plasma, with 50% cleared within 5 minutes after termination of infusion. The mechanisms for clearance of t-PA from the blood are poorly understood. Detectable levels of antibody against alteplase have been found in patients receiving the drug, although 12 days to 10 months later,

antibody determinations have been negative.

The second, reteplase, a recombinant, is a nonglycosylated deletion mutation of human t-PA containing 355 of 527 amino acids of native t-PA. The drug is indicated for acute myocardial infarction and is given as a 10 U + 10 U double bolus.

The most recent addition to the marketed rDNA-derived t-PAs is tenecteplase. This recombinant protein contains three modifications from natural human t-PA. In the kringle 1 domain of natural t-PA, threonine(T)103 replaced by arginine(R); the kringle 1 domain asparagine (N) 117 is replaced by glutamine(Q); and in the protease domain, four amino acids (lysine [K], histadine [H], and two arginines [R]) are replaced by four alanines (A). The drug is indicated for acute myocardial infarction. Bleeding at the injection site is similar to that with alteplase, but there is a reduction in the noncerebral bleeding complications. It is administered as a single, 5-second bolus.

DNase—Dornase Alpha (Pulmozyme)

According to the Cystic Fibrosis Foundation, cystic fibrosis (CF) is the most common fatal genetic disorder, afflicting approximately 30,000 patients, most of whom die before the age of 30 years. They develop thick mucous secretions and suffer from severe, frequent lung infections. Studies during the 1950s and 1960s determined that CF-related secretions in the lungs contained large amounts of DNA. Mucus-thickening DNA release resulted from an inflammatory response and ensuing white blood cell death. The enzyme DNase I specifically cleaves extracellular DNA, such as that found in the mucous secretion of CF patients, and has no effect on the DNA of intact cells. The U.S. FDA has approved a recombinant human DNase (75).

The enzyme DNase I is a glycoprotein containing 260 amino acids with an approximate molecular weight of 37,000 daltons. The recombinant protein is expressed by genetically engineered CHO cells encoding for the native enzyme, although DNase I was not purified or sequenced from human sources at the time. A degenerate sequence, based on the sequence of bovine DNase (263 amino acids), was used to synthesize probes and screen a human pancreatic DNA library. The primary amino acid sequence of rhDNase is identical to native human DNase I.

The only U.S. FDA–approved DNase product, Dornase alpha (inhalation solution), has been developed as a therapeutic agent for the management of CF. The product is supplied in single-use ampules delivering 2.5 ml of a sterile, clear, colorless solution containing 1.0 mg/ml of dornase alpha with no preservative. Administration is by nebulizer aerosol delivery systems.

Dornase alpha is indicated for daily administration in conjunction with standard CF therapies to reduce the frequency of respiratory infections requiring parental antibiotics to improve pulmonary function. The breakdown of DNA in infected sputum results in improved airflow in the lung and reduced risk of bacterial infection. The medicinal agent has been shown in clinical trials to have a positive effect on pulmonary function, which returned to baseline on stopping therapy. Although effective for the management of the respiratory symptoms of CF, dornase alpha is not a replacement for antibiotics, bronchodilators, and daily physical therapy. Two short-term studies have reported no adverse reactions. The agent also is in early clinical trials for the treatment of chronic bronchitis, a disease afflicting 400,000 patients in the United States alone.

Imiglucerase (Cerezyme)

Type 1 Gaucher disease, the most common form, is an inherited disorder. Fewer than 1 in 40,000 people in the general population have Gaucher disease. Patients with the disease lack the normal form of the enzyme glucocerebrosidase. They cannot break down glucocerebroside, causing a buildup of the compound within the lysosomes. This leads to the poor functioning of macrophages and an accumulation of “Gaucher cells” in the spleen, liver, and bone marrow. Some individuals experience few symptoms; others develop life-threatening

conditions. Imiglucerase is an analogue of glucocerebrosidase produced by rDNA technology. The drug consists of 497 amino acids with four glycosylation sites and differs from the human placental glucocerebrosidase by one amino acid (His 495 replaces Arg). Imiglucerase cares out the normal function of the missing enzyme.

Table 6.7. The Five families of Cytokine Receptors and Some Ligands

Receptor Families	Ligands
Class I cytokine receptors	IL-2, IL-7, IL-9, IL-11, IL-13, IL-15, CM-CSF, G-CSF
Class II cytokine receptors	INF-α, INF-β, INF-γ
Tumor necrosis factor receptors	TNF-α, TNF-β, CD30, CD40, FAS
Chemokine receptors	IL-8, RANTES, MIP-1, PF-4, MCAF
Immunoglobin superfamily receptors	IL-1, M-CSF

Cytokines

Cytokine is a generic term for the soluble protein molecules released by participating and interacting cells in the innate and adaptive immune systems. Cytokines communicate in a dynamic cellular network during an immune/inflammatory response to an antigen (75,76,77,78). Lymphokine and monokine are the terms used for a cytokine derived from lymphocytes and macrophages, respectively. Chemokines are a group of at least 25 structurally homologous, low-molecular-weight cytokines that stimulate leukocyte movement and regulate the migration of leukocytes from the blood to tissues. Cytokines, usually released and targeted to produce a localized effect, regulate the growth, differentiation, and activation of the hematopoietic cells responsible for the maintenance of the immune response. A wide array of glycoproteins, including interferons, interleukins, hematopoietic growth factors, and tumor necrosis factors, are cytokines. Cytokines can only act on target cells that express receptors for that cytokine. There are five families of cytokine receptor proteins: Class I cytokine receptors, Class II cytokine receptors, TNF receptors, chemokine receptors, and immunoglobulin superfamily receptors (Table 6.7). Cytokine research has entered an exciting growth phase fueled by genomics, cancer research, and a growing understanding of apoptosis. More than 100 human cytokines are being studied. Among the many reviews discussing the cytokines, several written for pharmacists or pharmaceutical scientists are excellent sources for a readable overview of the area (31,79,80,81,82,83,84,85).

Interferons

The interferons (31,80) are a family of cytokines discovered in the late 1950s with broad-spectrum antiviral and potential anticancer activity, making them biological response modifiers. Biotherapy (the therapeutic use of any substance of biological origin) of cancer is different than standard chemotherapy. That is, biotherapeutic agents belong to a group of compounds that enhance normal immune interactions (therefore, they also are immunomodulators) with cells in a specific or nonspecific fashion. Chemotherapeutics interact directly with the cancer cells themselves. Three types of naturally occurring interferons have been found in small quantities: leukocyte interferon (IFN-α), produced by lymphocytes and macrophages; fibroblast interferon (IFN-β), produced by fibroblasts, epithelial cells, and macrophages; and immune interferon (IFN-γ), synthesized by CD4+, CD8+, and natural killer lymphocytes. Both IFN-α and IFN-β, also known as type I interferons, exhibit approximately 30% primary sequence homology but no structural similarity to IFN-γ, a type II interferon. All three are glycoproteins. Previously only available in low yields by chemical synthesis or isolation, several rDNA interferon pharmaceuticals now have been marketed in the United States, including three IFN-α products, two IFN-β agents, and an IFN-γ drug (Table 6.4).

Interferon-α

At least 24 different human genes producing 16 distinct mature IFN-α molecules with slight structural variations are known (31,80,86). Human IFN-α proteins generally are composed of either 165 or 166 amino acids. The two primary subtype, IFN-α_{2a} and IFN-α_{2b}, both contain 165 amino acids, differing only at position 23, with IFN-α_{2a} containing a lysine group and IFN-α_{2b} an arginine group at this position. They have molecular weights of approximately 19,000 daltons. Although cultures of genetically modified *E. coli* produce two recombinant U.S. FDA-approved IFN-α products, IFN-α_{2a} and IFN-α_{2b}, their method of purification differs. Purification of IFN-α_{2a} includes affinity chromatography using a murine MAb, whereas that of IFN-α_{2b} does not.

Interferon-α_{2a} is commercially available as a sterile solution or a sterile, white-to-beige, lyophilized powder to reconstitute for subcutaneous or intramuscular injection (Table 6.8). Interferon-α_{2b} is available as a sterile, white-to-cream, lyophilized powder to reconstitute for subcutaneous or intramuscular injection

and in combination with the antiviral ribavirin. Storage of the lyophilized powders or the reconstituted solutions should be at 2 to 8°C. As lyophilized powders, IFN-α_{2a} and IFN-α_{2b} have expiration dates of 36 and 24 months, respectively, after manufacture. Reconstituted solutions, if stored properly, are stable for up to 30 days. During the manufacture of the rDNA IFN-α products, human albumin is added to minimize adsorption to glass and plastic by these cytokines. Solutions, therefore, should not be shaken.

Interferon-α possesses complex antiviral, antineoplastic, and immunomodulating activities. Approved indications are shown in Table 6.4. Although the precise mechanism of action of IFN-α is not known, it is believed to interact with cell surface receptors to produce the biological effects. The actions appear to result from a complex cascade of biological modulation and pharmacologic

effects that include the modulation of host immune responses; cellular antiproliferative effects; cell differentiation, transcription, and translation processes; and reduction of oncogene expression.

Table 6.8. Commercially Available rDNA Cytokines

Generic Name	Trade Name	Chemical Nature
Interferon-α_{2a}	Roferon-A	Human interferon (165 amino acids)
Interferon-α_{2b}	Intron A	Human interferon (165 amino acids)
Interferon alfacon-1	Infergen, CIFN	Modified interferon (166 amino acids)
Interferon-β_{1ba}	Avonex	Human interferon (165 amino acids)
Interferon-β_{1b}	Betaseron	Modified interferon (165 amino acids)
Interferon-γ_{1b}	Actimmune	Human interferon (140 amino acids)
Aldesleukin	Proleukin	Modified human IL-2 (132 amino acids)
Denileuin diftitox	Ontak	Modified IL + modified diphtheria toxin
Oprelvekin	Neumega	Modified IL-11 (177 amino acids)
Etanercept	Enbrel	Modified TNF + human lgG1

Interferon-α is filtered through the glomeruli in the kidney and undergoes rapid proteolytic degradation during tubular reabsorption. Toxicity generally is dose- and time-dependent, with fever, fatigue, myalgia, chills, and anorexia (all flu-like symptoms) generally occurring within 2 to 8 hours after administration of high doses.

Concensus interferon

Hepatitis C infection results in a chronic disease state in 50 to 70% of cases and is now the most important known cause of chronic liver disease (87). Following the acute phase, as many as 80% of patients may progress to the chronic phase of the infectious disease. An estimated 20% of patients with a chronic form of the disease progress to cirrhosis. The only agents shown to be effective in the treatment of hepatitis C are the interferons. A unique recombinant molecule, a concensus interferon, known as interferon alfacon-1, has been approved for the treatment of chronic hepatitis C infection. It contains 166 amino acids in a relationship in which each amino acid position in the molecule contains the most commonly occurring amino acid among all the natural IFN-α subtypes. Interferon alfacon-1 exhibits 5- to 10-fold higher biological activity when compared to either IFN-α_{2a} or IFN-α_{2b}.

Interferon-β

Normally produced by fibroblasts, human IFN-β (31,80,86) (Table 6.8) was first cloned and expressed in 1980; however, its instability made it unsuitable for clinical use. The more stable recombinant IFN-β_{1b}, a 165-amino-acid analogue of human IFN-β, differs from the native protein with a serine residue substituted for cysteine at position 17. The highly purified product of biotechnology has a molecular weight of 18,500 daltons. It is produced in a recombinant *E. coli.* Approved in December 1993 by the U.S. FDA, IFN-β_{1b} is indicated for the treatment of patients with exacerbating-remitting multiple sclerosis (MS). The National MS Society says that 250,000 to 300,000 Americans have this disease, with more than 60% of patients falling into the exacerbating-remitting category. A vial of recombinant IFN-β_{1b} contains 0.3 mg of protein with dextrose and human albumin as stabilizers. The sterile, white, lyophilized powder is reconstituted without preservative for single-use subcutaneous injection every other day. Before and after reconstitution, the preparation should be

refrigerated at 2 to 8°C. The refrigerated solution should be administered within 3 hours of reconstitution.

Results from a large, double-blind, placebo-controlled study have found that 8 million IU subcutaneously (the low-dose treatment group) of IFN-β every other day brought the most promising results, with a one-third reduction in exacerbations and a decrease by half in the frequency of severe attacks. Cranial magnetic resonance imaging showed that treated patients did not develop new lesions in the central nervous system and had less active lesions than patients treated with placebo. The exact mechanism of action of IFN-β_{1b} is not known. Its immunomodulating effects, however, may benefit patients with MS by decreasing the levels of endogenous IFN-γ. Levels of IFN-γ are believed to rise before and during acute attacks in patients with MS.

As observed with other interferons, flu-like symptoms are common on administration. During clinical trials, a suicide and four attempted suicides were reported. Depression and suicide also have been reported with patients receiving IFN-α.

Whereas IFN-β_{1b} of rDNA origin was the first to the market, IFN-β_{1a} also is now available. Interferon-β_{1a} is produced in mammalian cells and has the same amino acid sequence and carbohydrate side chain as natural IFN-β. Recombinant IFN-β_{1a} is administered to patients once weekly by intramuscular injection (30 μg). This differs from the subcutaneous administration every other day of rDNA-produced IFN-β_{1b}. Similar to pharmacotherapy with IFN-β_{1b}, the most common side effects of IFN-β_1 therapy include flu-like symptoms.

Interferon-γ

Human IFN-γ (31,80,86,88) is a single-chain glycoprotein with a molecular weight of approximately 15,500 daltons. The cytokine mainly exists as a noncovalent dimer of differentially glycosylated chains in solution in vivo. Glycosylation does not appear to be

necessary for biological activity. The 140-amino-acid IFN-γ_{1b} is produced by fermentation of a recombinant *E. coli.* Approved in 1990 by the U.S. FDA (Table 6.8), IFN-γ_{1b} is supplied as a sterile solution containing 100 μg of the drug for subcutaneous injection. Vials must be placed in a refrigerator at 2 to 8° C and neither frozen nor shaken.

Interferon-γ_{1b} possesses biological activity identical to the natural human IFN-γ derived from lymphoid cells. Although all the interferons share certain biological effects, IFN-γ differs distinctly from IFN-α and IFN-β by its potent capacity to activate phagocytes involved in host defense. These activating effects include the ability to enhance the production of toxic oxygen metabolites within phagocytes, resulting in a more efficient killing of various microorganisms. This activity is the basis for the use of IFN-γ_{1b} in the management of chronic granulomatous disease. Chronic granulomatous disease is a group of rare X-linked or autosomal genetic disorders of the phagocytic oxygen metabolite–generating system, leaving patients susceptible to severe infections. The drug extends the time that patients spend without being hospitalized for infectious episodes. Investigational applications of IFN-γ include the treatment of renal cell carcinoma, small-cell lung cancer, infectious disease, trauma, atopic dermatitis, asthma, allergies, rheumatoid arthritis, and venereal warts. Adverse reactions are similar to those reported for IFN-α.

Interleukins

Interleukins are cytokines involved in immune cell communication. Synthesized by monocytes, macrophages, and lymphocytes, interleukins serve as soluble messengers between leukocytes. Currently, at least 18 interleukins have been observed. One of the most studied cytokines is interleukin (IL)-2, originally called T-cell growth because of to its ability to stimulate growth of T lymphocytes.

Interleukin-2

Human IL-2 is a 133-amino-acid, 15,400-dalton protein that is O-glycosylated at a threonine in position 3. An intramolecular disulfide bond between cysteine 58 and cysteine 105 is essential for biological activity. A recombinant version of IL-2 is marketed as aldesleukin (Table 6.8) (31,80,86,89,90,91,92). Aldesleukin differs from the native protein by the absence of glycosylation, a lack of the N-terminal alanine residue at position 1 (132 amino acids), and the replacement of cysteine with serine at position 125 of the primary sequence. Sequence changes were accomplished by site-directed mutagenesis to the IL-2 gene before cloning and expression. Aldesleukin exists as noncovalent microaggregates with an average size of 27 recombinant IL-2 molecules. The recombinant drug does possess the biological activity of the native protein.

Aldesleukin is supplied as a lyophilized formulation of protein admixed with mannitol to provide bulk in the vial. Sodium dodecyl sulfate is present to ensure sufficient water solubility on reconstitution. The drug is administered as an intravenous infusion. Handling and storage considerations for aldesleukin are

consistent with those of other cytokines. Recombinant IL-2 should be administered within 48 hours after reconstitution.

Aldesleukin is used in cancer biotherapy (i.e., the therapeutic use of any substance of biological origin) as a biological response modifier for the treatment of metastatic renal cell carcinoma and metastatic melanoma. Aldesleukin also recently has been studied in the management of HIV infection. Although the exact mechanism of action is not established, IL-2 is known to bind to an IL-2 receptor that has been well studied. In vitro, IL-2 induces killer cell activity, enhances lymphocyte mitogenesis and cytotoxicity, and induces IFN-γ production. The extent of its antitumor effect is directly proportional to the amount of IL-2 administered. Side effects are the major dose-limiting factor, because aldesleukin is an extremely toxic drug. The manufacturer's labeling should be consulted for full details. Careful patient selection and thorough patient monitoring are essential. The incidence of nonneutralizing anti-IL-2 antibodies in patients treated on an every-8-hour regimen is quite high (76% in one clinical study).

Interleukin-2 fusion protein

Using ligation chemistry approaches during the preparation of recombinant proteins, researchers have created biologically active molecules that combine the activities of two individual proteins into “fusion molecules.” These fusion technologies hold promise for developing custom molecules expressing a wide variety of dual activities. The U.S. FDA has approved the fusion protein denileukin diftitox for the treatment of patients with persistent or recurrent cutaneous T-cell lymphoma (CTCL) whose malignant cells express the CD25 component of the IL-2 receptor (93,94,95). Cutaneous T-cell lymphoma is a general term for a group of low-grade, non-Hodgkin's lymphomas affecting approximately 1,000 new patients/year. Malignant T cells manifest initially in the skin. Over time, there is systemic involvement. For many patients, CTCL is a persistent, disfiguring, and debilitating disease that requires multiple treatments. Malignant CTCL cells express one or more of the components of the IL-2 receptor. Thus, the IL-2 receptor may be a homing device to attract a “killer drug.”

Denileukin diftitox is a rDNA-derived, cytotoxic IL-2 fusion protein that contains the first 389 amino acids of diphtheria toxin fused to amino acid residues 2 to 133 of human IL-2 (the IL-2 residues replace the amino acids of the receptor-binding domain of native diphtheria toxin). Thus, the biotech drug targets IL-2 receptors, and brings the diphtheria toxin directly to kill the CTCL target. Studies have shown that 30% of patients treated with this therapeutic fusion protein experience at least 50% reduction of tumor burden that is sustained for at least 6 weeks.

Interleukin-11

Interleukin-11 is a thrombopoietic growth factor that directly stimulates the proliferation of

hematopoietic stem cells and megakaryocyte progenitor cells (96). This induces megakaryocyte maturation, resulting in increased platelet production. Interleukin-11 is a 178-amino-acid glycosylated cytokine produced by bone marrow stromal cells. Primary osteoblasts and mature osteoclasts express mRNAs for an IL-11 receptor (IL-11Rα). Thus, bone-forming cells and bone-resorbing cells are potential targets of IL-11. In 1997, the U.S. FDA approved an rDNA-derived version of IL-11 produced in *E. coli.* Oprelvekin (Table 6.8) contains only 177 amino acids, lacking the amino terminal proline of the native IL-11. Produced in *E. coli*, the cytokine analogue is nonglycosylated. Oprelvekin has potent thrombopoietic activity in animal models of compromised hematopoiesis. It is indicated for the prevention of thrombocytopenia following myelosuppressive chemotherapy. Pharmacists should monitor for possible fluid retention and electrolyte states when it is used with chronic diuretic therapy.

Tumor Necrosis Factor

Tumor necrosis factors (TNFs), a family of cytokines produced mainly by activated mononuclear phagocytes, have both beneficial and potentially harmful effects, mediating cytotoxic and inflammatory reactions (31). The TNFs are endogenous pyrogens capable of inducing chills, fever, and other flu-like symptoms. Tumor necrosis factor-α, also called cachectin (and commonly referred to as TNF), and TNF-β, also called lymphotoxin, both bind to the same receptor and induce similar biological activities. Biological effects of TNF-α include selective toxicity against a range of tumor cells, mediation of septic shock, activation of elements of the immune system in response to Gram-negative bacteria, and induction/regulation of inflammation. The TNF-α of rDNA origin has been studied extensively, but it has not been developed into a useful drug.

Etanercept is a rDNA-produced fusion protein that binds specifically to TNF and blocks its interaction with cell surface TNF receptors (97,98). It is indicated for the treatment of moderate to severe active rheumatoid arthritis in adults and for juvenile rheumatoid arthritis in patients who have had an inadequate response to one or more disease-modifying antirheumatic drugs. It is a genetically engineered protein that includes two components. The extracellular, ligand-binding portion (p75) of the human TNF receptor is linked as a fusion protein to the Fc portion of the human IgG1 antibody. Each etanercept molecule binds specifically to two TNF molecules found in the synovial fluid of patients with rheumatoid arthritis, blocking the interaction of TNF with the TNF receptor. The drug inhibits both TNF-α and TNF-β. The Fc portion of the fusion protein helps to clear the etanercept-TNF complex from the body.

Hematopoietic Growth Factors

Hematopoiesis is the complex series of events involved in the formation, proliferation, differentiation, and activation of red blood cells, white blood cells, and platelets. Hematopoietic growth factors are cytokines that regulate these events (31,99,100,101,102). Investigators have identified and cloned at least 20 factors, including IL-3 (or multi-CSF), IL-4, IL-5, IL-6, IL-7, erythropoietin (EPO), granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), and stem cell factor. Figure 6.27 summarizes the elaborate hematopoietic cascade. All blood cells originate within the bone marrow from a single class of pluripotent stem cells. In response to various external and internal stimuli, regulated by hematopoietic growth factors, stem cells give rise to additional new stem cells (self-renewal) and differentiate into mature, specialized blood cells.

Erythropoietin–Epoetin Alpha (Epogen, Procrit)

Erythropoietin (31,99,103,104,105,106,107), a glycoprotein with a molecular weight of 30,000 to 34,000 dalton produced by the kidney, stimulates the division and differentiation of erythroid progenitors in the bone marrow, increasing the production of red blood cells. Epoetin alpha (sometimes called rHuEPO-α), a recombinant EPO prepared from cultures of genetically engineered mammalian CHO cells, consists of the identical 165 amino acid sequence of endogenous EPO. The molecular weight is approximately 30,400 daltons. The protein contains two disulfide bonds (linking cysteine 7 with 161 and 29 with 33) and four sites of glycosylation (one O-site and three N-sites); the disulfide bonds and glycosylation are necessary for the hormone's biological activity. Deglycosylated natural EPO or bacterial-derived EPO (without glycosylation) have greatly decreased in vivo activity, although in vitro activity is largely conserved. The sugars may play a role in thermal stability or the prevention of aggregation in vivo.

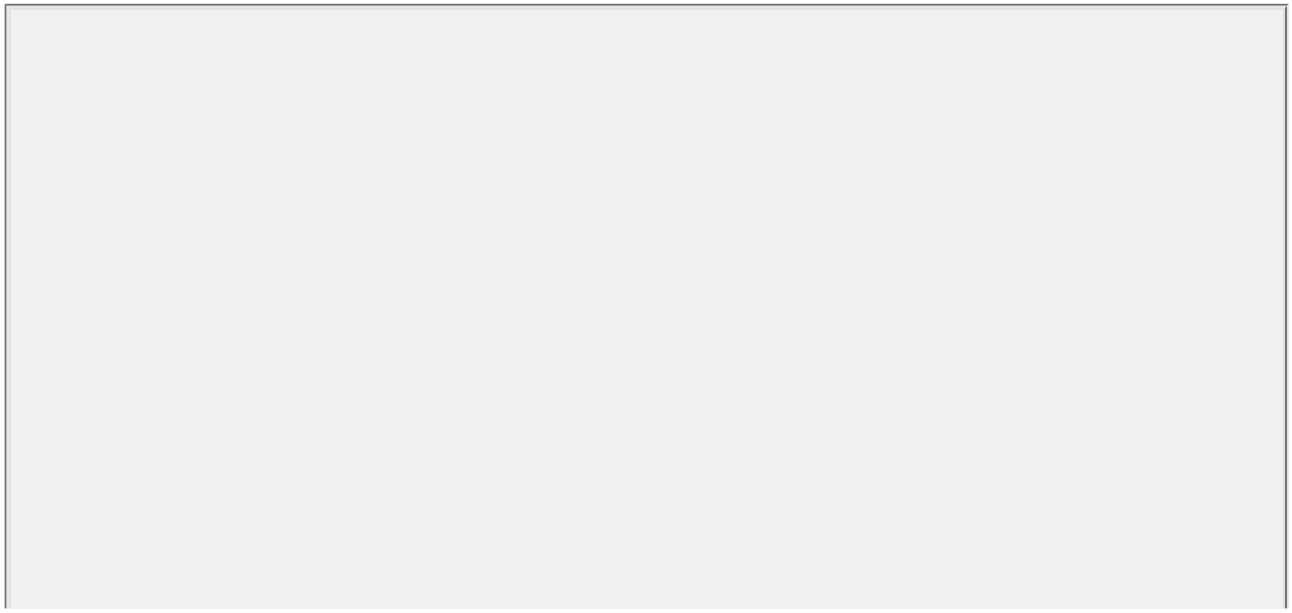
The marketed products are formulated as a sterile, colorless, preservative-free liquid for intravenous or subcutaneous administration. The vial should not be shaken, or the glycoprotein may become denatured, rendering it inactive. Epoetin alpha is indicated for the treatment of various anemias. Several of the conditions are listed in Table 6.4. Epoetin alpha represents a major scientific advance in the treatment of patients with chronic renal failure, serving as a replacement therapy for inadequate production of endogenous EPO by failing kidneys. Epoetin alpha may decrease the need for infusions in dialysis patients. By several mechanisms related to elevating the erythroid progenitor cell pool, epoetin alpha increases the production of red blood cells.

The manufacturer's full prescribing information should be consulted for dosing regimens, because the dose is titrated individually to maintain the patient's target hematocrit. The circulating half-life is 4 to 13 hours in patients with chronic renal failure. Peak serum levels are achieved within 5 to 24 hours following subcutaneous administration.

Colony-Stimulating Factors

The CSFs are glycoprotein cytokines that promote progenitor proliferation, differentiation, and some functional

activation. The name “colony-stimulating factor” results from the fact that these proteins often are assayed by their ability to stimulate the formation of cell colonies in bone marrow cultures. The names added to “CSF” reflect the types of cell colonies that arise in these assays.



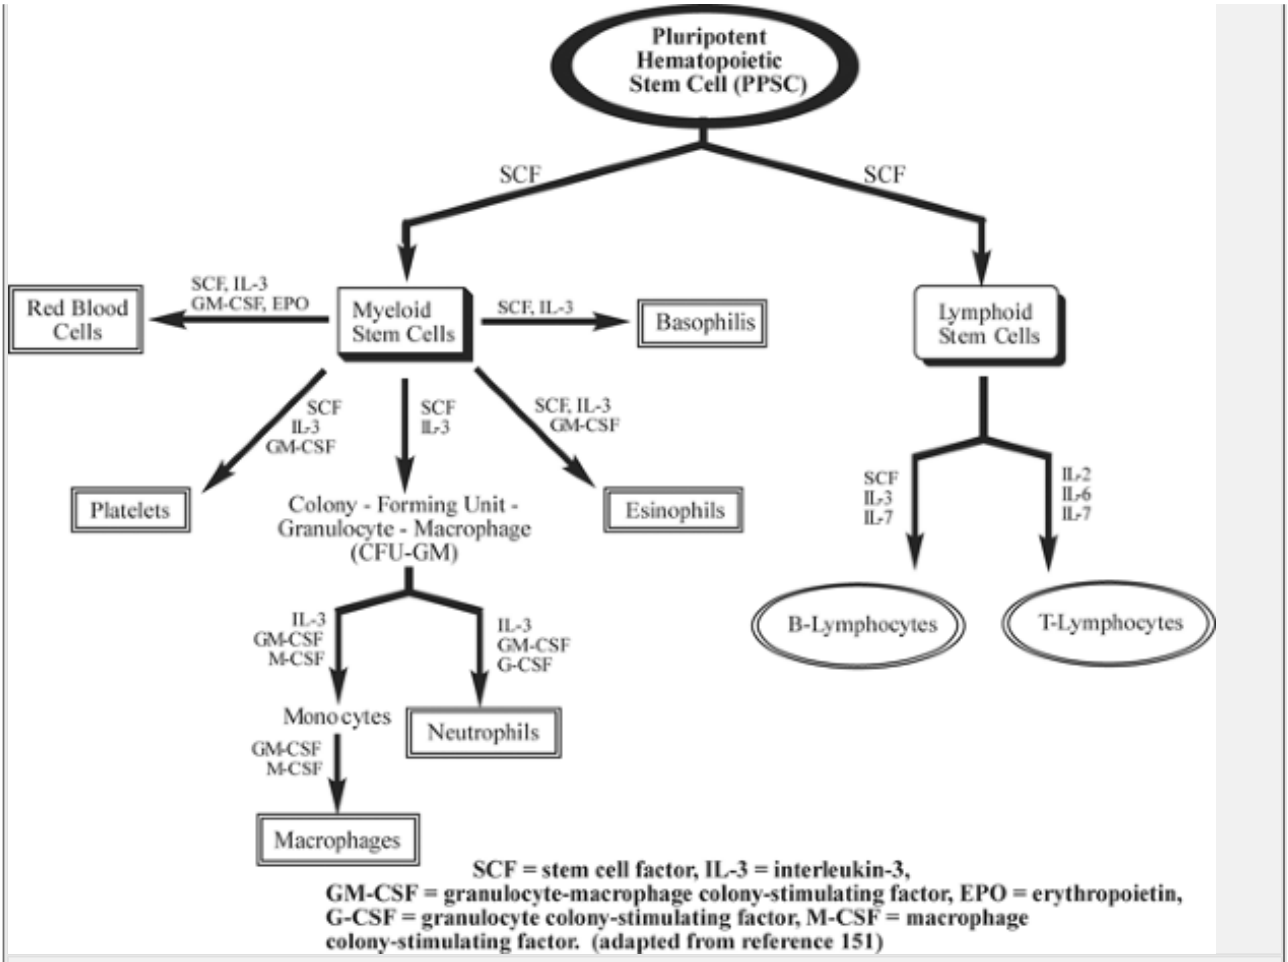


Fig. 6.27. Schematic overview of hematopoiesis.

Granulocyte colony-stimulating factor—Filgration (Neuprogen)

Recombinant DNA–derived G-CSF (31,99,108,109,110,111,112), or filgrastim, was approved by the U.S. FDA in 1991 to decrease the incidence of infection in patients with nonmyeloid malignancies who are receiving myelosuppressive anticancer drugs. Additional indications are shown in Table 6.4. Filgrastim is a 175-amino-acid, single-chain protein with a molecular weight of 18,800 daltons. Filgrastim, produced by a recombinant bacteria, differs from the endogenous human protein by the addition of a methionine at the N-terminus (recombinant methionyl G-CSF is sometimes called r-metHuG-CSF) and the lack of glycosylation. Glycosylation, however, does not appear to be necessary for the biological activity.

Filgrastim injectable solution should be refrigerated at 2 to 8°C and is packaged with a patented indicator that turns red at temperatures below -4°C. The vials should never be shaken before the dose is withdrawn (contains human albumin). Administration is by intravenous infusion or by subcutaneous injection or infusion. The drug is rapidly absorbed, with perk serum concentrations in 4 to 5 hours. Elimination half-life is approximately 3.5 hours.

Filgrastim is lineage selective for the neutrophil lineage type of white blood cells, whereas GM-CSF is multilineage, stimulating progenitors of neutrophils, monocytes, basophils, and eosinophils. The drug reduces the period of neutropenia, the number of infections, and the number of days the patient is on antibiotics. Filgrastim generally is well tolerated, with medullary bone pain being the most frequently encountered side effect.

Granulocyte-macrophage colony-stimulating factor—Sargramostim (Leukine)

The GM-CSF (31,99,108,109,110,111,112) has been produced by rDNA technology in the yeast *S. cerevisiae.* Sargramostim is a glycoprotein of 127 amino acids, differing from the endogenous human GM-CSF by substituting leucine at position 23. Also, the glycosylation pattern may differ from that of the native protein.

Sargramostim is supplied in vials of lyophilized powder (with mannitol) for intravenous infusion. Reconstituted with 1 ml of Sterile Water for Injection, USP

(without preservative), the drug should be administered within 6 hours. Vials are intended for single use only. The powder, reconstituted solution, and diluted solution require refrigeration at 2 to 8°C without being frozen or shaken.

Sargramostim's indications are shown in Table 6.4. Cellular division, maturation, and activation are induced through the binding of GM-CSF to specific receptors expressed on the surface of target cells. On 2-hour intravenous infusion, the alpha half-life is 12 to 17 minutes, followed by a slower decrease (beta half-life) of 2 hours. The manufacturer's label should be consulted for precautions. Additional indications for GM-CSF under study are as an adjuvant to chemotherapy and an adjuvant to AIDS therapy.

Other Growth Factors

Growth factors are cytokines responsible for regulating cell proliferation, differentiation, and function (31). They act as intercellular signals. Each cell type's response is specific for each particular growth factor and differs from growth factor to growth factor. Platelet-derived growth factor (PDGF) is an endogenous growth-promoting protein that is released from cells involved in the healing process and is evident at the cell proliferation stage of a healing open wound. A recombinant human PDGF B homodimer has been produced from genetically engineered *S. cerevisiae* cells (113). Becaplermin is the B-chain of the PDGF B protein. Thus, becaplermin also is referred to as rhPDGF-BB. The 25-kDa protein is formulated into a gel that mimics natural PDGF when applied to diabetic foot ulcers.

Clotting Factor VIII, Factor IX. and Anticoagulants

Antihemophiliac factor, or factor VIII, is required for the transformation of prothrombin (factor II) to thrombin by the intrinsic clotting pathway (31,74,114). Hemophilia A, a lifelong bleeding disorder, results from a deficiency of factor VIII. Conventional biotherapy for the treatment of hemophilia A includes protein concentrates from human plasma collected by transfusion services or commercial organizations. Therefore, the concentrates may contain other native human proteins and microorganisms, such as viruses (e.g., HIV and hepatitis), derived from infected blood. Four versions of recombinant factor VIII (antihemophiliac factor), highly purified, microorganism-free proteins are now available. All four therapeutic proteins are produced by the insertion of cDNA encoding for the entire factor VIII protein into mammalian cells. The mature, heavily glycosylated protein is composed of 2,332 amino acids (1–2 million daltons) and contains sulfate groups. Stability of the large protein is a concern. The products have proved to be safe and effective for reducing bleeding time in patients. There is the possibility, however, of induction of inhibitors in previously untreated patients.

Hemophilia B results when a patient is deficient in specific clotting factor IX (31). It affects males primarily and makes up approximately 15% of all hemophilia cases. A recombinant human factor IX is now available.

Surgeons have used medicinal leeches (*Hirudo medicinalis*) for years to prevent thrombosis in fine vessels of reattached digits. Hirudin is the potent, specific thrombin inhibitor isolated from the leech. Lepirudin is a rDNA-derived (recombinant yeast) polypeptide that differs from the natural polypeptide, having a terminal leucine instead of isoleucine and missing the sulfate group at Tyr 63 (115).

Vaccines

There are two types of immunization: active immunization, and passive immunization. Active immunization is the induction of an immune response either through exposure to an infectious agent or by deliberate immunization with a vaccine (vaccination) made from the microorganism or its products to develop protective immunity. Passive immunization involves the transfer of products produced by an immune animal or human (preformed antibody or sensitized lymphoid cells) to a previously nonimmune recipient host, usually by injection. Sufficient active immunity may take days, several weeks, or even months to induce (possibly including booster vaccinations), but it generally is long-lasting (even lifelong) through the clonal selection of genetically specific immunological memory B and T lymphocytes. Passive immunity, although often providing effective protection against some infection, is relatively brief, lasting only until the injected immunoglobulin or lymphoid cells have disappeared (a few weeks or months). Thus, vaccines enable the body to resist infection by diseases. In response to an injection of vaccine, the immune system makes antibodies, which recognize surface antigens found in the vaccine. If the subject is later exposed to a virulent form of the virus, the immune system is primed and ready to eliminate it. Many viral vaccines are produced from the antigens isolated from pooled human plasma of virus carriers. Vaccinations are among the most cost-effective and widely used public health interventions. Although generally safe, the minimal risk of vaccine-produced infections can be eliminated by administration of highly purified vaccine antigens of recombinant origin (31,115,116,117).

Two hepatitis B vaccines, Recombivax HB and Engerix-B, were marketed in 1986 and 1989 respectively. Both are derived from a hepatitis B surface antigen and are produced in yeast cells. The primary difference between the two appears to be in exact dosing regimens. The immunization regimen consists of three injections: initial, at 1 month, and at 6 months. The immune response and clinical reactions for both intramuscular and subcutaneous administration are

comparable. Vials containing the vaccine in solution should be stored at 2 to 8°C; freezing destroys potency.

There also is a marketed Lyme disease vaccine containing recombinant OspA (31,115,116). The vaccine is a sterile suspension of a noninfectious recombinant vaccine containing an immunodominant outer surface protein of *Borrelia burgdorferi* known as lipoprotein OspA. The antigen is adsorbed onto aluminum hydroxide as an adjuvant. Vaccine efficacy against definite Lyme disease is 78% after three doses.

Monoclonal Antibodies

Introduction to Antibodies

The human immune system is composed of two major branches or arms: the cell-mediated immune system, which includes macrophages, lymphocytes, and granulocytes, and the humoral immune system, which includes the antibody-secreting B cells or plasma cells (76,77,78). In contrast to the cell-mediated nature of the immune actions carried out by most lymphocytes, antibodies or immunoglobulins are soluble proteins that are produced in response to an antigenic stimulus. As part of the normal immune system, each B cell produces as many as 100 million antibody proteins (polyclonal antibodies) directed against bacteria, viruses, and other foreign invaders. Antibodies act by binding to a particular antigen, thereby "tagging" it for removal or destruction by other immune system components.

The production of antigen-"neutralizing" antibodies or immunoglobulins and the detection of a sufficient antibody titer are important concepts for an understanding of vaccinations and exposure to antigens. The humoral response to an antigen involves the creation of memory B cells and the transformation of B lymphocyte into plasma cells that serve as factories for the production of secreted antibodies. Approximately 4 days after initial contact with an antigen (immunization), IgM antibodies (one of five types of immunoglobulin structure) appear and then peak approximately 4 hours later. Approximately 7 days after exposure, IgG, the major class of circulating immunoglobulin, appears. The antibodies bind to the antigen and effect additional immune system-mediated events, "neutralizing" the antigen and leading to its elimination. The concentration of an immunoglobulin specific for a given antigen at a given time is referred to as the antibody titer and may be a measure of the effectiveness of the initial antigen exposure/vaccination to illicit immunologic memory

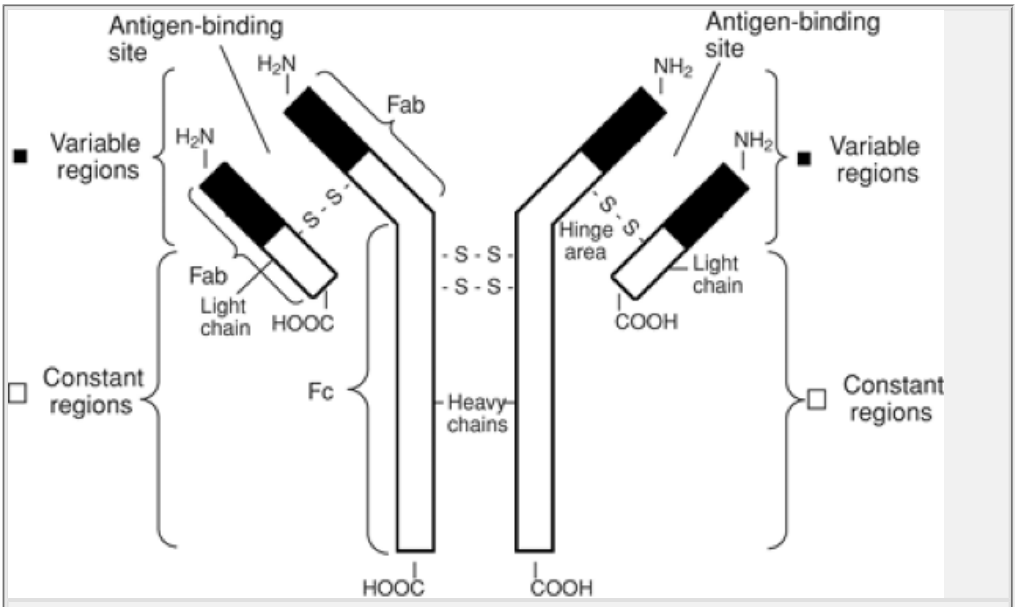

Fig. 6.28. Schematic model of an antibody molecule.

Antibody Structure

Antibodies are glycoproteins. The simplest structure of an immunoglobulin molecule consists of two identical long peptide chains (the heavy chains) and two identical short polypeptide chains (the light chains) interconnected by several disulfide bonds. The selectivity of any immunoglobulin for a particular antigen is determined by its structure and, specifically, by the variable or antigen-binding regions (Fig. 6.28). Enzymatic digestion of the antibody with papain yields the Fab fragment, which contains the antigen-binding sites, and the Fc fragment, which specifies the other biological activities of the molecule.

Hybridoma Technology

Monoclonal antibodies are ultrasensitive, hybrid immune system–derived proteins designed to recognize specific antigens. Nobel Laureates Kohler and Milstein first reported MAbs in 1975 (118). Monoclonal antibodies have been used in laboratory diagnostics, site-directed drugs, and home test kits (80,116,119,120,121,122). The B lymphocyte produces a wide range of structurally diverse antibody proteins with varying degrees of specificity in response to a single antigen stimulus. Because of their structural diversity, these antibodies would be called polyclonal antibodies. Monoclonal antibodies are homogeneous hybrid proteins produced by a selected, single clone of an engineered B lymphocyte. They are designed to recognize specific sites or epitopes on antigens.

Hybridoma technology (the technology used to produce MAbs) consists of combining or fusing two different cell lines: a myeloma cell (generally from a mouse) and a

plasma spleen cell (B lymphocyte) capable of producing an antibody that recognizes a specific antigen (Fig. 6.29). The resulting fused cell, or hybridoma, possesses some of the characteristics of both original cells: the myeloma cell's ability to survive and reproduce in culture (immortality), and the plasma spleen cell's ability to produce antibodies to a specific antigen.

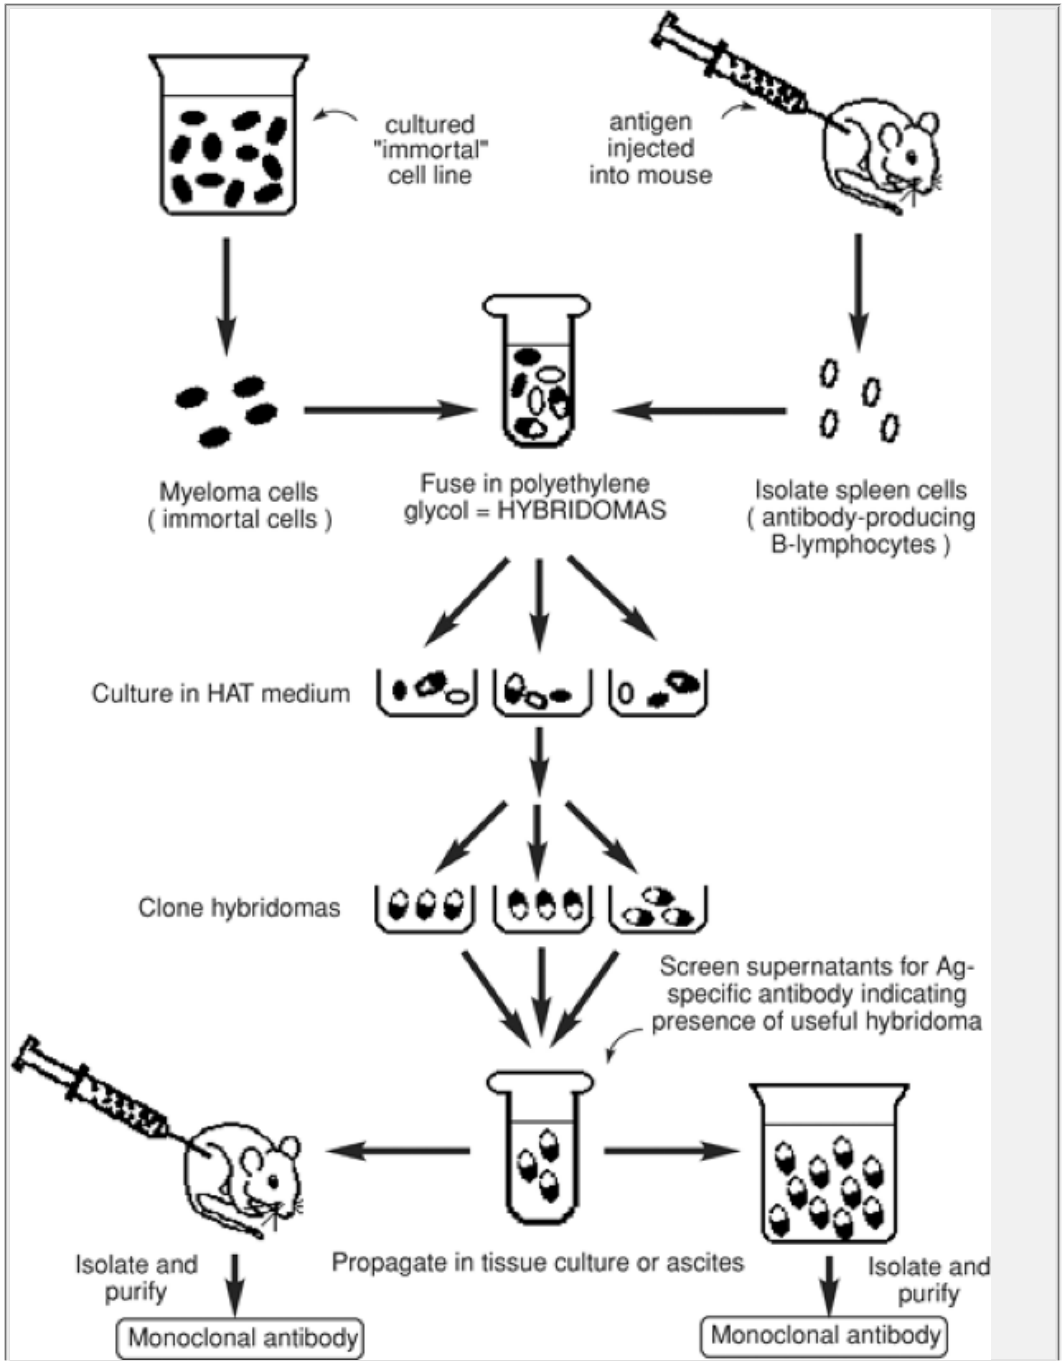

Fig. 6.29. Outline of hybridoma creation and monoclonal antibody (MAb) production.

Two myeloma variant cell lines with defects in nucleotide synthesis pathways are commonly used as fusion partners (80,119,120,123,124). One lacks the *HGPRT* gene coding for an essential enzyme in purine biosynthesis. The other lacks the *Tk* gene coding for a pyrimidine biosynthetic enzyme. Following fusion, the cells are cultured in a medium containing hypoxanthine, aminopterin, and thymidine (HAT medium). Correct hybridomas (one myeloma plus one spleen cell), although missing the gene from the myeloma partner, possess the gene from its spleen cell partner. Fused myeloma hybrids do not survive, because they lack the essential gene. Fused spleen cell hybrids do not grow in culture. Hybridomas, however, can be grown in large quantities, and clones producing antibodies with the appropriate specificity for the original antigen can be isolated from culture. Various techniques have been developed to select the single hybridoma clone producing the desired antibody (thus, MAb). Hybridomas are grown in in vitro cell culture or in vivo in mouse (murine) ascites to yield large amounts of MAbs (1–100 μg/mL in culture and 1 mg/mL in ascites).

Monoclonal antibodies are more attractive than polyclonal antibodies for diagnostic and therapeutic applications because of their increased specificity of antigen recognition. Thus, they can serve as target-directed “homing devices” to find and attach to the targeted antigen. Developments in hybridoma technology have led to highly specific diagnostic agents for home use in pregnancy testing and ovulation prediction kits; laboratory use in detection of colorectal cancer, ovarian cancer, and others; and design of site-directed therapeutic agents, such as trastuzumab to combat metastatic breast cancer and abciximab as an adjunct for the prevention of cardiac ischemic complications.

Monoclonal Antibody Immunogenicity

Nearly 25 years after the pioneering work of Kohler and Milstein, MAbs began to realize their therapeutic potential. Until recently, most MAbs were murine proteins based on their production. Initial clinical trials of murine MAbs showed that these mouse proteins were highly immunogenic in patients after just a single dose (125,126,127). Human patients formed antibodies to combat the foreign MAb that was administered. The human anti-mouse antibody response is known as HAMA. So, far from being the “magic bullets” that were proposed, immunogenic murine MAbs were useless in chronic therapy. Thus, a different approach was needed to eliminate the unwanted immune response (HAMA) in patients.

The variable regions of an immunoglobulin must be of a specific chemical structure with the ability to bind to the antigen they “recognize.” The part within the variable region that forms the intermolecular interactions with the antigen is the complementarity-determining region (CDR). The variable domains of antibody light and heavy chains each contain three CDRs.

It was determined that immune responses against the mouse-produced MAbs were directed against both the variable and the constant regions of the antibody. Human and murine antibodies are very homologous in chemical structure. Thus, an MAb should be engineered to decrease the immunogenicity of an MAb by replacing the mouse constant regions of an IgG with human constant regions, making the antibody less mouse-like (119,128,129,130,131,132). In practice, what generally occurs is the variable heavy-chain and variable light-chain domains (CDRs) of human immunoglobulins are replaced with those of a murine antibody, which possesses the requisite antigen specificity. This “chimeric” MAb will retain its ability to recognize the antigen (a property of the murine MAb), retain the many effector functions of an immunoglobulin (both murine and human), but be much less immunogenic (a property of a human immunoglobulin). A chimeric MAb, containing approximately 70% human sequence, will have a longer half-life than its murine counterpart in a human patient. Therapeutic MAbs that are chimeric include abciximab, ritiximab, infliximab, and basiliximab.

The discovery of the conserved structure of antibodies, particular IgGs, across many species suggested the possibility of chimeric antibodies, and the realization that the homology extended to the antigen-binding site facilitated the engineering of humanized immunoglobulins. Advances in phage display technology and the production of transgenic animals has lead to the production of humanized or fully human MAbs (119,129,130,131,132). Functional human antibody fragments (e.g., Fab fragments) can be displayed on the surface of bacteriophages. A bacteriophage, also called a phage, is a virus that infects bacteria. The expression of these human antibody fragments on the phage surface has facilitated efficient screening of large numbers of phage clones (phage display) for antigen-binding specificity (133). Once a fragment with the requisite antigen specificity is selected, it can be isolated and engineered into a humanized MAb (replacing up to 95% of the murine protein sequence) or a fully human MAb (100% human sequence). Transgenic strains of mice have been genetically engineered to possess most or all of the essential human antibody genes. Thus, on immunization with a foreign antigen, the transgenic mice will develop humanized or fully human antibodies in response. Both of these techniques, although very complex and expensive, have yielded U.S. FDA–approved, humanized antibody pharmaceuticals, such as daclizumab, palivuzumab, and trastuzumab. The half-life of humanized antibodies is dramatically enhanced (from hours to weeks), and immunogenicity is drastically reduced.

Monoclonal Antibody Therapeutic Agents

Hybridoma technology and advanced antibody engineering has led to the design of an increasing number of site-directed therapeutic agents for the treatment and prevention of transplant rejection, therapy in rheumatoid arthritis, treatment of non-Hodgkin's lymphoma, and other indications. These products (Table 6.9) are examples of murine, chimeric, and humanized MAbs, and they represent significant advances in pharmacotherapy.

Monoclonal Antibody Diagnostic Agents

Several ultrasensitive diagnostic MAb-based products have enjoyed great success; these include a variety of imaging agents for the detection of blood clots and cancer cells. A monoclonal Fab fragment, technetium-99m-arcitumomab (CEA-Scan), can detect the presence and indicate the location of recurrent and metastatic colorectal cancer. Colorectal cancer and ovarian cancer can be detected with satumomab pendetide (OncoScint CR/OV). Capromab pentetate (ProstaScint) is used for detection, staging, and follow-up of patients with prostate adenocarcinoma. Small-cell lung cancer can be detected with nofetumomab (Verluma). The first imaging MAb for myocardial infarction is imiciromab pentetrate (MyoScint). Pharmaceutical Research Manufacturing of America (PhRMA) reports that 59 of the 369 biotechnology agents in testing are MAb-based products, and most are diagnostics.

Table 6.9. Some U.S. Food and Drug Administration–Approved MAb Therapeutic Agents

Generic Name	Trade Name	MAb Type	Indication
Trastuzumab	Herceptin	Humanized	Refractory breast cancer
Muromonab-CD3	Orthoclone-OKT3	Murine	Reversal of transplant rejection
Infliximab	Remicade	Chimeric	Crohn's disease
Abciximab	ReoPro	Chimeric	Adjunct to PTCA for prevention of acute cardiac complications
Ritiximab	Rituxan	Chimeric	Treatment of B-cell non-Hodgkin's lymphoma
Basiliximab	Simulect	Chimeric	Prevention of transplant rejection
Daclizumab	Zenapax	Humanized	Prevention of transplant rejection
Palivizumab	Synagis	Humanized	Respiratory syncytial virus prophylaxis
Gemtuzumab	Mylotarg	Fusion MAb	Treatment of CD33-positive cute myeloid leukemia

Natalizumab	Tysabri	Humanized	Multiple sclerosis

Monoclonal Antibody–Based, In-Home Diagnostic Kits

The strong trend toward self-care, coupled with a heightened awareness by the public of available technology and an emphasis on preventive medicine, has increased the use of in-home diagnostics (134,135,136). Sales of in-home diagnostics were predicted to exceed $3.7 billion by 2006. Monoclonal antibody specifically minimizes the possibilities of interference from other substances that might yield false-positive test results. The antigen being selectively detected by MAb-based pregnancy test kits is human chorionic gonadotropin, the hormone produced if fertilization occurs and that continues to increase in concentration during the pregnancy. Table 6.10 lists some examples of MAb-containing in-home pregnancy test kits. Luteinizing hormone in the urine is the antigen detected by MAb ovulation prediction in-home test kits. These test kits can help to determine when a woman is most fertile, because ovulation occurs 20 to 48 hours after the luteinizing hormone surge. Table 6.10 also provides some examples of MAb-based, in-home ovulation prediction kits.

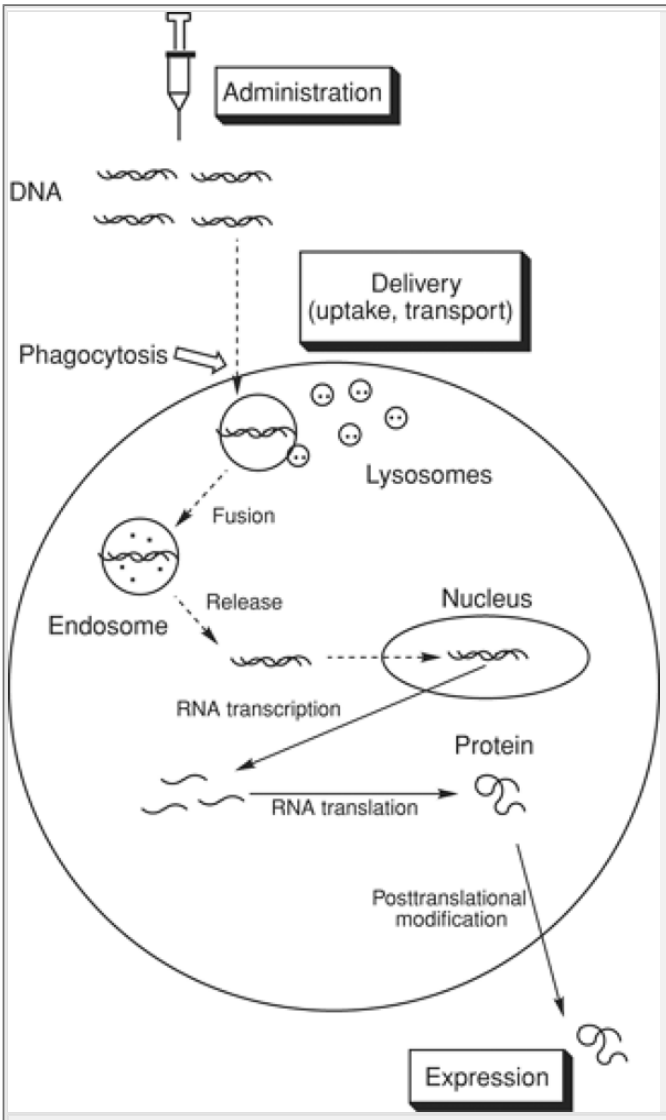

Fig. 6.30. Steps in gene therapy: administration, delivery, and expression. Dashed arrow represents uptake and transport.

Gene Therapy

The premise of gene therapy is that genes can be used as pharmaceutical products to cause in vivo production of therapeutic proteins. There is considerable confidence that gene therapy, as a therapeutic paradigm, will provide a number of novel pharmaceutical products, diagnostics, and therapeutic approaches in the next decade (137).

A major problem in gene therapy is similar to the problem encountered in all forms of drug therapy, that being the assurance of drug efficacy through efficient delivery of the therapeutic agent to its biological target in a fully functional form (138). Gene delivery is unique in the sense that it is the product of gene function, the protein, and not the gene itself that is the therapeutic agent. Hence, we must not only deliver the gene to its proper target but also assure that when the gene reaches its target, it will arrive in a form that will produce the therapeutic agent in such a form that it, too, will be assured of reaching its specified target. What is most critical in gene delivery is the effective modulation of the production of the therapeutic protein. Constitutive expression of some proteins may occur without adversely affecting the therapeutic efficacy. Constitutive expression of most genes is not desirable, however, and can even be life-threatening. The proper, controlled delivery of the protein necessitates the previous delivery of the gene to the cell nucleus, and this special consideration for gene delivery compared to conventional drugs warrants the development of novel vehicles for the delivery of genes to the cell nucleus. Most gene therapy protocols involve the use of viruses as gene carriers or vectors; however, there also are nonviral methods of gene delivery appearing in the National Institutes of Health-approved gene therapy protocols. In both cases, the steps involved in the delivery of the therapeutic agent include the following (Fig. 6.30) (139):

- Administration or introduction of the nucleic acid (DNA) into the body, which usually involves either in vivo or in vitro (ex vivo) techniques.

- Delivery of the nucleic acid from the site of administration to the nucleus, which includes directing the bioavailability, uptake of the nucleic acid (DNA) into the cell, and translocation of the nucleic acid from the cytosol to the nucleus.
- Expression of the nucleic acid product, including the normal steps in gene expression (transcription, translation, and posttranslational modification). Expression is vital to the therapeutic efficacy of the gene in the sense that controlled expression of genes is important for proper biological function. Current delivery technologies result in continuous gene expression.

The viral and nonviral vectors approach the problem of nucleic acid delivery from opposite directions. Viral vectors are reduced in complexity to make them less immunogenic yet maintain the efficient delivery properties, whereas nonviral vectors are altered to increase the complexity of their delivery systems to improve the specificity and efficiency of nucleic acid delivery. It is likely that the ideal vector will be a composite of viral and nonviral delivery vehicles. Some of the properties that might be features of the ideal delivery vector include:

- No limit in the size of the gene that can be incorporated into the vector.
- Absence of immunogenicity.
- Ability to target specific tissue or cell populations.
- Incorporation of elements that limit the expression of delivered genes to specific cell types.
- Ability to modulate the levels of gene expression in response to exogenous and endogenous signals.
- Stability and ease of productivity in large quantities at high concentrations.

Viral Vectors

Virus–based gene delivery arose from the attempt to exploit the highly evolved viral pathways for infection to achieve efficient delivery and expression of therapeutic genes in the body (137,140,141). Viral vectors

are attenuated or defective viruses engineered to carry therapeutic genes. Several different viruses have been developed as vectors for gene therapy, including the murine C-type oncovirus and HIV (retroviruses), adenovirus, adeno-associated virus, and the herpes simplex virus (Table 6.11). Ultimately, the therapeutic gene vectors should target specific types of genetically damaged cells, insert into a specific position in the cell's genome, and produce large amounts of the corrective protein in a regulated fashion.

Table 6.11. Comparison of the Properties of Various Vector Systems[a]

Features	Retroviral	Adenoviral	AAV	Herpes
Maximum insert size	7.0–7.5 kb	~30 kb	3.5–4.0 kb	150 kb
Concentrations (viral particles/mL)	$>10^8$	$>10^8$	$>10^{12}$	$>10^8$
Route of gene delivery	Ex vivo	Ex/in vivo	Ex/in vivo	Ex/in vivo
Integration	Yes	No	Yes/no	No
Duration of expression in vivo	Short	Short	Long	Long
Stability	Good	Good	Good	Good
Ease of preparation (scale-up)	Pilot scale-up, up to 20–50 L	Easy to scale up	Difficult to purify, difficult to scale up	—
Immunological problems	Few	Extensive	Not known	—
Preexisting host immunity	Unlikely	Yes	Yes	—
Safety problems	Insertional mutagenesis	Inflammatory response, toxicity	Inflammatory response, toxicity	—

Retrovirus

The retroviruses (*Retroviridae*) have three subfamilies: the *Spumavirinae* (foamy viruses), the *Lentivirinae*, and the *Oncovirinae* (142). The oncoviruses based on the murine C-type oncovirus are the vector of choice for gene therapy protocols. The retrovirus enters the target cells, where its RNA genome is converted to proviral DNA and transported to the nucleus. In the nucleus, the proviral DNA becomes integrated into the host chromosomal DNA, thus ensuring long term persistence and stable transmission to all progeny of the transduced cell (Fig. 6.31).

The murine leukemia viruses have been the most widely used as vectors for gene therapy. Human retroviral gene therapy requires replication-defective vectors capable of delivering the therapeutic gene to the target cells without causing severe infection by further replication. The proviral genome has a complex sequence of essential components necessary for mRNA reverse transcription and integration of the viral RNA (142). These elements serve to carry out packaging to ensure encapsidation of vector RNA, portions of the genome directing reverse transcription, and regions necessary for the integration of the vector DNA into the host cell chromosome in the ordered and reproducible manner characteristic of retroviruses. The protein coding sequences *gag*, *pol*, and *env*, however, can be discarded and replaced with the therapeutic gene.

The modified vector carrying the cDNA of the therapeutic gene is incapable of forming viral particle, since the *gag*, *pol*, and *env* genes are missing. Therefore, a retroviral packaging cell line is required to provide the viral "helper" functions that have been deleted from the vector. The *gag*, *pol*, and *env* genes are stably expressed in the packaging cell from helper plasmids that lack the ψ packaging sequence; therefore, the transcripts from the helper plasmid are not packaged in viral particles (Fig. 6.32). The gag, pol, and env proteins are produced by the helper plasmid and form the viral core and envelope proteins. The vector transcript carrying the ψ packaging sequence and the therapeutic gene is recognized by the gag proteins and are incorporated into the core particle, which then buds off into a one-time-only infective particle delivering the therapeutic gene to the target cell. The *gag*, *pol*, and *env* genes are not packaged in a viral particle, because the sequence carrying these genes is lacking the packaging signal.

Adenovirus (AV)

Adenoviruses are DNA viruses that belong to the *Adenoviridae* family of viruses. They are the most widely used DNA viruses for gene transfer vectors. The primary target for AV infection is the respiratory epithelial cells. The AV are large viruses and, hence, can carry large DNA inserts (up to 35 kb) (Table 6.11). They can transduce nondividing cells and produce very high titers in culture. They also are human viruses and are able to transduce a large number of different human cell types at a very high efficiency. Unlike the retroviruses, the AV do not integrate into the host cell chromosome but remain in the nucleus as an extrachromosomal element or episome. Because of the extrachromosomal nature of the dsDNA insert, the therapeutic gene is eliminated over time.

The major problem with AV vectors is immunotoxicity. Because the recombinant AV vectors are attenuated (not defective) viruses, they express several viral proteins. The result is induction of cytopathic and immunogenic responses in vivo. Some of the attempts to improve the AV as a therapeutic gene vector include (137):

-

Reduction of immunogenicity by further mutation of the genome to reduce viral protein production.

- Increasing the potency of the virus to reduce the immune challenge.
- Coadministration of immunosuppressants with the vector therapy.

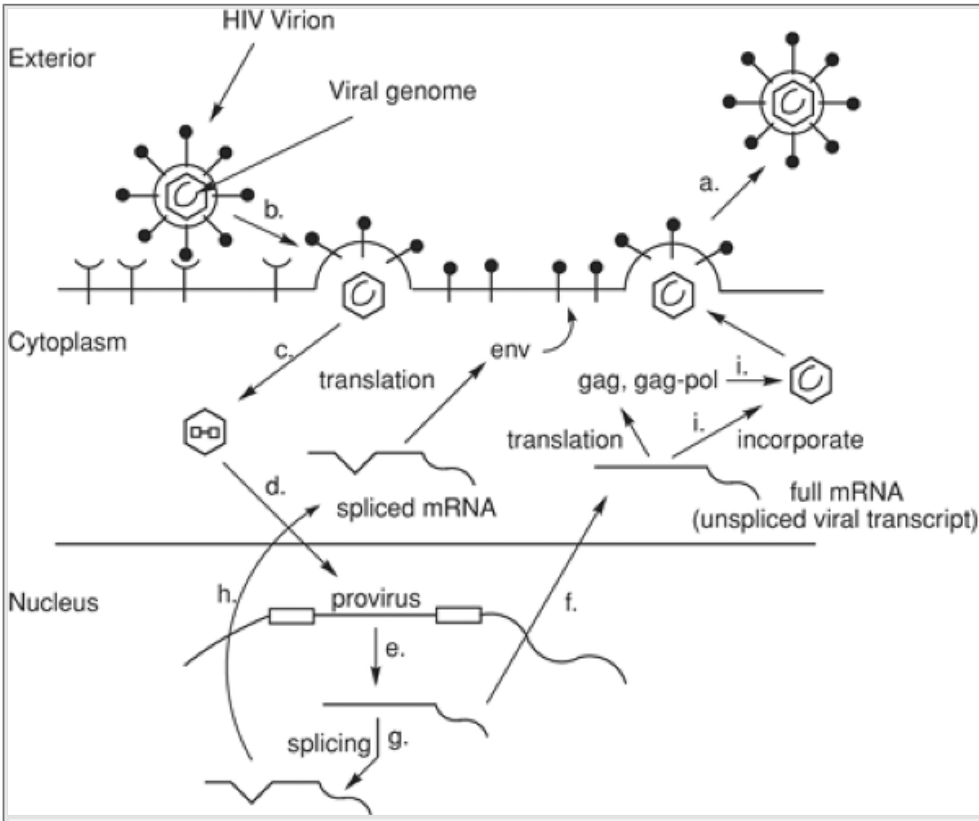

Fig. 6.31. Retroviral entry into target cells. The HIV virion is composed of a nucleoprotein core surrounded by an envelope. The core contains the viral genome, which consists of two identical positive, single-stranded RNA molecules and viral proteins. (a) The envelope is derived from the cell membrane when the virion buds from the cell. (b) Penetration into the cell is initiated by and dependent on specific interactions between the viral gp120 molecule, which is embedded in the viral envelope, and the cellular receptor, the CD4 molecule. (c) After partial uncoating of the virus, viral RNA is reverse transcribed to form a linear double-stranded DNA molecule. (d) This linear double-stranded DNA molecule is then translocated into the nucleus as part of a preintegration complex, where it integrates into the host genome. (e) The integrated viral DNA, called a provirus, is the template for transcription, a process that is under the strict regulation of the viral tat gene. (f and g) The initial viral transcript either is (f) transported to the cytoplasm without further processing to serve as genomic RNA or (g) remains in the nucleus, where it undergoes a series of splicing reactions regulated by the viral *rev* gene. (h) The viral *rev* gene generates mRNAs for viral protein synthesis. (i) The newly synthesized viral proteins (gag and gag-pol) associate with unspliced viral transcripts to form viral cores. (j) These viral cores bud through the cell membrane, acquiring the viral envelope.

Adeno-associated Virus

The adeno-associated virus (AAV) is a nonpathogenic, ssDNA virus belonging to the *Parvoviridae* family of viruses. This virus has two genes: The *cap* gene encodes for three viral coat proteins, and the *rep* gene encodes for four proteins involved in viral replication and integration. This virus needs additional genes to replicate that are provided by the helper virus, which usually is the adenovirus or herpes virus. Interest in this virus as a vector arose from the

discovery that the *rep* gene product directs the virus to integrate the viral DNA preferentially into human chromosome 19. The AAV vector is produced by replacing the *rep* and *cap* genes with the therapeutic gene. Without a helper virus, the AAV will integrate into the host genome and remain as a provirus. Because of the toxic nature of the *rep* gene products, it is difficult to develop a packaging cell line in which all of the protein can be stably produced, and this is a major problem with the AAV as a therapeutic gene vector. Also, because the rep proteins are missing in the therapeutic gene vector, the site-specific insertion in chromosome 19 is not observed. The AAV is a small vector that can only carry genes of approximately 4.8 kb. and the defective vector does not efficiently integrate into the genome of nondividing cells.

Herpes Simplex

Herpes simples virus (HSV) is a member of the alpha-herpes virus family that are nuclear DNA viruses with large genomes capable of carrying therapeutic genes up to 150 kb. These viruses are able to establish lifelong latent infections in which the viral genome exists as a stable episome in the host cell (143,144). Genes delivered by the HSV vector can be maintained indefinitely as an episome in long-lived cells, such as those of the nervous system. Herpes simplex viruses made replication deficient by deleting the transcriptional regulator gene IE-3

are used as therapeutic gene vectors. Plasmids containing the HSV origin of replication and packaging signal are termed “amplicons.” The amplicon also can be used as a vector in the presence of a helper virus, which usually is the IE-3–deficient HSV. In this case, the amplicon/helper virus requires a complementary cell line that provides the IE-3 gene products to assist in forming the replication-deficient viral vectors. Long-term expression is a major obstacle to routine use of this virus as a therapeutic vector.

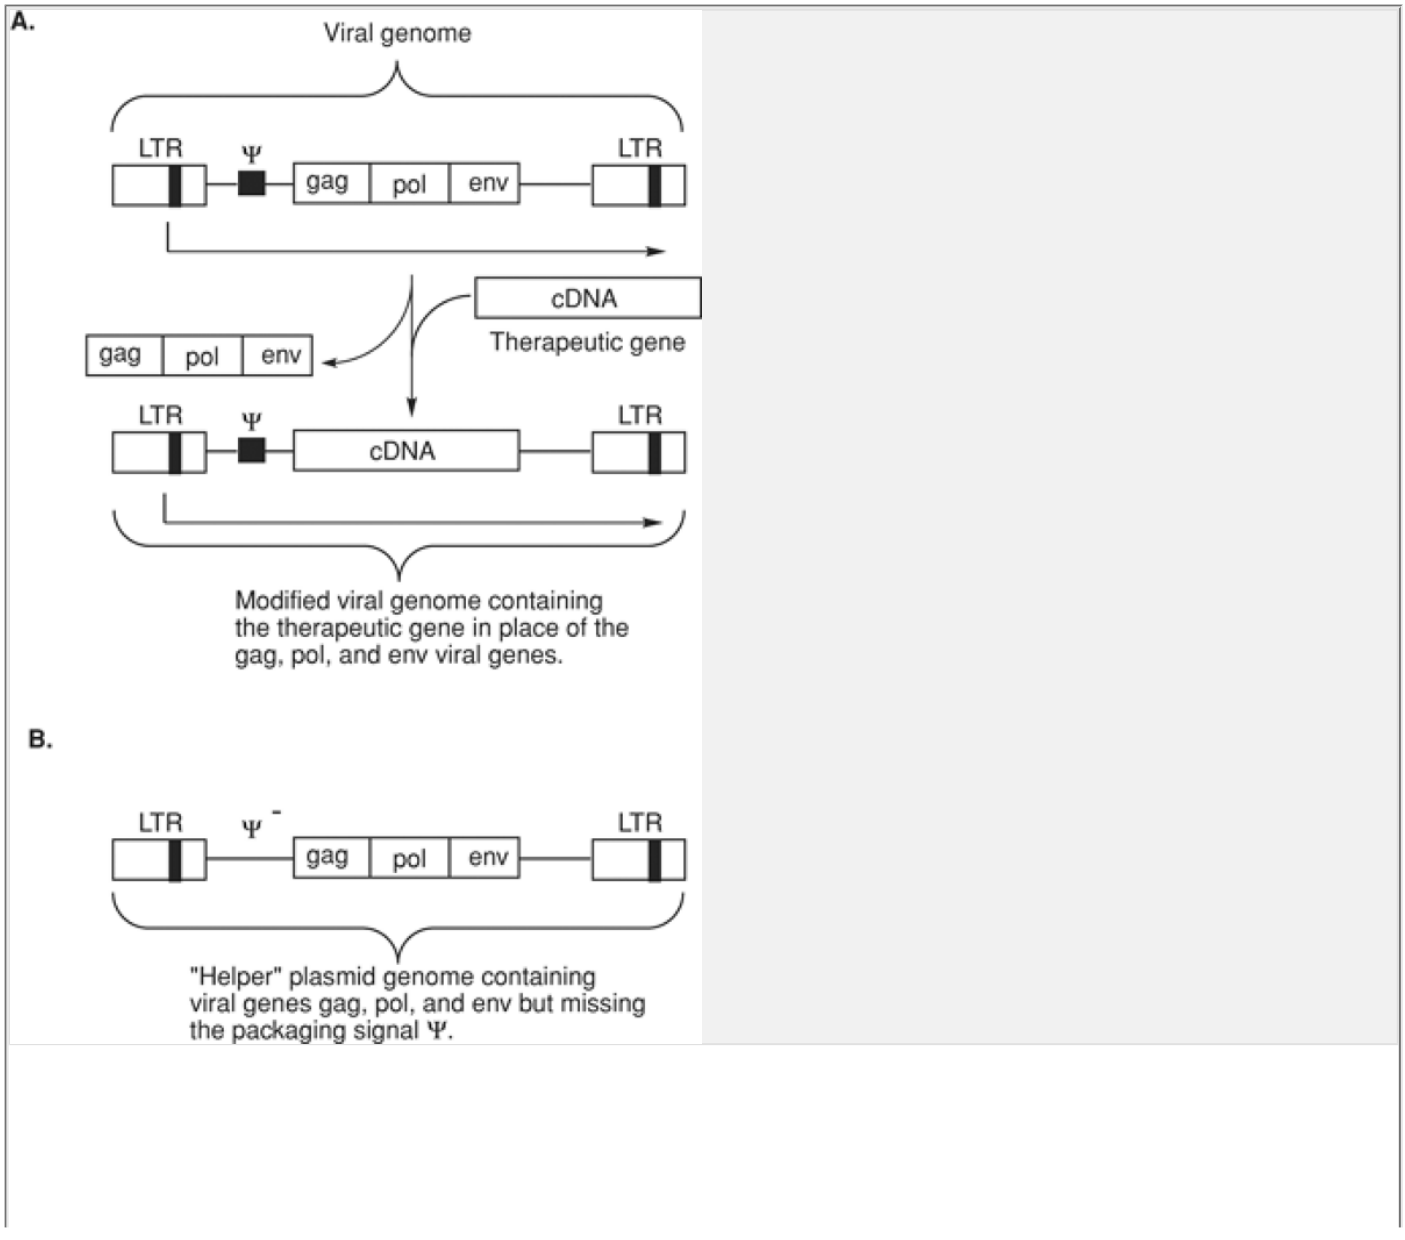

Fig. 6.32. (A) Schematic representation of the preparation of a single gene retroviral construct. The therapeutic gene replaces the retroviral *gag, pol*, and *env* genes. Expression of the therapeutic gene is driven off the viral long terminal repeat (LTR) containing the retroviral packaging signal sequence (ψ). (B) Schematic representation of a helper cell genome containing the retroviral *gag, pol*, and *env* genes but lacking the packaging signal sequence (ψ-).

Nonviral Vectors

Compared to the conventional small molecule drugs that are the mainstay of pharmaceutical care, the plasmids that are used to carry the therapeutic DNA (gene) in nonviral vectors are large, circular, hydrophilic macromolecules of bacterial origin with a hydrodynamic diameter between 100–200 nm and approximately 3,000 kDa in molecular weight (5–10 kbp) (Fig. 6.33) (137). Plasmids carry a net negative charge and are susceptible to nucleases, and their potential as a class of pharmaceuticals is limited by their colloidal and surface properties. The size and charge density of these particles are problematic when it comes to their delivery as therapeutic agents, and these properties depend on the number of base pairs and the DNA conformation. Supercoiled DNA has higher negative charge density than linear, or nicked-circular, DNA and, therefore, has a more negative zeta potential (electrophoretic mobility) than nicked-circular DNA that is slightly more negative than linear DNA (137). The zeta potential varies between -30 and -70 mV and effectively prevents the plasmid from crossing biological membranes. Plasmids contain the therapeutic gene of mammalian origin and other DNA sequences to control the gene expression in vivo. The plasmid also may contain genetic elements controlling mRNA stability and the timing of protein production, cell-specific promoters and enhancers to limit gene expression to specific sites in the body, as well as sequences to direct posttranslational processing and secretion of the gene product. Plasmids delivered by nonviral techniques do not integrate into the host genome at doses used but remain in the nucleus (extrachromosomal episomes). The plasmids will therefore persist in the target cells according to the biochemical half-life of the molecule, which can be anywhere from several months to a few hours. Therefore, as the transfected cells replicate, the DNA gradually is lost over time. The nonviral techniques thus provide a finite period of expression of the therapeutic gene. The advantage is that the techniques may be applied to both chronic and acute diseases, in which the

dose and frequency of administration is controlled by the clinician and the level of expression may be quickly adjusted—or even terminated—in response to a patient's changing clinical needs. Plasmids also contain nucleic acid sequences that allow them to be grown in bacteria, including a prokaryotic origin of replication and selectable markers, thus allowing the plasmids to be amplified through cloning in bacteria.

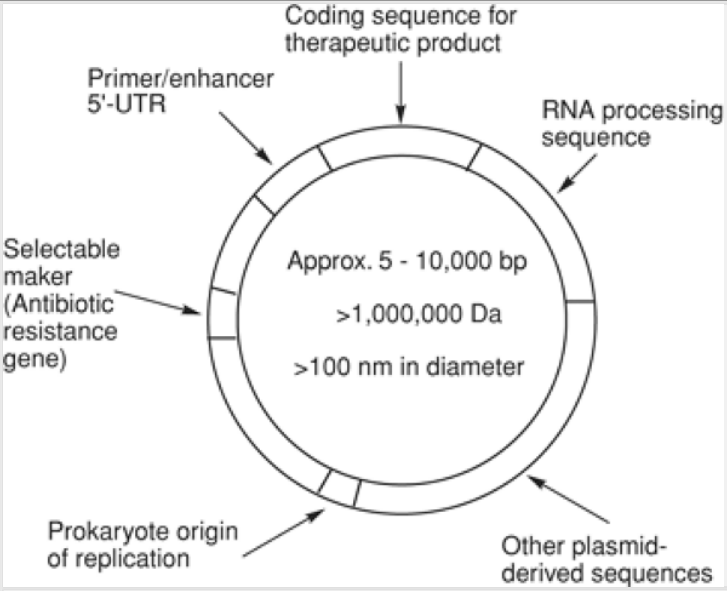

Fig. 6.33. Plasmid DNA constructed for gene delivery contains a therapeutic gene sequence, eukaryotic gene promoter regions, prokaryotic origins of replication, selectable markers, as well as RNA processing sequences and other plasmid-derived sequences. (Adapted from Ledley FD. Pharmaceutical approach to somatic gene therapy. Pharm Res 1996;13:1595–1614; with permission.)

Some of the specific barriers to the in vivo delivery of DNA can be identified (137):

Rapid degradation of DNA within tissues or blood by nucleases.

- Limited dispersion of DNA from the site of interstitial administration.
- The inability of DNA to cross intact basement membranes of the endothelium or epithelium effectively.
- The rapid clearance of DNA from the vascular compartment by cells of the reticuloendothelial system.
- The need for effective interaction with the surface of the target cell to induce internalization.
- Destruction of DNA in the endosomal/lysosomal compartments by nuclease, acid, and/or reducing agents.
- The need to penetrate to the nucleus of cells across the periplasmic membrane and nuclear membrane.

The elements of a nonviral gene delivery system include a gene coding for the therapeutic gene, a plasmid-based expression system, and a synthetic delivery system.

Direct Injection (30)

The microinjection of naked DNA in the form of circular plasmids often is used for introducing genes into embryos to engineer transgenic animals. Delivery is localized to the site of injection, and unless the injection is made directly into the cell, the problem of uptake of naked DNA into the cell limits the efficiency of the technique. There has been some success in using this technique to deliver genes to skeletal and cardiac muscle tissue; this success has been attributed to the possibility that the sarcoplasmic reticulum and transverse tubules found in muscle tissue are favorable structures for DNA uptake. The DNA uptake through the cavelolae in muscle via potocytosis involves invagination of the caveloae-rich membranes. There is potential for using direct injection of naked DNA in DNA vaccinations where delivery need not be widespread, because stimulation of the immune system is the goal of vaccination.

Electroporation

Electroporation is used in research for the transfection of a wide range of plant and animal cells, many of which are not amenable to transfection by other methods, such as calcium phosphate coprecipitation. Electroporation likely involves a physical interaction between the cell membrane and the applied electric field and, as such, may be relatively independent of cell type. The procedure involves charging a capacitor with a conventional power supply and then discharging the capacitor (2–10 kV/cm) through a cell suspension containing DNA over a very short time period (<5 microseconds [μs]). Mammalian cells have been transfected with a weaker pulse (0.53 kV/cm) and a longer duration (7,000 μs) (145). The DNA enters when the cells are exposed to a pulsed electric field, presumably disrupting the membrane lipids and creating pores in the cell membrane without damaging the membrane structure (146). The DNA concentration and voltage are critical parameters for electroporation. There is a sharply defined voltage for efficient transfection depending on the buffer and capacitance. The procedure should be applied over a range of voltages to determine the best voltage for the experimental conditions. The local potential difference across the cell is the driving force for membrane pore formation and is proportional to the product of the capacitor voltage and the cell diameter (147). Therefore, the voltage optimum for transfection will depend inversely on cell size (145).

Particle Bombardment

Particle bombardment involves the generation of a shockwave via an explosive device (148), compressed gas (149), or electrical discharge (150) to propel DNA-coated gold or tungsten particles into the target tissue. The gold particles usually are 1 to 3 μm in size; the tungsten particles are slightly larger (~4 μm). The particles are coated with DNA by precipitation through addition of calcium chloride and spermidine solutions to the plasmid DNA in the presence of a suspension of the gold or tungsten particles. The DNA-coated particles are deposited on macrocarrier disks, and a shockwave, generated as described above, accelerates the particles to a high velocity, enabling efficient penetration of target organs, tissues, or single cells in their path. Some acceleration devices can be finely tuned to adjust the velocity and resulting distribution of particles in various target tissues by varying the discharge voltage or gas pressure, bead density, and bead size. This technique is not likely to be widely used for gene delivery, because it is essentially a surgical procedure and the particles are only able to penetrate several millimeters into the target tissue. However, it may well have widespread use as a gene vaccine delivery vehicle

(151).

Calcium Phosphate Precipitation

One of the early methods of facilitating the transport of DNA into cells was the coprecipitation of DNA with calcium phosphate or calcium chloride and application the precipitate to a monolayer of cells (152). The mechanism of uptake is not fully understood, but it is postulated that the particulate nature of the calcium phosphate/DNA complex adheres to the cell membrane and is taken up by endocytosis. The pH of the buffer during the formation of the precipitate, the gradual formation of the precipitate

(overnight incubation of the DNA in the calcium phosphate N,N-bis(2-hydroxyethyl)-2-aminoethane sulfonic acid–buffered saline, 2XBBS), and the concentration of the DNA are critical factors in determining the efficiency of the procedure in delivering DNA to the cell (153,154). A pH in the region of 7.0 and DNA concentrations of 40 μg/ml result in the most efficient uptake of DNA by the mammalian cells. Calcium is an efficient facilitator of DNA uptake for a number of reasons. It increases the concentration of DNA on the cell surface through precipitation and protects the DNA from digestion by serum and intracellular nucleases. Calcium phosphate itself also induces phagocytosis. Additionally, the calcium phosphate precipitate may neutralize the negative charge on the DNA molecule, thus facilitating penetration of the lipid membrane and reducing repulsion of the negatively charged DNA by the negatively charged cell membrane. Other cations, including polyornithine, polylysine, polybrene, and diethylaminoethylamine, also have been used as cationic facilitators for cellular uptake of DNA (155,156). The most efficient facilitated DNA uptake is observed in cells at the exponential stage of growth. This technique, however, depends on the phagocytosis of the DNA/calcium phosphate particle, resulting in endosome formation and the exposure of the DNA to the intracellular endosome/lysosome degradation process.

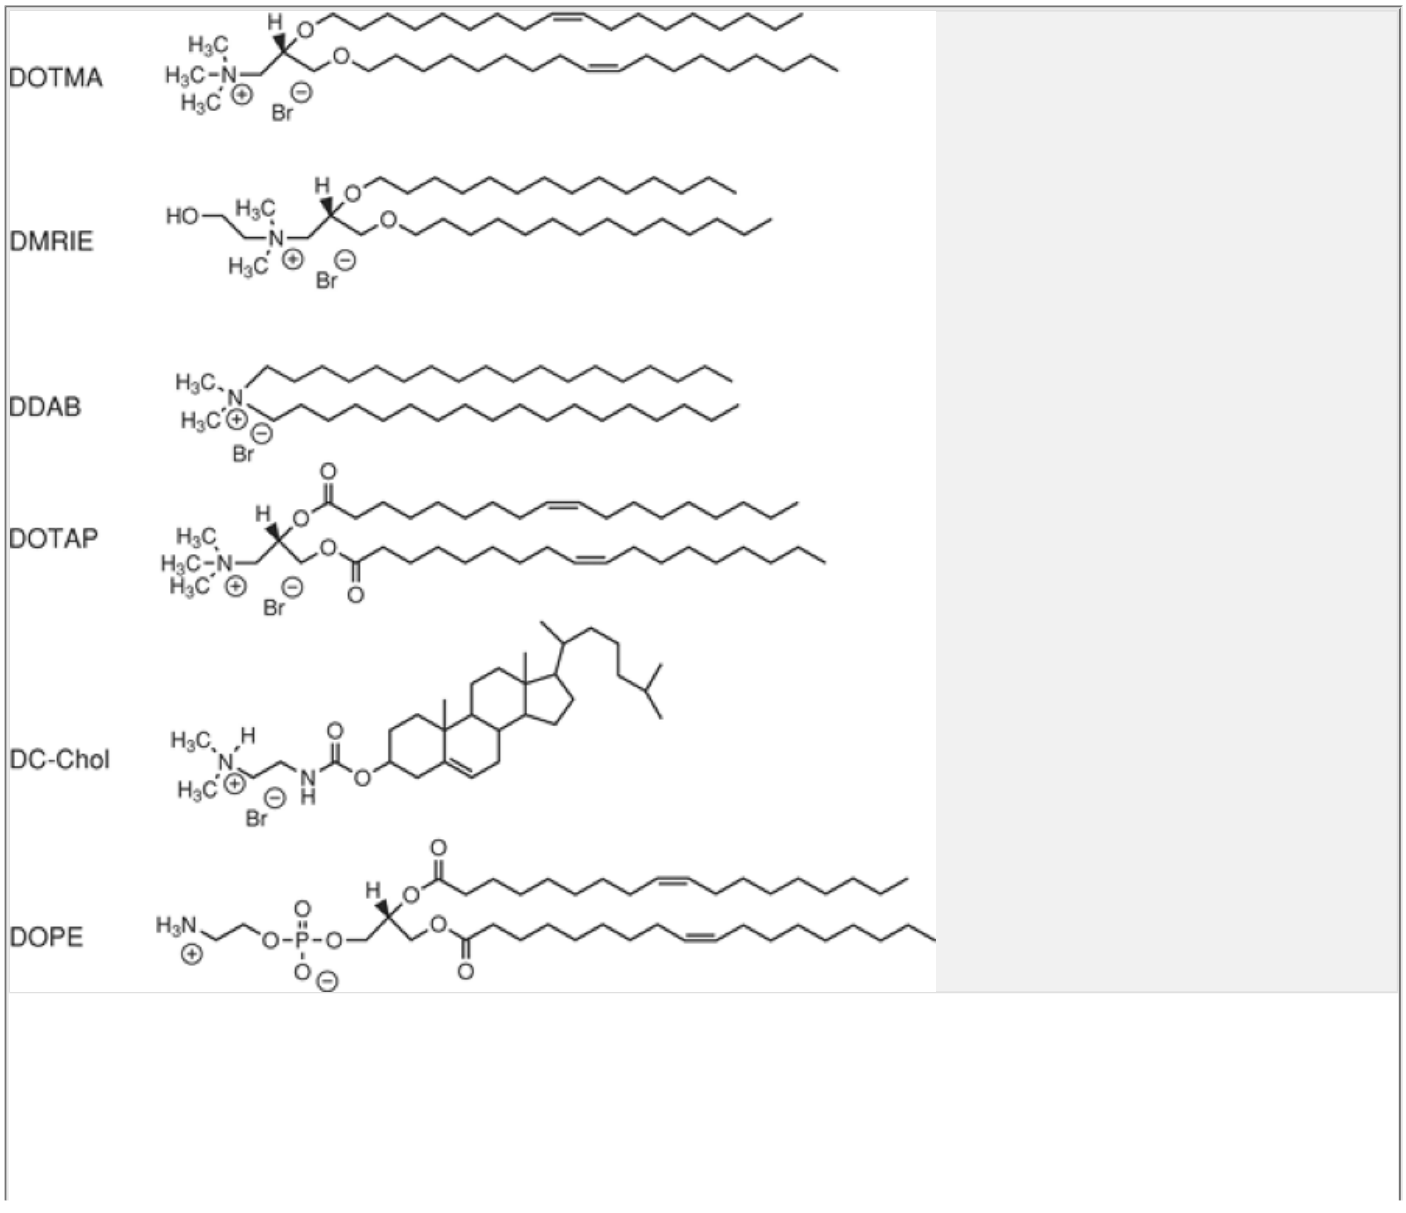

Fig. 6.34. Chemical structures of common cationic lipids: 1,2-dioleyl-oxyproply-3-trimethylammonium bromide (DOTMA), 1,2,-dimyristyl-oxypropyl-3,3-dimethyl-3(2-hydroxyethyl) ammonium bromide (DMRIE), N,N-dimethyl-N,N-dioctadecylammonium bromide (DDAB), 1,2-dioleoyloxy-proply-3-trimethylammonium bromide (DOTAP), 3β-[N-(N,N-dimethylaminoethyl)carbamoyl] cholesterol hydrobromide (DC-Chol), and 1,2-dioleoylpropyloxyphosphatidylethanolamine (DOPE).

Cationic Lipids

Cationic lipids, or “cytofectins” as they sometimes are called, are positively charged amphiphilic molecules that interact with the negatively charged phosphate backbone of DNA molecules, neutralizing the charge and promoting the condensation of DNA into a more compact structure (157,158,159). The chemical composition of the cationic lipids consists of the following (Fig. 6.34):

- A hydrophobic lipid anchor that aids in the formation of cationic liposomes that are critical components of the complex with DNA.
- A linker group that is located between the cationic head group of the molecule and the lipid tail.

  The linker determines the chemical stability and biodegradability of the cationic lipids. The most common link is the alkyl ether.
- The cationic head group that is responsible for the complexation of the liposome with the negatively charged DNA. The cationic group is a singly or multiply charged primary, secondary, tertiary, or quaternary amine. The common counterions found with the cationic lipids are the bromide, chloride, or trifluoroacetate anion.

The cationic lipids are most frequently used in a 0.5 molar ratio with a neutral, zwitterionic phospholipid (usually dioleoylphophatidylethanolamine) called the colipid. The cationic lipid and colipid form unilamellar and multilamellar liposomes that are approximately 100 and 300–700 nm, respectively, in diameter. The role played by the cationic lipid in the cationic liposome is multifold and includes causing the condensation of DNA to form a particle with specific colloidal properties, controlling the distribution of DNA particles in the body, causing the particles to interact with the target cell, and finally, inducing cytosis to aid entry of the particle into the cell. The colipid may play an active role in the internalization of DNA into the cell through facilitating the fusion of the DNA/lipid complex with the cell membrane or endosome membrane, releasing the DNA into the cytoplasm (Fig. 6.35).

The cationic liposomes are absorbed onto the surface of the negatively charged cyclic polynucleotide (plasmid) to form aggregates that gradually surround the larger segments of the DNA. At a critical lipid concentration, the processes of lipid fusion and DNA collapse are initiated. Subsequent increase in the lipid concentration causes the collapsed DNA structures to become coated in the lipid bilayers. The final product is like a “condensed nanoparticle,” with the lipid bilayers providing an internal structure that looks like the ridges of a fingerprint (160). Generally, the complexes formed with the larger multilamellar vesicles are more active than those formed with the smaller unilamellar vesicles.

The plasmid–lipid complexes tend to aggregate over time, and this aggregation is a function of a number of factors, which may include cationic lipid species, the DNA/cationic lipid ratio and concentrations, shearing force, temperature, solution viscosity, time, and salt and serum protein content. This instability necessitates that the plasmid–lipid complex be formed immediately before use and, therefore, limits the ability of the user to characterize and control the parameters of the formulations. The positive charge on the complex also results in an unfavorable interaction with negatively charged cellular proteins, leading to aggregation of the complex and premature release of the DNA. Additionally, cationic lipids interact with the complement system of the body and, therefore, are opsonized by the C3b/C4b components, resulting in rapid clearance by macrophages in the reticuloendothelial systems. The particle size and the zeta potential of the plasmid–lipid complexes depends on various factors, including the cationic lipid species, the amount and type of colipid; the particle size and composition of the liposomes used in the preparation; the molecular weight, form, and type of plasmid; the stoichiometry of the cationic lipid and DNA; the concentration of lipid and DNA in the final preparation; and the mixing procedure.

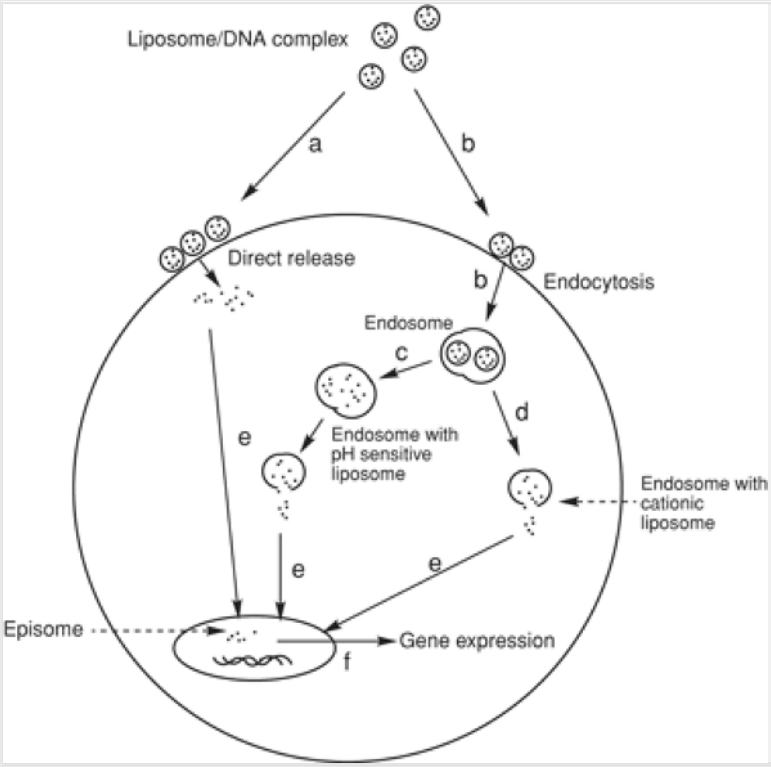

Fig. 6.35. Schematic representation of possible modes of interaction of liposomes with cells that lead to intracellular delivery. Liposomes can enter the cell by local destabilization of plasma membrane or fusion (a) or endocytosis (b). The releases of DNA by fusion is still not clear (c or d). The released DNA or cationic liposome-DNA complexes reach into the nucleus (e), and gene expression occurs (f). (Adapted from Singhal A, Huang L.Gene transfer in mammalian cells using liposomes as carriers. In: Wolff JA, ed. Gene Therapeutics. Boston: Birkhauser, 1994:118; with permission.)

Interaction of the plasmid–lipid complex with the target cell membrane occurs when the cationic lipid preparation has a high positive charge that results in an ionic interaction with the negatively charged cell membrane. The mechanism of transfer of the plasmid to the nucleus is poorly understood. Two hypotheses currently describe the mechanism, neither of which is mutually exclusive of the other (Fig. 6.35). One hypothesis suggests that the plasmid–lipid complex fuses with the target cell membrane and expels the plasmid into the cytosol, where it then makes its way to the nucleus, where it is taken up and remains as extrachromosomal material (episome). The second hypothesis suggests that the nanoparticle plasmid–lipid complex interacts with the target cell membrane and is absorbed through endocytosis. The colipid then aids in the fusion of the plasmid–lipid complex with the

endosomal membrane and the disintegration of the endosome before interaction with the lysosome and destruction of the plasmid.

Table 6.12. Actions of Cationic Lipids that Enhance Gene Delivery

- Protect the DNA against degradation by nucleases.
- Modify the size, charge, and surface characteristics of the DNA containing particulate to control its biodistribution within the body and access to the target cell.
- Improve the interaction of DNA with the surface of the target cell.
- Induce endocytosis.
- Improve release of DNA from the endosome.
- Improve the entry of DNA into the nucleus.

The presence of cationic lipids in the preparation may enhance gene delivery in several ways, including those indicated in Table 6.12.

Similar delivery systems have been designed using other cationic polymers, including lipopolyamines (161), amphipathic peptides (162), polylysine lipids (163), cholesterol (164), quaternary ammonium detergents (165), polyamidoamines called dendrimers, polyethylenimines or chitosan, diethylaminoethyl dextran (DEAE dextran), and polybrene.

Nonviral Targeted Gene Transfer

Receptor mediated uptake of nucleic acids is approached through the complexation of the DNA with protein ligands specific for cellular receptors. This technique is carried out by covalently linking the protein ligand to a positively charged polylysine polymer and then complexing the ligand/polymer unit to DNA by ionic interaction with the negatively charged phosphate groups. The interaction of polylysine with DNA causes the condensation of DNA into a compact torus-shaped (toroidal) protein/DNA structure that may be as small as 80 nm in diameter (166) and similar to that seen for the interaction of the cationic lipids with DNA. The protein retains its ability to interact with its receptor on the cell surface, and the resulting complex causes internalization of the DNA through endocytosis of the protein/receptor complex. The procedure for preparation of the covalent polylysine/ligand complex is illustrated in Fig. 6.36. The amino groups on the lysine side chains of polymers of lysine containing 90, 270, or 450 lysine monomers ($pLys_{90}$, $pLys_{270}$, or $pLys_{450}$, respectively) are derivatized with 3-(2-pyridyldithio)propionate to give the pyridyldithiopropionate intermediate that is then reduced with dithiothreitol to give the 3-mercaptopropionate–modified polylysine containing approximately one mercaptopropionate group per 50 lysine residues in the polymer. A pyridyldithiopropionate derivative of the ligand also is prepared and conjugated with the mercaptopropionate polylysine polymer through disulfide bond formation. This procedure generally results in approximately one ligand linked to every 50 residues of the polylysine polymer.

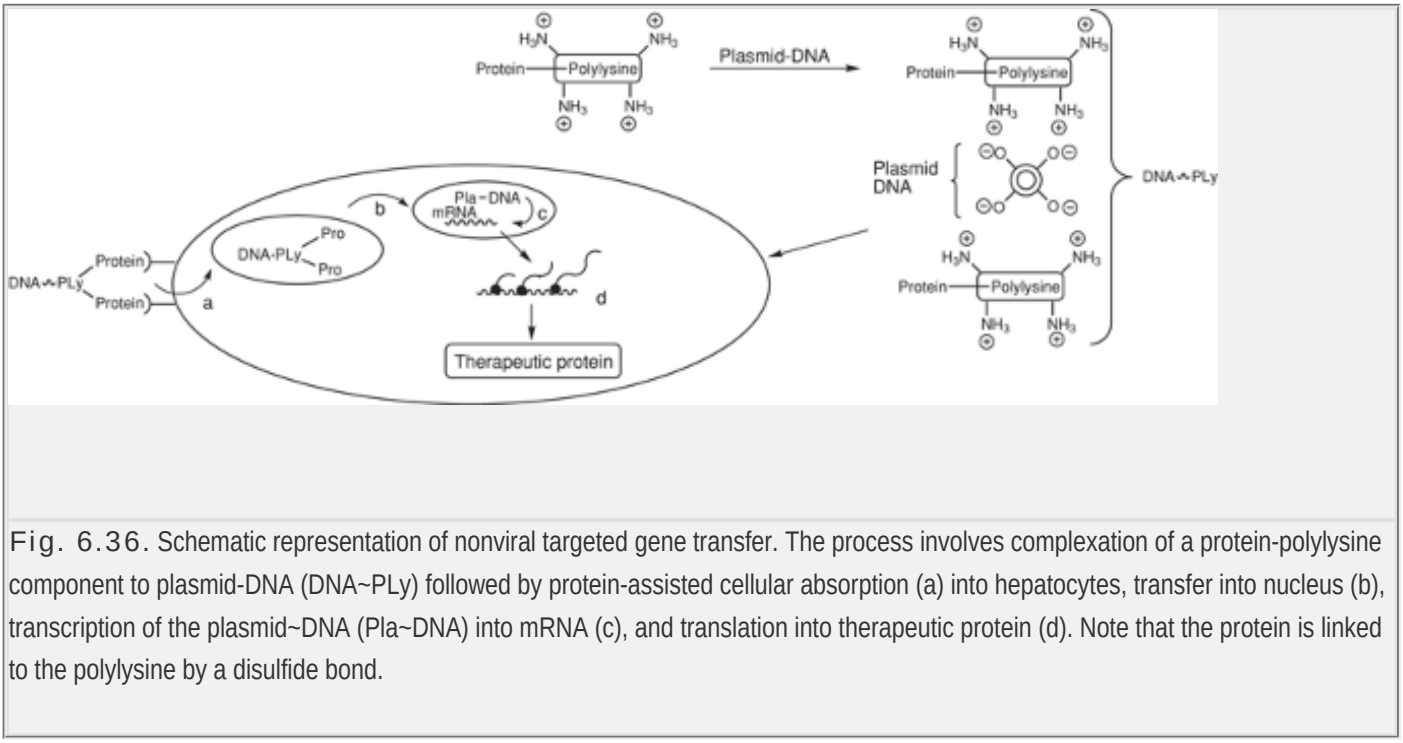

Fig. 6.36. Schematic representation of nonviral targeted gene transfer. The process involves complexation of a protein-polylysine component to plasmid-DNA (DNA~PLy) followed by protein-assisted cellular absorption (a) into hepatocytes, transfer into nucleus (b), transcription of the plasmid~DNA (Pla~DNA) into mRNA (c), and translation into therapeutic protein (d). Note that the protein is linked to the polylysine by a disulfide bond.

The ligand/polylysine covalent complex is subsequently mixed with DNA plasmids containing the therapeutic gene to be targeted to the cells containing the ligand receptor to condense the DNA and form the ligand/polylysine/DNA complex (Fig. 6.36). The targeted cells are exposed to the complex either in vitro through exposure of a cell culture to the complex or in vivo through intravenous injection of the complex into the animal. The following ligand/complexes have been used to deliver genes to specific cell targets:

- *Transferrin/polylysine/DNA*—hematopoietic cells, T-cells, pulmonary epithelial cells.
- *Asialoorosomucoid/polylysine/DNA*—liver cells.
-

Insulin/polylysine/DNA—liver cells

- *Surfactant B/polylysine/DNA*—epithelial airway cells.

P.160

- *Antithromobomodulin/polylysine/DNA*—epithelial airway cells.

Several small molecules, including folate, galactose, lactose, and N-acetyl galactosamine, also have been used to prepare polylysine/DNA complexes for delivery of DNA by receptor-mediated endocytosis.

The major factors limiting the in vivo effectiveness of the protein/DNA complexes may be the poor bioavailability to many target cells and their colloidal instability in physiological media. The endocytotic uptake of the receptor complex also limits the effectiveness of the delivery system, because the DNA is quickly destroyed in the endosome/lysosome pathway.

Artificial Chromosomes—YACs and HACs

A more recent development in gene delivery that has potential for developing into a therapeutic gene delivery system is the artificial chromosome. Genetic manipulation of the yeast genome has resulted in the development of yeast artificial chromosomes (YACs). These linear structures use the same basic functional elements as the normal linear mammalian and yeast chromosomes.

The capacity for YACs to carry very large fragments of foreign DNA permits the cloning of genes with all their natural genomic elements in correct spatial orientation. The YACs have been used in the preparation of large DNA fragments for sequencing in the Human Genome Project (HGP). They also have been very useful in the analysis of gene function and the creation of chromosome transgenic mice.

The potential of artificial chromosomes for gene therapy is currently being investigated (167,168,169). The development of a properly segregating, autonomously replicating “minichromosome” has the potential to eliminate the disadvantages of viral vectors, such as genomic insertional position effects, gene size restrictions, and lack of proper regulation of gene function.

The human chromosome is far larger and more complex than the yeast chromosome. In spite of numerous complications, the human artificial chromosome (HAC, or MAC) is being developed and the potential applications to gene therapy investigated (170). Two approaches are currently being used to create the HAC (Fig. 6.37). Small human chromosomes (i.e., minichromosomes) are being developed through truncation of the normal chromosome mediated by insertion of human telomeres (the specialized structure of the ends of the chromosome) into the chromosomal arms, creating shortened chromosomes of 3.5 to 9.0 Mb (megabases) in size (170). Alternatively, many steps have been taken toward creating an artificial chromosome through assembly of the known functional elements of a human chromosome with genomic DNA containing a human gene (171).

Pharmacokinetics and Metabolism of DNA

Genes can be delivered using either ex vivo or in vivo strategy. The ex vivo strategy encounters intracellular barriers presented by the cell that include the cell, endosome, and nuclear membranes (Fig. 6.38).

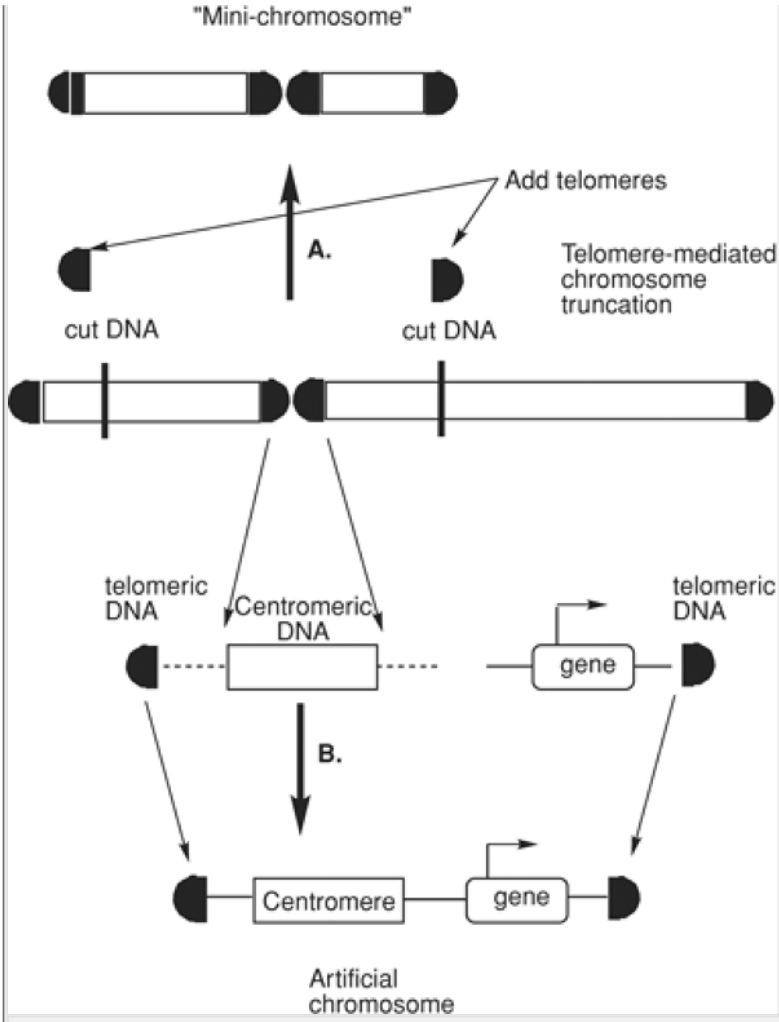

Fig. 6.37. Two approaches for manipulation of a human chromosome. (A) Minichromosomes can be generated in cultured cells by chromosome truncation mediated by the integration of telomeric sequences into chromosome arms. (B) Alternatively, artificial chromosomes might be constructed by combining the known functional elements of a human chromosome: telomeric DNA, centromeric DNA, and genomic DNA containing a human gene or selectable genetic marker.

Depending on the ex vivo vector used, the DNA can be delivered directly to the cell cytosol through fusion of the vector with the cell membrane, or the DNA may enter the cell through endocytosis, creating the endosomal membrane barrier. Endosomal DNA can be released from the endosome into the cytosol, or the endosome may fuse with the lysosome, resulting in degradation of the DNA by nucleases and the acidic environment of the lysosome. Cytosolic DNA is susceptible to a variety of nucleases found in cellular cytosol, and that which reaches the nuclear membrane is taken up by an active transport mechanism, possibly similar to that of protein uptake by the nuclear membrane (172). Once inside the nucleus, the transgene DNA is still susceptible to degradation by nucleases.

Delivery of DNA in vivo faces additional extracellular barriers posed by specific tissues and the immune system (Fig. 6.38). The blood-brain barrier, connective tissue, and epithelial cell linings are particular examples of cellular

structures that may impede delivery of DNA to the target cells. Humoral and cellular immune responses also pose serious barriers to successful delivery of DNA to target cells.

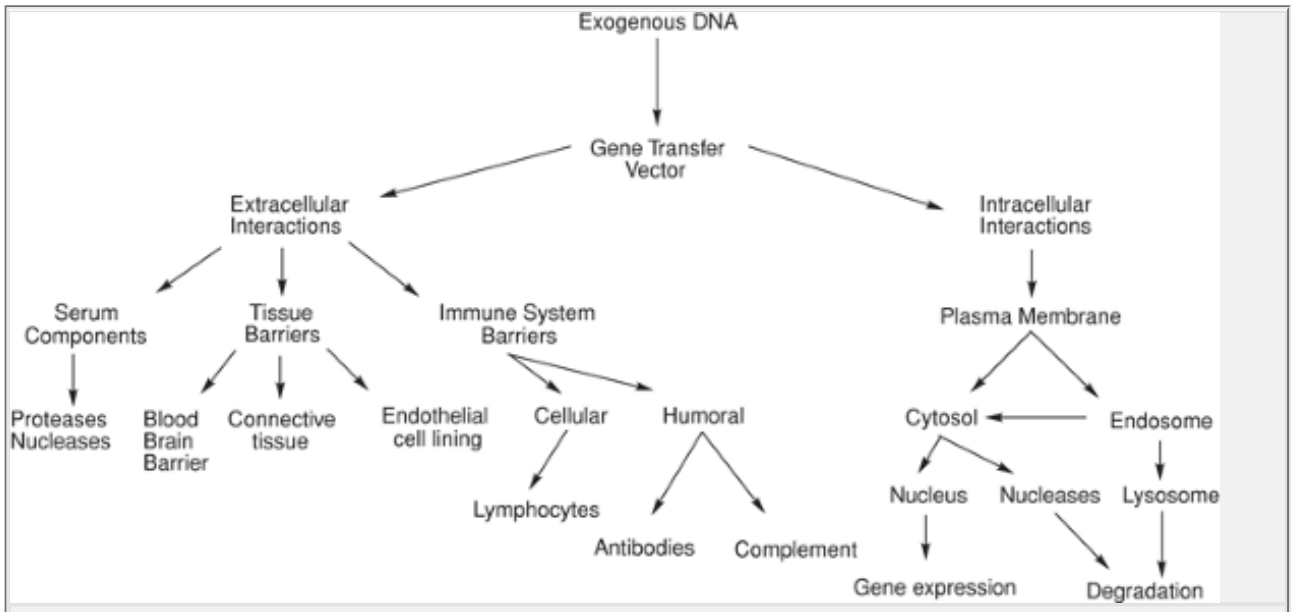

Fig. 6.38. Barriers to gene delivery.

The DNA is rapidly eliminated from the compartment into which it is administered as a result of both degradation through endo- and exonucleases and distribution to other compartments. The DNA is eliminated from the blood compartment by interaction with Kuppfer cells through a specific scavenger/ receptor interaction (173). An intravenously administered asialo-orosomucoid-polylysine-DNA complex is cleared from the blood with an apparent half-life of 2.5 min (174). The DNA taken up by the liver is eliminated with a half life of 1.0 to 1.3 hours, gene transcripts were evident for 1 to 12 hours, and the gene product persisted for 6 to 24 hours.

Different tissues have been shown to display different DNA pharmacokinetics. Genes and gene products have been observed as long as 19 months after direct injection without indication of plasmid integration or replication (175). Direct injection of the chloramphenicol acetyltransferase gene into the thyroid resulted in elimination of DNA from the gland with a half-life of 10 hours. The enzyme activity was maximal for 24 hours and eliminated through first-order kinetics with an apparent half-life of 40 hours (176). Similar results were recorded for synovial fluid intra-articular administration of plasmid DNA (177).

If the therapeutic gene is not incorporated into the host cell genome, adjusting the dose and administration schedule, as for any conventional drug therapy, can control the level of the therapeutic product. The formulation of the delivery vehicle and the design of the gene expression vector, however, affect the duration and level of therapeutic activity. Gene therapy also provides unique pharmacokinetic issues in that the apparent kinetic properties of the therapeutic agent are a combination of the intrinsic kinetic properties of the DNA vector, the RNA transcript, and the translated protein product (178). The intrinsic kinetic parameters are described by a six-compartment model of DNA pharmacokinetics (178). Flux between the compartments labeled Milieu, Endosome, Cell, RNA, Protein, and Product will reflect the biological process of uptake, endosomal transport into cells, transcription, translation, and secretion. Additionally, DNA will be subjected to degradation in each of the compartments. Although this model is a first approximation of the processes involved in using genes as medicines, a total description of DNA pharmacokinetics likely will include:

- Compartmental distribution and extracellular elimination of DNA after in vivo administration.
- Efficiency of DNA uptake into cells.
- Compartmentalization of DNA within the endosomal, cytoplasmic, and nuclear compartments of the cell.
- Rate of degradation of DNA within the cell.
- Rate of transcription of RNA from DNA.
- Stability of the mRNA.

- Rate of translation of the mRNA to create the new gene product.
- Rate of posttranslational modification of he gene product.
- Intracellular compartmentalization or secretion of the gene product.
- Pharmacokinetics of the gene product in the body.

Pharmacogenetics

With the completion of the HGP, there has been a visible shift from genomic research in gene structure to

research in gene function. The application of genetic information to disease diagnosis and drug therapy is a major development that will see tremendous changes over the next few years. The main benefit will be a reduction in the health care costs arising from drug toxicity and lack of efficacy in drug therapy.

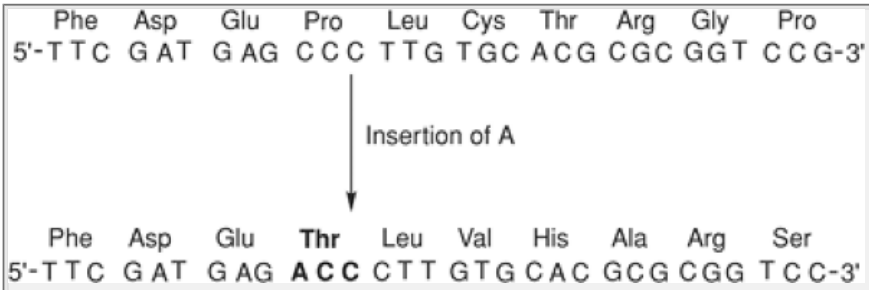

Fig. 6.39. An example of a frameshift point mutation. Adenosine is inserted between guanosine, which is the last nucleotide in the glutamic acid triplet, and cytosine, which is the first nucleotide in the proline triplet. The reading frame is shifted to the left by one nucleotide, thereby changing the sequence of amino acids from glutamic acid onward.

Mutations are the result of heritable, permanent changes in the DNA base sequence. These usually come about by one of three mechanisms: substitution, addition, or deletion. The number of base pairs involved in a single gene mutation can vary from a single base pair change, called a point mutation, to a large number of gross changes in the gene structure involving insertion, deletion, or rearrangements of a very large number of base pairs.

Point mutations may result in a variety of changes to the gene product. If the base change occurs within the reading frame of the gene product and produces a single change in one amino acid in the amino acid sequence of the gene product, it is termed a “missense point mutation.” Some of these point mutations result in no change in the amino acid sequence of the gene product and are termed “silent mutations.” Generally speaking, a point mutation in a gene that does not result in functional change of the gene product is termed a “polymorphism.” Mutations are defined as base changes causing a change in function of the gene product. This distinction is not rigidly adhered to, however, and many single base mutations causing changes in function of gene product frequently are called single-nucleotide polymorphisms (SNPs). In fact, SNPs have been defined as single base mutations that occur in 1% or more of the population (179). Many of these SNPs may be responsible for the production of a malfunctioning gene product that, in turn, is responsible for a serious disease. The well-used example here is the A → T mutation in the β-globin gene, in which the GAG glutamic acid codon is changed to the GTG valine codon, resulting in abnormal aggregation of the hemoglobin molecules and causing sickle cell anemia.

Point mutations occurring in the reading frame that convert an amino acid codon to a stop codon (TAA, TAG, or TGA) are termed “nonsense mutations” and result in the truncation of the gene product because of a premature stop in the translation process. These changes are very serious and may lead to loss of a large sequence of the carboxy terminus of the gene product especially if they occur in the 5′ region of the gene. One form of β-thalassemia results from a mutation of a CAG glutamine codon to the TAG stop codon early in the DNA sequence, resulting in premature termination of the translation process and total loss of the β subunit of the adult hemoglobin molecule.

A frameshift mutation occurs when, instead of changing a base pair, a base pair is inserted or deleted in the gene sequence. An insertion/deletion of more or less than three bases will result in a shift of the reading frame, and a different set of codons will be read 3′ (downstream) of the mutation (Fig. 6.39). These mutations have very serious effects and frequently result in the total loss of the gene product.

Point mutations occurring in the boundaries between the exons and introns may result in the inability of the pre-mRNA to splice properly and are termed “splice mutations.” These mutations may result in the loss of many amino acids in the gene product sequence or may cause a frameshift, resulting in total loss of functional gene product. Mutations also may occur in introns with the resultant formation of splice sites that also cause the pre-mRNA to splice abnormally.

Point mutations in promoter regions, termed “promoter mutations,” are responsible for reducing or eliminating the expression of a gene.

One of the gross changes in gene structure involves an unusual form of gene mutation termed the “trinucleotide repeat,” in which a trinucleotide sequence undergoes a dramatic increase in the number of copies of the trinucleotide in a gene sequence. Fragile X syndrome and Huntington's disease are both the result of this unusual mutation.

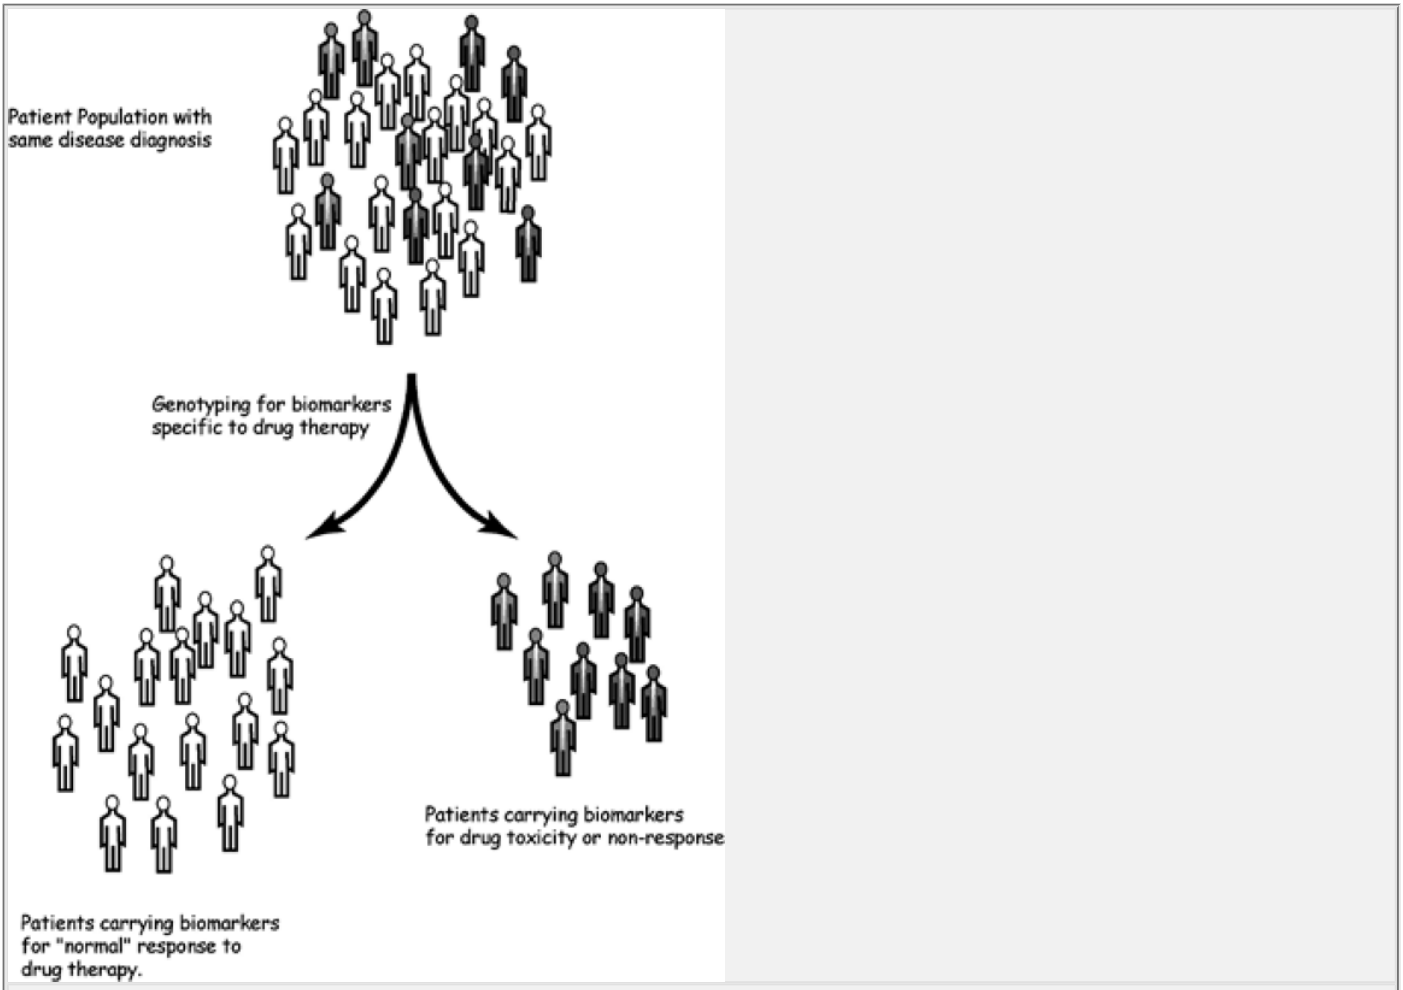

Fig. 6.40. Manipulating therapeutic outcomes: manipulating therapeutic outcomes through pharmacogenetic analysis of a population with the same disease diagnosis to eliminate those patients with genetic biomarkers indicating an adverse response to a particular drug therapy.

In the early 1950s, at the time of Watson and Crick's seminal paper on the structure of DNA, it was discovered that some patients who were undergoing surgery and had been treated with the muscle relaxant succinyldicholine

did not recover their respiratory function as quickly as expected. This problem eventually was traced to a lower-than-normal level of pseudocholinesterase activity in the patient's blood. The result was that the patient was not eliminating the muscle relaxant at the rate seen by “normal” patients; hence, the drug was acting longer than expected in a normal response. This problem was finally demonstrated to be a familial or hereditary problem. Similar “familial”-related abnormal responses to drug therapy were found in the use of primaquine therapy for the treatment of malaria and the use of isoniazid in the treatment of tuberculosis. In separate publications, Motulsky and Vogel coined the term “pharmacogenetics” to describe genetically determined variability in the effects of drugs on animal species, and the term then became defined as the study of interindividual variations in DNA sequences related to drug response.

In principle, one is able to manipulate the therapeutic outcome of a patient population by separating those patients who will not respond normally to a particular drug therapy from those who will, based on an analysis of established genetic biomarkers related to the drug's metabolic profile (Fig. 6.40). Patients who are homozygous for the genetic biomarkers indicating poor metabolism of the recommended therapeutic agent may, depending on the therapeutic window of the drug, exhibit a response resembling an overdose to the normal drug dose and require a reduced dose to achieve therapeutic levels (Patient A in Fig. 6.41), whereas those patients carrying the biomarkers indicating extensive metabolism may exhibit a lack of efficacy at normal doses and require an increased dose of the drug to achieve therapeutic activity (Patient D in Fig. 6.41). The patients who are homozygous or heterozygous for the normal (wild-type) genetic biomarker (Patients B and C, respectively, in Fig. 6.41) may require no alteration of the “normal” dose of the drug for adequate therapeutic outcome.

The application of genetic variation to drug therapy centered on the variations seen in a number of drug metabolism enzymes and much of the pharmacogenetic research have developed with the Phase I (oxidative) and

Phase II (conjugative) metabolic enzymes. Currently, considerable data relate SNPs in the coding and regulatory regions of these genes to poor metabolism of particular drugs that have the potential to result in drug overdoses in those patients carrying the genetic variations and given the “normal” dose of drug (Fig. 6.42).

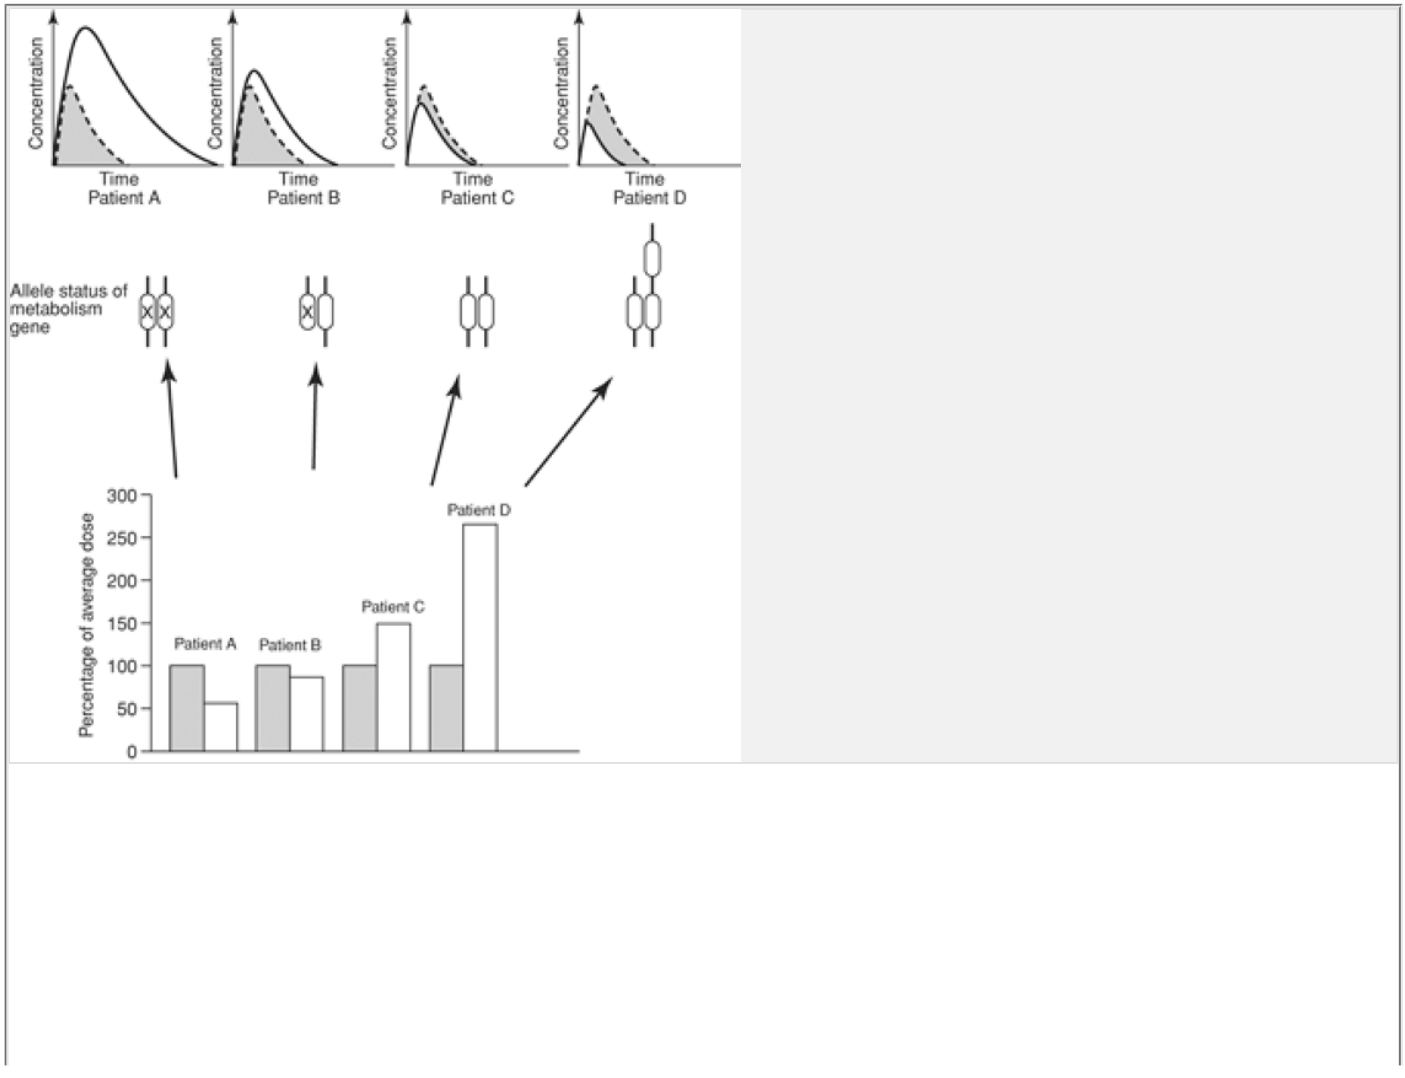

Fig. 6.41. Dose/Genotype Relationship: A schematic representation of the potential benefit of adjusting drug dose to patient genotype. The theoretical “normal” drug concentration/time curve is depicted by the dashed line in the concentration/time curves of Patients A-D at the top of the figure while the theoretical “genetic” drug concentration/time curve for each patient is expressed by the solid line. The allele status for each patient is shown below the theoretical plots. The oval containing the “X” indicates the presence of the detrimental allelic variation. The extra oval in Patient D indicates duplication of one of the normal alleles. The bar graph at the bottom of the figure indicates the normal doses (shaded) compared to the dose adjustments that should be made based on the patient's allele status (180).

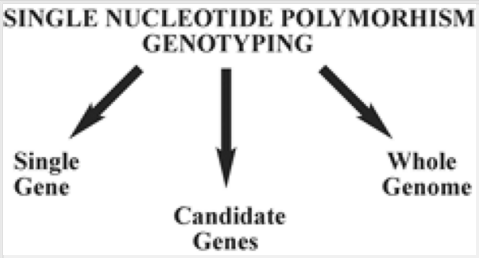

Fig. 6.42. Single-nucleotide polymorphism (SNP) genotyping: approaches to genotyping for drug therapy. The single gene approach has been used successfully in pharmacogenetic studies of a number of Phase I and Phase II metabolic enzymes. The candidate gene approach involves the selection of the genes for proteins that are demonstrated to be involved in a particular drug action, including metabolic enzymes, transport proteins, drug targets, and proteins involved in modular drug response pathways. The whole-genome approach uses SNPs evenly spaced throughout the genome.

The action of a drug on the body is a more complex interaction involving the metabolism of drugs, the transport of drugs throughout the body, and the interaction of the drug with its target. These features are known as the pharmacokinetics (absorption, distribution, metabolism, and excretion) and pharmacodynamics (drug–target interaction) of drug therapy. These genes are known as the candidate genes for the application of genetic information to drug therapy (Fig. 6.42).

Table 6.13. Specific Examples of the Application of Allelic Variation in Drug Therapy

Gene	Action	Drug	Therapy	Efficacy/Toxicity
CYP450 2D6	Drug metabolism	Codeine	Pain	Efficacy
CYP450 2C9	Drug metabolism	Warfarin	Coagulation	Toxicity (hemorrhage)
Thiopurine S-methyltransferase	Drug metabolism	Mercaptopurine	Acute lymphoblastic leukemia	Toxicity (myelotoxic)
HER2/neu	Drug target	Herceptin	Breast cancer	Efficacy
bcr/abl	Drug target	Gleevec	Chronic myelogenous leukemia	Efficacy
EFGR	Drug target	Erbitux	Colon cancer	Efficacy
Apolipoprotein E4	Marker	Tacrine	Alzheimer's disease	Efficacy
Cholesteryl ester transferase	Marker	Statins	Atherosclerosis	Efficacy
ATP-binding cassette B1	Drug transport	Saqinavir	HIV	Efficacy
		Indinavir	Leukemia	
		Ritonavir		

		Daunorubicin		
		Etoposide		
UDP-glucuronosyl-transferase 1A1	Drug metabolism	Irinotecan	Cancer	Toxicity (myelotoxic)
N-acetyltransferase 2	Drug metabolism	Isoniazid	Tuberculosis	Toxicity (hepatotoxic)
Pseudocholinesterase	Drug metabolism	Suxamethonium	Muscle relaxation during surgery	Toxicity (prolonged apnea)

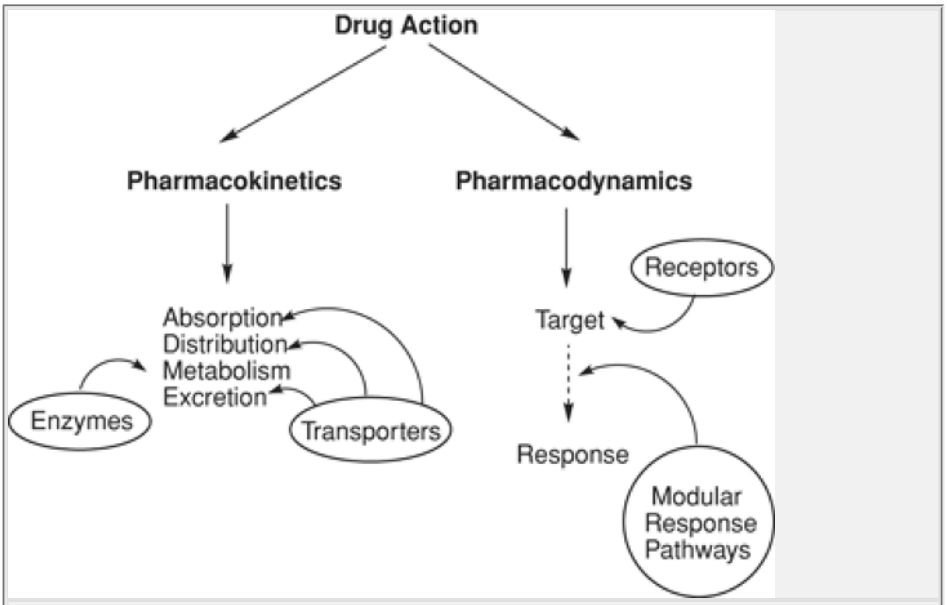

Fig. 6.43. Schematic representation of the multigenic therapeutic drug pathway.

Transport proteins that move drugs through membrane barriers are critical in the absorption, distribution, and excretion of drugs and drug metabolites, while enzymes are critical in the metabolism of drugs in the body (Fig. 6.43). The pharmacodynamic pathway is represented most abundantly by the drug receptor pathway of drug response. This involves drug receptors as well as the numerous biochemical events that occur subsequent to drug–receptor interaction and before the measurement of the pharmacological response. The complexity of the pharmacodynamic pathway can be simplified if one takes the modular biology approach and considers the many biochemical pathways between the drug–receptor interaction and the drug response to be linked modules of biochemical systems.

Thus, the candidate genes for the therapeutic dry pathway includes the genes for drug metabolism, drug transport, and drug response (Table 6.13).

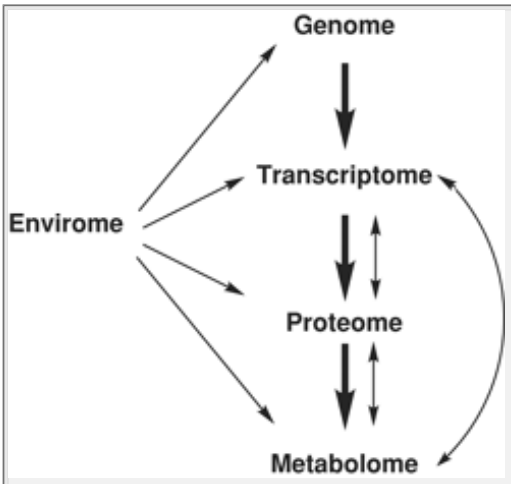

Fig. 6.44. A schematic representation of the biological organization of the '-omes'. This view represents the major flow of information from genome to transcriptome, to proteome and metabolome (⟶). Perturbation in this process can affect another (↔). The environment has an affect on expression and concentrations of transcripts, proteins, and metabolites as well as the genome by selecting from adaptive changes in subpopulations of cells (⟶). (Adapted from Griffin JL, Shockcor JP. Metabolic

profiles of cancer cells. Nat Rev Cancer 2004;4: 551–561; with permission.)

Finally, the whole-genome approach to SNP analysis on drug action suggested that a high density of coding and noncoding SNPs evenly spaced throughout the genome could be used to determine optimal drug therapy. In this case, the SNPs would be used as markers, as opposed to the functional SNPs of the individual gene approach. The use of linkage disequilibrium to map SNP loci that may be relevant to disease therapy indicated that linkage disequilibrium is highly variable in different parts of the genome, and those fragments appear to be inherited in blocks known as haplotype blocks. This has led to the international HapMap project, with the aim to map all the haplotype blocks in the human genome. The HapMap project has already demonstrated that haplotype blocks may contain several hundred SNPs, but also that only a few of these SNPs are needed to identify a particular block. These SNPs are known as haplotype tagged SNPs (htSNPs). Extension of the htSNP concept to candidate genes will reduce the number of htSNPs needed to characterize a drug therapy by limiting the htSNP variations to those SNPs in the candidate genes of the therapeutic drug pathway.

Pharmacogenomics and Personalized Medicine

To evaluate the effects of genetic variation on disease diagnosis and drug therapy, one must consider more than simply the genetics. The central dogma of gene function indicates that information flows from DNA to pre-mRNA to mRNA and finally protein. Therefore, it would be naïve to think that all the information in a cell is stored in the DNA. One also must consider the modifications to that message that may occur during the transcription of the DNA message to mRNA and the translation to protein. Additionally, consideration must be given to the subsequent modification that occur to proteins that also may alter their function in the cell. This complexity is summarized in Figures 6.44 and 6.45. The individual's phenotype is the result of gene expression, and this includes the genetic information (genome), the translated material (transcriptome), the transcribed proteins (proteome), and the effect that these translated proteins have on the metabolism within the cell (metabolome). It also is important to consider that the transcriptome, proteome, and metabolome are a direct result of genome expression; however, modifications to these components and to the genome occur as a result of environmental effects from the individual's envirome.

Personalized medicine is defined as the utilization of molecular biomarkers from an individual's genome, transcriptome, proteome, and metabolome under the influence of the individual's envirome in the assessment of predisposition to disease, screening and early diagnosis of disease, assessment of prognosis, pharmacogenomic prediction of therapeutic drug efficacy and risk of toxicity; and monitoring the illness until the final therapeutic outcome is determined (Fig. 6.45). A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (182).

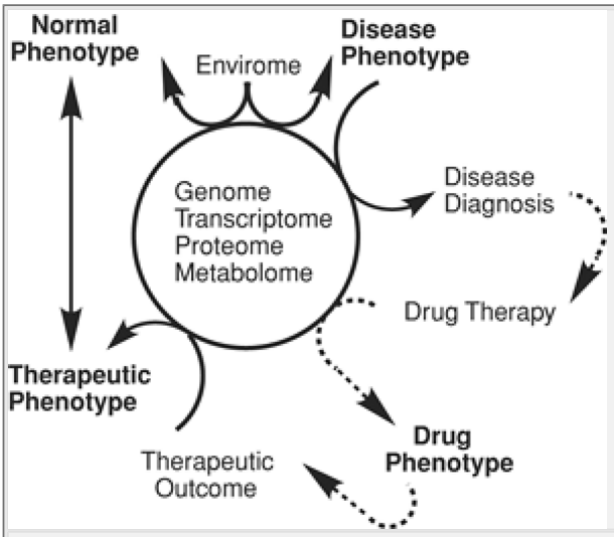

Fig. 6.45. Schematic representation of the concept of molecular profiling for personalized medicine. Dashed arrows indicate the critical components of pharmacogenomics; disease diagnosis, drug therapy, drug phenotype, and therapeutic outcome.

Table 6.14. Genotyping Technologies

Techniquea	Mechanism of Allele Discrimination	Reaction Formate	Detection Mechanism	Reference
Reverse dot blot	Hybridization	Solid support	Colorimetric	183
Microarray	Hybridization	Solid support	Fluorescence	179,184,185
DASH	Hybridization	Solid support	Fluorescence	186,187
Molecular beacons	Hybridization	Homogeneous reaction	FRET	188
5′-Nuclease cleavage (TaqMan)	Hybridization	Homogeneous reaction	FRET or FP	189,190
Cleavase (Invader Assay)	Hybridization	Homogeneous reaction	FRET, FP, MS	191,192,193,194
Biosensor microchip	Hybridization	Solid support	Electrochemical and fluorescence	195,196,197,198,199,200
AS-PCR	Primer extension	Homogeneous reaction	Fluorescence or FRET	201,202,203,204,205,206
AS-PE	Primer extension	Solid support	Fluorescence	207
APEX	Primer extension	Solid support	Fluorescence	208,209,210,211
FP-TDI	Primer extension	Homogeneous reaction	FRET or FP	191,212,213
MALDI-TOF MS	Primer extension	Homogeneous reaction	MS	214,215,216,217
Pyrosequencing	Primer extension	Homogeneous reaction or solid support	Luminescence	218,219,220,221,222
BioBeads and TagArrays	Primer extension	Homogeneous reaction and solid support capture	Fluorescence	223,224,225,226
OLA	Ligation	Homogeneous and solid support	Colorimetric and Fluorescence	227,228,229
RCA	Ligation	Solid support	Fluorescence	229,230,231,232
Closed tube	Ligation	Homogeneous reaction	FRET	233
Microsphere/microarray ligation	Ligation	Homogeneous reaction	Fluorescence	224,234

[a]DASH, dynamic allele-specific hybridization; AS-PCR, allele-specific polymerase chain reaction; AS-PE, allele-specific primer extension; APEX, arrayed primer extension; FP-TDI, fluorescence polarization template directed dye terminator incorporation; MALDI-TOF-MS, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; OLA, oligonucleotide ligation assay; RCA, rolling circle amplification.

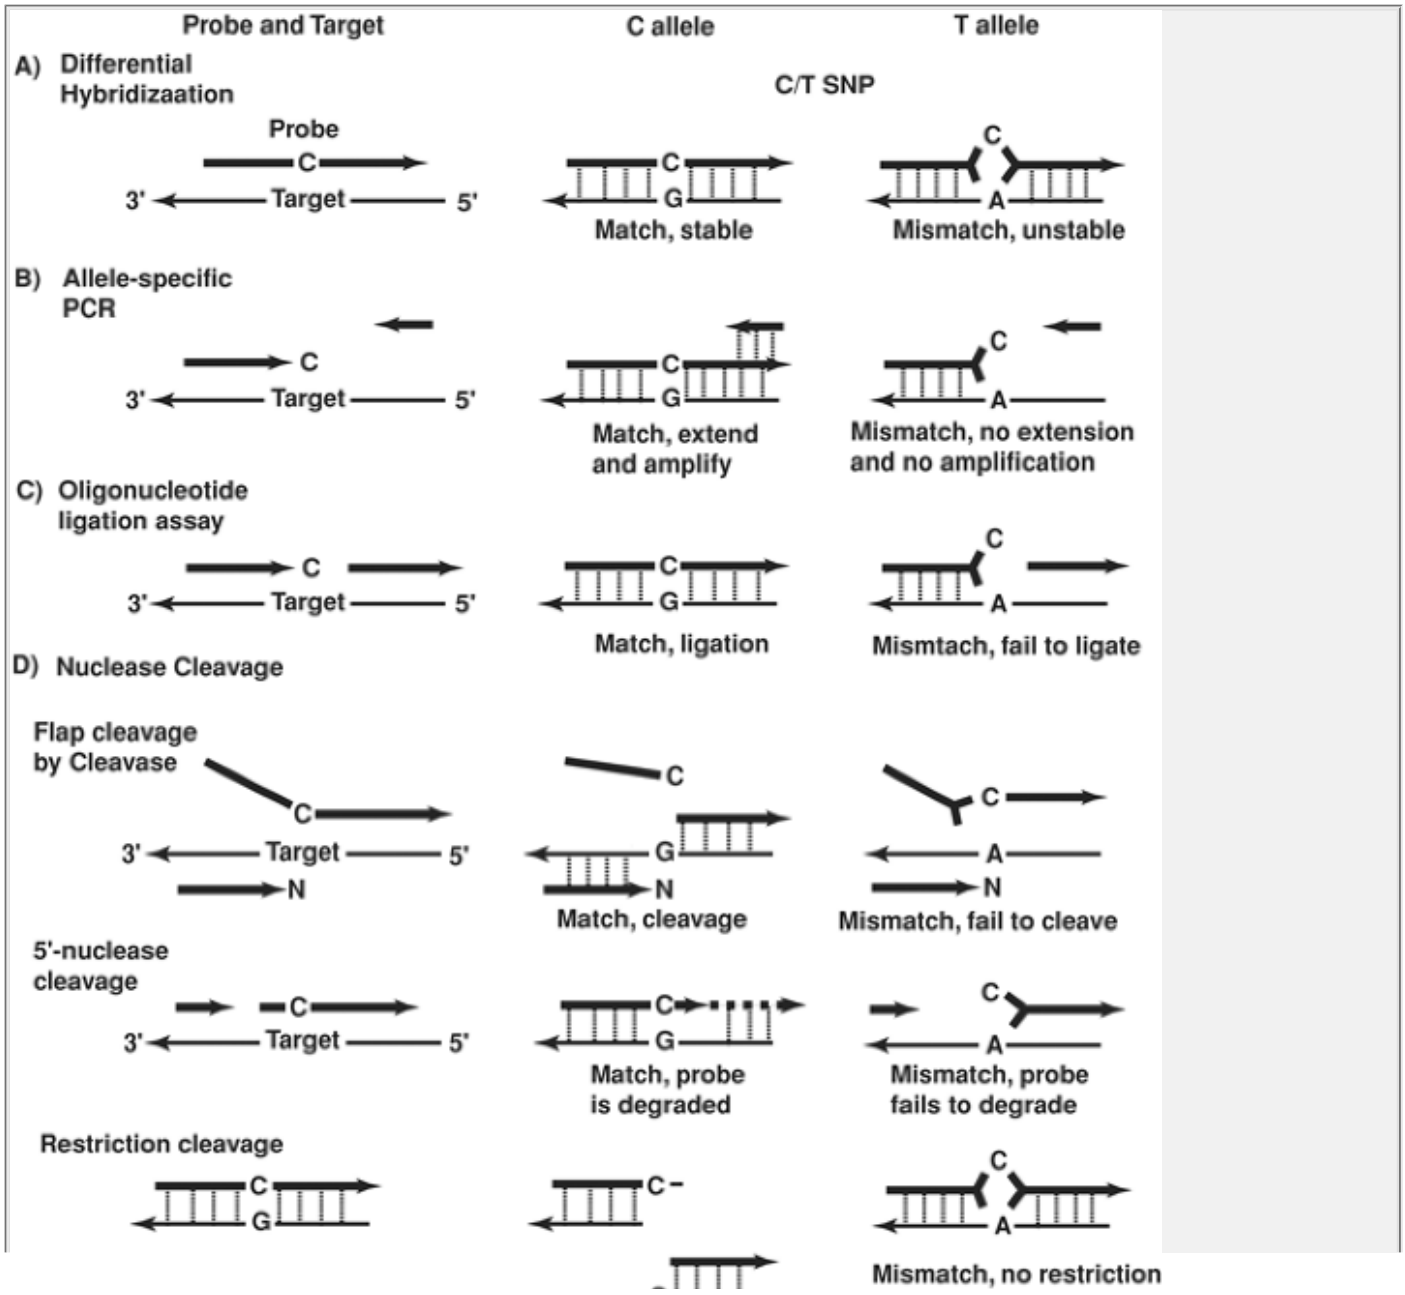
The application of genomic, transcriptomic, proteomic, and metabolomic technologies to the development of in vitro molecular biomarkers is molecular profiling. The molecular profiling of a patient's phenotype uses molecular biomarkers to provide a molecular basis to the normal or healthy patient phenotype in a particular envirome. Changes in molecular biomarkers in a disease state compared to the normal state provide a molecular characterization of the disease phenotype, which is used to provide a consistent, accurate diagnosis. The disease phenotype is used to choose the best therapy, which will alter the molecular biomarkers to a drug therapy phenotype (Fig. 6.45). The difference between the biomarkers used in the diagnosis and drug phenotype descriptions will be the result of drug therapy. A comparison of the therapeutic outcome with the patient's molecular biomarkers will provide a therapeutic phenotype for that particular therapeutic profile. The failure of many pharmacogenomic-based therapies are likely the result of inconsistencies in the disease diagnosis and/or assessment of therapeutic outcomes through a lack of sufficient molecular biomarkers or a lack of proper interpretation of the biomarkers. Further

complicating factors include the fact that the interaction of the environment with the genome, transcriptome, proteome, and metabolome is poorly understood; genetic regulation of metabolic pathways may be polygenic or oligogenic, with many different genes interacting in the regulatory process; the regulatory genes may exhibit allelic heterogeneity with many different predisposing risk alleles; different individuals may exhibit locus heterogeneity with different or an overlapping set of genes being important in a particular pathway; genetic interactions may be additive, synergistic, or epistatic; and resulting individual pathologies may be qualitative rather than all-or-nothing traits with thresholds determining clinical manifestations.

Genomics

Genomics is the technology behind the study of the full complement of genetic information, both coding and noncoding, in a organism's genome. The main genomics technique is the use of known SNPs as biomarkers to inform clinicians about subtypes of disease that require differential treatments and provide pharmacists with information for selection of the best therapeutic methodology to effectively manage the disease as well as provide an indication of the patients at risk of experiencing adverse reactions or those who will not respond to a given drug dose.

The general genotyping procedure for detecting known SNPs consists of PCR amplification of the region of interest in the genome, discrimination of the alleles in that region, and detection of the discrimination products. Many genotyping technologies are available to choose from, and each has their advantages and disadvantages (Table 6.14). Discriminating between the alleles in the genomic region being examined generally fall into one of the five techniques illustrated in Figure 6.46:



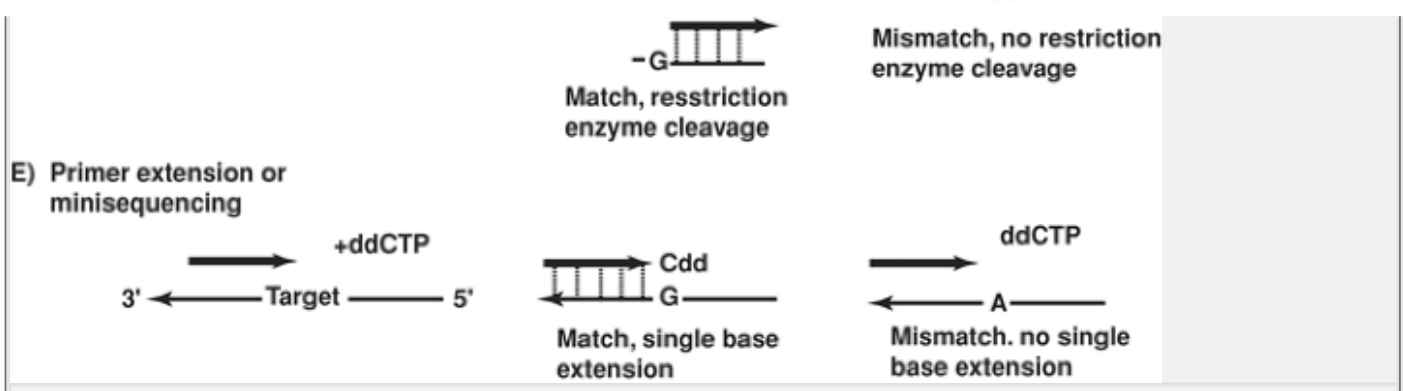


Fig. 6.46. Allele discrimination strategies for the detection of the C allele of a C/T transition. Figure summarizes the five main biochemical reaction principles that underlie the single-nucleotide polymorphism (SNP) genotyping technologies. Bold arrows indicate the probes; thinner arrows indicate the target. (From Syvanen AG. Accessing genetic variation: genotyping single-nucleotide polymorphisms. Nat Rev Genet 2001;2:930–942; Carlson CS, Newman TL, Nickerson DA. SNPing in the human genome. Curr Opin Chem Biol 2001; 5:78–85; with permission.)

- Differential hybridization.
- Allele-specific PCR.
- Oligonucleotide ligation assay.
- Nuclease cleavage (flap cleavage, 5′-nuclease cleavage, or restriction enzyme cleavage).
- Minisequencing or primer extension.

Each of these detection techniques may be carried out in homogeneous reaction medium or on a solid support. Technology also is available that will carry out the detection reaction in homogeneous medium, then use a solid support to capture the product (see the discussion on minisequencing below).

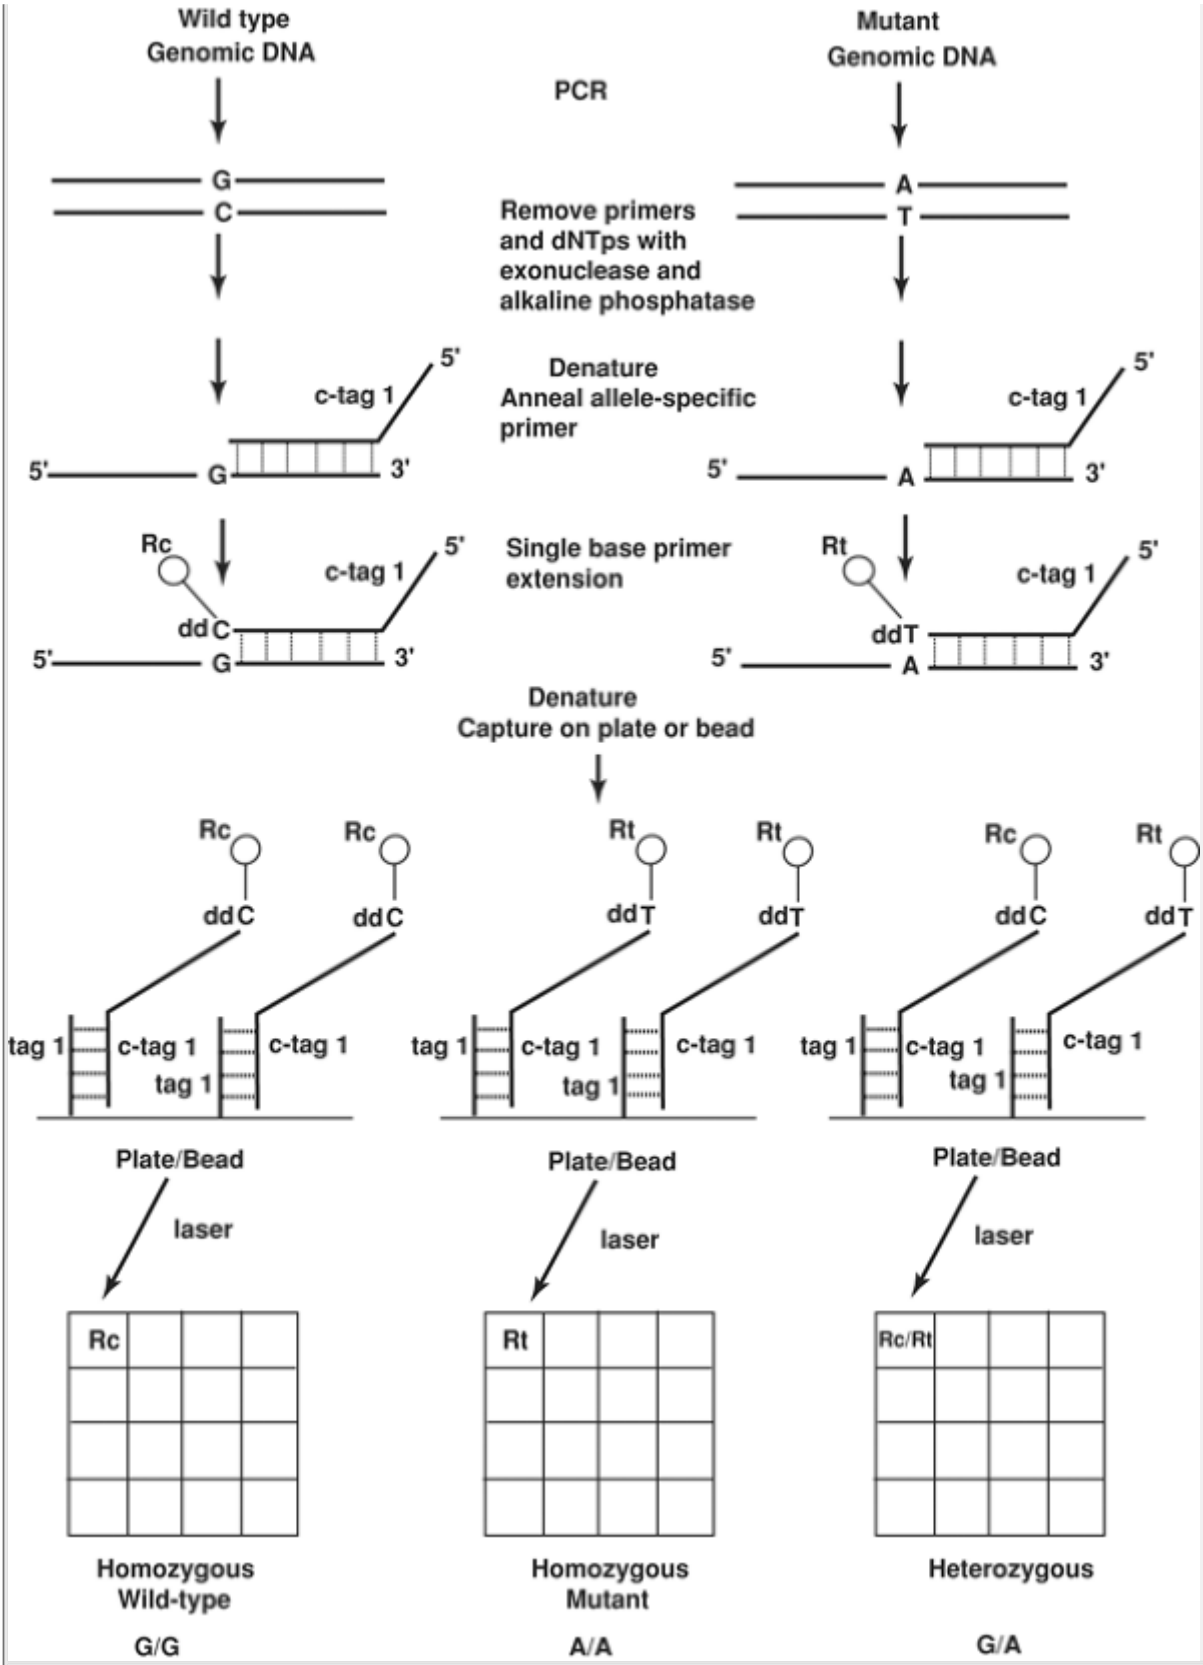

Fig. 6.47. Tag-Array and Bead technology. Tag 1 is specific for the G/A mutation at a particular position in the gene under investigation. Other tags can be designed for other single-nucleotide polymorphisms (SNPs) to permit multiplexing in the same well of the microtiter plate to produce and "array of arrays." R, reporter fluorescent label.

The technique of choice for high-throughput genotyping is the minisequencing/primer extension technique augmented with the 5′-tag technology to permit the purification of the extended products via specific tags (Fig. 6.47). The genomic region of interest is PCR amplified, and the amplified DNA is exposed to allele-specific primers with 5′-tags that are complementary to oligonucleotides immobilized at specific locations in the wells of microtiter plates or on specific colored

beads. Single base extension using DNA polymerase

and fluorescently labeled ddNTPs in solution is used to detect the SNP. The resulting fluorescently labeled and tagged DNA fragments are captured by complementary tags on microtiter plates or color-coded beads. Fluorescence resulting from laser excitation of the plates or beads is read by a detector and fed to a computer database for analysis and storage. Companies providing the single-base-extension tag–capture technology also provide a primer design service so that users can take advantage of multiplexing limited only by the capacity to design effective primers for the amplification and detection steps.

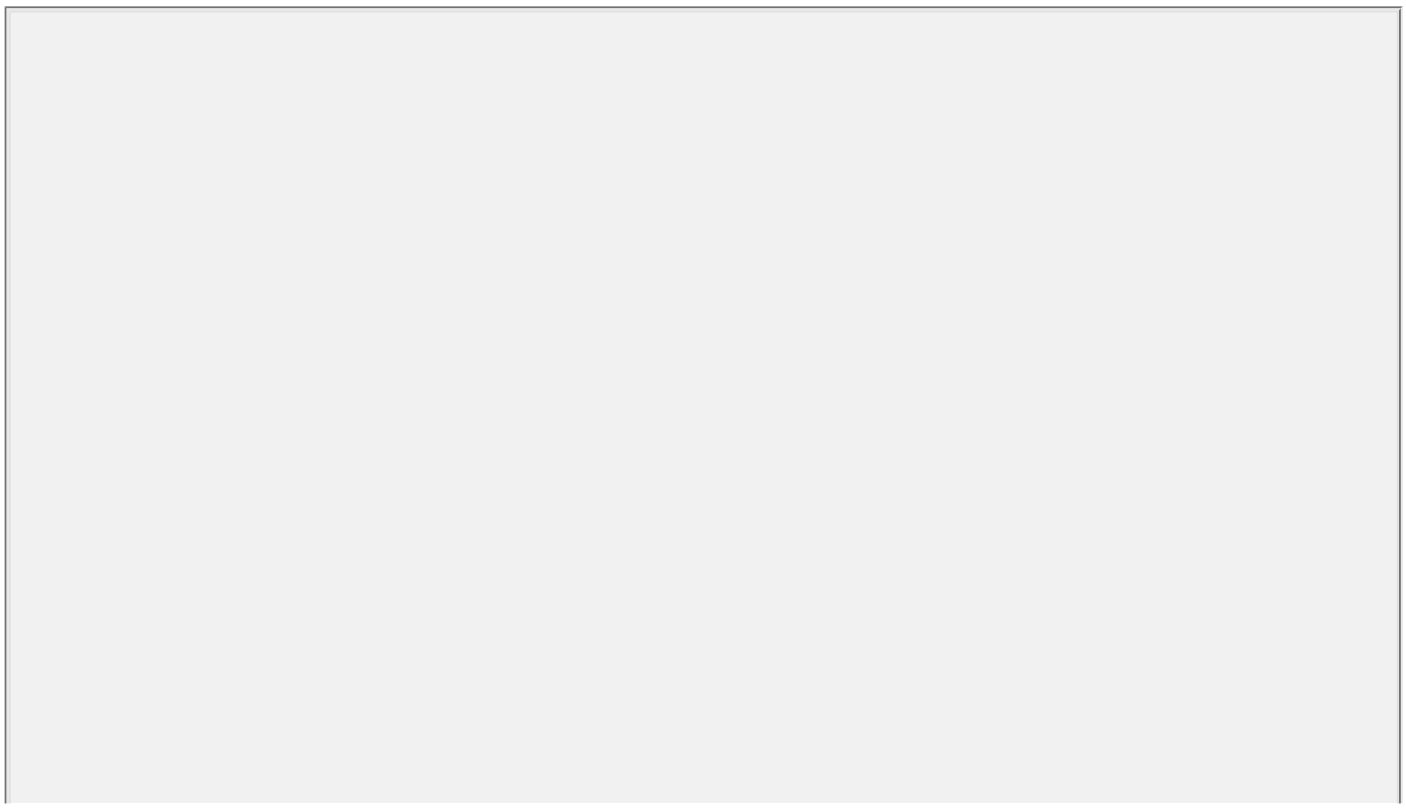
Transcriptomics

Transcriptomics is the technology behind the study of the full complement of mRNA transcripts in the cell's transcriptome and also is known as expression profiling. Methods of expression profiling are either “open” or “closed.” Open systems do not require any advance knowledge of the sequence of the genome being examined; closed systems require some advance knowledge and usually involve the use of oligonucleotide or cDNA array hybridization technologies (the gene chip) and quantitative polymerase chain (Fig. 6.48).

The cDNA arrays are prepared by spotting gene-specific PCR products, including full-length cDNAs, collections of partially sequenced cDNAs, or randomly chosen cDNAs from any library of interest onto a glass, silicon, gel, or bead matrix or a nylon or nitrocellulose membrane. The matrix (most often glass) is coated with polylysine, amino silanes, or amino-reactive silanes to assist in the attachment of the cDNA probes. The PCR products of the clones are purified and spotted onto the matrix by robots through contact printing or noncontact piezo or ink-jet devices. After cross-linking the probe to the matrix by UV irradiation, the probe is made single stranded by heat or alkali treatment. The mRNA target is prepared from both a test and reference sample by reverse transcription to produce cDNA, which is then labeled with fluorescent probes (one for the test and another for the reference). The fluorescent targets are pooled and hybridized to the probe array under very stringent conditions. Laser excitation of the hybridized samples on the matrix and comparison of the fluorescence intensity of the reference sample with the fluorescence intensity of the test sample using computer algorithms yield an emission characteristic of the increase or decrease of mRNA expression under test conditions.

Proteomics

Proteomics is the technology behind the study of the total protein complement of a genome, or the complete set of proteins expressed by a cell, tissue, or organism. The presence of an open reading frame in a DNA sequence indicates the presence of a gene, but it does not indicate gene transcription, RNA editing, translation, or posttranslational modification and the presence of isoforms. Analysis of the transcriptome does not indicate alteration of protein levels by proteolysis, recycling, and sequestration. Therefore, it is important to determine protein levels, protein expression, and protein–protein interactions directly.



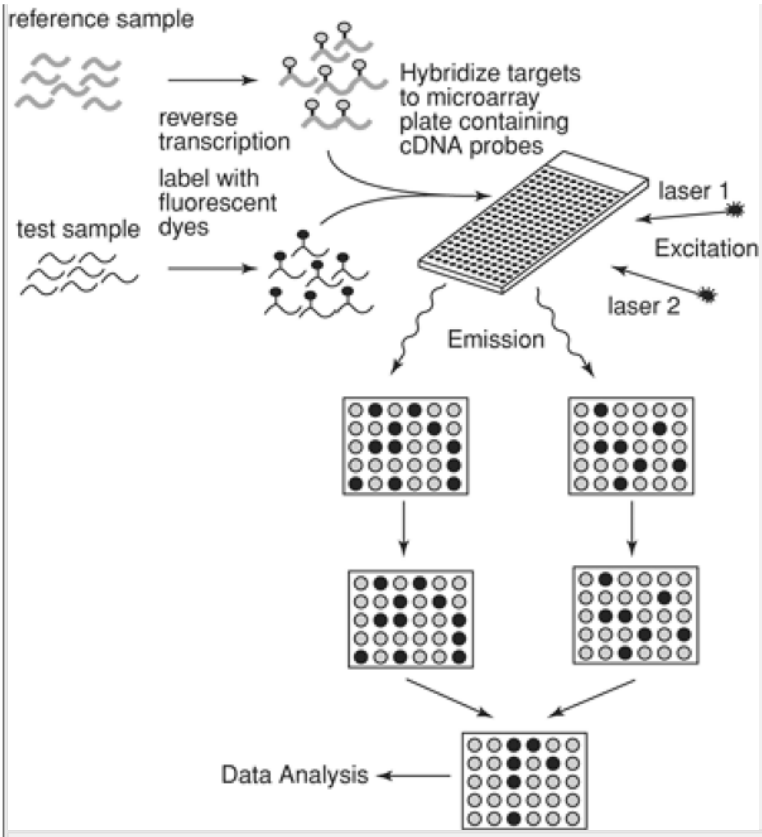


Fig. 6.48. (cDNA Chip): Schematic representation of a cDNA microarray chip. Probes of interest are obtained from DNA clones and printed on coated glass microscope slides. Analysis of mRNA expression is carried out by taking total mRNA from both a test and control sample; fluorescently labeling the samples with either Cye3- or Cye5-dUTP during a single round of reverse transcription; pooling the fluorescent targets and hybridizing to the immobilized probes on the array under very stringent conditions; laser excitation of the incorporated targets yields an emission with a characteristic spectra, which is measured using a scanning confocal laser microscope and analysed using a computer program (237).

Proteomics is divided into three main areas (238):

- Microcharacterization for large-scale identification of proteins and posttranslational modifications (238).
- Differential gel electrophoresis for comparison of protein levels (239).
- Protein–protein interaction studies using protein chips (240), mass spectrometry isotope-coded affinity tag technology (241), and the yeast two-hybrid system (242).

Metabolomics

Metabolomics is the technology behind the measurement of metabolite concentrations, fluxes, and secretions in cells and tissues (metabolome). Metabolomics is at the cross-roads of genotype/phenotype interactions, where the interrelationship of metabolic pathways is considered to be the fundamental component of an organism's phenotype. Metabolomics is distinguished by the fact that metabolites are not directly linked to the genetic code but actually are products of a concerted action of many enzyme networks and other regulatory proteins (243). Metabolites also are more complex than nucleic acids, which are composed of four nucleotides, or proteins, which in turn are composed of 20 different amino acids. As a result, metabolites cannot be

sequenced like genes and proteins so that their characterization requires that the structure of each metabolite be determined individually through description of elemental composition and stereochemical orientation of functional groups.

Metabolites are more than just products of enzyme-catalyzed reactions. They also are sensors and regulators of complex molecular interactions in the organism, and as a result, the composition of the metabolome can be altered by changes in the individual's environment. Therefore, a study of the metabolome is complicated not only by the uniqueness of the individual's genome but also by the uniqueness of the individual's environment. On the other side of the coin, however, one could consider the metabolome to be a very sensitive indicator of the individual's phenotype (244,245).

Metabolomics can be approached by using several different but related strategies:

- Target analysis investigates the primary metabolic effect of a genetic variation, in which the analysis usually is limited to the substrate and/or product of the protein expressed by the altered gene.
- Metabolic profiling limits the investigation to a number of predefined metabolites, usually in a specific metabolic pathway.
- Metabolomics is a comprehensive analysis (both identification and quantification) of metabolites in a biological system, which investigates the effect of multiple genetic variations on many different biochemical pathways.
- Metabolic fingerprinting is a strategy to screen a large number of metabolites for biological relevance in diagnostic or other analytical procedures in which it is important to rapidly distinguish between individuals in a population. Metabolic fingerprinting is the ultimate characterization of an individual's phenotype for disease diagnosis and drug therapy. Once the technological problems of high-throughput metabolic analysis is developed in this area, it will be a major competitor of SNP analysis in pharmacogenomics.

The analytical technologies used in metabolomic investigations are nuclear magnetic resonance and mass spectrometry alone or in combination with liquid or gas chromatographic separation of metabolites (243). Other techniques include thin-layer chromatography, Fourier-transform infrared spectrometry, metabolite arrays, and Raman spectroscopy.

Enviromics

Enviromics is the technology behind the measurement of environmental effects on disease diagnosis and drug therapy. This is a relatively new and undocumented area of pharmacogenomics, requiring considerable research to be carried out in the selection of environmental factors involved in personalized medicine and examining their effect on the genome, transcriptome, proteome, and metabolome in the production of molecular biomarkers.

The early concept of pharmacogenetics could be considered a very simple binary example of the gene–environment interaction, in which the environmental exposure is a drug and the genotype of the genes producing the metabolic enzymes involved in the metabolism of the particular drug are used to identify individuals at risk of adverse drug reactions or treatment failure. The population is then divided into the genotype that should avoid taking the drug and the genotype that should have the drug dose adjusted to avoid toxicity or treatment failure. It is, of course, naïve to assume that the drug is the only environmental factor playing a role in disease therapy. Indeed, under the holistic view of pharmacogenomics, a number of complicating factors lead to a successful drug therapy. Other examples of the binary gene–environment interaction are listed in Table 6.15.

Summary

Genetic technology has evolved over the past 30 years to the stage where we have determined the entire sequence of the 3 billion base pairs in the human genome. The impact that such a scientific advance will have on our lives has yet to be determined, but the social, legal, ethical, and economic issues are certain to be extensive and complex. The HGP is developing scientific technology for the manipulation and analysis of the human genome. In turn, this analysis will provide valuable information concerning the relationship between genotype and potential for serious genetic disease. The HGP is already paying dividends in the analysis and therapy of monogeneic diseases, such as CF. The greatest killers of Western society, however, such as cancer, diabetes, cardiovascular disease, and many others, not only involve multiple genes but also are subject to environmental factors. As a result, many serious diseases will only be predicted with a certain potential. The possibility of preventative therapy that manipulates an individual's environment to reduce that potential will add another dimension to health care.

Table 6.15. Relative Risk Patterns in Gene-environment Interactions (246,247,248)

Gene Variant	Environmental Exposure	Relative Risk For: (XP)a	(PKU)b	(Emphysema)c
—	—	1.0	1.0	1.0
√	—	~1.0	1.0	Modest
—	√	Modest	1.0	Modest
√	√	Very high	Very high	High

Absent = —; Present = √;

[a]XP = Xeroderma pigmentosum, UV associated skin cancer in which incidence significantly increased with mutations and UV light exposure; XP mutations without UV exposure should reduce risk of skin cancer.

[b]PKU = Phenylketonuria, a condition associated with dietary phenylalanine and a deficiency of phenylalanine hydroxylase resulting from recessive mutations in the causative gene.

[c]Emphysema associated with a deficiency in the α-1 antitrypsin gene; highest risk seen in smokers at genetic risk; smokers and nonsmokers at genetic risk exhibit increased risk of emphysema.

We are likely to be inundated with information regarding the genetic composition of individuals and populations. Information management will be a daunting task after completion of the HGP. Already, the relatively new science of bioinformatics is developing methods for storing and retrieving the vast amounts of information that the HGP is generating. The social, legal, and ethical implications involved in the storage and release of information about the human individual must balance the individual's right to self-determination and the control of personal information against the interests of third parties and the public (11,249,250). One can see that the HGP is creating a revolution in the medical sciences, but the social, legal, and economic sciences also are being challenged to reevaluate their vision of the social structure. The future will see an altered form of health care using a genetic information infrastructure to contain costs and to predict outcomes, create advanced personalized therapies, and develop a predict-and-manage paradigm of health care (251).

Chapter 7
Peptide and Protein Drugs

Michael Mokotoff

Introduction

Living cells produce a remarkable variety of macromolecules that serve as structural components, biocatalysts, hormones, receptors, or storehouse of genetic information. These macromolecules, proteins, nucleic acids, and polysaccharides are biopolymers constructed of monomer units or building blocks; for proteins the monomer units are α-amino acids. Proteins may contain substances other than α-amino acids, for example, glycoproteins also contain carbohydrates. The three-dimensional structure and the biological properties of proteins, however, are largely determined by the kinds of amino acids present, the order in which they are linked together in the polypeptide chain, and thus the spatial relationship of one α-amino acid to another.

Bacterial cells, plants, and animals contain a wide variety of peptides and proteins, consisting anywhere from 3 to 200 or more residues (each amino acid is considered to be a residue), many of which have profound biological activity. In humans, biological functions as varied as sexual reproduction, induction or augmentation of uterine contraction during labor, growth, calcium metabolism, formation of glucocorticoid and mineralocorticoid steroids, production of thyroid hormones, water balance, erythropoiesis, and glucose metabolism are known to be under the control of peptides and proteins. Proteins also are important as enzymes, as structural components of various tissues, and for receptor conformation. As a result, peptides and proteins are increasingly being used or investigated for their potential in drug therapy.

The production of many of these important peptides and proteins, via synthetic procedures as well as through biotechnology, very much involves the pharmaceutical industry. Of necessity, peptides of low to moderate molecular weight, chemically modified peptides, and those containing pseudopeptide bonds or fraudulent amino acids will continue to be made by synthetic procedures rather than through biotechnology. Therefore, this chapter discusses certain physicochemical properties of peptides and proteins, the limitations to their use as medicinal agents, the methodology used in their synthesis, and modifications aimed to improve their stability and biological action. With this backdrop, the chapter continues with a discussion of the importance of commercially available peptide and protein hormones that are used either diagnostically or in treating a variety of disease conditions. Many of these hormones are available as chemical analogues, and these also are discussed, particularly the chemical changes made and the implications of these changes to the resulting biological action.

History

Strange as it may seem to the reader, shortly before the end of the nineteenth century, it was not known that proteins consisted of peptide bonds between individual amino acids. The revelation that the linkages between amino acids were, indeed, amide bonds (peptide bonds) was not made until the early 1900s by two individuals, Hofmeister (1) and Fischer (2). The complexity of having multiple reactive functional groups in the amino acids, thus necessitating selective protection, led to great difficulty in the ability to synthesize peptides. The breakthrough came in 1932, when Bergmann and Zervas (3) developed a suitable blocking group for the α-amino function, the carbobenzoxy group (discussed later). Incentive for the further development of peptide synthesis came with the discovery

in the 1940s of the peptide antibiotics as biologically important natural products. In the 1950s, two important discoveries involving peptide hormones, the structure elucidation and synthesis of oxytocin by du Vigneaud et al. (4) and the determination of the structure of insulin by Sanger (5), helped to solidify the importance of amino acids, peptides, and their synthesis. In the late 1960s and early 1970s, two independent groups, led by Drs. Guillemin and Schally, reported on the isolation, identification, and synthesis of several important hypothalamic hormones, such as

thyrotropin-releasing hormone (6), luteinizing hormone releasing hormone (7), and growth hormone inhibiting factor (somatostatin) (8).

These discoveries led to further refinements in the synthesis of peptides, particularly such advances as the formation of the peptide bond via the coupling agent N,N′-dicyclohexylcarbodiimide (DCC) (9), the selective blocking of the α-amine functionality by the *tert*-butyloxycarbonyl (Boc) acid-sensitive group (10), and the 9-fluorenylmethyloxycarbonyl (Fmoc) base-sensitive group (11). Almost certainly, the ultimate achievement in peptide synthesis was the report by Merrifield (12) of his concept in which peptides could be more rapidly synthesized by "growing" the peptides on solid support. Merrifield's goals were to simplify and accelerate peptide synthesis in a way that would make the preparation of long peptides both practical and amenable to automation. These goals were realized in a few short years, and the solid-phase synthesis of a wide variety of peptides and proteins continues to appear in the literature.

The importance of these historical events can be measured, in part, by the fact that Nobel Prizes were awarded to those individuals most responsible for several of these advances. The following are quotes from the Nobel Prize Committee: Dr. du Vigneaud (Chemistry, 1955) "for his work on biochemically important sulfur compounds, especially for the first synthesis of a hormone"; Dr. Sanger (Chemistry, 1958) "for his work on the structure of proteins, especially that of insulin"; Drs. Guillemin and Schally (Medicine and Physiology, 1977, also with Dr. Yalow) for their work that "opened new vistas within biological and medical research far outside the border of their own spheres of interest"; Dr. Merrifield (Chemistry, 1984) for the development of a "simple and ingenious automated laboratory technique for rapidly synthesizing peptide chains in large quantities on a routine basis, called solid-phase peptide synthesis."

Chemical and Physical Properties of Peptides and Proteins

Peptides and proteins are very similar in that they are made up of repeating units, or residues, of α-amino acids that are linked together by peptide bonds, also known as amide bonds. Peptides with fewer than 15 residues are known as oligopeptides (e.g., gonadotropin-releasing hormone [GnRH] contains 10 residues); those consisting of 15 to 50 residues (e.g., adrenocorticotropin hormone consists of 39 residues) are known as polypeptides. A polypeptide that contains more than 50 amino acid residues generally is referred to as a protein (e.g., parathyroid hormone contains 84 residues) (13).

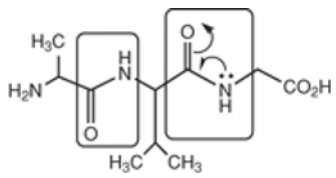

Fig. 7.1. A tripeptide, Ala-Val-Gly, indicating the planarity of the peptide bonds that are framed in the rectangles.

The Peptide Bond and Primary Structure of Peptides

A peptide consists of at least two amino acids linked by a peptide bond, an example of which is the tripeptide alanine-valine-glycine (Ala-Val-Gly) (Fig. 7.1). The properties of the peptide bonds that make up this tripeptide (framed in the rectangle of Fig. 7.1), like other amide bonds, are

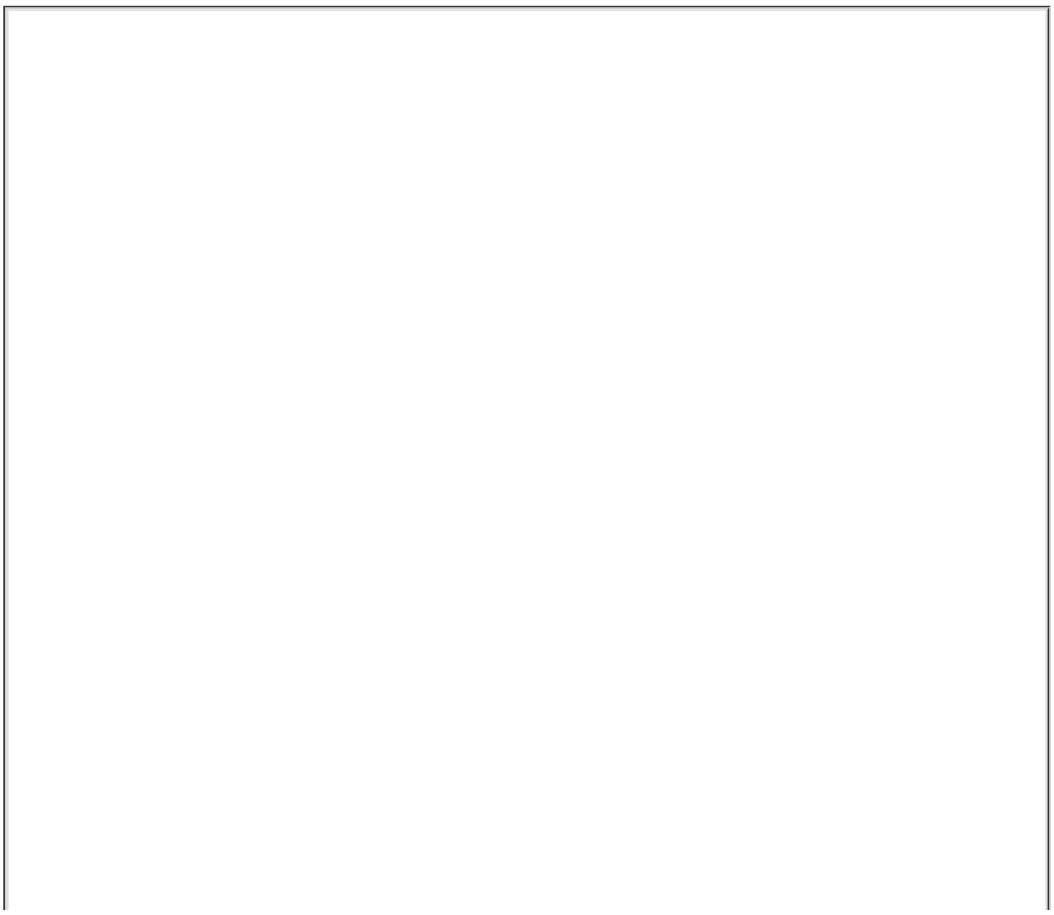
controlled by the conjugation that exists between the lone-pair electrons on the nitrogen and the adjacent carbonyl group. The major consequence of this conjugation is that peptide bonds are planar, as a result of the requirement that the nitrogen, carbon, and oxygen *p*-orbitals must lie in the same plane for the nitrogen lone-pair to conjugate with the carbonyl π-bond (14). It is this planarity and lack of free rotation about the C–N bond, which is so important for the three-dimensional shape of peptides and proteins, that accounts for the existence of two stable conformations, *cis* and *trans*. In natural peptides and proteins, however, the peptide bond largely exists in the *trans* form. The symbols for the natural, DNA-encoded amino acids found in human protein are shown in Table 7.1.

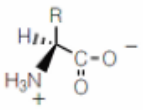
In the tripeptide shown in Figure 7.1, Ala-Val-Gly can be referred to as the primary structure of this peptide. That is, the primary structure of any peptide or protein is the number and sequence of the amino acids present (13). By convention, if the sequence is fully known, the peptide structures are written with the symbol for the α-amino, or N-terminal, residue at the left. This is followed, in order, with the symbols of all the other residues connected by hyphens and terminating on the right with the symbol for the carboxy or C-terminal residue. In the above example, Ala is the N-terminal residue and is understood, as written, to contain a free α-amino group, whereas Gly is the C-terminal residue and is understood, as written, to contain a free α-carboxylic acid. Several other conventions used in writing the primary structure of a peptide can be explained using the following model hexapeptide, Ac-Leu-Phe-Asp(OMe)-Lys(Ac)-Ser-Ile-NH_2. Ac-Leu is understood to mean that the α-amino group of the N-terminal amino acid is acetylated (Ac). When the symbol for an amino acid is followed in parentheses by an abbreviation, as is Asp(OMe) and Lys(Ac), this indicates

P.177

P.178

that the side chain is protected by the group named in the parentheses. The Asp side-chain carboxylic acid is protected as its methyl ester (OMe), and the Lys side-chain amino group is acetylated. Finally, the representation Ile-NH_2 is understood to indicate that the C-terminal residue does not exist as a free carboxyl but, rather, as its C-terminal amide, –CO–NH_2. Many important biologically active peptides actually exist as C-terminal amides, examples of which include GnRH, oxytocin, and vasopressin.





Name[b]			R	pI[c]	Acidity/ Basicity[d]
Alanine	Ala	A	$-CH_3$	6.02	N
Glycine	Gly	G	$-H$	5.97	N

Proline	Pro	P		6.30	N

[a]Selenocysteine, Sec, U, is a rare 21st amino acid that is found in both prokaryotic and eukaryotic protein (e.g., glutathione peroxidase), but is not coded for directly in the genetic code. It differs from Cys by the presence of Se in place of S.
[b]Name of amino acid, 3-letter, 1-letter abbreviation.
[c]pI is the pH at which each amino acid is ionically balanced, carries no net charge, and exists entirely in its zwitterion form.
[d]Side-chains are acidic (A), very weakly acidic (VWA), basic (B), very weakly basic (VWB), or neutral (N).

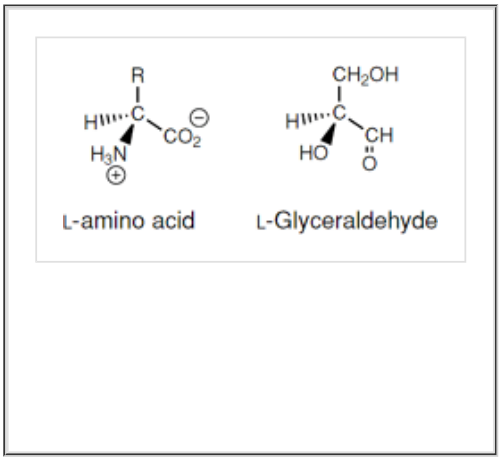
Table 7.1. Twenty, DNA Encoded, Amino Acids Found in Human Protein[a]

Stereochemical Features of Amino Acids, Peptides, and Proteins

Although some 300 different amino acids occur in nature, only 20 of these are DNA-encoded α-amino acids (selenocysteine, the twenty-first “natural” amino acid, is not actually coded for directly in the genetic code). The structures of the 20 natural amino acids can be found in Table 7.1. The amino acids in the table are not listed alphabetically; rather, they are tabulated according to properties determined by their side-chain (R) functionality. Interestingly, 19 of the DNA-encoded amino acids have the same stereochemistry and are chiral. The twentieth, Gly, is achiral, because its side-chain R-group is H. The 19 chiral amino acids are all configurationally related to L-glyceraldehyde and, therefore, are still known as L-amino acids, albeit this is an outdated nomenclature.



A more informative system for indicating the stereochemistry of chiral carbon uses the Cahn-Ingold-Prelog system, in which the four groups on an asymmetric carbon are ranked according to a set of rules, the so-called *R/S* nomenclature (15). Using this nomenclature, one can show that 18 of the 19 chiral, DNA-encoded amino acids are of the *S*-configuration, and only Cys is *R*. This results from the sequencing rules, in which the side-chain CH_2SH (sulfur bonded to carbon) takes precedence over CO_2H (oxygen bonded to carbon). In addition, the side chains of Ile and Thr each have an additional chiral center, and the DNA-encoded forms exist as Ile (*S,S*) and Thr (*S,R*) (Table 7.1).

Conformational Features of Peptides and Proteins

The primary structure of a peptide or protein previously was defined simply as its sequence, but it should be recognized that this only describes its linear, or one-dimensional, structure. If one wants to know more about a polypeptide or protein's three-dimensional shape, it is necessary to have information about its secondary structure, or its well-defined conformation that is controlled by torsional angles (also called dihedral angles or rotations) and hydrogen bonds. The tertiary structure, or well-defined folding, of a polypeptide or protein affords its biologically active, three-dimensional structure. Finally, some proteins also can exist in a quaternary structure, which occurs when two or more protein monomers (subunits) combine into a multisubunit protein.

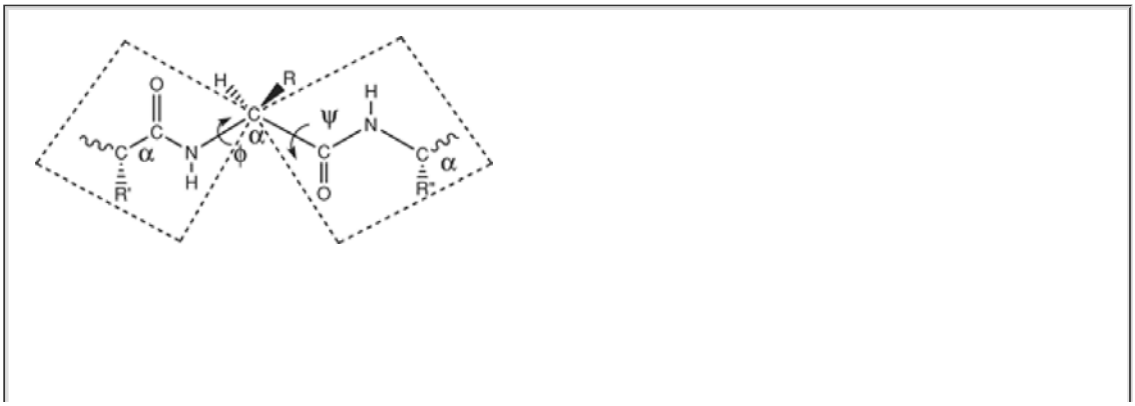


Fig. 7.2. Representation of a portion of a peptide backbone that indicates rotation about the N–C_α (angle φ, phi) and the C_α–C (angle ω, psi) bonds. Each C_α is a pivot point linking two adjacent peptide residues, as indicated by the dotted planes.

The conformation of a peptide is very much dependent on the spatial arrangement of the atoms that make up the bonds about each peptide residue of the backbone, which consists of repeating N–C_α–C units. These different conformations can vary by simple rotations without breaking a covalent bond or changing the chirality of atoms, in contrast to changing the configuration, which requires bond breaking. Consider Figure 7.2, which represents a section of a polypeptide chain containing two peptide units that can pivot about the central C_α, by rotation of the N–C_α and C_α–C bonds affording varying torsional angles φ (phi) and ψ (psi), respectively. As φ and ψ are rotated, varying conformations are formed, many of which are forbidden by steric interference caused by both backbone and side-chain atoms from adjacent residues (13,14,16). Those structures that have allowed φ and ψ values are further stabilized by hydrogen bonds formed between N–H....O==C of neighboring peptide bonds, giving rise to secondary structures.

The most common polypeptide and protein secondary *structures found in nature are the α-helix and the β-pleated sheet. The α-helix involving L-amino acids, first proposed by Pauling et al. (*17*) in 1951, is a right-handed spiral structure that often is found in fibrous and globular proteins, wherein the torsion angles φ and ψ are ideal for most residues. The α-helix has very definite and regular properties and often is referred to as a* 3.6_{13} *helix (*14*). A* 3.6_{13} *helix contains 3.6 residues per turn and forms an hydrogen-bonded ring of 13 atoms between every carbonyl* O^1 *and peptide* H^{13}*. This means that each carbonyl oxygen of residue n is bonded to the hydrogen on α-amino nitrogen n + 4 (*Fig. 7.3*). Not shown in* Figure 7.3 *are the side chains that project out from the helix.*

In a β-sheet conformation, unlike the α-helix coiled backbone, the polypeptide chain is nearly fully extended; two or more separate chains, or β-strands, can assemble side by side, wherein they are held together by hydrogen

bonds. The hydrogen bonds are, again, between the carbonyl oxygen and the NH group of the backbone. The β-sheet can exist in two types, parallel and antiparallel, and in both cases, the torsional angles φ and ψ are sterically favorable. In the former case, the two stretches of polypeptide or protein are oriented in the same direction, whereas in the latter case, the chains are oriented in opposite directions (Fig. 7.4). The β-sheet is not completely planar, and when viewed along the backbone, it resembles that of a pleated sheet. Furthermore, the side chains protrude on alternating sides of the β-sheet.

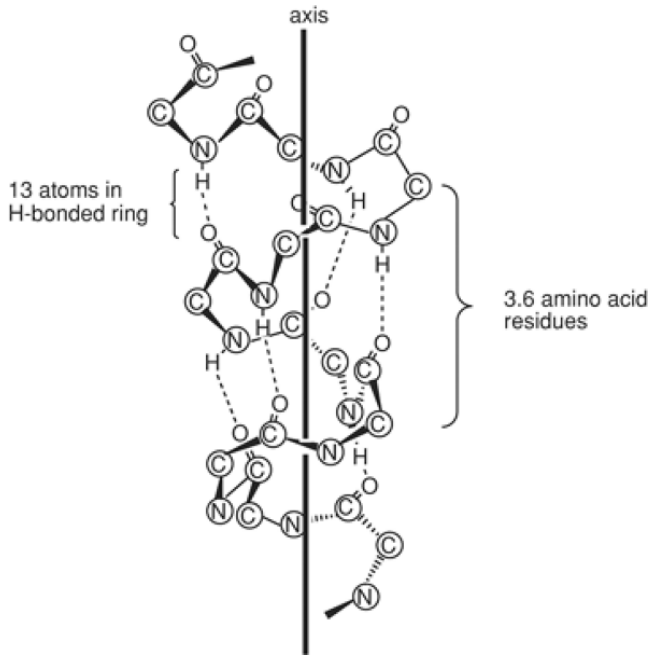

Fig. 7.3. Right-handed α-helix indicating H-bonds (dashed lines) that occur between each carbonyl oxygen and peptide N-H four residues removed; the ring formed by this H-bond contains 13 atoms. (From Horton HR, Moran LA, Ochs RS, et al. Principles of Biochemistry. Englewood Cliffs, NJ: Neil Patterson Publishers/Prentice Hall, 1993; with permission.)

Polypeptides and proteins can undergo other conformational changes, especially when they exist in relatively compact structures wherein the backbone can fold back on itself, or make a turn (i.e., a site where the polypeptide chain reverses its overall direction). It is these reverse turns (e.g., β-turn or hairpin bend) that afford proteins with globular properties (18). A further discussion of turns is beyond the scope of this chapter, but the interested reader can find many good discussions of this topic in other sources (16,19).

When a protein that exists as an α-helix, β-sheet, or combination of both folds into its biologically active globular shape, it becomes compacted and takes on a three-dimensional shape, or tertiary structure. In this case, amino acid residues, which might be far apart in the primary structure, may wind up quite close to each other, and this can be stabilized via noncovalent, usually hydrophobic interactions. That is, tertiary structures are formed and stabilized because of hydrophobic interactions between the side chains of amino acid residues. In some globular proteins, several subunits can combine with a well-defined stoichiometry and symmetry, giving rise to the quaternary structure of the protein. A good example of this is hemoglobin, the quaternary structure of which is a tetramer consisting of two α- and two β-chain subunits.

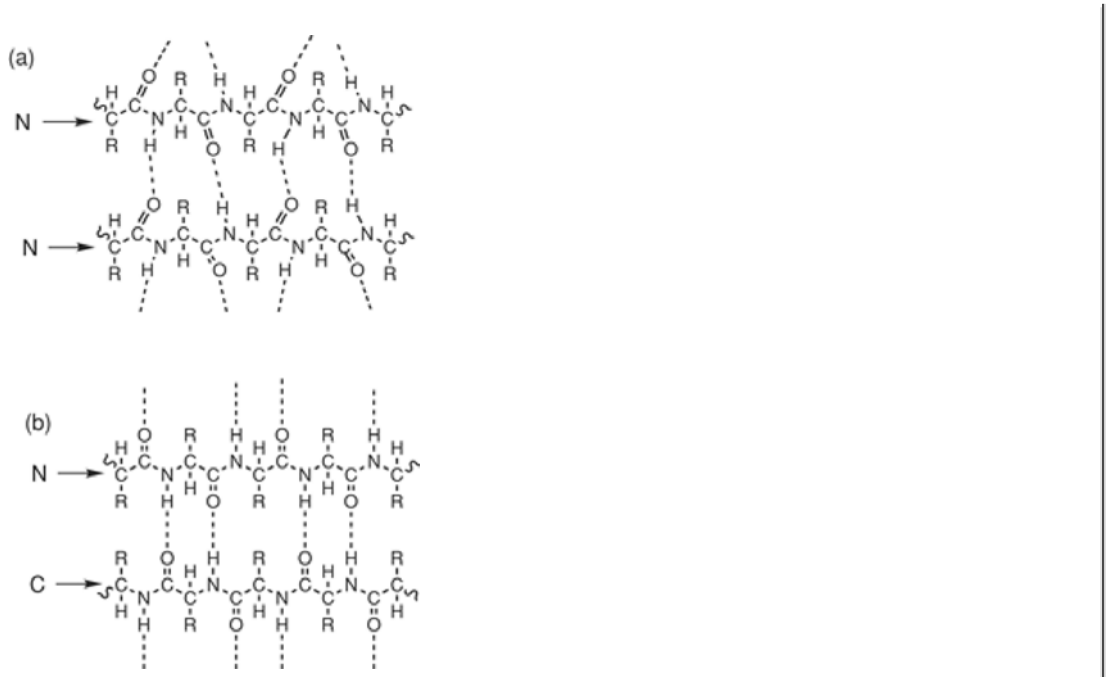

Fig. 7.4. Examples of (a) parallel and (b) antiparallel β-pleated sheets, shown with only two chains, that are held together by H-bonds (dashed lines). Note the difference in the H-bonds in the parallel (slanted and regularly spaced) and antiparallel (perpendicular with alternating wide and narrow spacing) sheets. (Adapted from Horton HR, Moran LA, Ochs RS, et al. Principles of Biochemistry. Englewood Cliffs, NJ: Neil Patterson Publishers/Prentice Hall, 1993; with permission.)

Metabolism and Drug Delivery Consequences

Peptides and proteins are metabolized quite extensively in the kidney, liver, and gastrointestinal (GI) tract via the enzymatic hydrolysis of the peptide bond. Metabolism also can occur in nasal mucosa, the lung, and blood. Because large proteins can assume complex tertiary structures, which thus better shields, or "hides," internal peptide bonds, they often are metabolized more slowly, or less completely, than smaller proteins or polypeptides (20).

The enzymes involved in peptide bond hydrolysis and, thus, the degradation of peptides and proteins are known as peptidases and can be found in the blood, in the vascular bed, in the interstitial fluid, on cell membranes, and within cells. These enzymes include carboxypeptidases (cleaves C-terminal residues), dipeptidyl

carboxypeptidases (cleaves dipeptides from the C-terminus), aminopeptidases (cleaves N-terminal residues), and amidases (cleaves internal peptide bonds). The oral administration of protein or peptide drugs generally results in very extensive metabolism within the GI tract, the loss of biological activity, and little to no systemic absorption of the original drug. This results from the prevalence of peptidases within the GI tract, wherein the protein or peptide drugs undergo first-pass metabolism. Even if these drugs are administered parenterally, they still can undergo extensive metabolism because of their secretion across the intestinal mucosa and from hydrolyzing enzymes found in plasma and the vascular bed.

The fate of orally administered peptide drugs occur as follows. As the peptide drugs enter the stomach, wherein the gastric juice has a pH of approximately 2, they are acted on by pepsin, an enzyme secreted by the gastric mucosa. This enzyme is known as an endopeptidase, which means that it can hydrolyze "internal" peptide bonds at the carbonyl side of aromatic (Tyr, Phe, and Trp) and acidic (Asp and Glu) amino acid residues. Exiting the stomach, the contents continue on into the small intestine, where the pH rises to approximately 7 and the peptidases

trypsin, chymotrypsin, and elastase continue the digestion. These enzymes are endopeptidases secreted by the pancreas. Trypsin generally cleaves at the carbonyl side of basic (Lys and Arg) residues, chymotrypsin at aromatic (Tyr, Phe, and Trp) residues, and elastase at small or sterically nonhindered (Ala, Gly, and Ser) residues. Finally, the oligopeptides that are remaining after endopeptidase hydrolysis are further acted on by two exopeptidases, carboxypeptidase and aminopeptidase. An exopeptidase is one that cleaves at the termini of peptides. The net result is a thorough breakdown of peptides and proteins into single amino acids and smaller dipeptides and tripeptides. For the most part, these enzymes are all specific for the natural amino acids of the L-configuration.

Chemical Methodology for Decreasing Proteolysis

The modification of peptides in a way that makes them more resistant to the onslaught of peptidases, thereby enhancing the biological activity and duration of action, is being pursued by peptide chemists. When metabolism studies indicate a predominant cleavage site, attempts can be made to replace that residue with another that retains the receptor-binding activity of the peptide while yielding enhanced resistance to peptidase activity. Often, this can be accomplished by replacing the offending L-residue with its enantiomer, the D-amino acid or another D-residue. Many peptidases are unable to cleave at peptide bonds consisting of a “fraudulent” D-amino acid, and peptides containing such changes can have enhanced biological activity because of an increase in their half-life. Such successes have been documented, as will be discussed later with the superagonists of GnRH. Also, the replacement of an L-amino acid with L-proline, or N-methylation of the amide nitrogen, offers the possibility of generating a peptide that is more resistant to enzymatic hydrolysis. The introduction of pseudo (ψ) peptide bonds (21) and the design of retro-inverso peptides (22) are two examples of strategies that can afford more peptidase-resistant peptides (discussed later).

Alternative Drug Delivery Methods for Peptides and Proteins

As evident from the previous discussion, a major barrier to the use of peptides as clinically useful drugs has to do with their poor delivery properties, because proteolytic enzymes present at most routes of administration are able to quickly metabolize most peptides. Peptides and proteins are, for the most part, hydrophilic in nature and, for this reason, do not readily penetrate lipophilic biomembranes. As well, they have short biological half-lives because of rapid metabolism and clearance, all of which deters from their efficient use in drug therapy. It is for these reasons that alternative drug delivery methods for peptides and proteins are an area of particular interest to the pharmaceutical industry.

An appreciation of the problems of drug absorption via different routes of administration was reported by Lee (23), wherein he compared the percentage of dose that is absorbed for two important peptides, insulin and an analogue of GnRH, leuprolide, when administered by the oral, nasal, buccal, rectal, vaginal, and subcutaneous (SC) routes. For example, dosing of insulin and leuprolide by the oral route afforded, in both cases, a mere 0.05% absorption; 30 and 2–3%, respectively, by the nasal route; and 80 and 65%, respectively, by the SC route. In addition to the above routes, alternative routes of administration for the delivery of peptide and protein drugs include transdermal, parenteral (including SC), targeted, and pulmonary routes (24). Space does not allow a detailed discussion of each of these routes, but several generalizations can be made.

Drug administration by the parenteral route, either intravenous (IV), intramuscular (IM), or SC injection, is certainly undesirable. Aside from the pain involved, it is a route that does not easily allow self-administration, especially when the drug has to be given IM or IV. In emergency situations, however, when rapid onset of action is warranted, the IV route is preferred. The peptide drug can act very fast, because it is placed directly into the bloodstream and no absorption is involved. On the other hand, when a more sustained action is desired, IM administration is preferred because of the ability to introduce larger volumes of fluid directly into skeletal muscle. The disadvantages of the IM route are pain after injection, possible degradation of the peptide at the injection site, slow absorption, and difficulty of self-injection. An SC injection of a peptide drug, which can be self-administered (e.g., insulin), affords a slower absorption rate when compared to the IM route and is useful for long-term therapy, but

there is decreased drug potency

P.181

because of degradation and poor absorption (25). There has been progress in improving parenteral dosage forms that allow better patient compliance, including biodegradable microspheres of poly(D,L-lactide-glycolide) for sustained-release IM injection of leuprolide acetate for up to 6 months and the administration of goserelin acetate dispersed in a copolymer matrix of D,L-lactic and glycolic acids. The latter is injected SC as a solid pellet for use up to 3 months (see later discussions on these GnRH analogues). More recently, pegylation, the attachment of a peptide or protein to various polyethylene glycol polymers, has gained in popularity as a way of improving the biological activity (26). For example, pegylated interferon-α_{2b} is commercially available as PEG-Intron and is used either alone or in combination with ribavirin for the treatment of patients with chronic hepatitis C.

The delivery of peptide and protein drugs by the nasal route has been studied extensively. Generally, the nasal route represents a significant improvement in bioavailability over the oral route, and it is noninvasive. Although the nasal route avoids first-pass hepatic metabolism, there is still a significant degree of enzymatic degradation that occurs in the nasal mucosa, especially by aminopeptidases (27). Also, the higher molecular weight of peptides and proteins, coupled with their more hydrophilic properties, generally affords compounds with poor absorptive properties. Therefore, to obtain successful nasal delivery of peptides and proteins, the coadministration of protease inhibitors and/or permeation enhancers generally is required. Still, only a very limited number of peptides, mostly of lower molecular weight, are commercially available for nasal use (e.g., calcitonin, desmopressin, and nafarelin).

The delivery of peptide and protein drugs via the pulmonary route (i.e., by inhalation therapy) is an area of considerable interest to the pharmaceutical industry (26). This method is noninvasive and allows the delivery of peptide and protein drugs to the lung epithelium, which is highly permeable and easily accessed via inhalation. That is not to say this methodology, which generally uses particles that are dry or liquid and delivers them with the use of dry-powder dispersers or liquid-aerosol generators, is not without problems (24). Issues such as protein stability, reproducible delivery devices, particle size, and bioavailability of the inhaled protein still need to be resolved before pulmonary delivery gains greater acceptance. Recently, however, studies regarding the systemic delivery of peptides and proteins via the lung, particularly with inhaled insulin (Exubera) for the treatment of diabetes, have sparked increased interest. Two other peptide hormones in development are Inhaled Leuprolide for prostate cancer and endometriosis and Inhaled Parathyroid Hormone for osteoporosis. A good treatise on inhalation therapy of peptide and protein drugs can be found in the book edited by Adjei and Gupta (27).

Major Methods of Peptide Synthesis

Although there have been many advances in the chemistry of peptide synthesis, the problems that can occur during the large-scale synthesis of even a medium-size peptide (e.g., 20–35 residues) can be quite challenging and expensive, especially when using the classical solution-phase methodology. The alternative method of peptide synthesis, on solid phase, has certainly grown in popularity and eliminated some of these problems, but is not without its own limitations. A description of these two methodologies, the synthesis of peptides in solution or by solid phase, is described below.

Synthesis in Solution

The synthesis of peptides in solution, either by stepwise elongation or segment condensation, allows one to isolate the intermediates along the way and purify them to homogeneity. As a result of this, the eventual final products usually are less contaminated with by-products and are easier to isolate in a homogeneous form. This method also is more amenable to the preparation of bulk quantities of peptides compared with the solid-phase method. The trade-off, however, is that the solution method is laborious and time-consuming, especially as the size of the peptide grows, wherein the problem of maintaining the peptide in solution becomes formidable. Also, when using the segment method, there is always the danger that racemization will occur during the coupling of the segments. One of the more prolific laboratories that report outstanding

achievements in the solution synthesis of complicated large peptides and proteins is that of Sakakibara (28) in Japan.

Selective Protection of the α-Amino Group

To be able to form a peptide bond between two amino acids (e.g., Ala-Val), the nucleophilicity of the amino function in Ala must be diminished. Thus, only the amino group of Val is nucleophilic, and only it can react with the activated carboxyl group (discussed later) of Ala. If this dipeptide is then to be elongated to a tripeptide (e.g., Gly-Ala-Val), the nucleophilicity of the Ala amine must be reinstated so that it now can react with an activated carboxyl group of Gly. The key then is to be able to easily protect and deprotect the amino functions of amino acids without inverting the chirality of the individual amino acids or disrupting any of the peptide bonds.

As mentioned previously, the first group that fit these criteria was the carbobenzoxy (Cbz) group discovered by Bergmann and Zervas (3) (Fig. 7.5). The advantages of the Cbz blocking group are that its amino acid derivatives are stable, crystalline, and therefore, commercially available for all the natural amino acids. When the Cbz group is bound to the α-amine, the resulting urethane functionality ($RO_2C–NH–$) imparts stability toward racemization (29). The Cbz group is stable to base, but it can be removed by treatment with hydrogen bromide in glacial acetic acid (HBr/AcOH) or liquid hydrogen fluoride (HF), both of

P.182

which are examples of acidolytic, not hydrolytic, cleavage resulting from protonation of the urethane carbonyl oxygen. In addition, the Cbz group is readily cleaved by catalytic hydrogenation in the presence of palladium (Pd/H_2) except when also in the presence of the sulfur-containing amino acids, Cys and Met, wherein the sulfur poisons the Pd catalyst. Conversely, the Cbz group is not useful for α-amino protection in solid-phase peptide synthesis (SPPS), because the two acidolytic methods used in Cbz cleavage also would cleave the side-chain blocking groups of the trifunctional amino acids. Additionally, Pd/H_2 cleavage is not useful in SPPS, because Pd, being a solid, would contaminate the polymers used in SPPS. A further disadvantage of the Cbz group is that on acidolytic cleavage, benzyl (Bzl) cations can form and, potentially, alkylate the amino acids Trp and Met. Therefore, the addition of a scavenger agent (e.g., anisole) that can preferentially react with Bzl cations usually is added to the acid cleavage reagent.

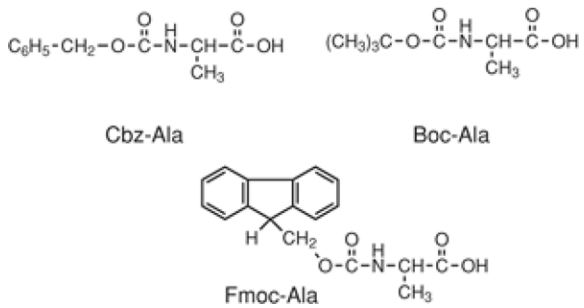

Fig. 7.5. Three urethane-type amino protecting groups—Cbz. Boc, and Fmoc—shown attached to Ala.

The introduction of the Boc group (10) was a significant step forward as a protecting group for the α-amino function (Fig. 7.5). In addition to the advantages mentioned above for the Cbz group, including the urethane protection against racemization, the Boc group's ease of cleavage under milder acidic conditions, such as trifluoroacetic acid (TFA), broadens its use in peptide synthesis, especially in SPPS. Furthermore, its resistance to cleavage by Pd/H_2 but sensitivity to TFA allows differential blocking of trifunctional amino acids when using both Boc and Cbz

groups. A disadvantage with the use of the Boc group is the possible formation of *tert*-butyl (Bu^t) cations which can alkylate the amino acids Trp and Met. Again, this can be minimized by the addition of a scavenger agent to the acidolytic cleavage reagent.

In the synthesis of peptides, the repeated use of acid in the cleavage of the α-amino protecting group can cause variable amounts of unwanted side products to occur. To circumvent the need for repeated acidolytic cleavages, Carpino and Han (11) introduced the now-popular Fmoc protecting group (Fig. 7.5). The main advantage of this urethane blocker is that it is stable to acid but readily cleaved by organic base, such as piperidine. Like Boc, it, too, is very useful in either solution or solid-phase synthesis. Because it is base labile, one can use various acid-labile blocking groups for the side chains of trifunctional amino acids. One disadvantage is that commercially available Fmoc amino acids are somewhat more expensive than the corresponding Boc or Cbz amino acids. Another disadvantage is that there can be some premature deblocking by the free amines that are the nucleophilic components of the coupling reaction.

Selective Protection of the α-Carboxyl Group

In the solution synthesis of peptides by the stepwise elongation method (the addition of one amino acid at a time) or segment condensation method (the synthesis of several segments, which are then joined to make the whole), the carboxyl function of the C-terminal residue must be blocked so that it does not partake in future coupling reactions. Clearly, the easiest to prepare and least expensive of the groups protecting the α-carboxyl function is the methyl or ethyl ester. These esters are only cleaved by alkaline hydrolysis, however, and that can lead to undesirable side reactions. Furthermore, these esters are not compatible with the conditions necessary to cleave the Fmoc group, in that piperidine can react with these simple esters.

The Bzl ester is another widely used blocker for the carboxyl function and is easily prepared with inexpensive reagents. It is readily cleaved with liquid HF or by Pd/H_2 yet is stable to TFA. The latter stability is the reason why the Bzl ester is especially useful when Boc amino acids are used. The TFA cleaves the Boc group but not the Bzl ester, whereas Pd/H_2 can cleave the Bzl group but not the Boc group.

The Bu^t ester is easily prepared with inexpensive reagents, is cleavable with TFA and other acidolytic reagents (HF), yet is stable to Pd/H_2. As a result, it is a very popular blocking group, because it is compatible with both Cbz and Fmoc amino acids. For example, the Cbz group can be cleaved via Pd/H_2, the Bu^t ester is stable. The converse, however, also is true: the Bu^t ester can be cleaved with TFA, and the Cbz group is stable. In the case of Fmoc amino acids, the Bu^t ester is stable under the basic conditions needed to cleave the Fmoc group.

Selective Protection of Trifunctional Amino Acids

A trifunctional amino acid, as seen in Table 7.1, has an additional functional group as part of its side chain. For ease of discussion, these can be divided into the following groups, as determined by their side-chain functionality: monoamino dicarboxylic acids (Asp and Glu), hydroxyl containing (Ser, Thr, and Tyr), sulfur containing (Cys and Met), basic (Arg, His, and Lys), and neutral (Asn, Glu, and Trp). In the discussion below, it is important to recognize that the goal is selective protection of the side-chain functionality so that it does not participate in any chemistry during the assembly of the peptide but, instead, undergoes cleavage at the end of the synthesis. That is, the side-chain protecting group should be stable to the conditions needed to cleave either the

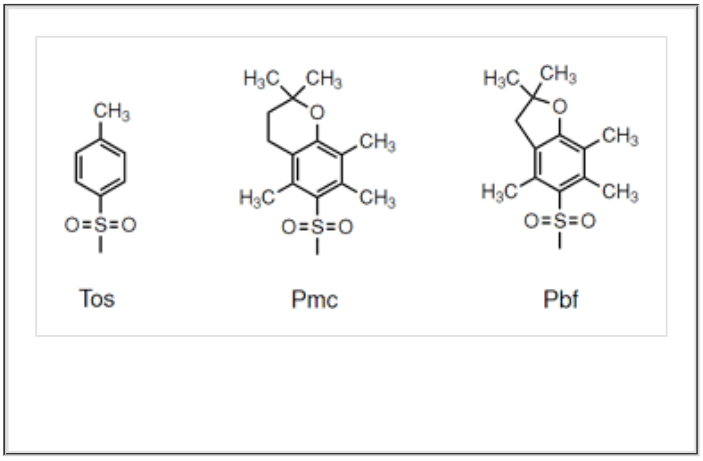
α-amino or α-carboxyl blocking groups during peptide chain elongation.

Irrespective of whether solution phase or SPPS is practiced, if Boc amino acids are used with monoamino dicarboxylic acids, then the side-chain carboxyl usually is protected as its Bzl ester. Because of the potential for intramolecular succinimide formation with Asp(Bzl) peptides, however, the replacement of Bzl with a cyclohexyl (cHex) ester reduces this undesirable side reaction (14). On the other hand, if Fmoc amino acids are used, then the side-chain carboxyl usually is protected as the Bu^t ester. Similarly, when using Boc-Ser and Boc-Thr, the hydroxyl function is protected as the Bzl ether. In the case of Tyr, however, the Bzl ether is not stable enough during repeated TFA treatments needed to cleave Boc groups. Therefore, in the case of

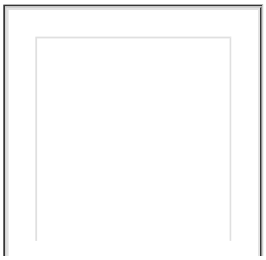
Boc-Tyr, the preferred blocking group for the phenolic hydroxyl is the 2-bromo-carbobenzoxy (2Br-Z, $BrC_6H_4CH_2OCO$). When N^{α}-Fmoc is used, the hydroxyl groups of Ser, Thr, and Tyr usually are protected as the Bu^t ether.

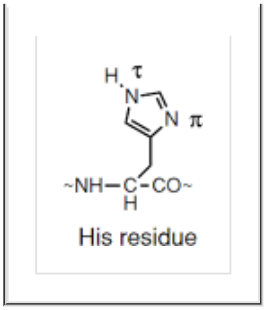
The amino acid Cys contains a free sulfhydryl (SH) function that is very nucleophilic, easily oxidized, and must be protected. A discussion of the several different blocking groups used to protect the sulfur is beyond the scope of this chapter, but the interested reader should consult those references whose main thrust is peptide synthesis (29,30). The amino acid Met does not contain a free SH but, rather, a methylthio ether, $S\text{-}CH_3$, and as such, it most often is used unprotected. Some investigators prefer using Boc-Met protected as its sulfoxide, Boc-Met(O), to prevent alkylation of the sulfur and partial conversion to the sulfoxide during the synthesis. The sulfoxidation is most common during the acidic cleavage of other blocking groups. The use of the sulfoxide as a blocking group would, of course, necessitate a reduction step at the end of the synthesis to convert Met(O) back to Met, which can be accomplished by the low/high-HF cleavage procedure (31). When using Fmoc-Met, the side chain is left unprotected.

Of the three basic amino acids, Arg, Lys, and His, Arg is the most basic and is mainly used with the guanyl nitrogen (N^G) protected, even though at pH 9, the guanidino group (pK_a = 12.5) is virtually fully protonated. When N^{α}-Boc is used, the preferred protection for N^G is the tosyl (Tos) group, which is cleavable with HF at the end of the synthesis. On the other hand, when using N^{α}-Fmoc, the popular N^G-blocker 2,2,5,7,8-pentamethyl-chroman-6-sulfonyl (Pmc) group often is used, which like the Tos group is of the sulfonyl type (see structure below). The presence of the aromatic methyl groups and the chroman oxygen impart greater acidolytic lability, and the Pmc group is cleavable with TFA at the end of the synthesis. Similarly, N^G-protection as Fmoc-Arg(Pbf), where Pbf is 2,2,4,6,7-pentamethyldihydro benzofuran-5-sulfonyl (below), is now commonly used. The advantage of the Pbf group is greater TFA lability when compared to its structural analog Pmc (13).

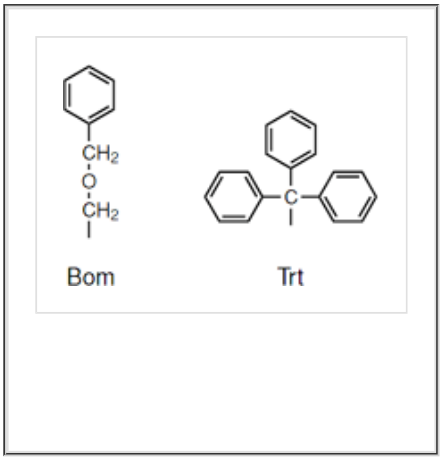


The side chain of basic amino acid Lys usually is protected with the 2-chloro-carbobenzoxy (2Cl-Z, $ClC_6H_4CH_2OCO$) group when using N^{α}-Boc, because the presence of the 2-Cl increases the stability of the group to repeated treatments with TFA necessary for removing Boc groups. When N^{α}-Fmoc protection is used, the side-chain amine is protected with the Boc group. Finally, the least basic of the three, His, is always used with the imidazole ring protected; otherwise, it is susceptible to racemization during activation of the carboxyl for peptide coupling. There are two different ring nitrogens in the imidazole ring of His, N^{π} and N^{τ}. The N^{π} electrons, which do not participate in the aromaticity of the imidazole ring as the N^{τ} electrons do, are responsible for causing racemization (29).





For this reason, Boc-His(N^{π}-Bom), wherein N^{π} is blocked with the benzyloxymethyl (Bom) group, is commercially available and widely used. When using Fmoc chemistry, however, peptide chemists often use Fmoc-His(N^{τ}-Trt), where Trt is the triphenylmethyl (trityl) group. Although the Trt group is attached at N^{τ}, it still suppresses racemization, both because it reduces the basicity of the imidazole ring and because its steric bulk hinders most racemization (13).



The aromatic, weakly nucleophilic Trp is susceptible to two side reactions, oxidation and alkylation of the indole ring by cations generated during acidolytic cleavage. Therefore, when using N^{α}-Boc chemistry, the formyl (For) group often is attached to the indole nitrogen (i.e., Boc-Trp(For)). The formyl group is removable at the end of the synthesis by cleavage treatment using the low/high-HF procedure (31). During peptide synthesis using N^{α}-Fmoc chemistry, Trp generally is used without side-chain

P.184

protection. The use of Fmoc-Trp(Boc) is advantageous, because it prevents Trp-sulfonated by-products from occurring during final deprotection of peptides containing Arg(Pmc) and Arg(Pbf) residues (32).

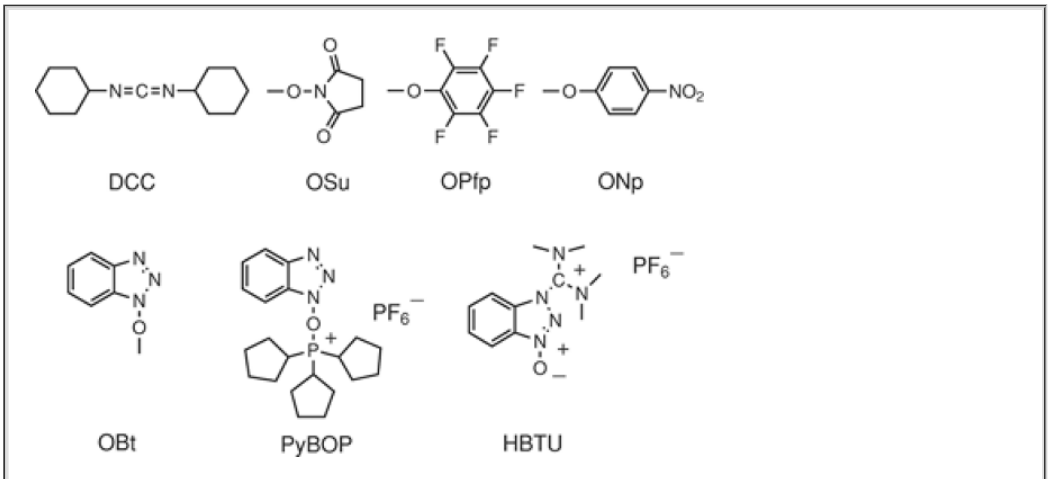


Fig. 7.6. Structures of several of the reagents used in peptide bond formation.

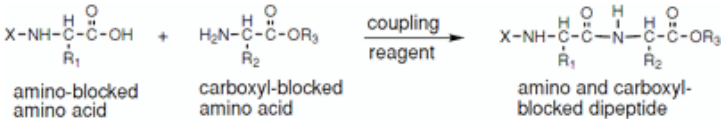
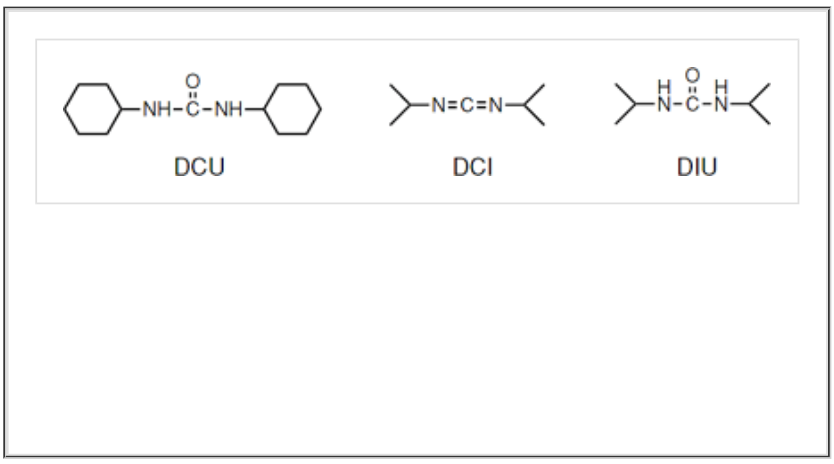
Finally, the neutral amino acids Asn and Gln can be used in peptide synthesis without side-chain protection provided that the chemist is aware of the potential for carboxamide side-chain dehydration to a nitrile during peptide bond formation. This nitrile formation, which can occur in the presence of a variety of carboxyl activating reagents, is dramatically minimized by the addition of 1-hydroxybenzotriazole (HOBt) to the activating solution (Fig. 7.6) (33). During N^{α}-Fmoc chemistry with Asn and Gln, the use of the Trt group to block the amide nitrogen has gained in popularity. This is because it prevents nitrile formation, enhances solubility in dimethylformamide (an organic solvent commonly used in peptide synthesis), and can be removed by later treatment with TFA.

Major Methods of Peptide Bond Formation

To form a peptide bond, one must activate the α-carboxyl group of a suitably blocked amino acid so that it can react with the free α-amino group of another suitably blocked amino acid or growing peptide. The activation methodologies most often used can be divided into three main classes: 1) the carbodiimide coupling reagents, 2) the active esters, and 3) the phosphonium and uronium coupling reagents.



The reagent DCC (Fig. 7.6), previously discussed as one of the important discoveries that helped to drive the field of peptide synthesis (9), probably is the most popular of the carbodiimide-type coupling reagents in use today. DCC is considered to be a dehydrating agent inasmuch as the results are a loss of a molecule of water from the amino and carboxyl groups involved in the coupling. Details of the mechanism can be found elsewhere (33). Advantages of the carbodiimides are their low cost, general insensitivity to moisture, and relatively fast coupling. Disadvantages are that extensive racemization can occur when coupling peptide segments, specifically the residue whose carboxyl is being activated, as well as nitrile formation from Asn and Gln residues, as mentioned above. The addition of HOBt to carbodiimide couplings, however, can very effectively minimize both of these disadvantages. Another annoying problem with DCC, more so with SPPS than with solution phase, is that its by-product, dicyclohexylurea (DCU), is highly insoluble in most solvents used in peptide coupling. Often, DCC is replaced with diisopropylcarbodiimide (DCI), because its by-product, diisopropylurea (DIU), is more soluble in the solvents used in SPPS and does not contaminate the solid phase.



An active ester is a suitably protected amino acid whose carboxyl group has been esterified with a hydroxyl moiety that is easily eliminated on attack of the carbonyl group by the nucleophilic amino component. When the hydroxyl moiety is a phenol, it will contain either an electron withdrawing group (e.g., *para*-nitrophenol, ONp) or electronegative elements (e.g., pentafluorophenol, OPfp), which affords a better leaving group (Fig. 7.6). When using Boc-

protected residues, two popular active esters employed are the ONp and N-hydroxysuccinimde (OSu) esters (Fig. 7.6). When using Fmoc-protected residues, the one active ester that is both commercially available and widely used is the OPfp ester (Fig. 7.6). These commercially available derivatives generally are crystalline and reasonably stable. On the other hand, the 1-hydroxybenzotriazole (OBt) active ester (Fig. 7.6) is very popular with both Boc and Fmoc chemistries. The OBt-esters, however, are not commercially available, because they usually are neither isolable nor stable and have to be prepared in situ from a protected amino acid, HOBt, and a carbodiimide. Still, this method finds wide use in both solution phase and SPPS.

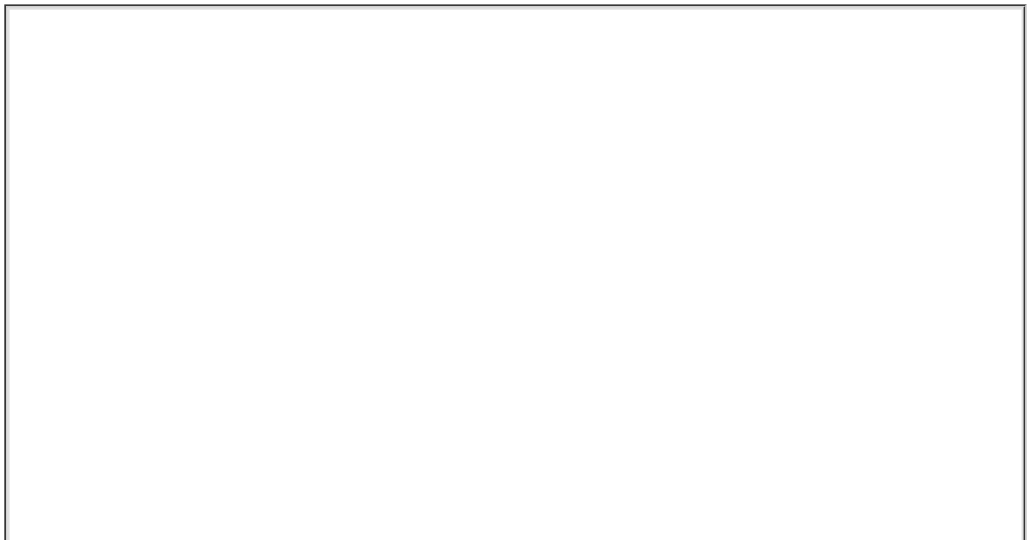
More recently, the use of phosphonium (e.g., benzotriazole-1-yl-oxy-tris-pyrrolidino phosphonium hexafluorophosphate (PyBOP)) and uronium (e.g., 2-(1H- benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)) coupling reagents have gained wide use in effecting peptide bond formation, particularly in SPPS (Fig. 7.6). The structures of PyBOP and HBTU both incorporate an equivalent of HOBt, and the final reactive Boc or Fmoc amino acid species is the corresponding OBt active ester (13).

P.185

Solid-Phase Peptide Synthesis

The Merrifield strategy of SPPS, as originally published in 1963 (12), consisted of attaching the N^{α}-Boc protected C-terminal amino acid of the peptide to be synthesized to a solid polymer support via an ester linkage (34). This ester linkage was designed to be stable to all chemical conditions involved in the elongation of the peptide but able to be cleaved from the polymer at the end of the synthesis without disturbing the integrity of the final peptide. An additional requirement was that the side-chain protecting groups should be stable during the synthesis but removable at the end, preferably at the same time that the final peptide was cleaved from the polymer. The original Merrifield solid support used to attach the growing peptide was a chloromethylated polystyrene polymer (resin). Today, several newer and more versatile polymers are popular and have, for the most part, replaced the original resin. A scheme that illustrates Merrifield's concept of SPPS is shown in Figure 7.7.

The following are some of the advantages gained when using the technique of SPPS. The attachment of the growing polypeptide to an insoluble polymer allows soluble reagents and by-products to be readily removed by simple filtering and washing of the insoluble polypeptide-bound polymer. This reduces the loss of valuable peptide that occurs, as the result of repeated isolation and purification of peptide intermediates, during solution-phase peptide synthesis. Another advantage is the ability to use excess soluble reagents to force reactions to completion and, thereby, achieve high yields, which then are readily removed by filtration of the growing insoluble peptide. The most valuable advantage is the ability to automate all the operations of the peptide synthesis, thus drastically reducing the time, labor, and cost involved in the synthesis. The disadvantages of SPPS are the inherent cost of using excess reagents and solvents to force the couplings to near completion and the actual purification of the final cleaved product, which can be difficult.



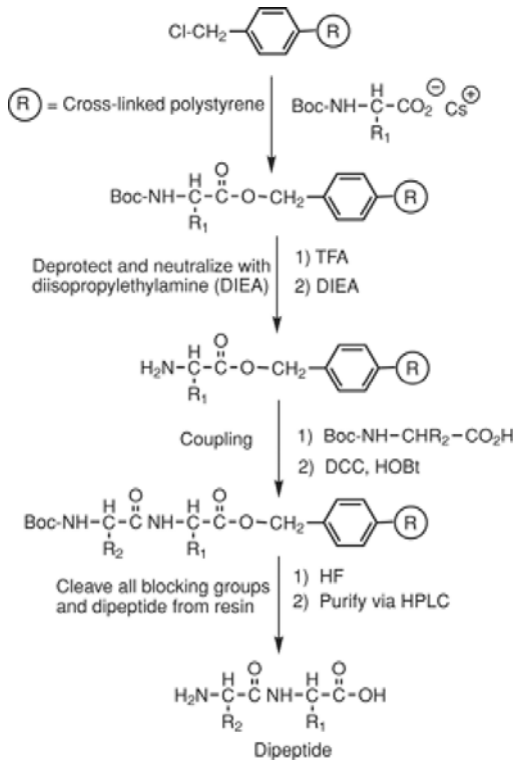


Fig. 7.7. A scheme based on Merrifield's methodology for Boc-based SPPS.

Boc Chemistry

The use of Boc-based SPPS for the synthesis of peptides with free C-terminal carboxylic acids generally requires that the peptide chains be linked to the resins as Bzl esters and that the side-chain protecting groups have a similar reactivity so that these bonds are stable to repeated TFA cleavage of the N^{α}-Boc group. The need for a more stable peptide Bzl ester linkage to the Merrifield solid support culminated in the development of the phenylacetamidomethyl (PAM) resin, and the need to synthesize peptide C-terminal amides gave rise to the 4-methylbenzhydrylamine (MBHA) resin (35) (Fig. 7.8). Merrifield, PAM, and MBHA resins linked to all the natural Boc-amino acids are now commercially available.

Fmoc Chemistry

The growth of N^{α}-Fmoc-based SPPS has been driven by the desire to avoid the repetitive acidolytic (TFA) treatment required in Boc-based SPPS as well as the final HF cleavage needed to remove the peptide from its resin and all remaining blocking groups. The repetitive TFA and final HF treatments often are the cause of unwanted by-products. The Fmoc-based SPPS allows the use of side-chain protection with Bu^{t}-derived esters, ethers, and urethanes that are stable to the recurring mild secondary base (piperidine) treatment necessary to cleave the N^{α}-Fmoc group. All the side-chain blockers can be cleaved, along with the peptide-to-resin linkage, via only one TFA treatment at the end of the synthesis. Problems that may be encountered during Fmoc-based SPPS are premature

cleavage of the Fmoc group and the potential for by-product formation during cleavage of the peptide from its resin when Met and Trp are present. These and other problems, as well as the resins most often used, are adequately addressed in the review by Wellings and Atherton (36).

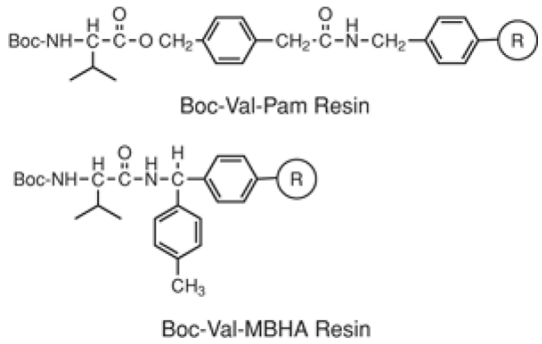

Fig. 7.8. Examples of Boc-Val attached to the phenylac-etamidomethyl (PAM) resin and to the 4-methylbenzhydrylamine (MBHA) resin. The former is used to prepare peptides with a C-terminal carboxylic acid, whereas the latter is used for the preparation of peptide C-terminal amides.

Combinatorial Peptide Synthesis

Perhaps the reader can surmise from the above discourse on peptide synthesis that the preparation of a single peptide, its purification, and biological testing is an arduous and time-consuming task. Therefore, building on Merrifield's SPPS methodology, investigators in the 1980s began developing methods for synthesizing large numbers of peptides simultaneously and screening them for biological activity. These ideas, which have firmly taken root within the medicinal chemistry discipline and now expanded to small organic molecules, are collectively referred to as combinatorial chemistry, or the ability “to make a large number of chemical variants all at one time; to test them for bioactivity ... and then to isolate and identify the most promising compounds for further development” (37). This gives rise to large numbers of biologically screenable compounds, usually referred to as a combinatorial library.

Two methods of combinatorial chemistry used in peptide and small molecule construction are known as parallel synthesis and split-and-mix synthesis. In the parallel synthesis approach, “all the products are assembled separately in their own reaction vessels,” as in a single well of a microtiter plate (38). A typical plastic microtiter plate contains eight rows and 12 columns of small wells and, thus, 96 wells in which combinatorial parallel synthesis can take place. For example, if eight different amino acids (already attached to a polymeric support) were distributed into each of the eight rows, then their SPPS coupling with a different blocked amino acid in each of the 12 columns would afford a 96-member library of dipeptides (Fig. 7.9). Of course, after removing unreacted chemicals and “reloading” each well with a different blocked amino acid, a 96-member library of tripeptides could be prepared, and so forth. After cleaving these dipeptides, tripeptides, or larger peptides from the polymer, the entire plate of 96 different compounds could be screened for biological activity. If many microtiter plates were used, one could see how a large library of peptides could be constructed. Today, robotic machines are used to carry out these repetitive steps, and hundreds or even thousands of compounds can be made in a single day.

The split-and-mix technique first developed by Furka and colleagues has been reviewed elsewhere (39). In the parallel method previously described, each well contains only one peptide, whereas in the split-and-mix technique, a single vessel may contain a mixture of closely related peptides. This occurs because the technique requires the repetition of three operations: 1) dividing the polymer (on which the peptide is growing) into equal portions, 2) coupling each portion with a different amino acid, and 3) homogenous mixing of these portions (Fig. 7.10). By using the method outlined in Figure 7.10, wherein one starts with only three amino acids bound to a polymer, the number of peptides obtained would triple after each coupling step, according to the formula 3^n. If all 20 of the natural amino acids were bound to a polymer, however, one could generate 3.2 million different peptides after only five couplings,

according to the formula 20^n (40).

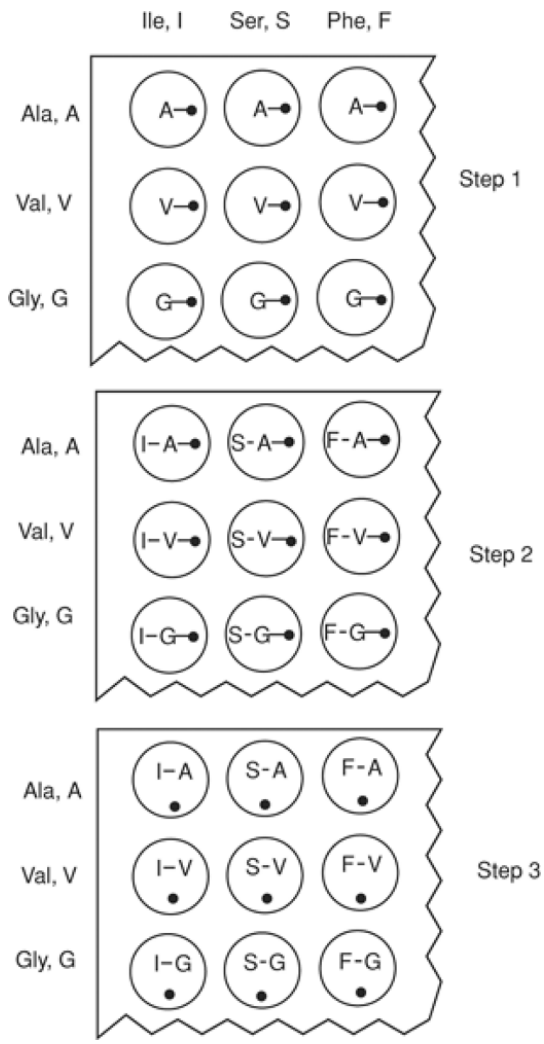

Fig. 7.9. Representation of a combinatorial parallel synthesis of a 96-member library of dipeptides in a typical plastic microtiter plate of eight rows and 12 columns; only the upper left three rows and three columns are shown. Step 1 shows three rows of wells containing three different amino acids that are already attached to a polymeric solid phase, as represented by the solid circles. In step 2, all eight rows are treated with the particular protected amino acids shown in each of the 12 columns, giving rise to 96 different polymer-bound dipeptides. In step 3, the dipeptides are cleaved from the solid support in preparation for testing them for biological activity.

The biological activity of each vessel is then evaluated, and those with the most potent activity would be processed by a variety of techniques to determine which particular peptide(s) is responsible for the activity

P.187

(13,38). An important difference between the split-and-mix technique and parallel synthesis is that the former method affords small quantities of a large number of peptides, whereas the latter method yields larger quantities of a smaller number of peptides (37). A discussion of the many novel techniques and advances in combinatorial peptide synthesis is beyond the scope of this chapter; the interested reader may want to check recent current reviews on this topic (13,41).

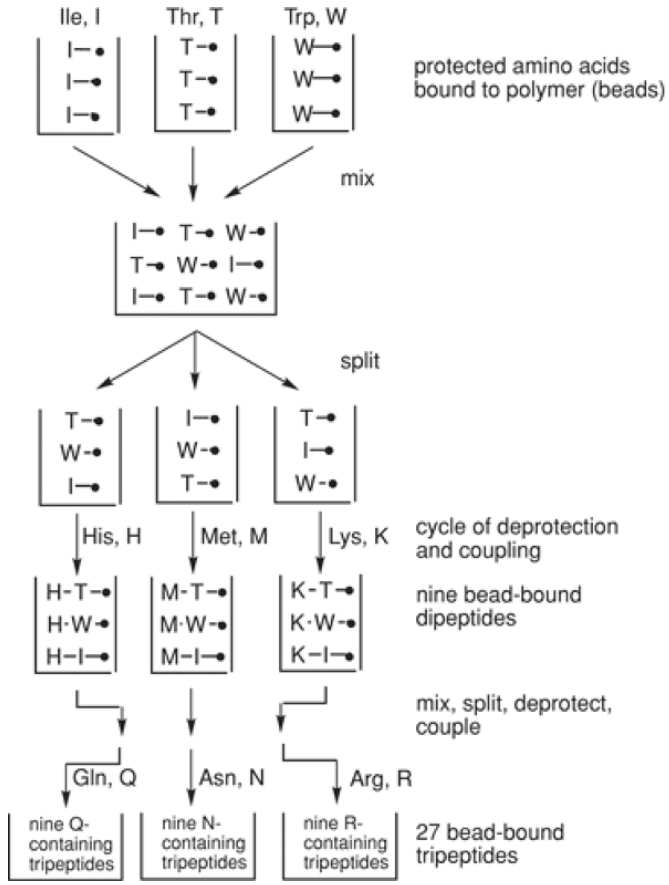

Fig. 7.10. Schematic representation of the split-and-mix technique.

Topological Modifications of Peptides

A common assumption is that the activity of a biologically active peptide depends on its three-dimensional structure. On the surface, where contact between ligand and receptor occurs, the relative spatial arrangements of the side-chain groups on the peptide pharmacophore are critical for receptor recognition and probably determine, in many cases, the affinity, selectivity, and activity of the peptide for a particular receptor protein. Therefore, side-chain modifications of a given peptide may provide important insights regarding the conformational and topological requirements for its activity (42).

Alternatively, other structure–activity studies of peptides have involved modifications of the peptide backbone. In this regard, there has been great interest in the replacement of some peptide bonds with pseudopeptide (ψ) bonds (21), because among other things, it may modify the backbone conformation as well as limit enzymatic degradation. Still another fascinating topological modification that has shown promise in limiting enzymatic degradation while retaining or enhancing biological activity is referred to as the retro-inverso modification (22). Both of these modifications, briefly mentioned above, will now be discussed in more detail.

Peptides Containing Pseudopeptide (↑) Bonds

Replacement of the normal peptide bond (–CONH–) with an isosteric unit generally does not alter the overall dimensions of the modified peptide. The replacement unit is referred to as a pseudopeptide bond, and a peptide analogue containing the modified bond is referred to as a pseudopeptide. The symbol ψ was originally introduced (43) with specific reference to the sulfur-based CH_2S peptide bond replacement and was later used for various CH_2S-containing pseudopeptides. The pseudopeptide bond replacement term took on a broader meaning,

however, and now is referred to by the symbols ψ[ ]. The ψ refers to the absence of the peptide bond, and the bracket, [ ], inserted between the named amino acid residue, specifies what the peptide bond replacement structure is. For example Alaψ[CH_2S]Gly refers to the pseudopeptide $NH_2CH(CH_3)CH_2SCH_2CO_2H$ (21). Several examples of the types of pseudopeptides that have been reported in the literature, as well as the nomenclature used to designate the replacements, are shown in Table 7.2. The ψ[CH_2NH] pseudopeptide replacement often has been used in attempts at modifying the peptide backbone (44). This unit has gained popularity because of its ready incorporation into peptides during conventional SPPS and the fact that it can afford receptor antagonists (45).

Table 7.2. Examples of Peptide Backbone Modifications

Unit-Replacing Peptide (–CONH–) Bond	Nomenclature Symbol
–CH_2S-	Ψ[CH_2S]
–$CONCH_3$–	Ψ[$CONCH_3$]
–COO–	Ψ[COO]
–COS–	Ψ[COS]
–$COCH_2$–	Ψ[$COCH_2$]

–CHOHNH–	Ψ[CHOHNH]

–CHOHCH$_2$O–	Ψ[CHOHCH$_2$O]
–CHOHCH$_2$–	Ψ[CHOHCH$_2$]

P.188

Retro-Inverso Peptides

Another modified peptide approach used to transform biologically active peptides with short half-lives (and, thus, of little therapeutic use) into potentially novel and more enzymatically stable analogues is that of the retro-inverso modification. This modification involves reversing one or more amide groups within the peptide backbone. The reversal can be accomplished by using a correctly substituted gem-diaminoalkyl residue (gXaa, where Xaa refers to the 3-letter notation for any amino acid, e.g., Val, and g indicates gem-diaminoalkyl) as the N-terminal residue and a substituted malonic acid residue (mXaa, where m stands for malonic acid) as the C-terminal residue (22,46). The aim of this topological approach is to devise analogues wherein a particular reversed peptide bond (–NHCO–) still maintains its planarity and the spatial orientation of the side chains is retained as close as possible to that of the original peptide. This necessitates that the chirality of amino acids placed between the gem-diaminoalkyl and malonic acid residues must be reversed (rXaa, where r refers to a reversed direction of the peptide bond) (Fig. 7.11) (47). Retro-inverso analogues of several bioactive peptides, particularly partial retro-inverso analogues, generally have displayed enhanced enzymatic stability as well as increased bioavailability and potency (46).

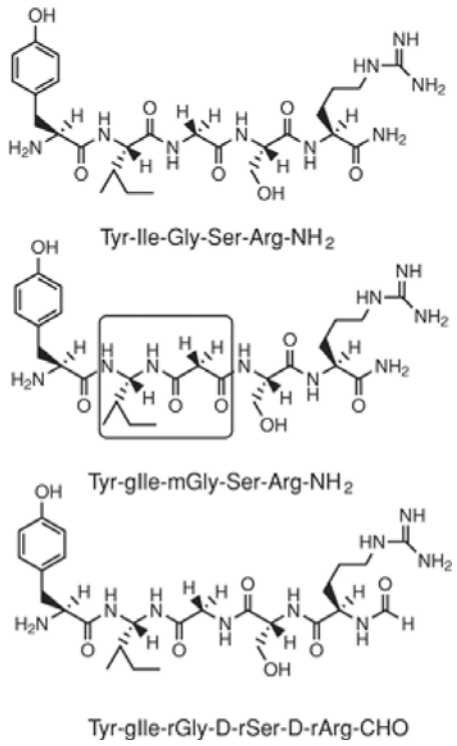

Fig. 7.11. A spatial representation of the antimetastic peptide, Tyr-Ile-Gly-Ser-Arg-NH_2 (all L-configuration), and two types of partial retro-inverso analogues. The portion enclosed in the frame is the so-called “pairwise” modified segment (46). (Adapted from Zhao M, Kleinman HK, Mokotoff M. Synthesis and activity of partial retro-inverso analogs of the antimetastatic laminin-derived peptide, YIGSR-NH_2. J

Peptide Res 1997;49:240–253; with permission.)

Therapeutic Peptide and Protein Hormones and Analogues

The following sections introduce a variety of peptide and protein hormones, both natural and their analogues, that are commercially available for the treatment of various diseases or are used for diagnostic purposes. These hormones are obtained synthetically, from natural sources, or via genetic engineering. They are listed, for the most part, according to their endocrine organ of origin.

Hormones of Hypothalamic Origin

The hypothalamus, a relatively small organ that is located in the brain and is responsible for thermoregulation, among other functions, is the secretory source for a number of peptide hormones that are transported to the pituitary gland situated immediately below it. These hormones regulate the synthesis of other peptide hormones produced by the anterior pituitary (adenohypophysis) and are thus called releasing hormones, releasing factors, or inhibitory factors, as the case may be. The release of these hypothalamic hormones is regulated via cholinergic and dopaminergic stimuli from higher brain centers, and their synthesis and release are controlled by feedback mechanisms from their target organs.

Gonadotropin-Releasing Hormone

Physicochemical properties

Gonadotropin-releasing hormone (GnRH) is a decapeptide (Fig. 7.12) that causes the release of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), from the anterior pituitary gland, but not in equal amounts (FSH release is partially inhibited by the gonadal protein inhibin). Therefore, GnRH is intimately involved in the control of both male and female reproduction. Medicinal chemists have capitalized on the relatively simple decapeptide structure of GnRH by preparing many analogues as potential fertility and antifertility agents, several of which are commercially available, especially those that are referred to as superagonists. It is known that GnRH can be degraded by enzymatic cleavage between Tyr^5-Gly^6 and Pro^9-Gly^{10} (48). Structure–activity relationship studies of GnRH analogues have shown that when Gly^6 is replaced with certain D-amino acids, as well as with changes in the peptide C-terminus, they generally are less susceptible to proteolytic enzymes, resulting in a longer-lasting action. For that reason, they are referred to as superagonists. Furthermore, when these D-amino acids at position 6 are hydrophobic, the half-life is enhanced (Fig. 7.12).

Physiological action of GnRH agents

In physiological doses, GnRH agonists are able to induce ovulation and spermatogenesis by increasing LH and FSH levels and the resulting sex steroid levels, as does the normal hormone.

P.189

In larger pharmacological (therapeutic) doses, however, GnRH agonists, especially the superagonists, block implantation of the fertilized egg, cause luteolysis of the corpus luteum, and can act as postcoital contraceptive agents (although not approved for this latter use). This “paradoxical” antifertility effect seen with the superagonists has been attributed to the fact that GnRH must be administered in a low-dose, pulsatile manner for it to be therapeutically effective as a fertility agent. Natural GnRH release from the hypothalamus occurs in a pulsatile manner. When GnRH or, especially, a superagonist is administered in pharmacological doses each day, LH and FSH levels will initially rise but then begin to fall after a few days because of target tissue desensitization/downregulation of pituitary GnRH receptors. The continued use of these agents in a nonpulsatile manner will result in a drastic drop of the gonadal steroid levels to near castrate levels in both males and females, thereby giving rise to their use in such conditions as precocious puberty, endometriosis, and advanced metastatic breast and prostate carcinoma.

Typically, however, the GnRH superagonists take approximately 2 weeks to finally desensitize the GnRH receptors, and during this time, there is a transient rise in LH and FSH levels, which often results in an initial "flare-up" of the original symptoms. The following discussion concerns the medicinal chemistry and medical use of the commercially available GnRH analogues (49).

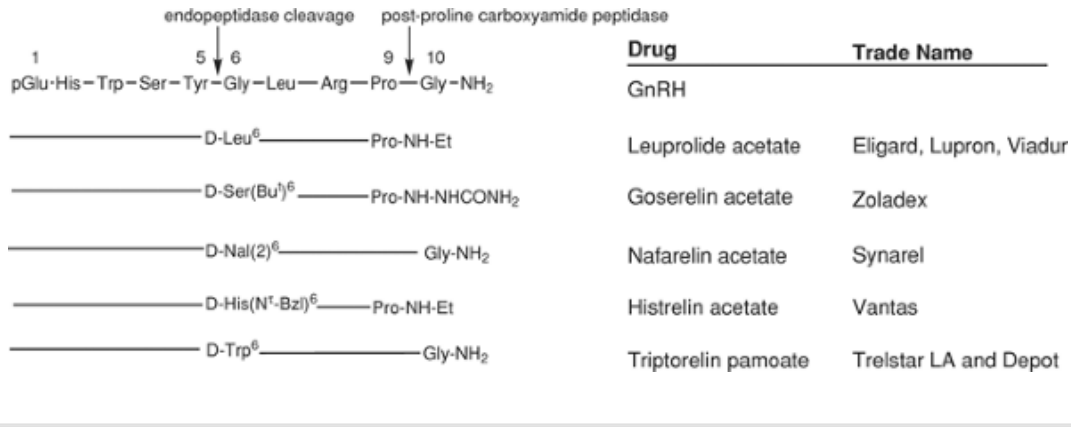

Fig. 7.12. GnRH-based drugs that are commercially available. Note that leuprolide, goserelin, nafarelin, histrelin, and triptorelin are all superagonists, contain a D-amino acid in place of Gly^6, and that three of the five are missing the C-terminal Gly (the line indicates an identical sequence of amino acids).

Specific drugs

Leuprolide Acetate

Leuprolide acetate, a synthetic nonapeptide analogue of GnRH that possesses greater potency than the natural hormone, is a superagonist that is commercially available. Note that leuprolide acetate contains substitutions that hinder enzymatic degradation, D-Leu and NH-Et in place of Gly^6 and Gly^{10}-NH_2, respectively (Fig. 7.12). Leuprolide acetate is reportedly 15-fold the potency of natural GnRH. When given continuously and in therapeutic doses, leuprolide acetate inhibits LH and FSH secretion by desensitizing/downregulating the GnRH receptors, as discussed above. After an initial stimulation, chronic administration of leuprolide acetate results in suppression of ovarian and testicular steroidogenesis. In premenopausal females, estrogens are reduced to postmenopausal levels; in males, testosterone is reduced to castrate levels.

Leuprolide acetate is administered by daily injections or as depot injections every month, every 3 months, every 4 months, or every 6 months as a palliative treatment in advanced prostatic carcinoma (as an alternative to orchiectomy). An implant version (Viadur) also is available for long-term palliative therapy; after implantation of the device into the upper arm, leuprolide acetate is continuously released over a 12-month period. Because dihydrotestosterone, a metabolite of testosterone, is able to stimulate the growth of prostate cancer, the ability of leuprolide acetate to bring testosterone to near castrate levels is why this drug finds use as a palliative in the advanced disease. The addition of a nonpeptidyl antiandrogen, such as flutamide or bicalutamide, to the leuprolide acetate regimen inhibits adrenal and testicular synthesized androgens from binding to or being taken up by target prostate cancer tissue. This combination therapy helps to control the initial flare-up, by blocking all sources of androgen, and is referred to as maximal androgen blockade.

Leuprolide acetate, in monthly and every-3-months depot formulations, is useful in treating women diagnosed with endometriosis, but not for longer than six months because of the chance of developing osteoporosis. Endometriosis, a painful disorder of the female reproductive tract, occurs in women during their childbearing years. The disease involves the growth of endometrial tissue (normally shed monthly with menstruation) in areas outside the uterus, usually the pelvic region, where it swells and bleeds internally during the monthly menstrual cycle. The inability of

the blood to leave the body leads to inflammation of the surrounding

areas as well as formation of scar tissue. Several of the symptoms of endometriosis are painful urination and bowel movements, severe menstrual cramps, pain during sexual intercourse, and the potential for infertility. Because estrogens stimulate the growth of endometrial tissue, the ability of this drug to drastically reduce estrogen levels suggests why leuprolide acetate is useful in treating endometriosis.

Central precocious puberty that is idiopathic, or gonadotropin dependent, can cause the development of secondary sexual characteristics in girls before the age of 8 years and in boys before the age of 9 years. In addition to the psychological and physiological changes that occur because of entering puberty too early, there is the risk of the child failing to reach his or her full adult height. Therefore, leuprolide acetate's ability to suppress LH and sex steroid levels (testosterone and estradiol) to prepubertal levels is the reason that leuprolide acetate is approved for use in treating children with this disease. Use of this drug in a child with precocious puberty will slow or stop that child's secondary sexual development, slow linear growth and skeletal maturation, and in girls, will bring about the cessation of menstruation.

Uterine leiomyomas (fibroids), which are benign neoplasms derived from smooth muscle, can cause, among other problems, excessive vaginal bleeding that may progress to anemia. Leuprolide acetate, concomitant with iron therapy, is used in treating the anemia that arises from uterine leiomyoma. The decrease in the formation of the steroid sex hormones reduces fibroid and uterine volume, produces a relief in the clinical symptoms (pelvic pain), and stops the excessive vaginal bleeding, thus correcting the anemia.

Goserelin Acetate

Goserelin acetate, like leuprolide acetate, is a synthetic superagonist nonapeptide analogue of GnRH that possesses greater potency than the natural hormone. Note that it contains D-Ser(Bu^t) and NH-$NHCONH_2$ in place of Gly^6 and Gly^{10}-NH_2, respectively (Fig. 7.12). That is, the C-terminal modification simply has an NH substituting for the CH_2 of Gly, and like the C-terminal change in leuprolide acetate, this inhibits enzymatic degradation of the peptide by the postproline carboxyamide peptidase.

Goserelin acetate is available in the form of a small, solid pellet that is administered as an SC implant for the palliative treatment of advanced, metastatic breast cancer in pre- and perimenopausal women or, similarly, as a palliative in advanced prostatic cancer. The rationale for this drug's use is, as described above, its ability as a superagonist to bring the levels of estradiol or testosterone to near castrate levels, thus slowing the progression of breast or prostate carcinoma, respectively. Additionally, goserelin acetate is approved for use in treating endometriosis for up to 6 months.

Goserelin acetate also is used in combination with the antiandrogen flutamide for shrinking prostate carcinoma before radiation therapy. This maximal androgen blockade combination is used when the prostate carcinoma has been staged as locally confined to the prostate gland, with one or both lobes as well as the seminal vesicles involved. The treatment should start 8 weeks before radiation treatment begins and be continued throughout the radiation therapy.

Furthermore, women who are to undergo hysterectomy for menorrhagia can benefit from previous treatment with goserelin acetate, because it is able to induce endometrial thinning. This thinning of the endometrium improves the operating environment by causing less intrauterine bleeding, increased postoperative amenorrhea, and decreased dysmenorrhea following surgery, which is why goserelin acetate is approved for inducing endometrial thinning prior to a patient undergoing a hysterectomy for heavy menstrual bleeding.

Nafarelin Acetate

Nafarelin acetate, another synthetic superagonist decapeptide analogue of GnRH, contains D-Nal(2)^6 [Nal = 3-(2-naphthyl)-Ala] in place of Gly^6, but the C-terminus, Gly^{10}-NH_2, is identical with natural GnRH (Fig. 7.12). Nafarelin acetate is available as a 0.2% nasal spray for the relief of endometriosis. Estrogen, of course, is needed for the growth of endometrial tissue; thus,

decreased estrogen leads to shrinkage of errant endometrial tissue. The observed side effects of nafarelin acetate are related to falling estrogen levels and include decreased libido, amenorrhea, hot flashes, and vaginal dryness. When used consistently, nafarelin acetate will inhibit ovulation and stop menstruation.

Nafarelin acetate also is used in children, male and female, for the treatment of central precocious puberty. By suppressing the release of LH, the estradiol or testosterone levels fall to prepubertal levels; early secondary sexual development is arrested, linear growth and skeletal maturation are slowed, and in girls, menstruation stops.

Histrelin Acetate

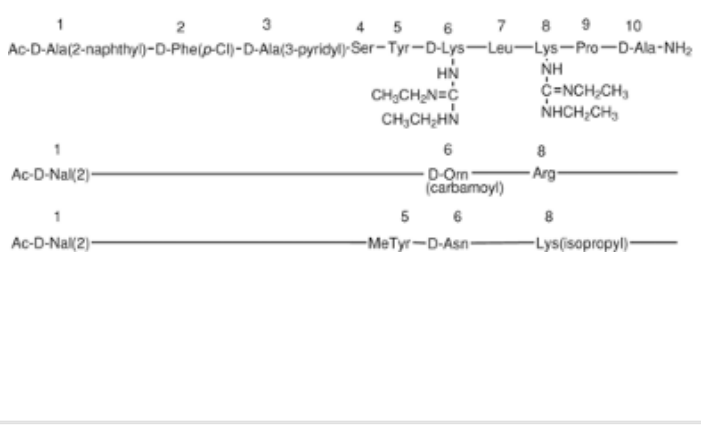
Histrelin acetate, a superagonist analogue of GnRH, contains D- His(N^{τ}-Bzl)^6 in place of Gly^6, and the C-terminus is identical with leuprolide acetate—namely, NH-Et in place of Gly^{10}-NH_2 (Fig. 7.12). This GnRH analogue is commercially available in the form of an implantable device (SC in the upper arm) that slowly releases the drug over a 12-month period, resulting in decreased testicular steroidogenesis, for the palliative treatment of advanced prostate cancer.

Triptorelin Pamoate

Triptorelin pamoate is another superagonist of GnRH, which like nafarelin acetate contains only a single amino acid substitution (D-Trp^6 for Gly^6) when compared to the natural hormone (Fig. 7.12). In the treatment of advanced prostate cancer, it is important to reduce serum testosterone levels to very low levels, which can be achieved surgically by orchiectomy. When this surgical method is unacceptable to the patient, an alternative approach is “chemical castration,” which can be achieved by use of estrogen therapy, leuprolide,

P.191

goserelin or histrelin acetates, and now, triptorelin pamoate. This product is available for IM depot injection (monthly or every 3 months), wherein serum testosterone concentration drops to a level generally seen in surgically castrated men.



Drug	Trade Name
Ganirelix acetate	Ganirelix acetate injection
Cetrorelix acetate	Cetrotide
Abarelix	Plenaxis

Fig. 7.13. GnRH-receptor antagonists.

Ganirelix Acetate

Ganirelix acetate is an analog of GnRH with substitutions at residues 1, 2, 3, 6, 8, and 10 (Fig. 7.13). It is not a superagonist but, rather, is a synthetic decapeptide with high antagonist activity and the first GnRH antagonist to be marketed. It is approved for the suppression of LH surges in women who are undergoing ovarian hyperstimulation fertility treatment; LH surges normally promote ovulation. The goal of this drug is to significantly reduce the number of medication days necessary to suppress the LH surge, thereby maintaining eggs in the ovaries. In vitro fertilization (IVF) treatment cycles were historically initiated by the administration of leuprolide acetate to suppress the premature release of LH. This inhibits ovulation so that the eggs remain available for retrieval by a fertility specialist. For this purpose, leuprolide acetate

usually is injected for as many as 26 days. Clinical studies have shown that ganirelix acetate can shut down the LH surge in only 5 days of treatment, that the suppression of LH is more pronounced than that of FSH, and that the shorter treatment time minimizes unpleasant side effects, such as hot flashes and headaches.

Cetrorelix Acetate

Cetrorelix acetate is an analogue of GnRH with amino acid substitutions at residues 1, 2, 3, 6, and 10 and differing from ganirelix at amino acids 1, 6, and 8 (Fig. 7.13). Each of these substitutions are synthetic, non-DNA-directed amino acids and, like ganirelix acetate, impart GnRH antagonist activity to cetrorelix acetate. This drug also is marketed for use in women undergoing assisted reproductive therapy (ART) procedures, in which it is necessary to control their LH surge. This allows the follicles to develop to a size, as determined by ultrasound, that increases the success of timed insemination and oocyte retrieval for IVF. Like ganirelix acetate, cetrorelix acetate has an advantage over GnRH agonists, such as leuprolide acetate, because it reduces the fertility therapy cycle to days rather than weeks.

Abarelix

Abarelix is another GnRH receptor antagonist with substitutions or alterations of the natural hormone at seven residues; the amino acids at positions 4, 7, and 9 are identical with those in GnRH. Abarelix differs from ganirelix at amino acids 1, 5, 6, and 8 (Fig. 7.13). Unlike ganirelix and cetrorelix, however, abarelix is not used in women undergoing ART but, rather, as a palliative in men with advanced prostate cancer. Like the superagonists, abarelix affords a drop in testosterone to castrate levels. Abarelix does not, however, cause the initial rise in testosterone levels and resulting flare-up of symptoms often seen with the superagonists. Still, because of the risk of life-threatening allergic reactions associated with its use, this drug is specifically relegated to a select group of men with advanced symptomatic prostate cancer who are not candidates for other hormone therapies and who choose not to undergo orchiectomy. Abarelix is available only from health care providers who have participated in a special education program that allows them to identify allergic reactions associated with its use.

Somatostatin

Physiological action

Somatostatin is a cyclic 14-peptide that was first isolated by Guillemin in 1973 and is probably the most thoroughly investigated and most important of the inhibitory factors produced by the hypothalamus (Fig. 7.14). The principal activity of somatostatin, which is of hypothalamic origin, is inhibition of the release of growth hormone (GH) from the anterior pituitary. Too much GH, as in pituitary tumors, causes acromegaly, a form of giantism. On the other hand, too little GH leads to dwarfism. Somatostatin also has been found in the pancreas and the GI tract, where it inhibits the secretion of both insulin and glucagon from the pancreas as well as the secretion of a variety of intestinal peptides (e.g., gastrin, secretin, pepsin, and renin). The short half-life of somatostatin, which is less than 3 minutes, has precluded its use as a therapeutic agent. Many derivatives of somatostatin have been prepared to increase its duration of action and/or to enhance its selectivity of action. The culmination of these structure–activity studies was the development of octreotide acetate.

Specific drugs

Octreotide Acetate

Octreotide acetate, a long-acting octapeptide analogue of somatostatin, has a half-life of approximately 100 minutes. A comparison of the primary structures of octreotide and somatostatin suggests little similarity, but from earlier work at the Salk Institute it was known that not all the residues in somatostatin were necessary to elicit its full biological activity. Other studies suggested that the essential fragment for its activity was the tetrapeptide Phe^{7}-Trp^{8}-Lys^{9}-Thr^{10} (Fig. 7.14). These earlier studies helped in the design of the potent drug now known

as octreotide acetate (50). This drug suppresses the secretion of gastroenteropancreatic peptides, such as gastrin, vasoactive intestinal peptide (VIP), insulin, and glucagon, as well as pituitary GH. Furthermore, it is more potent than natural somatostatin in inhibiting the release of glucagon, insulin, and GH.

Octreotide acetate is used by SC injection in the palliative treatment of patients with metastatic carcinoid tumors, which are tumors of the endocrine system, GI tract, and lung (gastroenteropancreatic). Carcinoid tumors secrete increasing amounts of vasoactive substances, including histamine, serotonin, bradykinin, and prostaglandins. Octreotide acetate inhibits or suppresses the release of these vasoactive substances and, thus, is useful in treating the severe diarrhea, facial flushing, and wheezing episodes that accompany carcinoid tumors. In addition, it finds use in the palliative management of VIP-secreting tumors (VIPomas, usually pancreatic tumors). Patients with VIPomas suffer a profuse, watery diarrhea syndrome, and octreotide acetate is able to help by decreasing the release of damaging intestinal tumor cell secretions. Octreotide also helps to reduce hypokalemia by correcting electrolyte imbalances.

An excessive secretion of GH from the pituitary can cause the disorder known as acromegaly, which is characterized by a progressive enlargement of the head, face, hands, feet, and thorax. Inasmuch as octreotide acetate is able to decrease the secretion of GH from the pituitary, it is used in treating patients with acromegaly who are unresponsive to previous pituitary radiation therapy or surgery. It is used in the treatment of acromegaly, because it reduces the blood levels of both GH and insulin-like growth factor-I (IGF-I). The long-acting repository form of octreotide acetate also is used in treating acromegaly, carcinoid tumors, and VIPomas, but in monthly depot injections.

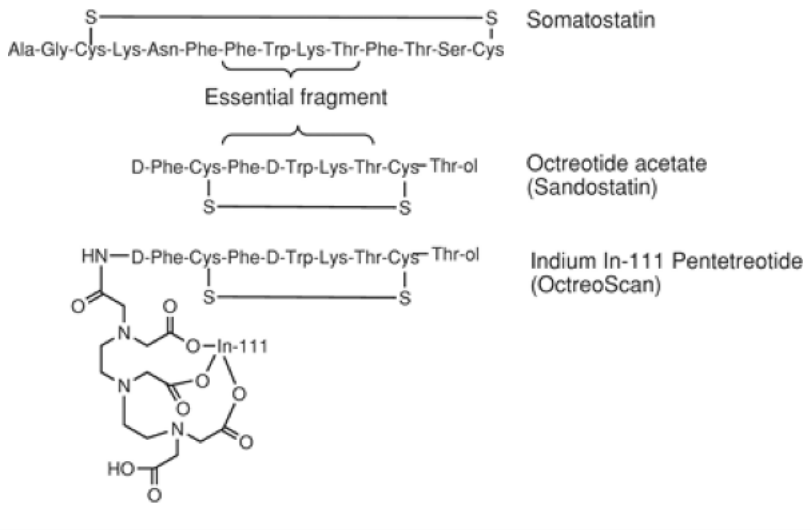


Fig. 7.14. Somatostatin and its analogue, octreotide.

Octreotide for IV injection is used in the treatment of acute bleeding from esophageal varices. Variceal bleeding occurs in about half the patients with cirrhosis of the liver and is responsible for about one-third of deaths in these patients. Octreotide is a potent vasoconstrictor that reduces portal and collateral blood flow by constricting visceral vessels, which leads to reduced portal blood pressure and decreases the bleeding.

Indium In-111 Pentetreotide (OctreoScan)

Somatostatin receptors have a broad distribution in normal tissue as well as in a variety of human malignancies (e.g., small cell lung, brain, breast, pituitary, and endocrine pancreatic cancers). For this reason, octreotide, which binds to somatostatin receptors, was converted to a radionuclide-containing peptide by reacting the amino terminus with an active ester of diethylenetriaminepenta acetic acid (DTPA) to give DTPA-octreotide and then chelated to the radionuclide ^{111}In (Fig. 7.14). This radiopharmaceutical is used as a diagnostic agent for the

early detection and localization of small tumors and their metastases in the body, especially tumors that originate from neuroendocrine cells.

Corticorelin Ovine Triflutate (Acthrel)

The primary function of corticotropin-releasing factor (CRF), a hypothalamic 41-peptide, is the regulation of the release of adrenocorticotropin hormone (ACTH) from the anterior pituitary gland, which then stimulates the release of hydrocortisone from the adrenal gland. The human peptide (hCRF) and the similar sequence found in sheep (oCRF) have been prepared by synthesis. The ovine form of the hormone, however, has replaced the human form because of its longer half-life and greater potency; hCRF is no longer commercially available.

Usually, ACTH deficiency in humans is associated with a pituitary disorder rather than with a deficiency of CRF, and oCRF can be used to distinguish between pituitary hypersecretion of ACTH (Cushing's disease) and ectopic ACTH secretion, both of which are conditions that cause a hypersecretion of hydrocortisone. In the case of ectopic ACTH secretion, the administration of oCRF will elicit little to no response in the production of ACTH and hydrocortisone. Therefore, synthetic oCRF trifluoroacetate salt is marketed as a diagnostic agent for patients with ACTH-dependent Cushing's syndrome.

Hormones Originating in the Anterior Lobe of the Pituitary Gland

The pituitary, lying just below the hypothalamus, is a small gland that can be divided into an anterior and a posterior lobe. This gland is responsible for the secretion

of several important peptide hormones, two of which are released by the posterior lobe. The anterior pituitary peptide hormones control important functions such as growth, reproduction, metabolic and ion balance, as well as a number of others.

Growth Hormone (GH)

A protein containing 191 amino acids, GH is secreted by the anterior pituitary in response to the liberation of GH-releasing factor from the hypothalamus. This contrasts with somatostatin, which inhibits the release of GH. The primary function of GH in the body is to promote skeletal growth. When GH is absent during childhood, or if there is an inadequate supply, dwarfism results. Before 1985, children of short stature were sometimes treated with human GH (hGH) of pituitary origin, which was obtained from cadavers, but hGH of natural origin was discontinued by the U.S. FDA when several young adults, who had received hGH as children, died. Their deaths were attributed to contaminated hGH. The contaminant was an infective agent, known as a prion, that causes Creutzfeldt-Jakob disease, a rare and fatal neurodegenerative disease (51). Naturally occurring hGH has been replaced with material that is prepared by recombinant DNA (rDNA) methodology.

Specific drugs

Somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Saizen, Serostim, Zorbtive)

Somatropin, which is hGH that is prepared by rDNA procedures, contains exactly the same sequence of 191 amino acids as the natural hormone. Several of these products are indicated for the long-term treatment of children who fail to grow because of inadequate secretion of the body's normal endogenous GH and for growth problems associated with chronic renal failure. Even adults who are diagnosed with GH deficiency, which can arise as a result of pituitary or hypothalamic disease, surgery, radiation therapy, or other reasons, can benefit from hGH replacement therapy. Turner's syndrome, a genetic disease in which there is a complete or partial absence of one of the two X chromosomes in females, causes short stature as one of its many symptoms. Girls suffering from Turner's syndrome can benefit from the use of Humatrope, Norditropin, or Nutropin during their growth years.

The anabolic properties of hGH is the basis for the orphan drug uses of several of these

recombinant products. It is used in AIDS-associated catabolism or weight loss, in cachexia resulting from AIDS, and as an anabolic agent in patients with severe burns. In addition, the anabolic property of rhGH is the reason for Zorbtive's use, along with specialized nutritional support, in the treatment of short-bowel syndrome.

Pegvisomant (Somavert)

This product contains 191 amino acid residues (of recombinant origin), the same number as in GH, but there are substitutions at residues 18, 21, 120, 167, 168, 171, 172, 174, and 179. This product is then covalently linked to several polyethylene glycol molecules, and this pegylated protein is a GH-receptor antagonist. Thus, pegvisomant binds to the GH receptor and blocks endogenous GH from binding. The result is a blocking of the GH-stimulated overproduction of IGF-I that contributes to the disabling symptoms and long-term health problems associated with acromegaly.

Gonadotropins

Chemistry

The gonadotropins, FSH and LH, are large glycoproteins released by the anterior pituitary on stimulation from GnRH produced by the hypothalamus. Both FSH and LH consist of two noncovalently associated α and β subunits. The α subunits both contain 92 amino acids and are identical in both hormones, whereas the β subunit in LH consists of 121 residues and 111 residues in FSH, with the β subunits being dissimilar (52). Thus, the β subunit gives each hormone its specific function.

Physiological properties

Both LH and FSH are referred to as gonadotropins, because they act on the male and female gonads, which results in the production of the sex steroids testosterone and estradiol, respectively. In the female, FSH and LH act in concert in regulating ovarian function: egg maturation, ovulation, and transformation of the ruptured follicle into the corpus luteum. In males, spermatogenesis is dependent on these two hormones. Specifically, FSH in females facilitates the maturation of ovarian follicle cells and their secretion of estradiol, whereas in males, it stimulates the maturation of sperm in the testes. In females, LH promotes ovulation, formation of the corpus luteum, and progesterone secretion; in males, it enables the secretion of testosterone from the testes.

According to the Research Initiative Committee and the Public Communications Committee of the Endocrine Society, “[I]nfertility is the inability of a sexually active couple, who is not using any contraception, to achieve pregnancy in one year, the time in which 90% of couples succeed.” In the case of male infertility, it generally is caused by the quality and/or quantity of the sperm produced. In the case of female infertility, however, it may be caused by several factors, such as the inability to produce an egg, to ovulate, for fertilization to occur, and for implantation of the fertilized ovum in the uterus. Several of the commercially available gonadotropins can help in enhancing both male and female fertility and are discussed below.

Specific drugs

Menotropins (Menopur, Repronex)

Menotropins are a natural product that is obtained from the urine of postmenopausal women and then biologically standardized (international units [IU]) for FSH and LH activities in an approximate ratio of 1:1. Menotropins are used in males with primary (hypothalamic) or secondary (pituitary) hypogonadism to stimulate spermatogenesis, providing they have been treated previously with human chorionic gonadotropin (hCG; a peptide hormone of placental origin that has activity very similar to LH; discussed below) to effect masculinization (increased testosterone

production). In females, menotropins and hCG are given sequentially for the purposes of

inducing ovulation in women who are having difficulty ovulating as a result of either hypothalamic or pituitary hormonal dysfunction. The menotropins are given for 7 to 12 days, and after clinical evaluation (via ultrasound) indicates the presence of a mature follicle, a single dose of hCG is given to simulate the typical LH surge that normally triggers ovulation. Also, women use the combination of menotropins and hCG to promote the development of multiple follicles when they are participating in an IVF program requiring the recruitment of follicles.

Follitropins

Follitropins are hormonal products that consist entirely of FSH and are used to stimulate ovarian follicle growth in women who do not have primary ovarian failure. In the absence of an adequate endogenous LH surge, however, hCG must be given following the use of follitropins to stimulate ovulation.

Urofollitropins (Bravelle)

Urofollitropin, a natural product like the menotropins, is obtained from the urine of postmenopausal women and then highly purified so as to contain only FSH, reportedly with only minute amounts of LH. Urofollitropin is used for its ability to stimulate follicle development, such as in women undergoing drug-induced pituitary suppression (GnRH antagonist or superagonist) for purposes of IVF (i.e., multiple follicle development or egg donation). When the number and size of the ovarian follicles are correct, as determined by ultrasound, hCG is administered so as to effect ovulation, and the oocytes are retrieved for IVF.

This drug also is indicated for women who have infertility caused by polycystic ovary syndrome, which generally is observed clinically as enlarged, cystic ovaries containing relatively small follicles. These patients often develop hirsutism, their androgen and LH levels appear elevated while their FSH levels are low, and the early exposure to these improper hormone levels may be causing the follicular atresia (53). The patient's monthly cycle is controlled by previous pituitary suppression via treatment with a GnRH superagonist or antagonist; urofollitropin, as an exogenous source of FSH, is administered and stimulates follicle maturation to preovulatory size, with little or no exposure of the follicles to additional LH. When the follicles have matured to preovulatory size, ovulation is assisted by the administration of hCG. The couple is then advised to engage in sexual intercourse daily, beginning on the day before hCG administration and until ovulation has occurred.

Lately, it has become desirable to have a nonnatural source of pure FSH. It is believed that exposure to increased amounts of LH early in follicular development, as would be the case with menotropins, is detrimental to fertility. Also, urofollitropin is derived from menopausal urine, and the supply of this natural product is limited. These problems are especially noteworthy in treating infertility in women with polycystic ovary syndrome and have given rise to recombinant forms of FSH.

Follitropin Alfa (Gonal-F, Gonal-F RFF, Gonal-F RFF Pen)

Follitropin alfa is a human FSH preparation of rDNA origin. Because FSH is a glycoprotein, alterations in the carbohydrate side-chain attachments afford different isoforms, which leads to different pharmacokinetic and pharmacodynamic properties. Because it is of recombinant origin and not isolated from urine, it is free of any additional substances, such as urinary proteins and LH.

Like urofollitropin, it is marketed for enhancing the development of multiple follicles that can then be induced to ovulate, via hCG administration, so that the oocytes can be collected for IVF. It also is used in treating women who wish to become pregnant and are anovulatory because of polycystic ovary syndrome, in whom it can enhance follicle maturation before hCG administration for final ovulation. All commercial products can be administered by SC injection. The RFF notation signifies Revised Formulation Female, and the RFF Pen notation indicates a prefilled, ready-to-use device designed to make self administration easier.

Men with infertility also can benefit from therapy with follitropin alfa if their infertility is related to hypothalamic or pituitary hormonal dysfunction and not primary testicular failure, because it

induces spermatogenesis. Just as with therapy using menotropins, pretreatment with hCG is performed for 3 months to achieve serum testosterone levels within the normal range, before hCG and follitropin alfa therapy.

Follitropin Beta (Follistim AQ)

Follitropin beta is a human FSH preparation of rDNA origin, which differs chemically from natural FSH and follitropin alfa only by slight variances in the composition of the carbohydrate side chains. In fact, the primary and tertiary structures of both follitropins alfa and beta are indistinguishable from those of human FSH of natural origin. Furthermore, bioassays and physiochemical studies indicate that follitropins alfa and beta are indistinguishable from each other. Therefore, it is not surprising that follitropin beta is approved for the same medical uses as follitropin alpha.

Lutropin Alfa (Luveris)

Lutropin alfa is the first pure human LH preparation and is of rDNA origin. According to physicochemical and biological assays, it is indistinguishable from human LH of natural origin. It is indicated for use in infertile women who are undergoing ART, specifically those with severe LH deficiency. It is meant to be coadministered with follitropin alfa so as to stimulate follicular growth in these women. When the follicles are of correct size, as determined by ultrasound examination, hCG would be administered to stimulate ovulation.

Adrenocorticotropin Hormone (H.P. Acthar Gel)

The anterior pituitary, under the influence of the hypothalamic hormone hCRF, releases ACTH, a single-chain peptide of 39 residues. ACTH is derived from a much larger precursor protein known as pro-opiomelanocortin, the latter of which is the precursor of the melanocyte-stimulating hormones, the lipotropins, and other biologically active

peptides. The sequence of 24-amino-acid residues beginning from the amino terminus contains all the biological activity of the parent. The remaining 15 C-terminal residues confer species specificity as well as enhancing the stability of ACTH toward proteolytic cleavage. Consider the fact that residues 1 through 24 are identical in humans, pigs, sheep, and beef, whereas the species differ only slightly from each other in the final 15 residues. Furthermore, N-terminal residues 1 through 13 in ACTH are identical with the full structure of α-MSH. The main action of ACTH on the adrenal cortex involves the release of the glucocorticoid hormone hydrocortisone and the mineralocorticoid (electrolyte balance) hormone aldosterone.

Commercial ACTH is obtained from natural sources and is available in 16% gelatin (repository gel) to prolong its release after SC or IM injection. ACTH has both anti-inflammatory and immunosuppressant properties, which contributes to its use in the treatment of acute exacerbations of multiple sclerosis.

Synthetic acth analog

Cosyntropin (Cortrosyn)

Cosyntropin is a synthetic polypeptide that consists of amino acid residues 1 through 24 of human ACTH, but that has the full biological activity of its parent. Because it is of synthetic origin, it is less allergenic than ACTH of natural origin. Cosyntropin is used as a diagnostic agent in the screening of patients suspected of having adrenocortical insufficiency. Normally, parenteral administration of cosyntropin acts rapidly on the adrenal cortex to effect release of plasma hydrocortisone; when performing the test, the hydrocortisone levels are compared to a control blood sample taken earlier.

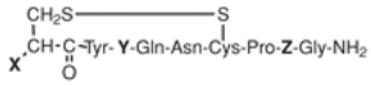
Hormones Released from the Posterior Lobe of the Pituitary Gland

As previously discussed, the pituitary gland is responsible for the secretion of several peptide hormones, only two of which are released by the posterior lobe. Actually, these two hormones,

oxytocin and vasopressin, are synthesized in neurons originating in the hypothalamus and are transported to the posterior pituitary for storage until release is required.

Oxytocin

Oxytocin is a cyclic 9-peptide that, like somatostatin, contains a ring that encompasses a disulfide bridge (Fig. 7.15). Oxytocin has uterotonic action, contracting the muscles of the uterus during gestation, and plays an important role in milk ejection (not milk secretion, which is regulated by the peptide hormone prolactin) from the mammary ducts into the nipples. Exogenous oxytocin most commonly is used for induction of labor, wherein it improves uterine contractions to achieve early vaginal delivery for fetal or maternal reasons (e.g., preeclampsia, Rh factor problems, pregnancy that has exceeded 42 weeks). It also finds use following delivery of the placenta, because it promotes contraction and vasoconstriction and helps to control postpartum bleeding.



Drug	Trade name
Oxytocin (**X** = NH_2 ; **Y** = Ile; **Z**= Leu)	Pitocin
Vasopressin (**X** = NH_2 ; **Y** = Phe; **Z**= Arg)	
Desmopressin acetate (**X** = H ; **Y** = Phe; **Z**= D-Arg)	DDAVP Stimate

Fig. 7.15. Structural relationship between oxytocin, vasopressin, and its analogue.

Vasopressin

Human vasopressin, or Arg-vasopressin, is chemically very similar to oxytocin and therefore sometimes is referred to as [Phe^3, Arg^8]oxytocin (Fig. 7.15). The physiological role of vasopressin is the regulation of water reabsorption in the renal tubules (an antidiuretic action, thus often referred to as the antidiuretic hormone). In high doses, vasopressin promotes the contraction of arterioles and capillaries, resulting in an increase in blood pressure, thus the name vasopressin. An inadequate output of pituitary antidiuretic hormone can cause diabetes insipidus, which is characterized by the chronic excretion of large amounts of pale urine and results in dehydration and extreme thirst.

Desmopressin Acetate

Desmopressin, as its acetate salt, is a synthetic analogue of vasopressin in which the N-terminal Cys is devoid of its α-amino function (1-Deamino) and where Arg^8 is present as its D-isomer (D-Arg^8), thus the commercial acronym DDAVP (Fig. 7.15). The presence of D-Arg and the absence of the N-terminal amine in the desmopressin structure have increased its half-life such that it is available for oral, parenteral, or nasal use. It is used by all three of these routes of administration to prevent or control polydipsia (excessive thirst), polyuria, and dehydration of patients with diabetes insipidus caused by a deficiency of vasopressin. It also has been approved for the treatment of nocturnal enuresis (bed-wetting), which is believed to be caused by an absence of the normal night time rise in vasopressin levels.

Desmopressin is known to cause an increase in both plasma factor VIII (antihemophilic factor) and plasminogen activator. It therefore is approved by the U.S. FDA for use, parenterally and nasally, in reducing spontaneous or trauma-induced bleeding episodes in patients with hemophilia A and type I Von Willebrand's disease, provided that their plasma factor VIII activity

is greater than 5%. Stimate, the nasal spray used in treating patients with hemophilia A and type I Von Willebrand's disease, is 15-fold the concentration of DDAVP nasal spray; the latter is used in treating diabetes insipidus.

Hormone of Placental Origin

If, after ovulation occurs in females, the liberated ovum is fertilized and then implants in the endometrium, the resulting placenta that forms between mother and fetus begins to release a hormone, hCG, the function of which is to maintain and prolong the life of the ovarian corpus luteum. The corpus luteum is important for the continued production of progesterone. Progesterone is especially important because it prepares the uterus for pregnancy and helps in the maintenance of the placenta. Human chorionic gonadotropin begins to appear in the maternal bloodstream and urine shortly after conception and implantation of the fertilized ovum. As a result of this early release of hCG, its detection in the urine forms the basis for the home pregnancy kits that have become so popular in the early prediction of pregnancy.

Human Chorionic Gonadotropin (hCG, Pregnyl)

Placental hCG is a complex protein that consists of an α and β subunit. The α subunit consists of 92 amino acids that are identical in sequence with that found in both LH and FSH, whereas the β subunit contains 145 amino acids and is responsible for its biological specificity. The biological actions of hCG closely resemble those of LH, but the former has a longer half-life than the latter and has minimal FSH activity.

Like LH, hCG stimulates the production of testosterone by the testes; therefore, it is used in treating male hypogonadism and prepubertal cryptorchidism in young males (age, 4–9 years), in whom it stimulates testicular descent. In treating infertility caused by pituitary dysfunction, hCG, in combination with menotropins (as discussed previously) or clomiphene, can induce ovulation and pregnancy in anovulatory females. This hCG, which is of natural origin, is purified from the urine of pregnant women.

Choriogonadotropin Alfa (Ovidrel)

Choriogonadotropin alfa is obtained by rDNA technology and is biologically and chemically identical to hCG of natural origin. It is used, like hCG of natural origin, for inducing ovulation in women with anovulatory infertility. Following proper pretreatment with a GnRH antagonist or superagonist to desensitize the pituitary, women participating in ART are treated with a follicle-stimulating agent (e.g., menotropins) to effect the final maturation of the follicles within the ovaries. Ultrasonograms are used to determine proper follicle maturation before the administration of choriogonadotropin alfa to induce ovulation. A distinct advantage of this product is that it can be self-administered by the patient via SC injection.

Hormone of Parathyroid Origin

Overview

The parathyroid glands (four) exist as two pairs, one pair of which is embedded on the back surface of each lobe (two) of the thyroid gland. These very small glands are responsible for the secretion of parathyroid hormone (PTH), the action of which is the regulation of both calcium and phosphate metabolism within bone and kidney. In humans, the Ca^{2+} concentration is carefully regulated, and when it falls below a normal level, the parathyroid glands secrete PTH, an 84-residue, single-chain protein. Depending on whether PTH is administered intermittently or continuously, it can either stimulate bone formation or breakdown (resorption), respectively.

Teriparatide (Forteo)

Teriparatide, a polypeptide prepared by rDNA techniques, consists of the first 34 amino acid residues from the N-terminal end of PTH. It has been shown to contain all the structural requirements for the full biological activity of PTH. When teriparatide is administered daily by SC injection, it stimulates osteoblastic activity at the expense of osteoclastic activity, and this

enhances bone formation. This is the basis for teriparatide's use in treating high-risk patients in danger of bone fracture resulting from osteoporosis, men with primary or hypogonadal osteoporosis, and women with postmenopausal osteoporosis.

Hormone Secreted by the Parafollicular C Cells of the Thyroid Gland

Overview

The majority of the thyroid gland contains follicular cells responsible for the production of the thyroid hormones. A second population of endocrine cells within the thyroid known as C (clear) cells, or parafollicular cells, produce the hormone calcitonin (CT), which has an opposing action to that of PTH in that it decreases the Ca^{2+} concentration in body fluids. It accomplishes this by inhibiting the activity of osteoclasts (i.e., decreasing Ca^{2+} release from bone by inhibiting bone resorption). The actual biosynthesis and release of CT is regulated by the concentration of Ca^{2+} in plasma (i.e., when it is high, CT secretion increases).

Salmon calcitonin (Fortical, Miacalcin)

Calcitonin is a single-chain polypeptide consisting of 32 amino acid residues (Fig. 7.16). Calcitonins as obtained from different species are identical at seven of the first nine residues, contain Gly at position 28, and all terminate with Pro-NH_2. The C-terminal proline amide (Pro-NH_2) is very important for the biological function of CT, as is the disulfide bridge between Cys residues at positions 1 and 7. In contrast, the residues from 10 through 27 can be varied and seem to influence CT's potency as well as its duration of action. Salmon CT differs from human CT at 16 amino acid residues

Only salmon CT is commercially available for medical use, because on a weight basis, it is approximately 45-fold more potent than human CT. Salmon CT, in parenteral form, is approved for treating Paget's disease of bone (generally seen in older persons; involves increased bone resorption

and softening of bones), postmenopausal osteoporosis, and hypercalcemia of malignancy (multiple myeloma or advanced breast carcinoma). Salmon CT also is available in a nasal spray formulation, which is used exclusively in the treatment of postmenopausal osteoporosis.

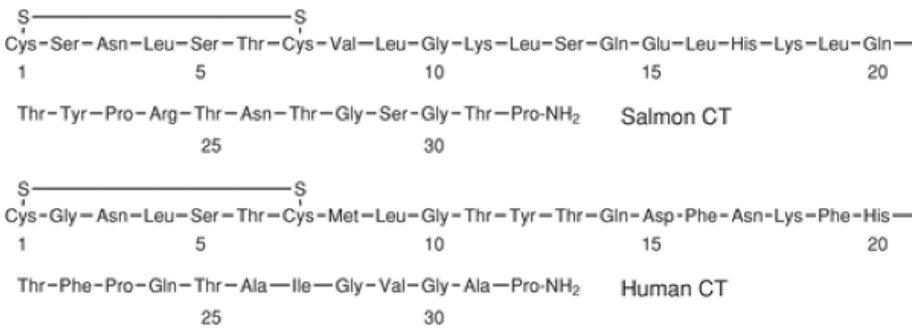


Fig. 7.16. Primary structures of salmon and human calcitonin (CT).

Hormones of Endocrine Pancreatic Origin

Overview

The exocrine pancreas consists mostly (~99%) of gland cells known as pancreatic acini, which

are responsible for secreting several digestive enzymes. The endocrine pancreas, or the remaining 1% of the gland, consists of a group of cells known as pancreatic islets or islets of Langerhans. Each of these islets consists of four distinct cell types, designated as α, β, γ, and δ cells. The α cells secrete glucagon, the β cells insulin and amylin, the δ cells a peptide that is identical with somatostatin of hypothalamic origin, and the γ cells pancreatic polypeptide, of which little concerning its physiological action is known. Insulin, glucagon, and somatostatin are essential in regulating carbohydrate, lipid, and amino acid metabolism. Insulin is responsible for promoting the storage of glucose as glycogen and effecting hypoglycemia, whereas glucagon mobilizes glucose from its glycogen stores and causes hyperglycemia. The primary action of somatostatin of hypothalamic origin is to inhibit the release of GH from the pituitary, but pancreatic somatostatin suppresses the production of both insulin and glucagon. Amylin, which is cosecreted with insulin from the β cells, has physiological actions that include slowing of gastric emptying, suppression of postprandial glucagon secretion, reduction of food intake, and inhibition in the secretion of both stomach acid and pancreatic digestive enzymes.

Inasmuch as Chapter 32 is devoted primarily to a discussion of insulin and oral hypoglycemic agents, we will thus be brief in our coverage of the pancreatic polypeptides.

Insulin

Insulin has anabolic properties that include the stimulation of both skeletal muscle and liver cells to incorporate glucose and convert it to glycogen, to synthesize proteins from amino acids in the blood, and to act on fat cells to enhance their uptake of glucose and the synthesis of fat. In short, insulin encourages anabolism rather than catabolism, because it promotes the synthesis of glycogen, proteins, and lipids. A deficiency of insulin, which characterizes the disease diabetes mellitus (DM), causes extreme changes in the entire metabolic pattern of individuals with DM. Patients with DM often demonstrate elevated blood glucose levels, excess glucose in the urine, and failure to properly utilize carbohydrate and lipids. Untreated DM can be fatal. Even when treated, however, there can be numerous circulatory and renal complications, and some metabolic abnormalities may lead to blindness (diabetic retinopathy).

Chemistry

Proinsulin, a single-chain protein of 86 amino acid residues, is synthesized in the β cells and enzymatically transformed therein to insulin. The conversion involves the cleavage of a connecting C-peptide, which contains between 30 and 35 residues, with the number and sequence varying among different species (human C-peptide consists of 35 residues). The resulting human insulin consists of two peptide chains, designated A (having 21 residues) and B (having 30 residues), which are interchain connected by two disulfide bonds. Furthermore, the A-chain also contains an intrachain disulfide bond between Cys^{6} and Cys^{11} (Fig. 7.17).

The primary sequences of insulin from several species are known, and porcine insulin is the closest to that of humans. Their A-chains are identical, and they differ only in their B-chains, with Ala^{30} (porcine) in place of Thr^{30} (human). Human and bovine insulin differ in each chain, with Ala^{8} and Val^{10} in the A-Chain (bovine) and

Ala^{30} in the B-chain (bovine). Nearly all human insulin is produced by rDNA technology, and insulin obtained from porcine sources is being phased out. Presently five genetically engineered human insulin products are marketed in which there have been small changes made in the amino acid composition, such as deletions, additions, reversal of order, or substitution, that determine if they are rapid-acting or long-acting. Further details of the chemistry and formulations of the commercially available insulin products are discussed in Chapter 32.

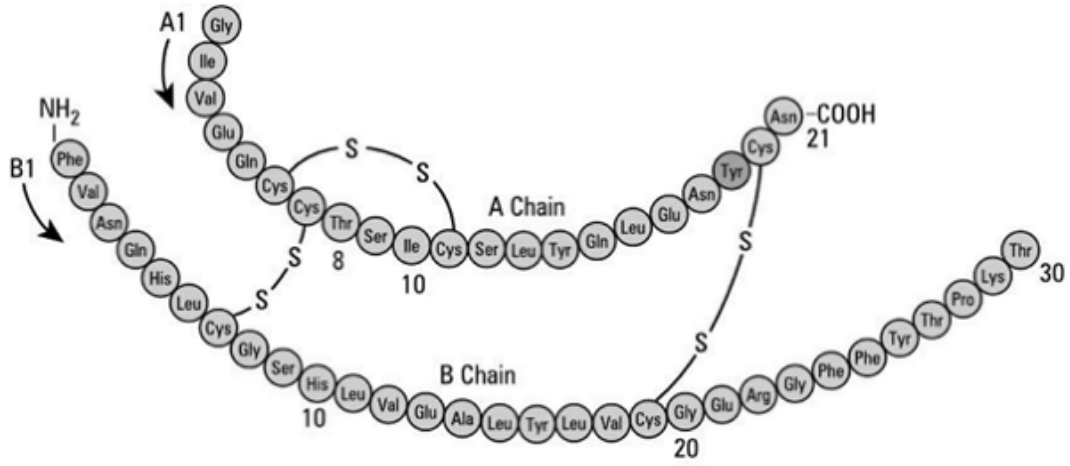

Fig. 7.17. Primary structure of human insulin chains A and B, including the interchain disulfide bonds A7-B7 and A20-B19 and intrachain disulfide bond A6-A11.

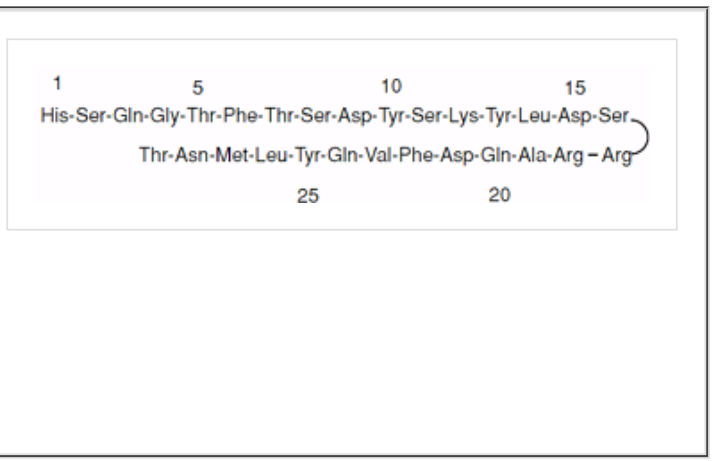
Specific drugs

Glucagon (GlucaGen)



Glucagon, a 29-amino-acid, straight-chain polypeptide of α-cell pancreatic origin, triggers liver glycogenolysis and gluconeogenesis, thereby elevating glucose levels. The principal action of glucagon is the liver-mediated release into the blood of abnormally high concentrations of glucose, which causes hyperglycemia. This means that glucagon has an effect on blood glucose levels that is opposite to what occurs with insulin.

Human glucagon of rDNA origin is marketed for the treatment of severe hypoglycemic reactions in patients with diabetes, as can occur when there is an overdose of insulin. In patients with type I diabetes, the increase in glucose, resulting from glucagon administration, may not be sufficient, and supplemental carbohydrates may need to be administered quickly, especially in children.

Table 7.3. Additional Significant Peptides and Proteins of Biological Interests

Name	Trade Name (If Applicable)	General Use or Action

Aldesleukin (Interleukin-2)	Proleukin	Protein of rDNA origin that is used in treating renal cell carcinoma and metastatic malignant melanoma.
Angiotensin II		8-peptide involved in blood pressure regulation.
Atrial natriuretic peptide		28-peptide, vasodilator, that increases glomerular filtration and diuresis.
Bradykinin		9-peptide, produced in response to tissue damage, inflammation, viral infections, etc. Produces pain, increased vascular permeability, and synthesis of prostaglandins.
Denileukin diftitox	Ontak	rDNA-derived fusion protein consisting of diphtheria toxin fragments A and B as well as interleukin-2. Used in treating cutaneous T-cell lymphoma.
Exenatide	Byetta	39-peptide known as an incretin mimetic; an agonist of glucagon-like peptide-1, used adjunctively in type II diabetes mellitus.
Insulin-like growth factor-I (human)		Protein of rDNA origin that has orphan drug status and is used in treating major burns requiring hospitalization.
Peginterferon Alfa-2a	Pegasys	Pegylated protein of rDNA origin containing 165 residues. Used either alone or in combination with antiviral agent ribavirin in chronic hepatitis C.
Secretin, synthetic human	Chirhostim	27-peptide used to evaluate exocrine pancreas function and in diagnosis of gastrinoma (Zollinger-Ellison syndrome).
Thymopentin	Timunox	Synthetic 5-peptide consisting of residues 32–36 of thymopoietin, an immunologically active polypeptide. It is an investigational drug used for its immunomodulating properties.
Thyrotropin Alfa	Thyrogen	Recombinant form of human thyroid-stimulating hormone (rhTSH). Used diagnostically for serum thyroglobulin testing.

Trastuzumab	Herceptin	Humanized monoclonal antibody that binds selectively to the epidermal growth factor receptor 2 (HER2) protein. Used in treating some breast carcinomas that overexpress HER2.
Vasoactive intestinal polypeptide		28-peptide that is structurally related to secretin and glucagon. It has a diverse biological actions. It has orphan drug status for the treatment of acute esophageal food impaction.

Amylin

Amylin is a 37-peptide that is structurally similar to CT. Amylin works together with insulin to regulate glucose concentrations after a meal. When in solution, amylin is viscous, unstable, and tends to aggregate; therefore it cannot be used parenterally and is not commercially available.

Pramlintide Acetate (Symlin)

Pramlintide acetate is a synthetic analogue of amylin (a 37-peptide) with proline substitutions at residues 25, 28, and 29. These substitutions change its physical properties such that it is commercially available for SC injection. When pramlintide is used in combination with insulin, it slows gastric emptying, lowers blood glucose levels after meals, and affords a feeling of fullness that leads to decreased caloric intake and the potential for weight loss. Pramlintide has been approved for use in adults with type I or type II diabetes as an adjunct along with insulin. The dose is quite different for type I (15–60 µg SC before meals) and type II diabetes (60–120 µg). The drug should be refrigerated before opening and may be kept at room temperature for up to 28 days after opening.

Other Biologically Significant Peptides and Proteins

Space does not allow us to discuss other biologically significant peptides and proteins as well as peptides and proteins not directly used in medicine. Table 7.3, however, summarizes some of the more interesting peptides and proteins.

P.199

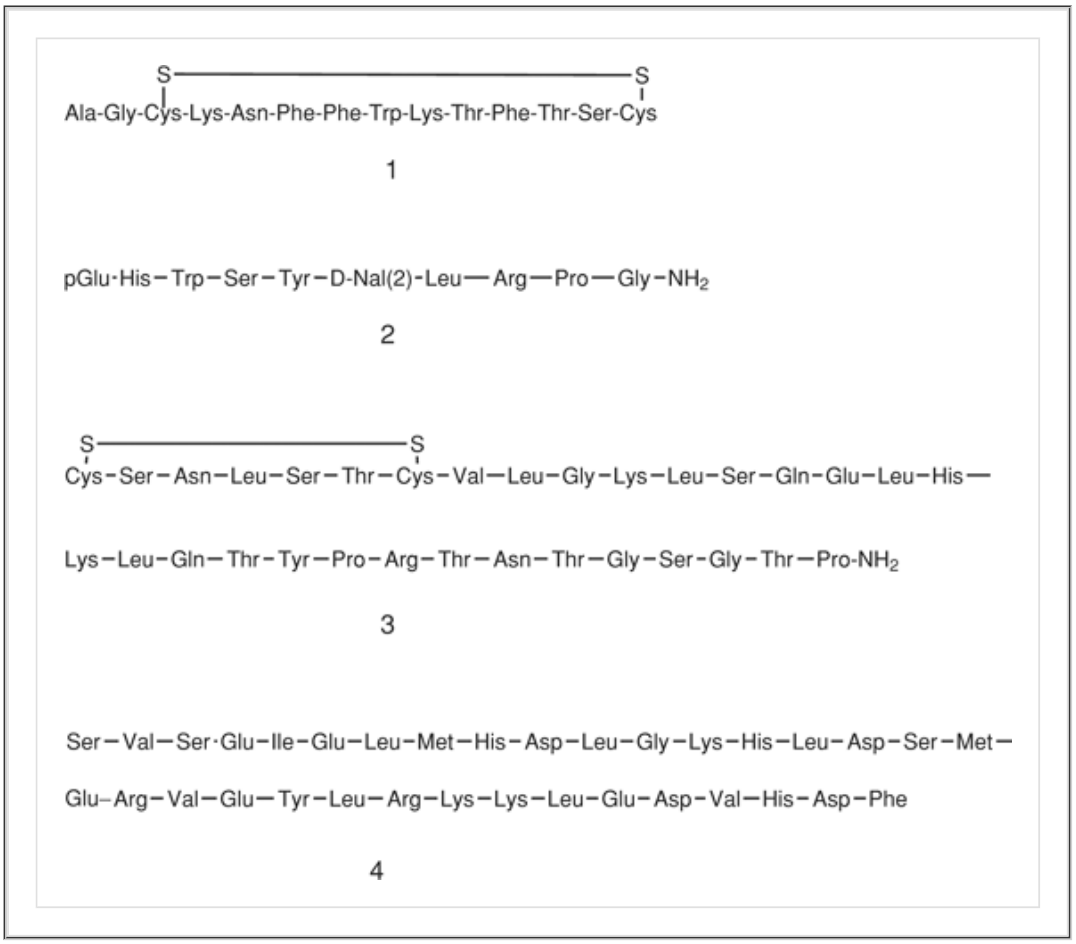
Case Study

Victoria F. Roche

S. William Zito

PB is your favorite grandma, and you are her favorite grandchild. She is 78 years old this weekend, and you are visiting her at the nursing home, where they are celebrating her birthday with a small party. Grandma has had a history of vertebral fractures associated with osteoporosis but has only been treating herself with chewable calcium supplements and vitamin D. After the party, you have some quiet time, and your grandma confides in you that she has been experiencing severe back pain, which requires her to lie down frequently during the day. She recalls that the pain started one night during an outing to the symphony with your mom. You suspect that grandma has had a recurrence of a vertebral fracture, and you make an appointment for her to be evaluated by her physician. On physical examination, her physician notes tenderness directly over a couple of areas of her spine, and a series of plain-film radiographs show two classic wedge deformities correlating with the area of tenderness. Her physician recommends a short period of bed rest, but grandma should avoid prolonged inactivity. Chewable aspirin was recommended for the pain, because

grandma has a great deal of trouble swallowing pills. The physician believes grandma to be at high risk for continued fractures, wants to prescribe a peptide hormone, and asks your opinion of the following peptides 1–4:



1. Identify the therapeutic problems in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 8
Antisense Therapeutic Agents

Marilyn Speedie

Introduction

Principles

Antisense therapeutic agents are based on a simple and elegant concept, as illustrated in Figure 8.1. As genes are expressed to produce specific proteins, the two complementary strands of DNA begin uncoiling within the nucleus. The “sense” strand carries nucleic acid bases in an order that specifies which amino acids should be assembled to produce the protein. The complementary, or “antisense,” strand is used as a template for assembling a complementary strand of messenger RNA (mRNA) in the process called transcription. The mRNA will have the same sequence as the sense strand of DNA but is made up of ribose sugars instead of deoxyribose sugars in the nucleotide backbone (ribonucleotides versus deoxyribonucleotides). In eukaryotes, the mRNA is further processed in the nucleus by capping and splicing and is transported into the cytoplasm, where ribosomes translate the mRNA into proteins. Antisense drugs are short stretches of deoxyribonucleotide analogues that bind to specific complementary areas of the mRNA (which have a “sense” sequence) by Watson-Crick base pairing. In doing so, they can induce a nuclease (RNase H) that cleaves the mRNA at the site of the binding or can physically block translation or other steps in mRNA processing and transport, thus stopping protein synthesis. Antisense drugs therefore work at an early stage in the production of a disease-causing protein and, theoretically, can be applied to a number of diseases for which the basic pathophysiology involves an overexpression or aberrant expression of a given protein molecule. Viral diseases, cancers, and inflammatory diseases are all examples of such diseases that potentially can be treated via antisense mechanisms.

Another use of antisense oligonucleotides is to modify mRNA splicing (1). Scientists were surprised when the human genome was sequenced and only approximately 30,000 human genes were found. To get the wide variety of proteins that humans produce, the pre-mRNAs produced from these genes are spliced in a variety of ways to produce several different mRNAs and, subsequently, several different proteins from each gene. It is estimated that up to 60% of human genes are alternatively spliced at the pre-mRNA stage. Aberrant splicing because of genetic mutations are estimated to cause approximately 50% of genetic disorders and lead to diseases such as β-thalassemia, cystic fibrosis, and a variety of cancers. Antisense oligonucleotides can be used to inhibit aberrant splicing, thus correcting the genetic defect. The oligonucleotides used for this purpose must not activate RNase H, which would destroy the pre-mRNA target before it could be correctly spliced, and must be able to effectively compete with splicing factors to gain access to the target pre-mRNAs.

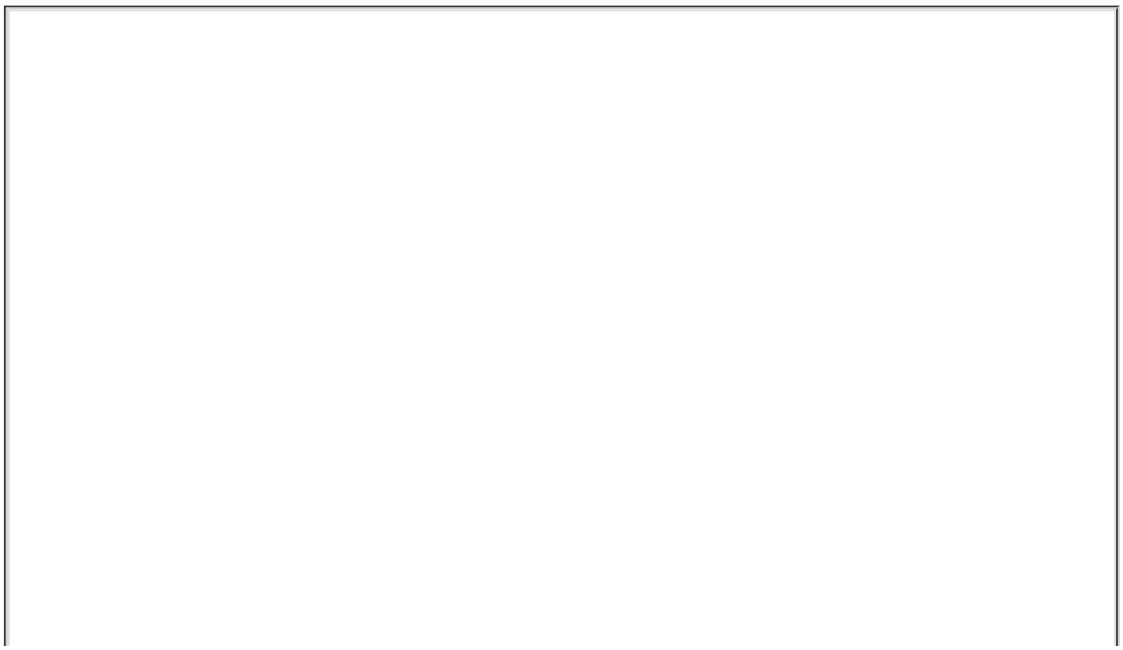
Recently, a new approach to antisense therapeutics has emerged with the discovery that small interfering RNAs (siRNAs) can be used therapeutically. Naturally occurring siRNAs have been known as part of the defense by eukaryotic cells against invasion by double-stranded RNA viruses. In 1998, Fire et al. (2) discovered that double-stranded RNA could induce a potent silencing effect on homologous genes in the nematode *Caenorhabditis elegans*. Scientists have extensively applied this principle to genetic analysis in mammalian cell culture. More recently, the general principle has been applied to the design of externally administered siRNA therapeutic agents that can be

used to target and silence specific target mRNA sequences involved in disease. As shown in Figure 8.2, double-stranded RNA molecules enter the cell and are cleaved by an enzyme called “Dicer” to generate 21 to 23 nucleotide fragments that contain two nucleotide 3′ overhangs and 5′-phosphate groups. Then, an ATP-dependent helicase recognizes these short duplexes and resolves siRNA into two single-stranded RNAs. One strand is incorporated into a high-molecular-weight protein complex termed “RNA-induced silencing complex” (RISC), where it serves to guide the RISC complex to the homologous target mRNA sequence, where cleavage occurs. Once one molecule of the mRNA is destroyed, the RISC complex moves on to other molecules of the same mRNA and is recycled to perform multiple rounds of catalysis. This property of RISC accounts for the potent nature of the silencing effect (3). The siRNA therapeutic agents are the most potent antisense agents available (4). In less than five years since the discovery of the silencing effect of double-stranded RNA molecules, the first potential agents are showing positive results in clinical trials for macular degeneration (5) and other diseases.

History

The beginning of antisense technology may be traced to a report of sequence-specific binding of a modified DNA to complementary mRNA in 1978 (6). The road from demonstration of the binding to an approved human therapeutic agent, however, has been one filled with alternating optimism and pessimism. Developmental steps included identifying the optimum chemistry for getting antisense molecules into cells and preventing nuclease destruction of the molecules while optimizing

binding to messenger. Design of antisense molecules to achieve selective binding to the target mRNA was essential if side effects were to be minimized. After several years of optimizing the parameters to improve efficacy in vitro (in tissue culture), scientists moved to testing antisense candidates in animal models. This did not prove to be an easy challenge, and it resulted in pessimism about the ultimate utility of the products. For a period, medical researchers were skeptical about the efficacy of the approach. Questions arose about the reproducibility of experiments and whether the pharmacological effects being observed in animal experiments were the result of sequence-specific antisense activity. Eventually, however, careful design of experiments to provide appropriate controls reversed the skepticism, and now scientists generally agree that antisense approaches can lead to useful medicinal agents (7,8).



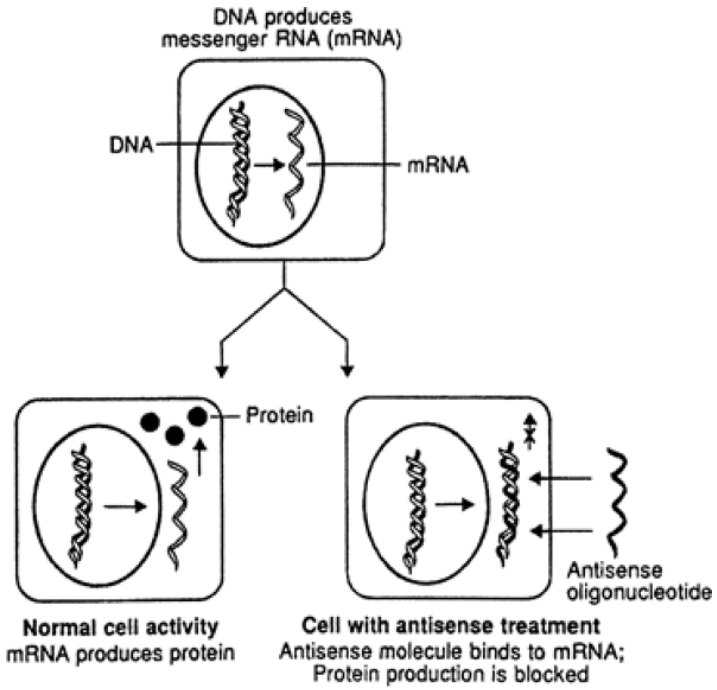


Fig. 8.1. Concept of antisense oligonucleotide inhibition of gene expression. The antisense oligonucleotide enters the cell and binds to specific complementary mRNA, causing it to be degraded or otherwise inhibiting synthesis of the corresponding protein.

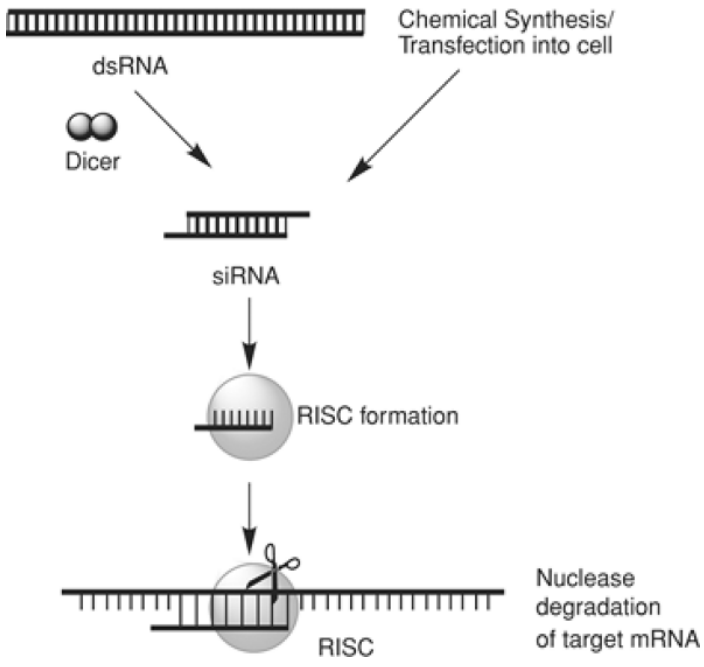

Fig. 8.2. Mechanism of action of siRNAs. The siRNAs are generated either from long, double-stranded RNA molecules processed by an enzyme called “Dicer” or by transfecting chemically synthesized double-stranded siRNA molecules into the cells. The siRNA is then incorporated into RNA-induced

silencing complex (RISC), which guides a nuclease to the target mRNA, which is subsequently degraded, thus blocking protein synthesis.

Problems associated with the automated synthesis and cost of antisense molecules have been overcome. Initially, each compound could only be synthesized in small amounts, and the costs of each synthesis would have limited their clinical use. Improvements to the technology during scale-up, however, have resulted in prices between $50 and $100 per gram—well within a useful range for pharmaceutical agents (7).

Many people believe that we are only beginning to exploit the full potential of antisense drug development. The first-generation drugs were mostly of a single chemical design, and a wide variety of second-generation chemistries with improved properties have been designed and are being tested. The initial studies with siRNAs have infused excitement into the field as well. A wide variety of therapeutic agents are in Phase I or Phase II of clinical trial development, and a few are in Phase III testing. Yet, there remains only one marketed antisense drug, fomivirsen, and several seemingly promising agents have not held up when subjected to randomized clinical trials. The challenges of fulfilling the promise of this class of drugs are formidable. Only time will tell how useful this approach to drug design will be.

Design of First-Generation Antisense Agents

General Consideration

Conceptually, the design of an antisense strand is simple, but designing an antisense therapeutic agent that will function in human disease is quite complicated. Many conditions must be satisfied for an antisense drug to function. It must be administered in a manner that delivers it to the site of action in the body without the drug being degraded by nucleases, which are ubiquitous in human cells. It must get into the cell of the target tissue and colocalize with its target RNA at a sufficient concentration for a bimolecular reaction to occur. It must have a structure that favors association with the target RNA and be designed to bind to a RNA region that is vulnerable to binding. Identification of the molecule with optimum binding generally is performed in tissue culture experiments for which 30 or 40 oligonucleotides, each approximately 30 nucleotides in length, are synthesized. These

oligonucleotides are complementary to different portions of the target mRNA and are used to determine where the binding can be best achieved, as indicated by inhibition of synthesis of the target protein. This “brute force” effort usually is quite successful, but it limits initial drug discovery, in general, to industrial laboratories that have the capability to efficiently synthesis large numbers of antisense molecules. Getting to the target cell, binding to the target mRNA and inhibiting protein synthesis are necessary—but still insufficient—to define successful antisense activity. For a target gene (and protein) to be suitable for an antisense approach, there must be sufficient turnover of the resultant protein that inhibiting its synthesis will have the desired effect within a reasonable period of time. This can be tested in tissue culture and in whole animals once the initial conditions are met.

Modifications in the base, sugar, and phosphate moieties as well as in the length of the polymer have been reported in attempts to create molecules with enhanced or more selective affinity for specific sites on the RNA, to enhance nuclease stability, to improve

cellular uptake and distribution, and to optimize distribution and clearance. Much work remains in defining the medicinal chemistry of these molecules and correlating the chemistry with the biological effects. To date, the most detailed work has been done with phosphorothioate deoxyoligonucleotides, as described below, but even with this class of molecules, our current knowledge does not yet allow optimal structures to be predicted and developed without screening multiple drug candidates.

Site of Binding

It is known that at some sites, the binding of antisense oligonucleotides to mRNA creates a substrate for RNase H, leading to greater efficacy, because the mRNA actually is cleaved. The antisense deoxyoligonucleotide is released and can bind to yet another mRNA molecule, thus amplifying its effect (9). Screens incorporating RNase H–mediated cleavage offer the potential to improve identification of the optimal antisense drug molecules, although these cell-free systems still leave many critical parameters undefined in terms of achieving a drug that will be active in vivo (10). Phosphorothioate oligonucleotide complexes with mRNA can serve as substrates for RNase H, whereas many other oligonucleotides do not create RNase H–susceptible complexes. This appears to account, at least in part, for the efficacy of the phosphorothioates, and second-generation molecules attempt to maintain the ability to be a RNase H substrate while improving other properties.

Although many studies focus on antisense drugs creating substrates for RNase H, it is important to realize that a number of other mechanisms have been identified, including inhibition of translation, inhibition of splicing, and degradation of RNA via other mechanisms. Furthermore, studies, especially with antiviral antisense molecules, have shown antisense sequence–independent effects, such as decreasing the adsorption of the virus, in addition to the antisense sequence–dependent effects. Therefore, studies that attribute the effect of a given antisense molecule to an antisense mechanism must be carefully controlled to demonstrate dose–response effects, sequence-specific effects, and measurement of the loss of the target RNA or protein or both (11,12). Figure 8.3 illustrates some of the possible sites of antisense oligonucleotide action in the transcription, processing, and translation of a specific gene product. As shown in Figure 8.3, favorite targets have included RNA splice sites, 5′-capping, 3′-adenylation sites, and translation start and termination sites (13). In reality, the choice of the portion of a mRNA to be a target for antisense drug action is quite empirical. Little is known about the shape of the mRNA molecules within cells, and no common structure exists among the target sequences for a variety of successful antisense drugs. Therefore, there is no easy way to predict what portion of the mRNA molecule will be available for binding to the drug. Scientists make 30 to 40 oligonucleotides of appropriate length that complements different portions of the mRNA and use them to “march down the message” in tissue culture experiments to see where binding is best (7).

Structural Considerations

The generalized structures illustrating some of the first-generation antisense oligonucleotides that were tested are shown in Figure 8.4 (14). Each was designed and tested with the goal of optimizing and balancing the affinity of binding for mRNA, nuclease resistance, and uptake into the cells. As seen in Figure 8.4, the first-generation antisense oligonucleotide agents use methylphosphonate modifications, 2′-O-methylribonucleotides, and phosphorothioate linkages. The methylphosphonate backbone yields a molecule that is nonionic, has good nuclease resistance, and forms a stable duplex with mRNA. The duplex formed is not a substrate for RNase H, however, and uptake is via passive diffusion. Of the first-generation oligonucleotide antisense

molecules, the class that has resulted in the broadest range of activities is the phosphorothioate class, in which one of the oxygen atoms in the phosphate group is replaced with a sulfur. The resulting compound is negatively charged, is chiral at each phosphorothioate, and is much more resistant to nuclease digestion than the parent phosphodiester compound. Compound length has been determined empirically. Molecules must have at least seven or eight complementary bases to bind to the target site and induce RNase H activity. Molecules less than 13 to 15 bases have lower specificity with complementary mRNA, and molecules longer than 20-mers result in more nonsequence specific interactions. Molecules in the range of approximately 15 to 20 bases (15- to 20-mers) are commonly synthesized, with 18 or 20 bases generally considered to be optimum (8).

Although the phosphorothioate molecules (unbound to mRNA) are relatively resistant to nucleases, some nuclease degradation occurs, primarily by exonucleases (which cleave the terminal bases) and, perhaps, with a

modest contribution by endonucleases (which cleave within the chain) as well. Phosphorothioates are taken up by a wide range of cells in vitro, and it is thought that uptake is enhanced by the negative charge, which allows binding to specific uptake proteins, resulting in receptor-mediated endocytosis. Uptake is both time- and temperature-dependent and is influenced by the cell type as well as the specific sequence and length of the oligonucleotide. Cationic lipids have been used in vitro to enhance uptake of phosphorothioate oligonucleotides in cells that otherwise take up little of the compounds (15).

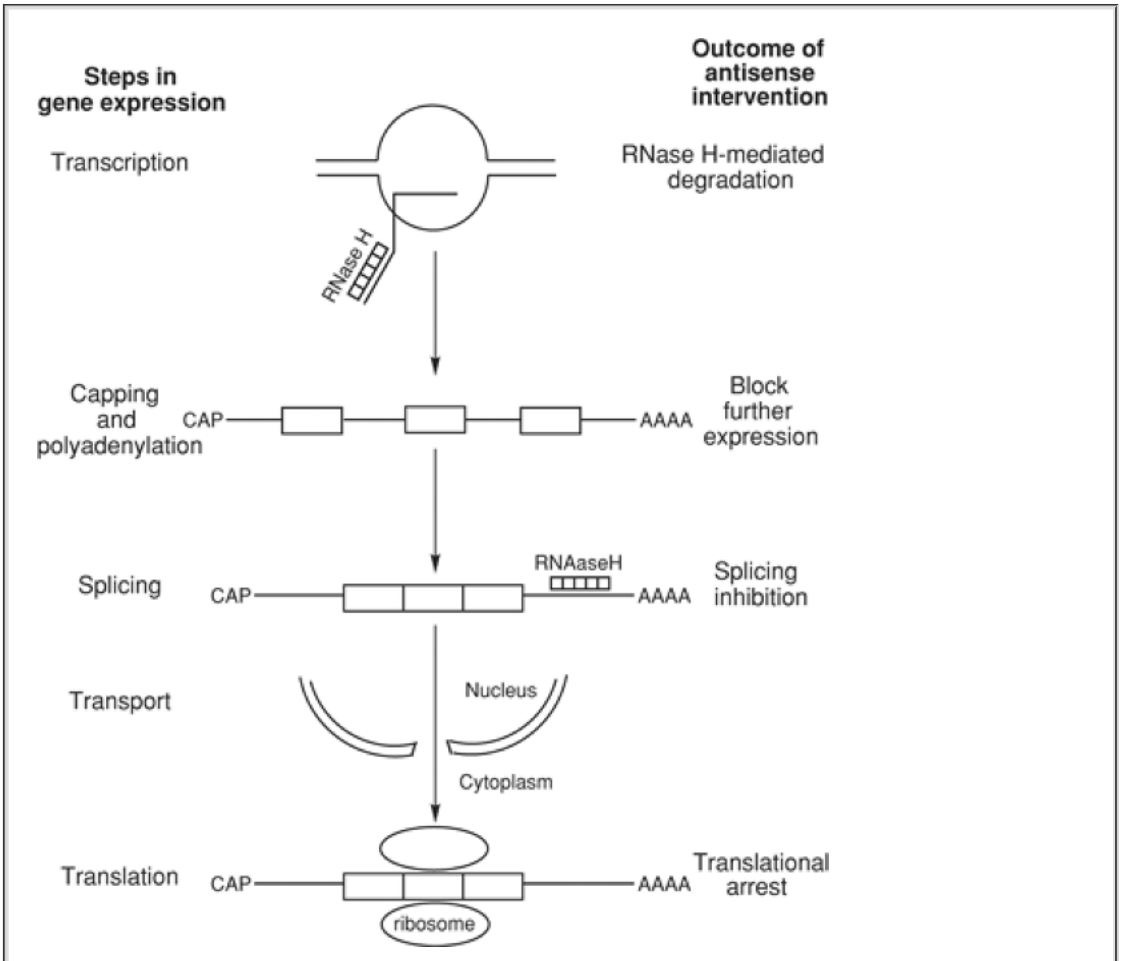

Fig. 8.3. Mechanism of action of antisense oligonucleotides. Each step in

gene expression is a potential target for antisense oligonucleotide activity. Steps in gene expression are indicated on the left, and the outcome of antisense binding is shown on the right. (Adapted from Rawls RL. Optimistic about antisense: Promising clinical results and chemical strategies for further improvements delight antisense drug researchers. Chem Engin News 1997;75:35–38; with permission.)

The negative charge also affects protein binding in vivo. The phosphorothiates exhibit a dissociation constant (kD) for albumin is approximately 150 micromolar, which is similar to that of aspirin or penicillin (16). Phosphorothioates are rapidly and extensively absorbed after parenteral administration and rapidly and extensively distributed to all peripheral tissues. No evidence indicates penetration of the blood-brain barrier. Clearance is primarily through metabolism by nucleases, with the degraded compounds being eliminated through the urine. Oral bioavailability is less than 5%, but the limiting factor may be degradation in the gut rather than absorption per se. Studies with a more stable 2′-methoxyphosphorothioate oligonucleotide showed a significant increase in oral bioavailability that appeared to be associated with improved stability of the analogs (14).

Potential Side Effects

Toxicological studies with phosphorothioate oligonucleotides have been performed with mice, monkeys, and to a lesser extent, humans. The dose-limiting effect in mice is a reversible immune stimulation observed as lymphoid hyperplasia, splenomegaly, and multiorgan monocellular infiltrate. These effects appear to be related to the terminal CpG dinucleotide that is cleaved by nucleases. In monkeys, the dose-limiting effect is sporadic drops in blood pressure associated with bradycardia and, at higher doses, abnormalities in blood clotting, perhaps resulting from interactions with thrombin. In humans, systemic intravenous administration of ISIS 2302 (a phosphorothioate that inhibits intercellular adhesion molecule 1 [ICAM-1]) caused no significant toxicities, including no

evidence of immune stimulation and no hypotension. A slight subclinical increase in activated partial thromboplastin time was observed at the highest dose (2 mg/kg) (17). Inflammation of the anterior chamber of the eye is the most common side effect of local (intravitreal injection) administration of fomivirsen (see below) for CMV retinitis.

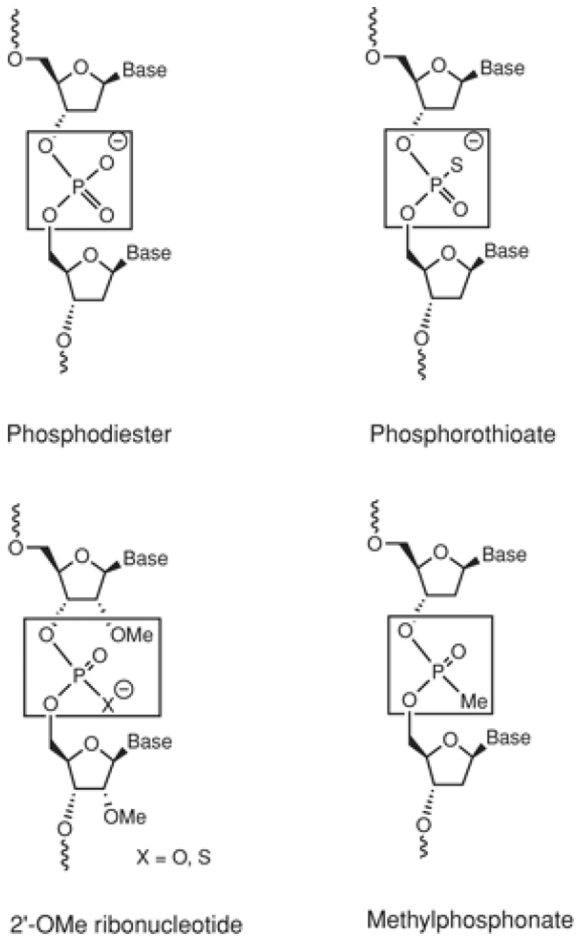

Fig. 8.4. First-generation generalized structures of natural DNA (phosphodiester) and three antisense oligonucleotide derivatives tested as antisense drugs. (Adapted from Agrawal S, Iyer RP. Perspectives in antisense therapeutics. Pharmacol Ther 1997;76:151–160; with permission.)

The major disadvantages of commonly used phosphorothioates are their relatively low affinity for their target mRNA and toxic side effects, especially the immune stimulation and clotting abnormalities. Efforts to design newer compounds have yielded some with enhanced serum stability, higher target affinity, and lower toxicity (18). These molecules are discussed later in this chapter.

Drug Therapy

Fomivirsen (Vitravene)

The first antisense therapeutic agent to reach the market is fomivirsen (ISIS 2922) (19). Fomivirsen is a 21-mer phosphorothioate oligodeoxynucleotide (Fig. 8.5). It inhibits human cytomegalovirus (CMV), a ubiquitous herpesvirus that is the most common cause of viral retinitis in immunocompromised patients, especially those with HIV infection. Cytomegalovirus infection is characterized by the progressive destruction of retinal cells and, if untreated, leads to retinal detachment and blindness. Even with treatment, some degree of visual loss occurs in nearly all patients with a diagnosis of CMV retinitis. It can affect one or both eyes.

Mechanism of Action

Fomivirsen inhibits CMV by at least two mechanisms. The first is a sequence-specific antisense binding to inhibit expression of immediate-early genes, thus preventing viral replication. The second is sequence-independent and involves inhibition of adsorption of CMV to host cells, probably by direct binding to viral coat proteins (20,21). The reduction of immediate-early protein synthesis occurs in a dose-dependent manner. Although it does inhibit viral replication, fomivirsen does not eradicate the virus whose DNA, as for all herpesviruses, is integrated into the human genome. Therefore, treatment will have to continue for the life of the patient.

Pharmacokinetics

The series of clinical trials that led to approval by the U.S. Food and Drug Administration involved 430 eyes in 330 patients. Fomivirsen significantly delayed progression of CMV retinitis in patients with AIDS, including those who had failed treatment with ganciclovir or foscarnet, the first-line therapies. Fomivirsen is administered by intravitreal injection at doses of 165 µg once weekly for three weeks of induction and then once every two weeks. It also can be administered in a dose of 330 µg on days 1 and 15 and then once a month thereafter. Mean maximum retinal concentrations of fomivirsen occur at 2 days, and the elimination half-life after a single, 115-µg dose in monkey retina was 78 hours. There are no systemic side effects. Ocular side effects include increased intraocular pressure and mild to moderate intraocular inflammation that can be reversed with topical steroid treatment. It is important that side effects be minor, because treatment will be lifelong.

Therapeutics

The U.S. Food and Drug Administration approved fomivirsen as second-line treatment of CMV retinitis in patients with AIDS who are intolerant or unresponsive to previous treatment for the disease (22). Alternative treatments include intravenous or oral ganciclovir, ganciclovir implant, cidofovir, and foscarnet (23). All are virustatic and share a common mechanism, inhibition of DNA polymerase. The disadvantages of these agents include the need for an indwelling catheter for intravenous administration of ganciclovir or foscarnet and the high cost and repeated surgeries needed for the surgically implanted, controlled-release ganciclovir pellets. In cell culture assays, however, fomivirsen showed additive antiviral activity with ganciclovir or foscarnet, so further study may show some benefit to combination therapy in human patients who have not yet failed with these agents.

The significance of fomivirsen goes beyond its efficacy for CMV retinitis. Fortunately, the better control of AIDS that is currently being achieved is decreasing the incidence of CMV retinitis. The impact of fomivirsen, however, on the quality of life of patients with the disease is dramatic. The further significance lies in the fact that it is the first antisense therapeutic agent. This achievement indicates that the concept can be developed into efficacious and safe drug products, including solving all the manufacturing, formulation, and analytical problems that this process entails.

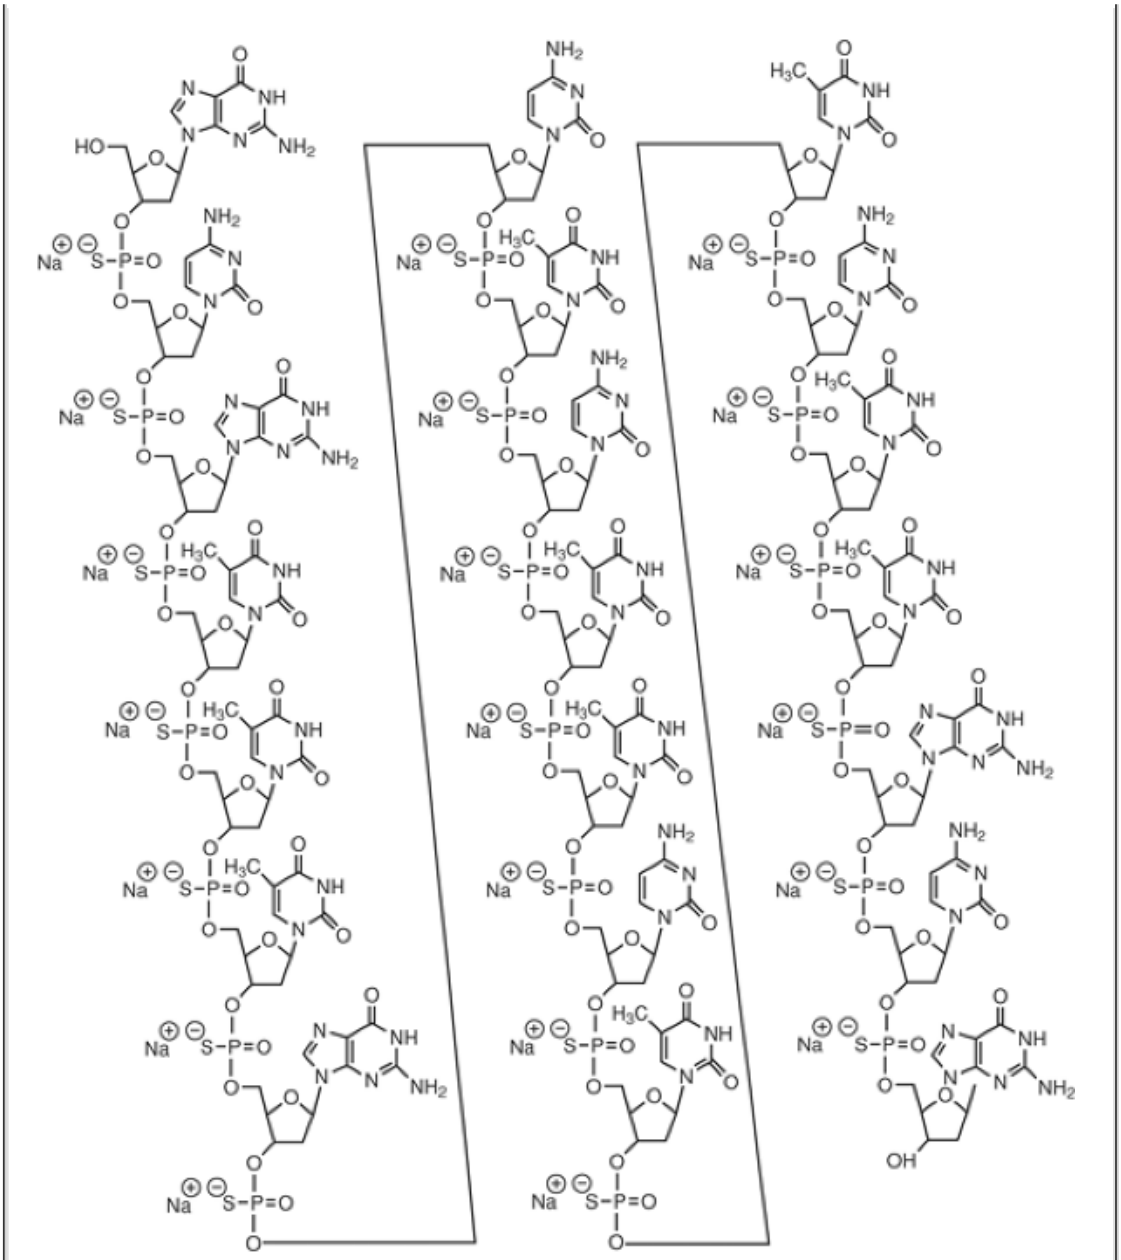

Fig. 8.5. Structure of fomivirsen, the first marketed antisense therapeutic agent. (Adapted from Field AK. Viral targets for antisense oligonucleotides: a mini review. Antiviral Res 1998;37: 67–81; with permission.)

Clinical Trials with Other Phosphorothioate Antisense Oligonucleotides

Alicaforsen (ISIS 2302)

Alicaforsen is a phosphorothioate oligodeoxynucleotide 20 bases in length with a sequence complementary to the 3′-untranslated region of the mRNA of human ICAM-1 (24). Hybridization of ISIS 2302 to mRNA inhibits expression of the ICAM-1 protein in response to inflammatory stimuli. Initial tests of activity were performed in mice using a analogous antisense oligonucleotide that is active against the analogous mouse ICAM molecule. Studies with this oligonucleotide showed that it had anti-inflammatory activity

in models of organ transplant rejection, ulcerative colitis, and collagen-induced arthritis. Toxicities in the mouse model were similar to those observed with other antisense oligonucleotides and were independent of the suppression of ICAM-1 expression. Immune stimulation, kidney changes, liver abnormalities, and increased clotting times were observed, but all toxicities were reversible and occurred at doses well above those required for pharmacological activity. No genetic toxicity was observed (25). In a Phase II human trial, 47% of

patients with Crohn's disease treated intravenously with ISIS 2302, but no patients treated with placebo, were in remission after 1 month of treatment. No clinically significant complications were observed (24). Illustrating the difficulty in actually getting a product to market, however, in two Phase III, randomized, double-blind, placebocontrolled trials, one with 150 patients and one with 180 patients, alicaforsen failed to show significant efficacy in inducing remission in patients with Crohn's disease and is not being further pursued by ISIS for this purpose (26). It is now being reinvestigated in a restructured, Phase III trial for use as an enema for treatment of ulcerative colitis.

Aprinocarsen (Affinitak, ISIS3521/LY900003)

Aprinocarsen is a phosphorothioate antisense agent targeted against protein kinase Cα, a protein that is implicated in malignant transformation and proliferation. It showed activity in Phase I and Phase II clinical trials against nonsmall-cell lung cancer when used in combination with cisplatin or the combination of cisplatin and gemcitabine (27). It proved to be disappointing, however, during initial Phase III trials. Eli Lilly was sponsoring Phase III trials to further explore its efficacy in combination with chemotherapeutic agents for lung cancer, but enrollment was terminated in March 2003, when a Phase III trial suggested that aprinocarsen did not have an added survival benefit when combined with paclitaxel and carboplatin therapy in patients with nonsmall-cell lung cancer (28).

Oblimersen sodium (Genasense, G-3139)

Genta is developing a phosphorothioate antisense drug called oblimersen sodium that is complementary to the first six codons of the open reading frame of the human bcl-2 mRNA sequence. Oblimersen turns off production of the apoptosis inhibitor Bcl2 in tumor cells. This appears to increase a tumor cell's sensitivity to a variety of other anticancer therapies and, ultimately, may lead to cell death. It is being investigated for use in treatment of myeloma and other cancers as well. In a recently reported Phase II trial (29), oblimersen was administered (3–7 mg/kg/d for 7 days) by continuous intravenous infusion. On day 4, patients started thalidomide (100–400 mg as tolerated) and dexamethasone (40 mg daily for 4 days) on 21-day cycles for three cycles. Oblimersen, dexamethasone, and thalidomide are well tolerated and result in encouraging clinical responses in patients with relapsed multiple myeloma. Phase III trials currently are underway with patients who have myeloma and chronic lymphocytic leukemia, as are earlier-stage trials with patients who have other cancers and other anticancer therapies (30).

These three drugs illustrate both the hope and the frustration that is experienced with this class of therapeutics. The antisense mechanism works in the cells, and protein synthesis can definitely be inhibited. Getting from cell culture observations to useful and effective therapies, however, is a long road, and several seemingly useful antisense agents have fallen by the wayside when tested in randomized, double-blind trials. Clearly, attention must be paid to getting the dosing schedule, formulation, and route of administration optimized.

Future Targets and Directions

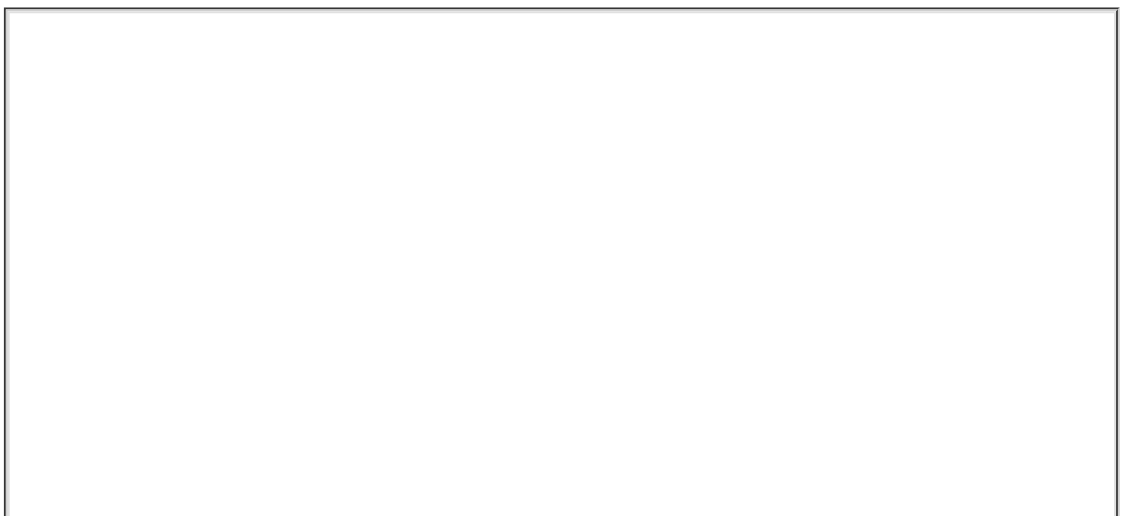
Design of Second- and Third-Generation Agents

Several alternative structures are being tested as second-generation antisense oligonucleotides. One of these involves a mixed backbone oligonucleotide (31). Studies have shown that the toxicity and immune stimulatory effects of phosphorothioates correlate with the nuclease cleavage of a terminal CG dinucleotide. The toxicity can be minimized by the use of 2′-O-methylribonucleosides in place of four deoxynucleotides at both the 3′ and 5′ end of the phosphorothioate oligonucleotide. These molecules have been termed “gapmers” (18). They retain the RNase H substrate properties of the original phosphorothioate molecule (oligonucleotides made up entirely of 2′-O-methylribonucleotides do not form RNase H susceptible duplexes) and have good duplex stability and better nuclease resistance. On intravenous administration, the hybrid oligonucleotides (or gapmers) exhibit rapid uptake and longer elimination half-lives, and analysis of tissues showed that mainly full-length oligonucleotides were present, consistent with the greater resistance to nuclease-mediated degradation compared to the nonhybrid phosphorothioate oligonucleotide. Excretion occurs primarily in the urine, and like phosphorothioates, the excretory products are mainly degraded products, with only trace amounts of the intact molecule. Studies in rats suggest that the mixed backbone oligonucleotides also may be orally bioavailable (25–30% of the administered dose), which would present a major advantage in the utility of antisense therapeutic agents, especially for chronic diseases.

Additional Developments

Mixed backbone hybrid oligonucleotides also have been made using methylphosphonate linkages at the ends. Methylphosphonates are nonionic, are resistant to nucleases, but do not lead to RNase H degradation. The reduced polyanionic nature of the mixed backbone oligonucleotide with methylphosphonate moieties have the potential to reduce the clotting abnormality associated with the use of phosphorothioate agents (14).

One goal for future development will be the design of orally available antisense products. Some attempts have included attaching a 2-methoxyethoxy group at the 2′ site of ribose on the bases at both ends of the oligonucleotide, creating 2′-methoxyphosphorothioate analogues and substituting aminopropoxy groups at the 2′ ribose site (7). Work will continue to develop orally available compounds, particularly for chronic diseases. The oral availability, however, must be balanced with penetration into target cells and tissues, binding to the mRNA, and RNase H induction.



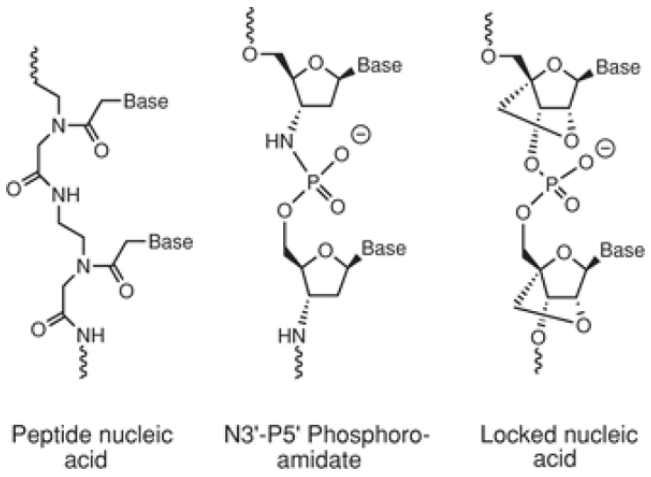


Fig. 8.6. Generalized structures of some second generation antisense oligonucleotides.

In some situations, RNase H induction is not desired, such as when inhibiting an aberrant splice site. The correctly spliced mRNA must be translated and not degraded if the desired effect is to be achieved. This approach has been used to treat the genetic blood disorder β-thalassemia, a disease in which a mutation in intron 2 of the β-globin gene causes aberrant splicing of the pre-mRNA and, as a consequence, β-globin deficiency. A phosphorothioate 2′-O-methyl oligonucleotide (that does not induce RNase H cleavage) was targeted to the aberrant splice site and restored correct splicing and β-globin production (1).

Another second-generation class of antisense molecules are the peptide nucleic acids, in which the deoxyribose backbone is replaced by polyamide linkages (Fig. 8.6). These molecules have favorable hybridization properties, are very stable in a biological environment, and seem to be nontoxic. They are electrostatically neutral, so solubility and cellular uptake are serious problems. They do not induce RNase H and, therefore, have been used to correct aberrant splicing (18).

Similarly, N3′-P5′ phosphoroamidates are another example of a modified phosphate backbone in which the 3′-hydroxy group of the 2′-deoxyribose ring is replaced by a 3′-amino group (Fig. 8.6). They have high affinity for the complementary RNA strand and are nuclease resistant. Additionally, they do not induce RNase H and, therefore, are most useful for correcting splicing (18).

One of the most promising second-generation modification is one called “locked nucleic acid” (LNA), in which the ribonucleotide contains a methylene bridge that connects the 2′-oxygen of the ribose with the 4′-carbon (Fig. 8.6). The LNAs have enhanced stability to nucleases and an extraordinarily high affinity for the target mRNA. They do not, however, activate RNase H. If degradation of the mRNA is desired, a chimeric DNA-LNA gapmer that contains a stretch of seven to eight DNA monomers in the center to induce RNase H activity should be used (18).

Finally, the newest molecules to induce excitement are the double-stranded siRNAs. The RNA interference is initiated by long, double-stranded RNA molecules that are processed into 21- to 23-nucleotide RNAs. These siRNAs are then incorporated into the RISC and serve to guide the nuclease that destroys the target RNA and stops protein synthesis. These molecules are extremely stable in the cell. In some experiments, they

have been made even more stable by introducing two 2′-O-methyl RNA nucleotides at the 5′ end and four methylated monomers at the 3′ end. This modification resulted in a prolonged silencing effect in the cell culture. Because the basic effect of siRNA is the same as that of the other antisense technologies, researchers will be able to benefit from all the work that has gone on with antisense molecules, including the importance of proper controls to prove that the observed effect is, in fact, caused by specific reduction in target gene synthesis and the importance of looking for unspecific effects mediated by the immune system (18).

Future Targets and Products in Development

A number of molecules are in various phases of testing. In addition to the three phosphorothioates in Phase III trials, as already described, a number of second-generation products are undergoing testing in humans. Promising early results have been presented describing studies in patients with age-related macular degeneration who were treated with an injection into the eyes of a chemically modified siRNA that targets vascular endothelial growth factor receptor-1 (VEGFR-1). By targeting VEGFR-1, pathogenic angiogenesis is downregulated, and new vascularization is blocked (5).

Monarsen, an antisense oligonucleotide targeted to the acetylcholinesterase gene, is delivered orally to treat patients with myasthenia gravis and exhibits efficacy in early trials. Myasthenia gravis is a chronic and debilitating autoimmune disease in which the body's immune system attacks acetylcholine receptors at the neuromuscular junction, interfering with normal muscular function. Monarsen offers a novel mechanism of action for the control of an isoform of the acetylcholinesterase enzyme that is believed to play a key role in the onset and progression of myasthenia gravis (5).

Many other antisense and siRNA products are in various stages of early phase trials, including compounds targeted as antivirals, anti-inflammatory agents, and other approaches to cancer. In summary, the concept of antisense technology has been proven, one first-generation phosphorothioate oligonucleotide drug has reached the market, and second-generation drugs with improved properties are under development. It seems likely that the list of marketed antisense drugs will continue to grow.

Chapter 9

Physicochemical and Biopharmaceutical Properties of Drug Substances and Pharmacokinetics

Sunil S. Jambhekar

Introduction

Throughout its history, the pharmacy profession has been concerned primarily with the manner in which drugs produce their pharmacological effects and the dosage forms through which drugs are administered. Since the early twentieth century, efforts have been directed to determining, understanding, and providing rational explanations of drug effects on biological systems, but we have been limited by our ability to correlate the observed physiologic events with a reasonable hypothesis or concept. Pharmacists, at one time, were closely involved in formulating a prescription written by a physician for a patient. Today, most of the formulating is done by the pharmaceutical manufacturer.

Early descriptions of drug action were confined to their reference as tonic or toxic effects. This approach was followed by the concept of receptor theory, which for decades remained primarily an operational concept that was useful for discussing the new actions of drugs on a molecular level (1). Research in receptor theories, however, has provided evidence that the drug receptors do exist as distinct entities, and a limited success has been attained in the characterization of receptors (2,3).

An extension of the receptor theory of drug action is an increased emphasis on the importance of physicochemical properties of the drug and the relationship of such properties to the pharmacological responses. Because these properties play an important role in determining biological action of pharmaceuticals, it is appropriate to refer to these properties as biopharmaceutical properties of drug substances. Examples of such properties include solubility, partition coefficients, diffusivity, degree of ionization, and polymorphism, which in turn are determined by the chemical structure and stereochemistry of drug substances.

A consideration of these biopharmaceutical properties is fundamental to discussing several important aspects of the overall effects. For a given chemical entity (drug), there often will be a difference in physiological availability and, presumably, in clinical responses, primarily because drug molecules must cross various biological membranes and interact with intercellular and intracellular fluids before reaching the elusive region termed the “site of action.” Under these conditions, the biopharmaceutical properties of the drug must contribute favorably to facilitate absorption and distribution processes to augment the drug concentration at various active sites. Furthermore, equally important is the fact that these biopharmaceutical properties of a drug must ensure a specific orientation on the receptor surface so that a sequence of events is initiated that leads to the observed pharmacological effects. Drug molecules that are deficient in the required biopharmaceutical properties may display generally marginal pharmacological action or be totally ineffective.

Biopharmaceutics may be defined as the study of the influence of formulation factors on the therapeutic activity of a drug product or dosage forms. It involves the study of the relationship between some of the physicochemical properties of a drug and the biological effects observed following the administration of a drug via various dosage forms or drug delivery systems. Almost any alteration in a drug delivery system is likely to alter the drug delivery rate and the amount of the drug delivered to the desired place in the body. This includes the chemical nature of the drug (e.g., ester, salts, and complexes), the particle size and surface area of the drug, the type of dosage forms (e.g., solution, suspension, capsule, and tablet), and the excipients and processes used in the manufacturing of the drug delivery systems.

Drugs, via drug delivery systems, most often are administered to human subjects by the oral route. Compared to other routes of drug administration, especially the intravenous route, the oral route is unusually complex with respect to the physicochemical conditions existing at the absorption site. Therefore, before we discuss how the biopharmaceutical properties of a drug in a dosage form may affect the availability and action of that drug, it is prudent to review the gastrointestinal physiology.

Gastrointestinal Physiology

Figure 9.1 schematically represents the gastrointestinal tract and some of the problems encountered in a consideration of drug absorption from the site following administration of a drug via dosage

forms (4). The stomach may be divided into two main parts: the body of the stomach, and the pylorus. Histologically, these parts correspond to the pepsin- and HCl-secreting area and the mucus-secreting area, respectively, of the gastric mucosa. In the human, the stomach contents usually are in the pH range of 1.0 to 3.5, with pH 1.0 to 2.5 being the most common range. Furthermore, there is a diurnal cycle of gastric acidity in humans. During the night, stomach contents usually are more acidic (pH ~1.3); during the day, because of food consumption, the pH is less acidic. The recovery of stomach acidity, however, occurs quite rapidly. The presence of protein, being amphoteric in nature, acts as an excellent buffer, and as digestion proceeds, the liberated amino acids increase the neutralizing capacity enormously.

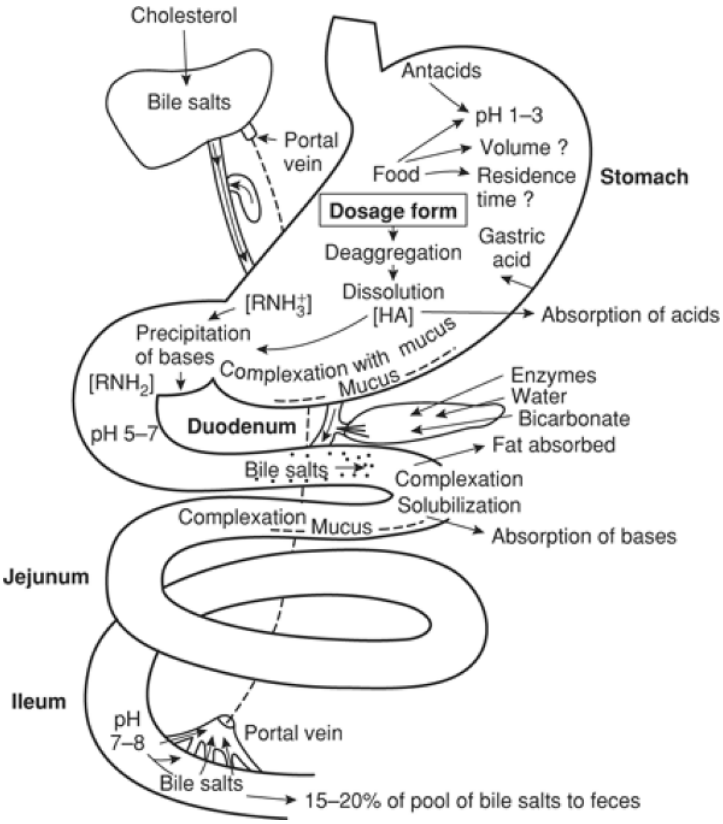

Fig. 9.1. Processes occurring along with drug absorption when drug molecules travel down the gastrointestinal tract and the factors that affect to drug absorption. (From Florence AT, Attwood D. Physiochemical Principles of Pharmacy, 2nd Ed. New York-Chapman and Hall, 1988, with permission).

The small intestine is divided anatomically into three sections: the duodenum, the jejunum, and the ileum. All three areas are involved in the digestion and absorption of food. The available absorbing area is increased by surface folds in the intestinal lining. The surface of these folds possesses villi and microvilli (Fig. 9.2). The duodenal contents in the human usually are in the pH range of 5 to 7. There is a gradual decrease in acidity along the length of the gastrointestinal tract, with the ultimate pH being 7 to 8 in the lower ileum. It has been estimated that approximately 8 L of fluid enter the upper intestine per day, with approximately 7 L of this arising from digestive juices and fluids and approximately 1 L arising from oral intake. Over the entire length of the large and small intestine and the stomach is the brush border, which consists of a uniform coating (thickness, 3 mm) of mucopolysaccharide. This coating layer serves to act as a mechanical barrier to bacteria or food particles.

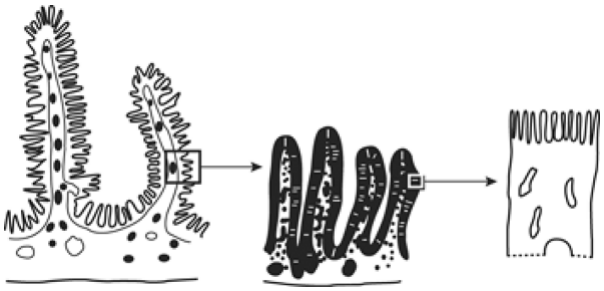

Fig. 9.2. The epithelium of the small intestine at different levels of magnification. From left to right: the intestinal villi and microvilli that constitute the brush border.

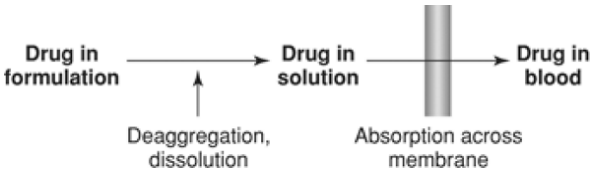

Fig. 9.3. Sequence of events in drug absorption from formulations of solid dosage forms.

When a dosage form containing a drug or drug molecules moves from the stomach through the pylorus into the duodenum, the dosage form encounters a rapidly changing environment with respect to pH. Furthermore, digestive juices secreted into the small bowel contain many enzymes not found in the gastric juices. Digestion and absorption of foodstuff occur simultaneously in the small intestine. Intestinal digestion is the terminal phase of preparing foodstuff for absorption and consists of two processes: completion of the hydrolysis of large molecules to smaller ones, which can be absorbed, and brining the finished product of hydrolysis into an aqueous solution or emulsion.

Drug absorption, whether from the gastrointestinal tract or from other sites, requires the passage of the drug in a molecular form across the barrier membrane. Most drugs are presented to the body as solid or semi-solid dosage forms, and the drug particles must first be released from these dosage forms. These drug particles must dissolve, and if they possess the desirable biopharmaceutical properties, they will pass from a region of high concentration to a region of low concentration across the membrane into the blood or general circulation (Fig. 9.3). Knowledge of biological membrane structure and its general properties is pivotal in understanding absorption processes and the role of the biopharmaceutical properties of drug substances.

Biological Membrane

The prevalent view is that the gastrointestinal membrane consists of a bimolecular lipoid layer that is covered on each side by protein with the lipid molecule oriented perpendicular to the cell surface (Fig. 9.4). The lipid layer is interrupted by small, water-filled pores with a radius of approximately 4 A, and a molecule with a radius of 4 A or less may pass through these water-filled pores. Thus, membranes have a specialized transport system to assist the passage of water-soluble material and ions through the lipid interior, a process sometimes termed to as “convective absorption.” The rate of permeation of such small molecules through the pore is affected not only by the relative sizes of the holes and the molecules but also by the interaction between permeating molecules

and the membrane. When permeation through the membrane occurs, the permeating substance is considered to have transferred from solution in the luminal aqueous phase to the lipid membrane phase, then to the aqueous phase on the other side of the membrane. Biological membranes differ from a polymeric membrane in that they are composed of small amphipathic molecules, phospholipids, and cholesterol. The protein layer associated with membranes is hydrophobic in nature. Therefore, biological membranes have a hydrophilic exterior and a hydrophobic interior. Cholesterol is a major component of most mammalian biological membranes, and its removal will render the membrane highly permeable. A cholesterol complexes with phospholipids, and its presence reduces the permeability of the membrane to water, cations, glycerides, and glucose. The shape of the cholesterol molecule allows it to fit closely with the hydrocarbon chains of unsaturated fatty acids in the bilayer. It is the general opinion that the cholesterol makes the membrane more rigid. The flexibility of the biological membrane to reform and adapt to a changed environment is its important feature. The details of membrane structure are still widely debated, and a more recent membrane model is shown in Figure 9.4.

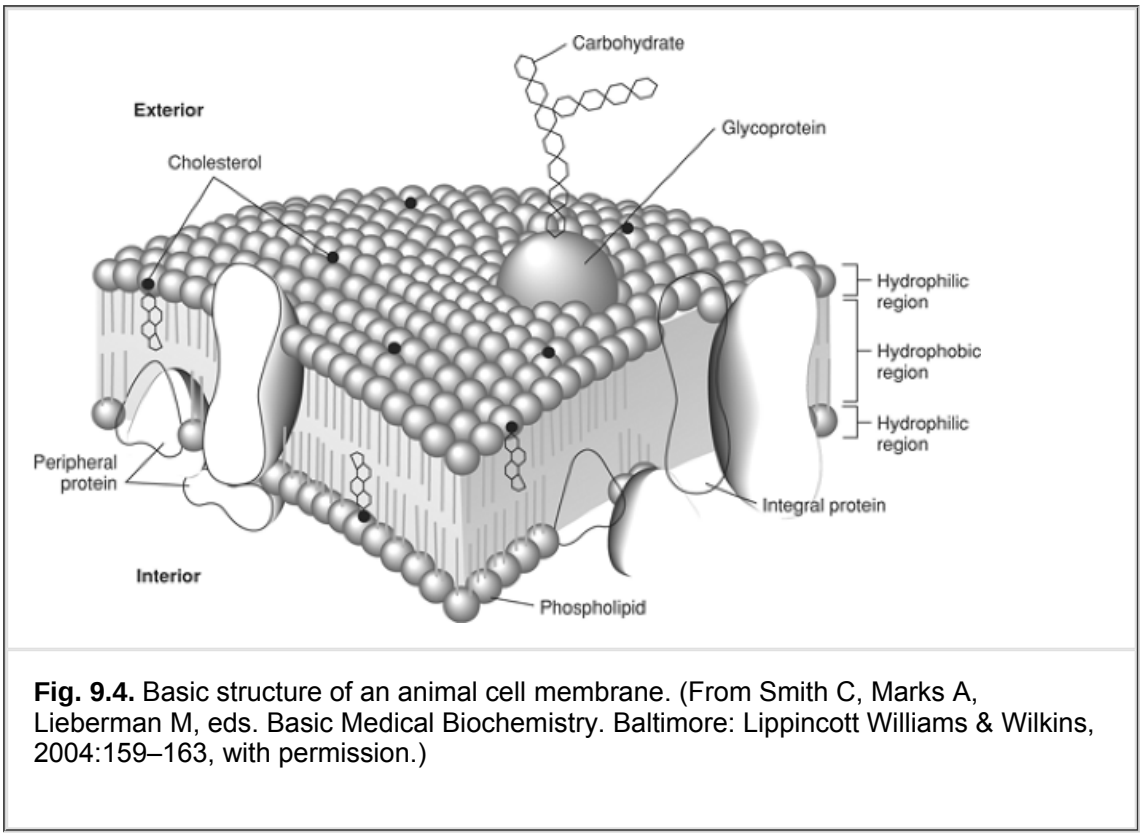

Fig. 9.4. Basic structure of an animal cell membrane. (From Smith C, Marks A, Lieberman M, eds. Basic Medical Biochemistry. Baltimore: Lippincott Williams & Wilkins, 2004:159–163, with permission.)

In addition to biopharmaceutical factors, several physiological factors also may affect the rate and extent of gastrointestinal absorption. These factors are as follows: properties of epithelial cells, segmental activity of the bowel, degree of vascularity, effective absorbing surface area per unit length of gut, surface and interfacial tensions, electrolyte content and their concentration in luminal fluid, enzymatic activity in the luminal contents, and gastric emptying rate of the drug from stomach.

Mechanisms of Drug Absorption

Drug transfer often is viewed as the movement of a drug molecule across a series of membranes and spaces (Fig. 9.5), which, in aggregate, serve as a macroscopic membrane. The cells and interstitial spaces lying between the gastric lumen and the capillary blood or structure between sinusoidal space and the bile canaliculi are examples. Each of the cellular membranes and spaces may impede drug transport to varying degrees; therefore, any one of them can be a rate-limiting step to the overall process of drug transport. This complexity of structure makes quantitative prediction of drug transport difficult. A qualitative description of the processes of drug transport across functional membranes follows.

Passive Diffusion

The transfer of most drugs across a biological membrane occurs by passive diffusion, a natural tendency for molecules to move from a higher concentration to a lower concentration. This movement of drug molecules is caused by the kinetic energy of the molecules. The rate of diffusion depends on the magnitude of the concentration gradient (*dC*) across the membrane and can be represented by the following equation:

$$\textbf{Eq. 9.1} \qquad -\frac{dC}{dt} = K \cdot dC = K(C_{abs} - C_b)$$

where $-dC/dt$ is the rate of diffusion across a membrane; K is a complex proportionality constant that includes the area of membrane, the thickness of the membrane, the partition coefficient of the drug molecule between the lipophilic membrane and the aqueous phase on each

P.213

side of the membrane, and the diffusion coefficient of the drug; C_{abs} is the drug concentration at the absorption site; and C_b is the drug concentration in the blood.

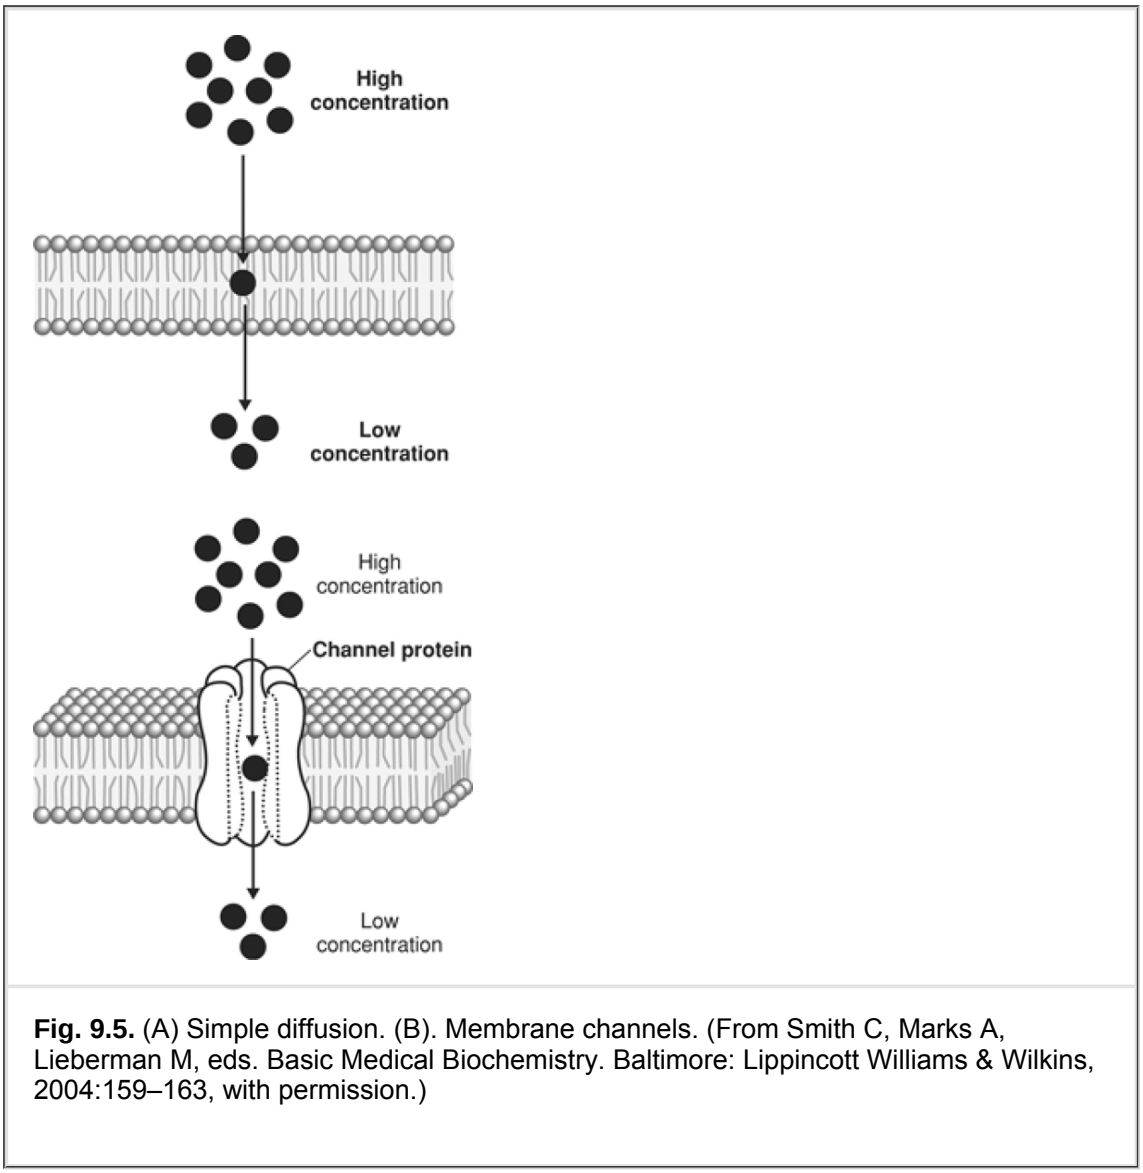

Fig. 9.5. (A) Simple diffusion. (B). Membrane channels. (From Smith C, Marks A, Lieberman M, eds. Basic Medical Biochemistry. Baltimore: Lippincott Williams & Wilkins, 2004:159–163, with permission.)

The gastrointestinal absorption of a drug from an aqueous solution requires transfer from the lumen to the gut wall followed by penetration of the epithelial membrane by a drug molecule to the capillaries of the systemic circulation. On entering the blood, the drug distributes itself rapidly in the blood. Because of the volume differences at absorption and distribution sites, the drug concentration in blood (C_b) will be much lower than the concentration at the absorption site (C_{abs}). This concentration gradient is maintained throughout the absorption process—that is, ($C_{abs} - C_b$). As a result, the concentration gradient (*dC* in Eq. 9.1), is approximately equal to C_{abs}, so Equation 9.1 can be written as

Eq. 9.2 $$-\frac{dC}{dt} = K \cdot C_1$$

Because absorption by passive diffusion is a first-order process, the rate of absorption (dC/dt in Eq. 9.2) is directly proportional to the concentration at the site of absorption (C_1). The greater the concentration of drug at the absorption site, the faster is the rate of absorption (Fig. 9.6). The percentage of dose absorbed at any time, however, remains unchanged.

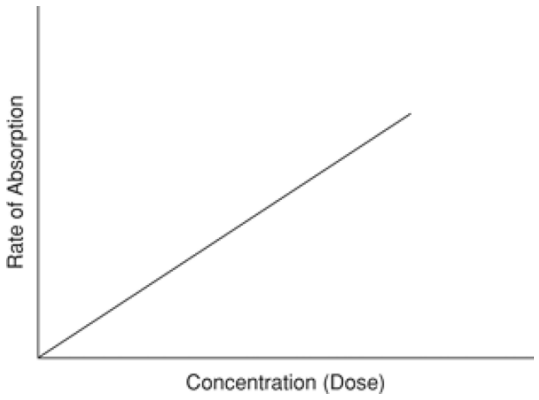

Fig. 9.6. Effect of drug concentration on the rate of absorption when passive diffusion is operative.

A major source of variation is membrane permeability, which depends on the lipophilicity of the drug molecule. This often is characterized by its partition between oil and water. The lipid solubility of a drug, therefore, is a very important physicochemical property governing the rate of transfer through a variety of biological membrane barriers. Figure 9.7 illustrates the role of partition coefficients in the drug absorption process from the colon and that a good correlation exists between the percentage of

drug absorption and the partition coefficient of an un-ionized drug.

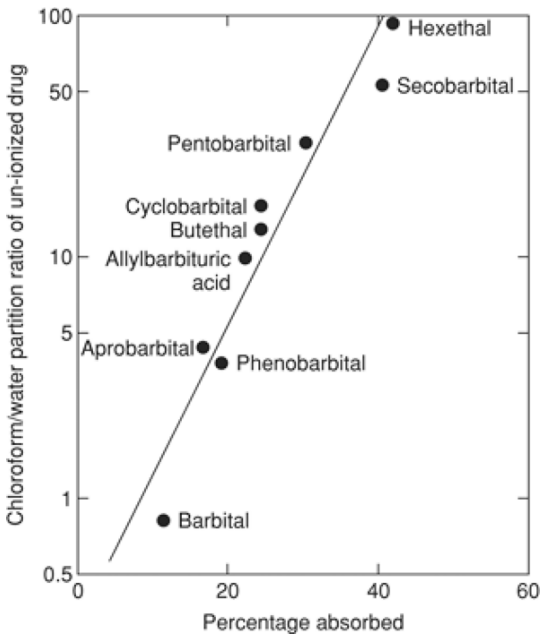

Fig. 9.7. Comparison between colonic absorption of barbiturates in the rat and lipid-to-water partition coefficient of the un-ionized form of the barbiturates. (From Schanker LS. Absorption of drugs from the colon. J Pharmacol Exp Ther 1959;126:283–294; with permission.)

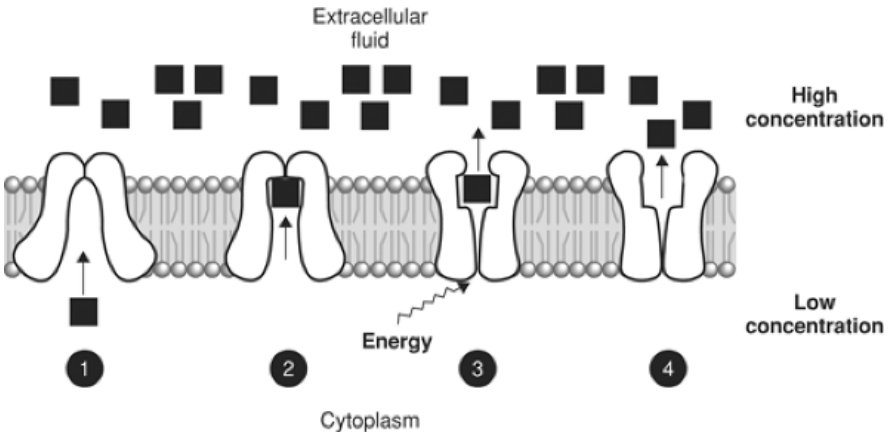

Fig. 9.8. Active transport. (From Smith C, Marks A, Lieberman M, eds. Basic Medical Biochemistry. Baltimore: Lippincott Williams & Wilkins, 2004:159–163, with permission.)

Carrier Mediated or Active Transport

Although most drugs are absorbed from the gastrointestinal tract by passive diffusion, some drugs of therapeutic interest and some chemicals of nutritional value, such as amino acids, di- and tripeptides, glucose, and folic acid, are absorbed by the action of transporter proteins (i.e., a carrier-mediated transport mechanism) (Fig. 9.8). In this type of transport, membranes have a specialized role. The usual requirement for active transport is structural similarities between the drug and the substrate normally transported across the membrane. Active transport differs from passive diffusion in the following ways: 1) The transport of the drug occurs against a concentration gradient, 2) the transport mechanism can become saturated at high drug concentration, and 3) a specificity for a certain molecular structure may promote competition in the presence of a similarly structured compound. This, in turn, may decrease the absorption of a drug. Active or facilitated absorption of a drug usually is explained by assuming that transporter proteins (i.e., carriers in membranes) are responsible for shuttling these solutes in mucosal or serosal direction. The number of apparent carriers in membranes, however, is limited. Therefore, the rate of transfer may be described by the following equation:

$$\textbf{Eq. 9.3} \qquad \text{Absorption rate} = \frac{dC}{dt} = V_{max} \cdot C / K_m + C$$

where C is the solute concentration at the absorption site and V_{max} (the maximum theoretical transfer rate) and K_m (the concentration of drug at half the V_{max}) are constants. Low doses or concentrations, when $K_m >> C$, reduce Equation 9.3 to

$$\textbf{Eq. 9.4} \qquad \frac{dC}{dt} = \frac{V_{max}}{K_m \cdot C} = K \cdot C$$

Equation 9.4 indicates that the apparent first order kinetics is observed. Under these conditions, there are sufficient numbers of carriers available so that a constant proportion of solute molecules presented to the membrane are transported across the membranes. As the solute concentration increases, the number of free carriers is reduced, and the proportion of solute molecules transferred across the membrane is reduced until a maximum absolute number saturation is reached. When $C >> K_m$,

$$\textbf{Eq. 9.5} \qquad \text{Absorption rate} = \frac{dC}{dt} = V_{max}$$

Equation 9.5 indicates that a further increase in solute concentration will not result in any further increase in the rate of absorption (Fig. 9.9). The capacity-limited

characteristics of carrier-mediated processes suggest that the bioavailability of drugs absorbed in

this manner should decrease nonlinearly with increasing doses. Therefore, the use of a large, single oral dose of these drugs is irrational, and if larger daily doses are necessary, one should use divided doses. Examples of substances that are actively transported include amino acids, methyldopa, 5-fluorouracil, penicillamine, and levodopa.

Fig. 9.9. Relationship between drug concentration and rate of absorption when an active transport process is operative.

Convective Absorption

The absorption of small molecules (molecular radii less than ~4 A) through water-filled pores of biological membrane is referred to as convective absorption. The rate of absorption because of this mechanism is equated to the product of a sieving coefficient, the rate of fluid or water absorption, and the concentration of solute in the luminal content. The sieving coefficient is indirectly related to the relative sizes of the pores and the molecules.

Ion-Pair Absorption

In 1967, Higuchi suggested that highly ionized compounds, such as quaternary ammonium compounds, may possibly be absorbed by an ion pair mechanism (6). In vitro, a relatively large organic anion can combine with relatively large cation to form an ion pair of neutral properties, which will then cross a water–organic solvent interface and transfer to an organic phase.

Physicochemical Factors Affecting Drug Absorption

The pH-Partition Hypothesis on Drug Absorption

Drug absorption is influenced by many physiological factors. Additionally, it also depends on many physicochemical properties of the drug itself. Shore, Brodie, Hogben, Schanker, Tocco, and others (5,7,8,9,10,11,12) concluded from their research that most drugs are absorbed from the gastrointestinal tract by a process of passive diffusion of the un-ionized moiety across a lipid membrane. Furthermore, the dissociation constant, lipid solubility, and pH of the fluid at the absorption site determines the extent of absorption from a solution. The interrelationship among these parameters is known as the pH-partition theory. This theory provides a basic framework for the understanding of drug absorption from the gastrointestinal tract and drug transport across the biological membrane. The principle points of this theory are as follows:

1. The gastrointestinal and other biological membranes act like lipid barriers.
2. The un-ionized form of the acidic or basic drug is preferentially absorbed.

3. Most drugs are absorbed by passive diffusion.
4. The rate of drug absorption and amount of drug absorbed are related to its oil–water partition coefficient (i.e., the more lipophilic the drug, the faster is its absorption).
5. Weak acidic and neutral drugs may be absorbed from the stomach, but basic drugs are not.

When a drug is administered intravenously, it is immediately available to body fluids for distribution to the site of action. All extravascular routes, however, can influence the overall therapeutic activity of the drug, primarily because of its dissolution rate, a step that is necessary for a drug to be available in a solution form. When a drug is administered orally in a dosage form such as a tablet, capsule, or suspension, the rate of absorption across the biological membrane frequently is controlled by the slowest step in the following sequence:

$$\text{Dosage form} \xrightarrow{\text{dissolution}} \text{Drug in solution} \xrightarrow{\text{absorption}} \text{Drug in general circulation}$$

In many instances, the slowest step, or the rate-limiting step, in the sequence is the dissolution of the drug. When dissolution is the controlling step, any factors that affect the rate of dissolution also must influence the rate of absorption. This, in turn, affects the extent and duration of action. Several factors can influence the dissolution rate of drug from solid dosage forms and, therefore, the therapeutic activity. These factors include solubility of a drug, particle size and surface area of drug particles, crystalline and salt form of a drug, and the rate of disintegration.

The absorption rate of drugs also can be affected by interaction or formation of complexes in the gastrointestinal tract. Generally, such complex formation reduces the concentration of free drug at the absorption site. Because the complexed drug is absorbed either slowly or not at all, the net effect is the reduction of concentration of drug at absorption site and slower rate of absorption.

Ionization and pH at Absorption Site

The fraction of the drug existing in its un-ionized form in a solution is a function of both the dissociation constant of a drug and the pH of the solution at the absorption site. The dissociation constant, for both weak acids and bases, often is expressed as the pK_a (the negative logarithm of a dissociation constant, K_a). The Henderson-Hasselbach equation for the ionization of a weak acid, HA, is derived from the following equation:

Eq. 9.6
$$HA + H_2O \rightleftharpoons A^- + H_3O^+$$

We may express the equilibrium constant as follows:

Eq. 9.7
$$K_a = \frac{[_aH_3O^+][_aA^-]}{[_aHA]}$$

where K_a is the equilibrium or dissociation constant and $_a$ is the activity coefficient. Assuming the activity coefficients approach unity in dilute solutions, the activity coefficient may be replaced by concentration terms, and Equation 9.7 becomes

P.216

Eq. 9.8
$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

The negative logarithm of K_a is referred to as the pK_a. Thus,

Eq. 9.9
$$pK_a = -\log K_a$$

Taking the logarithm of the expression for the dissociation constant of a weak acid in Equation 9.8 yields

Eq. 9.10
$$-\log K_a = \frac{-\log [H_3O] - \log[A^-]}{[HA]}$$

where A^- is the ionized form of a weak acid and HA is the un-ionized form.

Eq. 9.11
$$pH - pK_a = \frac{\log [\text{Ionized}]}{[\text{Un-ionized}]}$$

Assuming that α is the fraction of ionized species and that 1-α is the fraction remaining as the un-ionized form, Equation 9.11 can be written as

Eq. 9.12
$$pH - pK_a = \log \frac{\alpha}{1 - \alpha}$$

or

$$\textbf{Eq. 9.13} \qquad \frac{\alpha}{1-\alpha} = \text{antilog} \longleftrightarrow (\text{pH} - \text{p}K_a)$$

From Equation 9.13, the fraction or percentage of the absorbable and nonabsorbable forms of a weak acid can be calculated if the pH condition at the site of administration is known. Analogously, the dissociation or basicity constant for a weak base is derived as follows:

$$\textbf{Eq. 9.14} \qquad B + H_2O \longleftrightarrow BH^+ + OH^-$$

The dissociation constant, K_b, is derived as follows:

$$\textbf{Eq. 9.15} \qquad K_b = \frac{[_aOH]\ [_aBH]}{[_aB]} = \frac{[OH^-][BH]}{[B]}$$

and

$$\textbf{Eq. 9.16} \qquad \text{p}K_b = -\log K_b$$

The pK_a and pK_b values provide a convenient means of comparing the strength of weak acids and bases. The lower the pK_a, the stronger the acid, and the lower the pK_b, the stronger the base. The values for pK_a and pK_b of conjugate acid-base pairs are linked by the expression

$$\textbf{Eq. 9.17} \qquad \text{p}K_a + \text{p}K_b = \text{p}K_w$$

where pK_w is the negative logarithm of dissociation constant of water. Taking the logarithm of Equation 9.15 and rearranging yields

$$\textbf{Eq. 9.18} \qquad -\log K_b = \frac{-\log [OH^-] - \log [BH^+]}{[B]}$$

Although the dissociation constant of a weak base is described by the term K_b, it is conventionally expressed in terms of K_a, because of the relationship expressed in Equation 9.17.

Equation 9.18 can then be written as

$$\textbf{Eq. 9.19} \qquad \text{pH} = \text{p}K_w - \text{p}K_b - \log \frac{[BH^+]}{[B]}$$

Because pK_w – pK_b – pK_a, Equation 9.19 takes the following form for a weak base (BH^+ is the ionized form, and B is the un-ionized form):

$$\textbf{Eq. 9.20} \qquad \text{p}K_a - \text{pH} = \log \frac{[\text{Ionized}]}{[\text{Un-ionized}]}$$

Again, assuming that α is the fraction of ionized species and that 1 – α is the fraction of un-ionized species, Equation 9.20 becomes

$$\textbf{Eq. 9.21} \qquad \text{p}K_a - \text{pH} = \log \frac{\alpha}{1-\alpha}$$

or

$$\textbf{Eq. 9.22} \qquad \frac{\alpha}{1-\alpha} = \text{antilog}\ (\text{p}K_a - \text{pH})$$

From Equation 9.22, one can calculate the fraction or percentage of absorbable and nonabsorbable form of a weak base if the pH condition at the site of drug absorption is known. Figure 9.10 shows the pK_a values of several drugs and the relative acid or base strength of these compounds.

The relationship between pH and pK_a and the extent of ionization is given by Equations 9.13 and 9.22 for weak acids and weak bases, respectively. Accordingly, most weak acidic drugs are predominantly in the un-ionized form at lower pH of the gastric fluid and, therefore, may be absorbed from the stomach as well as from the intestine. Some very weak acidic drugs, such as phenytoin and many barbiturates, the pK_a values of which are greater than 8.0, are essentially un-ionized at all pH values. Therefore, for these weak acidic drugs, transport is more rapid and independent of pH, provided that the un-ionized form is lipophilic or nonpolar. Furthermore, it is important to note that the fraction un-ionized changes dramatically only for weak acids with pK_a values between 3 and 7. Therefore, for the weak acids, a change in the rate of transport with pH is expected, as shown in Figure 9.11 (13). Although the transport of weak acids with pK_a values less than 3.0 should theoretically depend on pH, the fraction un-ionized is so low that transport across the gut membrane may be slow even under the most acidic conditions.

Most weak bases are poorly absorbed, if at all, in the stomach, because they are present largely in the ionized form at pH 1–2. Codeine, a weak base with a pK_a of

approximately eight, will have about 1 in every 1 million molecules in its un-ionized form at gastric pH 1.0. Weakly basic drugs with a pK_a of less than four, such as dapsone, diazepam, and chlordiazepoxide, are essentially un-ionized through the intestine. Strong bases, which are those with pK_a values between 5 and 11, show pH-dependent absorption. Stronger bases, such as guanethidine

(pK_a > 11) are ionized throughout the gastrointestinal tract and tend to be poorly absorbed.

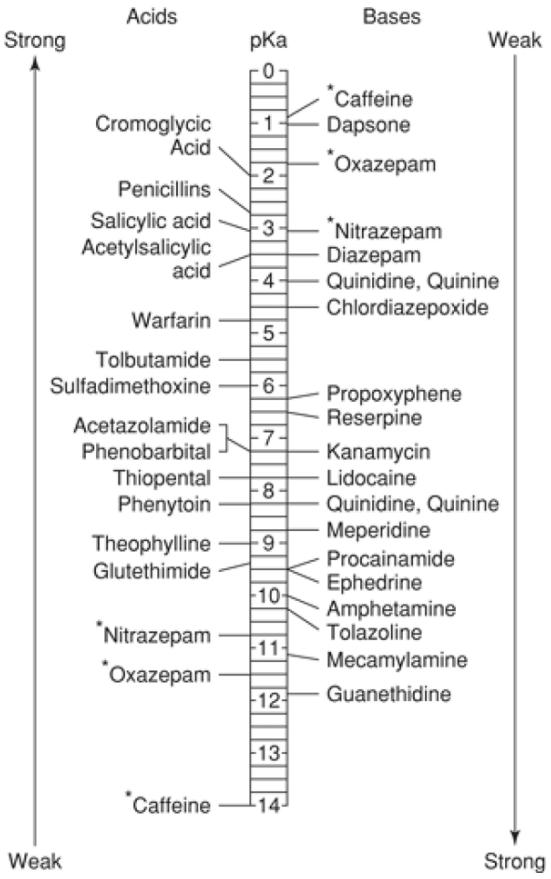

Fig. 9.10. The pK_a values of certain acidic and basic drugs. Drugs denoted with an asterisk are amphoteric (13). (From Rowland M, Tozer T. Clinical Pharmacokinetics: Concepts and Application, 2nd Ed. Philadelphia: Lea and Febiger, 1989, with permission.)

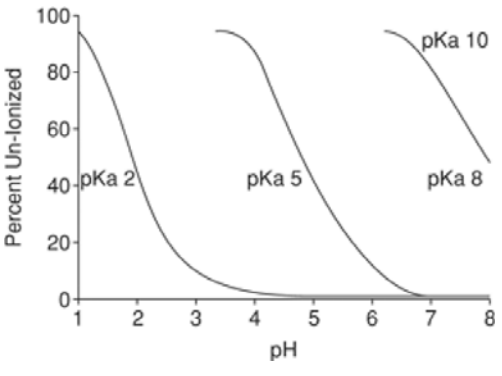

Fig. 9.11. For very weak acids, pK_a values greater than 8.0 are predominantly un-ionized at all pH values between 1.0 and 8.0. Profound changes in the un-ionized fraction occur with pH for an acid with a pK_a value that lies within the range of 2.0 to 8.0. Although the fraction un-ionized of even strong acids increases with hydrogen ion concentration, the absolute value remains low at most pH values shown. (From Rowland M, Tozer T. Clinical Pharmacokinetics: Concepts and Application, 2nd Ed. Philadelphia: Lea and

Febiger, 1989, with permission.)

Table 9.1. Comparison of Gastric Absorption of Acids and Bases at pH 1 and 8 in the Rat

	pK_a	% Absorbed at pH 1	% Absorbed at pH 8
Acids			
5-Sulfosalicylic acid	<2.0	0	0
5-Nitrosalicylic acid	2.3	52	16
Salicylic acid	3.0	61	13
Thiopental	7.6	46	34
Bases			
Aniline	4.6	6	56
p-Toluidine	5.3	0	47
Quinine	8.4	0	18
Dextromethorphan	9.2	0	16

The evidence of the importance of dissociation in drug absorption is found in the result of studies in which pH at the absorption site is changed (Tables 9.1 and 9.2). Table 9.2 clearly shows the decreased absorption of a weak acid at pH 8.0 compared to pH 1.0 (13). On the other hand, an increase to pH 8.0 promotes the absorption of a weak base with practically nothing absorbed at pH 1.0. The data in Table 9.2 also permits a comparison of intestinal absorption of acidic and basic drugs from buffered solutions ranging from pH 4.0 to 8.0 (14). These results are in agreement with the pH-partition hypothesis.

The pH-partition theory provides a basic framework for the understanding of drug absorption and, sometimes, is an oversimplification of a more complex process. For example, experimentally observed pH–absorption curves are less steep (Fig. 9.12) than that expected

theoretically and are shifted to higher pH values for bases and lower pH values for acids. This deviation, observed experimentally, has been attributed by several investigators to factors such as limited absorption of ionized species of drugs, the presence of an unstirred diffusion layer adjacent to the cell membrane, and a difference between lumenal pH and cell membrane surface pH.

Table 9.2. Comparison of Intestinal Absorption of Acids and Bases in the Rat at Several pH Values

		% Absorbed from Rat Intestine			
	pK_a	pH 4	pH 5	pH 7	pH 8

Acids					
5-Nitrosalicyclic acid	2.3	40	27	0	0
Salicylic acid	3.0	64	35	30	10
Acetylsalicylic acid	3.5	41	27	—	—
Benzoic acid	4.2	62	36	35	5
Bases					
Aniline	4.6	40	48	58	61
Amiopyrine	5.0	21	35	48	52
p-Toluidine	5.3	30	42	65	64
Quinine	8.4	9	11	41	54

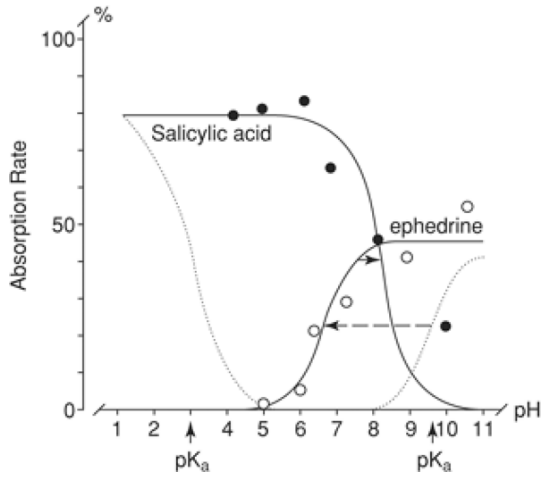

Fig. 9.12. Relationship between absorption rates of salicylic acid and ephedrine and bulk phase pH in the rat small intestine in vivo. Dashed lines represent curves predicted by the pH-partition theory in the absence of an unstirred layer. (From Winne D. The influence of unstirred layers on intestinal absorption in intestinal permeation. In: Kramer M, Lauterbach F, eds. Workshop Conference Hoechest, vol 4. Amsterdam: Excerpta Medica, 1977:58–64, with permission.)

Lipid Solubility

Partition coefficient

Some drugs may be poorly absorbed after oral administration even though they are available

predominantly in the un-ionized form in the gastrointestinal tract. This is attributed to the low lipid solubility of the un-ionized molecule. A guide to lipid solubility or lipophilic nature of a drug is provided by a property called the partition coefficient (*P*). This parameter therefore influences the transport and absorption processes of drugs, and it is one of the most widely used properties in quantitative structure–activity relationships.

The movement of molecules from one phase to another is called partitioning. Drugs partition themselves between the aqueous phase and lipophilic membrane. Preservative emulsions partition between the water and oil phases; antibiotics partition from body fluids to microorganisms; and drug and other adjuvants can partition into the plastic and rubber stoppers of containers. It therefore is important that this process is understood.

If two immiscible phases are placed adjacent to each other, with one containing a solute soluble in both phases, the solute will distribute itself between two immiscible phases until equilibrium is attained; therefore, no further transfer of solute occurs. At equilibrium, the chemical potential of the solute (free energy of the solute in solvent) in one phase is equal to its chemical potential in the other phase. If we consider an aqueous (w) and an organic (o) phase, we write according to theory:

Eq. 9.23 $$\mu_w^\Theta + RT \ln a_w = \mu_o^\Theta + RT \ln a_o$$

where *a* represents the activity coefficient of a solute (effect of solute concentration on intersolute interactions). Rearranging Equation 9.23 yields

Eq. 9.24 $$\frac{\mu_w^\Phi - \mu_o^\Phi}{RT} = \ln \frac{a_w}{a_o}$$

The term on the left side of Equation 9.24 is a constant at a given temperature and pressure. Therefore,

Eq. 9.25 $$\frac{a_w}{a_o} = \text{constant or } \frac{a_o}{a_w} = \text{constant}$$

These constants are the partition (*P*) or distribution coefficients (*D*). Because most drugs are ionic, their partition coefficients are pH-dependent and usually reported at pH 7.4 and are therefore appropriately called distribution coefficients. If the solute under consideration forms an ideal solution in either phases or in solvent, the activity coefficient can be replaced by the concentration term, and Equation 9.25 becomes

Eq. 9.26 $$P = \frac{C_o}{C_w}$$

Equation 9.25 is used conventionally to calculate the partition coefficient of a drug. In Equation 9.25, C_o, the concentration of drug in the organic or oil phase, is divided by the concentration in the aqueous phase. The greater the value of *P*, the higher the lipid solubility of the solute. It has been demonstrated for several systems that the partition coefficient can be approximated by the solubility of the solute in the organic phase divided by the solubility in the aqueous phase. Therefore, the partition coefficient is a measure of the relative affinities of the solute for an aqueous or nonaqueous or oil phase. The effect of lipid solubility and, hence, the partition coefficient on the absorption of a series of barbituric acid derivatives is shown in Table 9.3. The term partition coefficient is more commonly expressed exponentially as log *P*.

Table 9.3. Comparison of Barbiturate Absorption in Rat Colon and Partition Coefficient (Chloroform/Water) of Undissociated Drug

Barbiturate	Partition Coefficient	% Absorbed
Barbital	0.7	12
Apobarbital	4.9	17
Phenobarbital	4.8	20
Allylbarbital	10.5	23
Butethal	11.7	24

Cyclobarbital	13.9	24
Pentobarbital	28.0	30
Secobarbital	50.7	40
Hexethal	>100	44

It must be clearly understood that even though drugs with greater lipophilicity and, therefore, partition coefficient are better absorbed, it is imperative that drugs exhibit some degree of aqueous solubility. This is essential, because the availability of the drug molecule in a solution form is a prerequisite for drug absorption and the biological fluids at the site of absorption are aqueous in nature. Therefore, from a practical viewpoint, drugs must exhibit a balance between hydrophilicity and lipophilicity. This factor is always taken into account while a chemical modification is being considered as a way of improving the efficacy of a therapeutic agent.

Examples of polar or hydrophilic molecules that are poorly absorbed following oral administration and, therefore, must be administered parenterally include gentamicin, ceftrixine, and streptokinase. Lipid-soluble drugs with favorable partition coefficients generally are well absorbed after oral administration. Very often, the selection of a compound with higher partition coefficient from a series of research compounds provides improved pharmacological activity. Occasionally, the structure of an existing drug is modified to develop a similar pharmacological activity with improved absorption. Chlortetracycline, which differs from tetracycline by the substitution of a chlorine at C-7, substitution of an n-hexyl (Hexethal) for a phenyl ring in phenobarbital, or replacement of the 2-carbonyl of pentobarbital with a 2-thio group (thiopental) are examples of enhanced lipophilicity (Fig. 9.13).

It is important to note that even a minor molecular modification of a drug also may promote the risk of altering the efficacy and safety profile of a drug. For this reason, medicinal chemists prefer the development of a lipid-soluble pro-drug of a drug with poor oral absorption characteristics.

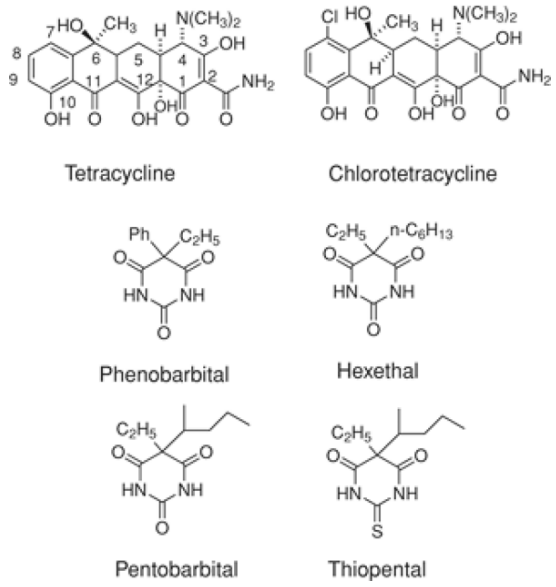

Fig. 9.13. Drug pairs in which chemical modification enhances lipophilicity.

Estimation of Drug Absorption

When different chemical entities are being investigated for their potential as drug candidates, dosage form performance is one of the possible contributing factors to poor bioavailability. Historically, the concept of bioavailability is closely, if not solely, associated with dosage form performance. Because poor bioavailability in particular is increasingly an issue in the drug discovery and development process, application of the bioavailability principles and techniques has been extended to include animal studies in the selection of potential drug candidates for their full development.

As the drug travels down the gastrointestinal tract following its oral administration, part of the dose may not be available for absorption for a number of reasons. These include its chemical degradation, physical inactivation because of binding and complexation with substances in the intestinal tract, incomplete dissolution of the dosage form, microbial biotransformation, insufficient contact time in the gastrointestinal tract, poor solubility and poor permeability across the gastrointestinal mucosa, or metabolism within the gut wall. Of the absorbed dose, some of the drug may be metabolized in transit during its first passage through the gut wall and the liver. Unchanged drug that reaches the hepatic portal vein may be extracted by the liver via biotransformation or biliary excretion. Thus, the bioavailability (f) of an orally administered dose of a drug comprises the individual fractions that survive several barriers encountered by the drug during its first passage from gut lumen to the sampling site, and it is described (19), in general, by the following relationship.

Eq. 9.27 $$f = F_a F_g F_b$$

where F_a, F_g, and F_b are the fractions of intact drug absorbed (F_a) that escape irreversible elimination as the drug passes sequentially from the gastrointestinal tract across the gut wall (F_g) and traverses the liver (F_b) into systemic circulation. Thus, bioavailability of a drug can be equal to or less than the fraction absorbed, depending on the extent of metabolism and loss during the absorption process. Therefore, poor blood levels of a drug can be a consequence of poor absorption or of good absorption accompanied by extensive metabolism.

There appear to be several common misperceptions (20) regarding the nature of absorption. Among these is that intestinal absorption, permeability, fraction of drug absorbed, and in some cases, even bioavailability are equivalent properties and, consequently, can be used interchangeably. Another common misperception is that absorption, permeability, and so on are discrete fundamental properties of a drug molecule and can be predicted solely from its chemical structure. In reality, however, drug absorption is quite a complex process dependent on drug properties such as solubility and permeability, formulation factors, and physiological variables such as regional permeability differences, pH,

luminal and mucosal enzymology, and intestinal motility, among others.

Publication of so-called “Rule of Five” (21) has generated widespread interest in regards to applying calculated physicochemical properties in the drug discovery process to separate out poor drug candidates before these go into clinical trials. According to the Rule of Five, poor intestinal absorption is associated with and attributed to the molecule possessing any two of the following properties: molecular weight greater than 750 daltons, number of hydrogen bond donors greater than five, number of hydrogen bond acceptors greater than 10, and calculated log P (partition coefficient) greater than five. These guidelines have been proven to be very useful for approximate predictions of intestinal drug absorption. The critical role of lipid solubility in drug absorption is a major guiding principle in the drug discovery and development process. Because the lipid-solubility of a drug molecule is the sum of the individual partition coefficients for each of its functional groups (see Chapter 2), the prediction of lipid solubility (c log P) can be estimated.

A recent examination (22) of the relationship of molecular surface properties with biological performance of a molecule has been revealing. Most notably, it has been demonstrated that polar surface area (PSA) of a drug molecule has a strong correlation predicting drug transport from human intestine and across the drug membrane. The PSA is defined as the sum of the Van der Waals surface areas for the polar atoms, oxygens, nitrogens, and attached hydrogen atom (or the number of H-bond donors and H-bond acceptors). (See http://www.molinspiration.com for calculating the PSA). The PSA is a major determinant for oral absorption and brain penetration of drugs that are transported by the transcellular route (movement across cell membranes). This property should be considered in the early phase of drug screening. Another related parameter, dynamic PSA (PSAd), has surfaced (23) as a parameter of value in predicting membrane permeability and oral absorption in humans. Interpolation of the sigmoidal plot for 20 selected compounds suggests that when the PSAd

is greater 140 Å^2, incomplete absorption (<10%) results, and when the PSAd value is less than 60 Å^2, drug absorption will be in excess of 90%.

A drug's absorption, as reflected in its bioavailability, is a fairly complex process, and although it is related to the drug structure, it is related in a complex manner. Failure to appreciate and understand these complexities, in an attempt to build models, may provide a prediction of marginal and low confidence. Both fraction absorbed and bioavailability are measures of the extent of absorption. Permeability, on the other hand, is related to the rate of absorption (20):

$$J = P_e \cdot SA \cdot dC \qquad \textbf{Eq. 9.28}$$

where J is the absorptive flux and is equal to the permeability (P_e) of intestinal mucosa to the drug, the surface area available (SA), and the drug concentration gradient (dC) across the mucosa. Factors that can influence permeability include structural characteristics of a drug, which include size, shape, solubility, charge, and surface area.

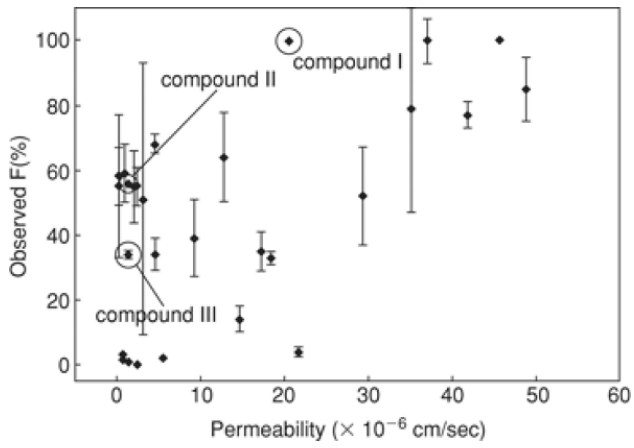

Fig. 9.14. Poor correlation between oral bioavailability and permeability as measured using Caco-2 cells for three compounds. (From Burton P, Goodwin J, Vidamas T, et al. Predicting drug absorption: how nature made it a difficult problem. J Pharm Exp Ther 2002;303:889–895and from Hilgers AR, Smith DP, Biermacher JJ, et al. Predicting oral absorption of drugs: a case study with novel class of antimicrobial agents. Pharm Res 2003;20:1149–1155; with permission.)

It has been argued (25), on a theoretical basis, that a fundamental relationship exists between the rate measured as a permeability coefficient and the extent of absorption. This has lead to the greater interest and increasing use of the in vitro permeability model to serve as an experimental surrogate for predicting oral absorption potential of drug candidates in drug discovery programs. Additionally, although in some instances (24,25) it has been possible to directly correlate absorption with permeability, more often poor correlation exists (20,26), as illustrated in Figure 9.14. At times, good absorption is observed for poorly permeable compounds. These poorly permeable but well-absorbed compounds exhibit high aqueous solubility, generally exceeding 2.5 mg/mL (20,22). This suggests that aqueous solubility may help to compensate for the poor in vitro permeability observed.

Estimating the extent of oral drug absorption and variation in drug absorption, therefore, can be of great value in the selection of a potential therapeutics agent and in identifying ways to optimize the oral drug delivery in patients. This may be facilitated by developing the predictive oral drug delivery models. In turn, these models permit the estimation of drug absorption without performing in vivo studies in humans and impart better understanding of the rate-limiting processes affecting drug absorption, which can assist in developing strategies for the development of oral drug delivery. There are three physical barriers to drug absorption: the dissolution resistance, the aqueous boundary layer resistance, and the membrane resistance (27,29).

Although physicochemical properties, such as solubility and permeability, and other properties, such as metabolic

stability and toxicity, may be important individually, the interrelationship of these properties is what

eventually determines the in vivo performance of a drug. In particular, the role of solubility is dependent on the potency, which will determine the dose. In other words, low solubility may be problematic for a high-dose drug; however, it may be more acceptable for a low-dose drug.

Measurement of Permeability

Although a variety of models (subcellular fraction, cell monolayer model, isolated intestinal tissue, and intestinal perfusion) are available to predict the permeability of a drug, the cell monolayer model and rat intestinal perfusion techniques are the most commonly used techniques.

Cell Monolayer

These models consist of cells grown on permeable inserts. Transport of compounds across the cell monolayer can be used to quantitate the permeability of a new chemical entity in a rapid manner. One of the most popular cell lines is Caco-2, derived from human colon adenocarcinoma cells. The monolayer exhibits ion conductance and possesses transepithelial electrical resistance indicative of fully formed tight junctions that restrict the paracellular transport of a chemical entity. Although Caco-2 cells are the most commonly used cells, Madin-Darby Canine Kidney (MDCK) cells are becoming more widespread in use, in part because of the shorter culture time (4–7 days versus 21–30 days for Caco-2 cells) needed for their use in permeability experiments.

Excellent correlation for permeability coefficient between MDCK and Caco-2 cells was observed for 55 compounds with known human intestinal absorption. Regardless of the type of cells used in determining permeability measurement, establishing the correlation between the permeability coefficient and the fraction of drug absorbed in vivo validates this approach.

Several clones of HT 29 cells have been used (30) to study different aspect of intestinal drug absorption. An enterocytic HT 29 clone, HT 29-18-C1, was proposed as a model to study intestinal permeability. The limitation of the cells is that these cells grow very slowly, and large number of cultured failed to develop acceptable barrier characteristics.

Biopharmaceutical Drug Classification

It is clear from the discussion thus far that the physicochemical properties, such as drug solubility and drug permeability, play a critical role in the drug absorption process. The following biopharmaceutical drug classification system (30,32) has been developed to optimize the development of an oral dosage form taking into consideration two rate-limiting factors, drug permeability and drug dissolution, the latter of which is related to drug solubility.

Class I Drugs (High Solubility and High Permeability)

Class I drugs provide both rapid dissolution and high membrane permeation. This class includes small molecule hydrophilic drugs that are not ionized in the gastrointestinal tract. Examples include acetaminophen, valproic acid, ketoprofen, dysopyramide, verapamil, propranolol, fluconazole, and metoprolol. Class I drugs are well absorbed and are affected by a limited set of interactions that alter drug absorption. Because gastric emptying frequently will control the rate of absorption for this class of drugs, interactions that delay gastric emptying will delay drug absorption. This can be important for class I analgesic drugs, for which a rapid rate of absorption and quick rise in the plasma level to within the therapeutic range is needed to alleviate pain quickly.

Class II Drugs (Low Solubility and High Permeability)

For immediate-release formulations of many poorly water-soluble drugs, the dissolution rate limits drug absorption. Along with this limitation, a greater impact on drug absorption will be observed with high oral doses. For example, the antifungal drug griseofulvin and the cardiac glycoside drug digoxin are both poorly water-soluble and possess similar dissolution profiles, which limit the rate of drug absorption. The extent of griseofulvin absorption, however, is incomplete for a typical dose of 500 mg, whereas a normal, 0.25-mg oral dose of digoxin usually provides a fairly complete absorption. Other examples are diazepam and nifedipine.

Any interactions that increase drug solubility and dissolution rate in the gastrointestinal tract will exert a positive effect on the gastrointestinal absorption of this class of drugs. The absorption of this class of drugs often is enhanced in proportion to the fat content of the coadministered meal. This is attributed to the increased gastrointestinal fluid volume from a coadministered meal, stimulated gastrointestinal secretions, and biliary solubilization effects that increase the dissolution rate.

Furthermore, increased gastric residence time as a function of the caloric density permits greater time for drug dissolution.

Class III Drugs (High Solubility and Low Permeability)

For drugs possessing high water solubility, the intestinal membrane permeation rate often is the rate-limiting step in drug absorption from immediate-release dosage forms. Many drugs in this class (e.g., acyclovir and chloramphenicol) also show region-dependent absorption with better absorption in the upper small intestine. Therefore, any interactions that compromise upper intestinal absorption may result in a significant decrease in oral bioavailability. Consequently, these drugs show a sharp decrease in absorption with a coadministered meal that is independent of fat content. Meals tend to decrease the absorption of some drugs in this category as a result of simple physical barrier that compromises the availability of drug molecules to the upper intestinal membrane.

Class IV Drugs (Low Solubility and Low Permeability)

Poor aqueous solubility may not necessarily impart high lipophilicity and, therefore, high membrane permeation

for a drug. Class IV drugs possess both low solubility and low permeability, both of which are undesirable for good drug absorption. Examples include furosemide and paclitaxel. Drugs in this class, however, still may be administered orally if the plasma concentrations obtained are sufficient to produce the desired therapeutic effect and the drugs do not possess a narrow therapeutic index.

Role of Transporters in Drug Absorption

The oral route of drug administration remains the most popular and convenient route of administration, despite its many shortcomings and challenges. Although the advantages associated with oral administration far outweigh the limitations, a major limitation for oral absorption relates to the interactions of drugs with intestinal membrane transporters and metabolizing enzymes (33). The rapidly growing awareness of transporters affecting the rate and extent of intestinal drug absorption has attracted attention in drug discovery and development. Intestinal membrane transporters affecting the rate of oral absorption are the influx peptide transporters (PepT1, PHTs, and HPT-1), bile salt transporter, phosphate transporter, nucleoside transporters, organic cation/anion transporters (OATP and OCTP), and fatty acid transporters. Transporters affecting drug efflux into the intestinal lumen include P-glycoprotein (P-gp), MRP2, BCRP, and MRP3. The primary intestinal enzyme affecting the absorption of drugs is CYP3A4, as well as the phase II enzymes, glutathione transferase, glucuronyltransferases, and sulfotransferases. Thus, inhibition of these membrane transporters and/or metabolizing enzymes and modulation of the expression of these membrane transporters and/or metabolizing enzymes are key factors affecting the rate and extent of drug absorption. Drug molecules recognized by OATP-B include bile acids, bilirubin and bilirubin glucuronides, estrogen and androgen sulfate conjugates, digoxin, pravastatin, fexofenadine, thyroid hormones, and other lipophilic organic anions. The PepT1 will transport peptide-like drugs, such as β-lactam antibiotics (penicillins and cephalosporins), angiotensin-converting enzyme inhibitors, rennin inhibitors, thrombin inhibitors, and di-/tripeptide pro-drugs of antivirals (valacyclovir).

Efflux Transporters

More recently (33,34,37), the role of efflux transporters in influencing the permeability as well as the overall bioavailability of drugs has emerged and gained considerable attention. Among these transporters is P-gp, which is expressed on the luminal surface of normal intestinal mucosa. Unlike absorptive transporters that increase the uptake of a substrate from intestinal lumen, P-gp impedes uptake by returning the portion of drug entering the mucosa back to the lumen in a concentration-dependent manner. Two types of P-gp have been observed in mammals: drug-transporting P-gp, and phospholipid-transporting P-gp.

The localization suggests that P-gp functionally can protect the body against toxic xenobiotics by excreting these compounds into bile, urine, and the intestinal lumen and by preventing their accumulation in brain and testes. Thus, P-gp may play a significant role in drug absorption and disposition in human and animals. An increasing number of drugs have been shown to be substrate for P-gp, including HIV protease inhibitors and verapamil, which also is an inhibitor of P-gp and, thus, can increase the intestinal permeability of other drugs

P-glycoprotein is a cell membrane–associated protein that transports a variety of substances. It has

been studied extensively as a mediator of multidrug resistance in cancer, but only recently has the role of P-gp expressed in normal tissue as a determinant of drug pharmacokinetics and pharmacodynamics been investigated.

P-glycoprotein is 170-kDa protein product of the *MDRI* gene. It is a dimer consisting of 1280 amino acids, with 12 transmembrane segments and two adenosine 5′-triphosphate (ATP)–binding domains. P-glycoprotein requires binding of ATP to both ATP-binding domains for the transport function. A proposed mechanism by which P-gp secretes substrates is illustrated in Figure 9.15.

Unlike most other transport proteins that recognize a few structurally similar substrates, P-gp recognizes a broad range of pharmacologically and structurally diverse compounds. In general, P-gp substrates are large, lipophilic compounds that tend to be cationic at physiological pH. An evaluation of 100 structurally diverse compounds revealed that P-gp substrates have a relatively high number of electron-donating groups (i.e., O, N, S, F, Cl, or groups with a π-electron orbital of an unsaturated system).

In recent years, the role of drug transporters in the intestinal epithelium as major determinants of drug

absorption has been recognized, and P-gp and other transporters have been implicated in modulating the absorption and/or intestinal elimination of drugs. Reduction in the small intestinal transit time (SITT) of a drug can decrease the peak plasma concentration and area under the plasma concentration–time curve, the rate and extent of absorption, and therefore, the bioavailability of a drug. Another potential consequence of increased transit has been proposed for digoxin and, possibly, other drugs that are substrate for P-gp in the small intestine. Because intestinal permeability of such compounds may depend on the relative activity of P-gp in the intestine, factors affecting this activity also may affect absorption. One determinant is drug concentration, which will influence the degree of saturation of the transporters. Another consideration is the specific activity of the transporters with the intestine itself. Evidence suggests that P-gp is not homogenously distributed throughout the intestinal tract but, rather, increases in abundance from the proximal to the distal small intestine. Therefore, drugs that may be substrate for P-gp but that are partly permeable may be well absorbed in the duodenum and proximal jejunum, which have little P-gp. Drugs that inhibit P-gp can alter the absorption, disposition, and elimination of coadministered drugs and can enhance bioavailability or cause unwanted drug–drug interactions.

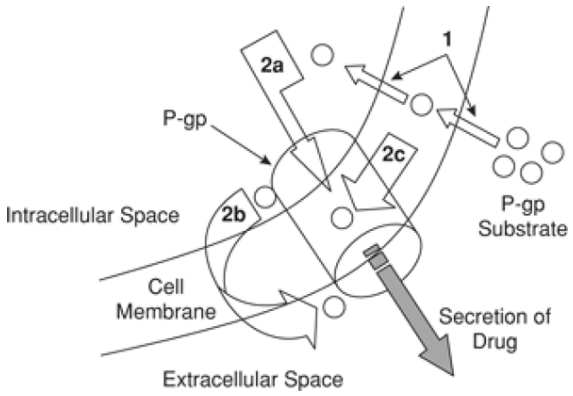

Fig. 9.15. Proposed mechanism by which P-glycoprotein (P-gp) secretes substrates. (1) Passive drug uptake across cell membrane. (2a) Formation of hydrophobic channel (pore) between the intracellular and extracellular space. (2b) Flippase activity, whereby the drug is flipped from the inner leaflet to the outer leaflet of the cell membrane. (2c) "Vacuum cleaner model," in which drug interacts with P-gp in the lipid bilayer and is subsequently secreted back into the extracellular space. (From Matheney C, Lamb M, Brouwer K, et al. Pharmacokinetics and pharmacodynamic implications of P-glycoprotein modulation. Reviews of Therapeutics 2001;21:778–796; with permission.)

Pro-drugs

Pro-drugs are designed to improve the permeability and oral absorption of the parent drug. They are more lipid soluble than the parent drug and should be rapidly converted to the parent compound during absorption from the gut wall, liver, or site of action. Examples of pro-drugs include pivampicillin, the pivalate ester pro-drug of ampicillin that is more lipid soluble, and therefore, more efficiently absorbed than the parent compound (35); valacyclovir, a L-valyl ester pro-drug of acyclovir; lisdexamfetamine, a L-lysinylamide pro-drug of amphetamine that is slowly hydrolyzed to amphetamine, and methyldopa, a pro-drug of methyldopamine that is decarboxylated in the brain to methyldopamine. The recognition that di- and tripeptides are transported from the intestine by their PepT1 transporter has led to the development of pro-drugs designed as di- or tripeptide analogues (36). For example, the dipeptidyl analogue of methyldopa increased the intestinal absorption of methyldopa by more than 20-fold.

Factors Affecting the Absorption of Drugs from Solid Dosage Forms and Suspensions

When a drug is administered orally via tablet, capsule, or suspension, the rate of absorption often is controlled by how fast the drug particles dissolve in the fluid at the site of administration. Hence, the dissolution rate often is the rate-limiting (slowest) step in the following sequence:

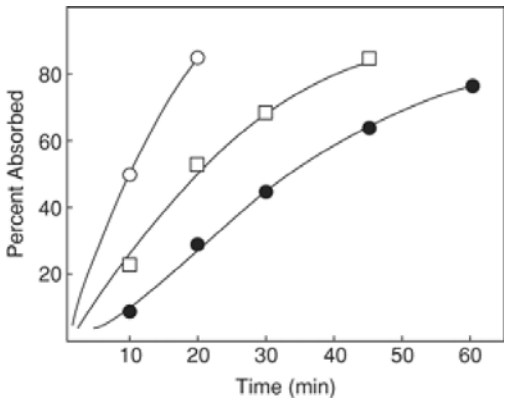

Fig. 9.16. Absorption of aspirin after oral administration of a 650-mg dose in solution (○), in buffered tablets (□), or in regular tablets (•). (From Kwan KC. Oral bioavailability and first-pass effects. Drug Metab Drug Dispos 1997;25:1329–1336, with permission.)

$$\text{Solid drug} \xrightarrow[\text{Step I}]{\text{Dissolution}} \text{Drug in solution} \xrightarrow[\text{Step II}]{\text{Absorption}} \text{Drug in systemic circulation}$$

If the dissolution of the drug is slow or controlling the rate of absorption (Step I), then dissolution is the rate-determining step. Factors controlling dissolution, such as solubility, ionization, or surface area, will then control the overall dissolution process. Figure 9.16 describes the absorption of aspirin from solution and from two different types of tablets.

It is clear from Figure 9.16 that aspirin absorption is more rapid from solution than from tablet formulations. This rapid absorption of aspirin is an indication that the rate of absorption is dissolution rate limited. A general relationship describing the dissolution of a drug was first reported by Noyes and Whitney (38). The equation derived by those authors is as follows:

$$\text{Eq. 9.29} \qquad \frac{dc}{dt} = KS(C_s - C_t)$$

where dc/dt is the dissolution rate, K is a constant, S is the surface area of the dissolution solid, C_s is the equilibrium solubility of drug in the solvent, and C is the concentration of drug in the solvent at time t.

The constant K in Equation 9.29 has been shown to be equal to D/h, where D is the coefficient of the dissolving material of the drug and h is the thickness of the diffusion layer surrounding the dissolving solid particles. This diffusion layer is a thin, stationary film of a solution adjacent to the surface of a solid particle (Fig. 9.17) and is saturated with drug (4); in other words, the drug concentration in the diffusion layer is equal to C_s, the equilibrium solubility. The term $(C_s - C_t)$ in Equation 9.29 represents the concentration gradient for the drug

between the diffusion layer and the bulk solution. If dissolution is the rate-limiting step in the absorption process, the term C_t in Equation 9.29 is negligible compared to C_s. Under this condition. Equation 9.29 is reduced to

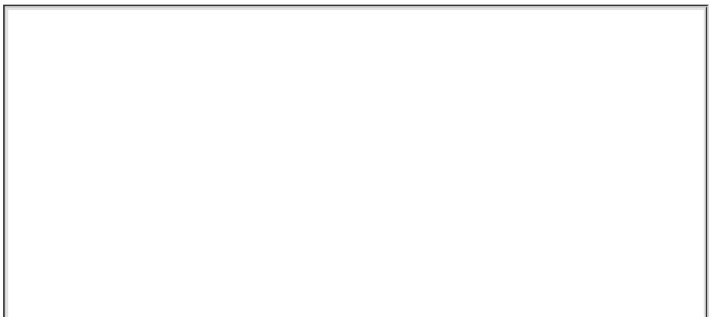
$$\frac{dc}{dt} = \frac{DSC_s}{h} \qquad \textbf{Eq. 9.30}$$

Equation 9.30 describes a diffusion-controlled dissolution process (4). It is visualized that when solid drug particles are introduced to the fluids at the absorption sites, the drug promptly saturates the diffusion layer (Fig. 9.17). This is followed by the diffusion of drug molecules from the diffusion layer into the bulk solution, which is instantly replaced in the diffusion layer by molecules from the solid crystal or particle. This is a continuous process. Although it oversimplifies the dynamics of the dissolution process, Equation 9.30 is a qualitatively useful equation and clearly indicates the effects of some important factors on the dissolution and, therefore, the absorption rate of drugs. When dissolution is the rate-limiting factor in the absorption, then bioavailability is affected. These factors are listed in Table 9.4.

Table 9.4. The Effect of Changing Parameters from the Dissolution Equation on the Rate of Solution

Equation Parameter	Comments	Effect on Rate of Solution
D (diffusion coefficient of drug)	May be decreased in presence of substances that increase viscosity of the medium	(–)
A (area exposed to solvent)	Increased by micronization and in “amorphous” drugs	(+)
δ (thickness of diffusion layer)	Decreased by increased agitation in gut or flask	(+)
C_s (solubility in diffusion layer)	That of weak electrolytes altered by change in pH by use of appropriate drug salt or buffer ingredient	(–) (+)
C (concentration in bulk)	Decreased by intake of fluid in stomach, by removal of drug by partition or absorption	(+)

The Noyes-Whitney equations (Eqs. 9.29 and 9.30) demonstrate that the equilibrium solubility (C_s) is one of the major factors determining the rate of dissolution. Changes in the characteristics of solvents, such as pH, affecting the solubility of the drug, affect its dissolution rate. Similarly, the use of a different salt or other physicochemical form of a drug, which exhibits a solubility different from the parent drug, usually affects the dissolution rate. Increasing the surface area of a drug exposed to the dissolution medium, by reducing the particle size, usually increases the dissolution rate. In the discussion to follow, some of the more important factors affecting dissolution and, therefore, absorption are presented in greater detail.



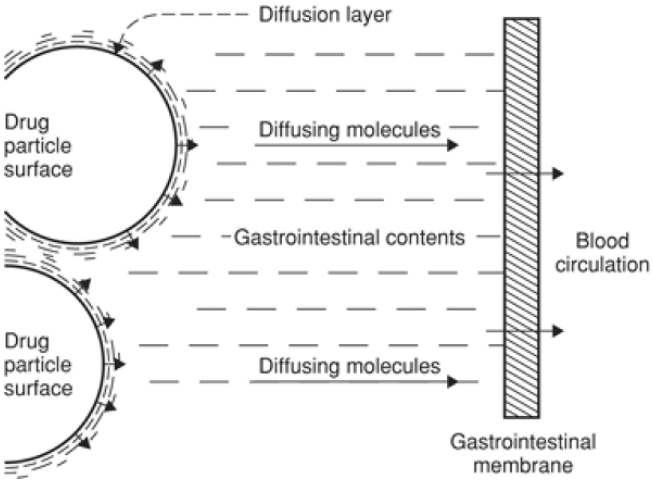


Fig. 9.17. Dissolution from a solid surface.

Dissolution

pH and Solubility of Weak Acids and Bases

Solubility is another factor determining the rate of dissolution. As solubility increases, so does the dissolution rate. One way of increasing solubility is to use salts. Salts of weak acids and weak bases generally have much higher aqueous solubility than the free acid or base; therefore, if the drug can be given as a salt, the solubility can be increased, and we should have improved dissolution (Fig. 9.18). This factor can lead to quite different peak plasma concentrations after oral administration.

The solubility of weak acids and bases is a function of the pH of the medium. Therefore, differences in the dissolution

P.225

rate are expected to occur in different regions of the gastrointestinal tract. The solubility of weak acid is obtained by

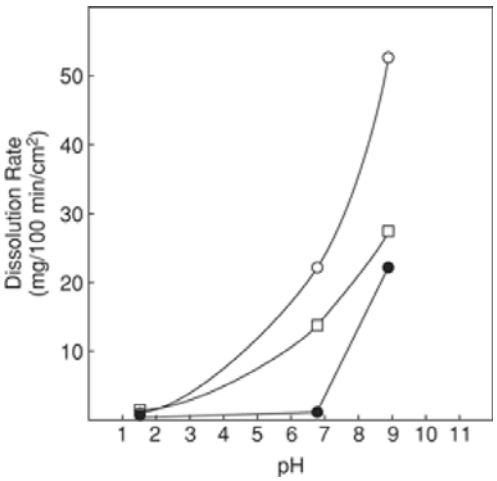

Fig. 9.18. The pH-dependent dissolution of salicylic acid (○), benzoic acid (□), and phenobarbital (•). (From Gibaldi M. Biopharmaceutics and Clinical Pharmacokinetics, 4th Ed. Philadelphia: Lea and Febiger, 1991, with permission.)

Eq. 9.31 $C_s = [HA] + [A^-]$

where [HA] is the intrinsic solubility of the un-ionized acid (i.e., C_o) and [A^-] is the concentration of its anion, which can be expressed in terms of its dissociation constant, K_a, and C_o; that is,

$$\textbf{Eq. 9.32} \qquad C_s = C_o + \frac{K_a C_o}{[H^+]}$$

Analogously, the solubility of a weak base is obtained by

$$\textbf{Eq. 9.33} \qquad C_s = C_o + \frac{C_o[H^+]}{K_a}$$

By substituting Equations 9.31 and 9.32 into Equation 9.30 for the term C_s, the following dissolution rate equations are obtained:

For weak acids:

$$\textbf{Eq. 9.34} \qquad \frac{dc}{dt} = \frac{K'(C_o + K_a C_o)}{[H^+]}$$

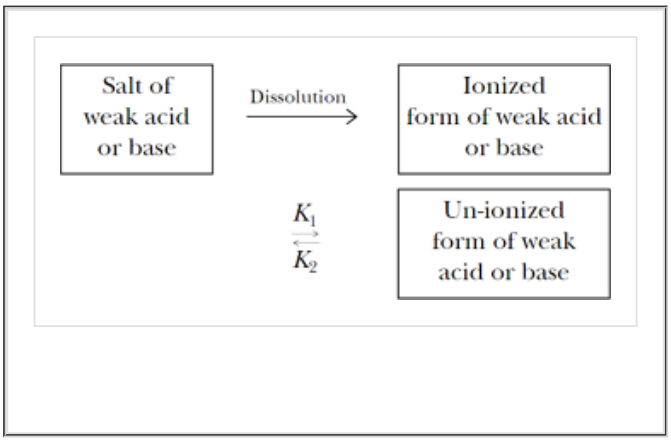
or

$$\textbf{Eq. 9.35} \qquad \frac{dc}{dt} = \frac{K' C_o(1 + K_a)}{[H^+]}$$

and for a weak base:

$$\textbf{Eq. 9.36} \qquad \frac{dc}{dt} = \frac{K' C_o(1 + [H^+])}{K_a}$$

Equations 9.34 through 9.36 show that K' is equal to DS/h. Equations 9.35 and 9.36 clearly suggest that the dissolution rate of weak bases decreases with increasing pH. Hence, the dissolution rate of weak bases is optimum in gastric fluid, but for weak acids, it is at a minimum. Furthermore, the dissolution rate of weak acids increases as the solid drug particles move to the more alkaline regions of the gastrointestinal tract. Figure 9.18 illustrates the dissolution rates of weak acids as a function of pH (39). The absorption of a salt of weak acid or base can be explained by using the following figure:



where K_1 and K_2 represent the rate constants associated with the formation of un-ionized and ionized species of a compound, respectively. The ratio of these two rate constants represents the dissociation constant of a compound. The absorption of the un-ionized species of a molecule disturbs the equilibrium of the process. To regain the equilibrium, some of the ionized species, therefore, is converted into un-ionized species, which are then absorbed through the membrane. This process, being a continuous one, permits the absorption of the un-ionized species to take place. Therefore, a drug molecule will eventually be absorbed.

The relatively poor dissolution of weak acids at the pH of gastric fluid further diminishes the importance of the stomach as a drug absorption site. Although gastric absorption of weak acids may occur from solution, it is unlikely that much of the drug dissolves and is absorbed during the short residence time as a solid dosage form in the stomach. A study by Ogata et al. (40) proposed that the critical value of solubility that separates acidic drugs from the absorption sites (stomach or intestine) is approximately 30 mg/mL in 0.1 N HCl when 1 g of drug is administered orally. Those authors found that if the solubility of a drug is less than 3 mg/mL, practically no absorption occurs in the stomach. Changes in the gastric pH also alter the solubility of certain drugs and may affect the dissolution and absorption rates. A patient with achlorhydria has a higher gastric pH and absorbs aspirin more rapidly than a normal subject. On the other hand, similar differences were not observed with respect to the

absorption rates of acetaminophen, a much weaker acid, the solubility of which would be unaffected by changes in pH (41).

The relationships between dissolution rate and hydrogen ion concentration, described in Equations 9.35 and 9.36, are approximations and tend to overpredict the dissolution rate of both weak acids in the small intestine and weak bases in the stomach. In reality, the hydrogen ion concentration of the bulk is not equal to the hydrogen ion concentration of the diffusion layer.

Salts

The dissolution rate of a particular salt usually is different from that of a parent compound. Sodium or potassium salts of weak acids dissolve more rapidly than the free acid. The same is true with HCl or other salts of weak bases. Table 9.5

P.226

illustrates the dissolution rate differences between some weak acids and their sodium salts (39). The differences in the dissolution rates of salt and parent compound can be explained by taking into consideration the pH of the diffusion layer. At a given pH, regardless of salt or free acids/bases, a drug will have a fixed solubility. The classical dissolution equation predicts a slower dissolution of a salt of a drug, and the concept of a diffusion layer becomes useful.

Table 9.5. Dissolution Rate of Weak Acids and Their Sodium Salts

Compound	pK_a	Dissolution Rate (mg/100 min/cm^2) 0.1 N HCl pH 1.5	0.1 M Phosphate pH 6.8	0.1 M Borate pH 9.0
Benzoic acid	4.2	2.1	14	28
Sodium salt		980	1770	1,600
Phenobarbital	7.4	0.24	1.2	22
Sodium salt		~200	820	1,430
Salicylic acid	3.0	1.7	27	53
Sodium salt		1,870	2,500	2,420
Sulfathiazole	7.3	<0.1	~0.5	8.5
Sodium salt		550	810	1,300

For sodium or potassium salts of weak acids, the pH of the solution in a diffusion layer is greater than the pH of the diffusion layer for the corresponding weak acid. On the other hand, the pH of the solution in the diffusion layer for hydrochloride salts of weak bases is always smaller than the diffusion layer of the corresponding free base. Therefore, effective solubility and dissolution rate of soluble salts on drug absorption are available in the literature. The potassium salt of penicillin V yields a higher peak plasma concentration of antibiotic than the corresponding free acid (42). Sodium salts of barbiturates are reported by Anderson (43) to provide a rapid onset of sedation. Some salts have a lower solubility and dissolution rate than their parent compounds. Examples include aluminum salts of weak acids and pamoate salts of weak bases. In these particular examples, insoluble films of either weak acids or pamoic acid appear to form in the dissolving solids and further retard the dissolution rate.

Surface Area and Particle Size

The surface area per gram (or per dose) of a solid drug can be changed by altering the particle size. For example, a cube that is 1 cm on each side has a surface area of 6 cm^2. If this cube is broken into cubes with sides of 0.1 cm, the total surface area is 60 cm^2. If the particles are broken up by grinding, then irregular shapes with even larger surface areas are created. Generally, as the surface area increases, the drug will dissolve more rapidly. Therefore, many poorly soluble and slowly dissolving drugs currently are marketed in a micronized or microcrystalline form. The problems of low water solubility and particle size were not fully appreciated, but they have resulted in reducing the therapeutic dose of some drugs without sacrificing therapeutic efficacy. For example, since the original marketing of spironolactone, its dose has been reduced from 500 to 25 mg as a result of a reformulation that includes micronization. The bioavailability of digoxin increased from 40 to 80–97% by reducing the particle size from 100 to approximately 10 nm. A similar result has been obtained for griseofulvin.

Polymorphism

Many pharmaceutical solids can exist in two or more crystalline forms called polymorphs (44,45). Polymorphism is the ability of the same drug molecule to crystallize into more than one different crystal structure that has a different arrangement and/or conformation of molecules in the crystal lattice. However, once they are in the solution phase, polymorphs share a common form. The different arrangements of atoms within the crystal unit cell can have a profound effect on physical and chemical properties of the final crystallized compound and on the final drug product. Amorphous solids consist of disordered arrangements of molecules that do not possess a distinguishable crystal lattice. Solvates are crystalline solid adducts containing either stoichiometric or nonstoichiometric amounts of a solvent incorporated within the crystal structure (44,45). If the incorporated solvent is water, the solvates are commonly known as hydrates. Polymorphs and/or solvates of a pharmaceutical solid or pharmaceutical excipients (e.g., lactose) can have different physical and chemical properties, such as melting point, chemical reactivity, apparent solubility and dissolution rate. These properties of a drug substance can affect the intended shelf-life (stability), rate of dissolution, the bioavailability/bioequivalence of the drug product. A metastable (amorphous) pharmaceutical solid form can change crystalline structure or solvate/desolvate in response to changes in environmental conditions or shelf-life storage. When such differences in physical properties are sufficiently large, bioavailability is altered, and it often is difficult to formulate a bioequivalent drug product using a different polymorph. The Biopharmaceutics Classification criteria of high solubility and rapid dissolution should be considered in product development decisions when polymorphism exists. Drug substances with different physical form include warfarin sodium, famotidine, and ranitidine, and those with solvation or hydration state include terazosin hydrochloride, ampicillin, and cefadroxil.

Some drugs that exist as polymorphs may have different solubility properties and, thus, different dissolution characteristics. Chloramphenicol palmitate and ritonavir provide good examples of how polymorphism can influence drug dissolution and, thus, drug bioavailability. Chloramphenicol palmitate is a broad-spectrum antibiotic known to crystallize in at least three polymorphic forms and one amorphous (metastable) form, B. The most stable form, known as form A, is the polymorph that is marketed, whereas the metastable form B is approximately eight times more soluble than form A, thus providing an eightfold difference in bioavailability. This large difference in bioavailability creates the danger of fatal dosages when the unwanted polymorph is unwittingly administered because of alterations in process and/or storage conditions. The HIV protease inhibitor ritonavir (Norvir) was withdrawn from the market because an undesirable polymorph of ritonavir had been produced during its shelf-life. Ritonavir was found to exist in only one monoclinic form during development and early manufacturing. This form, called “form I”, was not sufficiently bioavailable in the solid state by the oral route, requiring the initial product (Norvir) to be formulated as a capsule filled with a hydroalcoholic solution containing the dissolved drug. Two years after the product launch, several lots of Norvir capsules started failing dissolution specifications. Evaluation of the failed lots

revealed that a second crystal form of ritonavir, “form II”, had precipitated from the formulation during its shelf life. “Form II” was 50% less soluble compared to “form I”, resulting in failure of batches in dissolution test affecting its bioavailability and eventual withdrawal of the product from the market. Substantial time and effort went in identifying and correcting the problem. To ensure a continuous supply of this life-saving drug, a liquid formulation had to be introduced in the market until the issue of the polymorphic form was resolved. Hence, an inadvertent production of the “wrong” polymorph at the crystallization stage, or any transformations of one form to another during dosage form during processing (e.g., drying, milling, granulation, compression, spray drying, or freeze-drying), storage,

and scale-up, can result in pharmaceutical dosage forms that are either ineffective or toxic. This highlights that identification of different solid forms of a drug substance as well as determination of their physical and chemical properties, thermodynamic stabilities; and conditions kinetics of interconversion are essential for ensuring reproducible behavior of drug products.

Estimate of Dose Absorbed

Johnson and Swindell (46) proposed a simple predictive model that relates the aqueous solubility and absorption rate constant (K_a) to determine the maximum absorbable dose (MAD):

$$\text{Eq. 9.37} \qquad \text{MAD} = K_a C_s V t$$

where K_a is the first-order absorption rate constant; $C_s V$ is a constant, and t is the time.

Hilgers et al. (27) argued that Equation 9.37, proposed by Johnson and Swindell (46), assumes that the drug absorption occurs under highly quixotic conditions, such as the intestine is exposed to a saturation solution of a compound of interest for a time equal to the normal SITT. For interrelating permeability and solubility of a drug to estimate the absorption potential (30) as MAD by employing the predictive model, Hilger et al. (27) proposed a modified equation:

$$\text{Eq. 9.38} \qquad \text{MAD} = S \cdot K_a \cdot \text{SIV} \cdot \text{SITT}$$

where S is solubility and SIV is the small intestinal volume.

Briefly, the MAD calculates the total mass of drug that could theoretically be absorbed if a saturated solution of a compound with solubility S in the SIV were absorbed with a first-order absorption rate constant (K_a) for a time equivalent to SITT.

The absorption rate constant (K_a) was determined from Caco-2 permeability value with the assumption that the value of K_a and rat ileum permeability values are approximately equal and, consequently, that the estimated rat permeability (P_e) was converted to an absorption rate constant (K_a) from the following relationship:

$$\text{Eq. 9.39} \qquad K_a = P_e(A/V)$$

where V is the volume of the intestinal lumen and A is the surface area. For the rats used in this study (27), A/V was equal to 10 cm^{-1}.

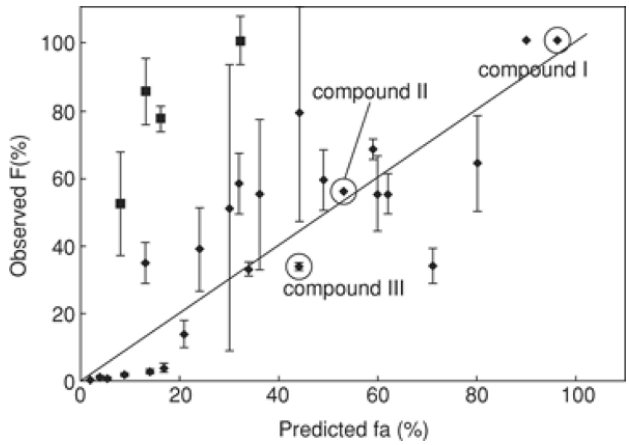


Fig. 9.19. A better correlation between observed bioavailability and predicted bioavailability when both aqueous solubility and permeability parameters of drugs are used to predict the fraction absorbed for three compounds. (From Burton P, Goodwin J, Vidamas T, et al. Predicting drug absorption: how nature made it a difficult problem. J Pharm Exp Ther 2002;303:889–895and adapted from Hilgers AR, Smith DP, Biermacher JJ, et al. Predicting oral absorption of drugs: a case study with novel class of antimicrobial agents. Pharm Res 2003;20:1149–1155; with permission.)

Employing Equations 9.37 and 9.38 for estimating the oral absorption of oxazolidinone antibiotics data obtained in rat and comparing the predicted MAD to the actually administered dose, Burton et al. (20) and Hilger et al. (27) reported the relationship illustrated in Figure 9.19.

It is clear from Figure 9.19 that better prediction of MAD is achieved when solubility, permeability,

and dose are taken into consideration. In spite of this, drug permeability is an important determinant of drug absorption; therefore, it is informative to explore mechanisms contributing to permeability in the light of structure-based models for absorption prediction.

The relationship between the estimate of MAD and the fraction absorbed is hyperbolic (28); analogous to the relationship between drug permeability and fraction absorbed. Incorporating the solubility term in Equation 9.37 yields a more realistic value of estimate of MAD for poorly to moderately soluble compounds. The concept of MDA therefore serves to combine two major determinants of oral drug absorption (i.e., intestinal permeability and solubility). In turn, the value of MDA can provide a practical guideline in the early drug discovery program.

If the dose of a potential drug candidate is projected to be greater than the calculated estimated dose absorbed, this serves a cautionary notice that the following should be examined: the potential for solubilization in the gastrointestinal tract, and the formulation variables that could ultimately result in an increased solubility

or drug dissolution during the gastrointestinal transit to increase the fraction absorbed.

To reach the systemic circulation, a drug must move from the intestinal lumen through an unstirred water layer and mucous coat adjacent to the epithelial cell structure. Movement across the epithelial layers takes place by two independent routes, transcellular flux (i.e., movement across the cells) and paracellular flux or movement between adjacent epithelial cells. The solute molecules then encounter a basement membrane, interstitial space, and mesenteric capillary wall to access the mesenteric circulation. Any and all of these microenvironments can be considered a resistance to solute molecule movement, each with an associated permeability coefficient. Therefore, the overall process consists of a number of resistances (i.e., reciprocal of permeability) in series. Furthermore, the influence of drug structure with permeability in these different domains may be different. For example, permeability in an unstirred water layer is inversely related to solute size, whereas paracellular permeability is a function of both size and charge. Furthermore, cations exhibit greater permeability than neutral species, which in turn manifest greater permeability than anions.

With respect to transcellular permeability, the relationship of solute structure with permeability depends on the mechanism. Historically, a passive diffusion pathway is assumed for most solutes. Nevertheless, a great number of solutes are identified as being associated with active absorption and secretary processes in intestinal epithelial cells. Additionally, although active transport involves specific interactions between a solute and transporter, passive diffusion is dependent on solute partitioning into the cellular plasma membrane and the diffusion coefficient within the membrane. Both processes, however, are influenced by the physicochemical and structural characteristics of the drug. Factors influencing plasma membrane partitioning are solute size, lipophilicity, hydrogen-bonding potential, and charge characteristics, whereas the diffusion coefficient is dependent on size or total molecular surface area. In general, a non-PSA favors partitioning.

For solutes that exhibit marginal (or a lack of) membrane affinity, permeability is low, resulting primarily from paracellular diffusion of the solute. As the propensity of the solute to partition into cell membrane increases, so does the permeability, as a result of the significant increase in surface area of the transcellular pathway relative to the paracellular route. This increase in permeability will approach a plateau, the so-called “aqueous boundary layer–limited situation,” in which diffusion across the cell is very rapid relative to diffusion of the solute through the unstirred water/mucous layer.

Table 9.6. Physicochemical Properties and Calculated Absorption Potential (AP) for Representative Drugs

Drug	*P*	*S* (mg/mL)	Dose (mg)	pK_a	F_{non} (pH 6.5)	AP	%ABS (range)
Acyclovir	0.018	1.3	200	9.5	1	–1.5	17 (12–23)
Chlorothiazide	0.54	0.4	250	6.7	0.6	–0.89	25 (10–

							40)
Griseofulvin	151	0.015	250	—	1	0.36	43 (35–51)
Hydrochlorothiazide	0.85	0.6	25	8.8	0.95	0.7	67 (50–90)
Phenytoin	295	0.014	100	9.2	0.99	1.0	90 (80–100)
Prednisolone	26	0.235	20	—	1	1.9	99
Digoxin	56	0.024	0.25	—	1	3.13	>90

P, partition coefficient; *S*, solubility; F_{non}, nonabsorbed fraction; %ABS, percentage of drug absorbed following an oral dose in human subjects.

In the case of ionizable solutes, permeability also is pH dependent. A neutral, uncharged species is capable of transcellular diffusion, whereas a charged species is restricted to the paracellular pathway. Thus, the observed permeability of such molecules is dependent on the relative concentrations of charged and neutral species.

Dressman et al. (47) developed an equation to determine the absorption potential (AP) of a drug by taking into consideration several of its physicochemical properties, including intrinsic solubility (S_o) of the un-ionized species of a drug, fraction of unionized form (F_{uni}) of a drug at a specific pH, volume of the luminal content (V_l), permeability of a drug in the gut wall (P_w), and the aqueous permeability (P_{aq}) of a drug. The equation is

$$\textbf{Eq. 9.40} \qquad F_{abs} = \left(\frac{P_w}{P_{aq}}\right)(F_{uni})\left(\frac{S_o V_l}{X_o}\right)$$

where F_{abs} is the fraction absorbed and X_o is the administered dose. With the assumption that, in many cases, the permeability ratio (i.e., P_w/P_{aq}) of a drug is proportional to its membrane-water coefficient (P), which can be correlated to the 1-octanol–water partition coefficient (P), Equation 9.40 was simplified to

$$\textbf{Eq. 9.41} \qquad \mathrm{AP} = \log\left(P \cdot F_{uni} \cdot \frac{S_o V_l}{X_o}\right)$$

where AP is a dimensionless parameter

Employing Equation 9.41 and selecting drugs that represent a wide range of absorption characteristics, from poorly absorbed compounds to those that are virtually completely absorbed, the utility of the AP parameter as a predictor of the fraction absorbed was assessed (47). The physicochemical properties, such as the partition coefficient, solubility, fraction available in un-ionized form, dissociation constant, fraction of dose absorbed, and calculated dimensionless parameter AP for drugs selected in this study (47), are reported in Table 9.6. The observed

correlation between the fractions absorbed and the AP is illustrated graphically in Figure 9.20.

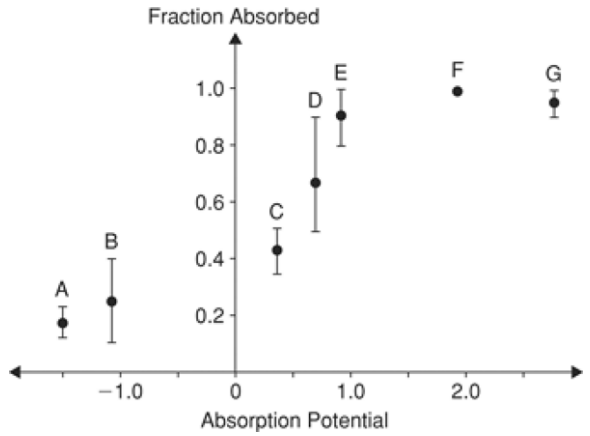

Fig. 9.20. The relationship between absorption potential (AP) and fraction absorbed for seven representative drugs (Table 9.6). A, acyclovir; B, chlorothiazide; C, micronized griseofulvin; D, hydrochlorothiazide; E, phenytoin; F, prednisolone; G, digoxin (Lanoxicap). (From Dressman JB, Amidon GL, Fleisher D. Absorption potential: estimating the fraction absorbed for orally administered compounds. J Pharm Sci 1985;74:588–589; with permission.)

From Table 9.6 and Figure 9.20, it is quite apparent that for the compounds selected in this study (47), the dimensionless parameter AP manifests a strong correlation to the fraction absorbed. Negative AP values correspond to poor drug absorption. For the range of AP values between zero and one, an increase in AP value correlates with an increase in fraction absorbed, whereas AP values greater than one indicate complete drug absorption.

Summary

At one time, it was common to assume that the biological response to a drug was simply a function of the intrinsic pharmacological activity of the drug molecule. Today, when assessing the potency of most drugs, consideration is given to plasma drug concentration–response rather than dose–response relationships. The concentration of a drug in the plasma is dependent on the rate and extent of absorption, which in turn is influenced by the physicochemical properties of drug substances. Drug absorption may markedly affect the onset and intensity of a biological response to a drug. Clinically significant differences in the absorption of closely related drugs, such as lincomycin and clindamycin, penicillin and pivampicillin, or secobarbital and sodium secobarbital, are invariably the result of significant differences in their physicochemical properties.

Dissolution is simply a process by which a solid substance goes into solution. The determination of dissolution rates of pharmaceutical substances from dosage forms does not predict their bioavailability or their in vivo performance; rather, it indicates the potential availability of drug substance for absorption. Therefore, it is essential for pharmacists and pharmaceutical scientists to know and understand the importance of dissolution and its potential influence on the rate and extent of absorption and availability for drugs.

Factors affecting the dissolution rate of a drug from a dosage form can be related to the physicochemical properties of a drug, formulation of a dosage form, and dissolution apparatus and test parameters. Additionally, a brief introduction of the role of intestinal transporters and metabolizing enzymes (CYP3A4) in drug absorption was provided. The role of intestinal permeability in drug absorption process, techniques of measuring intestinal permeability, and methods that permit the estimation of fraction of dose absorbed by taking into consideration the physicochemical properties of a drug also were discussed. Additionally, the biopharmaceutical drug classification based on the two physicochemical properties, solubility and permeability, of drugs and the implications of these properties on drug absorption were covered.

Pharmacokinetics

Introduction

The events following drug administration can be divided into two phases: a pharmacokinetic phase, in which the ability to adjust a dose, alter the dosage form, and alter the frequency and route of administration are related to drug concentration–time relationship in the body; and a pharmacodynamic phase, in which the drug concentration at the sites of action is related to the magnitude of effects produced. Once both of these phases have been defined for a drug, a dosage regimen for a drug can be established to achieve the optimum therapeutic goals in individual patients and to predict what may happen when a dosage regimen is changed.

The sites into which drugs are routinely administered are broadly classified as intravascular and extravascular. Intravascular administration refers to the placement of a drug directly into blood, either intravenously or intra-arterially. Because the drug is placed directly into blood, it is imperative that a drug administered intravascularly be given as a solution. The extravascular routes of administration include oral, intramuscular, sublingual, buccal, subcutaneous, dermal, rectal, and nasal routes. To enter the blood, a drug administered extravascularly must be absorbed from the site of administration. Additionally, if a drug is administered through solid dosage forms, such as tablets or capsules, then the drug must first dissolve at the site of administration. Therefore, the dissolution of a drug is essential before its absorption. On the other hand, no such absorption step is required when a drug is administered intravenously.

Pharmacokinetics is the scientific discipline that deals with the mathematical description of biological processes affecting drugs and affected by drugs. In addition to signifying the relationship of ADME (absorption, distribution,

metabolism, and excretion) processes to the intensity and time course of pharmacological effects of drugs, pharmacokinetics describes the time course of a drug's ADME processes, which take place following the administration of a drug. It therefore is necessary to describe and analyze these processes and their effects in relation to their rates, rate constants, or time course. A qualitative description of these processes is quite insufficient and seldom leads to adequate and accurate characterizations of the effects of drugs on the body and effects of the body on the drugs. Pharmacokinetics is a quantitative study whose purposes are:

1. To develop mathematical expressions that permit one to describe the temporal changes of the drug concentration;
2. To determine constraints that describes ADME processes succinctly;
3. To make predictions and extrapolations based on the mathematical expressions; and
4. To help establish dosage regimen that, in turn, will result in improved drug utilization in patients.

At a fundamental level, pharmacokinetics is a useful tool of pharmacists and physicians for optimizing the dosage regimen of drugs for individuals who may differ in their intrinsic response and their ability to absorb and eliminate drugs. Adjustment of dosage regimen to account for individual differences and disease states is, in essence, an exercise in clinical pharmacokinetics and clinical pharmacy practice.

A basic tenet of pharmacokinetics is that the magnitude of both the desired response and toxicity are functions of drug concentration in the blood. Furthermore, it is not only the efficacy of a drug at the site of action that determines the intensity and duration of its pharmacological or therapeutic effects but also the amount of a drug and the rate at which the drug gets to the site of action. The vital processes of the body may delay the transport of drug molecules across membranes, convert drug molecules into metabolites, and remove them from the body as metabolites and/or the unchanged form. In turn, this may result in therapeutic failure as a result of drug concentrations being too low or unacceptable toxicity, as a consequence of too high a drug concentration. Between these concentration limits lies a region associated with therapeutic success. This region may be regarded as a therapeutic range, or “therapeutic window.” Each drug may possess its own therapeutic window, and because the drug concentration rarely can be measured at the site of drug action, the drug concentration is measured at alternative and more accessible sites, such as plasma or serum and urine.

Figure 9.21 illustrates the concentration or therapeutic window for a drug. The terms “minimum toxic concentration” and “minimum effective concentration” describe the limits of the therapeutic range for a drug. If the administered dose of a drug produces the plasma concentration within this range, the drug will likely produce its therapeutic effect. The term “onset of action” is defined as the time at which the drug enters the therapeutic range (i.e., above the minimum effect concentration), and when the plasma concentration of a drug falls below the therapeutic range is defined as the termination of action. The time span between the termination and the onset of action is described as the duration of action.

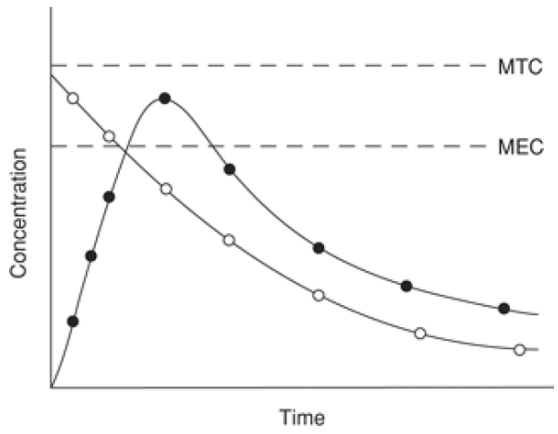

Fig. 9.21. Typical plasma concentration versus time profile following administration of a dose of a drug by intravascular (○) and extravascular routes (•).

It is clear from Figure 9.21 and the definitions above that an optimum dosage regimen might be defined as one that maintains the plasma concentration of a drug within the therapeutic range. Furthermore, it may be obvious from the above discussion that the success of a drug in providing the desired drug concentration depends on factors such as how rapidly the drug reaches the general circulation from the site of administration, particularly following the oral and other extravascular routes; whether the drug is reaching the general circulation in sufficient amounts to provide plasma concentration within the therapeutic range; and the pharmacokinetic properties of a drug.

The purpose of this section is to provide students with a brief overview and the functional understanding of basic pharmacokinetics and its application to how physicochemical properties of drug molecules affect pharmacokinetic properties. Emphasis is placed on how to carry out pharmacokinetic analysis of the data and on how to use the pharmacokinetic parameters for predictive purposes. The mathematical equations presented have been chosen because of their general utility for predicting the plasma concentrations following administration of a drug by intravascular and extravascular routes. Furthermore, this discussion attempts to review and illustrate how the chemical modification of a drug through molecular modifications may alter selected pharmacokinetic parameters of drugs and, therefore, possibly the pharmacological response in the drug discovery and development process.

Table 9.7 describes the dimensions of various pharmacokinetics parameters and provides examples of the corresponding typical dimensions reported in the literature, is provided at the end of the chapter.

Table 9.7. Dimensions of Measurement and Typical Dimensions for Important Pharmacokinetics Parameters

Pharmacokinetics Parameter	Dimension of Measurement	Examples of Typical Dimensions
Mass of drug (e.g., mass of drug in blood, mass of drug at the site of	Amount	mg, µg, etc.

administration, mass of drug in urine, and mass of metabolite in urine)		
Plasma and/or serum concentration	Amount per unit volume	$mg \cdot L^{-1}$, $\mu g \cdot mL^{-1}$, mg/L, µg/mL, etc.
Elimination half-life	Time	hr, min, etc.
All first-order rate constants (e.g., elimination, distribution, disposition, absorption, and intercompartmental transfer rate constants)	Reciprocal of time	hr^{-1}, min^{-1}, etc.
All the apparent volumes of drug distribution (e.g., V for one compartment model, and V_c and V_b for two-compartment model)	Volume or volume per unit weight of a subject	L, mL, etc. or $L \cdot kg^{-1}$, $mL \cdot kg^{-1}$ L/kg, mL/kg, etc.
Zero-order rate constant	Amount, concentration, or percentage per unit time	$mg \cdot hr^{-1}$, $\mu g \cdot mL \cdot hr^{-1}$, $\% \cdot hr^{-1}$, mg/hr, µg/hr, %/hr, etc.
All rates (zero as well as first order; e.g., absorption rate, elimination rate, and excretion rate)	Amount per time or concentration per time	$mg \cdot hr^{-1}$, $\mu g \cdot hr^{-1}$, $\mu g \cdot mL^{-1} \cdot hr^{-1}$, mg/hr, µg/hr, µg/mL/hr, etc.
All clearances (e.g., systemic, renal, metabolic, and creatinine clearance)	Volume per unit time or volume per unit time per unit weight	$mL \cdot hr^{-1}$, $L.hr^{-1}$, $mL \cdot hr^{-1} \cdot kg^{-1}$, $L \cdot hr^{-1} \cdot kg^{-1}$, mL/hr, L/hr, mL/hr/kg, etc.
Peak time	Time	hr, min, etc.
Dose administered (e.g., single intravenous or oral dose, loading dose, and maintenance dose)	Amount or amount per unit weight	mg, µg, $mg \cdot kg^{-1}$, mg/kg etc.
Peak concentration (e.g., for a single dose or multiple doses) etc.	Mass per unit volume	$mg \cdot L^{-1}$, $ng \cdot mL^{-1}$, mg/L, ng/mL.
Area under the plasma concentration–time curve (AUC)	Mass per volume × time	$mg \cdot L^{-1} \cdot hr$, $ng \cdot mL^{-1} \cdot hr$, mg/L/hr ng/mL/hr, etc.

Dosing interval	Time	hr, min., etc.
Absolute or relative bioavailability	Dimensionless	
Blood flow rate	Volume per unit time	$L \cdot hr^{-1}$, $mL \cdot hr^{-1}$, L/hr, mL/hr, etc.
Extraction ratios	Dimensionless	
Infusion rate	Mass per unit time or mass per unit time per unit weight	$mg \cdot kg^{-1}$, $\mu g \cdot kg^{-1}$, $\mu g \cdot kg^{-1} \cdot hr^{-1}$, mg/kg, µg/kg, µg/kg//hr, etc.

Compartmental Concepts

The most commonly employed approach to pharmacokinetic characterization of a drug is to depict the body as a system of compartments, even though these compartments often do not have any apparent physiologic reality. These frequently used compartmental models are illustrated in Figure 9.22.

The one-compartment model considers the body as a single homogenous unit (central compartment). This simplest model is particularly useful for pharmacokinetic analysis of plasma concentration vs. time for drugs that are very rapidly distributed in the body. The two-compartments model consists of a central component, which includes the plasma and other highly perfused organs, connected to a peripheral or tissue compartment. Each compartment can be considered to include a group of tissues, fluids, or parts of organs. A somewhat more complex model, illustrated in Figure 9.23, is the three-compartment model, which consists of a central compartment connected to more than one peripheral compartment that differ in their relative accessibility to a drug. This model may be chosen if the available data warrant such a model.

The selection of a model depends greatly on the site and tissue being sampled, the frequency of sampling collection, and the ultimate goals of the study. The general operating rule in selecting a model for pharmacokinetic analysis of plasma concentration versus time data is to postulate the minimum number of compartments necessary to accurately describe the pharmacokinetics of a given drug. An approach to selecting the number of compartments should be parsimonious, unless experimental evidence dictates that such parsimony may lead to errors in estimating the pharmacokinetic parameters of drugs and, therefore, the use of equations for predicting blood levels of drugs.

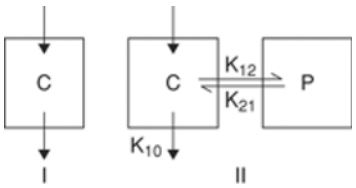

Fig. 9.22. Schematic representation of the one-compartment (I) and the two-compartment (II) models commonly used in pharmacokinetics. Arrows represent transfer of a drug because of the first-order process. C, central compartment (plasma, highly perfused organs); P, peripheral (tissue) compartment.

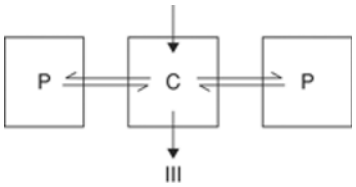

Fig. 9.23. Schematic representation of a three-compartment (III) model commonly used in pharmacokinetics. Arrows represent transfer of a drug because of the first-order process. C, central compartment; P, peripheral compartment.

Linear and Nonlinear Pharmacokinetics

Linear Pharmacokinetics

Many processes in pharmacokinetics can be described accurately by a first-order process. This means that the rate of drug biotransformation, the rate of transfer of a drug between compartments, and the rate of absorption and elimination of drugs from the body are directly proportional to the size of the dose administered. It also is true that passive diffusion is responsible for the transfer of a drug in the body and that a directly proportional relationship exists between the administered dose and the resulting drug concentration in the body. This dose proportionality often is used as an indicator of linear pharmacokinetics. It is important, however, to recognize that the pharmacokinetic parameters, such as the elimination half-life and the elimination rate constant, are independent of the size of the dose administered. Therefore, linear pharmacokinetics is regarded as dose-independent kinetics.

Nonlinear Pharmacokinetics

The rate of elimination of a few drugs (e.g., ethanol, salicylate, and phenytoin) by biotransformation and some other transfer processes involves protein carrier systems. These drugs are not removed from the body by a first-order process, which means that the elimination rate is not proportional to the concentration of drug or to the dose administered. In most of these cases, elimination follows zero-order kinetics—that is, the rate of change of drug concentration is independent of the drug concentration. A constant amount of a drug, rather than the constant percentage of the remaining amount of drug, is eliminated per unit time (i.e., mg/min or μg/mL/min).

The most frequently reported reason for the use of nonlinear kinetics is that biotransformation and transfer processes require protein-carrier systems. These systems are specific with respect to substrates that have finite capacities. The kinetics of these processes often are described by the Michaelis-Menten equation (Eqs. 9.3–9.5).

This nonlinear, or dose-dependent, elimination kinetics also may be the result of effects other than the limited capacity of biotransformation or elimination processes. If a drug is partly reabsorbed from the renal tubules by a recycling process with limited capacity, then the elimination of large doses proceeds relatively more rapidly than the elimination of smaller doses. Similarly, lesser binding of drugs to plasma constituents or tissues at higher dosing may result in relatively more rapid drug

elimination than is observed at lower drug concentrations.

Evidence suggests that some drug metabolites can inhibit their own formation. This process of product inhibition also can cause dose-dependent effects, with large doses being eliminated relatively more slowly than small doses. The rate of decline of a drug concentration in the postdistribution phase, at any given level of a drug in the body, will be independent of the dose in the case of simple Michaelis-Menten kinetics. In cases of product inhibition, this rate tends to decrease with increasing doses.

Intravascular Administration

Intravenous Bolus Administration and One-Compartment Model

Following the administration by intravenous injection, if a drug distributes very rapidly in the body, this confers on the body the characteristics of a one-compartment model, and if the drug elimination from the body can be described by a first-order process, then a plot of the logarithm of plasma drug concentration as a function of time yields a straight line, as shown in Figure 9.24.

The equation responsible for describing plasma drug concentration against time is as follows:

Eq. 9.42 $$C_p = (C_p)_0 e^{-Kt}$$

where C_p is the plasma drug concentration at time t, $(C_p)_0$ is the initial plasma drug concentration (i.e., t = 0)

immediately after the injection, K is the first-order elimination rate constant, and t represents time. Equation 9.42 also can be written as follows:

Eq. 9.43 $$\ln C_p = \ln(C_p)_0 - Kt$$

or

Eq. 9.44 $$\log C_p = \log(C_p)_0 - \frac{Kt}{2.303}$$

The initial plasma drug concentration, $(C_p)_0$, may be obtained by extrapolation of the line (Fig. 9.24) to t = 0 or the y-intercept of plasma drug concentration versus time plot. Figure 9.24 shows that a plot of the log of plasma drug concentration versus time will be linear under the stated condition.

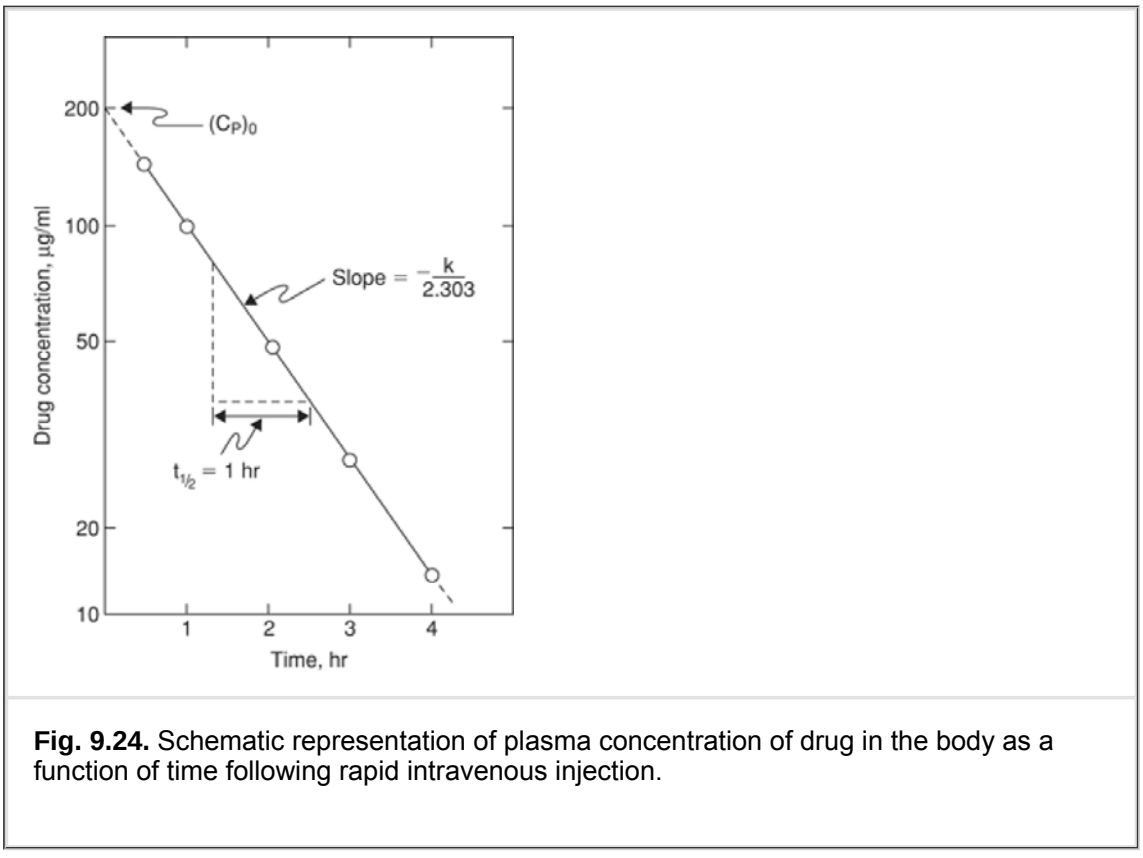

Fig. 9.24. Schematic representation of plasma concentration of drug in the body as a function of time following rapid intravenous injection.

Three primary factors determine the plasma concentration of the administered drug: 1) the route of

administration, 2) the uptake of drug by body tissues, and 3) the elimination of the drug from the body. In the case of intravenous administration, because the drug is introduced directly into the blood, there is no delay as a result of the absence of the drug absorption process. The drug plasma level, however, depends on the size of the dose, and the maximum plasma drug concentration occurs immediately after completion of the dose administration.

The Elimination Rate Constant and Half-life

The half-life of a drug is a major factor in determining the dosing frequency, which is a function of the drug's clearance and apparent volume of distribution (*V*). The relationship of a drug's half-life to the prediction of human pharmacokinetics and dosing regimen is shown in Figure 9.25 (48,49,50). Drugs with short half-lives are more likely to require frequent administration, whereas those with long half-lives tend to require dosing once daily. The two pharmacokinetic parameters that determine the half-life of a drug are clearance and volume of distribution. Dosing regimen is also linked to other factors, such as the drug pharmacodynamics, and drug concentrations associated with side effects versus those minimally required for efficacy.

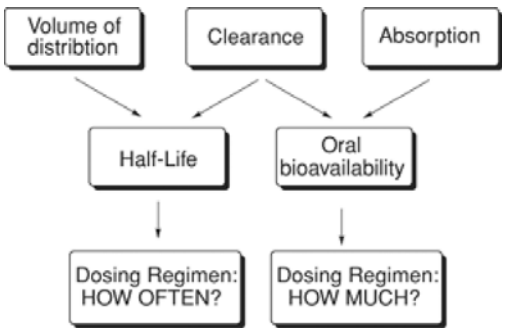

Fig. 9.25. The relationship of volume of distribution to the prediction of human kinetics.

The elimination rate constant (*K*) can be determined from the slope of the straight line as follows:

$$\text{Eq. 9.45} \qquad (\text{slope})\,(2.303) = -K$$

It is, however, much easier to determine the elimination rate constant by making use of the following relationship:

$$\text{Eq. 9.46} \qquad K = \frac{0.693}{t_{1/2}}$$

where $t_{1/2}$ is the time required for any drug concentration to decrease by half (i.e., 50%) and also is known as the biological or the elimination half-life. The elimination half-life is a pharmacokinetic property of a drug, and it is independent of the size of the administered dose when the administered drug exhibits the characteristics of a first-order process.

The elimination half-life ($t_{1/2}$) and the elimination rate constant (*K*) of a drug also play an important role in determining the plasma concentration of a drug at a given time. For instance, a drug with a short elimination half-life will be eliminated from the body much more quickly than a drug with a longer elimination half-life. These two parameters of a drug, therefore, become important in maintaining the desired drug blood levels in the body. In essence, these two parameters provide a quantifiable index of the presence of a drug in the body.

The process of drug elimination includes biotransformation and excretion, and it begins almost immediately, when circulation of blood distributes some of the drug to organs capable of metabolizing the drug or excreting it from the body. Among the organs of drug elimination, the liver is the principal site of biotransformation, and the kidney is primarily responsible for the excretion of unchanged drugs and their metabolites. Other organs, however, may also participate in the elimination of selected drugs.

The consequence of biotransformation of the drug to metabolite depends on the pharmacological activity of the individual metabolite(s). Metabolites may be active or completely inactive. Active

metabolites may be more or less potent than the parent drug, and they may exhibit similar or dissimilar action. The kinetics of distribution and elimination of metabolites may differ from those of the parent drug, because each metabolite differs from the parent drug in its physicochemical properties as a result of functional group additions or changes.

The elimination rate constant (K) is the sum of the individual rate constants that characterize the elimination of a drug from the body and the form of metabolite or unchanged drug. Thus,

$$K = K_u + K_m \qquad \textbf{Eq. 9.47}$$

where K_u and K_m represent the first-order rate constants associated with excretion and the form of metabolite or unchanged drug, respectively, removed from the blood.

The Apparent Volume of Distribution

Plasma or serum samples, collected immediately following the administration of equal doses (i.e., X_0) of two different drugs, may exhibit large differences in the drug concentration. This is because drug distribution in the body is largely a function of the physicochemical properties and, therefore, of the chemical structure of a therapeutic agent. The sole purpose of this parameter (V) is to relate the amount (mg) and the concentration (L^{-1}) of drug in the body at a given time. Therefore, it is important to recognize that knowledge of this parameter is essential for the determination of the dose of a drug required to attain the desired initial plasma concentration. The relationship of V to the prediction of human pharmacokinetics and dosing regiment is shown in Figure 9.25. Because it is not a true physical volume but, rather, a mathematical term that describes the behavior of a drug in the body with regard to its degree of partitioning between the plasma compartment and the remainder of the body, V is called "apparent." Drug partitioning into tissues represents a complex combination of physicochemical (lipophilicity, pK_a, plasma protein binding) and physiological parameters. Drugs that are equally bound to plasma proteins may yield different V values, because the drug with the greater tissue binding will yield the larger V. On the other hand, drugs with equal tissue binding may differ in V, with the compounds having the greater plasma protein binding yielding the smaller volume of distribution.

This relationship is shown in Equation 9.48:

$$(X)_t = V(C_p)_t \qquad \textbf{Eq. 9.48}$$

where $(X)_t$ and $(C_p)_t$ are the dose of the drug and its plasma concentration, respectively, at a given time. The apparent volume of drug distribution (V) is determined by rearranging Equation 9.48 as follows:

$$V = \frac{(X)_0}{(C_p)_t} = \frac{\text{Dose}}{(C_p)_0} \qquad \textbf{Eq. 9.49}$$

where X_0 is the administered dose of the drug and $(C_p)_0$ its initial plasma concentration.

V of a drug is usually a property of the drug rather than of a biological system, and it describes the extent to which a particular drug is distributed in the body tissues. The magnitude of V usually does not correspond to plasma, extracellular. or total body volume space but may vary from a few liters (7–10 L) to several hundred liters (≥200 L) in a 70-kg subject. The higher the value of V, the greater is the extent to which the drug is distributed in the body tissues, organs, or both. Furthermore, because body tissues, biological membranes, and organs are lipophilic in nature, the value of V is correlated with the lipophilicity of a drug, which in turn is influenced by the drug's chemical structure, pK_a, and protein binding. The more lipophilic the nature of the drug, the greater the value of V and the smaller the initial plasma concentration (assuming the administered doses of drugs are identical). Conversely, if the drug is hydrophilic, the drug will penetrate to a lesser extent into tissue; consequently, the plasma concentration will be higher and V smaller. It therefore is accurate to state that the value of V is influenced by the lipophilicity of the drug molecules.

In most situations, V is independent of the drug concentration, because doubling the amount of a drug in the body usually results in doubling of its plasma concentration (linear pharmacokinetics). This parameter, however, is constant for a drug. It remains independent of the dose administered and selected disease state. Other factors that may influence the blood composition, total body fluid, and the permeability characteristic of tissue may bring about changes in the value of V. Furthermore, because V reflects the extent to which a drug will penetrate into tissue, alteration in the permeability characteristics of tissue will alter V. Additionally, it is important to note that V of a drug may vary in infants, adults, and the geriatric population.

Many acidic drugs, including salicylates, sulfonamides, penicillins, and anticoagulants, are either highly bound to plasma proteins or are too water soluble to enter intracellular fluid and penetrate tissues in a significant amount. These drugs therefore have low volumes of distribution and low tissue to plasma concentration ratios. A given dose of these drugs will yield relatively higher plasma concentrations. It is tacitly assumed here that analytical problems in the determination of drug concentration are minimized or do not exist. Basic drugs, including tricyclic antidepressants and antihistamines, are extensively bound to extracellular tissues and are taken up by adipose tissues. The apparent volume of distribution for these drugs is large—often larger than the total body space. For example, the value of *V* for amphetamine is approximately 200 L (3 L/kg). The relatively small doses and large volume of distribution for amphetamine produces a low plasma concentration, which makes its quantitative detection in plasma a difficult task.

Theoretical limits for this parameter will be as low as 5 to 7 L (equivalent to the volume of the body fluid if the drug totally fails to penetrate the tissues or is extremely hydrophilic) to high as 200 L or greater. Because of differences in the magnitude of the apparent volume of distribution of a drug, a given dose of a drug with a relatively high *V* will provide low initial drug concentrations, and vice a versa (Eq. 9.48).

Clearance

One of the most important pharmacokinetic properties of a drug is clearance (*Cl*). In pharmacokinetic terms, clearance refers to the hypothetical volume of distribution from which the drug is entirely removed or cleared

in unit time (mL/min or mL min^{-1}). In other words, it is an index of drug elimination from the body. Clearance is a function both of the intrinsic ability of certain organs, such as kidneys and liver, to excrete or metabolize a drug and of the blood flow rate to these organs. The concept of clearance can be illustrated by assuming the elimination in a single organ as depicted in Figure 9.26.

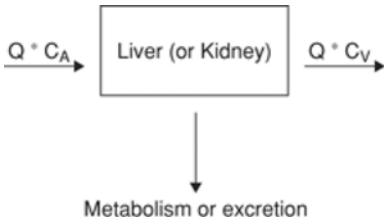

Fig. 9.26. Schematic representation of drug elimination by the liver (or kidney). Q · C_A is the rate at which the drug enters the liver (or kidney), and Q · C_V is the rate at which the drug leaves the liver (or kidney). The venous drug concentration (C_V) is less than the arterial drug concentration (C_A).

Under the conditions described in Figure 9.26, the venous concentration of drug (C_V) will always be less than the arterial concentration (C_A) because of the drug being eliminated or excreted during the passage of blood through the organ. The rate at which the drug enters the organ is the product of blood flow rate (*Q*) and the arterial concentration. The rate at which the drug leaves the organ, on the other hand, is equal to the product of blood flow rate and venous concentration:

$$\text{The rate in} = QC_A \qquad \textbf{Eq. 9.50}$$

$$\text{The rate out} = QC_V \qquad \textbf{Eq. 9.51}$$

The difference between the rate in and rate out is the rate of elimination of a drug by the organ:

$$\text{Elimination rate} = Q(C_A - C_V) \qquad \textbf{Eq. 9.52}$$

The dimensionless ratio of elimination rate to the rate at which a drug enters the organ (QC_A) is

defined as the extraction ratio (ER) and is obtained as follows:

$$\textbf{Eq. 9.53} \qquad \mathrm{ER} = \frac{Q(C_A - C_V)}{QC_A} = \frac{(C_A - C_V)}{C_A}$$

The extraction ratio (ER) of a drug ranges from zero to one depending on how well the organ eliminates or excretes the drug from the blood flowing through it. If an organ does not eliminate the drug, then $C_A = C_V$, and the extraction ratio is zero (low extraction ratio). If, on the other hand, the organ avidly removes the drug so that C_V [congruent] 0, then the extraction ratio is one (high extraction ratio). If liver is the organ responsible for metabolizing the drug, then the extraction ratio may be described by using the notation, E_H.

Using the extraction ratio number (i.e., ER of E_H), the drugs have been classified as having a low (ER < 0.3), intermediate (ER = 0.3–0.7) or high (ER > 0.7) extraction ratio drugs. Table 9.8 lists the representative drugs with their hepatic or extraction ratios. The influence of blood flow and intrinsic clearance of an organ on the clearance of a drug is determined by the extraction ratio of the drug.

The clearance of a drug (*Cl*) also may be viewed as a proportionality constant relating the elimination rate of a drug to its plasma concentrations at a given time and is expressed as

$$\textbf{Eq. 9.54} \qquad (Cl) = \frac{\text{rate of elimination}}{\bar{C}_p}$$

where $-C_p$ is the average plasma concentration of a drug at a time that corresponds to the rate of elimination. It follows from an earlier equation (Eq. 9.54) that

$$\textbf{Eq. 9.55} \qquad (Cl) = \mathrm{QER}$$

where *Q* and ER have been previously defined and, because the drug elimination follows a first-order process, clearance is independent of the drug concentrations or the dose administered.

Table 9.8. Hepatic and Renal Extraction Ratios of Selected Drugs and Metabolites

Low (< 0.3)	Intermediate (0.3–0.7)	High (> 0.7)
Hepatic extractiona		
Carbamazepine	Aspirin	Alprenolol
Diazepam	Quinidine	Arabinosyl-cytosine
Digitoxin	Codeine	Desipramine
Indomethacin	Nortriptyline	Doxepin
Phenobarbital		Isoproterenol
Phenytoin		Lidocaine
Procainamide		Meperidine
Salicylic Acid		Morphine
Theophylline		Nitroglycerin
Tolbutamide		Pentazocine
Valproic Acid		Propoxyphene

Warfarin		Propranolol
Atenolol	Cimetidine	(Many) Glucuronides
Cefazolin	Cephalothin	Hippurates
Chlorpropamide	Procainamide	(Some) Penicillins
Digoxin	(Some) Penicillins	(Many) Sulfates
Furosemide		
Gentamicin		
Lithium		
Phenobarbital		
Sulfisoxazole		
Tetracycline		

[a]At least 30% of the drug is eliminated by this route.

The total body clearance of a drug the from blood is equal to the ratio of the overall elimination rate to drug concentration (Eq. 9.54), where the overall elimination rate is comprised of the sum of the elimination processes occurring in all organs and the removal of a drug in all its forms. Therefore, the overall clearance, $(Cl)_s$, represents the renal clearance (i.e., unchanged form of a drug) and the metabolic clearance (i.e., removal of a drug as metabolic by kidney). It also is very useful to keep in mind that the clearance can be expressed as the product of the apparent volume of distribution (V) and the elimination rate constant (K) for drugs that exhibit characteristics of one compartment model. Thus,

Eq. 9.56 $$(Cl)_s = V_d K$$

Renal Clearance

Drug elimination occurs by renal excretion and an extrarenal pathway, usually hepatic metabolism. Renal clearance is defined as the proportionality constant between the urinary excretion rate and the plasma concentration:

Eq. 9.57 $$\left(\frac{dX_u}{dt}\right)_{\bar{t}} = (Cl)_r \overline{C_p}$$

where $(dX_m/dt)_{\bar{t}}$ is the average urinary excretion rate(mg/hr); $(Cl)_r$ is the renal clearance (mL/hr), and $\overline{C}_p$– is the plasma drug concentration. Equation 9.57, however, presents practical difficulty in measuring renal clearance, because the plasma drug concentration changes:

Eq. 9.58 $$(X_u)_t = (Cl)_r C_p dt$$

where $C_p dt$ corresponds to the area under the plasma concentration–time curve (AUC). The urine collection interval (dt) is composed of many such very small increments of time, and the amount of drug excreted in a collection interval is the sum of the drug amount excreted in each small time interval line. Then,

Eq. 9.59 $$(Cl)_r = \frac{\text{Total amount excreted (i.e., } (X_u)_\infty)}{(\text{AUC})_0^\infty}$$

where $(X_u)^\infty$ is the total amount excreted in the urine and $(AUC)_0^\infty$ is the area under the plasma concentration–time curve from $t = 0$ to $t = \infty$.

To account for all the administered drugs in the urine when the drug is administered intravenously often is not possible. This may be caused by the excretion of some of the drug via an extrarenal route, excretion of a metabolite via an extrarenal route, further biotransformation of primary metabolite into chemical forms that are not identified by the analytical method used, or formation of unknown and unidentified primary metabolites. If the total amount of metabolites can be identified in the urine, then one can determine the metabolite clearance using the following equation:

Eq. 9.60 $$(Cl)_m = \frac{\text{Total amount excreted (i.e.,} (X_{mu})_\infty)}{(\text{AUC})_0^\infty}$$

where $(X_{mu})^\infty$ is the amount of matabolite in the urine at time infinity.

Hepatic Clearance

Although metabolism can take place in many organs, the liver frequently has the greater metabolic capacity and, therefore, has been the most thoroughly studied. The most direct quantitative measure of the liver's ability to eliminate a drug is hepatic clearance, $(Cl)_H$, which includes biliary excretion clearance and hepatic metabolic clearance:

Eq. 9.61 $$(Cl)_H = Q_H E_H$$

where Q_H is the sum of the hepatic portal and hepatic arterial blood flow rates, the values of which are 1,050 and 300 mL/min, respectively.

Under conditions of normal body functions, the pharmacokinetic behavior of most drugs can be established within reasonable limits, and optimal dosage regimens can be designed using the observed values of the pharmacokinetic parameters of the drug. When, however, the renal function is compromised as a result of acute or chronic renal diseases or the patient's age, drugs that are eliminated predominantly through the kidneys are likely to be retained in the body for a longer duration and accumulate to the extent of providing toxic drug levels with repeated dosing. If the drug is converted to a metabolite, the accumulation of active metabolite also may lead to toxic effect, and although most metabolites are inactive, their accumulation with repeated dosing may produce toxic reactions by displacement of the parent drug from plasma protein and by inhibiting further drug metabolism.

Renal failure can result from a variety of pathologic conditions. If renal impairment is rapid in onset and short in duration, then renal failure is described as acute. The primary cause of acute renal failure may be prerenal (i.e., acute congestive heart failure or shock), intrarenal (i.e., acute tubule necrosis) or postrenal (i.e., hypercalcemia). The condition generally is reversible; however, complete restoration of renal function may take 6 to 12 months.

Chronic renal failure almost always is caused by intrinsic renal diseases and is characterized by slow, progressive development. Unlike the acute condition, chronic renal impairment generally is irreversible. The degree or loss of kidney functional capacity in the chronic condition is best described in terms of the intact “nephron” hypothesis, in which the diseased kidney is comprised of nephrons that are essentially nonfunctional because of pathologic conditions together with normal nephrons. Progressive renal impairment is the result of an increasing fraction of nonfunctional nephrons.

The prolonged and progressive nature of chronic renal failure is of particular concern in older

patients, who may require a variety of medications, both for their renal condition and for other unrelated conditions. The inability of

P.237

these patients to excrete drugs and drug metabolites adequately and the influence of their uremic conditions on the functions of other physiological systems require careful adjustments of drug dosage to obtain accurate and adequate blood levels without increased toxicity.

Compounds (e.g., drugs) are cleared by kidneys because of passive filtration through the glomeruli or by active secretion in the kidney tubule. Once in the nephrons, compounds also may be reabsorbed into the circulation. The glomerular filtration rate can be measured using any compound that is filtered by glomeruli and not secreted and reabsorbed. Although exogenous compounds, such as urea and inulin, can be used for this purpose, the relative ease of using endogenous creatinine has made this the method of universal choice. In principle, the following equation determines the relationship between the creatine clearance, $(Cl)_{cr}$, the serum creatinine concentration, $(\bar{C}_S)_{cr}$, and creatinine excretion rate, $(dX_\mu/dt)_t$·cr:

Eq. 9.62

$$(Cl)_{cr} = \frac{(dX_\mu/dt)_t \cdot cr}{(\bar{C}_s)_{cr}}$$

Serum creatinine concentration is constant unless there is a change in the rate of production of creatinine in the body or creatinine clearance. The creatinine clearance in normal kidneys is approximately 110 to 130 mL/min. This value declines with progressive renal impairment, and it drops to zero with severe renal impairment. Creatinine clearance values of 20 to 30 mL/min signify moderate renal impairment; values of less than 10 mL/min signify several renal impairment. Creatinine is poorly secreted and not subject to tubular reabsorption; therefore, its clearance is a useful measure of the glomerular filtration rate. Although creatinine clearance tells us about only one aspect of renal function (i.e., filtration), it is an excellent indicator for assessing the severity of renal impairment.

The extent to which decreased renal function influences drug elimination is a function of the percentage of circulating drug being cleared by the kidneys. From the literature, the influence of renal impairment on the elimination half-life of a drug clearly will be a direct function of the percentage of the drug cleared through the kidneys. If the elimination half-life of a drug that is cleared essentially unchanged via the kidneys is plotted against the endogenous creatinine clearance (Fig. 9.27), the result will be a hyperbola.

Intravenous Bolus Administration (Two-Compartment Model)

Following the administration of a drug intravenously, it usually takes a finite amount of time before the distribution equilibrium is attained in the body. During this distribution phase, the drug concentration in the plasma will decline more rapidly than during the postdistribution phase, as shown in Figure 9.28. There are three possible types of two-compartment models. They differ in whether the elimination of the drug occurs from the central compartment, the peripheral compartment, or both. These three types of two-compartment models are, mathematically, indistinguishable on the basis of available concentration data. The type of two-compartment model illustrated in Figure 9.22 most often is used to describe the pharmacokinetics of drugs. In this model, it is assumed that drug elimination from a two-compartment model occurs exclusively from the central compartment, because the site of biotransformation and excretion (i.e., liver and kidney) are well perfused with blood and presumably, therefore, rapidly accessible to

P.238

drug in the systemic circulation. Whether this distribution phase is apparent will depend on the early collection of blood samples. A distribution phase may last for only a few minutes or for several hours.

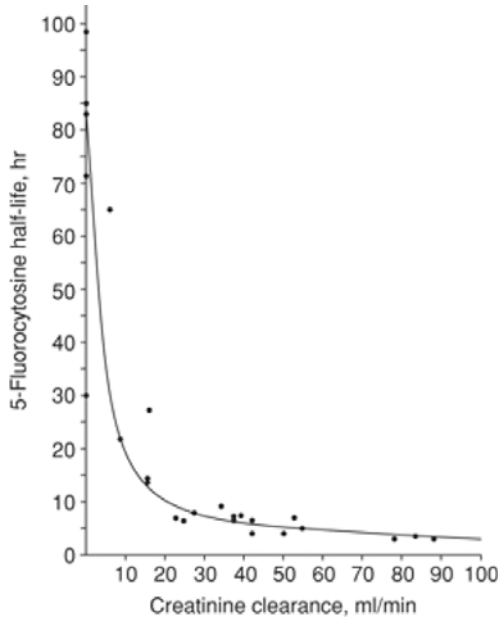

Fig. 9.27. Curvilinear relationship between the elimination half-life of 5-fluorocytosine and renal function (creatinine clearance). (from Gibaldi M. Biopharmaceutics and Clinical Pharmacokinetics, 4th Ed. Philadelphia: Lea and Febiger, 1991; with permission.)

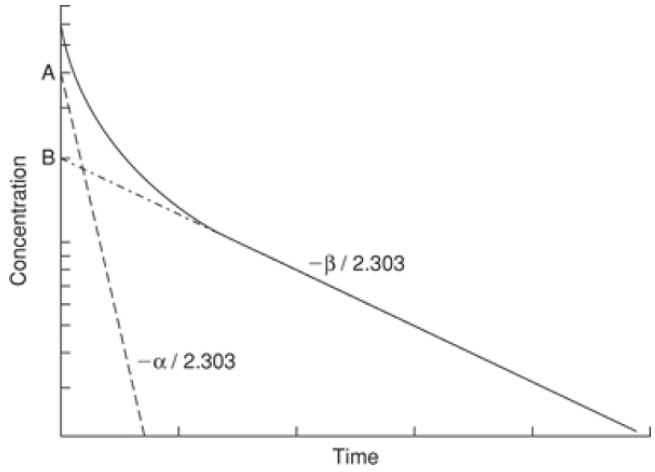

Fig. 9.28. Semilogarithmic plot of drug concentration in the plasma against time following administration of a rapid intravenous injection when the body may be represented as a two compartment open model. The dashed line is obtained by "feathering" the curve.

A semilogarithmic plot of plasma drug concentration as a function of time (Fig. 9.28) after rapid intravenous injection of a drug often can be resolved into two linear components. This can be done graphically by employing the residual, or "feathering," method, as shown in Figure 9.28, in which the slopes of rapid and slow disposition phases will permit the determination of α and β, respectively, in Eq. 9.63. The intercepts on the concentration axis are designated A and B. The entire plasma concentration–time curve may be described by the following equation:

Eq. 9.63 $$C_p = Ae^{-\alpha t} + Be^{-\beta t}$$

where α and β are the first-order distribution and disposition rate constants, respectively. A biexponential decline in the plasma drug concentration justifies, mathematically, the representation of

the body as a two-compartment model.

The intercompartmental rate constants (K_{21} and K_{12}) (Eqs. 9.64 and 9.66) and the elimination rate constant (K_{10}) (Eq. 9.65) for a drug that exhibits the characteristics of a two-compartment model can be determined from the knowledge of α, β, A, and B (Fig. 9.28). This is achieved by employing the following equations:

Eq. 9.64 $$K_{21} = \frac{A\beta + B\alpha}{A + B}$$

where K_{21} is the rate constant associated with the transfer of a drug from compartment II to compartment I (i.e., from the peripheral to the central compartment):

Eq. 9.65 $$K_{10} = \frac{\alpha\beta}{K_{21}}$$

where K_{10} is the elimination rate constant of the drug.

Eq. 9.66 $$K_{12} = \alpha + \beta - (K_{21} + K_{10})$$

where K_{12} is the rate constant associated with the transfer of the drug from compartment I to compartment II (i.e., from the central compartment to the peripheral compartment). Determination of these rate constants permits an assessment of the relative contribution of distribution and the elimination processes to the drug concentration versus time profile. The knowledge of the transfer rate constant (K_{12}) also is required to calculate the amount of drug in the peripheral compartment (X_p) as a function of time after an intravenous administration:

Eq. 9.67 $$X_p = \frac{X_0 K_{12}}{(\beta - \alpha)}(e^{-\alpha t} - e^{-\beta t})$$

where X_0 is the administered dose.

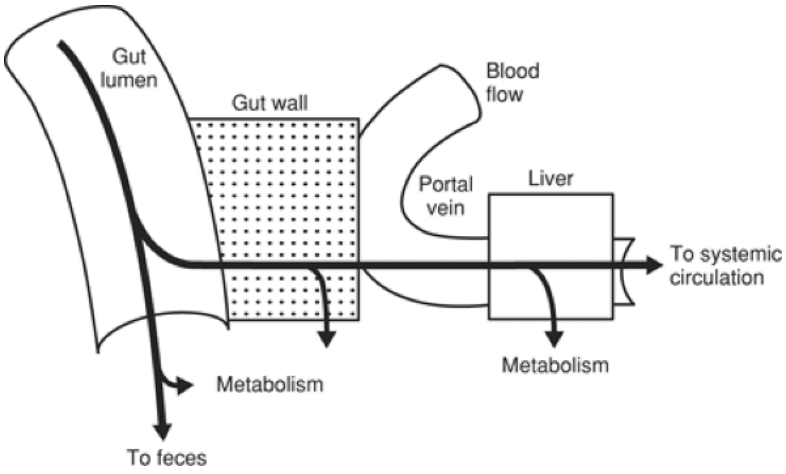

Fig. 9.29. After oral administration, a drug must pass sequentially through the gut lumen, gut wall, and then through the liver before reaching the general circulation. Metabolism may occur in the lumen before absorption, in the gut wall during the absorption, or in the liver after absorption and before reaching the systemic circulation. (From Rowland M, Tozer T. Clinical Pharmacokinetics: Concepts and Application, 2nd Ed. Philadelphia: Lea and Febiger, 1989; with permission.)

Extravascular Route of Administration

When a drug is administered by extravascular routes, absorption is a requisite for a drug to reach the general circulation. Absorption is defined here as a process of a drug proceeding from the site of administration to the site of measurement within the body, generally blood, plasma, or serum. Figure 9.29 represents the passage of a drug through the gastrointestinal tract into the general circulation.

When a drug is administered orally, there are several possible sites for drug loss. One such site is the gastrointestinal lumen, where the decomposition of a drug may occur. If it is assumed that the drug survives destruction in

the gut lumen and is metabolized by enzymes as it passes through the membrane of the gastrointestinal tract, then even though the drug leaves the site of administration, it is considered not to be absorbed systemically. Indeed, loss at any site in the gastrointestinal tract before reaching the site of measurement may contribute to a decrease in the systemic absorption of the drug. The requirement for an orally administered drug to pass through the gastrointestinal tract makes the extent of absorption not always complete. The loss of a drug as it passes for the first time through gastrointestinal membrane and the lining, during absorption, is known as the first-pass effect. Figure 9.30 represents the time course of a drug and metabolite at each site in the body.

The rate or the change in the amount of drug in the body (dX/dt) following administration of a drug by an extravascular route is a function of both the absorption rate (K_aX_a) and the elimination rate (KX):

Eq. 9.68

$$\frac{dX}{dt} = K_aX_a - KX$$

where K_aX_a is the first-order absorption rate, KX is the first-order elimination rate, and K_a and K are the first-order absorption and elimination rate constants, respectively.

When the absorption rate is greater than the elimination rate (i.e., $K_aX_a > KX$), the amount of drug in the body and the drug concentration in the plasma increase with time. Conversely, when the amount of drug remaining at the absorption site (X_a) is sufficiently small, the elimination rate exceeds the absorption rate (i.e., $KX > K_aX_a$); therefore, the amount of drug in the body and the drug concentration in the plasma decrease with time.

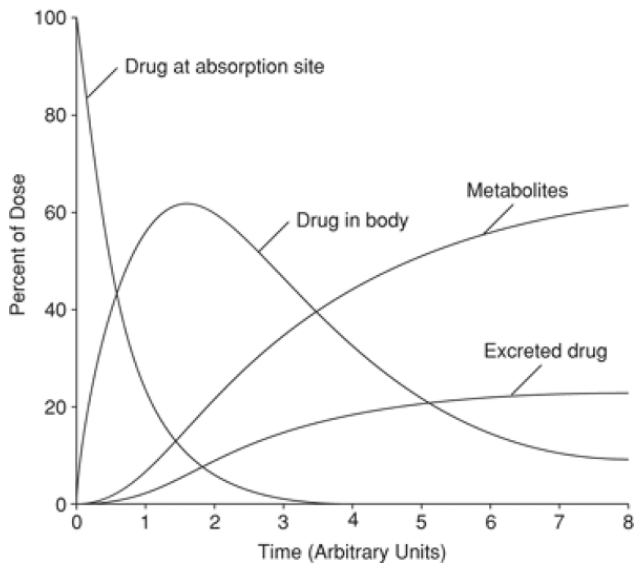

Fig. 9.30. Time course of a drug at each site following an extravascular administration.

The maximum, or peak, plasma concentration after drug administration occurs at the moment when the absorption rate equals the elimination rate (i.e., $K_aX_a = KX$). The faster the drug is absorbed, the higher the maximum plasma concentration and the shorter the time required following administration of a dose to observe the peak plasma concentration. Integration of Equation 9.68 from $t = 0$ to $t = t^*$ and converting the amount to the concentration results in the following equation:

Eq. 9.69

$$C_p = \frac{K_aF(X_a)_0}{V(K_a - K)}(e^{-Kt} - e^{-K_at})$$

where $(X_a)_0$ is the administered dose and F is the fraction of the administered dose that is absorbed and available to reach the general circulation. Equation 9.69 often is used to determine plasma concentration after administration of a drug by an extravascular route when the administered drug manifests the characteristics of a one-compartment model.

The absorption rate constant (K_a) of a drug frequently is larger than the elimination rate constant (K). Under such a condition, at some time after drug administration, the value of the term e^{-Kt} in Equation 9.69 approaches zero, indicating that no more drug is available for absorption, and Equation 9.69 simplifies to

$$\textbf{Eq. 9.70} \qquad C_p = \frac{K_a F(X_a)_0}{V(K_a - K)}(e^{-Kt})$$

$$\textbf{Eq. 9.71} \qquad C_p = \text{Intercept}(e^{-Kt})$$

$$\textbf{Eq. 9.72} \qquad \log C_p = \log \text{Intercept} - \frac{Kt}{2.303}$$

When the absorption is complete, the term X_aK_a disappears from the Equation 9.68, and the equation is reduced to

$$\textbf{Eq. 9.73} \qquad -\frac{dX}{dt} = KX$$

During the postabsorption phase, the decline in the plasma concentration with time follows first-order kinetics. A typical plot of plasma concentration versus time is shown in Figure 9.31, where the intercept of the extrapolated line (I^*) is a complex function of absorption and elimination rate constants (K_a and K, respectively) as well as the dose or amount absorbed, $F(X_a)_0$, and the apparent volume of distribution (V). It is, however, incorrect to assume that the intercept approximates the ratio of dose over the apparent volume of distribution unless the drug is rapidly and completely absorbed, which rarely occurs.

Importance of Absorption Rate

The influence of absorption on the drug concentration time profile is shown in Figure 9.32. Administration of an

equal dose of a drug in three different dosage forms or by three different extravascular routes or three different formations results in threefold the drug in the plasma. The faster the drug is absorbed (i.e., $K_a >>> K$), the greater the peak plasma concentration and the shorter the time required to achieve peak plasma drug concentration.

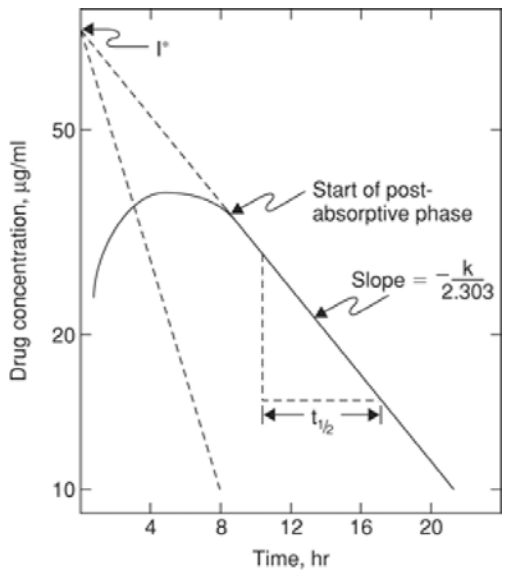

Fig. 9.31. Typical semilogarithmic plot of drug concentration versus time profile in plasma following the administration of a drug by an extravascular route. The dashed line represents the "feathered line" used to obtain the absorption rate constant (K_a).

Many drugs do not exhibit demonstrable pharmacological effects or do not elicit a desired degree of pharmacological response unless a minimum concentration is reached at the site of an action and, therefore, a minimum therapeutic concentration in the plasma. Thus, the absorption rate of a drug may affect the clinical response if it fails to yield the minimum effective concentration. As evident in Figure 9.32, the more rapid the absorption of a drug, the faster its onset of response (i.e., curve A). When the drug is absorbed rather slowly (curve C), the minimum effective concentration is just barely attained. The intensity of maximum pharmacological effects is a function of the drug concentration. The data presented in Figure 9.32 suggest that the administered dose of a drug in curve A may

produce a more intense response than observed in curves B and C.

The peak plasma drug concentration is always lower following administration of a drug by the extravascular route compared with its initial plasma concentration following administration of an identical dose by intravenous solution. In the former, at peak time, some drugs may still remain at the absorption site and some has been eliminated, whereas the entire dose is in the body immediately following the intravenous administration.

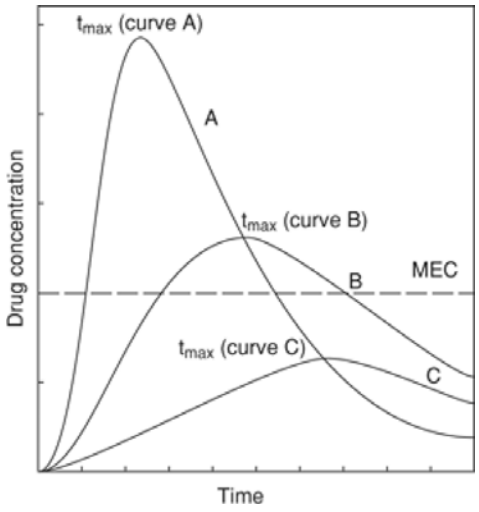

Fig. 9.32. A plasma concentration versus time profile illustrating the influence of absorption rate constant (K_a) on the rate of absorption as reflected in the peak time (t_{max}) and peak plasma concentration $(C_p)_{max}$.

The delay between drug administration and a drug reaching the general circulation may be of particular importance when a rapid onset of effect is desired. This delay is termed "lag time," and it can be anywhere between a few minutes to many hours. Lag time generally is attributed to the slow and poor absorption of the drug, either because of slow disintegration and dissolution of the drug from the dosage form or because of slow removal of the coating material from coated tablets.

Determination of Peak Time

The determination of peak time (t_{max}) can be achieved by employing the following equation:

$$\textbf{Eq. 9.74} \qquad t_{max} = \frac{\ln(K_a/K)}{(K_a - K)}$$

where K_a and K are the first-order absorption and elimination rate constants, respectively. Equation 9.74 shows that the peak time is a function only of the relative magnitude of the absorption and elimination rate constants. As the rate of absorption decreases (i.e., smaller K_a value), the peak time will be higher, as shown in Figure 9.32, progressing from curve C to curve A.

The rate of drug absorption varies when the extravascular route is changed, when the formulation of a drug is changed, or when the dosage form is changed. These changes will be reflected in different peak times for the same dose of a drug. The peak time will be unaffected, however, by a mere change in the size of the administered dose. In many disease states, the impairment in the renal function may affect the elimination rate constant, thereby producing a change in the peak time.

Determination of Peak Plasma Concentrations

The peak (maximum) plasma drug concentration, (C_p)max, in the body occurs at time t_{max}, which is described by substituting t_{max} for time t in Equation 9.69:

$$\textbf{Eq. 9.75} \qquad (C_p)_{max} = \frac{K_a F(X_a)_0}{V(K_a - K)}(e^{-Kt_{max}} - e^{-K_a t_{max}})$$

Equation 9.75 is further simplified into

$$\textbf{Eq. 9.76} \qquad (C_p)_{max} = \text{Intercept}(e^{-Kt_{max}} - e^{-K_a t_{max}})$$

where the intercept of the plasma drug concentration versus time is equal to $K_a F(X_a)_0 / V(K_a - K)$, as described earlier in Equations 9.70 through 9.72.

A much simpler expression can be obtained as follows: At peak time,

$$\textbf{Eq. 9.77} \qquad e^{-K_a t_{max}} = \frac{K}{K_a} e^{-Kt_{max}}$$

Substituting for $e^{-Kt_{max}}$ in Equation 9.75 yields

$$\textbf{Eq. 9.78} \qquad (C_p)_{max} = \frac{K_a F(X_a)_0}{V(K_a - K)} \left(\frac{K_a - K}{K_a} \right) (e^{-Kt_{max}})$$

which, on the cancellation of terms, is readily simplified into

$$\textbf{Eq. 9.79} \qquad (C_p)_{max} = \frac{F(X_a)_0}{V} (e^{-Kt_{max}})$$

where F is the fraction of the dose absorbed, $(X_a)_0$ is the administered dose, V is the apparent volume of distribution, and K and t_{max} are elimination rate constants and peak time, respectively. Equation 9.79 suggests that the peak plasma concentration of a drug is a function of a dose entering the general circulation, the apparent volume of distribution, and the first-order rate constants for absorption and elimination. Again, like the absorption rate constant, the fraction of the administered dose reaching the general circulation will depend on the route of administration, the formulation, and the dosage form. These factors therefore will contribute to the peak plasma concentration of a drug.

Bioavailability

The bioavailability of a drug is defined as the rate and extent to which the administered dose of a drug reaches the general circulation. Generally, rapid and complete absorption of a drug is desirable if it is used for pain, allergy response, insomnia, and other conditions for which a quick onset of action is desired. As indicated earlier (Fig. 9.32), the more rapid the absorption, the shorter the onset of action and the greater the intensity of a pharmacological response. Bioavailability determines the amount of administered dose that reaches the circulation, which also is related to rate of drug clearance (Fig. 9.25).

The efficacy of a single dose is a function of both the rate and the extent of absorption. Thus, for two dosage forms or two extravascular routes to be comparable with regard to the bioavailability following the administration of a drug, the absorption rate of a drug and the extent to which a drug reaches the general circulation from each dosage form or extravascular route must be comparable.

The useful estimate of relative absorption rates of a drug from different products, through different routes of administration or different conditions (i.e., with or without food or in the presence of other drugs, etc.) can be made by comparing the magnitude of time of occurrence of peak concentration, peak concentration, and area under the peak plasma concentration curve, $(AUC)^{\infty}_0$. The peak time and peak plasma concentration can be determined by employing Equations 9.74 and 9.76 or 9.79, respectively, and the extent of absorption can be determined as described below.

Estimating the Extent of Absorption

The extent of absorption can be estimated by determining the total area under the plasma drug concentration–time curve, $(AUC)^{\infty}_0$, or the total amount of an unchanged drug excreted in urine, $(X_u)_{\infty}$, after the administration of a drug. $(AUC)^{\infty}_0$ can be estimated by several methods, such as a planimeter, which is an instrument for measuring the area of a plan figure, and the cut-and-weight method, which weighs the paper of plasma concentration–time curve. The weight is converted to weight per unit area. The most common methods, however, are the application of trapezoidal rule and equation, when possible. In a single-dose study, we cannot determine the area under the plasma concentration time curve by the use of trapezoidal rule alone. In this case, a widely used practice is to determine the area under the plasma concentration–time curve from $t = 0$ to $t = t^*$ (the last sampling time) by means of trapezoidal rule and estimate the remaining area by employing the following equation:

$$\textbf{Eq. 9.80} \qquad (AUC)^{\infty}_{t^*} = C_p^*/K$$

where $(AUC)_{t_*}^{\infty}$ is the area under the plasma concentration–time curve from the last sampling time to time ∞, C_p^* is the last observed plasma concentration, and K is the first-order elimination rate constant. This area under the curve, $(AUC)_{t_*}^{\infty}$, will be added to the area under the curve obtained

from $t = 0$ to $t = t^*$ to calculate the total area under the plasma concentration–time curve:

$$\textbf{Eq. 9.81} \qquad (\mathrm{AUC})_0^{\infty} = (\mathrm{AUC})_0^{t^*} + (\mathrm{AUC})_{t^*}^{\infty}$$

When an intravenous administration of a drug exhibits the characteristics of a one-compartment model, the total area under the plasma concentration vs. time curve is estimated by the following equation:

$$\textbf{Eq. 9.82} \qquad (\mathrm{AUC})_0^{\infty} = \frac{\mathrm{dose}}{VK}$$

where VK is the systemic clearance of a drug.

Following the administration of a drug by an intravenous injection, if it is necessary to use a two-compartment model, the area under the plasma concentration–time curve from $t = 0$ to $t = t^*$ (the last sampling time) may be estimated by using trapezoidal rules, as mentioned earlier. Additionally, the area under plasma concentration–time curve from $t = t^*$ to $t = \infty$ may be computed using the following equation:

$$\textbf{Eq. 9.83} \qquad (\mathrm{AUC})_{t^*}^{\infty} = C_p^*/\beta$$

where C_p^* is the last observed plasma concentration and β is the first-order disposition rate constant.

When a drug is administered by an extravascular route, one may use the following equation to determine $(\mathrm{AUC})_0^{\infty}$:

$$\textbf{Eq. 9.84} \qquad (\mathrm{AUC})_0^{\infty} = \frac{F(\mathrm{dose})}{VK}$$

If it is desired to assess the relative extent of drug absorption from a product, the total area under the plasma concentration from the product to that obtained for a reference drug standard is compared. The reference standard may be an intravenous injection, an orally administered aqueous or water-miscible solution, or another product accepted as a standard.

When it is desired to assess the absolute bioavailability, the reference drug standard becomes an intravenous injection, and when it is desired to judge the bioequivalence, the reference standard is an innovator product. If the $(\mathrm{AUC})_0^{\infty}$ values are identical following the administration of equal doses of a drug through a test product and the reference intravenous solution, we conclude that the drug from the test product is completely absorbed and not subject to presystemic metabolism.

Frequently, however, the standard is an innovator product or another established product. If the $(\mathrm{AUC})_0^{\infty}$ values are identical following the administration of equal doses of the test and reference products, we conclude that the test product is completely bioavailable relative to the standard. It is essential to use the term “relative to the standard,” because we do not know if the standard is completely absorbed or available. Additionally, when two products produce comparable peak plasma drug concentrations and t_{max} and the reference standard is an innovator product, then the products are judged to be bioequivalent.

By using the ratio of area under the plasma concentration–time curve for extravascular to intravenous routes, one can determine the absolute bioavailability of a drug from a test product as follows:

$$\textbf{Eq. 9.85} \qquad F = \frac{(\mathrm{AUC})_0^{\infty}\ \mathrm{oral}}{(\mathrm{AUC})_0^{\infty}\ \mathrm{IV\ solution}}$$

where F is the absolute bioavailability of a drug or the fraction of the administered dose that reaches the general circulation following the administration of equal dose of a drug. If the administered doses of a drug are different then the AUC_0^{∞}, then estimates can be scaled approximately to permit comparison under identical conditions or equivalent doses—assuming, of course, that $(\mathrm{AUC})_0^{\infty}$ is directly proportioned to the administered dose. The relative bioavailability (F_{rel}) of a drug from a test product may be determined by using the following expression:

$$\textbf{Eq. 9.86} \qquad F_{rel} = \frac{(\mathrm{AUC})_0^{\infty}\ \mathrm{test\ product}}{(\mathrm{AUC})_0^{\infty}\ \mathrm{reference\ standard}}$$

Equation 9.86 assumes that the doses administered from each product are identical, and if not, the $(\mathrm{AUC})_0^{\infty}$ values should be scaled for the dose differences.

The determination of bioavailability from the urinary excretion of an unchanged drug following administration by intravenous solution can be assessed using the following equations:

$$\textbf{Eq. 9.87} \qquad (X_u)_{\infty} = \frac{(\mathrm{dose})K_u}{K}$$

where $(X_u)\infty$ is the amount of drug excreted in unchanged form in the urine after administration of a

dose and K_u and K are the first-order excretion and the elimination rate constants, respectively. On the other hand, for drugs administered by an extravascular route, the amount of an unchanged drug excreted in urine, $(X_u)_\infty$, is obtained by

$$\text{Eq. 9.88} \qquad (X_u)_\infty = \frac{F(\text{dose})K_u}{K}$$

where F is the fraction of the administered dose that reaches the general circulation. Therefore, the bioavailability of a drug following its extravascular administration can be expressed as

$$\text{Eq. 9.89} \qquad F = \frac{(X_u)_\infty \text{ extravascular}}{(X_u)_\infty \text{ intravascular}}$$

To determine the assessment of relative bioavailability (F_{rel}), Equation 9.89 becomes

$$\text{Eq. 9.90} \qquad F_{ref} = \frac{(X_u)_\infty \text{ test product}}{(X_u)_\infty \text{ standard product}}$$

and Equations 9.89 and 9.90 are applicable under the condition that the administered doses are identical. The utility of these equations depends on how much of the drug is eliminated by urinary excretion, the sensitivity of the analytical procedure, and the variability in urinary output of the drug. Many drugs are extensively metabolized, with little, if any, drug appearing in an unchanged form in the urine. In such cases, the bioavailability is estimated from the plasma concentration time data.

Presystemic or First-Pass Metabolism

Following oral administration, a drug must pass sequentially from the gastrointestinal lumen, through the gut wall, and through the liver before reaching the general circulation (Fig. 9.29). Because the gut wall and liver are the sites of drug metabolism, a fraction of the amount of drug absorbed may be eliminated or metabolized before reaching the general circulation. Therefore, an oral dose of a drug may be completely absorbed yet incompletely available to reach the general circulation because of presystemic or first-pass effect (metabolism) in the gut wall or liver. If such is the case, it will be reflected in the values of $(AUC)_0^\infty$ for the administered dose.

Criteria have been developed to identify and quantify the extent of presystemic metabolism and to indicate when it is occurring. The determination of presystemic metabolism requires only that the systemic availability of a drug is less than the fraction of the dose absorbed. The fraction absorbed may be determined from the urinary excretion of a drug and metabolite after oral administration of a drug relative to that after intravenous administration. Many drugs undergoing presystemic metabolism in humans have been identified on the basis of this type of information. Differentiation between the gut wall and the liver as the site of presystemic metabolism in humans is more difficult, though relatively easy in animals.

The liver is the most important site of presystemic elimination because of high levels of drug-metabolizing enzymes, its ability to rapidly metabolize different types of drugs, and its unique anatomical location. The following are selected examples of drugs that are subject to considerable hepatic first-pass metabolism: the β-blockers propranolol and metoprolol; the analgesics propoxyphene, meperidine, and pentazocine; the antidepressants imipramine and nortriptyline; and the antiarrhythmic lidocaine.

Hepatic presystemic metabolism is most easily understood when liver is the sole organ of drug elimination. Under these conditions, the clearance of the drug, as determined following intravenous administration of the drug, is equal to

$$\text{Eq. 9.91} \qquad (Cl)_H = \frac{\text{dose}}{(\text{AUC})_0^\infty}$$

Hepatic clearance, however, also is equal to

$$\text{Eq. 9.92} \qquad (Cl)_H = Q_H \cdot E_H$$

where $(Cl)_H$ is the hepatic clearance, Q_H is the hepatic blood flow rate, and E_H is the dimensionless hepatic extraction ratio of the drug. Hepatic blood flow rate (Q_H) has a mean range from approximately 1.1 to 1.8 L/min, with an average of approximately 1.5 L/min. The hepatic extraction ratio (E_H) of a drug may range from zero to one, depending on the liver's ability to metabolize the drug. The maximum hepatic clearance of a drug, excluding hepatic metabolism, is equal to hepatic blood flow; this occurs when $E_H = 1.0$. The fraction of a drug eliminated from portal blood (Fig. 9.29) during the absorption phase is given by the hepatic extraction ratio (E_H); the remainder of the drug (i.e., $1 - E_H$) escapes into the systemic circulation and then is cleared from the circulation by the

liver according to Equation 9.56.

If the fraction of the oral dose is absorbed and then subjected to hepatic presystemic metabolism, the AUC_0^∞ following oral administration of a drug is given by

$$\textbf{Eq. 9.93} \qquad (\mathrm{AUC})_0^\infty = \frac{F(X_a)_0(1 - E_H)}{Q_H \cdot E_H}$$

Because $Q_H \cdot E_H$ is equal to hepatic clearance (Eq. 9.92), which under these conditions is given by the ratio of an intravenous dose to an area under the concentration–time curve, $(AUC)_0^\infty$ IV, Equation 9.93 can be rewritten as

$$\textbf{Eq. 9.94} \qquad \frac{(\mathrm{AUC})_0^\infty \text{ oral}}{(\mathrm{AUC})_0^\infty \text{ IV}} = \frac{F(X_a)_0(1 - E_H)}{(X_a)\text{ IV}}$$

The ratio of $(AUC)_0^\infty$ after oral and intravenous administration of equal doses of drugs is the systemic availability (i.e., the fraction absorbed). If it is assumed that the drug is completely absorbed (i.e., $F = 1$), then Equation 9.94 reduces to

$$\textbf{Eq. 9.95} \qquad F = (1 - E_H)$$

Equation 9.95 shows that the systemic availability of the drug depends on the hepatic extraction ratio of the drug, and those drugs with low hepatic extraction ratios, such as antipyrine, tolbutamide, and warfarin, undergo little presystemic metabolism.

An estimate of hepatic extraction ratio (E_H) may be made from determination of the clearance of a drug following intravenous administration and comparing this value to the mean value of liver blood flow according to Equation 9.92, when rearranged:

$$\textbf{Eq. 9.96} \qquad E_H = \frac{(Cl)_H}{Q_H}$$

The intravenous clearance of propranolol is approximately 1.05 L/min. Assuming that the average liver blood flow is approximately 1.5 L/min, we can determine that the hepatic extraction for propranolol (E_H) is 0.7 and that the fraction absorbed (F) is 0.3. This means that even though propranolol is well absorbed, only 30% of the oral dose is available for systemic circulation.

This type of information, in conjunction with the value of the fraction absorbed (F), has been used to substantiate the predominantly hepatic presystemic elimination of several drugs, including propranolol, lidocaine, pentazocine, and so on. The plasma concentrations for pentazocine, following the oral administration of a 100-mg dose and an intravenous administration of a 30-mg dose, are shown in Figure 9.33. Figure 9.33 shows that

P.244

even though the intravenous dose is smaller, this route of administration provides higher plasma concentration than an oral dose. The systemic availability (F) of pentazocine after oral administration was reported to be 11 to 32%, with a mean of 18%. This low systemic availability is consistent with its high hepatic clearance.

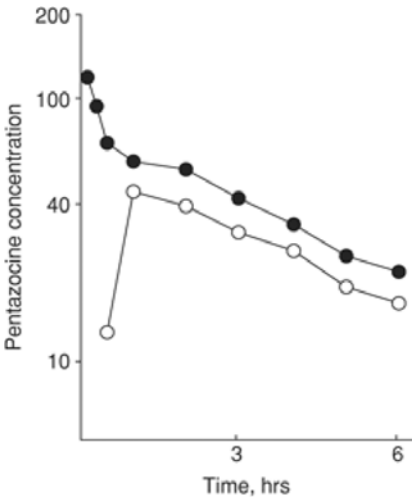

Fig. 9.33. Pentazocine concentration in plasma (ng/mL) after administration of 100 mg orally (○) or 30 mg intravenously (•). (From Ehrnebo M, Boreus L, Lonroth U.

Bioavailability and first-pass metabolism of oral pentazocine in man. Clin Pharmacol Ther 1977;22:888–892; with permission.)

Intravenous Infusion

If a drug is administered intravenously at a constant rate, its plasma concentration at any time will be provided by the following equation:

$$\textbf{Eq. 9.97} \qquad C_p = \frac{Q}{VK}(1 - e^{-Kt})$$

where Q is the constant infusion rate (dose/unit time) and VK is the systemic clearance of the drug.

The plasma drug concentration will rise (Fig. 9.34) with time after the start of an infusion and will slowly approach a constant level, at which the rate of elimination of the drug from the body equals the rate of infusion.

After the commencement of an infusion, it takes approximately 4.32 elimination half-lives of the drug for the plasma concentration of the drug to be within 5% of the constant plateau level and seven elimination half-lives for the concentration to be within 1% of the plateau level. The plateau, or true steady-state, plasma concentration, $(C_p)_{ss}$, can be determined from Equation 9.97 by recognizing that the term (e^{-Kt}) approaches zero with increased time. Therefore,

$$\textbf{Eq. 9.98} \qquad (C_p)_{ss} = \frac{Q}{VK}$$

Equation 9.98 permits one to calculate the infusion rate necessary to attain and then maintain the desired steady-state plasma concentration of a drug if the systemic clearance of the drug is available. Equation 9.98 also provides a convenient way to determine the apparent volume of distribution of a drug by means of intravenous infusion experiment if the infusion rate (Q), the elimination rate constant (K), and the steady-state plasma concentration $(C_p)_{SS}$ are known.

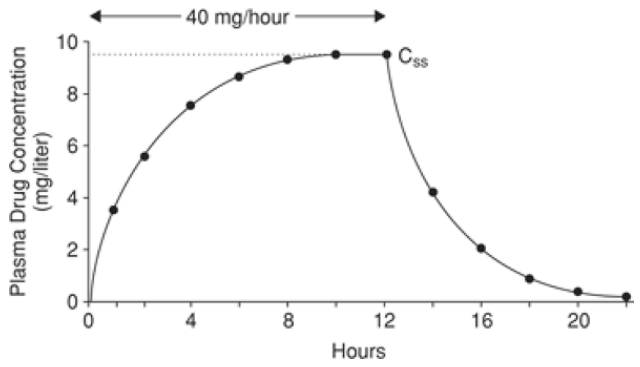

Fig. 9.34. Typical plasma concentration versus time profile following administration of a drug by intravenous infusion.

The decline of plasma concentration after the infusion is stopped can be calculated using the following equation:

$$\textbf{Eq. 9.99} \qquad (C_p)_{t'} = (C_p)_T e^{-Kt'}$$

where $(C_p)t'$ is the plasma concentration at time t' following the cessation of infusion, and $(C_p)_T$ is the plasma concentration at the time the infusion is stopped.

Because the time required to reach the steady-state plasma drug concentration will be quite long for a drug with a long elimination half-life, the administration of an intravenous loading dose often is convenient to attain the desired drug concentration immediately and then maintain this concentration by the continuous infusion. The loading dose (D_L) required to attain the desired drug concentration is calculated as follows:

$$\textbf{Eq. 9.100} \qquad D_L = (C_p)_{ss} V$$

$$\textbf{Eq. 9.101} \qquad D_L = \frac{Q}{K}$$

Using Equation 9.98 or 9.101, one can determine the infusion rate (Q) needed to maintain the plasma concentration obtained by the administration of the loading dose (D_L).

Repetitive Drug Administration (Multiple Dosing)

If a fixed intravenous dose of a drug is administered repeatedly at a constant time interval (τ), the plasma

P.245

concentration of a drug at any time may be calculated using the following expression:

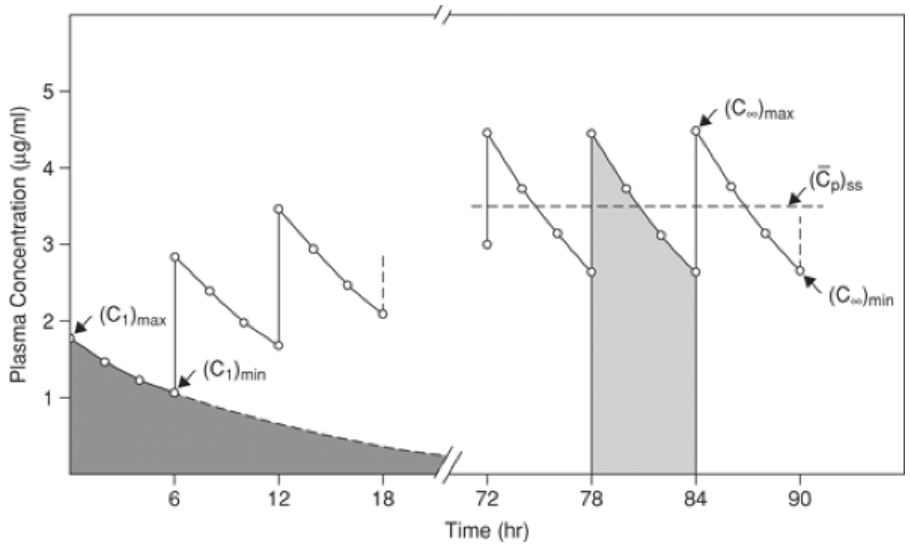

Fig. 9.35. A typical plasma concentration versus time profile for a drug administered intravenously as a fixed dose (X_0) at a fixed dosing interval (τ).

$$\textbf{Eq. 9.102} \qquad (C_p)_t = \frac{X_0}{V}\left(\frac{1 - e^{-nK\tau}}{1 - e^{-K\tau}}\right)e^{-Kt}$$

where n is the number of doses that have been administered, t is the time between $t = 0$ and $t = \tau$, τ is dosing interval, X_0 is the dose administered, V is the apparent volume of distribution of the drug, and K is the elimination rate constant. At the plateau, Equation 9.102 reduces to

$$\textbf{Eq. 9.103} \qquad (C_p)_\infty = \frac{X_0}{V}\left(\frac{e^{-Kt}}{1 - e^{-K\tau}}\right)$$

where $(C_p)_\infty$ is the steady-state plasma concentration.

The maximum plasma concentration of a drug (Fig. 9.35) at the steady state, $(C_p)_\infty$ max, and its minimum plasma concentration at the steady state, $(C_p)_\infty$ min, can be determined by setting $t = 0$ and $t = \infty$, respectively. Equation 9.102 then becomes

$$\textbf{Eq. 9.104} \qquad (C_p)_\infty \max = \frac{X_0}{V}\left(\frac{1}{1 - e^{-K\tau}}\right)$$

and

$$\textbf{Eq. 9.105} \qquad (C_p)_\infty \min = \frac{X_0}{V}\left(\frac{1}{1 - e^{-K\tau}}\right)e^{-K\tau}$$

When drugs are administered as repetitive doses (multiple doses), it often is of practical use to determine the “average” plasma concentration at the plateau or

steady state, $(\overline{C}_p)_{ss}$ average. This is obtained by

Eq. 9.106 $$(\overline{C}_p)_{ss}\ \text{average} = \frac{X_0}{VK\tau}$$

where t is the dosing interval, X_0 is the administered dose, and VK is its systemic clearance. Equation 9.106 clearly indicates that by knowing the apparent volume of distribution and the elimination rate constant, obtained from the administration of a single intravenous bolus dose, the average plasma concentration of a drug can be predicted for the intravenous bolus administration of a fixed dose (X_0) at a constant dosing interval (t). Equation 9.106 clearly indicates that only the size of the dose (X_0) and the dosing interval (t) may be adjusted to obtain the desired average steady-state plasma drug concentration.

It is important to recognize that the average steady-state plasma drug concentration, $(\overline{C}_p)_{ss}$ average, is neither the arithmatic nor geometric mean of $(C_p)_{\infty}$ max and $(C_p)_{\infty}$ min but, rather, the ratio of the area under the plasma concentration–time curve during the dosing interval (t) at the plateau over the dosing interval (t). We know from Equation 9.82 that the ratio of a dose over systemic clearance (VK) equals the area under the plasma concentration–time curve, $(AUC)_0^{\infty}$. Therefore, substituting dose/clearance from Equation 9.82 into Equation 9.106 provides the following:

Eq. 9.107 $$(C_p)_{ss}\ \text{average} = \frac{(AUC)_0^{\infty}}{\tau}$$

where $(AUC)_0^{\infty}$ represents the area under the plasma drug concentration–time curve following the administration of a single intravenous bolus dose.

When the drug is administered by oral route (Fig. 9.36), the mathematical expressions are more complex than analogous equations for intravenous administration:

Eq. 9.108 $$(C_p)_{\infty} = \frac{K_a F (X_a)_0}{V(K_a - K)}\left(\frac{e^{-Kt}}{1 - e^{-K\tau}} - \frac{e^{-K_a t}}{1 - e^{-K_a \tau}}\right)$$

P.246

where $(X_a)_0$ is the dose administered; F is the fraction absorbed; K_a and K are the first-order absorption and the elimination rate constants, respectively; V is the apparent volume of distribution; and t and t are time and dosing intervals, respectively. Following the administration of each successive dose in the postabsorption period, Equation 9.100 reduces to

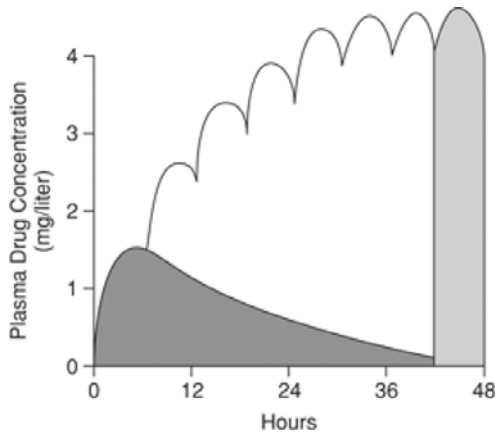

Fig. 9.36. A typical plasma concentration versus time profile for a drug administered orally as a fixed dose $(X_a)_0$ at a fixed dosing interval (τ).

$$\textbf{Eq. 9.109} \qquad (C_p)_{\infty\,\min} = \frac{K_a F (X_a)_0}{V(K_a - K)} \left(\frac{e^{-K\tau}}{1 - e^{-K\tau}} \right)$$

The average steady-state plasma concentration of a drug when administered by an extravascular route can be obtained using the following equation:

$$\textbf{Eq. 9.110} \qquad (C_p)_{ss\ \text{average}} = \frac{F(X_a)_0}{VK\tau}$$

or, by substituting Eq. 9.84 into Eq. 9.110,

$$\textbf{Eq. 9.111} \qquad (C_p)_{ss\ \text{average}} = \frac{(\text{AUC})_0^\infty}{\tau}$$

where F is the fraction absorbed or absolute bioavailability of a drug. Taking the ratio of Equations 9.110 over 9.106 following the attainment of the steady-state condition permits one to determine the bioavailability of a drug; of course, this assumes that the administered doses are identical.

Repeated administration of a fixed dose at a constant dosing interval (t) produces a gradual increase of drug levels in the body until the steady-state condition is attained. This increase is the result of drug accumulation factor (R) because of the sequential dosing of the drug. Therefore, predicting the degree of accumulation of a drug under defined conditions becomes important. Multiplying each side of Equation 9.106 by the apparent volume of distribution and dividing by the administered dose, Equation 9.112 is obtained:

$$\textbf{Eq. 9.112} \qquad \frac{X_{ss}\ \text{average}}{X_0} = \frac{1}{K\tau} = \frac{1.44 t_{1/2}}{\tau}$$

where

X_{ss} average/X_0 = R = drug accumulation factor

where X_{ss} average is the "average" amount of drug in the body at the steady-state condition. The ratio of the average amount of a drug at its steady state and the administered dose is defined as drug accumulation (R). Equation 9.112 describes that the magnitude of drug accumulation is a function of the elimination half-life of a drug and the chosen dosing interval. For example, if a drug with an elimination half-life of 12 hours (i.e., K = 0.0577 hr^{-1}) is administered every 6 hours (t), the ratio of X_{ss} average over dose is 2.9. This means that repeated administration of a fixed dose of a drug in the body is approximately 2.9-fold the amount administered in a single dose. It also is clear from Equation 9.112 that the drug accumulation ratio (R) is directly proportional to the elimination half-life of the drug ($t_{1/2}$) and inversely proportional to the dosing interval (t); however, R is independent of the size of the administered dose.

Because considerable time may elapse before a steady-state condition is attained as a result of repeated drug administration, it often is desirable to administer a large dose initially (i.e., loading dose) to achieve the desired drug levels immediately. Equation 9.42, which describes the time course of drug concentration after a single intravenous bolus dose, may be written as

$$\textbf{Eq. 9.113} \qquad (C_p)_1 \text{ min} = \frac{X_0}{V}(e^{-K\tau})$$

where $(C_p)_1$ min is the drug concentration immediately before administration of the second dose of the same size as the first one (i.e., the minimum concentration occurs at $t = t$ following administration of the first dose). The minimum steady-state plasma concentration, $(C_p)_\infty$ min, is given by Equation 9.105. Thus, the ratio of $(C_p)_\infty$ min to $(C_p)_1$ min (i.e., Eqs. 9.105 and 9.113) is another way to measure the drug accumulation (R). This ratio may be calculated by means of the following expression:

$$\textbf{Eq. 9.114} \qquad R = \frac{(C_p)_\infty \text{ min}}{(C_p)_1 \text{ min}} = \frac{1}{1 - e^{-K\tau}}$$

This ratio of minimum drug concentrations, numerically, is not equal to the ratio of the "average" dose of a drug at steady state and the dose administered (Eq. 9.112).

P.247

If one wished to administer a loading dose (D_L) that produces the minimum concentration equal to $(C_p)_\infty$ min:

$$\textbf{Eq. 9.115} \qquad (C_p)_1 \text{ min} = (C_p)_\infty \text{ min} = \frac{D_L}{V}e^{-K\tau}$$

Dividing the Equation 9.105 by Equation 9.115 will result in

$$\textbf{Eq. 9.116} \qquad 1 = \frac{D}{D_L(1 - e^{-K\tau})}$$

Equation 9.116, on rearrangement, yields an expression to determine the loading dose (D_L):

$$\textbf{Eq. 9.117} \qquad \frac{D_L}{D} = \frac{1}{(1 - e^{-K\tau})}$$

In Equations 9.116 and 9.117, D_L is the loading dose and D is the maintenance dose. Equation 9.117 permits the calculation of loading dose for the chosen maintenance dose and dosing interval (t) and is applicable for the administration of a drug not only by an intravenous bolus but also by the extravascular route. When a drug is administered by the extravascular route, however, it is essential that each maintenance dose be administered following the complete absorption of a drug from the previous dose. Conversely, Equation 9.117 also permits the determination of the maintenance dose required to maintain the minimum drug level produced by the administration of the initial dose for any chosen dosing interval.

Plasma Protein Binding in Pharmacokinetics

Drug binding to plasma proteins affects drug distribution and elimination as well as the pharmacological effect of a drug. The high molecular weight of plasma proteins restricts their passage across capillaries, and their low lipid solubility prevents them from crossing the cell membrane. Analogously, binding of drugs to plasma protein restricts their passage across cell membranes. Only that fraction of the drug concentration that is freely circulating or unbound can penetrate the cell membrane and be subject to glomerular filtration. Hepatic metabolism of most drugs is also limited by the availability of free fraction of drug in the blood. Because the interaction of drugs with plasma protein is a rapidly reversible process, one may view the plasma protein-binding phenomenon as being temporary storage of a drug, subject to instant recall.

Drug binding to plasma protein may be attributed to ionic, Van der Waals, and hydrogen bonding. The most important contribution to drug binding in the plasma is made by albumin, which comprises approximately 50% of the total plasma protein. In healthy subjects, albumin concentration in the plasma is approximately 4 g/100 mL. During pregnancy and other diseases, however, low levels of plasma protein may be observed. Albumin binds a wide variety of drug molecules; however, it plays a particularly important role in the binding of weak acidic and neutral drugs.

α_1-Acid glycoprotein is another important binding protein with an affinity for basic drugs. α_1-Acid glycoprotein is a low-molecular-weight protein. It is an acute-phase reactant, and its concentration in plasma rises in inflammation, malignant diseases, and stress. Conversely, its plasma concentration falls in hepatic diseases and nephrotic syndrome. The average concentration of α_1-acid glycoprotein is approximately 40 to 100 mg/100 mL. The presence of other plasma proteins plays a limited role in drug binding. The drug proteins interactions can be described by applying the law of mass action:

$$\textbf{Eq. 9.118} \qquad D_F + \text{free sites} \underset{K_2}{\overset{K_1}{\rightleftharpoons}} D_B$$

where D_F and D_B represent the free and bound drug, respectively, and K_1 and K_2 are the rate constant of association and dissociation, respectively. Thus,

$$\text{Eq. 9.119} \qquad K = \frac{K_1}{K_2} = \frac{[D_B]}{[D_F][\text{free sites}]}$$

$$\text{Eq. 9.120} \qquad K = \frac{K_1}{K_2} = \frac{[D_B]}{[D_F][nP - D_B]}$$

where K is the equilibrium association constant, K_1 and K_2 are binding rate constants, n is the number of available binding sites per mole of protein, and $[D_F]$, $[D_B]$, and P are the molar concentration of free drug, bound drug, and protein, respectively.

The binding rate constants K_1 and K_2 appear to be large, because the equilibrium is established almost immediately. The value of the equilibrium constant (K) varies from zero, at which essentially no drug is bound, to greater than 10^6, at which almost all drug is bound to the protein. The fraction of drug in the plasma that is free or unbound (f_p) is then obtained as follows:

$$\text{Eq. 9.121} \qquad f_p = \frac{[D_F]}{[D_F] + [D_B]}$$

$$\text{Eq. 9.122} \qquad f_p = \frac{[D_F]}{[D_T]}$$

where $[D_T]$ is the total drug concentration in the plasma. In most cases, for a given amount of drug in the body, the greater the binding of drug to plasma protein and the larger is the total drug concentration of drug in the plasma. Changes in drug binding usually affect the blood level of total drug and play a role in pharmacokinetic variability.

The free fraction of drug in the plasma (f_p) depends on the magnitude of the equilibrium constant (K), the total drug concentration, $[D_T]$, and the protein concentration, $[P]$. In theory, there are limited numbers of

binding sites on the protein. As the drug concentration in the plasma increases, the number of available free sites decreases; therefore, the fraction of available free drug increases. In reality, however, the fraction unbound drug in plasma for most drugs, when administered in therapeutic doses, is essentially constant over the entire drug concentration range. Concentration-dependent changes in the fraction of free drug in the plasma are most likely to occur with drugs exhibiting a high association constant (K = 10^5 to 10^6) administered in large doses.

The relationship between bioavailability and area under the plasma concentration–time curve is nonlinear and absorption rate dependent when the plasma protein binding of a drug is concentration dependent. Two drug products from which a drug is equally well absorbed will produce different values for the area under the plasma concentration–time curve if a difference exists in the absorption rate. Generally, such a comparison will overestimate the extent of drug absorption of the more slowly absorbed product.

The clearance of many drugs from blood is directly proportional to free fraction in the plasma (f_p). The steady-state concentrations of these drugs is inversely proportional to the free fraction in the plasma. On the other hand, clearance of some drugs is largely independent of plasma protein binding. The direction and magnitude of the effect of plasma protein binding on the elimination half-life of a drug depends on the size of the drug's apparent volume of distribution (V) and whether the drug exhibits restrictive clearance (i.e., has an intrinsic clearance less than the liver blood flow). The half-life of a restrictively cleared drug with relatively small apparent volume of distribution (i.e., V < 0.25 L/kg) may show a small decrease in elimination half-life when there is decrease in plasma protein binding (i.e., an increase in the free fraction in plasma. Conversely, the half-life of a nonrestrictively cleared drug with a small apparent volume of distribution may show a small increase in half life when the free fraction is increased. Drugs with a large value for the apparent volume of distribution (i.e., V > 0.5 L/kg) either will be essentially independent of the changes in plasma protein binding (restrictive clearance) or will show an increase in half-life that is directly proportional to the increase in free fraction (nonrestrictive clearance).

The classical methods of studying protein binding of drugs include equilibrium dialysis and ultrafiltration. The latter may provide quick measurements but is not necessarily as accurate as the equilibrium dialysis method. Detailed discussions on this may be found in textbooks listed in *Suggested Readings*.

Statistical Moment Analysis

Statistical moment analysis is a noncompartmental method, based on statistical moment theory, for calculation of the absorption, distribution, and elimination parameters of a drug. This approach to estimating pharmacokinetic parameters has gained considerable attention in recent years.

Table 9.9. Drug Concentration and Drug Concentration–Time Data During and After a 1-Hour, Constant-Rate Infusion

Time (hours)	Concentration (µg/mL)	Concentration-Time (µg/mL/hr)
0.5	3.2	1.6
1.0	5.9	5.9
2.0	4.2	8.4
3.0	3.0	9.0
4.0	2.1	8.4
5.0	1.5	7.5
6.0	1.1	6.6
8.0	0.5	4.0

The zero moment in the drug plasma concentration–time curve is the total area under the plasma concentration–time curve from $t = 0$ to $t = \infty$, $(AUC)_0^{\infty}$. Estimates of the area under this curve are useful in calculating bioavailability as well as drug clearance, which is the ratio of dose over area under the concentration–time curve for an intravenous dose.

The first moment of the plasma concentration–time profile is the total area under the concentration–time curve resulting from plot of the product of plasma concentration and time (i.e., $C_p t$) versus time, as illustrated in Table 9.9 and Figure 9.37 (39).

Column 2 of Table 9.9 shows the concentration vs. time data obtained following a 1-hour constant-rate infusion, and column 3 also includes concentration-time values for the product of concentration × time. These values are plotted against time in Figure 9.34. The area

under the curve for the concentration–time plot can be obtained by employing trapezoidal rule. The total area under the curve for the product of concentration × time is termed the “area under the first-moment curve” (AUMC).

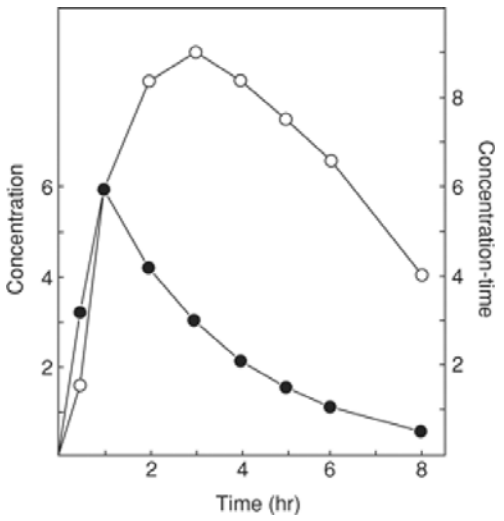

Fig. 9.37. Plots of drug concentration (μg/mL; •) and drug concentration × time (μg/mL/hr; ○) versus time during and after 1 hour of a constant-rate infusion. The area under the concentration versus time plot to infinity is AUC; the area under the concentration × time versus time plot to infinity is AUMC. (From Gibaldi M. Biopharmaceutics and Clinical Pharmacokinetics, 4th Ed. Philadelphia: Lea and Febiger, 1991; with permission.)

The ratio of the AUMC over the area under the concentration–time curve for any drug, according to the theory, is the assessment of the mean residence time (MRT). The MRT provides a quantitative estimate of the persistence of a drug in the body, and like the half-life of a drug, MRT or persistence is a function of distribution and elimination of a drug. Comparison of MRTs following administration of a drug as an intravenous bolus or via any other extravascular route provides information regarding the mean absorption time (MAT).

One of the most useful properties of statistical moment analysis is that it permits estimation of the apparent volume of distribution that is independent of drug elimination (i.e. regardless of the model chosen to describe the concentration time data).

Mean Residence Time (MRT)

The MRT of a drug following administration of a single dose is provided by the following equation:

$$\textbf{Eq. 9.123} \qquad \mathrm{MRT} = \frac{\mathrm{AUMC}}{\mathrm{AUC}}$$

The MRT for a drug administered intravenously provides a useful estimate of the persistence time in the body. Therefore, in this sense, it is related to the half-life of a drug. When applied to a drug that distributes rapidly (i.e., one-compartment model), it has been shown that

$$\textbf{Eq. 9.124} \qquad \mathrm{MRT} = \frac{1}{K}$$

where K is the elimination rate constant.

Because the half-life of a drug is equal to $0.693/K$, half-life is a measurement of the time required to eliminate 50% of the administered dose. The MRT, on the other hand, indicates the time required to eliminate 63.2% of the administered dose.

When a drug is administered by an extravascular route, statistical moment analysis theory also can be employed for estimating the rate of absorption. This approach, however, requires the calculation of MRT for intravascular as well as extravascular routes, because the method is based on the differences in MRT for different modes of administration. In general,

$$\textbf{Eq. 9.125} \qquad \mathrm{MAT} = (\mathrm{MRT})_{\mathrm{EV}} - (\mathrm{MRT})_{\mathrm{IV}}$$

where $(\mathrm{MRT})_{\mathrm{EV}}$ is the MRT following administration of a drug by an extravascular route and $(\mathrm{MRT})_{\mathrm{IV}}$ is the MRT for the intravenous bolus dose. When the administered drug follows the first-order process,

$$\text{Eq. 9.126} \qquad (\text{MRT})_{EV} = \frac{1}{K_a}$$

where K_a is the first-order absorption rate constant. Under these conditions,

$$\text{Eq. 9.127} \qquad K_a = \frac{1}{\text{MAT}}$$

and the absorption half-life is obtained by 0.693/MAT.

The statistical moment theory offers an attractive alternative for the evaluation and estimation of the absorption data, and even in the absence of intravenous data, this method permits the ranking of several dosage forms, with respect to drug release and absorption, from the available MRT values.

Summary

From this discussion, the efficacy of a drug is not determined by its pharmacodynamic characteristics alone, but efficacy also depends, to a large extent, on the pharmacokinetic parameters of the drug, because ADME processes control the rate and extent to which an administered dose of a drug reaches its site of action.

In light of a high degree of structural variability of drugs, multiplicity of kinetics and metabolite kinetics, the task of establishing a clear correlation between the structured chemistry of substituents and their pharmacokinetic properties appears somewhat daunting. The pharmacokinetic fate of a drug molecule, however, appears to be a consequence of its physicochemical properties and, therefore, may, to some extent, be predicted from its chemical structure.

Although the drug in the formulation has received considerable attention, many of the alterations in the formulation may be considered as chemical changes. Most of what has been reported applies primarily to the gastrointestinal absorption of drugs and may be viewed as attempts to:

1. Maximize the rate of absorption by increasing the rate of dissolution (i.e., micronization, salt of acid or bases, amorphous form and metastable polymorph, etc.).
2. Decrease the loss of a drug because of its degradation in the stomach (i.e., acid, insoluble esters or salt, and chemically stable derivatives of a drug).
3. Extend the duration of action by reducing the rate of a drug's release from a dosage form (e.g., timed release, depot-forming injectable, macrocrystals, and slowly dissolving salts).
4. Decrease the loss of a drug by reducing the complex formation.

These examples for enhancing gastrointestinal absorption represent the response to a particular problem with the parent compound and, therefore, may be viewed as

“corrective” research. It is of considerable interest to see this aspect of research become “predictive and preventive,” in which the pharmacokinetic parameters of drugs are required in the early phases of drug design to optimize the effectiveness of drugs.

An immediate problem facing those who would consider optimizing all factors of a drug is physically locating the receptor site and defining the ideal time course for the drug–receptor interaction, sustained effects, and so on. An ideal drug molecule should reach the site of action, arrive rapidly in sufficient quantity, remain at the site of action for sufficient time, be excluded from other sites, and be removed from the site, when appropriate. Such an ideal drug molecule rarely exists, however, and alternate approaches are chosen to optimize the effectiveness of a drug. Furthermore, if a correlation exists between a biological response and the blood levels of a drug in the biological fluid, then the pharmacokinetic parameters play an important role in influencing the biological response, because these parameters influence the magnitude of the blood level of a drug in the body. The task of examining the examples of drugs illustrating the connection between biological response and pharmacokinetics study is not an easy one, but the results do convey the important facts that:

1. Pharmacokinetic parameters influence the biological responses, which are critical in drug design, and
2. Pharmacokinetic parameters can be modified by subtle structural changes, which in turn may influence the desired blood level.

The ultimate goal is to design a drug molecule that exhibits the desired pharmacological effect as a result of the proper balance of ADME processes. Figure 9.37 illustrates how modification of a parent structure can influence the availability of a drug to the receptor site (53).

The following are some of the processes shown in Figure 9.38 that may be altered by changing a substituent group on the drug molecule:

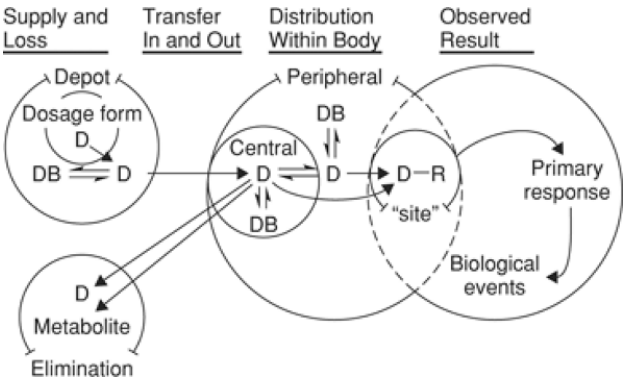

Fig. 9.38. How some of the processes can be altered by changing a substituent group on a drug molecule.

I. Supply and loss:
   A. Rate of transfer from the dosage form.
   B. Binding of a drug in the depot and
   C. Stability of a drug in the depot.

II. Distribution in the body:
   A. Binding of a drug in the central and peripheral compartments.
   B. Apparent volume of distribution and
   C. Transfer of a drug to the receptor sites.

III. Drug-receptor interaction.

Consider the following well-known example for the design of a urinary tract anti-effective. The site of infection is the urinary tract. The example selected is the pro-drug, methenamine. In acidic pH, methenamine is converted to formaldehyde, which acts as an antibacterial agent (Fig. 9.39). Tablets of methenamine often are enteric coated to prevent conversion to formaldehyde in the stomach. Methenamine is cleared intact from the kidney into the urine, where it is hydrolyzed to formaldehyde if the pH is less than 6.5. The rate of hydrolysis is controlled by the urinary pH.

The influence of structural effects on pharmacokinetic parameters can be illustrated using the following examples: The steady-state levels of the antibiotic carbenicillin are twice those of ampicillin. These higher blood levels of carbenicillin following intravenous administration have been attributed to its efficacy in the treatment of relatively resistant infections, such as *Pseudomonas* sp. The reason for these differences in the higher steady-state plasma concentration is the larger apparent volume of distribution for ampicillin, because the elimination rate constants are similar. If all the factors were equal, one may argue that an increased value for the apparent volume of distribution is a clinical advantage, because bacteria germinate more frequently in the tissue than in the blood. The effectiveness of an antibiotic depends on its penetration into tissues, particularly inflamed tissue. Thus, if plasma protein binding is equal for both antibiotics, the antibiotic with a larger volume of distribution would appear to be reaching the site of action with better efficacy, but this is by no means unequivocal. Therefore, the spectrum of research activity in the area of antibiotics would imply that the following goals for molecular modifications are generally pursued:

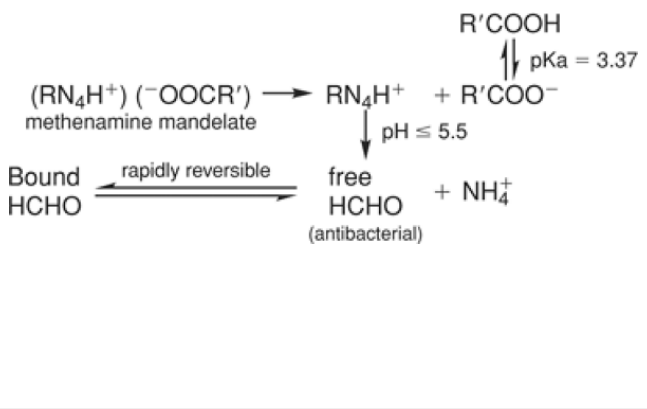

Fig. 9.39. Conversion of methenamine to formaldehyde in acidic pH.

1. Increased tissue distribution.
2. Longer half-life to maintain a higher blood level and decrease the frequency of dose administration.
3. Decreased binding capacity to foods and plasma protein.

Acknowledgment

The author would like to acknowledge Dr. Philip Breen, Associate Professor of Pharmaceutics, School of Pharmacy and the University of Arkansas for Medical Sciences, for helpful discussions and suggestions in preparing this chapter.

Chapter 10

Drug Metabolism

David A. Williams

What is a poison?

All substances are poisons;

There is none that is not a poison.

The right dose differentiates a poison from a drug.

—Paracelsus (1493–1541)

Introduction

Humans are exposed throughout their lifetime to a large variety of drugs and nonessential exogenous (foreign) compounds (collectively termed "xenobiotics") that may pose health hazards. Drugs taken for therapeutic purposes as well as occupational or private exposure to the vapors of volatile chemicals or solvents pose possible health risks; smoking and drinking involve the absorption of large amounts of substances with potential adverse health effects. Furthermore, the ingestion of natural toxins in vegetables and fruits, pesticide residues in food, as well as carcinogenic pyrolysis products from fats and protein formed during the charbroiling of meat have to be considered. Most of these xenobiotics undergo enzymatic biotransformations by xenobiotic-metabolizing enzymes in the liver and extrahepatic tissues and are eliminated by excretion as hydrophilic metabolites. In some cases, especially during oxidative metabolism, numerous chemical procarcinogens form reactive metabolites capable of covalent binding to biopolymers, such as proteins or nucleic acids—critical components that can lead to mutagenicity, cytotoxicity, and carcinogenicity. Therefore, insight regarding the biotransformation and bioactivation of xenobiotics becomes an indisputable prerequisite for the assessment of drug safety and risk estimation of chemicals and drugs.

Detoxication and toxic effects of drugs and other xenobiotics have been studied extensively in various mammalian species. Frequently, differences in sensitivity to these toxic effects were observed and can now be attributed to genetic differences between species in the isoenzyme/isoforms of cytochrome P450 monooxygenases (CYP450). The level of expression of the CYP450 enzymes is regulated by genetics and a variety of endogenous factors, such as hormones, gender, age, and disease, as well as the presence of environmental factors, such as inducing agents. Drugs were developed and prescribed under the old paradigm that "one dose fits all," which largely ignores the fact that humans (both adults and children) are genetically and metabolically different, resulting in a variable response to drugs.

Drugs can no longer be regarded as chemically stable entities that elicit the desired pharmacological response and then are excreted from the body. Drugs undergo a variety of chemical changes in humans by enzymes of the liver, intestine, kidney, lung, and other tissues, with subsequent alterations in the nature of their pharmacological activity, duration of activity, and toxicity. Thus, the pharmacological and toxicological activity of a drug (or xenobiotic) is, in many ways, the consequence of its metabolism.

Drug therapy is becoming oriented more toward controlling metabolic, genetic, and environmental illnesses (e.g., cardiovascular disease, mental illness, cancer, and diabetes) rather than short-term therapy. In most of these cases, drug therapy lasts for months or even years, and the problem of drug toxicity from long-term therapy has become increasingly important.

The practice of prescribing several drugs simultaneously is common. Thus, an awareness of possible drug–drug interactions is essential to avoid catastrophic synergistic effects and chemical, enzymic, and pharmacokinetic interactions that may produce toxic side effects.

The study of xenobiotic metabolism has developed rapidly during the past few decades (1,2,3,4,5,6,7,8,9). These studies have been fundamental in the assessment of drug efficacy, safety, and the design of dosage regimens; in the development of food additives and the assessment of potential hazards of contaminants; in the evaluation of toxic chemicals; and in the development of pesticides and herbicides and their metabolic fate in insects, other animals, and plants. The metabolism of drugs and other xenobiotics is fundamental to many toxic processes, such as carcinogenesis, teratogenesis, and tissue necrosis. Often, the same enzymes involved in drug metabolism also carry out the regulation and metabolism of endogenous substances. Consequently, the inhibition and induction of these enzymes by drugs and xenobiotics may have a profound effect on the normal processes of intermediary metabolism, such as tissue growth and development, hematopoiesis, calcification, and lipid metabolism.

Familiarity with the mechanisms of drug metabolism often can predict the consequences of drug–drug interactions, drug–food interactions, and herbal drug–drug interactions to explain a patient's adverse responses to drug regimens. Incorporating pharmacogenomics into the selection of drug regimens will change the way in which drugs are chosen for patients. Selection based on the patient's individual genetic makeup could eliminate the unpredictable response of drug treatment because of genetic polymorphisms that effects metabolism, clearance, and tolerance. Pharmacogenomic testing to predict

a patient's phenotype (i.e., poor metabolizer) and, thus, their ability to metabolize drugs will become common in the future. Armed with such knowledge, improved selection of proper drug regimen and dose can be assured before therapy begins.

Clinical Significance

The basic principles of drug metabolism may inform a wide variety of clinical decisions regarding pharmacotherapy. For example, a

thorough understanding enables a careful assessment for drug-drug interactions in particular patient cases. Drugs, as chemical entities, can be substrates, inhibitors, or inducers of metabolic enzymes. The interplay of these roles potentially influences serum drug concentrations in ways that may directly affect the desired outcome, i.e., decreases in levels that may prevent therapeutic efficacy or increases that may enhance risks of toxicity. There are certainly many more theoretical pharmacokinetic interactions that invoke these mechanisms than are actually seen in clinical practice. Through careful observation and analysis of unexpected and possibly concentration-dependent events, one could more readily identify and document which interactions are of greater clinical significance by virtue of their actual occurrence in patients. The clinician would then be poised to recommend appropriate dosage adjustments or medication changes based on the actual outcomes of these interactions.

In addition, the biotransformation of drugs may produce reactive metabolites which, through basic chemical reactions, may interact with the components of cellular membranes and proteins in a manner that disrupts normal structure and function. A working knowledge of those functional groups within drug molecules that may be more susceptible to reactive metabolite formation could help explain toxic sequelae when they emerge during a medication trial. This could be useful information whenever alternative therapeutic agents within a given chemical class are being considered.

Ongoing discoveries from studies in the pharmacogenetics field are expanding the drug metabolism literature in directions that hint at the future prospect of truly individualized drug regimens. The need to keep abreast of these new developments is both compelling and exciting, and their application builds upon the principles presented in this chapter.

Mark D. Watanabe, PharmD, PhD, BCPP
Assistant Clinical Specialist, Department of Pharmacy Practice, Northeastern University, Boston, MA

The increased knowledge of drug metabolism, fed by the need for greater safety evaluation of drugs and chemicals, has resulted in a proliferation of publications (e.g., *Drug Metabolism Reviews, Drug Metabolism and Disposition*, and *Xenobiotica*) and a series of monographs that present the current state of knowledge of foreign compound metabolism from biochemical and pharmacological viewpoints (3,4,5,6,7,8,9).

Pathways of Metabolism

Drugs, plant toxins, food additives, environmental chemicals, insecticides, and other chemicals foreign to the body undergo enzymic transformations that usually result in the loss of pharmacological activity. The term “detoxication” describes the result of such metabolic changes. Although drug metabolism usually leads to detoxication, the processes of oxidation, reduction, glucuronidation, sulfation, and other enzyme-catalyzed reactions may lead to the formation of a metabolite having therapeutic or toxic effects. This process often is referred to as “bioactivation.” One of the earliest examples of bioactivation was the reduction of Prontosil to the antibacterial agent sulfanilamide. Other examples of drug metabolism leading to therapeutically active drugs include the hydroxylation of acetanilid to acetaminophen as well as the N-demethylation of the antidepressant imipramine to desipramine and the anxiolytic diazepam to desmethyldiazepam. The insecticide parathion is desulfurized by both insects and mammals to paraoxon.

Most drugs and other xenobiotics are metabolized by enzymes normally associated with the metabolism of endogenous constituents (e.g., steroids and biogenic amines). The liver is the major site of drug metabolism, although other xenobiotic-metabolizing enzymes are found in nervous tissue, kidney, lung, plasma, and the gastrointestinal tract (digestive secretions, bacterial flora, and the intestinal wall).

Although hepatic metabolism continues to be the most important route of metabolism for xenobiotics and drugs, other biotransformation pathways play a significant role in the metabolism of these substances. Among the more active extrahepatic tissues capable of metabolizing drugs are the intestinal mucosa, kidney, and lung (see the discussion of extrahepatic metabolism). The ability of the liver and extrahepatic tissues to metabolize substances to either pharmacologically inactive or bioactive metabolites before reaching systemic blood levels is termed “first-pass metabolism” or the “presystemic first-pass effect.” Other metabolism reactions occurring in the gastrointestinal tract are associated with the bacteria and other microflora of the tract. The bacterial flora can affect metabolism through the 1) production of toxic metabolites, 2) formation of carcinogens from inactive precursors, 3) detoxication, 4) exhibition of species differences in drug metabolism, 5) exhibition of individual differences in drug metabolism, 6) production of pharmacologically active metabolites from inactive

precursors, and 7) production of metabolites not formed by animal tissues.

Phase 1 Reactions

The pathways of xenobiotic metabolism are divided into two major categories. Phase 1 reactions (biotransformations) include oxidation, hydroxylation, reduction, and hydrolysis. In these enzymatic reactions, a new functional group is introduced into the substrate molecule, an existing functional group is modified, or a functional group or acceptor site for Phase 2 transfer reactions is exposed, thus making the xenobiotic more polar and, therefore, more readily excreted.

Phase 2 Reactions

Phase 2 reactions (conjugation) are enzymatic syntheses whereby a functional group, such as alcohol, phenol, or amine, is masked by the addition of a new group, such as acetyl, sulfate, glucuronic acid, or certain amino acids, which further increases the polarity of the drug or xenobiotic. Most substances undergo both Phase 1 and Phase 2 reactions sequentially.

Those xenobiotics that are resistant to metabolizing enzymes or are already hydrophilic are excreted largely unchanged. This basic pattern of xenobiotic metabolism is common to all animal species, including humans, but species may differ in details of the reaction and enzyme control.

Factors Affecting Metabolism

As indicated earlier, drug therapy is becoming oriented more toward controlling metabolic, genetic, and environmental illnesses rather than short-term therapy associated with infectious diseases. In most cases, drug therapy lasts for months or even years, and the problems of drug–drug interactions and chronic toxicity from long-term drug therapy have become more serious. Therefore, a greater knowledge of

drug metabolism is essential. Several factors influencing xenobiotic metabolism include:

1. *Genetic factors.* Individual differences in drug effectiveness (drug sensitivity or drug resistance), drug interactions, and drug toxicity may depend on racial and ethnic characteristics with the population frequencies of the many polymorphic genes and the expression of the metabolizing enzymes. Pharmacogenetics focuses primarily on genetic polymorphisms (mutations) responsible for interindividual differences in drug metabolism and disposition (10). Genotype–phenotype correlation studies have validated that inherited mutations result in two or more distinct phenotypes causing very different responses following drug administration. The genes encoding for CYP2A6, CYP2C9, CYP2C19, and CYP2D6 are functionally polymorphic; therefore, at least 30% of CYP450-dependent metabolism is performed by polymorphic enzymes. For example, mutations in the *CYP2D6* gene result in poor, intermediate, or ultrarapid metabolizers of more than 30 cardiovascular and central nervous system drugs. Thus, each of these phenotypic subgroups experience different responses to drugs extensively metabolized by the CYP2D6 pathway ranging from severe toxicity to complete lack of efficacy. For example, ethnic specificity has been observed with the sensitivity of the Japanese and Chinese to ethanol as compared to Caucasians, CYP2C19 polymorphism (affects ~20% Asians and ~3% Caucasians) and the variable metabolism of omeprazole (proton pump inhibitor) and antiseizure drugs, and the polymorphic paraoxonase–catalyzed hydrolysis of the neurotoxic organophosphates and lipid peroxides (atherosclerosis) (see the discussion of genetic polymorphism).

   Incorporating pharmacogenomics, the study of heritable traits affecting patient response to drug treatment, into drug therapy will alter the way in which drug regimens are chosen for patients based on their individual genetic makeup (10), thus eliminating the unpredictable response of drug treatment because of genetic polymorphisms that effect metabolism, clearance, and tolerance. Understanding how individuals are genetically predisposed to differences in metabolism risk may result in new classes of drugs that are metabolized by nonpolymorphic CYP450 enzymes.

2. *Physiologic factors.* Age is a factor because the very young and the old have impaired metabolism. Hormones (including those induced by stress), sex differences, pregnancy, changes in the intestinal microflora, diseases (especially those involving the liver), and nutritional status also can influence drug and xenobiotic metabolism.

   Because the liver is the principal site for xenobiotic and drug metabolism, liver disease can modify the pharmacokinetics of drugs metabolized by the liver (11,12,13). Several factors identified as major determinants of the metabolism of a drug in the diseased liver are the nature and extent of liver damage, hepatic blood flow, the drug involved, the dosage regimen, and the degree of participation of the liver in the pharmacokinetics of the drug. Liver disease affects the elimination half-life of some drugs but not of others, although all undergo hepatic biotransformation (Table 10.1). Some results have shown that the capacity for drug metabolism is impaired in chronic liver disease, which could lead to drug overdosage. Consequently, because of the unpredictability of drug effects in the presence of liver disorders, drug therapy under these circumstances is complex, and more than the usual caution is needed (13).

Table 10.1. The Effect of Liver Disease in Humans on the Elimination Half-Life of Various Drugs[a]

Difference Reported	No Difference Reported
Acetaminophen	Chlorpromazine
Amylbarbital	Dicoumarol
Carbenicillin	Phenytoin

Hexobarbital	
Isoniazid	
Lidocaine	
Meperidine	
Meprobamate	

Pentobarbital
Phenobarbital
Prednisone
Rifamycin
Tolbutamide
Theophylline
[a]Clearance is disputable but may be increased.

Substances influencing drug and xenobiotic metabolism (other than enzyme inducers) include lipids, proteins, vitamins, and metals. Dietary lipid and protein deficiencies diminish microsomal drug-metabolizing activity. Protein deficiency leads to a reduction in hepatic microsomal protein and lipid deficiency; oxidative metabolism is decreased because of an alteration in endoplasmic reticulum (ER) membrane permeability affecting electron transfer. In terms of toxicity, protein deficiency would increase the toxicity of drugs and xenobiotics by reducing their oxidative microsomal metabolism and clearance from the body.

3. *Pharmacodynamic factors.* Dose, frequency, and route of administration, plus tissue distribution and protein binding of the drug, affect its metabolism.
4. *Environmental factors.* Competition of ingested environmental substances with other drugs and xenobiotics for the metabolizing enzymes and poisoning of enzymes by toxic chemicals, such as carbon monoxide or pesticide synergists, alter metabolism. Induction of enzyme expression (the number of enzyme molecules is increased, but the activity is constant) by other drugs and xenobiotics is another consideration.

   Such factors may change not only the kinetics of an enzyme reaction but also the whole pattern of metabolism, thereby altering the bioavailability, pharmacokinetics, pharmacological activity, or toxicity of a xenobiotic. Species differences in response to xenobiotics must be considered during the extrapolation of pharmacological and toxicological data from experiments in animals to humans. The primary factors in these differences probably are the rate and pattern of drug and xenobiotic metabolism in the various species.

Drug Biotransformation Pathway (Phase 1)

Human Hepatic Cytochrome P450 Enzyme System

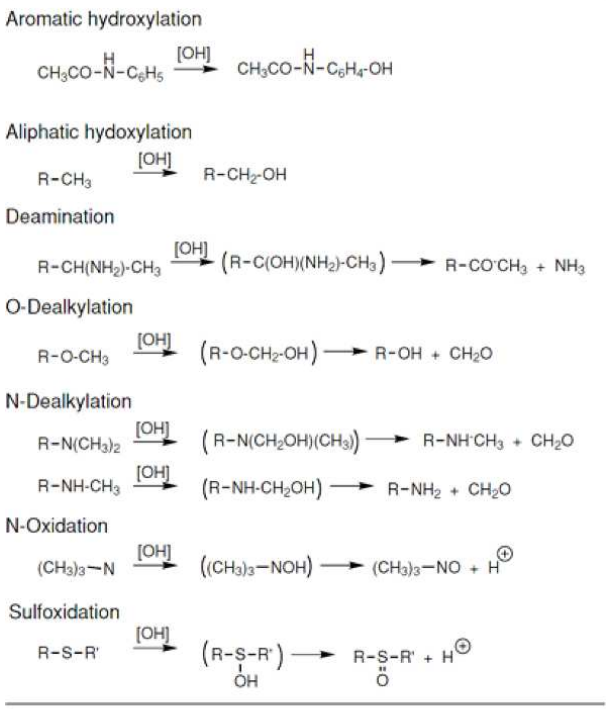
Introduction

Oxidation probably is the most common reaction in xenobiotic metabolism. This reaction is catalyzed by a group of membrane-bound monooxygenases found in the smooth ER of the liver and other extrahepatic tissues, termed the “cytochrome P450 monooxygenase enzyme system” (14) (hereafter, the abbreviation CYP450 will be used for this enzyme system). Additionally, CYP450 has been called a mixed-function oxidase or microsomal hydroxylase. The tissue homogenate fraction containing the smooth ER is called the microsomal fraction. The CYP450 functions as a multicomponent electron-transport system responsible for the oxidative metabolism of a variety of endogenous substrates (e.g., steroids, fatty acids, prostaglandins, and bile acids) and exogenous substances (xenobiotics), including drugs, carcinogens, insecticides, plant toxins, environmental pollutants, and other foreign chemicals. Central to the functioning of this unique superfamily of heme proteins is a iron protoporphyrin. The iron protoporphyrin is coordinated to the sulfur of cysteine and has the ability to form a complex with carbon monoxide, the result of which is a complex that has its major absorption band at 450 nm (thus the title of these metabolizing CYP450 enzymes). The CYP450 has an absolute requirement for NADPH (reduced form of nicotinamide adenine dinucleotide phosphate) and molecular oxygen (dioxygen). The rate at which various compounds are metabolized by this system depends on the species, strain, nutritional status, tissue, age, and pretreatment of the animals. The variety of reactions catalyzed by CYP450 include (Table 10.2) the oxidation of alkanes and aromatic compounds; the epoxidation of alkenes, polycyclic hydrocarbons, and halogenated benzenes; the dealkylation of secondary and tertiary amines and ethers; the deamination of amines; the conversion of amines to N-oxides, hydroxylamine, and nitroso derivatives; and the dehalogenation of halogenated hydrocarbons. It also catalyzes the oxidative cleavage of organic thiophosphate esters, the sulfoxidation of some thioethers, the conversion of phosphothionates to the phosphate derivatives, and the reduction of azo and nitro compounds to primary aromatic amines.

The most important function of CYP450 is its ability to “activate” molecular oxygen (dioxygen), permitting the incorporation of one atom of oxygen into an organic substrate molecule concomitant with the reduction of the other atom of oxygen to water. The introduction of a hydroxyl group into the hydrophobic substrate molecule provides a site for subsequent conjugation with hydrophilic compounds (Phase 2), thereby increasing the aqueous solubility of the product for its transport and excretion from the organism. This enzyme system not only catalyzes xenobiotic transformations in ways that usually lead to detoxication but also, in some cases, in ways that lead to products

having greater cytotoxic, mutagenic, or carcinogenic properties. A nonheme, microsomal flavoprotein monooxygenase is responsible for

the oxidation of certain nitrogen- and sulfur-containing organic compounds.



having greater cytotoxic, mutagenic, or carcinogenic properties. A nonheme, microsomal flavoprotein monooxygenase is responsible for the oxidation of certain nitrogen- and sulfur-containing organic compounds.

Table 10.2. Hydroxylation Mechanisms Catalyzed by Cytochrome P450

Components of CYP450

The CYP450 consists of at least two protein components: a heme protein called cytochrome P450, and a flavoprotein called NADPH-CYP450 reductase, containing both flavin mononucleotide (FMN) and flavin dinucleotide (FAD). The CYP450 is the substrate- and oxygen-binding site of the enzyme system, whereas the reductase serves as an electron carrier, shuttling electrons from NADPH to CYP450. A third component essential for electron transport from NADPH to CYP450 is a phospholipid, phosphatidylcholine, that facilitates the transfer of electrons from NADPH-CYP450 reductase to CYP450 (14). Although the phospholipid does not function in the system as an electron carrier, it has great influence on the CYP450 monooxygenase system. The phospholipid makes up approximately one-third of the hepatic ER and contributes to a negatively charged environment at neutral pH.

Of the three components involved in microsomal oxidative xenobiotic metabolism, CYP450 is important because of its vital role in oxygen activation and substrate binding. The CYP450 is an integral membrane protein deeply imbedded in the membrane matrix. The environment surrounding the enzyme is negatively charged at neutral pH because of the phospholipids. The electron components of CYP450 are located on the cytoplasmic side of the ER and the hydrophobic active site toward the lumen of the ER (15). The active site of CYP450 consists of a hydrophobic substrate-binding domain in which is imbedded an iron protoporphyrin (heme) prosthetic group. This group is exactly like that of hemoglobin, peroxidase, and the b-type cytochromes. The iron in the iron protoporphyrin is coordinated with four nitrogens via a tetradentate to the porphyrin ring. X-ray studies reveal that in the ferric state, the two nonporphyrin ligands are water and cysteine (Fig. 10.1). The cysteine thiolate ligand (proximal) is present in all states of the enzyme and is absolutely essential for the formation of the reactive oxenoid intermediate. The sixth (distal) coordination position is occupied by an easily exchangeable ligand, most likely water, which is labile and easily exchanged for stronger ligands, such as cyanide, amines, imidazoles, and pyridines. The ferrous form loses the water ligand completely, leaving the sixth position open for binding ligands such as oxygen and carbon monoxide.

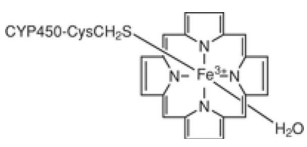


Fig. 10.1. Ferric heme thiolate catalytic center of CYP450. The porphyrin side chains are deleted for clarity.

The vast array of xenobiotics presents a unique challenge to the human body to metabolize these lipophilic foreign compounds and makes it impractical to have one enzyme for each compound or each class of compounds. Therefore, whereas most cellular functions usually are very specific, xenobiotic oxidation requires CYP450s with diverse substrate specificities and regioselectivities (multiple sites of oxidation). Several types of CYP450 enzymes can be found in a single species of animal. For example, the rat has more than 40 different CYP450 genes, each coding for a different version of the enzyme (isoform) that can metabolize almost any lipophilic compound to which they are exposed.

Classification of the CYP450 Multigene Family

Nebert et al. (16,17) classified the CYP450 supergene family on the basis of their structural (evolutionary) relationships The CYP450 monooxygenases resulting from this supergene family have been subdivided into families with greater than 40% amino acid homology and subfamilies with greater than 55% homology (16,17). The CYP450s are named using the root symbol CYP (CYtochrome P450), followed by an Arabic numeral designating the family member (e.g., CYP1, CYP2, or CYP3), a letter denoting the subfamily (e.g., CYP1A, CYP2C, CYP2D, or CYP2E), and another Arabic numeral representing the individual gene. Names of genes are written in italics. The nomenclature system is based solely on sequence similarity

among the CYP450s and does not indicate the properties or function of individual P450s. Of the more than 17 CYP450 isoforms that have been identified to date, the major isoforms responsible for drug metabolism in the liver are presented in Figure 10.2 (18). It is quite evident that the CYP3A and CYP2C families are the isoforms most involved in the metabolism of clinically relevant drugs, and the CYP1A2 isoform is predominantly involved in the bioactivation of environmental substances.

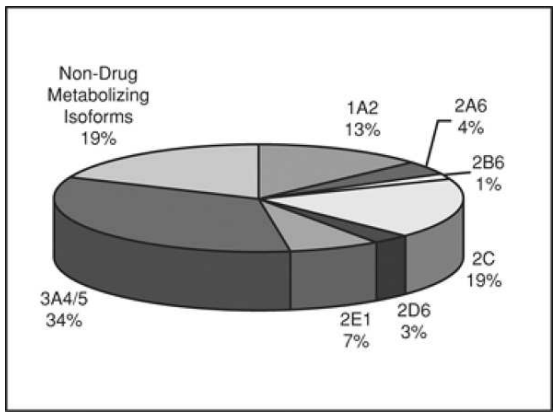

Fig. 10.2. Total human CYP450 isoforms expressed in the liver that metabolize drugs.

The CYP450s probably evolved initially for the regulation of endogenous substances, such as for metabolization of cholesterol to maintain membrane integrity and for steroid biosynthesis and metabolism, rather than for metabolizing foreign compounds. The CYP450s are either involved in highly specific steroid hydroxylations located in the inner mitochondrial membrane or bound to the ER of the cell having broad substrate specificity. In evolutionary terms, CYP450s evolved from a common ancestor, and only more recently (during the last 100 million years) have CYP450 genes taken on the role of producing enzymes for metabolizing a vast array of lipophilic foreign compounds. The emergence of the xenobiotic CYP450 genes probably evolved from the steroidogenic CYP450s for enhancing animal survival by synthesizing new CYP450s for metabolizing plant toxins in the food chain. It is not surprising that animals and humans possess a large array of diverse CYP450 enzymes capable of handling a multitude of xenobiotics. Interindividual variation in the expression of xenobiotic CYP450 genes (genetic polymorphism) or their inducibility may be associated with differences, such as in individual susceptibility to cigarette smoke carcinogenesis. Certain CYP450 isoforms that clearly exhibit genetic polymorphism are known to metabolize and generally inactivate therapeutic agents. The extent of CYP450 polymorphisms in humans is being investigated to determine the risk or protection against cancer. Food mutagens typically are carcinogens in tissue, but they are activated by CYP1A2 in the liver and CYP3A. Specific forms of CYP450 in hepatic microsomes are regulated by hormones (e.g., CYP3A subfamily) and are induced or inhibited by drugs, food toxins, and other environmental xenobiotics (see the section on induction and inhibition of CYP450 isoforms). Identification of a specific CYP450 isoform as the major form responsible for metabolism of a drug in humans permits reconciliation of its toxicity or other pharmacological effects.

Substrate Specificity

No evidence exists that the active oxygenating species differ between CYP450s, suggesting that the substrate specificities, substrate

affinity, regioselectivity, and rates of reaction probably are a consequence of topographic features of the active site of apoproteins (14,15,19,20). Because a primary function of these enzymes is the metabolism of hydrophobic substrates, it is likely that hydrophobic forces are important in the binding of many substrates to the apoproteins. Nonspecific binding is consistent with the multiple substrate orientations in the active site necessary for the broad regioselectivities observed. A specific binding requirement would decrease the diversity of substrates. Some CYP450 isoforms have constrained binding sites and, thus, metabolize small organic molecules (e.g., CYP2E1): CYP1A1/2 have planar binding sites and only metabolize aromatic planar compounds (i.e., polycyclic aromatic hydrocarbons [PAHs]); CYP2D6 exhibits high affinities with specific apoprotein interactions (hydrogen bonds, ion-pair formation) for specific substrates, such as lipophilic amines; and CYP3A4 has broader affinity for a variety of lipophilic substrates (molecular weight, 200–1,200 daltons). If the CYP450 isoforms are tightly membrane bound, substrate access to the active site would be limited to compounds that can diffuse through the membrane, whereas a different CYP450 isoform may be bound less tightly and will metabolize hydrophilic compounds.

In the past, the CYP450s often were referred to as having broad and overlapping specificities, but it became apparent that the broad substrate specificity can be attributed to multiple isoenzymic forms of CYP450. The phenotype of an individual with respect to the forms and amounts of the individual CYP450s expressed in the liver can determine the rate and pathway of the metabolic clearance of a compound (see the discussion of genetic polymorphism). Significant differences exist between humans and animal species with respect to the catalytic activities and regulation of the expression of the hepatic drug-metabolizing CYP450s. These differences often make it difficult to extrapolate to humans the results of CYP450-mediated metabolism studies performed experimentally in animal species. Caution is warranted in the extrapolation of rodent data to humans, because some isoforms are similar between species (e.g., CYP1A and CYP3A subfamilies) whereas others are different (e.g., CYP2A, CYP2B, CYP2C, and CYP2D).

The unique and diverse characteristics of the CYP450 ensure that predicting the metabolism of xenobiotics will be difficult. To date, no crystal structure for a mammalian membrane-bound CYP450 isoform has been described.

Other CYP450 Isoforms

The other CYP450 isoforms catalyzing the oxidation of steroids, bile acids, fat-soluble vitamins, and other endogenous substances include the following: CYP4, arachidonic acid or fatty acid metabolism; CYP5, thromboxane A_2 synthase converts arachidonic acid into thromboxane A_2, which causes platelet aggregation; CYP7A, 7α-hydroxylase catalyzes the rate-determining step in the biosynthesis of bile acids from cholesterol; CYP7B, brain-specific form of 7α-hydroxylase catalyzing the synthesis of the neurosteroids, 7α-hydroxy dehydroepiandrosterone, and 7α-hydroxy pregnenolone; CYP8A, prostacyclin synthase catalyzes the synthesis of prostaglandin I_2 and the regulation of hemostasis that opposes CYP5; CYP8B, 12α-hydroxylase in bile acid biosynthesis; CYP11A1, the first step in mitochondrial steroid biosynthesis that oxidatively cleaves the 17-side chain of cholesterol to pregnenolone, with defects in this enzyme lead to a lack of glucocorticoids, feminization, and hypertension; CYP11B1, a mitochondrial 11β- hydroxylase that hydroxylates 11-deoxycortisol to hydrocortisone or 11-deoxycorticosterone to corticosterone; CYP11B2, mitochondrial aldosterone synthase that hydroxylates corticosterone at the 18-position to aldosterone; CYP17, 17α-hydroxylase and 17,20-lyase (two enzymes in one) are required for production of testosterone and estrogen (lack of this enzyme affects sexual development at puberty); CYP19, aromatase, catalyzes the aromatization of ring A of testosterone to estrogen (lack of this enzyme causes an estrogen deficiency and failure of females to develop at puberty); CYP21, C21 steroid hydroxylase (lack of this enzyme prevents cortisol synthesis, diverting excess 17-hydroxy progesterone into overproduction of testosterone biosynthesis); CYP24, mitochondrial 25-hydroxyvitamin D_3 24-hydroxylase for the degradation/inactivation of vitamin D metabolites; CYP26A1, all-*trans*-retinoic acid hydroxylase, may be involved in terminating the retinoic acid signal and thus turning off a developmental switch.; CYP26B1, retinoic acid hydroxylase may hydroxylate the *cis*-retinoic acids not recognized by the CYP26A1; CYP26C, retinoic acid hydroxylase, function is not known; CYP27A1, 27-hydroxylase, oxidizes cholesterol 17-side chain as the first step in bile acid biosynthesis to the feedback inhibitors, cholic acid, and chenodeoxycholic acid, and 25-hydroxy-vitamin D_3; CYP27B1, mitochondrial vitamin D_3 1-α-hydroxylase activates vitamin D_3; CYP27C1, unknown function; CYP39, 7-hydroxylase of 24-hydroxy cholesterol with unknown function; CYP46, cholesterol 24-hydroxylase with unknown function; CYP51, lanosterol 14α-demethylase, for converting lanosterol into cholesterol, inhibited by ketoconazole.

Cytochrome P450 Isoforms Metabolizing Drugs/Xenobiotics (18,19,20)

Figure 10.3 shows the participation (%) of hepatic CYP450 isoforms in the metabolism of drugs and xenobiotics (21). Outstanding is the fact that more than one-third of all the drugs are metabolized by one isoform, CYP3A4, increasing the potential for drug–drug interactions. When two drugs are metabolized by the same isoform, only one drug can serve as a substrate at one time, increasing the likelihood of a drug–drug interaction, especially if one drug has a lower therapeutic threshold.

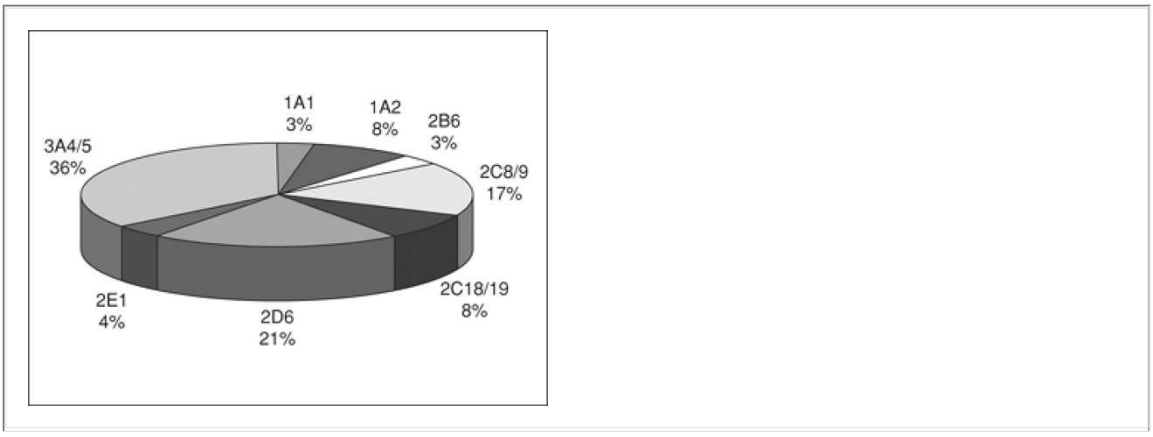

Fig. 10.3. Percentage of clinically important drugs metabolized by human CYP450 isoforms.

Family 1

The CYP1A subfamily plays an integral role in the metabolism of two important classes of environmental carcinogens, PAHs, and arylamines (Tables 10.3 and 10.4) (22). The PAHs commonly are present in the environment as a result of industrial combustion processes and in tobacco products. Several potent carcinogenic arylamines result from the pyrolysis of amino acids in cooked meats and can cause colon cancer in rats. Environmental and genetic factors can alter the expression of this subfamily of these enzymes.

CYP1A1

The CYP1A1 (also called aromatic hydrocarbon hydroxylase) is expressed primarily in extrahepatic tissues, small intestine, placenta, skin, and lung as well as in the liver in response to the presence of CYP1A1 inducers, such as PAHs (i.e., in cigarette smoke and the carcinogen 3-methylcholanthrene), α-naphthoflavone (a noncarcinogenic inducer related to dietary flavones), and indole-3-carbinol (found in Brussel sprouts and related vegetables). The CYP1A1 metabolizes a range of PAHs, including a large number of procarcinogens and promutagens. Diethylstilbestrol and 2- and 4-hydroxyestradiol (catecholestrogens) are oxidized by CYP1A1 to their quinone analogues, which normally are reduced to inactive metabolites (23). In the absence of a detoxifying reduction step, however, the quinones may accumulate and initiate carcinogenic processes or cell death by covalently damaging DNA or cellular proteins. Interindividual variation in the inducible expression of CYP1A1 might be related to a genetic difference in aromatic hormone (Ah) receptor expression, which could explain differences in individual susceptibility to cigarette smoke–induced lung cancer. Therefore, genetic factors appear to be important in the expression of the *CYP1A1* gene in humans and its involvement in human carcinogenesis. Women who smoke are at greater risk than men of developing lung cancer (adenocarcinoma) and chronic obstructive

pulmonary diseases. The mechanism for the induction of the *CYP1A1* gene begins with binding of the inducing agents to a cytosolic receptor protein, the Ah receptor, which is translocated to the nucleus and binds to the DNA of the *CYP1A1* gene, thus enhancing its rate of transcription. The presence of the Ah receptor in hepatic and intestinal tissues may have implications beyond xenobiotic metabolism and may play a role in the induction of other genes for the control of cellular growth and differentiation. On the other hand, CYP1A1 may metabolize procarcinogens to hydroxylated inactive compounds that are not mutagenic. The question of how the bowel protects itself from ingested compounds known to be activated by CYP1A1 (i.e., PAH) remains unanswered (22).

CYP1A2

The CYP1A2 (also known as phenacetin O-deethylase, caffeine demethylase, or antipyrine N-demethylase) catalyzes the oxidation (and, in some cases, bioactivation) of arylamines, nitrosamines, and aromatic hydrocarbons and the bioactivation of promutagens and procarcinogens, caffeine, and other substances (Tables 10.3 and 10.4). It is expressed in the liver to the extent of 13% (range of up to 40%), intestine, and stomach and is induced by smoking, PAHs, and isosafrole (a noncarcinogenic dietary compound). CYP1A2 is primarily responsible for the activation of the carcinogen aflatoxin B1 under ordinary conditions of human exposure and the pneumotoxin ipomeanol. The latter activation occurs in the liver and not in the lungs by CYP2F1 and CYP4B1 as previously thought. Evidence for polymorphism of this isoform has been reported, and it is likely that low CYP1A2 activity will be associated with altered susceptibility to the bioactivation of procarcinogens, promutagens, and other xenobiotics known to be substrates for this enzyme. The expression of the *CYP1A2* gene in the stomach becomes an important issue for gastric carcinogenesis induced by smoking and the metabolic activation of the procarcinogens, arylamines, to mutagens (22).

Clinical studies have suggested that the N-demethylation of imipramine is greater in smokers than in nonsmokers.

Methadone

Family 2

CYP2A6

The CYP2A6 is the only member of this subfamily that is expressed primarily in the liver and also may be expressed in lung and nasal epithelium. It has a low level of hepatic expression and represents approximately 4% of the total hepatic CYP450 isoforms (Fig. 10.2). It catalyzes the 7-hydroxylation of coumarin (coumarin 7-hydroxylase), hydroxylation of aflatoxin B1, nicotine (C-oxidation to cotinine),

naproxen, tacrine, clozapine, mexiletine, and cyclobenzaprine as well as the bioactivation of nitrosamines and procarcinogens. The CYP2A6 exhibits polymorphism with an incidence of 2% in the Caucasian population. This population is characterized as poor metabolizers. Smokers with a defective *CYP2A6* gene smoke fewer cigarettes, implicating a genetic factor in nicotine dependence.

Table 10.6. Some Substrates and Reaction Type for Human Subfamily CYP2Ca

CYP2C8	CYP2C9		CYP2C19
Amiodarone	Amitriptyline	Piroxicam	Amitriptyline
Amodiaquine	Carvedilol	***Ramelteon***	Carisoprodol
Benzphetamine	Celecoxib	Rosiglitazone	Cilostazol

			(*R*)-Warfarin

*Drugs in bold italic have been reported to cause drug-drug interactions.

CYP2B6

Limited data are available regarding the CYP2B6 isoform, and it represents less than 1% of the total hepatic CYP450 isoforms. Its level of expression is low, and phenobarbital appears to induce its formation. The role of CYP2B6 in human drug metabolism is questionable, although cyclophosphamide, ifosfamide, bupropion, and nicotine are metabolized by this isoform (Table 10.5).

CYP2C

The human CYP2C subfamily is the most complex family consisting of CYP2C8, CYP2C9, and CYP2C19, metabolizing approximately 25% of the clinically important drugs (Fig. 10.3), including S-warfarin, S-mephenytoin, and tolbutamide (Table 10.6). It represents

approximately 20% of the total CYP450 isoforms in the liver (Fig. 10.2). The CYP2C8 is expressed primarily in extrahepatic tissues (kidney, adrenal, brain, uterus, breast, ovary, and intestine) and metabolizes the tricyclic antidepressants, diazepam, and verapamil. Its level of expression is less than CYP2C9 and CYP2C19. Both CYP2C9 and CYP2C19 are found primarily in the liver and intestine. The expression of CYP2C19 in the liver is less than that for CYP2C9. Both CYP2C9 and CYP2C19 exhibit polymorphism (difference in the DNA sequence for the *CYP2C* gene) that changes the enzyme's ability to metabolize its substrates (i.e., poor metabolizer phenotype). Because of this genetic difference in expressing CYP2C isoforms, it is important to be aware of a person's race when prescribing drugs that are metabolized differently by different populations (see the section concerning genetic polymorphism). The CYP2C9 is involved in tolbutamide methyl hydroxylation and is a factor in the 4′-hydroxylation of phenytoin, 6/7– hydroxylation of S-warfarin, and R-mephenytoin. The CYP2C19 (S-mephenytoin hydroxylase) is the isoform associated with the 4′-hydroxylation of S-mephenytoin. The CYP2C subfamily apparently is not inducible in humans.

CYP2D6

The CYP2D6 polymorphism is, perhaps, the most studied CYP450 (see the section on genetic polymorphism). This enzyme is responsible for at least 30 different drug oxidations, representing approximately 21% of the clinically important drugs (Fig. 10.3). The CYP2D6 is only 3% expressed in the liver and minimally expressed in the intestine, and it does not appear to be inducible (Fig. 10.2). Because there may be no other way to clear drugs metabolized by CYP2D6 from the system, poor metabolizers of CYP2D6 substrates may be at severe risk for adverse drug reactions or drug overdose. The metabolism of debrisoquine by CYP2D6 is one of the most studied examples of metabolic polymorphism, with its molecular basis of defective metabolism being well understood (Table 10.7) (see the section on genetic polymorphism). This isoform metabolizes a wide variety of lipophilic amines and is probably the only CYP450 for which a charged or ion-pair interaction is important for substrate binding. It also appears to preferentially catalyze the hydroxylation of a single enantiomer (stereoselectivity) in the presence of enantiomeric mixtures. Quinidine is an inhibitor of CYP2D6, and concurrent administration with CYP2D6 substrates results in increased blood levels and toxicity for these substrates. If the pharmacological action of the CYP2D6 substrate depends on the formation of active metabolites, quinidine inhibition results in a lack of a therapeutic response. The interaction of two substrates for CYP2D6 can prompt a number of clinical responses. For example, depending on which substrate has the greater affinity for CYP2D6, the first-pass hepatic metabolism of the substrate (drug) with weaker affinity will be inhibited by a second substrate having greater affinity. The result of this will be a decrease and prolongation of elimination of the first substrate, leading to a higher plasma concentration and an increased potential for adverse toxicity.

CYP2E1

Few drugs are metabolized by CYP2E1, but it plays a major role in the metabolism of numerous halogenated hydrocarbons (including volatile general anesthetics) and a range of low-molecular-weight organic compounds, including dimethyformamide, acetonitrile, acetone, ethanol, and benzene, as well as in the activation of acetaminophen to its reactive metabolite, N-acetyl-p-benzoquinoneimine (Table 10.8) (24,25). The CYP2E1 is of most interest because of the toxicity and carcinogenicity of its metabolites. This isoform is expressed in the liver (7%), kidney, intestine, and lung, and it is inducible by ethanol, isoniazid, 4-methylpyrazole, and other chemicals (see Table 10.12). It also is known as microsomal ethanol-oxidizing system, benzene hydroxylase, or aniline hydroxylase. The CYP2E1 is induced in alcoholics, and there is a polymorphism associated with this isoform that is more common in Chinese people. This isoform also appears to be related to smoking-induced cancer (c.f., CYP1A2). Most of the same compounds that induce CYP2E1 also are substrates for the enzyme. The induction of this enzyme in humans can cause enhanced susceptibility to the toxicity and carcinogenesis of CYP2E1 substrates. Some evidence shows interindividual variation in the in vitro liver expression of this isoform. Diabetes and dietary alterations (i.e., fasting and obesity) result in the induction of CYP2E1. Ketogenic diets (increased serum ketone levels), including those deficient in carbohydrates or high in fat, are known to enhance the metabolism of halogenated hydrocarbons in rats (25). The mechanism of induction appears to be a combination of an increase in CYP2E1 transcription, mRNA translation efficiency, and stabilization of CYP2E1 against proteolytic degradation. The induction of CYP2E1 resulting from ketosis (i.e., starvation, a high-fat diet, uncontrolled diabetes, and obesity) or exposure to alcoholic beverages or other xenobiotics may be detrimental to individuals simultaneously exposed to halogenated hydrocarbons (increased hepatotoxicity from exposure to halothane, chloroform). Chronic alcohol intake is known to enhance the hepatotoxicity of halogenated hydrocarbons. Testosterone appears to regulate CYP2E1 levels in the kidney and pituitary growth hormone for regulating hepatic levels of CYP2E1. Kidney damage from halocarbons was greater for male rats but not for female rats. This finding may have implications for sexual differences in the nephrotoxicity of CYP2E1 substrates in humans.

Family 3

CYP3A4

The CYP3A subfamily includes the most abundantly expressed CYP450s in the human liver and intestine (extrahepatic metabolism). Although CYP3A4 is responsible for approximately two-thirds of CYP3A-mediated drug metabolism, the other minor isoforms (CYP3A5, CYP3A7, and CYP3A43) also contribute. The

CYP3A5 is the best studied of the minor CYP3A isoforms. Approximately 20% of human livers express CYP3A5. The expression of CYP3A5 shows interethnic differences, with the wild-type CYP3A5*1 allele being more common in Africans than in Caucasians and Asians. In individuals who express CYP3A5, 17 to 50% of the total hepatic CYP3A is this isoform. Additionally, CYP3A5 also is expressed in a range of extrahepatic tissues and is inducible via pregnane X receptor. Both CYP3A4 and CYP3A5 exhibit significant overlap in substrate specificity but can differ in catalytic activity and regioselectivity. Results from a comparison of CYP3A4 and CYP3A5 enzyme kinetics indicate that CYP3A5 has different enzymic characteristics from CYP3A4 in some CYP3A-catalyzed reactions. The enzyme kinetics for CYP3A5 suggest a faster substrate turnover than with CYP3A4.

Table 10.7. Some Substrates and Reaction Type for Human CYP2D6 Isoforma

Alprenolol (4-hydroxylation)
Amitriptyline (10-hydroxylation)

Tropisetron (hydroxylation of indole ring)
Venlafaxine

[a]Drugs in bold italic have been reported to cause drug–drug interactions.

Approximately one-third of the total CYP450 in the liver and two-thirds in the intestine is CYP3A4. This isoform is responsible for the metabolism of more than one-third of the clinically important drugs. The CYP3A4 is expressed in the intestine, lung, placenta, kidney, uterus, and brain and is glucocorticoid inducible. The CYP3A7 is predominantly expressed in fetal liver (~50% of total fetal CYP450 enzymes) but also is found in some adult livers and extrahepatically. The CYP3A7 has a specific role in hydroxylation of retinoic acid, 16α-hydroxylation of steroids, and hydroxylation of allylic and benzylic

carbons and, therefore, is of relevance both to normal development and to carcinogenesis. The most recently discovered CYP3A isoform is CYP3A3. In addition to a low level of expression in liver, it is expressed in prostate and testis. Its substrate specificity currently is unclear. Polymorphisms predicting absence of active enzyme have been identified.

Table 10.8. Some Substrates and Reaction Type for Human CYP2E1 Isoform[a]

Acetaminophen (*p*-benzoquinone imine)
Styrene (epoxidation)
Theophylline (C-8 oxidation)
Disulfiram
Halogenated Hydrocarbons
  Dehalogenation of chloroform, methylene chloride
Volatile Anesthetics (fluorinated hydrocarbons)
  Enflurane, Halothane, Methoxyflurane, Sevoflurane, Desflurane
Miscellaneous Organic Solvents
  Ethanol (to acetaldehyde)
  Glycerin
  Dimethylformamide (N-demethylation)
  Acetone
  Diethylether
  Benzene (hydroxylation)
  Aniline (hydroxylation)
  Acetonitrile (hydroxylation to cyanohydrin)
  Pyridine (hydroxylation)

[a]Drugs in bold italics have been reported to cause drug–drug interactions.

The CYP3A4 subfamily metabolizes a wide range of clinically important drugs (Table 10.9) and is inhibited by a number of xenobiotics, including erythromycin (Table 10.10). It also appears to activate aflatoxin B1 and, possibly, benzo[a]pyrene metabolism. The

interindividual differences reported for the metabolism of nifedipine, cyclosporine, triazolam, and midazolam probably are related to changes in induction and not to polymorphism. Binding of CYP3A is predominantly lipophilic (14). Drugs known to be substrates for CYP3A4 have a low and variable oral bioavailability that may be explained by prehepatic metabolism by a combination of intestinal CYP3A4 and P-glycoprotein in the enterocytes of the intestinal wall (see the section on oral bioavailability). Therefore, it is the expression and function of CYP3A4 that governs the rate and extent of metabolism of the substrates for the CYP3A subfamily. The induction of the CYP3A subfamily by phenobarbital in humans may ultimately be responsible for many of the well-documented interactions between barbiturates and other drugs (19,20).

Clearly, no one animal model or combination of animal models reflects the metabolic capabilities of humans. By having a complete understanding of the factors (e.g., inducers, inhibitors, and effect of disease state) that alter the expression and activity of the enzyme responsible for the metabolism of a particular compound, and by a determination of responsible isoforms and patient phenotyping, it may be possible to predict drug interactions and metabolic clearance.

An alphabetical listing of the clinically important drugs and their CYP450 isoforms catalyzing their oxidative metabolism is presented in Table 10.11.

Catalytic Cycle of Cytochrome P450: Steps of the Catalytic Cycle

The many variant CYP450 isoforms that have been isolated show a remarkable uniformity for the catalytic mechanism (21,26,27). The current view illustrating the cyclic mechanism for the reduction and oxygenation of CYP450 as it interacts stepwise with substrate molecules, electron donors, and oxygen is shown in Figure 10.4 and can be summarized as follows (26,27):

Step a. The ferric CYP450 binds reversibly with a molecule of the substrate (RH), resulting in a complex analogous to an enzyme–substrate complex. The binding of the substrate facilitates the first one-electron reduction step.

Step b. The substrate complex of ferric–CYP450 undergoes reduction to a ferrous–CYP450 substrate complex by an electron originating from NADPH and transferred by the flavoprotein, NADPH-CYP450 reductase, from the FNMH2/FADH complex.

Step c. The reduced CYP450 complex readily binds dioxygen as the ferrous iron sixth ligand to form oxy–CYP450 complex.

Step d. Oxy–CYP450 undergoes auto-oxidation to a superoxide anion.

Step e. The ferric superoxide anion undergoes further reduction by accepting a second electron from the flavoprotein (or possibly cytochrome b5) to form the equivalent of a two-electron-reduced complex,

P.265
P.266
P.267
P.268

peroxy–CYP450. The cycle can be aborted (uncoupled) from subsequent substrate hydroxylation at this step by xenobiotics, which can cause the superoxide anion to disproportionate to hydrogen peroxide and dioxygen with regeneration of the starting point of the cycle, the ferric heme protein–substrate complex.

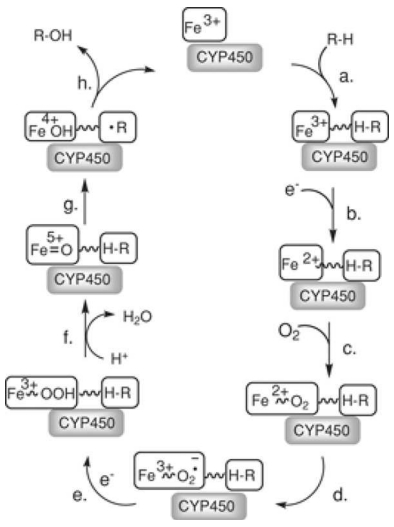

Fig. 10.4. Cyclic mechanism for CYP450. The substrate is RH, and the valence state of the heme iron in CYP450 is indicated.

Step f. The ferric peroxy–CYP450 complex undergoes heterolytic cleavage of peroxide anion to water and to a highly electrophilic perferryl oxenoid intermediate (Fe^{5+}==O) or a perferryl oxygen–cysteine–porphyrin resonance-stabilized complex. This perferryl oxygen species represents the catalytically active oxygenation species.

Step g. Abstraction of a hydrogen from the substrate by the perferryl oxygen species gives rise to a carbon-centered radical–perferric hydroxide pair, radical addition to a π-bond, or electron abstraction from a heteroatom to form a heteroatom-centered radical–cation perferryl intermediate.

Step h. Subsequent radical recombination (oxygen rebound) or electron-transfer (deprotonation) yields the hydroxylated product and the regeneration of the ferric–CYP450 complex.

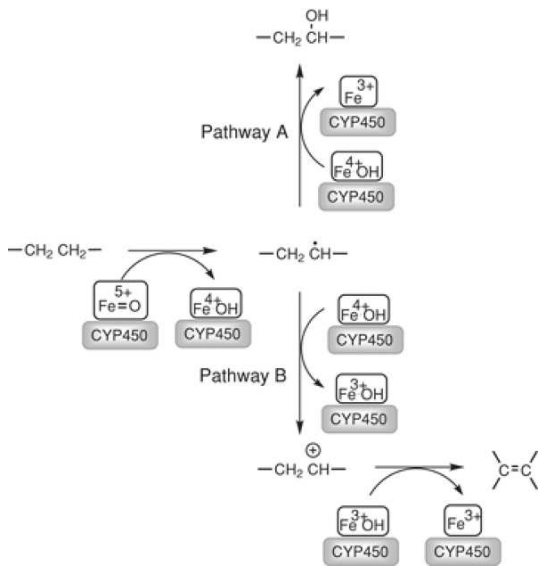

Fig. 10.5. Proposed mechanisms for the hydroxylation and dehydrogenation of alkanes.

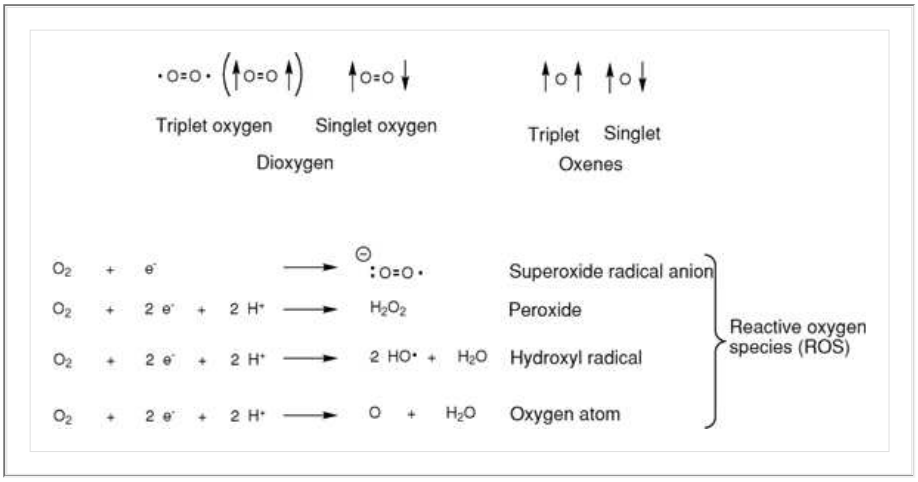
Oxygen Activation

Elemental oxygen (dioxygen) is a relatively unreactive form of oxygen that exists as an unpaired diradical in the triplet form. Alternatively, singlet oxygen is a form of dioxygen in which the diradical electrons are paired. In this form, oxygen is too reactive for biological systems. Free oxygen atoms (oxenes), formed by splitting dioxygen, are highly reactive but are not known to exist in biochemical processes. The solution to the problem of a reactive form of oxygen lies in the suggestion that the reduction of dioxygen occurs to one of the reactive oxygen species (ROS), such as superoxide radical anion, peroxide, hydroxyl radical, or oxygen atom.

Any of these ROS could oxidize an organic substrate with the net insertion of an oxygen atom. In each case, reductive reactions are required for activation of dioxygen to one of the ROS from electrons supplied by NADPH. The generation of a carbon-

centered radical and a hydroxyl radical with triplet oxygen atom has been found to be relevant to a number of enzymatic and chemical reactions involving oxenoids (oxygen rebound mechanism) (28). The function of CYP450 monooxygenases usually is the hydroxylation of a substrate. A reactive radical-like iron oxenoid intermediate is generated that is reactive enough to split aliphatic C-H bonds, add to bonds α to heteroatoms, or remove single electrons from heteroatoms. The mechanisms of CYP450 are not fully understood, and the reactive oxygen intermediate has not been isolated or even spectroscopically observed.



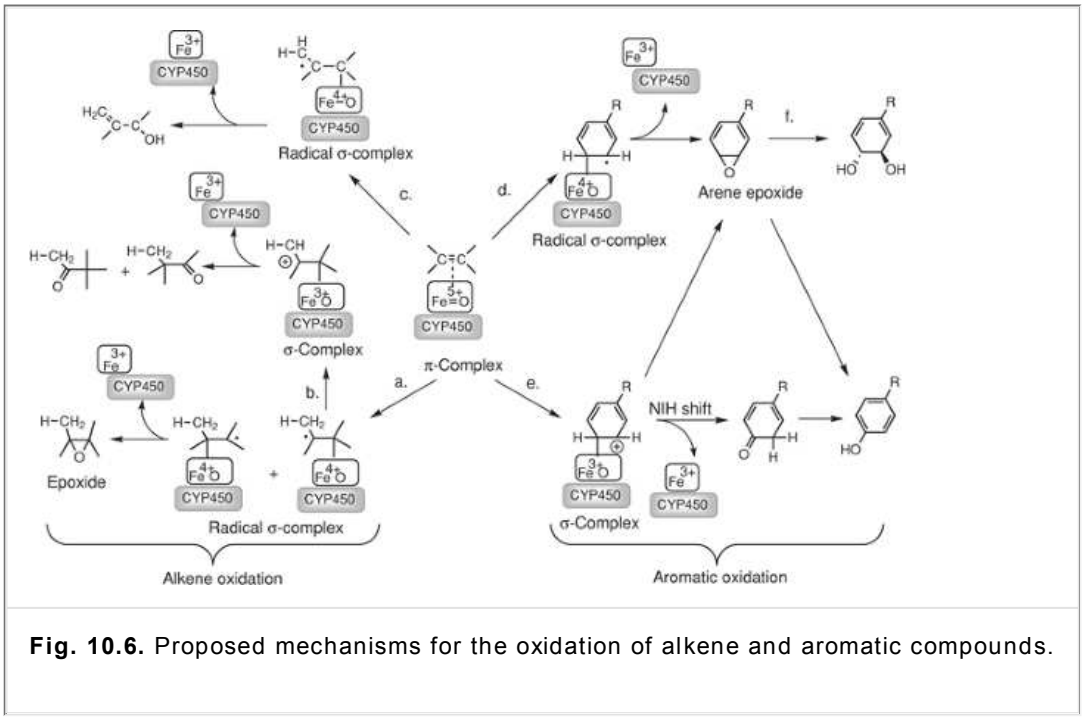


Fig. 10.6. Proposed mechanisms for the oxidation of alkene and aromatic compounds.

Up to the final step, the oxidizable substrate has been an inactive spectator in the chemical events of oxygen activation. None of the preceding oxygenated intermediates has been sufficiently reactive to abstract hydrogen from the substrate. The perferryl–iron oxenoid complex (Step g), however, is a competent hydrogen abstractor, even for relatively inert terminal methyl groups on hydrocarbon chains. Evidence shows that the oxidant is selective in its choice of hydrogen atoms, balancing stability of the resulting carbon radical with stereochemical constraints. Because the inert aliphatic region of the substrate has been converted to a highly reactive radical, the process is described as substrate activation. Various studies have shown that the hydroxylation or alkene formation proceeds not by a direct one-step insertion of the oxygen atom but, rather, by a two-step, two-electron process involving radical or cationic substrate intermediates with subsequent radical recombination (oxygen rebound) to products (Fig. 10.5) (28).

Despite considerable experimental evidence, the proposed mechanism and intermediates of monooxygenation of unsaturated substrates (alkenes, alkynes, and aromatics) remains controversial (19,20,29,30,31). The

proposed mechanism for the oxidation of π-bonds in alkenes involves a stepwise sequence of one-electron transfer between the radical complex and the perferryl oxygen intermediate ($[Fe^{5+}{=}{=}O]$) (alkene oxidation) (Fig. 10.6). Following the initial formation of an unsaturated CYP450 π-complex, the one-electron transfer yields a radical σ-complex which can either collapse to arene or alkene epoxide (steps a or d, Fig. 10.6), undergo a 1,2-group migration to a carbonyl product (steps a and b, Fig. 10.6), or give a vinyl hydroxylated product (step c, Fig. 10.6), or a σ-complex which can break down to a phenol (step e, Fig. 10.6). The presence of an oxygen radical in the porphyrin ring allows some substrate radicals to covalently bond through N-alkylation of a pyrrole nitrogen rather than recombining with $(Fe–OH)^{3+}$. This

deviation from the normal course of reaction explains the suicide inhibition exhibited by some xenobiotics, such as the oral contraceptives, erythromycin, and paroxetine (32,33).

In the case of aromatic oxidations (Fig. 10.6), following the initial formation of an arene CYP450 π-complex, one-electron transfer yields either a π-complex or a radical σ-complex. The radical σ-complex can collapse to the arene epoxide (Fig. 10.6, step d), or the π-complex can proceed to a σ-complex followed by a NIH shift (1,2-group migration) to a phenolic product (Fig. 10.6, step e). Arene oxides are highly unstable entities and rearrange (NIH shift) nonenzymatically to phenols or hydrolyzed enzymatically with epoxide hydrolase to 1,2-dihydrodiols (trans configuration) (Fig. 10.6, step f), which subsequently are dehydrogenated to 1,2-diphenols. The oxidation of aromatic compounds can be highly specific to individual CYP450 isoforms, suggesting that substrate binding and orientation in the active site may dominate the mechanism of oxidative catalysis.

Heteroatom-containing substrates usually undergo hydroxylation adjacent (α) to the heteroatom, as compared to other positions. Reactions of this type include N-, O-, and S-dealkylation as well as dehydrohalogenations and oxidative deamination (dealkylation) reactions. Two mechanisms have been suggested (Fig. 10.7). One is the

abstraction of a hydrogen atom from the carbon adjacent to the heteroatom, and the resultant carbon radical is stabilized by the heteroatom. Alternatively, abstraction of an electron from the heteroatom to form a heteroatom radical subsequently transfers a hydrogen atom from the more labile α-carbon to generate a carbon radical. Collapse of the carbon radical–perferric hydroxide radical pair hydroxylates the carbon adjacent to the heteroatom, generating an unstable geminal hydroxy heteroatom-substituted intermediate (e.g., carbinolamine, halohydrin, hemiacetal, hemiketal, or hemithioketal) that breaks down, releasing the heteroatom and forming a carbonyl compound (29,30,31).

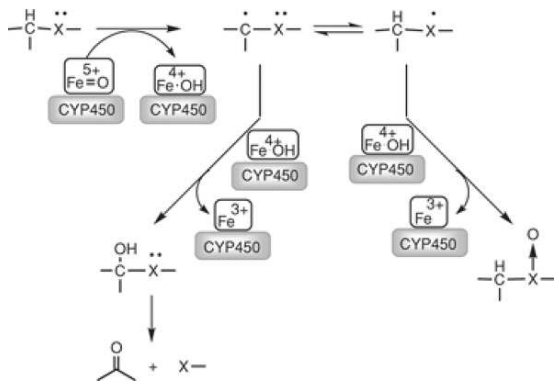

Fig. 10.7. Proposed mechanism for heteroatom-compound oxidation, dealkylation, and dehalogenation.

Xenobiotics containing heteroatoms (N, S, P, and halogens) frequently are metabolized by heteroatom oxidation to its corresponding heteroatom oxide (tertiary amine to its N-oxide, sulfides to sulfoxides, or phosphines to phosphine oxides). Heteroatom oxidation also can be attributed to a microsomal flavin-containing monooxygenase. As is the case with heteroatom α-hydroxylation, one-electron oxidation of the heteroatom occurs as the first step to form the heteroatom cation perferric hydroxide radical intermediate, which collapses to generate the heteroatom oxide. This reaction is favored by the absence of α-hydrogens and stability of the heteroatom radical-cation (29,30,31).

All the known oxidative reactions catalyzed by CYP450 monooxygenase can be described in the context of a mechanistic scheme involving the ability of a high-valent iron oxenoid species to bring about the stepwise one-electron oxidation through the abstraction of hydrogen atoms, abstraction of electrons from heteroatoms, or addition to π-bonds. A series of radical recombination reactions completes the oxidation process.

Induction and Inhibition of Cytochrome P450 Isoforms

Induction

Many drugs, environmental chemicals, and other xenobiotics enhance the metabolism of themselves or of other coingested/inhaled compounds, thereby altering their pharmacological and toxicological effects (34,35,36). Prolonged administration of a drug or xenobiotic can lead to enhanced metabolism of a wide variety of other compounds. Enzyme induction is a dose-dependent phenomenon.

Drugs and xenobiotics exert this effect by inducing transcription of CYP450 mRNA and synthesis of xenobiotic-metabolizing enzymes in the smooth ER of the liver and other extrahepatic tissues (34,35). This phenomenon is termed “enzyme induction,” which has been used to describe the process by which the rate of synthesis of an enzyme is increased relative to the rate of synthesis in the uninduced organism. In many older studies of mammalian systems, the term “induction” was inferred from the increase in enzyme activity, but the amount of enzyme protein had not been determined. Enzyme induction is important for interpreting the results of chronic toxicities, mutagenicities, or carcinogenesis and explaining certain unexpected drug interactions in patients.

Many drugs and xenobiotics stimulate the activity of the CYP450 isoforms, as shown in Table 10.12. These stimulators have nothing in

common as far as their pharmacological activity or chemical structures are concerned, but they are all metabolized by one or more of the CYP450 isoforms. Most are lipid soluble at physiologic pH. Polycyclic aromatic hydrocarbons in cigarette

smoke, xanthines and flavones in foods, halogenated hydrocarbons in insecticides, polychlorinated biphenyls, and food additives are but a few of the environmental chemicals that alter the activity of CYP450 enzymes (37).

Enzyme induction can alter the pharmacokinetics and pharmacodynamics of a drug, with clinical implications for the therapeutic actions of a drug and increased potential for drug interactions. As a result of induction, a drug may be metabolized more rapidly to metabolites that are more potent, more toxic, or less active than the parent drug. Induction also can enhance the activation of procarcinogens or promutagens. Not all inducing agents enhance their own metabolism; for example, phenytoin induces CYP3A4 but is hydroxylated by CYP2C9, which is constitutive. Some of the more common enzyme inducers of CYP450 subfamilies, which also may be substrates for the same CYP450 isoform, include phenobarbital (CYP2B6, CYP2C, and CYP3A4), rifampicin (CYP3A4), and cigarette smoke (CYP1A1/2) (Table 10.12). The broad range of drugs metabolized by these CYP450 subfamilies (Table 10.11) and that also are affected by these enzyme inducers raises the issue of clinically significant drug interactions and their clinical implications. Examples of a clinical CYP450–drug interaction and an herbal drug–drug interaction include rifampin and oral contraceptives as well as St. John's wort and oral contraceptives. Both induce the expression of CYP3A4, thereby reducing the serum levels of the oral contraceptive because of increased oxidative metabolism of the oral contraceptives by CYP3A4 to less active metabolites, increasing the risk for pregnancy. Drugs poorly metabolized by CYP450 enzymes are less affected by enzyme induction. Inducers of CYP450 isoforms also stimulate the oxidative metabolism or synthesis of endogenous substances, such as the hydroxylation of androgens, estrogens, progestational steroids (synthetic oral contraceptives), glucocorticoids, vitamin D, and bilirubin, decreasing their biological activity. These enzyme inducers also might be implicated in deficiencies associated with these steroids. For example, the induction of C-2 hydroxylation of estradiol and synthetic estrogens by phenobarbital, dexamethasone, or cigarette smoking in women results in the increased formation of the principal and less active metabolite of these estrogenic substances, reducing their effectiveness (38). Thus, cigarette smoking in premenopausal women could result in an estrogen deficiency, increasing the risk of osteoporosis and early menopause. Postmenopausal women who smoke and take estrogen replacement therapy may lose the effectiveness of the estrogen.

In addition to enhancing metabolism of other drugs, many compounds, when chronically administered, stimulate their own metabolism, thereby decreasing their therapeutic activity and producing a state of apparent tolerance. This self-induction may explain some of the change in drug toxicity observed in prolonged treatment. The sedative action of phenobarbital, for example, becomes shorter with repeated doses and can be explained in part on the basis of increased metabolism.

The time course of induction varies with different inducing agents and different isoforms, except that CYP1A induction involves the Ah receptor. Increased transcription of CYP450 mRNA has been detected as early as 1 hour after the administration of phenobarbital, with maximum induction after 48 to 72 hours. After the administration of PAH, such as 3-methylcholanthrene and benzo[a]pyrene, maximum induction of the CYP1A subfamily is reached within 24 hours. Less potent inducers of hepatic drug metabolism may take as long as 6 to 10 days to reach maximum induction (34,35). Exposure to a variety of xenobiotics may preferentially increase the hepatic content of specific forms of CYP450 (34,35,36). Therefore, the process of enzyme induction involves the adaptive increase in the content of specific enzymes in response to the enzyme-inducing agent. Other inducible metabolizing enzymes include uridine diphosphate (UDP)–glucuronosyl transferase and glutathione transferase.

Specific Inducers

Phenobarbital and rifampin

Phenobarbital and rifampin probably are the enzyme inducers that have been studied most extensively. These drugs could alter the pharmacokinetics and pharmacodynamics of many concurrently administered drugs listed in Tables 10.6 (CYP2C) and 10.9 (CYP3A4), raising the issue of clinically significant drug interactions.

Cigarette smoke

Cigarette smoke has been shown to increase the hydrocarbon-inducible isoforms CYP1A1 and CYP1A2 in the lungs, liver, small intestine, and placenta of cigarette smokers. A decrease in the pharmacological action and stimulation of the metabolism of several drugs is the end result. Cigarette smoking has been reported to lower the blood levels of theophylline, imipramine, estradiol, pentazocine, and propoxyphene; to decrease the urinary excretion of nicotine; and to decrease drowsiness from chlorpromazine, diazepam, and chlordiazepoxide. The plasma levels, half-life, or total clearance for diazepam, however, are unchanged.

Dietary substances

A diet containing Brussel sprouts, cabbage, and cauliflower was found to stimulate CYP450 activity in rat intestine (39). It was subsequently determined that indole derivatives (indole-3-carbinol) were responsible for the enzyme induction. Other examples of chemicals found naturally in foods that enhance metabolism in animals are flavones, safrole, eucalyptol, xanthines, β-ionone, and organic peroxides. Volatile oils in soft woods (e.g., cedar) have been shown to be enzyme inducers.

Alcohol

Sober alcoholics show an increase in CYP2E1 enzyme activity, leading to more rapid clearance of drugs and xenobiotics that are substrates for this isoform from the body. As discussed previously, hepatic CYP2E1

oxidizes ethanol, and chronic ethanol intake increases the activity of CYP2E1 through enzyme induction (24). When intoxicated, alcoholics are more susceptible to the action of various drugs because of inhibition of drug metabolism as a result of an excessive quantity of alcohol in the liver and an additive or synergistic effect in the central nervous system. The basis for this inhibition is unknown. Furthermore, moderate ethanol consumption reduces the clearance of some drugs, presumably because of competition between ethanol and the other drugs for hepatic biotransformation. The changes in drug metabolism in alcoholics also can be attributed to other factors, such as malnutrition, other drugs, and the trace chemicals that determine the flavor and odor of alcoholic beverages. Heavy drinkers metabolize

phenobarbital, tolbutamide, and phenytoin more rapidly than nonalcoholics do, which may be clinically important because of problems in adjusting drug therapy in alcoholics.

Inhibition

Another method of altering the in vivo effects of xenobiotics metabolized by CYP450s is through the use of inhibitors (Table 10.10). The CYP450 inhibitors can be divided into three categories according to their mechanism of action: reversible inhibition, metabolite intermediate complexation of CYP450, or mechanism-based inactivation of CYP450 (36,40,41). The polysubstrate nature of CYP450 is responsible for the large number of documented interactions associated with the inhibition of drug oxidation and drug biotransformation.

Reversible inhibition

Reversible inhibition of CYP450 is the result of reversible interactions at the heme–iron active center of CYP450, the lipophilic sites on the apoprotein, or both. The interaction occurs before the oxidation steps of the catalytic cycle, and their effects dissipate quickly when the inhibitor is discontinued. The most effective reversible inhibitors are those that interact strongly with both the apoprotein and the heme–iron. It is widely accepted that inhibition has an important impact on the oxidative metabolism and pharmacokinetics of drugs with a metabolism that cosegregates with that of an inhibitor (Tables 10.3 and 10.6,10.7,10.8,10.9) (40,41). Drugs interacting reversibly with CYP450 include the fluoroquinolone antimicrobials, cimetidine, the azole antifungals, quinidine (specific for CYP2D isoforms), and diltiazem. Cimetidine is the only H-2 antagonist that inhibits CYP450 by interacting directly with the CYP450 heme–iron through one of its imidazole ring nitrogen atoms. Cimetidine is not a universal inhibitor of CYP450 oxidative metabolism, but it does bind differentially to several CYP450 isoforms (Table 10.10). Cimetidine inhibits the oxidation of theophylline (CYP1A), chlordiazepoxide (CYP2C), diazepam (CYP2C), propranolol (CYP2C and CYP2D), warfarin (CYP2C), and antipyrine (CYP1A) but not that of ibuprofen (CYP2C), tolbutamide (CYP2C), mexiletine (CYP2D), 6-hydroxylation of steroids (CYP3A), and carbamazepine (CYP3A) (36). The imidazole-based azole antifungals are potent inhibitors of CYP3A and of the CYP450-mediated biosynthesis of endogenous steroid hormones. The azole antifungals exert their fungiostatic effects through inhibition of fungal CYP450, inhibiting the oxidative biosynthesis of lanosterol to ergosterol, thereby affecting the integrity and permeability of the fungal membranes.

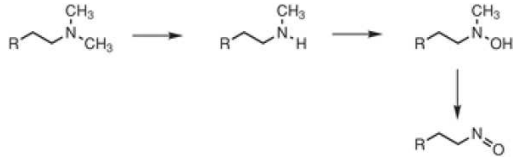

Fig. 10.8. Sequence of oxidation of dialkylamine to nitroso metabolite intermediate.

CYP450 complexation inhibition

Noninhibitory alkylamine drugs have the ability to undergo CYP450-mediated oxidation to nitrosoalkane metabolites (Fig. 10.9), which have a high affinity for forming a stable complex with the reduced (ferrous) heme intermediate for the CYP2B, CYP2C, and CYP3A subfamilies. This process is termed “metabolite intermediate complexation” (40,41). Thus, the CYP450 isoform is unavailable for further oxidation, and synthesis of the new enzyme is required to restore CYP450 activity. The process relies on at least one cycle of the CYP450 catalytic cycle to generate the required heme intermediate. The macrolide antibiotics, troleandomycin, erythromycin, and clarithromycin, as well as their analogues are selective inhibitors of CYP3A4 that are capable of inducing the expression of hepatic and extrahepatic CYP3A4 mRNA and induction of their own biotransformation into nitrosoalkane metabolites. The clinical significance of this inhibition with CYP3A4 is the long-lived impairment of the metabolism of a large number of coadministered substrates for this isoform and the potential for drug–drug interactions and time-dependent nonlinearities in their pharmacokinetics on long-term administration (Tables 10.9 and 10.10). For the macrolides to be so metabolized, they must possess an unhindered dimethylamino sugar, and the whole compound must be lipophilic. Other alkylamine-based drugs demonstrating this type of inhibition include orphenadrine (antiparkinson drug), the antiprogestin, mifepristone (CYP3A), and SKF525A (the original CYP450 inhibitor). Methylenedioxyphenyl compounds (i.e., the insecticide synergist piperonyl butoxide and the flavoring agent isosafrole) generate metabolite intermediates that form stable complexes with both the ferric and ferrous state of CYP450.

Mechanism-based inhibition

Certain drugs that are noninhibitory of CYP450 contain functional groups that, when oxidized by CYP450, generate metabolites that

bind irreversibly to the enzyme. This process is termed “mechanism-based inhibition” (“suicide inhibition'') and requires at least one catalytic CYP450 cycle either during or subsequent to the oxygen-transfer step, when the drug is activated to the inhibitory species. Alkenes and alkynes were the first functionalities found to inactivate CYP450 by generation of a radical intermediate that alkylates the heme structure (see the section on alkene and alkyne hydroxylation) (32,33,40,41). Iron is lost from the heme and abnormal N-alkylated porphyrins are produced. Drugs that are mechanism-based inhibitors of CYP450 include the 17α-acetylenic estrogen, 17α-ethinyl

estradiol, the 17α-acetylenic progestin, norethindrone (norethisterone), and their radical intermediates that N-alkylate heme of CYP3A; chloramphenicol and its oxidative dechlorination to an acyl moiety that alkylates CYP450 apoprotein; cyclophosphamide (CYP3A) and its generation of acrolein and phosphoramide mustard; spironolactone and its 7-thio metabolite that alkylates heme; 8-methoxypsoralen (a furocoumarin) and its epoxide metabolite that alkylates the CYP450 apoprotein of CYP2A6; 21-halosteroids; halocarbons; and secobarbital. The selectivity of CYP450 isoform destruction by several of these inhibitors indicates the involvement of this isoform in its bioactivation of such drugs.

Oxidations Catalyzed by Cytochrome P450 Isoforms

Aliphatic and alicyclic hydroxylations

The accepted mechanism for the hydroxylation of alkane C-H bonds is shown in Figure 10.5 and has been reviewed in detail elsewhere (29,30,31). The principal metabolic pathway for the methyl group is oxidation to the hydroxymethyl derivative followed by its nonmicrosomal oxidation to the carboxylic acid (e.g., tolbutamide) (Fig. 10.9). On the other hand, some methyl groups are oxidized only to the hydroxymethyl derivative, without further oxidation to the acid. Where there are several equivalent methyl groups, usually only one is oxidized. For aromatic methyl groups, the para methyl is the most vulnerable.

Alkyl side chains often are hydroxylated on the terminal or the penultimate carbon atom (e.g., pentobarbital) (Fig. 10.9). The isopropyl group is an interesting side chain that undergoes hydroxylation at the tertiary carbon and at either of the equivalent methyl groups (e.g., ibuprofen) (Fig. 10.9). Hydroxylation of alkyl side chains attached to an aromatic ring does not follow the general rules for alkyl side chains, because the aromatic ring influences the position of hydroxylation. Generally, oxidation occurs preferentially on the benzylic methylene group and, to a lesser extent, at other positions on the side chain.

The methylene groups of an alicycle are readily hydroxylated, generally at the least hindered position, or at an activated position—for example, α to a carbonyl (cyclohexanone), α to a double bond (cyclohexene), or α to a phenyl ring (tetralin). The products of hydroxylation often show stereoisomerism. Nonaromatic heterocycles generally undergo oxidation at the carbon adjacent to the heteroatom (e.g., phenmetrazine) (Fig. 10.9).

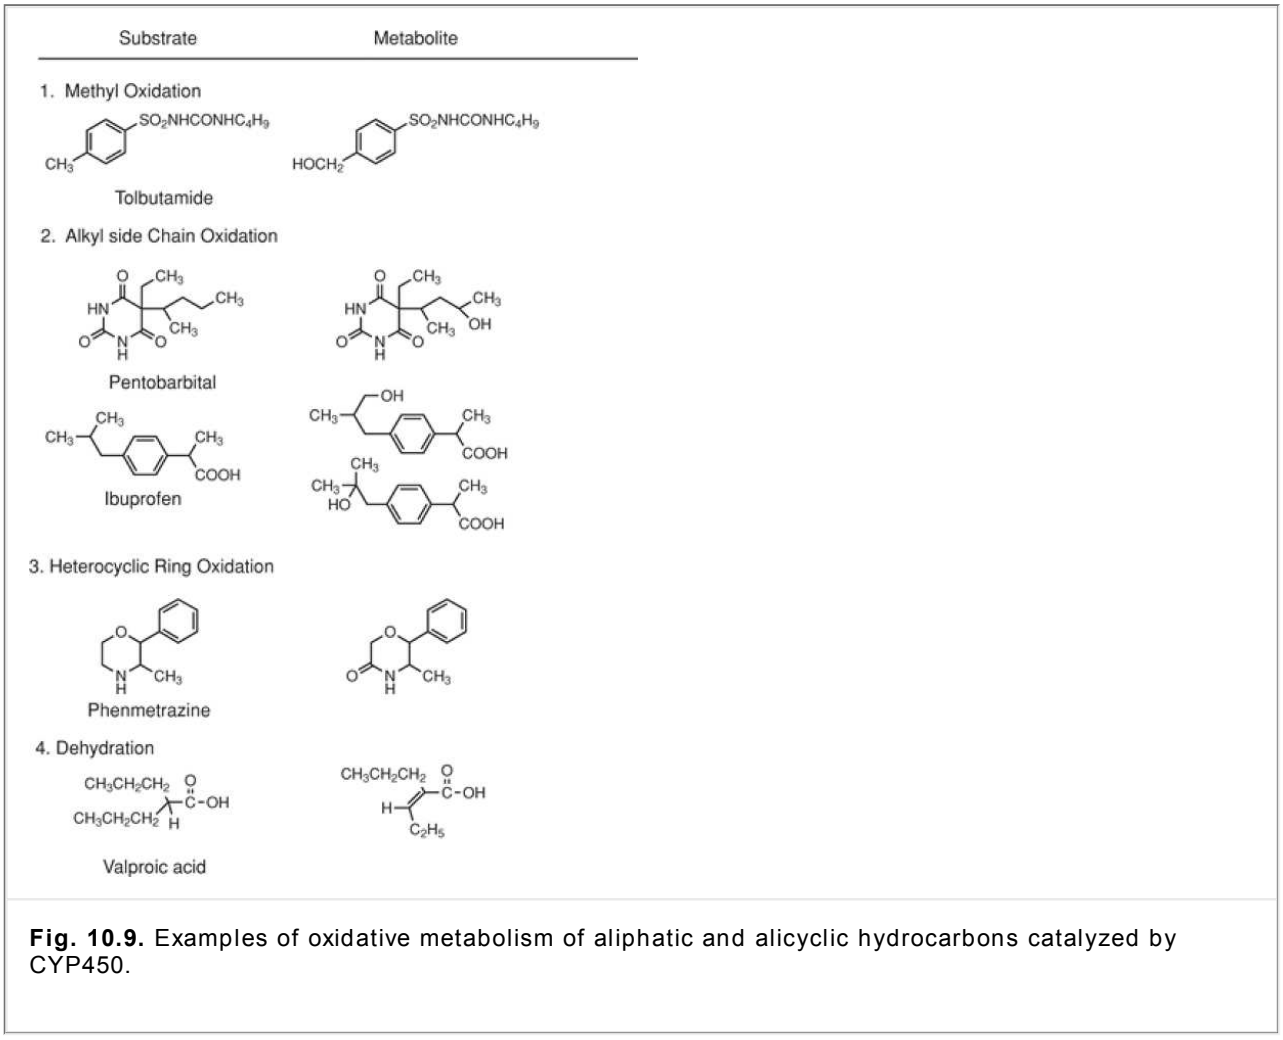

Fig. 10.9. Examples of oxidative metabolism of aliphatic and alicyclic hydrocarbons catalyzed by CYP450.

In addition to hydroxylation reactions, CYP450s can catalyze the dehydrogenation of an alkane to an alkene(olefin). The reaction is thought to involve the formation of a carbon radical, electron transfer to the perferryl complex of CYP450 giving a carbocation, and deprotonation to a dehydrogenated product alkene (Fig. 10.5) (29,30,31). An example of the ability of CYP450 to function as both a dehydrogenase and a monooxygenase has been demonstrated with the antiseizure valproic acid. Whereas the major metabolic products in humans are β-oxidation and acyl glucuronidation, several alkenes are formed, including (E)2-ene isomer (Fig. 10.9) (42). Presumably, the

CYP3A subfamily catalyzes these reactions. The factors determining whether CYP450 catalyzes hydroxylation (oxygen rebound/recombination) or dehydrogenation (electron transfer) remain unknown, but hydroxylation generally is favored. In some instances, dehydrogenation may be the primary product (i.e., 6,7-dehydrogenation of testosterone).

Alkene and alkyne hydroxylation

The oxidation of alkenes yields primarily epoxides and a series of products derived from 1,2-migration (see previous discussion) (Fig. 10.6). The stereochemical configuration of the alkene is retained during epoxidation. The epoxides can differ in reactivity. Those that are highly reactive either undergo pH-catalyzed hydrolysis to excretable vicinal dihydrodiols or react covalently (alkylate) with macromolecules, such as proteins or nucleic acids, leading to tissue necrosis or carcinogenicity. Moreover, the ubiquitous epoxide hydrolase can catalyze the rapid hydrolysis of epoxides to nontoxic vicinal dihydrodiols. Several drugs (carbamazepine, cyproheptadine, and protriptyline), however, were found to form stable epoxides at the 10,11-position during biotransformation (Fig. 10.10). The fact that these epoxides could be detected in the urine indicates that these oxides are not particularly reactive and should not readily react covalently with macromolecules.

The epoxidation of terminal alkenes is accompanied by the mechanism-based ("suicide") N-alkylation of the heme–porphyrin ring. If the π-complex attaches to the alkene at the internal carbon, the terminal carbon of the double bond can irreversibly N-alkylate the pyrrole nitrogen of the porphyrin ring (32,33). The heme adduct formation is mostly observed with monosubstituted, unconjugated alkenes (i.e., 17α-ethylenic steroids and 4-ene metabolite of valproic acid).

In addition to the formation of epoxides, heme adducts, and hydroxylated products, carbonyl products also are created. These latter products result from the migration of atoms to adjacent carbons (i.e., 1,2-group migration). For example, during the CYP450-catalyzed oxidation of trichloroethylene, a 1,2-shift of chloride occurred to yield chloral (Fig. 10.10).

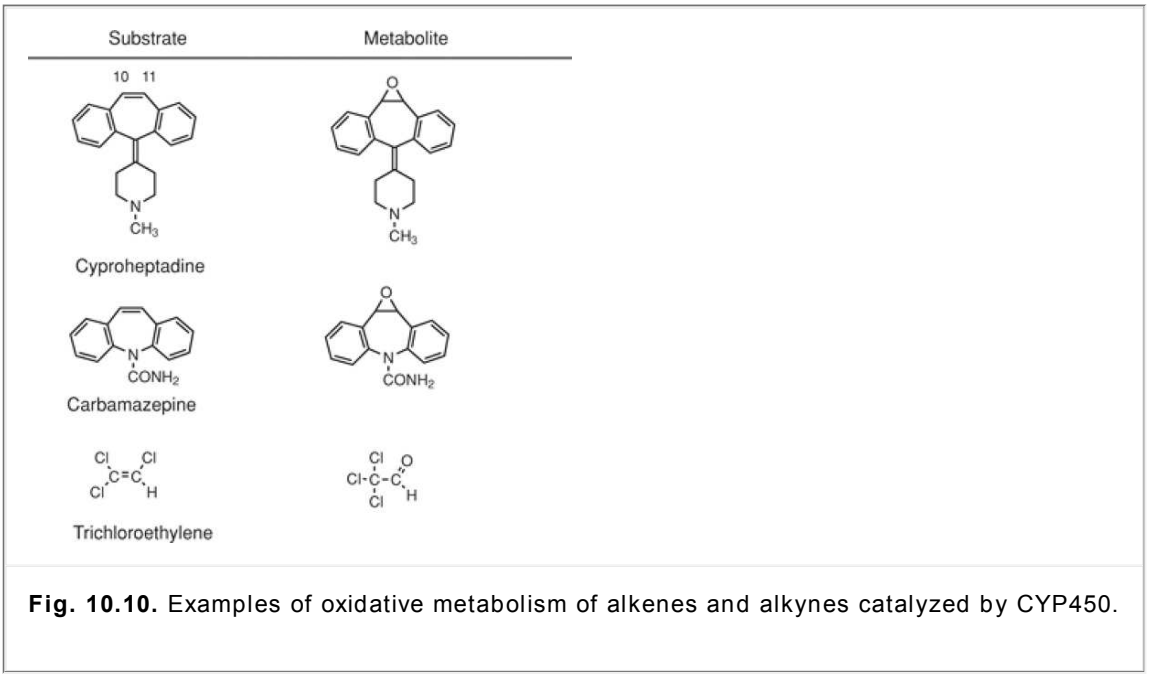

Fig. 10.10. Examples of oxidative metabolism of alkenes and alkynes catalyzed by CYP450.

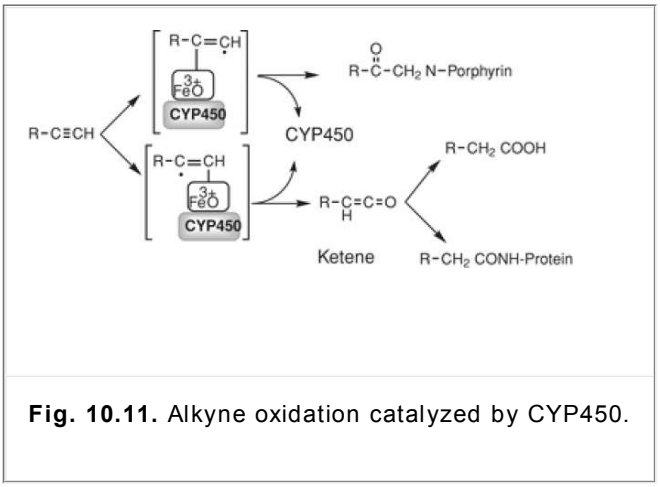

Fig. 10.11. Alkyne oxidation catalyzed by CYP450.

Like the alkenes, alkynes (acetylenes) are readily oxidized but usually faster. Depending on which of the two alkyne carbons are attacked, different products are obtained (32,33). If attachment of CYP450 occurs on the terminal alkyne carbon, a hydrogen atom migrates, forming

a ketene intermediate that readily hydrolyzes with water to form an acid or that can alkylate nucleophilic protein side chains (i.e., lysinyl or cysteinyl) to form a protein adduct (Fig. 10.11). The effect of attaching the perferryl oxygen at the internal alkenyl carbon is N-alkylation of a pyrrole nitrogen in the porphyrin ring by the terminal acetylene carbon, with the formation of a keto heme adduct (Fig. 10.11). The latter mechanism has been proposed for the irreversible inactivation of CYP3A4 with 17α-alkenyl steroids (i.e., 17α-ethinyl estradiol).

Aromatic hydroxylation

The metabolic oxidation of aromatic carbon atoms by CYP450 depends on the isoform catalyzing the oxidation and the oxidation potential of the aromatic compound. The products usually are phenolic products, and the position of hydroxylation can be influenced by the type of substituents on the ring according to the theories of aromatic electrophilic substitution (Fig. 10.6). For example, electron-donating substituents enhance *p*- and *o*-hydroxylation, whereas electron-withdrawing substituents reduce or prevent *m*-hydroxylation. Moreover, steric factors also must be considered, because oxidation usually occurs at the least hindered position. For monosubstituted benzene compounds, parahydroxylation usually predominates, with some ortho product being formed (Fig. 10.12). When there is more than one phenyl ring, usually only one is hydroxylated (e.g., phenytoin).

Traditionally, the hydroxylation of aromatic compounds by CYP450 has been considered to be mediated by an arene oxide (epoxide) intermediate followed by the "NIH shift," as discussed previously (29,30,31) (Fig. 10.6). The formation of phenols and the isolation of urinary dihydrodiols, catechols, and glutathione conjugates (mercapturic acid derivatives) implicates arene oxides as intermediates in the metabolism of benzene and substituted benzenes in mammalian systems. The arene oxides

also are susceptible to conjugation with glutathione to form premercapturic acids (see the section on glutathione conjugation).

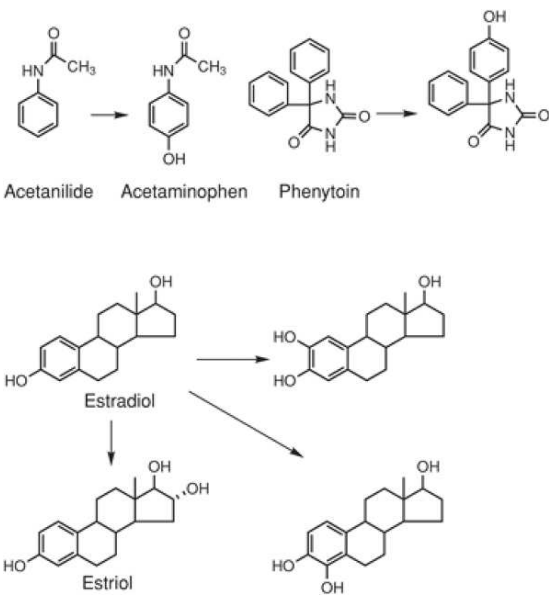

Fig. 10.12. Examples of oxidative metabolism of aryl compounds catalyzed by CYP450.

The CYP1A2 and CYP3A subfamilies are important contributors to 2- and 4-hydroxylation of estradiol, and CYP3A4 is an important contributor for the 2-hydroxylation of the synthetic estrogens (e.g., 17α-ethinyl estradiol) (38). The principal metabolite (as much as 50%) for estradiol is 2-hydroxyestradiol, with 4-hydroxy and 16α-hydroxyestradiol as the minor metabolites (Fig. 10.12). The 2-hydroxy metabolite of both estradiol and ethinyl estradiol have limited or no estrogenic activity, whereas the C-4 and C-16 α-hydroxy metabolites have a potency similar to estradiol. In humans, 16α-hydroxyestradiol is the major estrogen metabolite in pregnancy and in breast cancer. The metabolites 16α-hydroxyestrone and 4-hydroxyestrone may be carcinogenic in specific cells, because they are capable of damaging cellular proteins and DNA after their further activation to quinone intermediates.

Xenobiotic-metabolizing enzymes not only detoxify xenobiotics but also cause the formation of active intermediates (bioactivation), which in certain circumstances may elicit a diversity of toxicities, including mutagenesis, carcinogenesis, and hepatic necrosis (37). In addition to glutathione, some nucleophiles, such as other sulfhydryl compounds (most effective), alcohols, and phosphates, can react with arene oxides. Many of these nucleophiles are found in proteins and nucleic acids. The covalent binding of these bioactive epoxides to intracellular macromolecules provides a molecular basis for these toxic effects (see the discussion of toxicity from oxidative metabolism).

N-dealkylation, oxidative deamination, and N-oxidation

N-dealkylation

The dealkylation of secondary and tertiary amines to yield primary and secondary amines, respectively, is one of the most important and frequently encountered reactions in drug metabolism. The proposed mechanism for oxidative N-dealkylation involving α-hydrogen abstraction or an electron abstraction from the nitrogen by the perferryl oxygen has been discussed previously (29,30,31) (Fig. 10.7).

Typical N-substituents removed by oxidative dealkylation are methyl, ethyl, n-propyl, isopropyl, n-butyl, allyl, and benzyl. Usually,

dealkylation initially occurs with the smaller alkyl group. Substituents that are more resistant to dealkylation include the tert-butyl (no α-hydrogen) and the cyclopropylmethyl. In general, tertiary amines are dealkylated to secondary amines faster than secondary amines are dealkylated to primary amines. This difference in rate has been correlated with lipid solubility. Appreciable amounts of secondary and primary amines therefore accumulate as metabolites that are more polar than the parent amine, thus slowing their rates of diffusion across membranes and reducing their accessibility to receptors. Frequently, these amine metabolites contribute to the pharmacological activity of the parent substance (e.g., imipramine) (Fig. 10.13) or produce unwanted side effects, such as hypertension, resulting from the N-dealkylation of N-isopropylmethoxamine to methoxamine. The design of an analogous drug without these unwanted drug metabolites can be achieved by proper choice of replacement substituents, such as substituting the N-isopropyl group in N-isopropylmethoxamine with a tert-butyl (N-tert-butylmethoxamine or butoxamine). N-dealkylation of substituted amides and aromatic amines occurs in a similar manner. N-substituted nonaromatic nitrogen heterocycles undergo oxidation on the α-carbon to a lactam (cotinine) as well as N-dealkylation (nicotine to nornicotine, cotinine, and norcotinine) (Fig. 10.13).

Oxidative deamination

The mechanism of oxidative deamination follows a pathway similar to that of N-dealkylation. Initially, oxidation to the imminium ion occurs, followed by decomposition to the carbonyl metabolite and ammonia. Oxidative deamination can occur with α-substituted amines, exemplified by amphetamine (Fig. 10.13). Disubstitution of the α-carbon inhibits deamination (e.g., phentermine). Some secondary and tertiary amines as well as amines substituted with bulky groups can undergo deamination directly, without N-dealkylation (e.g., fenfluramine). Apparently, this behavior is associated with increased lipid solubility.

N-oxidation

In general, N-oxygenation of amines form stable N-oxides with tertiary amines and amides, and hydroxylamines with primary and secondary amines,

when no α-protons are available (e.g., mephentermine and arylamines) (Fig. 10.13). Tertiary amines having one or more hydrogens on the adjacent carbon dealkylate via the N-oxide. Rearrangement of the N-oxide to a carbinolamine, which subsequently collapses, gives rise to the secondary amine. The amine metabolites can be N-conjugated, increasing their excretion.

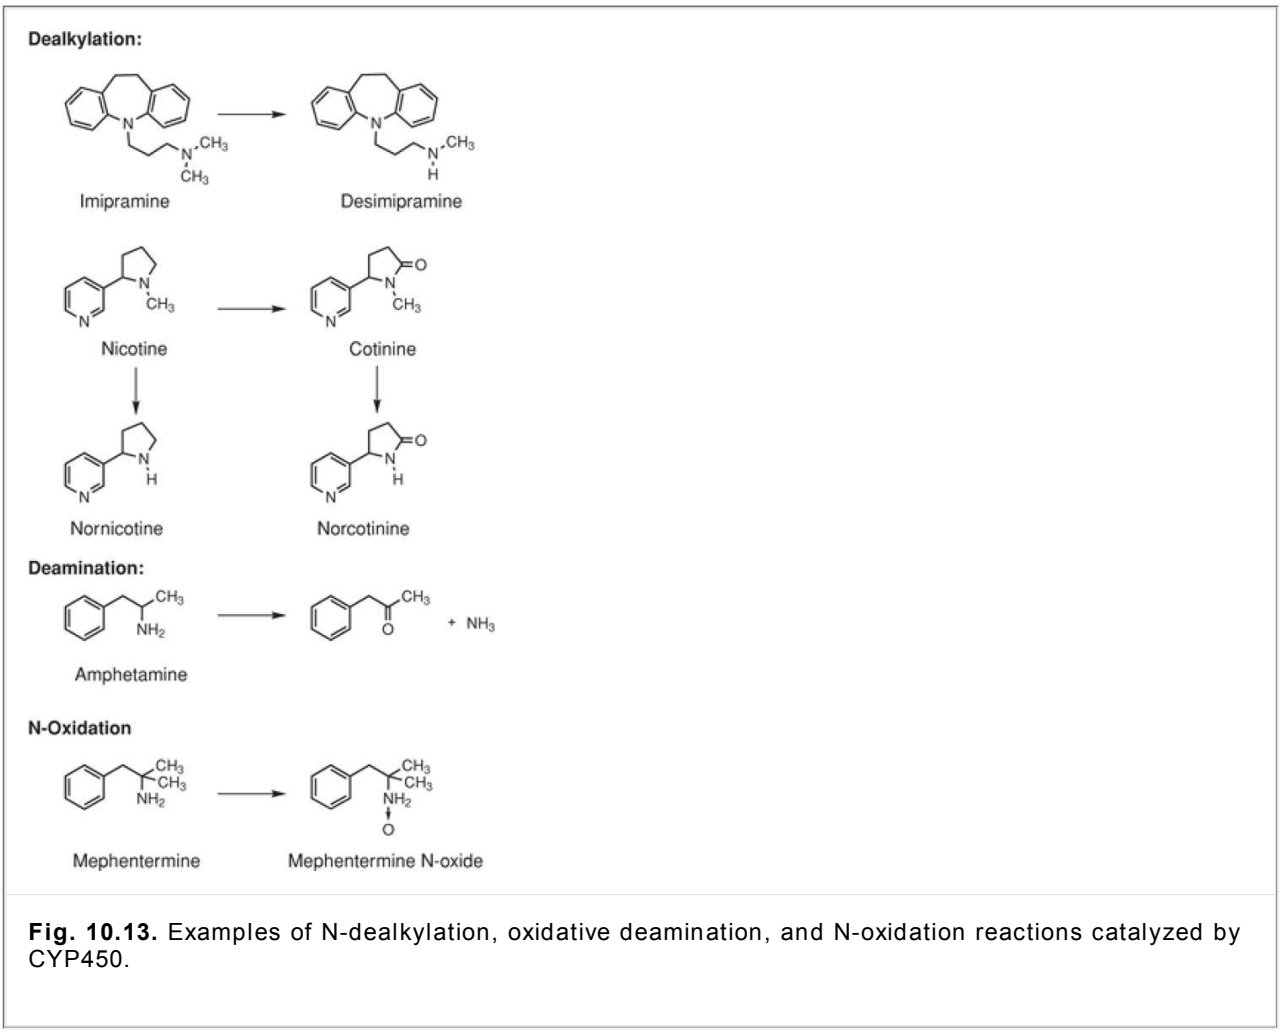

Fig. 10.13. Examples of N-dealkylation, oxidative deamination, and N-oxidation reactions catalyzed by CYP450.

O- and S-dealkylation

Oxidative O-dealkylation of ethers is a common metabolic reaction with a mechanism of dealkylation analogous to that of N-dealkylation; oxidation of the α-carbon, and subsequent decomposition of the unstable hemiacetal to an alcohol (or phenol) and a carbonyl product

(29,30,31). Thioethers also are dealkylated by the same mechanism to hemithioacetals. The majority of ether groups in drug molecules are aromatic ethers (e.g., codeine, prazocin, and verapamil). For example, codeine is O-demethylated to morphine (Fig. 10.14). The rate of O-dealkylation is a function of chain length (i.e., increasing chain length or branching reduces the rate of dealkylation). Steric factors and ring substituents influence the rate of dealkylation but are complicated by electronic effects. Some drug molecules contain more than one ether group, in which case usually only one ether is dealkylated. The methylenedioxy group undergoes variable rates of dealkylation to the 1, 2-diphenolic metabolite. Metabolism of such a group also is being capable of forming a stable complex with and inhibiting CYP450.

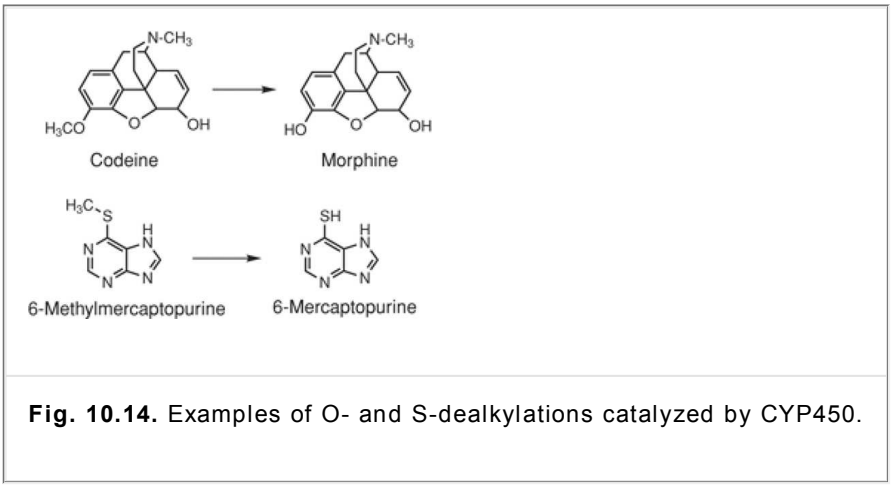

Fig. 10.14. Examples of O- and S-dealkylations catalyzed by CYP450.

Aliphatic and aromatic methyl thioethers undergo S-dealkylation to thiols and carbonyl compounds. For example, 6-methylthiopurine is demethylated to give the active anticancer drug 6-mercaptopurine (Fig. 10.14). Other thioethers are oxidized to sulfoxides (see N- and S-oxidations).

Dehalogenation

Many halogenated hydrocarbons, such as insecticides, pesticides, general anesthetics, plasticizers, flame retardants, and commercial solvents, undergo a variety of different dehalogenation biotransformations (24,25). Because of our potential exposure to these halogenated compounds as drugs and environmental pollutants in air, soil, water, or food, it is important to understand the interactions between metabolism and toxicity. Some halogenated hydrocarbons form glutathione or mercapturic acid conjugates, whereas others undergo dehydrohalogenation and reductive dehalogenation catalyzed by CYP2E1. In many cases, reactive intermediates, including radicals, anion, and cations, are produced that may react with a variety of tissue molecules.

Halogenated hydrocarbons differ in their chemical reactivity as a result of the electron-withdrawing properties of the halogens on adjacent carbon atoms, resulting in the α-carbon developing an electrophilic character. The halogen atoms also have the ability to stabilize α-carbon cations, free radicals, carbanions, and carbenes.

Oxidative dehydrohalogenation is a common metabolic pathway for many halogenated hydrocarbons (25,29,30,31). The CYP450-catalyzed oxidation generates the transient gem-halohydrin (analogous to alkane hydroxylation) that can eliminate the hydrohalic acid to form carbonyl derivatives (aldehydes, ketones, acyl halides, and carbonyl halides) (Fig. 10.7). This reaction

requires the presence of at least one halogen and one α-hydrogen. gem-Trihalogenated hydrocarbons are more readily oxidized than are the gem-dihalogenated and monohalogenated compounds. The acyl and carbonyl halides formed are reactive metabolites that can react either with water to form carboxylic acids or nonenzymatically with tissue molecules (with a potential for eliciting increased toxicity). Chloramphenicol ($RNHCOCHCl_2$) is biotransformed into an acyl halide ($RNHCOCOCl$) that selectively acylates the apoprotein of CYP450 (40,41).

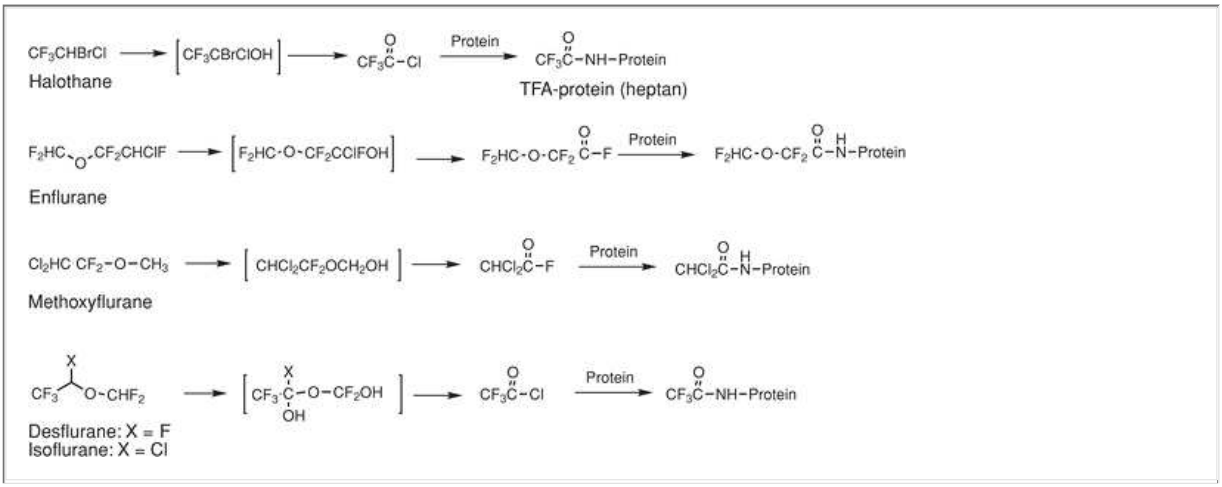

Fig. 10.15. CYP2E1-catalyzed metabolism of fluorinated volatile anesthetics to antigenic proteins.

An excellent example of oxidative dehydrohalogenation leading to significant hepatotoxicity and nephrotoxicity is seen with the fluorinated inhalation anesthetics (Fig. 10.15). The toxicity of halothane and the fluranes is related to their metabolism to either an acid chloride (or fluoride) or a trifluoroacetate intermediate (see Fig. 18.7). The CYP2E1 has been identified as the isoform catalyzing the biotransformation of the fluranes (25,43,44). The hydroxylated intermediate decomposes spontaneously to reactive intermediates, an acid chloride (or fluoride) or trifluoroacetate, that can either react with water to form halide anions and a fluorinated carboxylic acid or bind covalently to tissue proteins to produce an acylated protein. The acylated protein becomes a “hapten,'' stimulating an immune response and a hypersensitivity reaction. Halothane has received the most attention because of its ability to cause “halothane-associated” hepatitis. This immunologic reaction occurs after repeated exposure in surgical patients to trifluoroacetylate protein. The patient is sensitized to future exposures of the volatile anesthetic. After subsequent exposure to a fluorinated anesthetic, the antigenic trifluoroacetylate protein stimulates an immune response, producing halothane-like hepatitis. Because of the common metabolic pathway involving CYP2E1 for enflurane, isoflurane, desflurane, and methoxyflurane, halothane-exposed patients who have halothane hepatitis can show cross-sensitization to one of the other fluranes, triggering an idiosyncratic hepatic necrosis. The formation of antigenic protein is related to the amount of CYP2E1-catalyzed metabolism for each agent: halothane (20–40%) > enflurane (2–8%) > isoflurane (0.2–1.0%) > desflurane (<0.1%). Enough fluoride ion is generated from oxidative dehalogenation during flurane anesthesia to produce subclinical nephrotoxicity. Interestingly, female rats metabolize halothane more slowly than males do and are less susceptible to hepatotoxicity than males are. For patients with preexisting liver dysfunction, isoflurane or desflurane may be a better choice of anesthetic.

In today's environment, most humans have been exposed to many CYP2E1-inducing agents (including recreational, industrial, agricultural chemicals, and alcohol), having an unknown effect on hepatic toxicity from volatile anesthetics. Enhanced activity for CYP2E1 has been observed in obesity, isoniazid therapy, ketogenic diets, and alcoholism.

Azo and nitro reduction

In addition to the oxidative systems, liver microsomes also contain enzyme systems that catalyze the reduction of azo and nitro compounds to primary amines. A number of azo compounds, such as Prontosil and sulfasalazine (Fig. 10.16), are converted to aromatic primary amines by azoreductase, an NADPH-dependent enzyme system in the liver microsomes. Evidence exists for the participation of CYP450 in some reductions. Nitro compounds (e.g., chloramphenicol and nitrobenzene) are reduced to aromatic primary amines by a nitroreductase, presumably through nitrosamine and hydroxylamine intermediates. These reductases are not solely responsible for the reduction of azo and nitro compounds; reduction by the bacterial flora in the anaerobic environment of the intestine also may occur.

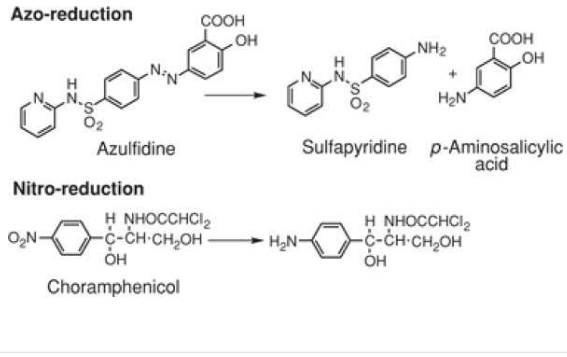

Fig. 10.16. CYP450-catalyzed reduction of azo and nitro compounds.

N- and S-Oxidations Catalyzed by Flavin Monooxygenase

The major hepatic monooxygenase systems responsible for the oxidation of many drugs, carcinogens, pesticides, aromatic polycyclic hydrocarbons, and other xenobiotics containing nitrogen, sulfur, or phosphorus are CYP450 monooxygenase and microsomal flavin-containing monooxygenase (FMO) (45). The FMO exhibits broader substrate specificities than CYP450 monooxygenases and has a mechanism distinctly different from that of CYP450 monooxygenases. Because oxygen activation occurs before substrate addition, any compound binding to 4α-hydroperoxyflavin, the enzyme-bound monooxygenating FMO intermediate, is a potential substrate. Typically, FMO catalyzes oxygenation of the N- and S-heteroatoms (“soft nucleophiles'') (Fig. 10.17) but not heteroatom dealkylation reactions. The products formed from FMO-catalyzed oxidation are consistent with a direct two-electron oxidation of the heteroatom. Thus, FMO constitutes an alternative biotransformation pathway for N- and S-containing lipophilic xenobiotics. Normally, FMO is not inducible by phenobarbital, nor is it affected by CYP450 inhibitors. With few exceptions, however, xenobiotic substrates for FMO also are substrates for the isoforms of CYP450, producing similar oxidation products. Which monooxygenase is responsible for the oxidation can be readily determined, because FMO is thermally labile in the absence of NADPH whereas CYP450 is stable.

Of the many nitrogen functional groups in xenobiotics, only secondary and tertiary acyclic, cyclic, and arylamines as well as hydroxylamines and hydrazines are oxidized by FMO and excreted in the urine (Fig. 10.17). The tertiary amines form stable amine oxides, and secondary amines are sequentially oxidized to hydroxylamines, nitrones, and a complex mixture of products. Secondary N-alkylarylamines can be N-oxygenated to reactive N-hydroxylated metabolites, which are responsible for the toxic, mutagenic, and

carcinogenic activity of these aromatic amines. For example, the chemically unstable hydroxylamine intermediates of aromatic amines degrade into bladder carcinogens (see the discussion for this type of toxic mechanism under glucuronic acid conjugation), and the hydroxamic acid intermediates of N-arylacetamides are bioactivated into liver carcinogens. Hepatic FMO, however, will not catalyze the oxidation of primary alkyl- or arylamines, except for the carcinogenic N-hydroxylated derivatives of 2-aminofluorene, 2-aminoanthracene, and other amino PAHs.

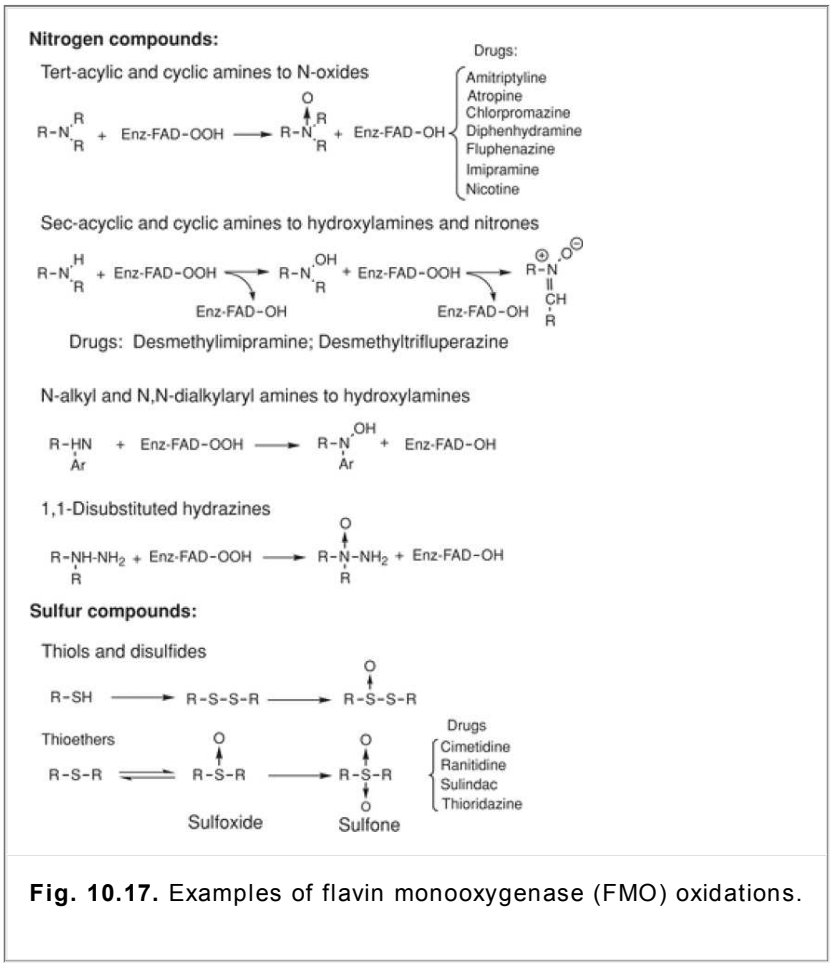

Fig. 10.17. Examples of flavin monooxygenase (FMO) oxidations.

S-oxidation occurs almost exclusively by FMO (Fig. 10.17). Sulfides are oxidized to sulfoxides and sulfones, thiols to disulfides, and thiocarbamates, mercaptopyrimidines, and mercaptoimidazoles (i.e., the antithyroid drug methimazole) via sulfenates (RSOH) to sulfinates (RSO_2H), all of which are eliminated in the urine.

The FMO does not catalyze epoxidation reactions or hydroxylation at unactivated carbon atoms of xenobiotics. Primary aromatic amines and amides, aromatic heterocyclic amines and imines, and the aliphatic primary amine phentermine are N-oxidized by CYP450 to hydroxylamines. The CYP450 oxidizes carbon disulfide to carbon dioxide and hydrogen sulfide and the antipsychotic phenothiazines to sulfoxides.

The major steps in the catalytic cycle for FMO are shown in Figure 10.18 (45,46). Like most of the other monooxygenases, FMO requires NADPH and oxygen as cosubstrates to catalyze the oxidation of the xenobiotic

substrate. Unlike CYP450, however, the xenobiotic being oxidized does not need to be bound to the 4α-hydroperoxyflavin intermediate (FAD-OOH) for oxygen activation to occur. Apparently, FMO is present within the cell in its enzyme-bound activated hydroperoxide (Enz-FAD-OOH) state ready to oxidize any suitable lipophilic substrate that binds to it. The FMO uses a nonradical, nucleophilic displacement type of mechanism binding dioxygen with a reduced flavin. The reactive oxygen intermediate is a reactive derivative of hydrogen peroxide, flavin-4α-hydroperoxide (Fig. 10.18, insert), which is reactive enough to successfully attack a lone electron pair on a heteroatom, such as nitrogen or sulfur, but not reactive enough to attack a typical C-H bond. These studies suggest the xenobiotic substrate interacts with the 4α-hydroperoxyflavin form of FMO and is oxidized by oxygen transfer from Enz-FAD-OOH to form the oxidized product. Neither the substrate nor the oxidized substrate is essential for any other steps in the cycle. Steps 2 to 5 simply regenerate the oxygenating agent Enz-FAD-OOH from Enz-FAD-OH, NADPH, oxygen, and a proton. Any compound readily crossing cell membranes by passive diffusion and penetrating to the FMO-bound hydroperoxyflavin intermediate is a potential substrate, thus explaining the broad substrate specificity exhibited for FMO. The fact that the xenobiotic substrate is not required for activation of the FMO-hydroperoxyflavin state distinguishes FMO from CYP450 monooxygenases, in which substrate binding initiates the CYP450 catalytic cycle and activation of oxygen to the perferryl oxygenating agent. It is not unusual for FMO oxidation products to undergo reduction to the parent xenobiotic, which can enter into repeated redox reactions (termed “metabolic cycling”).

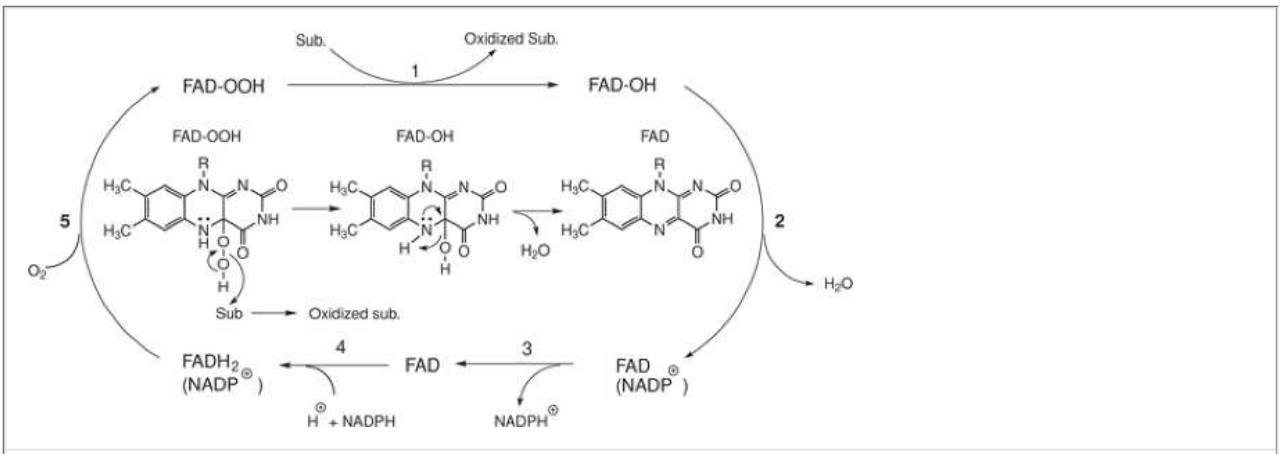

Fig. 10.18. Flavin monooxygenase (FMO) catalytic cycle. Oxygenated substrate is formed by nucleophilic attack of a substrate (Sub.) by the terminal oxygen of the enzyme-bound hydroperoxyflavin (FAD-OOH), followed by heterolytic cleavage of the peroxide (1). The release of H_2O (2) or of $NADP^+$ (3) is rate-limiting for reactions catalyzed by liver FMO. Reduction of flavin by NADPH (4) and addition of oxygen (5) complete the cycle by regeneration of the oxygenated FAD-OOH.

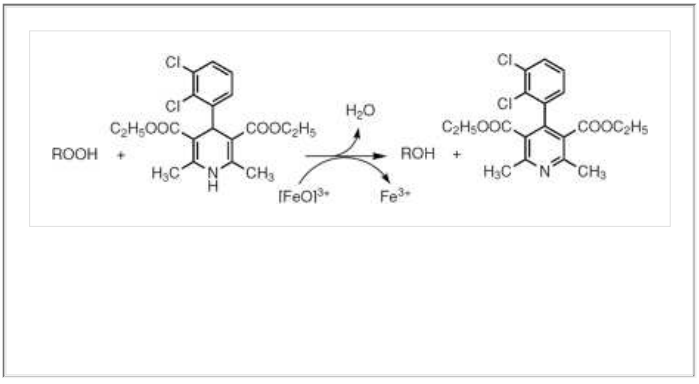
Results of substrate specificity studies suggest that the number of ionic groups on endogenous substrate is an important factor enabling FMO to distinguish between xenobiotic and endogenous substrates, preventing the indiscriminate oxidation of physiologically important amine and sulfur compounds (47). Without exception, FMO readily catalyzes the oxidation of uncharged amines or sulfur compounds (in equilibrium with its respective monocation or monoanion; for sulfur compounds, the charge is on sulfur atom). The FMO will not catalyze the oxidation of dianions (e.g., thiamine pyrophosphate), dications (e.g., polyamines), dipolar ions (e.g., amino acids and peptides), or other polyionic compounds with one or more anionic groups (i.e., COO) distal to the heteroatom (e.g., coenzyme A).

Unlike the CYP450 system, only three isoforms of hepatic FMO have been characterized in the adult human liver (48,49): minor form I (or FMO 1A1), which is the major form in fetal tissue; major form II (FMO 1D1); and form III, of which little is currently known. The substrate specificities for these isoforms have not been reported. The availability of different forms of FMO may be of clinical importance in the pharmacological and toxicological properties of FMO-dependent drug oxidations.

Peroxidases and Other Monooxygenases

Peroxidases are hemoproteins and, perhaps, the most closely related enzymes to CYP450 monooxygenase (50,51). The normal course of peroxide (ROOH)-catalyzed oxidation involves the formation of the $[FeO]^{+3}$ intermediate, analogous to the perferryl complex in CYP450. It can perform heteroatom oxygenation and aromatization (oxidation) of 1,4-dihydropyridines (calcium channel blockers).



Other monooxygenases catalyzing oxidation reactions similar to CYP450 include dopamine β-monooxygenase, a mammalian copper-containing enzyme catalyzing carbon hydroxylation, epoxidation, S-oxygenation, and N-dealkylation reactions, and nonheme iron–containing enzymes from bacteria and plants.

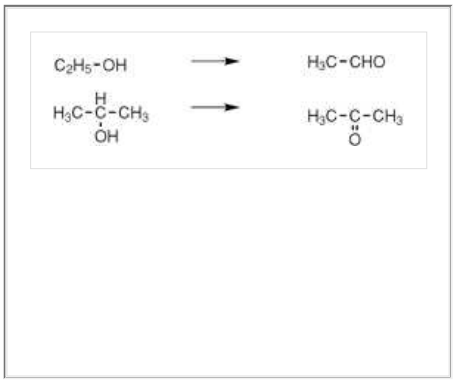
Nonmicrosomal Oxidations

In addition to the microsomal monooxygenases, other oxidases and dehydrogenases that catalyze oxidation reactions are present in the mitochondrial and soluble fractions of tissue homogenates.

Oxidation of alcohols

Alcohol dehydrogenase is an NAD-specific enzyme located in the soluble fraction of tissue homogenates. It exhibits a broad specificity for

alcohols. Most primary alcohols are readily oxidized to their corresponding aldehydes. Some secondary alcohols are oxidized to the ketones, whereas other secondary and tertiary alcohols are excreted either unchanged or as their conjugate metabolite. Some secondary alcohols also show mixed activity because of steric factors and a lack of substrate affinity for the enzyme.



Oxidation by alcohol dehydrogenase is the principal pathway for ethanol metabolism, but the microsomal isoform CYP2E1 also plays a significant role in ethanol metabolism and tolerance. Apparently, two-thirds of ingested ethanol is oxidized by alcohol dehydrogenase and the remainder by CYP2E1; during intoxication, however, ethanol induces the expression of CYP2E1. The induction of CYP2E1 contributes to the activation of some xenobiotics, increasing the vulnerability of heavy drinkers to anesthetic drugs, over-the-counter analgesics, prescription drugs, and chemical carcinogens. In turn, the excessive amounts of acetaldehyde generated cause hepatotoxicity, lipid peroxidation of membranes, formation of protein adducts, and other cellular changes.

The toxicity of methanol and ethylene glycol in humans has long been recognized, but frequent reports of such toxicity are not surprising given the number of consumer products containing methanol and ethylene glycol (automotive antifreeze). Methanol (wood alcohol or methyl alcohol) is commonly used as a solvent in organic synthetic procedures, and is available to consumers in a variety of products, ranging from solid fuels (Sterno), paint removers, solvent for “ditto'' copying machines, motor fuels, antifreeze, to alcoholic beverages (unintentional ingredient). Oral methanol toxicity in humans is characterized by its rapid absorption from the gut, followed by a latent period of many hours before metabolic acidosis (lowered blood pH and bicarbonate levels) and ocular toxicity are evident. The metabolic acidosis and blindness result from the excessive accumulation of formic acid and the inability of the hepatic tetrahydrofolate pathway to oxidize formate to carbon dioxide. The rate of elimination of methanol from the blood is relatively slow compared to that of ethanol, accounting for its long latency period. Its half-life ranges from 2 to 3 hours at low blood concentration to 27 hours at high blood concentration. Evidence supports the singular role of liver alcohol dehydrogenase in the metabolism of methanol to formaldehyde, although it is oxidized slowly by alcohol dehydrogenase (approximately one-sixth the rate of ethanol). The demonstration that methanol is a substrate for alcohol dehydrogenase provides a rational basis for the use of ethanol in the treatment of methanol toxicity. Ethanol depresses the rate of methanol oxidation by acting as a competitive substrate for alcohol dehydrogenase, reducing the formation of formaldehyde. On the other hand, formaldehyde is not usually detected in the blood because of its rapid metabolism by aldehyde dehydrogenase to formate. Although human exposure to methanol vapor is less prevalent, methanol is rapidly absorbed through the skin or by inhalation, and depending on the severity of exposure, this can result in methanol poisoning. Ethylene glycol is oxidized to hydroxyacealdehyde and glyoxal and, subsequently, to oxalate by aldehyde dehydrogenase. When eliminated into the urine, oxalate forms calcium oxalate crystals that can block the kidney tubules. 4-Methylpyrazole (Fomepizole) is an alcohol dehydrogenase inhibitor that is used as an antidote for the treatment of methanol or ethylene glycol poisoning. 1,4-Butanediol is a solvent that has became popular as a date-rape drug and drug-of-abuse because of its metabolism to γ-hydroxybutyrate (see Chapter 15), which binds to the γ-hydroxybutyrate receptor, which in turn produces central nervous system sedation with amnesia.

Alcohol dehydrogenase also functions as a reductase when it catalyzes the reduction of an aldehyde or ketone to an alcohol. In addition, other NADP- or NAD-dependent dehydrogenases in the cytosol are capable of reducing a variety of ketones. Ketones are stable to further oxidation and, consequently, yield reduction products as major metabolites. Examples of reduction include the sedative-hypnotic chloral hydrate to trichloroethanol, the opioid antagonist naltrexone to 6-β-hydroxynaltrexol, the opioid analgesic methadone to α-methadol, the antipsychotic haloperidol to hydroxyhaloperidol, and the antiemetic dolasetron to dihydrodolasetron. These alcohol metabolites are all pharmacologically active.

Aldehyde dehydrogenase

A NAD-specific aldehyde dehydrogenase catalyzes the oxidation of endogenous aldehydes, such as those produced by the oxidation of primary alcohols or the deamination of biogenic amines, and of exogenous aldehydes to the corresponding carboxylic acids. By inhibiting this enzyme, disulfuram (Antabuse) and metronidazole produce an unpleasant set of reactions (flushing, abdominal cramping, and headache) when small amounts of alcohol are ingested. Antabuse is used therapeutically in controlling alcohol abuse. Aldehyde dehydrogenase deficiency exhibits significant polymorphic expression in Chinese patients.

Molybdenum hydroxylases

Molybdenum hydroxylases are additional non-CYP450 enzymes capable of catalyzing the oxidation of drugs. The molybdenum hydroxylases, which include aldehyde oxidase, xanthine oxidase, and xanthine dehydrogenase, are more commonly found in the cytosol of mammalian liver and carry out the oxidation and detoxification of a number of structurally different azaheterocycles (52). The efficient oxidation of endogenous purine nucleosides suggests that their metabolism and detoxification might be an important physiological role for the molybdenum hydroxylases. Among the azaheterocycles metabolized are derivatives of pyridine, quinoline, pyrimidine, purine, quinazoline, and pteridines. These hydroxylases generally oxidize the α-carbon to the nitrogen of the azaheterocycle to oxo metabolites

(also known as lactams). The molybdenum hydroxylases contain a common electron-transfer system in each subunit: one molybdenum atom, two Fe/S clusters, and one flavin adenine dinucleotide molecule. The molybdenum hydroxylases catalyze their reactions differently than CYP450 and other hydroxylase enzymes, requiring water rather than molecular oxygen as the source of the oxygen atom incorporated into the metabolite, and with the concomitant reduction of molecular oxygen to superoxide (53,54). The active sites possess a catalytically labile Mo^{V}-OH (or, possibly, Mo^{VI}-OH_2) group that is transferred to the substrate during the course of the hydroxylation reaction.

Aldehyde oxidase

In addition to metabolizing some aldehydes, aldehyde oxidase also oxidizes a variety of azaheterocycles but not thia- or oxaheterocycles. Of the various purine nucleosides metabolized by aldehyde oxidase, the 2-hydroxy- and 2-amino derivatives are more efficiently metabolized, and for the N^9-substituents, the typical order of preference is the acyclic nucleosides is as follows: 9-[(hydroxy-alkyloxy)methyl]-purines) > 2′-deoxyribofuranosyl > ribofuranosyl > arabinofuranosyl > H. The kinetic rate constants for purine analogues revealed that the pyrimidine portion of the purine ring system is more important for substrate affinity than the imidazole portion. Aldehyde oxidase is inhibited by potassium cyanide and menadione (synthetic vitamin K).

Aldehyde oxidase metabolizes an assortment of azaheterocycles including the short-acting sedative-hypnotic drug zaleplon (a pyrazolo[1,5α] pyrimidine derivative) to its 5-oxo metabolite; the anticancer drug thioguanine to 8-oxothioguanine; the α_2-adrenergic agonist brimonidine (a pyrimidine derivative) to its 2-oxo-, 3-oxo-, and 2,3-dioxo- metabolites; quinine and quinidine to their 2-quinolone metabolites; the pro-antiviral drug famiclovir (a purine derivative) to its active 6-oxo metabolite (penciclovir); O^6-benzylguanine to its 8-oxo metabolite (also formed primarily from CYP3A4); the metabolism of the anticancer drug DACA (an acridine-4-carboxamide derivative) to its 9-acridone metabolite; and the antiseizure drug zonisamide (a 1,2-benzisoxazole derivative) primarily by reductive cleavage of the 1,2-benzisoxazole ring to 2-sulfamoylacetylphenol. Although the azaheterocycles thiazole and oxazole are not metabolized by aldehyde oxidase, their carbocyclic analogues, benzothiazole, benzoxazole, and 1,2-benzisoxazole, are metabolized. On the other hand, the heterocycles, benzothiophene and benzofuran, which do not contain a nitrogen atom, are not metabolized by or inhibit aldehyde oxidase.

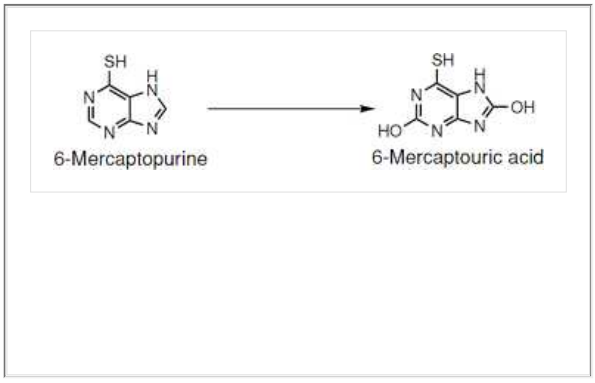
The hepatotoxic and neurotoxic 1-methyl-4-phenyl-1,2,3, 6-tetrahydropyridine (MPTP) is metabolized by aldehyde oxidase to its nontoxic MP-2-pyridone metabolite (MPTP lactam). Although S-cotinine is formed primarily from S-nicotine in human smokers by CYP2A6, in vitro studies suggest that aldehyde oxidase contributes to S-nicotine metabolism by oxidizing the intermediate metabolite (S-nicotine Δ-1′,5′ -imminium ion) to S-cotinine. These results suggest that hepatic aldehyde oxidase is a key detoxification enzyme for MPTP and S-nicotine.

Both aldehyde oxidase and xanthine oxidase contribute to the first-pass hepatic metabolism of orally administered methotrexate (a 2,4-diaminopteridine) to its 7-hydroxymethotrexate metabolite.

Xanthine oxidase and xanthine dehydrogenase

Xanthine oxidase and xanthine dehydrogenase represent different forms of the same gene product. Xanthine dehydrogenase and xanthine oxidase are interconvertable; thus, these two enzyme forms and their reactions often are referred to as xanthine oxidoreductase. Xanthine oxidase is the rate-limiting enzyme in purine catabolism of hypoxanthine to uric acid via xanthine. Both xanthine oxidase and xanthine dehydrogenase play important roles in the

metabolism of a number of purine anticancer drugs to their active and inactive metabolites. Although xanthine oxidase is strongly inhibited by the antigout drug allopurinol, aldehyde oxidase oxidizes it to oxypurinol. Only xanthine dehydrogenase requires NAD^+ as an electron acceptor for the oxidation of azaheterocycles. 6-Mercaptopurine is metabolized by xanthine oxidase to 6-mercapturic acid.



Oxidative Deamination of Amines

Monoamine oxidase (MAO) and diamine oxidase catalyze oxidative deamination of amines to the aldehydes in the presence of oxygen. The aldehyde products can be metabolized further to the corresponding alcohol or acid by aldehyde oxidase or dehydrogenase.

Monoamine oxidase

Monoamine oxidase is a mitochondrial membrane flavin-containing enzyme that catalyzes the oxidative deamination of monoamines according to the following equation:

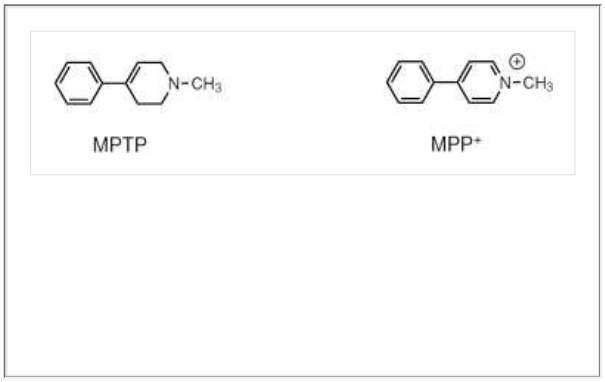
$$R\text{-}CH_2\text{-}NH_2 + O_2 \longrightarrow [R\text{-}CH{=}NH] \longrightarrow R\text{-}CHO + NH_4^{\oplus}$$

Substrates for this enzyme include several monoamines, secondary and tertiary amines in which the amine substrates are methyl groups. The amine must be attached to an unsubstituted methylene group, and compounds having substitution at the α-carbon atom are poor substrates for MAO (e.g., aniline, amphetamine, and ephedrine) but are oxidized by the microsomal CYP450 enzymes rather than by MAO

(Fig. 10.13). For secondary and tertiary amines, alkyl groups larger than a methyl and branched alkyl groups (i.e., isopropyl, t-butyl, or β-phenylisopropyl) inhibit MAO oxidation, but such substrates may function as reversible inhibitors of MAO. Nonselective irreversible inhibitors of MAO include hydrazides (phenelzine) and tranylcypromine and the MAO-B selective inhibitors pargyline and selegiline. Monoamine oxidase is important in regulating the metabolic degradation of catecholamines and serotonin in neural tissues, and hepatic MAO has a crucial defensive role in inactivating circulating monoamines or those that originated in the gastrointestinal tract and were absorbed into the systemic circulation (e.g., tyramine).

Two types of MAO are isolated: MAO-A, and MAO-B. They show dissimilar substrate preferences and different sensitivities to inhibitors. The type MAO-A is found mainly in peripheral adrenergic nerve terminals and shows substrate preference for 5-hydroxytryptamine, norepinephrine, and epinephrine. The type MAO-B is found principally in platelets and shows selectivity for nonphenolic, lipophilic β-phenethylamines. Common substrates to both MAO-A and MAO-B are dopamine, tyramine, and other monophenolic phenylethylamines.

A contaminant in the synthesis of reversed esters of meperidine, MPTP was discovered to be a highly selective neurotoxin for dopaminergic cells, producing parkinsonism (47). The neurotoxicity of MPTP is associated with cellular destruction in the substantia nigra along with severe reductions in the concentration of dopamine, norepinephrine, and serotonin. The remarkable neurotoxic action for MPTP involves a sequence of events beginning with the metabolic activation of MPTP to the toxic metabolite MPP^+ (1-methyl-4-phenylpyridinium ion) by MAO-B, specific uptake and accumulation of MPP^+ in the nigrostriatal dopaminergic neurons, and ending with the inhibition of oxidative phosphorylation (of NADH dehydrogenase in complex I). This inhibition results in mitochondrial injury depriving the sensitive nigrostriatal cells of oxidative phosphorylation with their eventual cell death (neurotoxic actions of MPP^+). The MAO-B inhibitors (e.g., deprenyl) blocked this biotransformation.



Diamines, such as $H_2N\text{-}(CH_2)_n\text{-}NH_2$, in which n is less than six, are not attacked and show little affinity for MAO. If the intermolecular distance between the amine groups is increased, the rate of oxidation by MAO increases. Evidently, the second amine group interferes with attachment of the amine to the enzyme.

Diamine oxidase

Diamine oxidase attacks both diamines and histamine in much the same way that MAO attacks monoamines, forming aldehydes. This enzyme is inhibited by carbonyl-blocking reagents and produces hydrogen peroxide, supporting the role of pyridoxal phosphate and the flavin prosthetic groups in the catalytic action of the enzyme. Diamine oxidase is recovered in the supernatant after centrifugation and removal of particulate matter. It is present in kidneys, intestines, liver, lung, and nervous tissue. It limits the biological effects of histamine and the polymethylene amines putrescine and cadaverine. It also attacks monoamines, but at a higher substrate concentration.

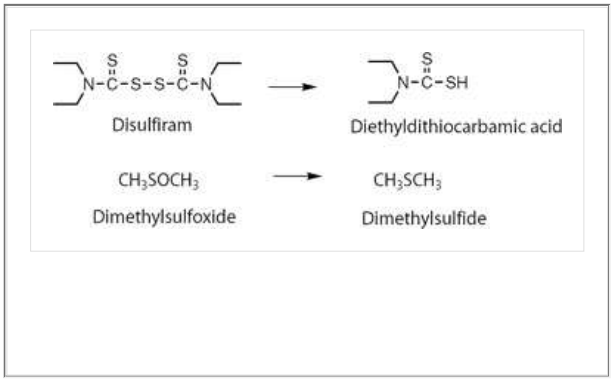
$H_2N\text{-}(CH_2)_4\text{-}NH_2$ Putrescine

$H_2N\text{-}(CH_2)_5\text{-}NH_2$ Cadaverine

Plasma amine oxidases are in blood plasma of mammals and include spermine oxidase, which deaminates spermine and other polyamines.

Miscellaneous Reductions

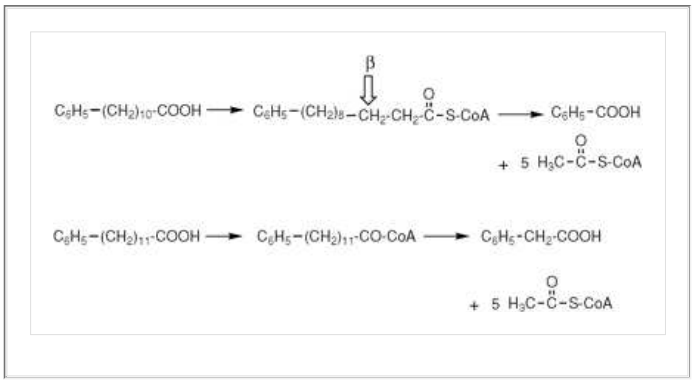
Disulfides (e.g., disulfiram), sulfoxides (e.g., dimethylsulfoxide), N-oxides, double bonds such as those in progestational steroids, and dehydroxylation of aromatic and aliphatic hydroxyl derivatives are examples of reductions occurring in microsomal or nonmicrosomal (usually cytosol enzymes) fractions.



Various studies regarding the biotransformation of xenobiotic ketones have established that ketone reduction is an important metabolic pathway in mammalian tissue. Because carbonyl compounds are lipophilic and may be retained in tissues, their reduction to the hydrophilic alcohols and subsequent conjugation are critical to their elimination. Although ketone reductases may be closely related to the alcohol dehydrogenases, they have distinctly different properties and use NADPH as the cofactor. The metabolism of xenobiotic ketones to free alcohols or conjugated alcohols has been demonstrated for aromatic, aliphatic, alicyclic, and unsaturated ketones (e.g., naltrexone, naloxone, hydromorphone, and daunorubicin). The carbonyl reductases are distinguished by the stereospecificity of their alcohol metabolites.

β-Oxidation

Alkyl carboxylic acids, as their coenzyme A (CoA) thioesters, are metabolized by oxidation at the β–χαρβον to the carboxylic carbon (β-oxidation). This pathway involves the oxidative cleavage of two carbon units at a time (as acetate), beginning at the carboxyl terminus and continuing until no more acetate units can be removed. The reaction is terminated when a branch (e.g., valproic acid) or aromatic group is encountered. The metabolism of even and odd phenylalkyl acids can serve as an example:



Hydrolysis

In general, esters and amides are hydrolyzed by enzymes in the blood, liver microsomes, kidneys, and other tissues. Esters and certain amides are hydrolyzed rapidly by a group of enzymes termed "carboxylesterases." The more lipophilic the amide, the more favorable it is as a substrate for this enzyme. In most cases, the hydrolysis of an ester or amide bond in a toxic substance results in bioinactivation to hydrophilic metabolites that are readily excreted. Some of these metabolites may yield conjugated metabolites (i.e., glucuronides).

Carboxylesterases include cholinesterase (pseudocholinesterase), arylcarboxyesterases, liver microsomal carboxylesterases, and other unclassified liver carboxylesterases. Cholinesterase hydrolyzes choline-like esters (succinylcholine) and procaine as well as acetylsalicylic acid. Genetic variant forms of cholinesterase have been identified in human serum (e.g., succinylcholine toxicity when administered as ganglionic blocker for muscle relaxation). Meperidine is hydrolyzed only by liver microsomal carboxylesterases (Fig. 10.19). Diphenoxylate is hydrolyzed to its active metabolite, diphenoxylic acid, within 1 hour (Fig. 10.19). Presumably, the peripheral pharmacological action of diphenoxylate is attributed to zwitterionic diphenoxylic acid, which is readily eliminated in the urine.

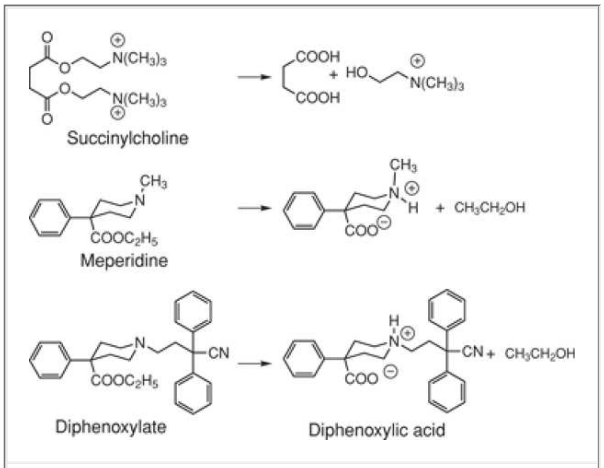


Fig. 10.19. Examples of hydrolysis reactions.

A distinct type of esterase is the enzyme serum paraoxonase (PON1), which appears to act as an important guardian against the neurotoxicity of organophosphates and cellular damage from oxidized lipids in the LDL proteins (55). The PON1 (A-esterase) is similar to arylesterase in that it catalyzes the hydrolysis of phenyl acetate and other aryl esters. Without PON1, the organophosphate is free to react with, and irreversibly inhibit, acetylcholinesterse (see Chapter 12). Additionally, PON1 exhibits a substrate-dependent polymorphism. Individuals who are susceptible to the toxic effects of organophosphates such as paraoxon and chlorpyrifos (Dursban) are deficient in this isoenzyme.

Esters that are sterically hindered are hydrolyzed more slowly and may appear unchanged in the urine. For example, approximately 50% of a dose of atropine appears unchanged in the urine of humans. The remainder appears to consist of unhydrolyzed biotransformed products.

As a rule, amides are more stable to esterase hydrolysis than are esters, and it is not surprising to find amides excreted largely unchanged. This fact has been exploited in developing the antiarrhythmic drug procainamide. Procaine is not useful because of its rapid esterase hydrolysis,

but 60% of a dose of procainamide was recovered unchanged from the urine of humans, with the remainder being mostly N-acetylprocainamide. On the other hand, the deacylated metabolite of indomethacin (a tertiary amide) is one of the major metabolites detected in human urine. Amide hydrolysis of phthalylsulfathiazole and succinylsulfathiazole by bacterial enzymes in the colon releases the antibacterial agent sulfathiazole.

Summary

In summary, Phase 1 metabolic transformations introduce new and polar functional groups into the molecule, which may produce one or more of the following changes:

1. Decreased pharmacological activity (deactivation)
2. Increased pharmacological activity (activation)
3. Increased toxicity (carcinogenesis, mutagenesis, cytotoxicity)
4. Altered pharmacological activity

Drugs exhibiting increased activity or activity different from the parent drug generally undergo further metabolism and conjugation, resulting in deactivation and excretion of the inactive conjugates.

Drug Conjugation Pathways (Phase 2)

Conjugation reactions represent probably the most important xenobiotic biotransformation reaction (53,54). Xenobiotics usually are lipophilic, well absorbed in the blood, but slowly excreted in the urine. Only after conjugation (Phase 2) reactions have added an ionic hydrophilic moiety, such as glucuronic acid, sulfate, or glycine, to the xenobiotic is water solubility increased and lipid solubility decreased enough to make urinary elimination possible. The major proportion of the administered drug dose is excreted as conjugates into the urine and bile. Conjugation reactions may be preceded by Phase 1 reactions. For xenobiotics with a functional group available for conjugation, conjugation alone may be its fate.

Traditionally, the major conjugation reactions (glucuronidation and sulfation) were thought to terminate pharmacological activity by transforming the parent drug or Phase 1 metabolites into readily excreted ionic polar products. Moreover, these terminal metabolites would have no significant pharmacological activity (i.e., poor cellular diffusion and affinity for the active drug's receptor). This long-established view changed, however, with the discoveries that morphine 6-glucuronide has more analgesic activity than morphine in humans and that minoxidil sulfate is the active metabolite for the antihypertensive minoxidil. For most xenobiotics, conjugation is a detoxification mechanism. Some compounds, however, form reactive intermediates that have been implicated in carcinogenesis, allergic reaction, and tissue damage.

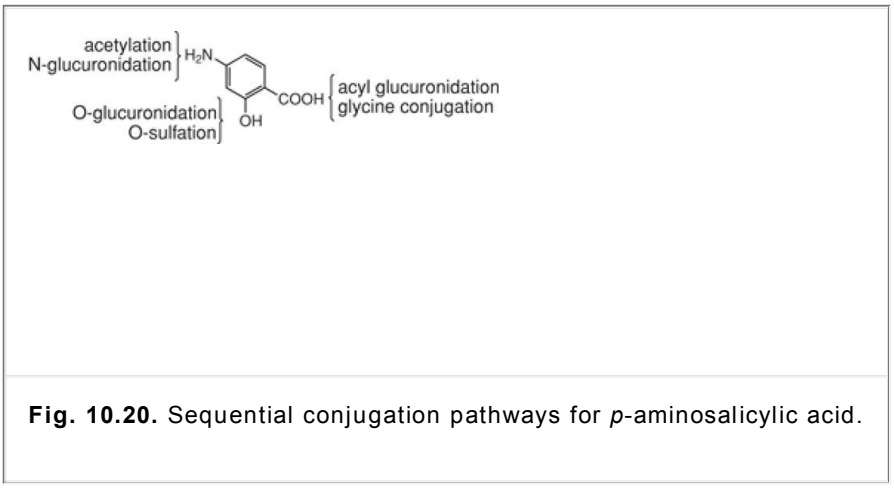

Fig. 10.20. Sequential conjugation pathways for *p*-aminosalicylic acid.

Sequential conjugation for the same substance gives rise to multiple conjugated products (see *p*-aminosalicylic acid in Fig. 10.20). The xenobiotic can be a substrate for more than one metabolizing enzyme. For example, different conjugation pathways could compete for the same functional group. The outcome is an array of metabolites excreted in the urine or feces. The factors determining the outcome of this interplay include availability of cosubstrates, enzyme kinetics (V_{max}), substrate affinity (K_m) for the metabolizing enzyme, and tissues. When a cosubstrate is low or depleted, the competing reactions can take over. The reactivity of the functional group determines all subsequent events. For example, major conjugation reactions are sulfation, ether glucuronidation, and methylation for the phenolic hydroxyl groups; acetylation, sulfation, and glucuronidation for amine groups; and amino acid conjugation and ester glucuronidation for carboxyl groups.

Conjugation enzymes may show stereospecificity toward enantiomers when a racemic drug is administered. The metabolite pattern of the

same drug when administered orally may be different when administered intravenously because of presystemic intestinal conjugation. A current and in-depth review of the different Phase 2 conjugations is available in Mulder (56).

Glucuronic Acid Conjugation

Glucuronide formation probably is the major and most common route for xenobiotic Phase 2 metabolism to water-soluble metabolites, and it accounts for the major share of the conjugated metabolites found in the urine and bile (56). Its significance lies in the readily available supply of glucuronic acid in the liver and in the many functional groups forming glucuronide conjugates (e.g., phenols, alcohols, carboxylic acids, and amines).

Mechanism of Glucuronide Conjugation

The reaction involves the direct condensation of the xenobiotic (or its Phase 1 product) with the activated form of glucuronic acid, UDP–glucuronic acid (UDPGA). The overall scheme of reactions is shown in Figure 10.21. The reaction between UDPGA and the acceptor compound is catalyzed by UDP–glucuronosyl transferases (UGT), a multigene family of isozymes located along the ER of liver, epithelial cells of the intestine, and other extrahepatic tissues. Its unique location in the ER along with the CYP450 isoforms has important physiologic effects in the neutralization of reactive

metabolites generated by the CYP450 isoforms and in controlling the levels of reactive metabolites present in these tissues.(Fig. 10.22). This cartoon depicts the spatial orientation and the interrelationship of the ER membrane–bound enzymes such as CYP450, UGTs, and membrane-bound transporters (57). The transporters carry the UDPGA and xenobiotics (D) from the cytosol into the ER lumen and transport the glucuronide metabolite from the ER lumen into the cytosol. The presence of the active site for UGT toward the ER lumen catalyzes the reaction between the substrate and UDPGA. The resultant glucuronide has the β-configuration about carbon 1 of glucuronic acid. With the attachment of the hydrophilic carbohydrate moiety containing an easily ionizable carboxyl group (pK_a = 3–4), a lipid-soluble substance is converted into a conjugate that is poorly reabsorbed by the renal tubules from the urine and is excreted more readily into the urine or, in some cases, into the bile. Endogenous substances conjugated with glucuronic acid include steroids, bilirubin, and thyroxine. Not all glucuronides are excreted by the kidneys. Some are excreted into the intestinal tract with bile (enterohepatic cycling), where β-glucuronidase in the intestinal flora hydrolyzes the C^1-O-glucuronide back to the aglycone (xenobiotic or their metabolites) for reabsorption into the portal circulation.

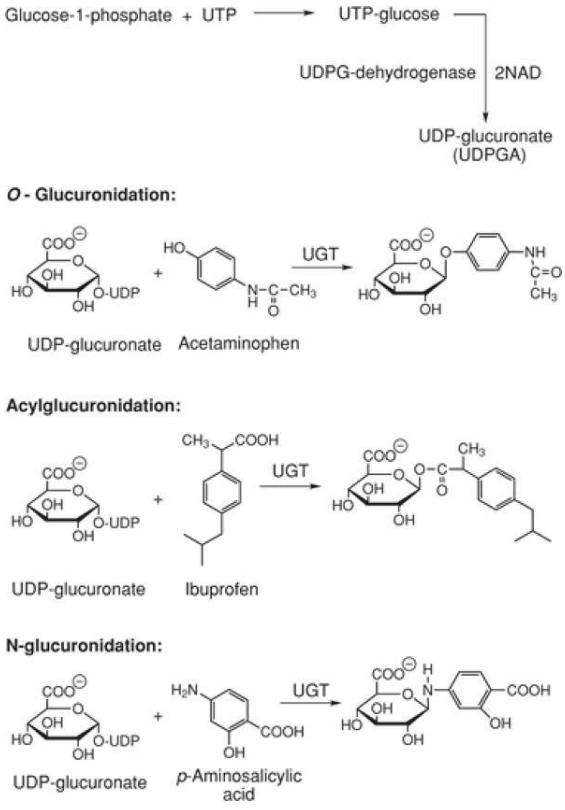

Fig. 10.21. Glucuronidation pathway catalyzed by UDP-glucuronosyl transferases (UGTs).

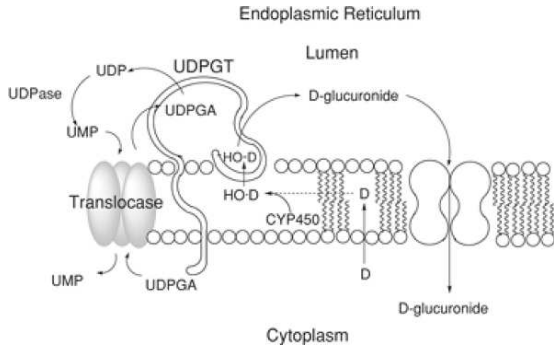

Fig. 10.22. Proposed topological model of UGT. A lipophilic drug (D) reaches the active site of CYP450 from the membrane or cytoplasm and is hydroxylated. The hydroxylated metabolite is transferred to UGT, where glucuronidation occurs, followed by release into the lumen and excretion from the cell. The UDPGA is synthesized in the cytoplasm and transported via translocase. (Adapted from Oesch F. Metabolic transformation of clinically used drugs to epoxides: new perspectives in drug–drug interactions. Biochem Pharmacol 1976;25 1935–1937; with permission.)

UGT Families

The UGTs have been classified into families according to similarities in amino acid sequences, analogous to the CYP450 family. The human UGT family is divided into two subfamilies, UGT1 and UGT2 (58). Considerable overlap in substrate specificities exists between the two families. The human UGT1A1 isoform is primarily responsible for the glucuronidation of bilirubin, estradiol, and other estrogenic steroids; UGT1A3 and UGT1A4 catalyze the glucuronidation of drugs with tertiary amines to form quaternary glucuronides and hydroxylated xenobiotics; UGT1A6 exhibits limited substrate specificity for planar phenolic substances; UGT1A9 has a wide range of substrate specificity and can glucuronidate nonplanar phenols, plant substances (e.g., anthraquinones and flavones), steroids, and other phenolic drugs; and UGT1A10 glucuronidates mycophenolic acid an inhibitor of inosine monophosphate dehydrogenase. Human family 2 isoform UGT2B4 is homologous to UGT2B7 and catalyzes the glucuronidation of the 6α-hydroxyl group of bile acids; UGT2B7 glucuronidates, the highest number of substrates, including the 3- and 6-glucuronidation of morphine and 6-glucuronidation of codeine; UGT2B11 glucuronidates a wide range of planar phenols, bulky alcohols, and polyhydroxylated estradiol metabolites; and UGT2B15 catalyzes the glucuronidation of the

17α-hydroxyl group of dihydrotestosterone and other steroidal compounds as well as phenolphthalein. The UGT1A isoforms are inducible with 3-methylcholanthrene and cigarette smoking, and the UGT2B family is inducible by barbiturates. Approximately 40% of the glucuronides are produced by UGT2B7, 20% by UGT1A4, and 15% by UGT1A1.

UGT Distribution

The human liver has been established as the most important tissue for all routes of metabolism, including glucuronidation. Studies have shown that the rate of glucuronidation is not uniform in the different sections of the liver: The UGT1A6 content was greatest in the middle but also found in the bile duct epithelium and in the endothelium of the hepatic artery and portal vein; UGT2B2 was uniformly distributed throughout the liver. The UGTs expressed in the intestine include UGT1A1 (bilirubin-glucuronidating isoform), UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT1A9, and UGT1A10. Substrate specificities of intestinal UGT isoforms are comparable to those in the liver. The UGT isoforms in the intestine can glucuronidate orally administered drugs, such as morphine, acetaminophen, α- and β-adrenergic agonists and other phenolic phenethanolamines, as well as other dietary xenobiotics, reducing their oral bioavailability (first-pass metabolism). Although UGT isoforms are found in kidney, brain, and lung, they are not uniformly distributed, with UGT1A6 being the isoform that is ubiquitous in extrahepatic tissue.

O-, N-, and S-Glucuronides

The xenobiotics forming glucuronides with alcohols and phenols are ether glucuronides. Aromatic and some aliphatic carboxylic acids form ester (acyl) glucuronides. Aromatic amines form N-glucuronides, and sulfhydryl compounds form S-glucuronides, both of which are more labile to acid compared with the O-glucuronides (Fig. 10.21). Some tertiary amines (e.g., tripelennamine) have been reported to form quaternary ammonium N-glucuronides. Substances containing a 1,3-dicarbonyl structure (e.g., phenylbutazone) can undergo formation of C-glucuronides by direct conjugation without previous metabolism. The acidity of the methylene carbon of the 1,3-dicarbonyl group determines the degree of C-glucuronide formation.

Acyl Glucuronides

Drug–acyl glucuronides are reactive conjugates at physiologic pH. The acyl group of the C^1-acyl glucuronide can migrate via transesterification from the original C-1 position of the glucuronic acid to the C-2, C-3, or C-4 positions (Fig. 10.21). The resulting positional isomers are not hydrolyzable by β-glucuronidase, giving the appearance of a new unknown conjugate. Under physiologic or weakly alkaline conditions, however, the C^1-acyl glucuronide can hydrolyze in the urine to the parent substance (aglycone) or undergo acyl migration to an acceptor macromolecule. The pH-catalyzed migration of the acyl group from the drug C^1-O-acyl glucuronide to a protein or other cellular constituent occurs with the formation of a covalent bond to the protein (59). The acylated protein becomes a

"hapten" and could stimulate an immune response against the drug, resulting in the expression of an hypersensitivity reaction or other forms of immunotoxicity. A high incidence of anaphylactic reactions have been reported for several nonsteroidal anti-inflammatory drugs (NSAIDs; benoxaprofen, zomepirac, indoprofen, alclofenac, ticrynafen, and ibufenac) that have been removed from the market. All of these NSAIDs are metabolized by humans to acyl glucuronides. Similar reactions have been reported for other NSAIDs, including tolmetin, sulindac, ibuprofen, ketoprofen, and acetylsalicylic acid. The frequency of the immunotoxic response may be related to the stability of the acyl glucuronide, the chemical rate kinetics for the migration of the acyl group, and the concentration and stability/half-life of the antigenic protein. When the acyl glucuronide is the primary metabolite, in patients with decreased renal function (i.e., elderly individuals), or when probenecid is coadministered, renal cycling of the unconjugated (aglycone) parent drug or metabolite is likely to occur, resulting in the plasma accumulation of the aglycone. The reduced elimination of the acyl glucuronide increases its hydrolysis back to the aglycone or the migration of the C^1-O-acyl group to an acceptor macromolecule.

Bioactivation and Toxic Glucuronides

Generally, glucuronides are biologically and chemically less reactive than their parent molecules and are readily eliminated without interaction with intracellular substances. Some glucuronide conjugates, however, are more active than the parent drug (60). Morphine, for example, forms the 3-O- and 6-O-glucuronides in the intestine and in the liver. The 3-O-glucuronide is the primary glucuronide metabolite of morphine, with a blood concentration 20-fold that of morphine. Pharmacologically, it is an opiate antagonist. On the other hand, 6-O-glucuronide, with a blood concentration twice that of morphine, is a more potent μ-receptor agonist and, whether administered orally or parentally, is 650-fold more analgesic than morphine in humans. Thus, the analgesic effects of morphine are the result of a complex interaction of the drug and its two metabolites with the opiate receptor. Apparently, the 6-O-glucuronide can pass into the brain via an anion-transport system.

Glucuronidation also is capable of promoting cellular injury (e.g., hepatotoxicity and carcinogenesis) by facilitating the formation of reactive electrophilic (electron-deficient) intermediates and their transport into target tissues (37). The induction of bladder carcinogenesis by aromatic amines may result from the glucuronidation of N-hydroxylarylamine. These O-glucuronides become concentrated in the urine, where they are readily hydrolyzed by the acid pH of the urine back to the

N-hydroxylarylamines. Elimination of water under these conditions leads to the formation of electrophilic arylnitrenium species. This reactive species can bind covalently with endogenous cellular constituents (e.g., nucleic acids and proteins), initiating carcinogenesis.

Sulfation and glucuronidation occur side by side, often competing for the same substrate (most commonly phenols, i.e., acetaminophen). The balance between sulfation and glucuronidation is influenced by such factors as species, dose, availability of cosubstrates, and inhibition and induction of the respective transferases.

Sulfate Conjugation

Sulfate conjugation is an important reaction in the biotransformation of steroid hormones, catecholamine neurotransmitters, thyroxine, bile acids, phenolic drugs, and other xenobiotics (56). The major physiologic consequence of sulfate conjugation of a drug or xenobiotic is its increased aqueous solubility and excretion, because the pK_a of the sulfonate groups is approximately one to two. The sulfate conjugates are almost totally ionized in physiologic solutions and possess a smaller volume of distribution than unconjugated steroids and drugs. In certain instances, however, sulfate conjugation can result in bioactivation to reactive electrophiles or therapeutically active conjugates (e.g., minoxidil sulfate). The cytosolic sulfotransferases generally associated with the conjugation of phenolic steroids, neurotransmitters, and xenobiotics. The membrane-bound sulfotransferases are localized in the Golgi apparatus of most cells and are responsible for the sulfation of glycosaminoglycans, glycoproteins, and the tyrosinyl group of peptides and protein but generally are not associated with xenobiotic metabolism.

Mechanism of Sulfate Conjugation

A xenobiotic is sulfated by transfer of an active sulfate from 3′-phosphoadenosine-5′-phosphosulfate (PAPS) to the acceptor molecule, a cytosolic reaction catalyzed by a multigene sulfotransferases (Fig. 10.23); PAPS is formed enzymatically from adenosine triphosphate (ATP) and inorganic sulfate. Sulfate conjugation is a reaction principally of phenols and, to a lesser extent, of alcohols to form highly ionic and polar sulfates (R-O-SO_2H). The availability of PAPS and its precursor inorganic sulfate determines the reaction rate. The total pool of sulfate usually is limited and can be readily exhausted. With increasing doses of a drug, conjugation with sulfate becomes a less predominant pathway. At high doses with a competing substrate (i.e., acetaminophen), glucuronidation usually predominates over that of sulfation, which prevails at low doses. Other precursors for sulfate include L-methionine and L-cysteine. When PAPS, inorganic sulfate, or the sulfur amino acids are low or depleted, or when a substrate for sulfation is given in high doses, competing reactions with glucuronidation can take over. Additionally, O-methylation is a competing reaction for catecholamine.

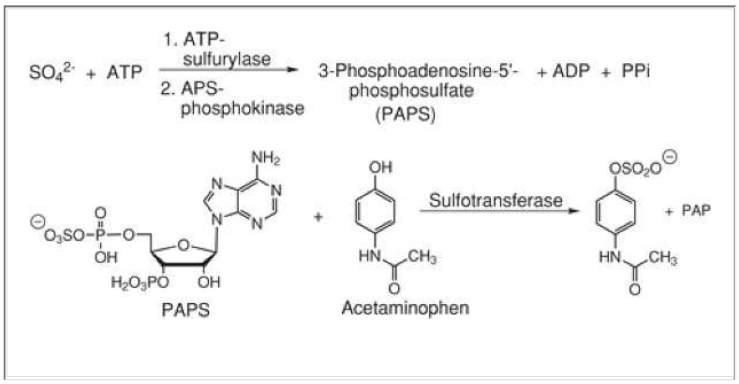

Fig. 10.23. Sulfation pathways.

Sulfotransferase Family

In humans, sulfotransferases are divided into two families, SULT1 and SULT2 (61). The isoforms SULT1A1, SULT1A2, and SULT1A3 catalyze the sulfation of many phenolic drugs, catecholamine, hormones, aromatic amines, and other xenobiotics (62). The SULT1A1/2 (formerly known as phenol sulfotransferase thermally stable) preferentially sulfates small planar phenols in the micromolar concentration range, estradiol and synthetic estrogens, phytoestrogens, acetaminophen, the N-oxide of minoxidil, and N-hydroxyaromatic and heterocylic amines; SULT1A3 (formerly known as phenol sulfotransferase thermally labile) selectively sulfates the catecholamines dopamine, norepinephrine, and epinephrine as well as the N-oxide of minoxidil, thyroid hormones, but not estrogenic steroids and other hydroxy steroids; SULT1B1 catalyzes the sulfation of the thyroid hormones; SULT1C1 is involved with the bioactivation of procarcinogens via sulfation; SULT1E1 (formerly known as estrogen sulfotransferase) preferentially sulfates estradiol in the nanomolar range; SULT2A1 (formerly known as dehydroepiandrosterone [DHEA] sulfotransferase) conjugates DHEA, estradiol (micromolar range), the synthetic estrogens, and other estrogen metabolites; and SULT2B1 (formerly known as hydroxysteroid sulfotransferase) sulfates DHEA and pregnenolone.

Sulfate conjugation appears to be an important reaction in the transport and metabolism of steroids. Sulfation decreases the biological activity of the steroid, because the steroid sulfates are not capable of binding to their receptors. It provides for the transport of an inactive form of the steroid to its target tissue, where the active steroid is regenerated by sulfatases at the target tissue.

Sulfotransferase Distribution

The SULT1A families are abundantly expressed in the liver, small intestine, brain, kidneys, and platelets (61). For example, phenol is sulfated by a sulfotransferase in the liver, kidneys, and intestines, whereas steroids are sulfated only in the liver. The broad diversity of compounds sulfated in human tissues results, in part, from the multi-isoforms of the cytosolic sulfotransferases and their overlapping substrate specificities. Sulfate conjugates are almost totally ionized and, therefore, are excreted mostly in the urine, but biliary elimination is common for steroids. On hydrolysis of biliary sulfate conjugates in the intestine by sulfatases, the parent drug (or xenobiotic) or its metabolites may be reabsorbed into the portal circulation for eventual elimination in the urine as a sulfate conjugate (enterohepatic cycling). The rate of sulfation appears to be age dependent, decreasing with age. An important site of sulfation, especially after oral administration, is the intestine. The result is a presystemic first-pass effect: decreasing drug bioavailability of several drugs for which the primary route of conjugation is sulfation. Drugs such as isoproterenol, albuterol, steroid hormones, α-methyldopa, acetaminophen, and fenoldopam are affected. Competition for intestinal sulfation between coadministered substrates may influence their bioavailability with either an enhancement of or a decrease in therapeutic effects. An example would be coadministration of acetaminophen and the oral contraceptive ethinyl estradiol.

Bioactivation and Toxicity

As with glucuronidation, sulfation is a detoxication reaction, although sulfate conjugates have been reported to be pharmacologically active (e.g., minoxidil sulfate, dehydroepiandrosterone sulfate, and morphine 6-sulfate) or to be converted into unstable sulfate conjugates that form reactive intermediates implicated in carcinogenesis and tissue damage. Sulfation of an alcohol generates a good leaving group and can be an activation process for alcohols to produce a reactive electrophilic species (37). Like the N-glucuronides, however, N-sulfates are capable of promoting cytotoxicity by facilitating the formation of reactive electrophilic intermediates. Sulfation of N-oxygenated aromatic amines is an activation process for some arylamines that can eliminate the sulfate to an electrophilic species capable of reacting with proteins or DNA (e.g., 2-acetylaminofluorene). The N-sulfation of arylamines to arylsulfamic acids ($R\text{-}NHSO_3H$) is a minor pathway.

Stereoselectivity

The SULT1A3 displays stereoselectivity in the sulfation of chiral phenolic phenethanolamines. This isoform may be responsible, in part, for the enantiomer-specific metabolism observed for the β-adrenergic agonists. For example, the (+)-enantiomers of terbutaline and isoproterenol and the (–)-enantiomer of albuterol are selectively sulfated.

Conjugation with Amino Acids

Conjugation with amino acids is an important metabolic route in the metabolism of xenobiotic carboxylic acids before elimination (56). Glycine, the most common amino acid, forms water-soluble ionic conjugates with aromatic, arylaliphatic, and heterocyclic carboxylic acids. These amino acid conjugates usually are less toxic than their precursor acids and are excreted readily into the urine and bile. These reactions involve the formation of an amide or peptide bond between the xenobiotic carboxylic acid and the amino group of an amino acid, usually glycine. The xenobiotic must first be activated to its CoA thioester before reacting with the amino group (Fig. 10.24). The formation of the xenobiotic acyl CoA thioester is of critical importance in intermediary metabolism of lipids as well as intermediate- and long-chain fatty acids.

The major metabolic biotransformations for xenobiotic carboxylic acids include conjugation with either glucuronic acid or glycine. The metabolic fate of these carboxylic acids depends on the size and type of substituents adjacent to the carboxyl group. Most unbranched aliphatic acids are completely oxidized and do not usually form conjugates, although branched aliphatic and arylaliphatic acids are resistant to β-oxidation and form glycine or glucuronide conjugates. Interestingly, substitution of the α-carbon

favors glucuronidation rather than glycine conjugation. Benzoic and heterocyclic aromatic acids are principally conjugated with glycine. Glycine conjugation is preferred for xenobiotic carboxylic acids at low doses, and glucuronidation is preferred at high doses with broad substrate selectivity. In humans and some species of monkeys, glutamine forms a conjugate with phenylacetic acids and related arylacetic

acids. Bile acids form conjugates with glycine and taurine by the action of enzymes in the microsomal fraction rather than in the mitochondria.

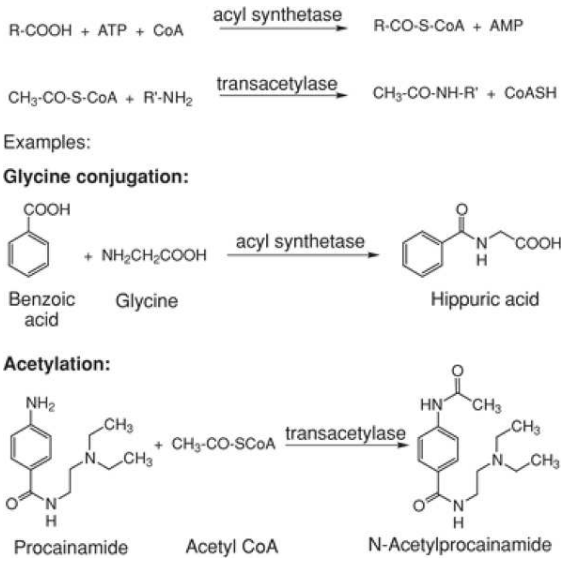

Fig. 10.24. Amino acid conjugation pathways of carboxylic acids with glycine and acetylation pathways.

In contrast to the enhanced reactivity and toxicity of the various glucuronide, sulfate, acetyl, and glutathione conjugates, amino acid conjugates have not proven to be toxic. It has been proposed that amino acid conjugation is a detoxication pathway for reactive acyl CoA thioesters.

Conjugation with CoA

Several carboxylic acid–containing drugs (e.g., zomiperac and benzoxaprofen) have been implicated in rare but serious adverse reactions. These carboxylic acids were withdrawn in the late 1980s from the market because of unpredictable allergic reactions that may have been caused by carboxylic acid–protein adducts formed by reaction of their reactive acyl glucuronide or acyl CoA thioesters with endogenous proteins. The carboxylic acids can be bioactivated via two distinct pathways: UGT-catalyzed conjugation with glucuronic acid to acyl glucuronides, or acyl CoA synthetase–catalyzed formation of acyl CoA thioesters. The reactive CoA thioester intermediates of carboxylic acids are electrophilic and, therefore, can contribute to the acylation of target proteins. The acyl CoA thioester serves as an obligatory intermediate in the formation of glycine and carnitine ester. Therefore, their appearance in metabolism studies and urine is of significance, because they serve as biomarkers for the formation acyl CoA thioesters, which may provide the link between protein-reactive acyl CoA thioesters and the rare and unpredictable idiosyncratic drug reactions in humans.

A nontoxic reaction involving acyl CoA thioesters includes chiral inversions of the 2-arylpropionic acids ("profens"), a major group of NSAIDs that exist in two enantiomeric forms (59). The anti-inflammatory activity (inhibition of cyclooxygenase) for the NSAIDs resides with the S-(+)-enantiomer. The intriguing aspect for the metabolism of the NSAID is their unidirectional chiral inversion from the R-(–)- to the S-(+)-enantiomer (Fig. 10.25). The NSAID acyl CoA thioester is the critical intermediate for this chiral inversion of the 2-arylpropionic acids, and the formation of the thioester is stereospecific for the pharmacologically inactive R-enantiomer (61). Racemic ibuprofen and related anti-inflammatory 2-arylpropionic acids (e.g., benoxaprofen, carprofen, cicliprofen, clidanac, fenoprofen, indoprofen, ketoprofen, loxoprofen, and naproxen) undergo in vivo metabolic inversion to the more active S-enantiomer via the formation, epimerization, and hydrolysis of their respective acyl CoA thioesters (63). The unidirectional *R*- to *S*-inversion of ibuprofen is attributed to the stereoselective thioester formation of *R*-Ibuprofen CoA, not to the stereoselectivity of either the epimerization or hydrolysis steps (64). *S*-(+)-Ibuprofen does not form its CoA thioester in vivo. Because the formation of 2-arylpropionyl CoA thioester is analogous to the activation and metabolism of medium and long-chain fatty acids, it seems possible that conditions either elevating (e.g., diabetes or fasting) or depleting CoA may alter CoA thioester formation of the 2-arylpropionic acids and their in vivo metabolic inversion. Amino acid conjugation (i.e., CoA activation) is more sensitive to steric hindrance than is glucuronidation (e.g., arylacetic acids).

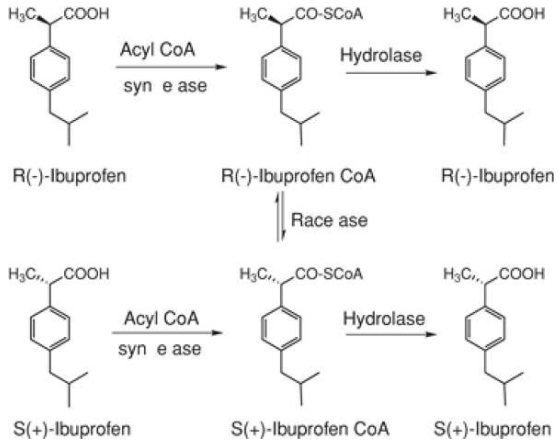

Fig. 10.25. Coenzyme A (CoA) conjugation pathway: Stereospecific inversion of R(–)- to S(+)-ibuprofen.

Acetylation

Acetylation is principally a reaction of amino groups involving the transfer of acetyl CoA to primary aliphatic and aromatic amines, amino acids, hydrazines, or sulfonamide groups (56). The liver is the primary site of acetylation, although extrahepatic sites have been identified. Sulfonamides, being difunctional, can form either N^1 or N^4 acetyl derivatives, and in some instances, the diacetylated derivative has been identified. Secondary amines are not acetylated. Acetylation may produce conjugates that retain the pharmacological activity of the parent drug (e.g., N-acetylprocainamide) (Fig. 10.24).

The existence of genetic polymorphism in the rate of acetylation has important consequences for drug therapy and tumorigenicity of xenobiotics. Acetylation polymorphism has been associated with differences in human drug toxicity between the two acetylator phenotypes, slow and fast acetylators. Slow acetylators are more prone to drug-induced toxicities and accumulate higher blood concentrations of the unacetylated drug (e.g., hydralazine and procainamide-induced lupus erythematous, isoniazid-induced peripheral nerve damage, and sulfasalazine-induced hematologic disorders) than fast acetylators do. Fast acetylators eliminate the drug more rapidly by

conversion to its relatively nontoxic N-acetyl metabolite. For some drug substances, however, fast acetylators may pose a greater risk of liver toxicity than slow acetylators, because fast acetylators produce toxic metabolites more rapidly (e.g., isoniazid forms the hepatotoxic monoacetylhydrazine metabolite). Thus, differences in acetylator phenotype can influence adverse drug reactions.

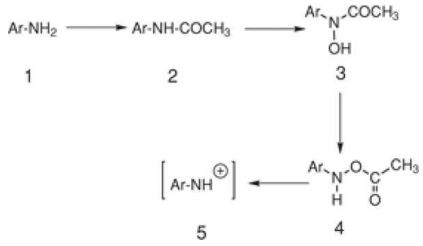

Fig. 10.26. Bioactivation of acetylated arylamines.

The possibility arises that genetic differences in acetylating capacity may confer differences in susceptibility to chemical carcinogenicity from arylamines. The tumorigenic activity of arylamines (1 in Fig. 10.26) may be the result of a complex series of sequential metabolic reactions commencing with N-acetylation (2 in Fig. 10.26), subsequent oxidation to arylhydroxamic acids (3 in Fig. 10.26), and metabolic transformation to acetoxyarylamines by N, O-acyltransferase (4 in Fig. 10.26). The acetoxyarylamine can eliminate the acetoxy group to form the reactive arylnitrenium ion (5 in Fig. 10.26), which is capable of covalently binding to nucleic acids and proteins, thus increasing the risk for development of bladder and liver tumors (65). The rapid acetylator phenotype is expected to form the acetoxyarylamine metabolite at a greater rate than the slow acetylator and, thereby, to present a greater risk for development of tumors compared with the slow acetylator.

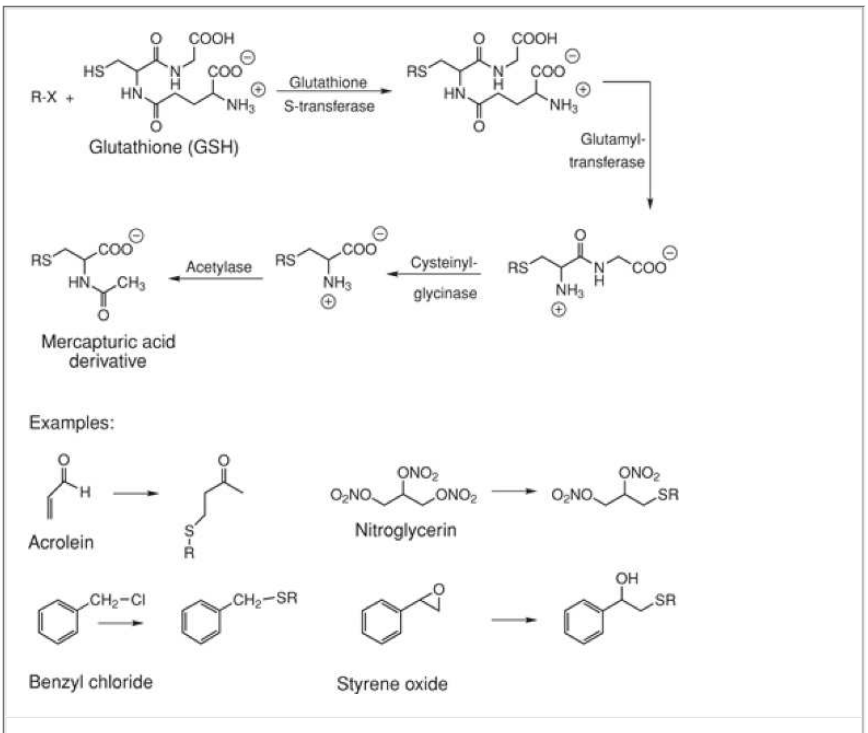

Fig. 10.27. Glutathione and mercapturic acid conjugation pathways.

Glutathione Conjugation and Mercapturic Acid Synthesis

Mercapturic acids are S-derivatives of N-acetylcysteine synthesized from glutathione (GSH) (53,54). It is generally accepted that most compounds metabolized to mercapturic acids first undergo conjugation with glutathione, catalyzed by the enzyme glutathione S-transferase (GST), a multigene isoenzyme family that is abundant in the soluble supernatant liver fractions. In humans, GSTs are divided into two isoforms, GSTM1 and GSTT1. The principal drug substrates for GSTM1 are the nitrosourea and mustard-type anticancer drugs. The GSTT1 isoform metabolizes small organic molecules, such as solvents, halocarbons, and electrophilic compounds (e.g., αβ-unsaturated carbonyl compounds). The reaction is depicted in Figure 10.27.

The enzyme GST apparently increases the ionization of the thiol group of GSH, increasing its nucleophilicity toward electrophiles and conjugating with these potentially harmful electrophiles, thereby protecting other vital nucleophilic centers in the cell, such as nucleic acids and proteins. Glutathione also is capable of reacting nonenzymatically with nucleophilic sites on neighboring macromolecules. Once conjugated with GSH, the electrophiles usually are excreted in the bile and urine.

A range of functional groups yields thioether conjugates of GSH as well as products other than thioethers (Fig. 10.27). The nucleophilic attack by GSH occurs on electrophilic carbons with leaving groups (e.g., halogen [alkyl, alkenyl, aryl, or aralkyl halides], sulfate [alkylmethanesulfonates], and nitro [alkyl nitrates] groups), ring opening of small ring ethers (epoxides and β-lactones, e.g., β-propiolactone), and the Michael-type addition to the activated β-carbon of an α,β-unsaturated carbonyl compound (e.g., acrolein). Organic nitrate esters (e.g., the coronary vasodilator nitroglycerin) undergo a dismutation reaction that results in the oxidation of GSH to GSSG (through formation of the labile S-nitrate conjugation product) and reduction of the nitrate ester to an alcohol and inorganic nitrite. The lack of substrate specificity gives argument to the fact that glutathione transferase has undergone adaptive changes to accommodate the variety of xenobiotics to which it is exposed. Usually, the conjugation of an electrophilic compound with GSH is a reaction of detoxication, but some carcinogens have been activated through conjugation with GSH (29,30,31).

The enzymatic conjugation of GSH with epoxides provides a mechanism for protecting the liver from injury caused by certain bioactivated intermediates (see the subsequent Metabolic Bioactivation section). Not all epoxides are substrates for this enzyme, but the more chemically reactive epoxides appear to be better substrates. Important among the epoxides that are substrates for this enzyme are those produced from halobenzenes and PAHs through the action of CYP450 monooxygenase. Epoxide formation exemplifies bioactivation, because the epoxides are reactive and potentially toxic, whereas their GSH conjugates are inactive. Conjugation of GSH with the epoxides of aryl hydrocarbons eventually results in the formation of hydroxymercapturic acids (premercapturic acids), which undergo acid-catalyzed dehydration to the mercapturic acids. The halobenzenes usually are conjugated in the para position.

Monohalogenated, gem-dihalogenated, and vicinal dihalogenated alkanes undergo glutathione transferase–catalyzed conjugation reactions to produce S-substituted glutathione derivatives that are metabolically transformed into the more stable and less toxic mercapturic acids. This common route of metabolism occurs through nucleophilic displacement of a halide ion by the thiolate anion of glutathione (see the discussion on glutathione conjugation). The mutagenicity of the 1,2-dihaloethanes (e.g., the pesticide and fumigant ethylene dibromide) has been attributed to GSH displacing bromide with the formation of the S-(2-haloethyl) glutathione, which subsequently rearranges to a reactive episulfonium ion electrophile that, in turn, alkylates DNA. Many of the halogenated hydrocarbons exhibiting nephrotoxicity undergo the formation of similar S-substituted cysteine derivatives.

The mercapturic acid pathway appears to have evolved as a protective mechanism against xenobiotic-induced hepatotoxicity or

carcinogenicity, serving to detoxify a large number of noxious substances that we inhale or ingest or that are produced daily in the human body. A correlation exists between the hepatotoxicity of acetaminophen and levels of GSH in the liver. The probable mechanism of toxicity that has emerged from animal studies is that acetaminophen is CYP1A2- and CYP2E1-oxidized to the N-acetyl-*p*-benzoquinonimine intermediate that conjugates with and depletes hepatic GSH levels (Fig. 10.28). This action allows the benzoquinonimine to bind covalently to tissue macromolecules. The mercapturic acid derivative of acetaminophen represents approximately 2% of the administered dose of acetaminophen. Thus, the possibility exists that those toxic metabolites that usually are detoxified by conjugating with GSH exhibit their hepatotoxicity (or, perhaps, carcinogenicity) because the liver has been depleted of GSH and is incapable of inactivating them. Pretreatment of animals with phenobarbital often hastens the depletion of GSH by increasing the formation of epoxides or other reactive intermediates.

Methylation

Methylation is a common biochemical reaction but appears to be of greater significance in the metabolism of

endogenous compounds than for drugs and other foreign compounds (56). Methylation differs from other conjugation processes in that the O-methyl metabolites formed may, in some cases, have as great or greater pharmacological activity and lipophilicity than the parent molecule (e.g., the conversion of norepinephrine to epinephrine). Methionine is involved in the methylation of endogenous and exogenous substrates, because it transfers its methyl group via the activated intermediate S-adenosylmethionine to the substrate under the influence of methyl transferases (Fig. 10.29). Methylation results principally in the formation of O-methylated, N-methylated, and S-methylated products.

O-Methylation

The process of O-methylation is catalyzed by the magnesium-dependent enzyme catechol-O-methyltransferase (COMT) transferring a methyl group to the meta- or, less frequently, the paraphenolic-OH (regioselectivity) of catecholamines (e.g., norepinephrine) as well as by their deaminated metabolites. It does not methylate monohydric or other dihydric phenols. The meta:para product ratio depends greatly on the type of substituent attached to the catechol ring. Substrates specific for COMT include the catecholamines norepinephrine, epinephrine, and dopamine; the catechol amino acids L-DOPA and α-methyl-DOPA; and 2- and 4-hydroxyestradiol metabolites of estradiol. The enzyme is thought to function in the biological inactivation of the adrenergic neurotransmitter norepinephrine as well as other endogenous and exogenous catechol-like substances. It is found in liver, kidneys, nervous tissue, and other tissues.

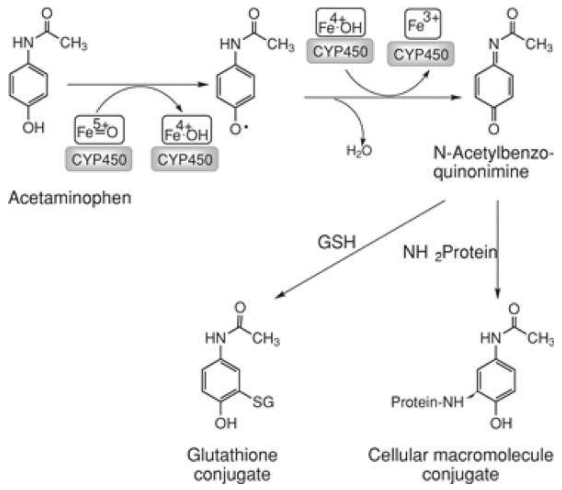

Fig. 10.28. Proposed mechanism for the CYP450-catalyzed oxidation of acetaminophen to its N-acetyl-*p*-benzoquinoneimine intermediate, which can further react with either glutathione (GSH) or cellular macromolecules (NH_2-protein).

Hydroxyindole-O-methyltransferase, which is O-methylates N-acetylserotonin, serotonin, and other hydroxyindoles, is found in the pineal gland and is involved in the formation of melatonin. This enzyme differs from COMT in that it does not methylate catecholamines and has no requirement for magnesium iron.

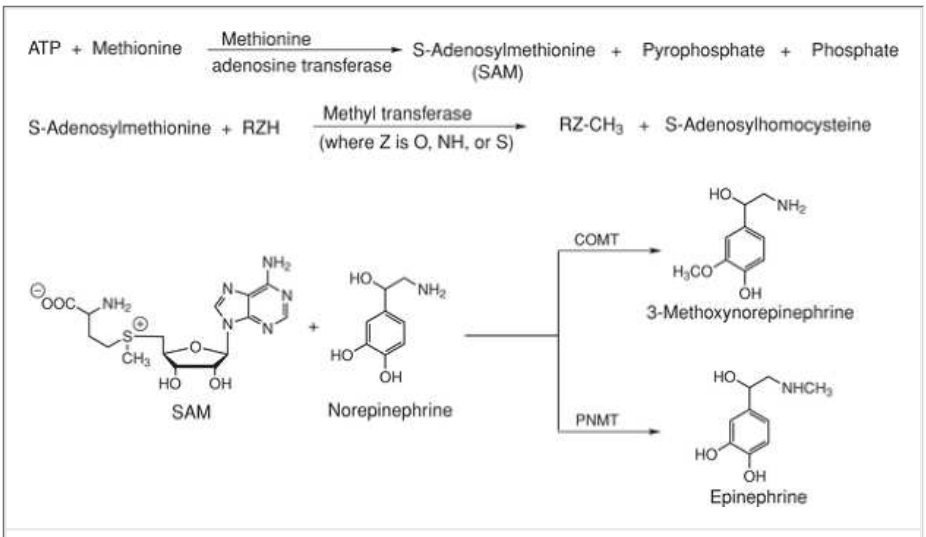

Fig. 10.29. Methylation pathways.

N-Methylation

The N-methylation of various amines is among several conjugate pathways for metabolizing amines. Specific N-methyltransferases catalyze the transfer of active methyl groups from S-adenosylmethionine to the acceptor substance. Phenylethanolamine-N-methyltransferase methylates a number of endogenous and exogenous phenylethanolamines (e.g., normetanephrine, norepinephrine, and norephedrine) but does not methylate phenylethylamines. Histamine-N-methyl transferase specifically methylates histamine, producing the inactive metabolite N^1-methylhistamine. Amine-N-methyltransferase will N-methylate a variety of primary and secondary amines from a number of sources, including endogenous biogenic amines (serotonin, tryptamine, tyramine, and dopamine) and drugs (desmethylimipramine, amphetamine, and normorphine). Amine-N-methyl transferases seem to have a role in recycling N-demethylated drugs.

Thiol Methylation

Thiols generally are considered to be toxic, and the role of thiol S-methyl transferases is a nonoxidative detoxification pathway of these compounds (see the discussion of flavin-containing monooxygenases). The S-methylation of sulfhydryl compounds also involves a microsomal enzyme requiring S-adenosylmethionine. Although a wide range of exogenous sulfhydryl compounds are S-methylated by this microsomal enzyme, none of the endogenous sulfhydryl compounds (e.g., cysteine and GSH) can function as substrates. Clearly, S-methylation represents a detoxication step for thiols. Dialkyldithiocarbamates (e.g., disulfiram) and the

antithyroid drugs (e.g., 6-propyl-2-thiouracil), mercaptans, and hydrogen sulfide (from thioglycosides as natural constituents of foods, mineral sulfides in water, fermented beverages, and bacterial digestion) are S-methylated. Other drugs undergoing S-methylation include captopril, thiopurine, penicillamine, and 6-mercaptopurine.

Conjugation of Cyanide

The toxicity of hydrogen cyanide is the result of its ionization to cyanide ion in biological tissues. It is a powerful metabolic inhibitor that arrests cellular respiration by inactivating cytochrome enzymes that are fundamental to the respiratory process as well as combining with hemoglobin to form cyanomethemoglobin, which is incapable of transporting oxygen to tissues. With the wide prevalence of cyanoglycosides in plant materials, the ability to detoxify cyanide is a vital function of the liver, erythrocytes, and other tissues. Rhodanase, a mitochondrial enzyme in liver and other tissues, catalyzes the formation of thiocyanate from cyanide rapidly in the presence of thiosulfate and colloidal sulfur, but cysteine and GSH are poor sulfur donors. The detoxification of cyanide depends on the availability of a physiologic pool of thiosulfate, the origin of which is not known. A possible source for thiosulfate is the transamination of cysteine to β-mercaptopyruvate and transfer of the mercapto group by a sulfur transferase to sulfite-producing thiosulfate. Depletion of this pool increases cyanide toxicity. In the presence of excess cyanide, however, minor pathways for cyanide metabolism may occur, including oxidation to cyanate (NCO^-), reaction with cobalamin (vitamin B_{12}) to form cyanocobalamin, and the formation of 2-iminothiazolidine-4-carboxylic acid from the nonenzymatic reaction between cysteine and cyanide (66).

$$S_2O_3^{2-} + CN^- \longrightarrow CNS^- + SO_3^{2-}$$

Elimination Pathways

Most xenobiotics are lipid-soluble and are altered chemically by the metabolizing enzymes, usually into less toxic and more water-soluble substances, before being excreted into the urine (or, in some cases, bile). The formation of conjugates with sulfate, amino acids, and glucuronic acid is particularly effective in increasing the polarity of drug molecules. The principal route of excretion of drugs and their metabolites is in the urine. If drugs and other compounds foreign to the body are not metabolized in this manner, substances with a high lipid–water partition coefficient could be reabsorbed readily from the urine through the renal tubular membranes and into the plasma. Therefore, such substances would continue to be recirculated, and their pharmacological or toxic effects would be prolonged. Very polar or highly ionized drug molecules often are excreted in the urine unchanged.

Urine

Tubular reabsorption is greatly reduced by conversion of a drug into a more polar substance with a lower partition coefficient. In general, the more resistance a drug is to the metabolizing enzymes, the greater the therapeutic action and the smaller the dose needed to achieve a particular therapeutic goal.

Urine is not the only route for excreting drugs and their metabolites from the animal body. Other routes include bile, saliva, lungs, sweat, and milk. The bile has been recognized as a major route of excretion for many endogenous and exogenous compounds.

Enterohepatic Cycling of Drugs

The liver is the principal organ for the metabolism and eventual elimination of xenobiotics from the human body in either the urine or the bile. When eliminated in the bile, steroid hormones, bile acids, drugs, and their respective conjugated metabolites are available for reabsorption from the duodenal–intestinal tract into the portal circulation, undergoing the process of enterohepatic cycling (EHC) (67). Nearly all drugs are excreted in the bile, but only a few are concentrated in the bile. For example, the bile salts are so efficiently concentrated in the bile and reabsorbed from the gastrointestinal tract that the entire body pool recycles several times per day. Therefore, EHC is responsible for the conservation of bile acids, steroid hormones, thyroid hormones, and other endogenous substances. In humans, compounds excreted into the bile usually have a molecular weight greater than 500Da, whereas with rats, the critical molecular weight is 325Da. Consequently, biliary excretion is more common in rats than in humans. Compounds with a molecular weight between 300 and 500Da are excreted in both urine and bile. Some compounds would not be expected to be excreted in the bile because of a molecular weight of less than 300Da and a relatively nonpolar structure. Compounds excreted into bile usually are strongly polar substances that may be charged (anionic; e.g., dyes) or uncharged (e.g., cardiac glycosides and steroid hormones). Biotransformation of this type of compound by means of Phase 1 and Phase 2 reactions would produce a conjugated metabolite, which usually is anionic, more polar, and has a molecular weight greater than that of the parent compound. They most often are present as their glucuronide conjugates, because glucuronidation adds 176Da to the molecular weight of the parent compound. Unchanged drug in the bile is excreted with the feces, metabolized by the bacterial flora in the intestinal tract, or reabsorbed into the portal circulation.

Not unexpectedly, the bacterial intestinal flora is directly involved in EHC and the recycling of drugs through the portal circulation (see the discussion of extrahepatic metabolism). A conjugated drug and metabolites excreted via the bile may be hydrolyzed by enzymes of the bacterial flora, releasing the parent drug or its Phase I metabolite for reabsorption into the portal

circulation (68). Among the numerous compounds metabolized in the enterohepatic circulation are the estrogenic and progestational steroids, digitoxin, indomethacin, diazepam, pentaerythritol tetranitrate, mercurials, arsenicals, and morphine. The oral ingestion of xenobiotics inhibiting the gut flora (i.e., nonabsorbable antibiotics) can effect the pharmacokinetics of the initial drug.

The impact of EHC on the pharmacokinetics and pharmacodynamics of a drug depends on the importance of biliary excretion of the drug relative to renal clearance and on the efficiency of gastrointestinal absorption. The EHC becomes dominant when biliary excretion is the major clearance mechanism for the drug. Because the majority of the bile is stored in the gallbladder and released on the ingestion of food, intermittent spikes in the plasma drug concentration is observed following reentry of the drug from the bile via EHC. From a pharmacodynamic point of view, the net effect of EHC is to increase the duration of a drug in the body and to prolong its pharmacological action.

Chronic treatment with the enzyme inducer phenobarbital enhances the biliary excretion of drug molecules and their metabolites by increasing liver size, bile flow, and more efficient transport into the bile. This behavior is not shared by all inducers of the CYP450 monooxygenases. The route of administration also may influence excretion pathways. Direct administration into the portal circulation might be expected to result in more biliary excretion than could be expected via the systemic route.

Drug Metabolism and Age

Approximately 30% of the population is older than 65 years of age and is responsible for more than 50% of the national drug expenditures. People older than 65 years represent a significant portion of the population; they are the most medicated and account for more than one-third of all prescription drugs dispensed. The average elderly patient in a health care facility could receive as many as 10 medications daily, which results in the potential for a greater incidence of adverse drug reactions. The widespread use of medications in the elderly will increase the potential for an increased incidence of drug-related interactions. Not unexpectedly, these interactions will be related to changes in drug metabolism and clearance from the body (Table 10.13). The interpretation of the age-related alteration in drug response must consider the contributions of absorption, distribution, metabolism, and excretion (69). Drug therapy in the elderly is expected to become one of the more significant problems for clinical medicine. It has been well documented that the metabolism of many drugs and their elimination is impaired in the elderly.

Metabolism in the Elderly

The decline in drug metabolism because of old age is associated with physiological changes that have pharmacokinetic implications affecting the steady-state plasma concentrations and renal clearance for the parent drug and its metabolites (70,71). Those changes relevant to the bioavailability of drugs in the elderly are decreases in hepatic blood flow, glomerular filtration rate, hepatic microsomal enzyme activity, plasma protein binding, and body mass. Because the rate of a drug's elimination from the blood through hepatic metabolism is determined by hepatic blood flow, protein binding, and intrinsic clearance, a reduction in hepatic blood flow can lead to an increase in drug bioavailability and decreased clearance, with the symptoms of drug overdose and toxicity as the outcome. Drugs for which elimination is dependent on hepatic blood flow have a high extraction ratio and undergo extensive first-pass metabolism when administered orally. Available evidence suggests that age is associated with a reduction in first-pass metabolism of some, but certainly not all, drugs. Those orally administered drugs exhibiting a reduction in first-pass metabolism in the elderly include the dihydropyridine calcium antagonists, chlormethiazole, diazepam, lorazepam, chlordiazepoxide, alprazolam, propranolol, verapamil, labetalol, theophylline, morphine, amitriptyline, and nortriptyline. The bioavailability of drugs with low extraction ratios depends on the percentage of drug–protein binding and not on first-pass hepatic metabolism. Inasmuch as drug binding to plasma proteins is an important factor in the rate of

drug metabolism, it appears not to be a significant factor in the elderly.

Table 10.13. Effect of Age on the Clearance of Some Drugs

No Change	Decrease
Acetaminophen*	Alprazolam
Aspirin	Amitriptylene
Diclofenac	Carbenoxolone
Digitoxin	Chlordiazepoxide
Diphenhydramine	Chlormethiazole
Ethanol	Clobazam
Flunitrazepam	Desmethyldiazepam
Heparin	Diazepam
Lormetazepam	Labetalol
Midazolam	Lidocaine
Nitrazepam	Lorazepam
Oxazepam	Morphine
Phenytoin*	Meperidine
Prazosin	Nifedipine and other dihydropyridines
Propylthiouracil	Norepinephrine
Temazepam	Nortriptyline
Thiopental*	Phenytoin
Tolbutamide*	
Warfarin	Piroxicam
	Propranolol
	Quinidine
	Quinine
	Theophylline

	Verapamil

***Drugs for which clearance is disputable but may be increased.**

Age-related changes in drug metabolism are a complicated interplay between the age-related physiological changes, genetics, environmental influences (diet and nutritional status, smoking, and enzyme induction), concomitant diseases states, and drug intake. In most studies, the elderly appear just as responsive to drug-metabolizing enzyme activity (Phase I and Phase II) as young individuals. All the common pathways of drug conjugation, including glucuronidation, sulfation, and glycine conjugation, are variably affected by aging. Given the number of factors that determine the rate of drug metabolism, it is not surprising that the effects of aging on drug elimination by metabolism has yielded variable results even for the same drug. Therefore, the bioavailability of a drug in the elderly and the potential for drug toxicity is largely dependant on its extraction ratio and mode of administration. The fact that drug elimination may be altered in old age suggests that initial doses of metabolized drugs should be reduced in older patients and then modified according to the clinical response (70,71). A decrease in hepatic drug metabolism coupled with age-related alterations in clearance, volume of distribution, and receptor sensitivity can lead to prolonged plasma half-life and increased drug toxicity (Table 10.13).

Drug Interactions

Although drug–drug interactions constitute only a small proportion of adverse drug reactions in the elderly, they are important, because they often are predictable and, therefore, avoidable or manageable. Their frequency is related to the age of the patient, the number of drugs prescribed, the number of physicians involved in the patient's care, and the presence of increasing frailty. The most important mechanisms for drug–drug interactions are the inhibition or induction of drug metabolism. Interactions involving a loss of action of one of the drugs are at least as frequent as those involving an increased effect. Although only approximately 10% of potential interactions result in clinically significant adverse events, death or serious clinical consequences are rare, but low-grade, clinical morbidity in the elderly may be much more common. Nonspecific complaints (e.g. confusion, lethargy, weakness, dizziness, incontinence, depression, and falling) should all prompt a closer look at the patient's drug list. A number of strategies can be adopted to decrease the risk of potential clinical problems. The number of drugs prescribed for each individual should be limited to as few as necessary. The use of drugs should be reviewed regularly, and unnecessary agents withdrawn if possible, with subsequent monitoring. Patients should be encouraged to engage in a “prescribing partnership” by alerting physicians, pharmacists, and other health care professionals to symptoms that occur when new drugs are introduced. Health care professionals should develop a strategy for monitoring their drug treatment looking for the drug–drug interactions that have been encountered.

Those CYP substrates reported to cause drug–drug interactions are shown in Tables 10.3 through 10.10 in bold italics.

Fetal Metabolism

The ability of the human fetus and placenta to metabolize xenobiotics is well established. A 1973 clinical study reported that women ingest an average of 10 drugs during pregnancy, not including anesthetics, intravenous fluids, vitamins, iron, nicotine, cosmetic products, artificial sweeteners, or exposure to environmental contaminants. The majority of these substances readily cross the placenta, thus exposing the fetus to a large number of xenobiotic agents. The knowledge regarding the effects of prenatal exposure to drugs, environmental pollutants (e.g., smoking), and other xenobiotics (e.g., ethanol) on the fetus has led to a decrease in the exposure to these substances during pregnancy. The human fetus is at special risk from these substances because of the presence of the CYP450 monooxygenase system, which is capable of metabolizing xenobiotics during the first part of gestation. Placentas of tobacco smokers have shown a significant increase in the rate of placental CYP450 monooxygenase activity (CYP1A subfamily). Concern for this type of enzyme activity is increasing, because this enzyme system is known to catalyze the formation of reactive metabolites capable of covalently binding to macromolecules producing permanent effects (e.g., teratogenic, hepatotoxic, or carcinogenic) in the fetus and newborn. A more disturbing fact is that the other conjugation enzymes (i.e., glucuronosyl transferases, epoxide hydrase, glutathione transferase, and sulfotransferase), which are important for the formation of Phase 2 conjugates of these reactive metabolites, are found in low to negligible levels, increasing the exposure of the fetus to these potentially toxic metabolites.

Fetal drug metabolism functions either as a protective mechanism against environmental xenobiotics to transform active molecules into inactive molecules or as a toxifying system when transforming innocuous substances into reactive molecules. The placenta is not a barrier protecting the fetus from xenobiotics; almost every drug present in the maternal circulation will cross the placenta and reach the fetus. For some drugs, however, the placental efflux transport protein, P-glycoprotein (P-gp; discussed later), functions as a maternofetal barrier, pumping drugs and P-gp substrates out of the fetal circulation back into the maternal circulation (72) and protecting the fetus from exposure to potentially harmful teratogenic xenobiotics/drugs and endogenous substances that have been absorbed through the placenta. The P-gp inhibitors should be carefully evaluated for their potential to increase fetal susceptibility to drug/chemical-induced teratogenesis. On the other hand, selective inhibition of P-gp could be used clinically to improve pharmacotherapy of the unborn child. Depending on the pharmacological activity of the parent substance or its metabolites, both fetal and adult maternal drug metabolism may be viewed as complimentary yet contradictory. Because metabolites generally are more water

soluble than the parent substance, drug metabolites, when formed in the fetus, may be trapped and accumulate on the fetal side of the placenta. Such accumulation can result in drug-induced toxicities or developmental defects. The difference between fetal and adult metabolism, however, can be used advantageously and constitutes the rational for transplacental therapy (e.g., the administration of betamethasone several days before delivery can increase the production of surfactant in the fetal lung and prevent respiratory distress syndrome in the neonate).

The activity of CYP3A isoenzymes in the human fetal liver is similar to that seen in adult liver microsomes. The fetal activity for CYP3A7 isoenzyme is unusual as most other fetal isoenzymes of CYP450 exhibit 5 to 40% of the adult isoenzymes. Fetal and neonatal drug-metabolizing enzyme activities may differ from those in the adult.

Neonatal Metabolism

From the day of birth, the neonate is exposed to drugs and other foreign compounds persisting from pregnancy as well as those transferred via breast milk. Fortunately, many of the drug-metabolizing enzymes operative in the neonate developed during the fetal period. The routine use of therapeutic agents during labor and delivery, as well as during pregnancy, is widespread, and consideration must be given to the fact that potentially harmful metabolites can be generated by the fetus and newborn. Consequently, the use of drugs capable of forming reactive metabolic intermediates should be avoided during pregnancy, delivery, and the neonatal period. The activity of Phase 1 and Phase 2 drug-metabolizing enzymes is high at birth but decreases to normal levels with increasing age. Evidence suggests increased activity of drug-metabolizing enzymes in liver microsomes of neonates resulting from treatment of the mother during the pregnancy with enzyme inducers (e.g., phenobarbital).

Genetic Polymorphism

The reality of drug therapy is that many drugs do not work in all patients. By current estimates, the percentage of patients who will react favorably to a specific drug ranges from 20 to 80%. Drugs have been developed and dosage regimens prescribed under the old paradigm that "one dose fits all," which largely ignores the fact that humans are genetically different, resulting in interindividual differences in drug metabolism and disposition (10). It is widely accepted that genetic factors have an important impact on the oxidative metabolism and pharmacokinetics of drugs. Genotype–phenotype correlation studies (pharmacogenetics) have shown that inherited mutations in CYP450 genes (alleles) result in distinct phenotypic subgroups. For example, mutations in the *CYP2D6* gene result in poor (PM), intermediate (or extensive [EM]), and ultrarapid (UM) metabolizers of CYP2D6 substrates (73) (Table 10.7). Each of these phenotypic subgroups experience different responses to drugs extensively metabolized by the CYP2D6 pathway, ranging from severe toxicity to complete lack of efficacy. Genetic studies confirm that "one dose does not fit all," leaving the question of why we would continue to develop and prescribe drugs under the old paradigm. As early as 1997, the U.S. Food and Drug Administration (FDA) recognized that identifying genetic polymorphisms might allow the safe dosing, marketing, and approval of drugs that would otherwise not be approved and advised pharmaceutical companies to incorporate the knowledge of genetic polymorphisms into drug development (see sidebar below). Importantly, pharmacogenomic testing (the study of heritable traits affecting patient response to drug treatment) can significantly increase the likelihood of developing drug regimens that benefit most patients without severe adverse events.

U.S. FDA Advisory on Genetic Polymorphism

"When a genetic polymorphism affects an important metabolic route of elimination, large dosing adjustments may be necessary to achieve the safe and effective use of the drug ... indeed in some cases understanding how to adjust the dose to avoid toxicity may allow the marketing of a drug that would have an unacceptable level of toxicity were its toxicity unpredictable and unpreventable."

—U.S. FDA

Guidance of Industry, Drug Metabolism/Drug Interaction Studies in the Drug Development Process: Studies in Vitro, April 1997.

Polymorphisms are expressed for a number of metabolizing enzymes, but the polymorphic CYP450 isoforms that are most important for drug metabolism include CYP2A6, CYP2C9, CYP2C19, and CYP2D6. These polymorphic isoforms give rise to phenotypic subgroups in the population differing in their ability to perform clinically significant biotransformation reactions with obvious clinical ramifications (74). Metabolic polymorphism may have several consequences; for example, when enzymes that metabolize drugs used either therapeutically or socially are deficient, adverse or toxic drug reactions may occur in these individuals. The discovery of genetic polymorphism resulted from the observation of increased frequency of adverse effects or no drug effects after normal doses of drugs to some patients (e.g., hyper–central nervous system response from the administration of the antihistamine doxylamine or no analgesic response with codeine). A polymorphism is a difference in DNA sequence found at 1% or greater in a population and expressed as an amino acid substitution in the protein sequence of an enzyme resulting in changes in its rate of activity (V_{max}) or affinity (K_m). Thus, mutant DNA sequences can lead to interindividual differences in drug metabolism. Furthermore, the polymorphisms do not occur with equivalent frequency in all racial or ethnic groups. Because of these differences, it is important to be aware of a person's race and ethnicity

when giving drugs that are metabolized differently by different populations (73,75). Because no other way exists to adequately clear these drugs from the body, PMs may be at greater risk for adverse drug reactions or toxic overdoses. The signs and symptoms of these overdoses are primarily extensions of the drug's common adverse effects or pharmacological effects (Table 10.14) (75). The level of adverse reactions or overdosage depends very much on the overall contribution of the mutant isoform to the drug's metabolism. Perhaps the most interesting explanation for the various mutant isoforms is that they evolved as protective mechanisms against alkaloids and other common substances in the food chain for the different ethnicities. Although much effort has gone into finding polymorphisms of C*YP3A4* and *CYP1A2* genes, none has yet to be discovered.

Table 10.14. Impact of Human CYP450 Polymorphisms on Drug Treatment in Poor Metabolizers

Polymorphic Enzyme	Decreased Clearance	Adverse Effects (overdosage)	Reduced Activation of Prodrug
CYP2C9	*S*-Warfarin	Bleeding	Losartan
	Phenytoin	Ataxia	

	Losartan		
	Tolbutamide	Hypoglycemia	
	NSAIDs	GI bleeding?	
CYP2C19	Omeprazole		Proguanil
	Diazepam	Sedation	
CYP2D6	TC antidepressants	Cardiotoxicity	Tramadol
	SSRIs	Serotonin syndrome	Codeine
	Anti-arrythmic drugs	Arrythmias	Ethylmorphine
	Perhexiline	Neuropathy	
	Haloperidol	Parkinsonism?	
	Perphenazine		
	Zuclopenthixol		
	S-Mianserin		
	Tolterodine		
CYP2A6	Nicotine		

Occasionally, one derives benefit from an unusual CYP phenotype. For example, cure rates for peptic ulcer treated with omeprazole are substantially greater in individuals with defective CYP2C19 because of the sustained high plasma levels achieved.

CYP2C9 and CYP2C19

The CYP2C9 and CYP2C19 are the main isoforms for the metabolism of the antiseizure drug phenytoin and for the anticoagulant S-warfarin. Although CYP2C19 metabolizes fewer drugs than CYP2D6 does, the drugs CYP2C19 does metabolize are clinically important (Table 10.6). Deficit of CYP2C19 is found in the PM phenotype, which is only seen in 8 to 13% of Caucasians, 20 to 30% of the Asian population (11–23% of Japanese and 5–37% of Chinese), up to 20% of the black African-American population, 14 to 15% of Saudi Arabians and Ethiopians, and up to 70% of Pacific Islanders (73,75). The more common mutant allele in these individuals is *CYP2C19*2*, which expresses an inactive enzyme. The large interindividual variability observed in the therapeutic response to the antiseizure drug mephenytoin is attributed to CYP2C19 polymorphism, which catalyzes the *p*-hydroxylation of its S-stereoisomer (74). The R-enantiomer is N-demethylated by CYP2C8 with no difference in its metabolism between PMs and EMs.

The CYP2C9 is the primary isoform for the metabolism of the antiseizure drug phenytoin, the anticoagulant S-warfarin, and the hypoglycemic drug tolbutamide. Other clinically important drugs are listed in Table 10.6. At least six different mutant *CYP2C9* alleles have been identified; of these, the two alleles primarily responsible for CYP2C9 deficiency are *CYP2C9*2* and *CYP2C9*3* and code for enzymes with reduced affinity for substrates (73,75). A deficiency of this isoform, however, is seen in 8 to 13% of Caucasians, 2 to 3% of African Americans, and 1% of the Asians. Individuals with the PM phenotype who possess this deficient isoform variant are ineffective in clearing S-warfarin (so much so that they may be fully anticoagulated on just 0.5 mg of warfarin per day) and in the clearance of phenytoin, which has a potentially very toxic narrow therapeutic range. On the other hand, the pro-drug losartan will be poorly activated and ineffective.

CYP2D6

The CYP2D6 is of particular importance, because it metabolizes a wide range of commonly prescribed drugs, including antidepressants, antipsychotics, β-adrenergic blockers, and antiarrhythmics (Table 10.7). The CYP2D6 deficiency is a clinically important genetic variation of drug metabolism characterized by three phenotypes: UM, EM and PM. The PM phenotype is inherited as an autosomal recessive trait,

with 5 of 30 of the known *CYP2D6* gene mutations leading to either zero expression or the

expression of a nonfunctional enzyme (73). Approximately 12 to 20% of Caucasians express the *CYP2D6*4* allele, and 5% express the other *CYP2D6* alleles. Up to 34% of African Americans express the *CYP2D6*17* allele, and 5% express the other *CYP2D6* alleles. Up to 50% of Chinese express the *CYP2D6*10* allele, and 5% express the other *CYP2D6* alleles (these individuals are referred to as PM) (73,75). Conversely, the 20 to 30% of Saudi Arabians and Ethiopians who express the *CYP2D6*2XN* allele are known as UMs of CYP2D6 substrates, because they express excess enzyme as a result of having multicopies of the gene (73). Inasmuch as CYP2D6 is not inducible, individuals of Ethiopian and Saudi Arabian descent have genetically developed a different strategy to cope with the (presumed) high load of alkaloids and other substances in their diet; thus, the high expression of CYP2D6 using multiple copies of the gene. Those individuals who are deficient in CYP2D6 will be predisposed to adverse effects or drug toxicity from antidepressants or neuroleptics caused by inadequate metabolism or long half-lives, but the metabolism of pro-drugs in these patients will be ineffective because of lack of activation (e.g., codeine, which must be metabolized by O-demethylation to morphine). Those with the UM phenotype will require a dose that is much higher than normal to attain therapeutic drug plasma concentrations (e.g., one patient required a daily dose of ~300 mg of nortryptyline to achieve therapeutic plasma levels) or a lower dose for pro-drugs that require metabolic activation. Individuals with the PM phenotype also are characterized by loss of CYP2D6 stereoselectivity in hydroxylation reactions. It can be anticipated that large differences in steady-state concentration for CYP2D6 substrates will occur between individuals with the different phenotypes when they receive the same dose. Depending on the drug and reaction type, a 10- to 30-fold difference in blood concentrations may be observed in the PM-phenotype debrisoquine polymorphism (76).

CYP2A6

The CYP2A6 is of particular importance, because it activates a number of procarcinogens to carcinogens and is the major isoform metabolizing nicotine to cotinine. Approximately 15% of Asians express the *CYP2A6*4del* allele, and 2% of Caucasians express the other *CYP2AD6*2* allele. Both these alleles express zero or a nonfunctional enzyme; these individuals are referred to as having the PM phenotype (73,75). A benefit from being a PM of CYP2A6 substrates might be the protection from some carcinogens and smoking because of the high plasma levels of nicotine achieved with fewer cigarettes.

Acetylation

Acetylation, a nonmicrosomal form of metabolism, also exhibits polymorphisms and was first demonstrated in the acetylation of isoniazid (see the section on acetylation). Several forms of acetyl transferase occur in humans. Some clinically used drugs undergoing polymorphic acetylation include isoniazid, procainamide, hydralazine, phenelzine, dapsone, caffeine, some benzodiazepines, and possibly, the carcinogenic secondary N-alkylarylamines (2-aminofluorene, benzidine, and 4-aminobiphenyl). Intestinal acetyl transferase appears not to be polymorphic (i.e., 5-aminosalicylic acid). The proportion of the fast acetylation phenotype is approximately 30 to 45% in Caucausians, 89 to 90% in the Oriental population, and 100% in Canadian Eskimos. Drug-induced systemic lupus erythematosus from chronic procainamide therapy is more likely to appear with slow acetylators.

Other Polymorphic Metabolizing Enzymes

The polymorphism for CYP2E1 is expressed more in Chinese than in Caucasians. Those with the CYP2E1 PM phenotype exhibit tolerance to alcohol and less toxicity from halohydrocarbon solvents.

The only FMO pathway exhibiting polymorphism is the genetic disease trimethylaminuria, in which individuals excrete diet-derived free trimethylamine in the urine. Usually, trimethylamine undergoes extensive FMO N-oxidation.

In human populations, serum PON1 exhibits a substrate-dependent polymorphism to the neurotoxic effects of organophosphates in those susceptible individuals that are deficient in PON1 (i.e., PM phenotype) (55). The PON1 catalyzes the hydrolysis of paraoxon, chlorpyrifos (Dursban), and other organophosphates.

Polymorphism has been associated with serum cholinesterases (particularly succinyl cholinesterase, causing skeletal muscle paralysis), alcohol dehydrogenases, aldehyde dehydrogenases, epoxide hydrolase, and xanthine oxidase (74). Approximately 50% of the Oriental population lack aldehyde dehydrogenase, resulting in high levels of acetaldehyde following ethanol ingestion and causing nausea and flushing. People with genetic variants of cholinesterase respond abnormally to succinylcholine, procaine, and other related choline esters. The clinical consequence of reduced enzymic activity of cholinesterase is that succinylcholine and procaine are not hydrolyzed in the blood, resulting in prolongation of their respective pharmacological activities.

A suggestion has been made that those with EM phenotypes may be more prone than those with PM phenotypes to develop cancers, because they are better able to activate procarcinogens. Such interindividual variations may have a major influence in determining the risk of cancer. The activity of a particular CYP450 isoform may be a rationale for predicting the individual risk from exposure to carcinogenic compounds.

Our increasing knowledge of genetic polymorphism has contributed a great deal to our understanding about interindividual variation in the metabolism of drugs, including how to change dose regimens accordingly to minimize drug toxicity and improve therapeutic efficacy. In humans, drugs not subject to polymorphic metabolism also exhibit substantial interindividual variation in their disposition, which is attributed to a great extent to environmental factors (e.g., inducing agents, smoking, and alcohol ingestion).

Oral Bioavailability

Oral bioavailability (see Chapter 9) is the fraction of the total dose of a drug that reaches the systemic circulation. The low oral bioavailability for a drug may be the result of disintegration and dissolution properties of the drug formulation, solubility of the drug molecule in the gastrointestinal environment, membrane permeability, presystemic intestinal metabolism, hepatic first-pass metabolism, or susceptibility to membrane transporters, such as P-gp efflux. Other routes of administration (e.g., subcutaneous, intravenous, inhalation, and nasal) for susceptible drugs have been investigated in an attempt to overcome the pronounced presystemic metabolism. The extent of first-pass metabolism depends on the drug delivery system, because a formulation may increase or decrease the rate of dissolution, the

residence time of a drug in the gastrointestinal tract, and the dose. The more prolonged the residence time, the greater the efficiency of first-pass metabolism. The drug form and delivery system should yield optimal bioavailability and pharmacokinetic profiles, resulting in a reproducible clinical response.

Studies are being performed to determine the effect of presystemic and hepatic first-pass metabolism on the toxicity and carcinogenicity of xenobiotics. For a nontherapeutic toxic substance, the existence of a first-pass effect is desirable, because the liver can bioinactivate it, preventing its distribution to other parts of the body. On the other hand, first-pass metabolism may increase its toxicity by biotransforming the toxicant to a more toxic metabolite, which can reenter the blood and exert its toxic effect.

Presystemic First Pass Metabolism

Although hepatic metabolism continues to be the most important route of metabolism for xenobiotics, the ability of the liver and intestine to metabolize substances to either pharmacologically inactive or bioactive metabolites before reaching systemic blood levels is called prehepatic or presystemic first pass metabolism, which results in the low systemic availability for susceptible drugs. Sulfation and glucuronidation are major pathways of presystemic intestinal first-pass metabolism in humans for acetaminophen, phenylephrine, terbutaline, albuterol, fenoterol, and isoproterenol.

The discovery that CYP3A4 is found in the mucosal enterocytes of the intestinal villi signifies its role as key determinant in the oral bioavailability of its numerous drug substrates (Table 10.9) (77). Drugs known to be substrates for CYP3A usually have a low and variable oral bioavailability that may be explained by presystemic first-pass metabolism by the small intestine CYP450 isoforms. The concentration of functional intestinal CYP3A is influenced by genetic disposition, induction, and inhibition, which to a great extent determines drug blood levels and therapeutic response. Xenobiotics when ingested orally can modify the activity of intestinal CYP3A enzymes by induction, inhibition, and stimulation. By modulation of the isoform pattern in the intestine, a xenobiotic could alter its own metabolism and that of others in a time- and dose-dependent manner. Its concentration in the intestine is comparable to that of the liver. The oral administration of dexamethasone induces the formation of CYP3A and erythromycin inhibits it. The glucocorticoid inducibility of CYP3A4 also may be a factor in differences of metabolism between males and females. Studies have suggested that intestinal CYP3A4 C-2 hydroxylation of estradiol contributed to the oxidative metabolism of endogenous estrogens circulating with the enterohepatic recycling pool (38). Norethisterone has a low oral bioavailability of 42% because of oxidative first-pass metabolism (CYP3A), but levonorgestrel is completely available in women with no conjugated metabolites.

Several clinically relevant drug interactions between orally coadministered drugs and CYP3A4 can be explained by a modification of drug metabolism at the CYP450 level. If a drug has high presystemic elimination (low bioavailability) and is metabolized primarily by CYP3A4, then coadministration with a CYP3A4 inhibitor can be expected to alter the drug's pharmacokinetics by reducing its metabolism, thus increasing its plasma concentration. Drugs and some foods (e.g., grapefruit juice) that are known inhibitors, inducers, or substrates for intestinal CYP3A4 can potentially interact with the metabolism of a coadministered drug, affecting its area under the curve and rate of clearance (Tables 10.10 and 10.12) (78). Inducers can reduce absorption and oral bioavailability, whereas these same factors are increased by inhibitors. For example, erythromycin can enhance the oral absorption of another drug by inhibiting its metabolism in the small intestine by CYP3A4. By virtue of being competitive substrates for CYP3A4, prednisone, prednisolone, and methylprednisolone (but not dexamethasone) are competitive inhibitors of synthetic glucocorticoid metabolism. This is because a major metabolic pathway for synthetic glucocorticoids involves CYP3A4. In addition to coadministered drugs, metabolic interactions with exogenous CYP3A4 substrates secreted in the bile are possible. The poor oral bioavailability for cyclosporine is attributed to a combination of intestinal metabolism by CYP3A4 and efflux by P-gp (79).

Because the intestinal mucosa is enriched with glucuronosyltransferases, sulfotransferases, and glutathione transferases, presystemic first-pass metabolism for orally administered drugs susceptible to these conjugation reactions results in their low oral bioavailability (65). Presystemic metabolism often exceeds liver metabolism for some drugs. For example, more than 80% of intravenously administered albuterol is excreted unchanged in urine, with the balance as glucuronide conjugates, whereas when albuterol is administered orally, less than 5% is systemically absorbed because of intestinal sulfation and glucuronidation. Presystemic metabolism is a major pathway in humans for most β-adrenergic agonists,

such as glucuronides or sulfates for terbutaline, fenoterol, albuterol, and isoproterenol, morphine (3–O-glucuronide), acetaminophen (O-sulfate), and estradiol (3–O-sulfate). The bioavailability of orally administered estradiol or ethinyl estradiol in females is approximately 50%. Mestranol (3-methoxyethinyl estradiol) has greater bioavailability, however, because it is not significantly conjugated. Levodopa has a low oral bioavailability because of its metabolism by intestinal L-aromatic amino acid decarboxylase. The activity of this enzyme depends on the percentage bound of its cofactor pyridoxine (vitamin B_6). Tyramine, which occurs in fermented foods such as cheeses and red wines, ripe bananas, and yeast extracts, is metabolized by both MAO-A and MAO-B in the gut wall.

The extensive presystemic first-pass sulfation of phenolic drugs, for example, can lead to increased bioavailability of other drugs by competing for the available sulfate pool, resulting in the possibility of drug toxicity (56). Concurrent oral administration of acetaminophen with ethinyl estradiol resulted in a 48% increase in ethinyl estradiol blood levels. Ascorbic acid, which is sulfated, also increases the bioavailability of concurrently administered ethinyl estradiol. Sulfation and glucuronidation occur side by side, often competing for the same substrate, and the balance between sulfation and glucuronidation is influenced by several factors, such as species, doses, availability of cosubstrates, inhibition, and induction of the respective transferases.

First-Pass Metabolism

Several orally administered drugs are known to undergo liver first-pass metabolism during their transport to the systemic circulation from the gastrointestinal tract (e.g., metoprolol). Thus, the liver can remove substances from the blood after their absorption from the gastrointestinal tract, thereby preventing distribution to other parts of the body. This effect can seriously impair the bioavailability of an orally administered drug, reducing the amount of the drug that reaches the systemic circulation and, ultimately, its receptor to produce its pharmacological effect. Drugs subject to first-pass metabolism are included in Table 10.15.

Table 10.15. Examples of Drugs Exhibiting First-Pass Metabolism

Acetaminophen	Isoproterenol	Oxprenolol
Albuterol	Lidocaine	Pentazocine
Alprenolol	Meperidine	Propoxyphene
Aspirin	Methyltestosterone	Propranolol
Cyclosporin	Metoprolol	Salicylamide
Desmethylimipramine	Dihydropyridines	Terbutaline
Fluorouracil	(Nifedipine)	Verapamil
Hydrocortisone	Nortriptyline	
Imipramine	Organic nitrates	

P-Glycoprotein

Description of P-Glycoprotein

P-glycoprotein is a transmembrane ATP-dependent active transport protein that is strategically expressed in the luminal endothelial cells of organs associated with lipophilic xenobiotic absorption and distribution. For example, in the intestinal mucosa, P-gp functions to move xenobiotics into the intestine to block their absorption into the portal circulation; in the endothelial cells of the brain, as a blood-brain barrier to move substances out of the brain into systemic circulation; and in the endothelial cells of the renal proximal tubules of the kidney and in the canicular membranes of hepatocytes, to increase xenobiotic elimination into the urine and bile, respectively (81). Additionally, P-gp is expressed in the endothelial cells of the adrenal cortex and medulla, of the testis and ovaries, of the peripheral nerves (functions as a blood-nerve barrier), and of the pancreas; in the epithelial cells of the placenta, where it serves as the maternofetal barrier for the fetus; and in the stem cells of the bone marrow. The particular localization of P-gp suggests that this transmembrane transporter protein probably evolved as a protective mechanism against the absorption of xenobiotics to increase their transport out of these organs and tissues. It appears that the substrates, inhibitors, or inducers are nonselective for various P-gps. P-glycoprotein should exhibit saturation/nonlinear kinetics; at or near saturation concentrations, an increase in drug absorption can result in a two- to threefold increase in plasma drug concentration. Activity of P-gp is controlled by a variety of endogenous and environmental stimuli that evoke stress responses, including cytotoxic agents, heat shock, irradiation, genotoxic stress, inflammation, inflammatory mediators, cytokines, and growth factors.

Another factor that must be considered in the oral bioavailability of many CYP3A4 substrates is intestinal P-gp (80). Originally discovered as a transmembrane transporter protein associated with the resistance (elimination) of anticancer drugs, P-gp also can play a role in how a drug is absorbed, distributed, metabolized, and eliminated from the body (79,80). Considering its role as a transporter protein (efflux pump), it is logical that it should exhibit saturable (nonlinear) kinetics. P-glycoprotein exhibits a broad specificity for a large number of substrates, inhibitors, and inducers (Table 10.16). The common link between P-gp substrates is that most of the same compounds also are substrates for CYP3A4. The close physical location of P-gp and CYP3A4 in the endothelial cells of the intestinal mucosa allows these proteins to work in concert with each other to decrease drug plasma concentrations of CYP3A4 substrates, suggesting a complementary protective mechanism for these two proteins, forming a barrier to the absorption intestinal of CYP3A4 substrates. Hepatic and renal P-gp also appear to function in a complementary manner, promoting the elimination of substrates into the bile and urine, respectively. For example, if a drug is a substrate for intestinal P-gp, its oral absorption will be

incomplete, and this same drug will be actively transported by the renal tubules into the urine, enhancing its elimination. On the other hand, inhibiting P-gp would be expected to improve the oral bioavailability of P-gp substrates, but if the inhibitor also is a substrate for CYP3A4, increased metabolism (presystemic) would occur. Drugs with low oral bioavailability or high first-pass metabolism may be particularly susceptible to alterations in the transport kinetics of P-gp. Because P-gp exhibits saturation (nonlinear) kinetics, drugs with low dosages can have their oral bioavailability enhanced by increasing its oral dosage, thus saturating the P-gp pump. As with CYP3A4, there is significant interindividual variation (4- to 10-fold) in the intestinal expression of P-gp, which could explain the variance observed in the pharmacokinetics for CYP3A4 substrates. The interactive nature of CYP3A4 and P-gp will be of importance in controlling and improving the oral bioavailability of CYP3A4 substrates and drug regimens. The presence of inhibitors of P-gp in grapefruit juice (e.g., 6,7-dihydroxybergamottin and other furanocoumarins) has confirmed that the inhibition of efflux transport of drugs and of drug metabolism by CYP3A4 could be an important cause of drug–grapefruit juice interaction (82).

Table 10.16. Some Substrates, Inhibitors, and Inducers for P-Glycoprotein

*CYP3A4 substrate, inhibitor or inducer.

In summary, oral bioavailability for xenobiotics is dependent on a combination of factors, including physical properties of the drugs and formulation and biological factors such as metabolizing enzymes, membrane permeability, and the membrane efflux pump, P-gp.

Extrahepatic Metabolism

Because the liver is the primary tissue for xenobiotic metabolism, it is not surprising that our understanding of mammalian CYP450 monooxygenase is based chiefly on hepatic studies. Although the tissue content of CYP450s is highest in the liver, CYP450 enzymes are ubiquitous, and their role in extrahepatic tissues remains unclear. The CYP450 pattern in these tissues differs considerably from that in the human liver (83). In addition to liver tissue, CYP450 enzymes are found in lung, nasal epithelium, intestinal tract, kidney and adrenal tissues, and brain. It is possible that the expression of the polymorphic genes and induction of the isoforms in the extrahepatic tissues may affect the activity of the CYP450 isoforms in the metabolism of drugs, endogenous steroids, and xenobiotics. Therefore, characterization

of CYP450, UGT, SULT, and other polymorphic drug-metabolizing enzymes in extrahepatic tissues is important to our overall understanding about the biological importance of these isoform families to improved drug therapy, design of new drugs and dosages forms, toxicity, and carcinogenicity.

The mucosal surfaces of the gastrointestinal tract, the nasal passages, and the lungs are major portals of entry for xenobiotics into the body and, as such, are continuously exposed to a variety of orally ingested or inhaled airborne xenobiotics, including drugs, plant toxins, environmental pollutants, and other chemical substances. As a consequence of this exposure, these tissues represent a major target for necrosis, tumorigenesis, and other chemically induced toxicities. Many of these toxins and chemical carcinogens are relatively inert substances that must be bioactivated to exert their cytotoxicity and tumorigenicity. The epithelial cells of these tissues are capable of metabolizing a wide variety of exogenous and endogenous substances, and these cells provide the principal and initial source of

biotransformation for these xenobiotics during the absorptive phase. The consequences of such presystemic biotransformation is either a decrease in the amount of xenobiotics available for systemic absorption by facilitating the elimination of polar metabolites or toxification by activation to carcinogens, which may be one determinant of tissue susceptibility for the development of intestinal cancer. The risk of colon cancer may depend on dietary constituents that contain either procarcinogens or compounds modulating the response to carcinogens.

Intestinal Metabolism

Mounting evidence shows that many of the clinically relevant aspects of CYP450 may, in fact, occur at the level of the intestinal mucosa and could account for differences among patients in dosing requirements. The intestinal mucosa is enriched especially with CYP3A4 isoform, glucuronosyl transferases, sulfotransferases, and GSTs, making it particularly important for orally administered drugs susceptible to oxidation (77), glucuronidation or sulfation conjugation pathways (56), or glutathione conjugation pathways. The highest concentrations of CYP450s occur in the duodenum, with gradual tapering into the ileum. In the human intestine, CYP2E, CYP3A, CYP2C8, CYP2C9, CYP2C19, and CYP2D6 have been identified. Therefore, intestinal CYP450 isoforms provide potential presystemic first-pass metabolism of ingested xenobiotics affecting their oral bioavailability (e.g., hydroxylation of naloxone) or bioactivation of carcinogens or mutagens. It is not surprising that dietary factors can affect the intestinal CYP450 isoforms. For example, a two-day dietary exposure to cooked Brussel sprouts significantly decreased the 2α-hydroxylation of testosterone yet induced CYP1A2 activity for PAH. An 8-oz. glass of grapefruit juice inhibited the sulfoxidation metabolism of omeprazole (CYP3A4) but not its hydroxylation (CYP2C19), thus increasing its systemic blood concentration. These types of interactions between a drug and a dietary inhibitor could result in a clinically significant drug interaction.

In the intestine, UGT isoforms can glucuronidate orally administered drugs, such as morphine, acetaminophen, α- and β-adrenergic agonists and other phenolic phenethanolamines, and other dietary xenobiotics. This is a result of reduction in their oral bioavailability (increasing first-pass metabolism), thus altering their pharmacokinetics and pharmacodynamics. The UGTs expressed in the intestine include UGT1A1 (bilirubin-glucuronidating isoform), UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT1A9, and UGT1A10. Substrate specificities of intestinal UGT isoforms are comparable to those in the liver. Glucuronidase hydrolysis of biliary glucuronide conjugates in the intestine can contribute to EHC of the parent drug.

Likewise, the sulfotransferases in the small intestine can sulfate orally administered drugs and xenobiotics for which the primary route of conjugation is sulfation (e.g., isoproterenol, albuterol, steroid hormones, α-methyldopa, acetaminophen, and fenoldopam), decreasing their oral bioavailability and, thus, altering their pharmacokinetics and pharmacodynamics. Competition for intestinal sulfation between coadministered substrates may influence their bioavailability with either an enhancement or a decrease of therapeutic effects. Sulfatase hydrolysis of biliary sulfate conjugates in the intestine can contribute to EHC of the parent drug.

The occurrence of intestinal CYP450 enzymes and bacterial enzymes in the microflora allows the metabolism of relatively stable environmental pollutants and food-derived xenobiotics (i.e., plants contain a variety of protoxins, promutagens, and procarcinogens) into mutagens and carcinogens (68). For example, cruciferous vegetables (Brussel sprouts, cabbage, broccoli, cauliflower, and spinach) are all rich in indole compounds (e.g., indole 3-carbinol), which with regular and chronic ingestion are capable of inducing some intestinal CYP450s (CYP1A subfamily) and inhibiting others (CYP3A subfamily). It is likely that these vegetables also would alter the metabolism of food-derived mutagens (e.g., heterocyclic amines produced during charbroiling of meat are CYP450 N-hydroxylated and become carcinogenic in a manner similar to arylamines) and carcinogens.

The extent of a drug's metabolism in the small bowel and its role in clinically relevant drug interaction remain to be evaluated and must be taken into account during oral pharmacokinetics analysis of future drug interaction studies. Clinically significant interaction will not always occur when a drug is combined with other isoform subfamily substrates. Oral coadministration of a drug with drugs that interact with its metabolism need not be avoided. The blood concentration of the drug must be monitored closely, however, and the dose should be adapted to avoid adverse drug reactions.

Intestinal Microflora

When drugs are orally ingested or there is considerable biliary excretion of a drug or its metabolites into the gastrointestinal tract, such as with a parentally administered drug (EHC or recirculation), the intestinal bacterial microflora can have a role in the metabolism of these drugs. The microflora plays an important role in the enterohepatic recirculation of xenobiotics via their conjugated metabolites (e.g., digoxin, the oral contraceptives norethisterone and ethinyl estradiol, and chloramphenicol) and endogenous substances (steroid hormones, bile acids, folic acid, and cholesterol), which reenter the gut via the bile (68). Compounds eliminated in the bile are conjugated with glucuronic acid, glycine, sulfate, and glutathione, and once secreted into the small intestine, the bacterial β-glucuronidase, sulfatase, nitroreductases, and various glycosidases catalyze the hydrolysis of the conjugates. The activity of orally administered conjugated estrogens (e.g., Premarin) involves the hydrolysis of the sulfate conjugates by sulfatases, releasing estrogens to be reabsorbed from the intestine into the portal circulation. The clinical use of oral

antibiotics (e.g., erythromycin, penicillin, clindamycin, and aminoglycosides) has a profound effect on the gut microflora and the enzymes responsible for the hydrolysis of drug conjugates undergoing EHC. Bacterial reduction includes nitro reduction of nitroimidazole, azo reduction of azides (sulfasalazine to 5-aminosalicylic acid and sulfapyridine), and reduction of the sulfoxide to its sulfide. The sulfoxide of sulindac is reduced by both gut microflora and hepatic CYP450s. Other ways in which bacterial flora can affect metabolism include the

following: 1) production of toxic metabolites, 2) formation of carcinogens from inactive precursors, 3) detoxication, 4) exhibition of species differences in drug metabolism, 5) exhibition of individual differences in drug metabolism, 6) production of pharmacologically active metabolites from inactive precursors, and 7) production of metabolites not formed by animal tissues. In contrast to the predominantly hepatic oxidative and conjugative metabolism of the liver, gut microflora is largely degradative, hydrolytic, and reductive, with a potential for both metabolic activation and detoxication of xenobiotics.

Lung Metabolism

Some of the hepatic xenobiotic biotransformation pathways also are operative in the lung (84,85). Because of the differences in organ sizes, the total content of the pulmonary xenobiotic-metabolizing enzyme systems generally is lower than in the liver, creating the impression of a minor role for the lung in xenobiotic elimination. The CYP2E1 is the CYP450 isoform that is expressed in the lung to the greatest extent. The other CYP450s, FMO, epoxide hydrolase, and the Phase 2 conjugation pathways, however, are comparable to those in the liver. Thus, the lungs may play a significant role in the metabolic elimination or activation of small-molecular-weight inhaled xenobiotics. When drugs are injected intravenously, intramuscularly, or subcutaneously, or after skin absorption, the drug initially enters the pulmonary circulation, after which the lung becomes the organ of first-pass metabolism for the drug. The blood levels and therapeutic response of the drug are influenced by genetic disposition, induction, and inhibition of the pulmonary metabolizing enzymes. By modulation of the CYP450 isoform pattern in the lung, a xenobiotic could alter its own metabolism and that of others in a time- and dose-dependent manner. Because of its position in the circulation, the lung provides a second-pass metabolism for xenobiotics and their metabolites exiting from the liver, but it also is susceptible to the cytotoxicity or carcinogenicity of hepatic activated metabolites. Antihistamines, β-blockers, opioids, and tricyclic antidepressants are among the basic amines known to accumulate in the lungs as a result of their binding to surfactant phospholipids in lung tissue. The significance of this relationship to potential pneumotoxicity remains to be seen.

Nasal Metabolism

The nasal mucosa is recognized as a first line of defense for the lung against airborne xenobiotics, because it is constantly exposed to the external environment (86). Drug metabolism in the nasal mucosa is an important consideration not only in drug delivery but also for toxicological implications because of xenobiotic metabolism of inhaled environmental pollutants or other volatile chemicals. The CYP450 enzymes in the nasal epithelial cells can convert some of the airborne chemicals to reactive metabolites, increasing the risk of carcinogenesis in the nasopharynx and lung (e.g., nitrosamines in cigarette smoke). The most striking feature of the nasal epithelium is that CYP450 catalytic activity is higher than in any other extrahepatic tissue, as well as the liver. Nasal decongestants, essences, anesthetics, alcohols, nicotine, and cocaine have been shown to be metabolized in vitro by CYP450 enzymes from the nasal epithelium. Because the CYP450s in the nasal mucosa are active, first-pass metabolism should be considered when delivering susceptible drugs to the nasal tissues. Flavin monooxygenases, carboxylesterases, aldehyde dehydrogenase, and other conjugation (Phase 2) enzymes also are active in the nasal epithelium.

Metabolism in Other Tissues

The isoforms of CYP450s and their regulation in the brain are of interest in defining the possible involvement of CYP450s in central nervous system toxicity and carcinogenicity. The CYP450s in the kidney and adrenal tissues include isoforms primarily involved in the hydroxylation of steroids, arachidonic acid, and 25-hydroxycholcalciferol.

Stereochemical Aspects of Drug Metabolism

In addition to the physicochemical factors that affect xenobiotic metabolism, stereochemical factors play an important role in the biotransformation of drugs. This involvement is not unexpected, because the xenobiotic-metabolizing enzymes also are the same enzymes that metabolize certain endogenous substrates, which for the most part are chiral molecules. Most of these enzymes show stereoselectivity but not stereospecificity; in other words, one stereoisomer enters into biotransformation pathways preferentially but not exclusively. Metabolic stereochemical reactions can be categorized as follows: substrate stereoselectivity, in which two enantiomers of a chiral substrate are metabolized at different rates; product stereoselectivity, in which a new chiral center is created in a symmetric molecule and one enantiomer is metabolized preferentially; and substrate-product stereoelectivity, in which a new chiral center of a chiral molecule is metabolized preferentially to one of two possible diastereomers (87). An example of substrate stereoselectivity is the preferred decarboxylation of S-α-methyldopa to S-α-methyldopamine, with almost no reaction for R-α-methyldopa. The reduction of ketones to stereoisomeric

alcohols and the hydroxylation of enantiotropic protons or phenyl rings by monooxygenases are examples of product stereoselectivity. For example, phenytoin undergoes aromatic *p*-hydroxylation of only one of its two phenyl rings to create a chiral center at C-5 of the hydantoin ring, methadone is reduced preferentially to its α-diastereometric alcohol, and naltrexone is reduced to its 6-β-alcohol. An example of substrate-product stereoselectivity is the reduction of the enantiomers of warfarin and the β-hydroxylation of S-α-methyldopamine to (1*R*,2*S*)-α-methylnorepinephrine, whereas *R*-α-methyldopamine is hydroxylated only to a negligible extent. In vivo studies of this type often can be confused by the further biotransformation of one stereoisomer, giving the false impression that only one stereoisomer was formed preferentially. Moreover, some compounds show stereoselective absorption, distribution, and excretion, which proves the importance of also performing in vitro studies. Although studies regarding the stereoselective biotransformation of drug molecules are not yet extensive, those that have been done indicate that stereochemical factors play an important role in drug metabolism and, in some cases, could account for the differences in pharmacological activity and duration of action between enantiomers (see the discussion of chiral inversion of the NSAIDs).

Metabolic Bioactivation: Role in Hepatotoxicity, Idiosyncratic Reactions, and Chemical Carcinogenesis

Drug-Induced Hepatotoxicity

Drug-induced hepatotoxicity is the leading cause of hepatic injury, accounting for approximately half of all cases of acute liver failure in the U.S. (88,89). Recent studies have shown that drug-induced hepatotoxicity represents a larger percentage of adverse drug reactions

than reported previously and that the incidence and severity of drug-induced liver injury is underestimated among the general population.

Acetaminophen overdose is the leading cause for calls to Poison Control Centers (>100,000 calls/year) and accounts for more than 56,000 emergency room visits, 2,600 hospitalizations, and an estimated 458 deaths from acute liver failure each year. Among the listed drugs in Table 10.17, acetaminophen is the most frequent hepatotoxic agent and can cause extensive hepatic necrosis with as little as 10 to 12 g (30–40 tablets). Chronic alcohol intake enhances acetaminophen hepatotoxicity more than five times as compared to acute alcohol intake, yet acetaminophen is heavily marketed for its safety as compared to nonsteroidal analgesics. U.S. drug manufacturers continue to market and promote Extra-strength acetaminophen products (500–750 mg/tablet) and a variety of Extra-strength acetaminophen-drug combination products. Self-poisoning with acetaminophen (paracetamol) also is a common cause of hepatotoxicity in the Western World. To reduce the number of acetaminophen poisonings in the UK, OTC sales of acetaminophen are limited to 16 tablets per packet.

Drug-induced hepatic damage is also the most frequent reason that new therapeutic agents are not approved by the U.S. FDA (e.g., ximelagatran in 2004) and the most common adverse drug reaction leading to withdrawal of a drug from the market (Table 10.17). Hepatotoxicity almost always involves metabolism with Phase I CYP450 enzymes rather than Phase II enzymes. More than 600 drugs, chemicals, and herbal remedies can cause hepatotoxicity, of which more than 30 drugs have either been withdrawn from the U.S. market

because of hepatotoxicity or have carried a black box warning for hepatotoxicity since 1990. Table 10.17 includes some of the more common drugs that have exhibited drug-induced hepatotoxicity ranging from severe, requiring the drug's regulatory withdrawal from the market (italics in Table 10.17); moderate to severe, requiring black box warning restrictions (bold in Table 10.17); or mild to moderate, requiring frequent liver function monitoring.

Table 10.17. Some Drugs Causing Hepatic Injury[a]

Acarbose
Acetaminophen
Allopurinol
Amiodarone
Amprenavir
Anagrelide
Atomoxetine
Atorvastatin
Azathioprine
Bicalutamide
Bosentan
Bromfenac (1998)
Carbamazepine
Celecoxib
Dapsone
Deferasirox
Diclofenac
Disulfiram
Duloxetine
Efavirenz
Ethotoin
Ethosuximide
Felbamate
Fenofibrate
Fluconazole
Flutamide
Fluvastatin
Gemfibrozil
Gemtuzumab
Griseofulvin
Halothane
Imatinib
Indinavir
Infliximab
Interferon-β_{1a}
Interferon-β_{1b}
Isoflurane
Isoniazid
Isotretinoin
Itraconazole
Ketoconazole
Ketorolac
Lamivudine
Leflunomide

Lovastatin
Meloxicam
Methotrexate
Methsuximide
Methyldopa
Nabumetone
Naproxen
Nefazodone (2005)
Nevirapine
Niacin (SR)
Nitrofurantoin
Olanzapine
Oxaprozin
Peg-interferon-α_{2a}
Pemoline (2005)
Pentamidine
Pioglitazone
Piroxicam
Pravastatin

Trovafloxacin
Valproic acid
Voriconazole
Ximelagatran (2004)
Zileuton
Zifirlukast

[a]Drugs in italics have exhibited severe drug-induced hepatotoxicity were withdrawn either voluntarily or by a regulatory agency (year given). Drugs in bold have exhibited moderate–severe drug-induced hepatotoxicity requiring a black box warning restricting their use. The other drugs have exhibited mild to moderate drug-induced hepatotoxicity that may need frequent liver transaminase testing for those at risk (see Table 10.18).

However, Watkins (90) recently reported in the Journal of the American Medical Association that 1/3 of 106 patients taking a maximum daily acetaminophen dose of 4 grams for 8 days, either alone or in combination with Hydrocodone, exhibited a 3-fold increase in liver enzymes associated with acetaminophen-induced liver injury. This 3-fold increase in transminase levels is a signal for potential liver safety concerns in those individuals who are at risk of acetaminophen-induced liver toxicity. Drug-induced injury is most common and includes hepatic necrosis and steatosis, which can affect significant portions of the liver (88). Drugs reported to cause hepatocellular necrosis include acetaminophen, methyldopa, valproic acid, trazodone, nefazodone, venlafaxine, and lovastatin. Drug-induced liver damage occurs after a prolonged period of drug administration.

Some Drugs Exhibiting Drug-induced Hepatotoxicity Never Approved for Use in United States

Drugs with reactive metabolites that were used in other countries but never approved in the United States include: alpidem, amineptine, amodiaquine, cinchophen, dihydralazine, dilevalol, ebrotidine, glafenine, ibufenac, isoxicam, niperotidine, perhexiline, pirprofen, and tilbroquinol.

The most commonly used indicators of hepatotoxicity (i.e., liver injury) are increased levels of the liver transaminases, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) (88,89). Drug-induced hepatotoxicity can develop rapidly, often before abnormal laboratory tests are noticed, which are characterized by rapid elevations in ALT and AST of 8 to 500 times the upper normal limit, with variable elevations in bilirubin. Drugs causing acute liver injury (hepatocellular necrosis) exhibit elevations in hepatic transaminases ranging from 50 to 100 times higher than the normal level. On the other hand, the elevations of ALT and AST in alcoholic liver disease are two- to three times higher than normal. Some hepatotoxins, however, do not elevate transaminases, whereas nonhepatic toxins can elevate ALT.

Most drug-induced hepatotoxicity is of an idiosyncratic nature, occurring in a small percentage of patients (1 in 5,000) who ingest the drug (88,89). These reactions tend to be of two distinct types: 1) hypersensitivity reactions that are immune mediated, occurring within the first 4 to 6 weeks, and are associated with fever, rash, eosinophilia, and a hepatitis-like picture (e.g., phenytoin, sulindac and allopurinol); and 2) metabolic idiosyncratic reactions that tend to occur at almost any time during the first year of treatment (e.g., troglitazone and isoniazid). The incidence of overt idiosyncratic liver diseases varies with the drug, ranging from approximately 1 in 100 with isoniazid to 1 in 1,000 with phenytoin, to 1 in 10,000 or more with sulindac and troglitazone, and 1 in 100,000 with diclofenac. To detect a single case of drug-induced hepatotoxicity with 95% confidence requires the number of patients studied to be threefold the incidence of the reaction. For one adverse drug reaction in 10,000 patients, at least 30,000 patients need to be evaluated. Thus, many drugs are approved before liver toxicity is observed. It is the responsibility of postmarketing surveillance and monitoring of liver transaminases to identify potential cases of liver-adverse drug reactions.

Risk factors (Table 10.18) for drug-induced liver injury, such as age, gender, genetic predisposition, multiple drugs or dietary supplements, and degree of alcohol consumption, appear to increase the susceptibility to drug-induced hepatotoxicity (88,89). Patients with mild to moderate chronic liver disease do not appear to be at increased risk for idiosyncratic hepatic injury from drugs. However, the drugs in Table 10.17 should be used with caution in these patients, because such patients may have altered metabolism of these drugs and, therefore, may be at increased risk for liver injury. The coadministration of drugs in Table 10.17 with enzyme inducers, such as phenobarbital, phenytoin, ethanol, and/or cigarette smoke, can induce hepatic enzymes, resulting in the enhancement of hepatotoxicity.

Most hepatic adverse effects associated with drugs occur in adults rather than children. Drug-induced liver injury occurs at a higher rate in patients older than 50 years, and drug-associated jaundice also occurs more frequently in the geriatric population (88,89). This age-risk may be the result of increased frequency of drug exposure, multidrug therapy, and age-related changes in drug metabolism.

For reasons that are unclear, drug-induced liver injury affects females more than males: Females accounted for approximately 79% of all reactions to acetaminophen and 73% of all idiosyncratic drug-induced reactions (88). Females exhibit increased risk of hepatic injury from drugs such as atorvastatin, nitrofurantoin, methyldopa, and diclofenac.

Genetic factors as a result of enzyme polymorphism in affected individuals may decrease the ability to metabolize or eliminate drugs, thus increasing their duration of action and the drug exposure and/or decreasing the ability to modulate the immune response to drugs or metabolites. Chronic ingestion of alcohol may also predispose many patients to increased hepatotoxicity from drugs by lowering the store of glutathione (a detoxifying mechanism), which prevents trapping of the toxic metabolites as mercapturate conjugates that are excreted in the urine.

Table 10.18. Risk factors for drug-induced liver injury

Race	Some drugs exhibit different toxicities based on race because of individual CYP450 polymorphism. For example, blacks and Hispanics may be more susceptible to isoniazid (INH) toxicity.
Age	Elderly persons are at increased risk of hepatic injury because of decreased clearance, drug-to-drug interactions, reduced hepatic blood flow, variation in drug binding, and lower hepatic volume. In addition, poor diet, infections, and multiple hospitalizations are important reasons for drug-induced hepatotoxicity. Hepatic drug reactions are rare in children (e.g., acetaminophen, halogenated general anesthetics).
Gender	Although the reasons are unknown, hepatic drug reactions are more common in females. Females are more susceptible to acetaminophen, halothane, nitrofurantoin, diclofenac, and sulindac.
Alcohol	Alcoholics are susceptible to drug toxicity, because alcohol induces liver injury and cirrhotic changes that alter drug metabolism. Alcohol causes depletion of glutathione (hepatoprotective) stores, making the person more susceptible to toxicity by drugs (e.g., acetaminophen, statins).
Liver disease	Patients with chronic liver disease are not uniformly at increased risk of hepatic injury. Although the total CYP450 level is reduced, some patients may be affected more than others. The modification of doses in persons

	with liver disease should be based on knowledge of the specific CYP450 isoform involved in the metabolism. Patients with HIV infection who are coinfected with hepatitis B or C virus are at increased risk for hepatotoxic effects. Similarly, patients with cirrhosis are at increased risk to hepatotoxic drugs (e.g., methotrexate, methyldopa, valproic acid).
Genetic factors	Genetic (polymorphic) differences in the formation of CYP450 isoforms (2C family and 2D6) can result in abnormal reactions to drugs, including idiosyncratic reactions (see Table 10.18).
Other comorbidities	Patients with AIDS, renal disease, diabetes mellitus, persons who are malnourished, and persons who are fasting may be susceptible to drug reactions because of low glutathione stores.
Pharmacokinetics	Long-acting drugs may cause more injury than shorter-acting drugs, as well as sustained-release drug product formulation.
Drug adulterants	Contaminants are often found in noncertified herbal supplements (e.g., hepatitis C).

Other factors include the effect of drug formulation (sustained vs. rapid release; increased exposure) on pharmacokinetics, e.g., elimination half-life of the drug or adulterants (e.g., enzyme inducers) in dietary supplements.

Drug-induced hepatotoxicity can be categorized as intrinsic (predictable) or idiosyncratic (unpredictable) drug reactions (89). Most drugs involved in hepatotoxicity belong to the idiosyncratic group. Intrinsic heptotoxins produce liver injury in a dose-related manner when the toxic amount of drug is ingested without bioactivation, such as these toxins found in the *Amanita* mushroom. Fortunately, few drugs are intrinsic heptotoxins. Idiosyncratic hepatotoxicity is the result of the toxic effects of a drug's metabolites.

The common trigger for both mild and severe forms of hepatotoxicity is bioactivation of relatively inert functional groups to reactive electrophilic intermediates, which is considered to be an obligatory event in the etiology of many drug-induced idiosyncratic hepatotoxicity (91,92). A great deal of evidence now shows that reactive metabolites are formed from drugs known to cause idiosyncratic hepatotoxicity, but how these toxic species initiate and propagate tissue damage remains poorly understood. However, the relationship between bioactivation and the occurrence of hepatic injury is not simple. For example, many drugs at therapeutic doses undergo bioactivation in the liver but are not hepatotoxic. The tight coupling of bioactivation with bioinactivation pathways may be one reason for the lack of hepatotoxicity with these drugs. Examples of bioinactivation (detoxification) pathways include glutathione conjugation of quinones by glutathione S-transferases (GSTs) and hydration of arene oxides to dihydrodiols by epoxide hydrolases. When reactive metabolites are poor substrates for such detoxifying enzymes, they can escape bioinactivation and, thereby, damage proteins and nucleic acids, prompting hepatotoxicity.

Most drugs, however, are not directly chemically reactive but, through the normal process of drug metabolism, may form electrophilic, chemically reactive metabolites (90,91,92). Formation of chemically reactive metabolites is mainly catalyzed by CYP450 enzymes (Phase I), but products of Phase II metabolism (e.g., acylglucuronides, acyl CoA thioesters, or N-sulfonates) also can lead to toxicity. However, if Phase I drug bioactivation is closely coupled with Phase II bioinactivation (e.g. glutathione conjugation to mercapturates), then the net chemical process is one of detoxification if the final product is rapidly cleared. Toxicity may accrue when accumulation of a chemically reactive metabolite that, if not detoxified, can lead to covalent modification of biological macromolecules. The identity of the target macromolecule and the functional consequence of its modification will dictate the resulting toxicological response. The CYP450 enzymes are present in many organs, mainly the liver but also the kidney and lung, and thus can bioactivate chemicals to cause organ-specific toxicity. Evidence for the formation of reactive metabolites was found for five of the six drugs that have been withdrawn from the marketplace since 1995 and for 8 of the 15 drugs that have black box warnings. Evidence for reactive metabolite formation has been found for acetaminophen, bromfenac, diclofenac, clozapine, and troglitazone (91,92,93). Acetaminophen is the most studied hepatotoxin. The current hypotheses of how reactive metabolites leads to liver injury suggests that hepatic (target) proteins can be modified by reactive metabolites. Much more important may be the identification of the target proteins modified by these toxic metabolites and how this reactions alters the function of

the target proteins. Additionally, it is important to note that the toxicity of reactive metabolites also may be mediated by noncovalent binding mechanisms, which may have profound effects on normal liver physiology. Technological developments in the wake of the genomic revolution now provide unprecedented power to characterize and quantify covalent modification of individual target proteins and their functional consequences (93). Such information should dramatically improve our understanding of drug-induced hepatotoxic reactions. Moreover, covalent binding per se does not necessarily lead to drug hepatotoxicity. The regioisomer of acetaminophen, 3-hydroxyacetanilide, becomes covalently bound to hepatic proteins in rodents without inducing hepatotoxicity (94).

Hard/Soft Acids/Bases

The nonenzymatic reaction of an electrophilic metabolite with a nucleophilic molecule usually occurs via a substitution or addition mechanism involving the donation of an electron pair by the nucleophile to an acceptor molecule, an electrophile, with subsequent formation of a covalent bond and an adduct product (Coles B. Effects of modifying structure on electrophilic reactions with biological nucleophiles. Drug Metab Rev. 1984–1985;15:1307–34). The most accepted concept classifies

electrophiles and nucleophiles according to Pearson's “hard-soft acid-bases” (HSAB) model. Thus, hard electrophiles have a formal positive charge at the electrophilic center, and the valence electrons are not easily delocalized or polarized (e.g., acylonium ions, carbocations, nitrenium ions, Figs. 10.30 and 10.33), whereas soft electrophiles have a partial positive charge density and valence electrons that are delocalized (polarized), such as activated double bonds of α,β-unsaturated carbonyl compounds as shown in Fig. 10.32. Hard nucleophiles have high electronegativity (oxygen and nitrogen groups) and low polarization of valence electrons, whereas soft nucleophiles have low electronegativity and are more polarizable. The softest biological nucleophilic sites are cysteine thiol groups on proteins and glutathione (GSH). The primary and secondary amino groups of lysine and histidine or the hydroxyl groups of serine or threonine on proteins are hard nucleophiles, whereas the hardest nucleophiles are the oxygen atoms of purines and pyrimidines on DNA and RNA.

Based on the HSAB theory, the reaction rates and selectivities of electrophiles and nucleophiles are dependent upon comparable states of “hardness.” Specifically a soft electrophile such as quinoneimine will react predominantly with a soft nucleophile such as the thiol group of cysteine. A hard electrophile such as the acylonium ion formed from acyl glucuronide will react with hard nucleophiles such as the hydroxyl group of serine. This preferential non-enzymatic reactivity is due primarily to the high-energy transition state that acts as a barrier to the reaction of a hard electrophile with a soft nucleophile such as, the delocalized double bonds of p-benzoquinoneimines, p-benzoquinonemethides, and other α,β-unsaturated carbonyl intermediates which react by Michael- Type addition of the nucleophile to the polarized (partial positive charge) located on the β-carbon.

Adduct formation is dependent not only upon the physiochemical nature of the electrophilc but also upon the microenvironment of the nucleophilic center, which can vary significantly even among centers of the same elemental type (e.g., sulfur or amino groups). Thus, nucleophilic reactivity among free sulfhydryl groups on proteins can be diverse and, consequently, soft electrophilic metabolites will form adducts with the more reactive thiol groups on a given protein or free thiols on glutathione. This diversity in nucleophilic reactivity is a function of both steric and electronic factors mediated primarily by the tertiary structure of a protein. For example, adjacent acidic and basic amino acids on a protein significantly influence the reactivity of the target nucleophilic group. Depending upon the physiochemical nature of the electrophile, the resulting electrophilic metabolite can produce toxicity by reacting with either a soft thiol nucleophilic sites on proteins and free thiols such as GSH or harder nucleophilic centers on DNA and RNA to produce adducts.

For example, metabolic epoxidation of an aromatic ring produces an epoxide, a relatively hard electrophilic metabolite that will form a ring-opened hydroxyl adduct primarily with hard nucleophilic centers on guanine and adenine on DNA, and not with soft thiol nucleophiles. On the other hand, a soft electrophile such as the N-acetyl p-benzoquinone imine metabolite of acetaminophen will form adducts with thiol groups on proteins and free thiols on GSH, but not with hard nucleophilic groups on lysine or serine on proteins or with those on guanine and adenine on DNA. Glutathione offers little protection against carcinogens, most of which are hard nucleophiles. These examples show that the bioactivated metabolite can exhibit distinct electrophilic characteristics and different nucleophilic target molecules. Thus, soft electrophiles are associated with organ-specific toxicities, e.g., heptatotoxicity, renal toxicity, and hard electrophiles with carcinogenicity.

It therefore is necessary to identify targets for these reactive metabolites (i.e., covalently modified macromolecules) that are critical to the toxicological process. Hard electrophiles generally react with hard nucleophiles, such as the basic groups in DNA and lysine ω-amino residues in proteins. Soft electrophiles react with soft nucleophiles, which include cysteine residues in proteins and in glutathione. Unfortunately, no simple rules predict the target macromolecules for a particular chemically reactive metabolite or the biological consequences of a particular modification. Furthermore, noncovalent interactions also

play a role, because covalent binding of hepatotoxins is not indiscriminate with respect to proteins. Even within a single protein, there can be selective modification of an amino acid side chain found repeatedly in the primary structure. Thus, the microenvironment (e.g., pK_a and hydrophobicity) of the amino acid in the tertiary structure appears to be the crucial determinant of selective binding and, therefore, the impact of covalent binding on protein function. In turn, the extent of binding and the biochemical role of the protein will determine the toxicological insult of drug bioactivation. The resulting pathological consequences will be a balance between the rates of protein damage and the rates of protein replacement and cellular repair.

Drug-Induced Idiosyncratic Reactions

Idiosyncratic drug reactions (IDR; type B adverse drug reactions) occur in from 1 in 1,000 to 1 in 50,000 patients, are not predictable from the known pharmacology or toxicology of the drug, are not produced experimentally in vitro and in vivo, and are dose independent. The occurrence of IDRs during late clinical trials or after a drug has been released can lead to severe restriction of its use and even its withdrawal. The IDRs usually do not result from the drug itself, because most people can tolerate the drug, but, rather, from a unique set of patient characteristics, including gender, age, genetic predisposition, and a lack of drug-metabolizing enzymes, that may increase the risk of these adverse drug reactions. Most IDRs are caused by hypersensitivity reactions and can result in hepatocellular injury. The hepatic injury occurs within 1 week to 12 months after initiation of drug therapy and often is accompanied by systemic characteristics of allergic drug reactions, such as rash and fever. Signs of hepatic injury reappear with subsequent administration of the same drug with only one or two doses. Hypersensitivity reactions can be severe and associated with fatal reactions as a multiorgan clinical syndrome usually characterized by the following: 1) fever; 2) rash; 3) gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea, or abdominal pain); 4) generalized malaise, fatigue, or achiness; and 5) respiratory symptoms (e.g., dyspnea, cough, or pharyngitis). Examples of drugs causing IDRs through a hypersensitivity mechanism include penicillin, methyldopa, chlorpromazine, erythromycin, azathioprine toxicity in thiopurine methyltransferase–deficient individuals, sulfonamide and acetaminophen hepatotoxicity in alcoholics and in UGT1A6 deficient cats, ivermectin neurotoxicity in Collie dogs deficient in P-gp, perhexilene hepatotoxicity in CYP2D6-deficient individuals, phenytoin toxicity in CYP2C9-deficient individuals, and valproic acid hepatotoxicity.

The clinical features of some cases of drug-induced idiosyncratic hepatotoxicity strongly suggest an involvement of the immune system (95). These clinical characteristics include the following: 1) concurrence of rash, fever, and eosinophilia; 2) delay of the initial reaction (1–8 weeks) or requirement of repeated exposure to the culprit drug; 3) rapid recurrence of toxicity on reexposure to the drug; and 4) presence of antibodies specific for native or drug-modified hepatic proteins. Our current understanding of drug-induced adaptive immune responses is largely based on the hapten hypothesis.

Idiosyncratic drug reactions that are connected with hepatotoxicity involve the formation of reactive metabolites (91,92). Such reactions

are not predictable, but current bioanalytical technology have enabled the in vivo identification of the formation of reactive metabolites, as evidenced by the detection of biomarkers (i.e., mercapturate or cysteine adducts) in urine, drug-specific antibodies, or antibodies to CYP isoforms (93). As a result, some drugs known to cause hepatic injury continue to be used, because the drug's benefit outweighs its risk and no alternative efficacious drug exists. For example, isoniazid, a drug commonly used to treat tuberculosis, is implicated in approximately 15 to 20% of the individuals who show increased serum transaminases after receiving the drug as a single agent for tuberculosis prophylaxis. Of these individuals, an estimated 1 in 1,000 patients may develop severe hepatic necrosis. Additionally, NSAIDs, including cyclooxygenase-2 inhibitors, commonly are associated with idiosyncratic liver injury. Most of the idiosyncratic toxins listed in Table 10.19 that have been studied to date produce reactive metabolites.

Current hypotheses regarding IDRs suggest that metabolic activation of a drug to a reactive metabolite is a

necessary yet insufficient step in the generation of an idiosyncratic reaction (91,92). Evidence for this hypothesis comes from drugs that are associated with hepatotoxicity (Table 10.19) and the detection of a drug-metabolite specific antibodies in affected patients.

Table 10.19. Some Examples of Idiosyncratic Toxins

Abacavir	Hypersensitivity
Acetaminophen	Hepatotoxicity
Amiodarone	Hepatotoxicity
Aromatic anticonvulsants	Hypersensitivity
Cefaclor	Hepatotoxicity
Clozapine	Agranulocytosis
Diclofenac	Hepatotoxicity
Felbamate	Aplastic anemia
Fibrates	Hepatotoxicity
Halothane	Hepatotoxicity
Indomethacin	Hepatotoxicity
Isoniazid	Hepatotoxicity
Levamisole	Hepatotoxicity
Nefazodone	Hepatotoxicity
Nevirapine	agranulocytosis
Oral contraceptives	Hepatotoxicity
Paroxetine	Hepatotoxicity
Phenytoin	Hepatotoxicity
Statins	Hepatotoxicity
Sulfonamides	Stevens-Johnson syndrome
Tamoxifen	Hepatotoxicity
Tacrine	Hepatotoxicity
Tienilic acid	Hypersensitivity
Ticlopidine	
Troglitazone	
Valproic acid	
Vesnarinone	
Penicillinaminea	

Agranulocytosis	
Hepatotoxicity	
Hepatotoxicity	
Agranulocytosis	
Hypersensitivity	

[a]Does not produce reactive metabolites.

For the other drugs that have been associated with idiosyncratic hepatotoxicity but that do not have black box warnings, either evidence for hepatotoxicity was not available or suitable studies had not been carried out. High doses increase the risk for an IDR (e.g., cloazapine at 300 mg/day vs. olanzapine 20 mg/day). Strong evidence also exists that T cells play an important role in immune-mediated IDR and can trigger cell death. In patients exhibiting IDR, pretreatment with immunosuppressants prevented the IDR (rash). The incidence of IDRs also appears to be lower in patients with low T-cell counts.

The hapten hypothesis proposes that the reactive metabolites of the drugs act as haptens and covalently bind to endogenous proteins to form immunogenic drug–protein adducts triggering either antibody or cytotoxic T-cell responses (92,96). The hapten hypothesis is supported by the detection of antibodies that recognize drug-modified hepatic proteins in the sera of drug-induced liver injury (DILI) patients. For example, antibodies that recognize trifluoroacetate-altered hepatic proteins have been detected in the sera of patients with halothane-induced hepatitis. Such drug-specific antibodies or autoantibodies that recognize native liver proteins also have been found in patients with liver injury caused by other drugs, such as diclofenac. In patients who developed IDRs of the liver and other organs, drug-specific T cells have been detected, and in some cases, T-cell clones were generated. Most drugs are small molecules and are unlikely to form haptens. Electrophilic acylators (hard electrophiles) can react with the lysine ω-amino residues (hard nucleophiles) of the target protein or guanosine residues of DNA. How much chemical modification is required to trigger an IDR remains unknown. Halothane is the most studied molecule for supporting this hypothesis regarding IDRs (91). Therefore, it is not surprising that irreversible chemical modification of a protein, which has a profound effect on function, is a mechanism of idiosyncratic hepatotoxicity. However, it is important to note that a number of drugs (e.g., penicillins, aspirin, and omeprazole) rely on covalent binding to proteins for their efficacy; thus, prevention of their covalent binding through chemical modification of the compound also may, inadvertently, lead to loss of efficacy.

Drug-induced stress and/or damage of hepatocytes may trigger activation and inflammatory responses of the immune system within the liver (95,96). Evidence to support this idea has been obtained mainly from studies of liver injury induced by overdoses of acetaminophen, which is one of the few drugs that provide an experimental animal model of drug-induced liver injury. Evidence is growing that the initial benzoquinoneimine-induced hepatocyte damage may lead to activation of immune cells within the liver, thereby stimulating hepatic infiltration by inflammatory cells. Activated T cells of the immune system produce a range of inflammatory mediators, including cytokines, chemokines, and reactive oxygen and nitrogen species, that contribute to the progression of liver injury. On the other hand, the immune cells also represent a major source of hepatoprotective factors.

Reactive Metabolites Resulting from Bioactivation

Electrophiles

The concept that small organic molecules can undergo bioactivation to electrophiles and free radicals and elicit toxicity by chemical modification of cellular macromolecules has its basis in chemical carcinogenicity and the pioneering work of the Millers (97) and Gillette et al. (98,99,100). A number of different types of reactive metabolites exist; however, they may be broadly classified as either electrophiles (Fig. 10.30) or free radicals (Fig. 10.31) (93,101). These reactive metabolites are short-lived, with half-lives of generally less than 1 minute, and usually are not detectable in plasma or urine except as phase 2 conjugates or other biomarkers. Electrophiles are reactive because they possess electron-deficient centers (polarization-activated double bonds or positive-charge acylators) (Figs. 10.30 and 10.32) and can form covalent bonds with electron-rich biological nucleophiles. They are either soft electrophiles that react directly with soft nucleophiles (:Nuc), such as the thiol groups in either glutathione or cysteine residues within proteins, or hard electrophiles that react with hard nucleophiles, such as basic groups in DNA and lysine ω-amino residues in proteins, or are mediated by bioinactivation enzymes, such as glutathione transferase or epoxide hydrase. Softness or hardness are associated with the polarizability of the electrophilic/nucleophilic species (see Hard/Soft Acids/Bases). Activated double bonds are soft electrophilic intermediates as shown in Fig. 10.32.

Examples of activated double bond electrophiles include α, β-unsaturated carbonyl compounds, quinones, quinoneimines, quinonemethides and diiminoquinones as shown in Fig. 10.32B. These electrophilic intermediates are highly polarized and can react with nucleophiles in a 1,4-Michael-type addition at the more electrophilic or β-carbon of the activated double bond intermediate to the addition product (Fig. 10.32A). Specific examples of activated double bond electrophiles that have been proposed for the anticancer drug leflunamide, the food antioxidant butylated hydroxytoluene, acetaminophen, the antiandrogen flutamide, the anticonvulsant felbamate and the cytotoxic cyclophosphamide as shown in Fig. 10.32C. The bioinactivation pathways for these electrophilic intermediate can involve either direct addition, with or without transferases, depending upon the degree of polarization and reactivity of the electrophilic intermediate (hard vs soft electrophiles).

Other commonly found electrophilic intermediate for drug molecules in Fig. 10.30 include the formation of ketenes from the bioactivation of acetylenic groups (e.g.,

ethinylestradiol) (Fig. 10.30-2), isocyanates from thiazoldinediones (e.g., the “glitazones”) (Fig. 10.30-4) (93), acylonium ions from halogenated hydrocarbons (e.g., halothane) (Fig. 10.30-3) (93) and carboxylic acids, β-dicarbonyl from furans (e.g., furosemide) (Fig. 10.30-5) (93), activated thiophene-S-oxide from thiophenes, such as ticlopidine, tenoxicam which cause an IDR, agranulocytosis (Fig. 10.30-6) (93), and epoxides and arene oxides from olefins and aromatic compounds (Fig 10.30-7)(93). Drug possessing structural features

prone to metabolic epoxidations are abundant. Therefore the incidence of epoxide metabolites in mediating adverse biologic effects has aroused concern about clinically used drugs known to be metabolized to epoxides. Metabolically produced epoxides have been reported for allobarbital, secpbarbital, protriptyline, carbamazepine, cyproheptadine, and are implicated with 8-methoxypsoralen and other furanocoumarins (6,7-dihydroxybergamottin in grapefruit juice), phenytoin, phensuximide, phenobarbital, mephobarbital, lorazepam, and imipramine (81). The alarming biologic effects of some epoxides, however, do not imply that all epoxides have similar effects. Epoxides vary greatly in molecular geometry, stability, electrophilic reactivity, and relative activity as substrates for epoxide-transforming enzymes (e.g., epoxide hydrolase, glutathione S-transferase, and other).

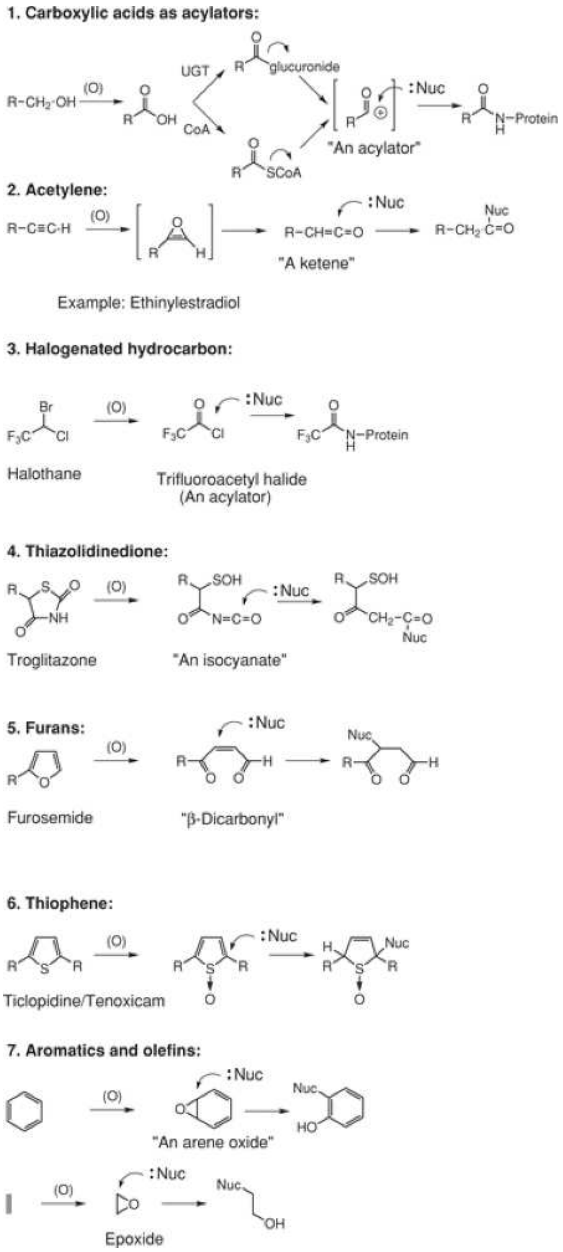

Fig. 10.30. Some examples of electrophilic intermediates resulting from bioactivation. NUC = nucleophiles.

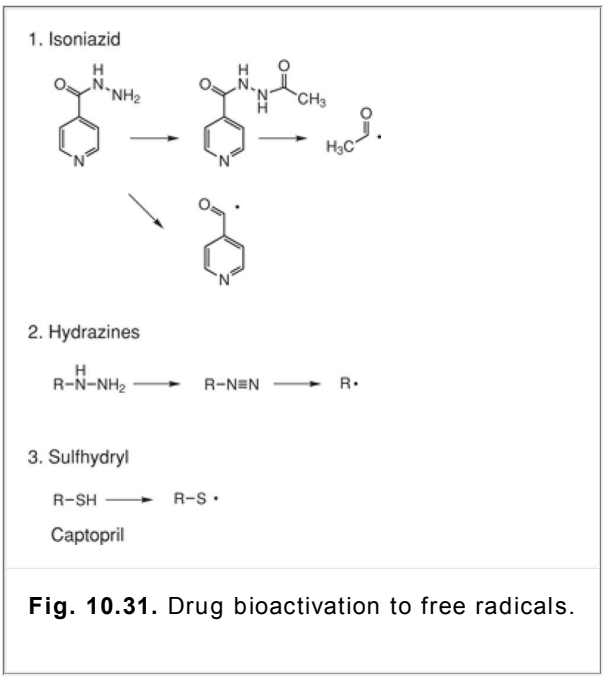

Fig. 10.31. Drug bioactivation to free radicals.

Some carboxylic acid–containing drugs have been implicated in rare IDRs, which was the basis for the market withdrawal of the NSAIDs, zomiperac, and benzoxaprofen. These drugs (e.g., NSAIDs, fibrates, "statins," and valproic acid) can be bioactivated to acyl glucuronides or acyl CoA thioesters (Fig. 10.30A). These products are electrophilic acylators that can acylate target proteins if they escape inactivation by S-glutathione–thioester formation. A crucial factor is the concentration of acyl glucuronides in hepatocytes because of their transport by conjugate export pumps, where acylglucuronides may selectively acylate canalicular membrane proteins. Acyl CoA esters may be either rapidly hydrolyzed or further metabolized in hepatocytes. Evidence is accumulating that acyl glucuronides can alter cellular function by haptenation of

peptides, target protein acylation or glycation, or direct stimulation of neutrophils and macrophages. The role of acyl CoA reactive metabolites is less clear. It should be noted that some noncarboxylic acid drugs can be biotransformed by oxidative metabolism in the liver to the respective carboxylic acids.

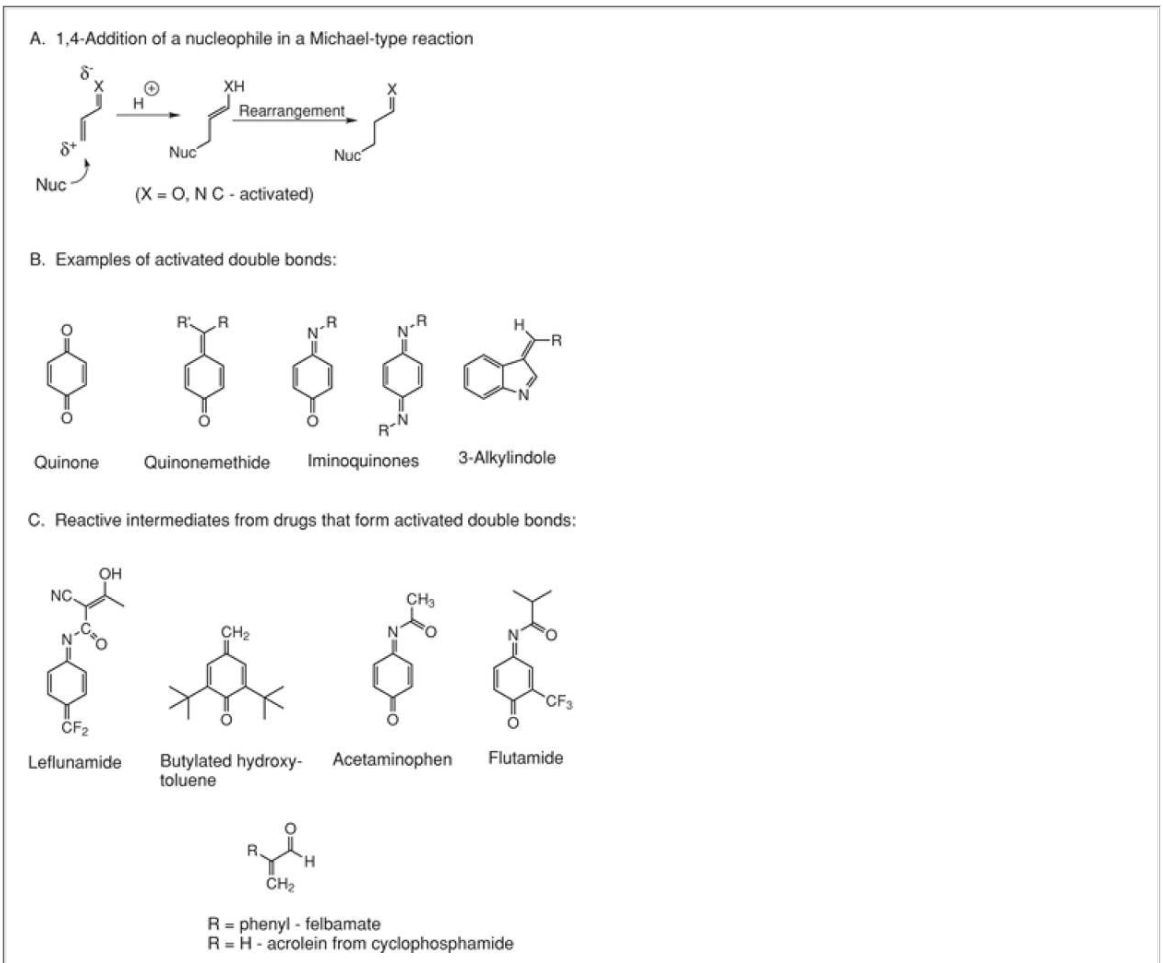

Fig. 10.32. Some examples of activated double bonds as electrophilic reactive intermediates.

Free Radicals

Cytochrome P450 activates molecular dioxygen to generate reactive oxygen species (ROS), such as singlet oxygen ($^1O_2$) or superoxide (see Oxygen Activation p. 269). Reactive metabolites that possess unpaired electrons are free radicals (molecular species which contain an odd unpaired electron) which can react with molecular oxygen (ground state triplet) to generate intracellular oxidative stress damage (93,98,99,100). Free radicals usually abstract a hydrogen atom from other molecules rather than becoming covalently bound. Free radical reactions can be self-propagating by abstracting a hydrogen atom from the double bond of a lipid that initiates a chain reaction leading to lipid peroxidation, oxidative stress or other types of modification of biological molecules.

Some examples of free-radicals generated by the bioactivation of drug molecules are shown in Fig. 10.31. Isoniazid is acetylated to its major metabolite acetylisoniazid, which is hydrolyzed to acetylhydrazine and isonicotinic acid (Fig. 10.31-1). Acetylhydrazine is further metabolized by the CYP2E1 to an N-hydroxy intermediate that hydrates into an acetyl radical, which can then initiate the process that leads to hepatic necrosis. Other carbon-centered radicals are formed from hydrazines such as the antihypertensive hydralazine, and thio-radicals from the ACE inhibitor captopril (Fig. 10.31-2 and -3).

Bioinactivation Mechanisms

Several enzyme systems exist as cellular defense (detoxification) pathways against the chemically reactive metabolites generated by CYP metabolism (91,92,102,103). These include GST, epoxide hydrolase, and quinone reductase, as well as catalase, glutathione peroxidase, and superoxide dismutase, which detoxify the peroxide and superoxide by-products of metabolism. The efficiency of the bioinactivation process is dependent on the inherent chemical reactivity of the electrophilic intermediate, its affinity and selectivity of the reactive metabolite for the bioinactivation enzymes, the tissue expression of these enzymes, and the rapid upregulation of these enzymes and cofactors mediated by the cellular sensors of chemical stress. The reactive metabolites that can evade these defense systems may damage target proteins and nucleic acids by either oxidation or covalent modification.

The most abundant agents of cellular defense are thiols. Glutathione is a soft electrophile and, therefore, will only react noncatalytically with soft electrophiles, such as activated double bonds (Fig. 10.32). Glutathione conjugation to mercapturates is one of the most important defenses against hepatocellular injury. Glutathione protects cellular enzymes and membranes from toxic metabolites, and its inadequate stores can compromise efficient detoxification of the reactive metabolites. The subsequent inability to detoxify the reactive metabolites can result in hepatocellular injury. The rate-limiting factor for glutathione synthesis is the intracellular concentration of cysteine. N-acetylcysteine is often used as an alternative to glutathione to trap the iminoquinone intermediate in the treatment of acute

acetaminophen toxicity. Glutathione plays a protective role in the hepatic tissue injury produced by acetaminophen but not by furosemide.

The relationship between bioactivation, bioinactivation, and DNA adduct formation has been well established for a number of hepatocarcinogens. Glutathione conjugation of hard electrophiles becomes more efficient when catalyzed by GSTs, an important example being the detoxication of the hepatocarcingen aflatoxin. Aflatoxin, a hepatocarcinogen and a hepatotoxin found in mold growing

on peanuts, is converted into aflatoxin B1 epoxide in rodents, which is more readily detoxified by GST enzymes than by epoxide hydrolase. The balance between these transferase reactions explains the greater DNA damage in humans compared with rodents, because human forms of GST are less able to catalyze the conjugation of aflatoxin epoxide compared with the rodent forms. Transgenic knockout mice have been used to establish the role of bioactivation by CYP450 and bioinactivation by GSTs for a number of carcinogenic polyaromatic hydrocarbons.

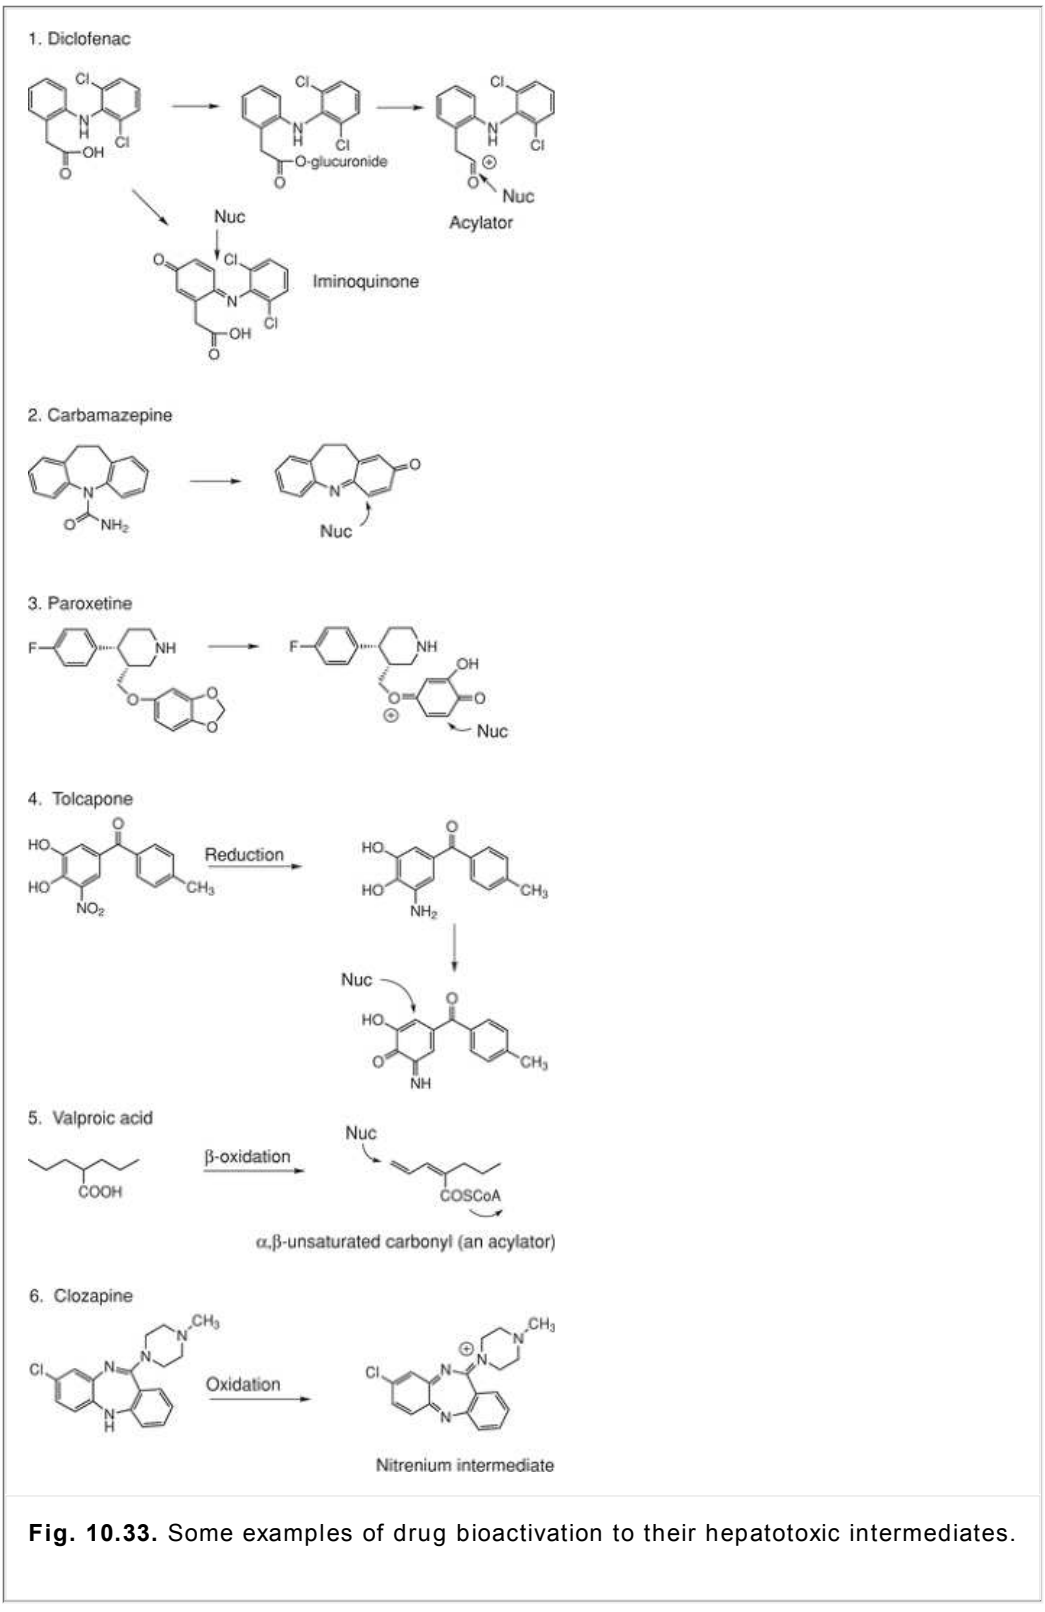

Fig. 10.33. Some examples of drug bioactivation to their hepatotoxic intermediates.

Substances that detoxify free radicals include the antioxidants vitamin C, vitamin E, and carotene, which scavenge free radicals, including reactive metabolites and reactive oxygen species generated as a consequence of chemical stress.

Specific Examples

Some examples of bioactivation to hepatotoxic or IDR electrophilic intermediates are shown in Fig. 10.33. Bioactivation may occur by both oxidation and conjugation reactions, such as those with diclofenac, which undergoes the formation of an acyl glucuronide and/or acyl CoA (acylator intermediates) or to produce iminoquinones via formation of a phenol intermediator (Fig. 10.33-1) (92). The anticonvulsant carbamazepine is 2-hydroxylated and the elimination of the amide group yields the reactive quinoneimine intermediate (Fig. 10.33-2), and the antidepressant paroxetine and other xenobiotics with the common methylenedioxyphenyl nucleus undergo methylene oxidation to a

p-quinoid intermediate (Fig. 10.33-3). The COMT inhibitor used in the treatment of Parkinsonism, tolcapone, the nitro group is first reduced to an amine, then oxidized to a *o*-quinoneimine (Fig. 10.33-4). The mitochondrial/hepatotoxocity of the anticonvulsant valproic acid results from the formation of an activated α,β-unsaturated CoA thioester via mitochrondrial β-oxidation, most commonly associated with the oxidation of fatty acids (Fig. 10.33-5). The agranulocytosis resulting from the ingestion of the antipsychotic clozapine is bioactivated by its oxidation by hypochlorous acid in neutrophils to a nitrenium intermediate (Fig. 10.33-6) (93). The effect of structure modification for troglitazone that reduced its hepatotoxicity is shown in Fig. 10.34. The *p*-dihydroxy elements of the chroman ring nucleus (outlined in bold bonds in Fig. 10.34) of troglitazone is bioactivated to an activated double bond (*p*-quinone) and has been replaced with a pyridine ring that is not bioactivated, although the thiazolidone ring can be bioactivated to an isocyanate (Fig. 10.30) (92).

The oxidation of acetaminophen to the chemically reactive N-acetyl-*p*-benzoquinoneimine (Fig. 10.32), is catalyzed by the isoforms CYP1A2 and CYP2E1, which can either react covalently with glutathione to form an inactive product or with cellular macromolecules, initiating the processes leading to hepatic necrosis (Fig. 10.28) (93). The usual route for acetaminophen metabolism is either glucuronidation. If insufficient UDP-glucuronic acid is present, then bioactivation will dominate.

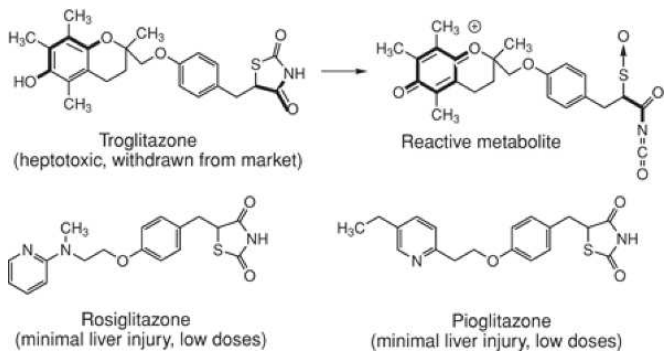

Fig. 10.34. The effect of structure modification on the drug-induced hepatotoxicity of troglitazone.

Furosemide, a frequently used diuretic drug, is reportedly a human hepatocarcinogen. The hepatic toxicity apparently results from metabolic activation of the furan ring to a β-dicarbonyl intermediate (Fig. 10.30-5) (93). Ticlopidine and tenoxicam, reported to cause agranulocytosis, do so via metabolic activation of the thiophene ring to an S-oxide (Fig. 10.30-6) (93). The agranulocytosis resulting from the ingestion of clozapine is via its bioactivation to a nitrenium ion intermediate (Fig. 10.33-6) (96,97,98,99,100,101).

Drug-Induced Chemical Carcinogenesis

The mechanism whereby xenobiotics are transformed into chemical carcinogens is generally accepted as bioactivation to reactive metabolites, which are responsible for initiating carcinogenicity (98,99,100). Many carcinogens elicit their cytotoxicity through a covalent linkage to DNA. This process can lead to mutations and, potentially, to cancer. Most chemical carcinogens of concern are chemically inert but require activation by the xenobiotic-metabolizing enzymes before they can undergo reaction with DNA or proteins (cytotoxicity). There are many ways to bioactivate procarcinogens, promutagens, plant toxins, drugs, and other xenobiotics (37) (Fig. 10.35). Oxidative bioactivation reactions are by far the most studied and common. Conjugation reactions (Phase 2), however, are also capable of activating these xenobiotics to produce electrophiles, in which the conjugating derivative acts as a leaving group. These reactive metabolites are mostly electrophiles, such as epoxides, quinones, or free radicals formed by the CYP450 enzymes or FMO. The reactive metabolites tend to be oxygenated in sterically hindered positions, making them poor substrates for subsequent bioinactivation transferases, such as epoxide hydrolase and GST. Therefore, their principal fate is formation of covalent linkage to intracellular macromolecules, including enzyme proteins and DNA. Experimental studies indicate that the CYP1A subfamily can oxygenate aromatic hydrocarbons (e.g., PAHs) in sterically hindered positions to arene oxides. Activation by N-hydroxylation of polycyclic aromatic amines (e.g., aryl N-acetamides) appears to depend on either FMO or CYP450 isoforms. The formation of chemically reactive metabolites is important, because they frequently cause a number of different toxicities, including tumorigenesis, mutagenesis, tissue necrosis, and hypersensitivity reactions.

Our understanding of these reactions was advanced by the studies of the Millers (97) and Gillette et al. (98,99,100). They proposed that the proportion of the dose that binds covalently to critical macromolecules could depend on the quantity of the reactive metabolite is formed.

A scheme illustrating the complexities of drug-induced chemical carcinogenesis is shown in Fig. 10.35. Reactions that proceed via the open arrows eventually lead to neoplasia. Some carcinogens may form the “ultimate carcinogen” directly through CYP450 isoform bioactivation; others, like the PAHs (e.g., benzo[a]pyrene), appear to involve a multistep reaction sequence forming an epoxide, reduction to a diol by axpoxide hydrase and perhaps, the formation of a second epoxide group on another part of the molecule.

Other procarcinogens form the N-hydroxy intermediate that requires transferase-catalyzed conjugation (e.g., O-glucuronide and O-sulfate) to form the “ultimate carcinogen.” The quantity of “ultimate carcinogen” formed should relate directly to the proportion of the dose that binds or alkylates DNA.

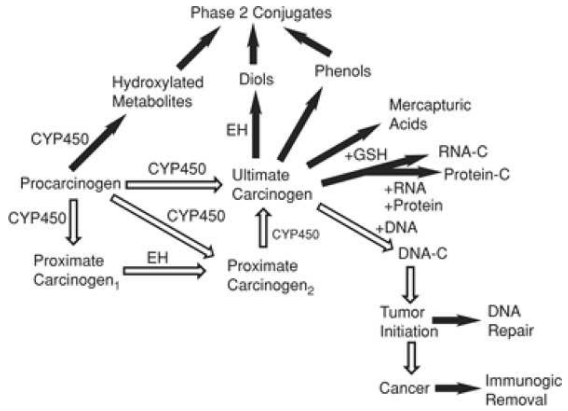

Fig. 10.35. The bioactivation of procarcinogens and a proposed mechanism of chemical carcinogenesis.

The solid-arrow reaction sequences in Figure 10.35 are intended to show detoxification mechanisms, which involve several steps. First, the original chemical may form less active products (phenols, diols, mercapturic acids, and other conjugates). Second, the "ultimate carcinogen" may rearrange so as to be prevented from its reaction with DNA (or whatever the critical macromolecule is). Third, the covalently bound DNA may be repaired. Fourth, immunologic removal of the tumor cells may occur. Several mechanisms within this scheme could regulate the quantity of covalently bound carcinogen: 1) The activity of the rate-limiting enzyme, such as epoxide hydrolase, CYP450 isoform, or one of the transferases, could be involved; 2) the availability of cosubstrates, such as glutathione, UDP-glucuronic acid, or PAPS, may be rate-limiting; 3) relative CYP450 activities for detoxification and activation must be considered; 4) availability of alternate reaction sites for the ultimate carcinogen (e.g., RNA and protein may be involved); 5) and possible specific transport mechanisms that deliver either the procarcinogen or its ultimate carcinogen to selected molecular or subcellular sites.

It is now well established that numerous organic compounds that are essentially nontoxic as long as their structure is preserved can be converted into cytotoxic, teratogenic, mutagenic, or carcinogenic compounds by normal biotransformation pathways in both animals and humans (37). The reactive electrophilic intermediate (hard acids) involves its reaction with cellular constituents (hard bases) forming either detoxified products or binding covalently with essential macromolecules, initiating processes that eventually lead to the toxic effect. A better understanding of the mechanisms underlying these reactions may lead to more rational approaches to the development of nontoxic therapeutic drugs. For the present, it seems that new advances in drug therapy cannot occur without some risk of causing structural tissue lesions. Special attention to risk factors is required for drugs that will be used for long periods in the same patient.

Some toxic chemicals exert their toxic action by lethal injury or biological auto-oxidation (radical lipid peroxidation). Lethal injury involves the disruption of cellular energy metabolism by inhibition of oxidative phosphorylation or adenosine triphosphatase, resulting in disruption of subcellular organelles, cell death, and tissue necrosis. Because the early stages of lethal injury are reversible, complete recovery may occur. Auto-oxidation is the process whereby cellular components are irreversibly oxidized and damaged by free radicals or free radical–generating systems. This results in the oxidation and depletion of glutathione, various thiol enzymes, or lipid peroxidation, which in turn leads to the disruption of cellular membranes and to cell death, tissue necrosis, and death of the organism. When cell death does not occur, nonlethal changes, such as mutations and malignant transformations, are likely.

Drug–Drug Interactions

Drug–drug interactions represent a common clinical problem, which has been compounded by the introduction of many new drugs and the expanded the use of herbal medicines. Between 1999 and 2005, approximately 100 drug–drug interactions were reported, of which approximately 50% involved CYP450 inhibition. Drug–drug interactions occur when the efficacy or toxicity of a medication is changed by coadministration of another substance, drug, food (i.e., grapefruit), or herbal product (103,104). Pharmacokinetic interactions often occur as a result of a change in drug metabolism. For example, CYP3A4 oxidizes more than 60% of the clinically used drugs with a broad spectrum of structural features, and its location in the small intestine and liver permits an effect on both presystemic and systemic drug disposition. Some interactions with CYP3A4 substrates/inhibitors also may involve inhibition of P-gp. Other clinically important drug interactions resulting from coadministration of CYP3A4 substrates or inhibitors include rhabdomyolysis with the coadministration of some 3-hydroxy-3-methylglutaryl–CoA reductase inhibitors ("statins"), symptomatic hypotension with some dihydropyridine calcium antagonists, excessive sedation from benzodiazepine or nonbenzodiazepine hypnosedatives, ataxia with carbamazepine, and ergotism with ergot alkaloids.

The clinical importance of any drug–drug interaction depends on factors that are drug-, patient-, and administration-related. Drugs with low oral bioavailability or high first-pass metabolism are particularly susceptible to drug–drug interactions as a result of coadministration of inhibitors that alter absorption, distribution, and elimination. Generally, a doubling or more in the plasma drug concentration has the potential for enhanced adverse or beneficial drug response. Less pronounced pharmacokinetic interactions may still be clinically important for drugs with a steep concentration–response relationship or narrow therapeutic index. In most cases, the extent of drug interaction varies markedly among individuals; this is likely to be dependent on interindividual differences in CYP450 content (polymorphism), preexisting medical conditions, and possibly, age. Interactions may occur under single-dose conditions or only at steady state. The pharmacodynamic consequences may or may not closely follow pharmacokinetic changes. Drug–drug interactions may be most apparent when patients are stabilized on the affected drug and the CYP450 substrates or inhibitors are then added to the regimen (103). One reason for the increased incidence of drug–drug interactions is the practice of simultaneously prescribing several potent drugs as well as

concurrently ingesting nonprescription products and herbal products.

P.316

Although drug–drug interactions constitute only a small proportion of adverse drug reactions, they have become an important issue in health care. Many of the drug–drug interactions can be explained by alterations in the metabolic enzymes in the liver and other extrahepatic tissues, and many of the major pharmacokinetic interactions between drugs are caused by hepatic CYP450 isoenzymes being affected by coadministration of other drugs. Some drugs act as potent enzyme inducers, whereas others are inhibitors. Drug–drug interactions involving enzyme inhibition, however, are much more common. Understanding these mechanisms of enzyme inhibition or induction is extremely important to give appropriate multidrug therapies. In the future, individuals at greatest risk for drug–drug interactions and adverse events need to be identified. Cytochrome P450s play a dominant role in the metabolism and elimination of drugs from the body, and their substrates are shown in Tables 10.3 and 10.6 through 10.9. Drugs in bold italics have been associated with drug interactions (103). Inhibitors of CYP450 are shown in Table 10.10. Pharmacokinetic interactions may arise when the biotransformation and elimination of a drug are impaired by coadministered drugs. Thus, drugs may compete for biotransformation by a common CYP450. Adverse drug reactions, including toxicity, can occur if elimination is dependent on a CYP450 that exhibits defective gene variants. Thus, the genetic makeup of the individual (see the section on genetic polymorphism) has a major influence on the duration of drug action as well as on drug efficacy and safety. CYP450 pharmacogenetics affects the tendency for certain drug–drug interactions to occur. Thus, the future safe use of drug combinations in patients may require genotyping and phenotyping of individuals before the commencement of therapy. Identification of subjects who metabolize drugs in a different fashion from the general population should minimize the impact of pharmacogenetic variation on drug pharmacokinetics.

Many drug–drug interactions are a result of inhibition or induction of CYP450 enzymes. Metabolism-based enzyme inhibition usually involves competition between two drugs for the enzyme-active site. Metabolic drug–drug interactions occur when drug A (or its metabolite) alters the pharmacokinetics of a coadministered drug B by inhibiting, activating, or inducing the activity of the enzymes that metabolize drug B. Inhibitory drug–drug interactions could result in serious adverse effects, including fatalities in patients receiving multiple medications. This process is usually competitive, begins with the first dose of the inhibitor, and the extent of inhibition correlates with their relative affinities for the enzymes and the metabolic half-lives of the drugs involved. On the other hand, mechanism-based (irreversible) inhibition results from a metabolite that binds irreversibly with a covalent bond to the enzyme, rendering the enzyme inactive. Enzyme-specific CYP450 inhibitors, including metabolism- and mechanism-based inhibitors, or are metabolized by specific CYP450 isoforms and are usually excluded from further consideration for new drug development. Not only is CYP3A4 the most abundant isoform in human liver, it also metabolizes more than 60% of the drugs in clinical use, which renders CYP3A4 highly susceptible to both metabolism- (reversible) and mechanism-based inhibition. The CYP3A subfamily is involved in many clinically significant drug–drug interactions, including those involving nonsedating antihistamines and cisapride, that may result in cardiac dysrhythmias. For example, inhibitors of CYP1A2 can increase the risk of toxicity from clozapine or theophylline. Inhibitors of CYP2C9 can increase the risk of toxicity from phenytoin, tolbutamide, and oral anticoagulants (e.g., warfarin). Inhibitors of CYP3A4 can increase the risk of toxicity from many drugs, including carbamazepine, cisapride, cyclosporine, ergot alkaloids, lovastatin, pimozide, protease inhibitors, rifabutin, simvastatin, tacrolimus, and vinca alkaloids. Inhibitors of CYP2D6 can increase risk of toxicity of many antidepressants, opiate analgesics, and psychotherapeutic agents. An excellent example of a metabolism-based inhibition drug–drug interaction that resulted in a life-threatening ventricular arrhythmia associated with QT prolongation (torsades de pointes) occurred when CYP3A4 substrates or inhibitors were coadministered with terfenadine, astemizole, cisapride, or pimozide. This potentially lethal drug interaction led to the withdrawal of terfenadine and cisapride from clinical use and to the introduction of fexofenadine, the metabolite of terfenadine, which does not have this interaction. Examples of enzyme inducers include barbiturates, carbamazepine, glutethimide, griseofulvin, phenytoin, primidone, rifabutin, and rifampin. Some drugs, such as ritonavir, may act as either an enzyme inhibitor or an enzyme inducer, depending on the situation. Drugs metabolized by CYP3A4 or CYP2C9 are particularly susceptible to enzyme induction.

Mechanism-based inhibition is characterized by NADPH-, time-, and concentration-dependent enzyme inactivation, occurring when some drugs are converted by CYP450s to reactive metabolites (103). Mechanism-based inactivation of CYP3A4 by drugs can be the result of chemical modification of the heme, the apoprotein, or both, as a result of covalent binding of the modified heme to the protein. The clinical pharmacokinetic effect of a CYP3A4 inactivator is a function of its enzyme kinetics (i.e., K_m and V_{max}) and the synthesis rate of new or replacement enzyme. Predicting drug–drug interactions involving CYP3A4 inactivation is possible when pharmacokinetic principles are followed. Such prediction may become difficult, however, because the clinical outcomes of CYP3A4 inactivation depend on many factors associated with the enzyme, the drugs, and the patients.

Some of the clinically important drugs that have been identified to be mechanism-based CYP3A4 inhibitors include antibiotics (e.g., erythromycin), anticancer drugs (e.g., irinotecan), antidepressants (e.g., fluoxetine and paroxetine), anti-HIV agents (e.g., ritonavir and

P.317

delavirdine), antihypertensives (e.g., dihydralazine and verapamil), steroids and their receptor modulators (e.g., ethinyl estradiol, gestodene, and raloxifene), dihydrotestosterone reductase inhibitors (e.g., finasteride), and some herbal constituents (e.g., bergamottin and glabridin). Compared to the more common metabolism-based (reversible) inhibition, mechanism-based inhibitors of CYP3A4 usually are the cause for unfavorable drug–drug interactions, because the inactivated CYP3A4 must be replaced by newly synthesized CYP3A4 protein. Most CYP3A4 inactivators also are P-gp substrates/inhibitors, confounding the in vitro–to–in vivo extrapolation. Clinicians should have good knowledge about these CYP3A4 inactivators and avoid their combination use.

The clinical significance of CYP3A inhibition for drug safety and efficacy warrants closer understanding of the mechanisms for each inhibitor. Furthermore, such inactivation may be exploited for therapeutic gain in certain circumstances.

By understanding the unique functions and characteristics of these enzymes, health care practitioners may better anticipate and manage drug interactions. They also may predict or explain an individual's response to a particular therapeutic regimen.

Beneficial Drug–Drug Interactions

A beneficial drug interaction, for example, is the coadministration of a CYP3A4 inhibitor with cyclosporine, which allows reduction of the dosage and cost of the immunosuppressant. Certain HIV protease inhibitors, such as saquinavir, have a low oral bioavailability because of intestinal CYP3A4 metabolism. The oral bioavailability of saquinavir can be profoundly increased by the addition of a low dose of a CYP3A4 inhibitor, such as ritonavir. This concept of altering drug pharmacokinetics by adding a low, subtherapeutic dose of a CYP3A4 inhibitor (ritonavir) to increase the oral bioavailability of another protease inhibitor,

lopinavir (CYP3A4 substrate), led to the marketing of Kaletra, a new drug combination of lopinavir and ritinavir.

Grapefruit Juice–Drug Interactions

Historical Significance of Grapefruit Juice

The discovery that grapefruit juice can markedly increase the oral bioavailability of CYP3A4 drugs was based on an unexpected observation from an interaction study between the dihydropyridine calcium channel antagonist felodipine and ethanol in which grapefruit juice was used to mask the taste of the ethanol. Subsequent investigations confirmed that grapefruit juice significantly increased the oral bioavailability of felodipine by reducing presystemic felodipine metabolism through selective inhibition of CYP3A4 expression in the intestinal wall (106).

Grapefruit juice is a beverage often consumed at breakfast for its health benefits and to mask the taste of drugs or foods. Unlike other citrus fruit juices, however, grapefruit juice can significantly increase the oral bioavailability of drugs that are metabolized primarily by intestinal CYP3A4, causing an elevation in their serum concentrations (Table 10.20). Those drugs with high oral bioavailabilities (>60%), however, are all likely safe to take with grapefruit juice, because their high oral bioavailability leaves little room for elevation by grapefruit juice. The importance of the interaction appears to be influenced by individual patient susceptibility, type and amount of grapefruit juice, and administration-related factors.

Grapefruit juice can alter oral drug pharmacokinetics by different mechanisms. Irreversible inactivation of intestinal CYP3A4, which can persist up to 24 hours, is produced by grapefruit juice given as a single, normal, 200- to 300-mL drink or by whole fresh fruit segments (Table 10.20). As a result, presystemic metabolism is reduced, and oral drug bioavailability increased. Enhanced oral drug bioavailability can occur up to 24 h after juice consumption. Inhibition of P-gp is a possible mechanism that increases oral drug bioavailability by reducing intestinal and/or hepatic efflux transport. Inhibition of organic anion–transporting polypeptides by grapefruit juice and apple juice has been observed; intestinal uptake transport appeared to be decreased as oral drug bioavailability was reduced. Numerous medications used in the prevention or treatment of coronary artery disease and its complications have been observed or predicted to interact with grapefruit juice. Such interactions may increase the risk of rhabdomyolysis when dyslipidemia is treated with the HMG-CoA reductase inhibitors (“statins”). Such interactions also might cause excessive vasodilatation when hypertension is managed with the dihydropyridines felodipine, nicardipine, nifedipine, nisoldipine, or nitrendipine. An alternative agent could be amlodipine. The therapeutic effect of the angiotensin II type I receptor antagonist losartan may be reduced by grapefruit juice. Grapefruit juice interacting with the antidiabetic agent repaglinide may cause hypoglycemia, and interaction with the appetite suppressant sibutramine may cause elevated blood pressure and heart rate. In angina pectoris, administration of grapefruit juice could result in atrioventricular conduction disorders with verapamil or attenuated antiplatelet activity with clopidrogel. Grapefruit juice may enhance the drug toxicity for antiarrhythmic agents, such as amiodarone, quinidine, disopyramide, or propafenone, and for the congestive heart failure drug carvediol. Some drugs for the treatment of peripheral or central vascular disease also have the potential to interact with grapefruit juice. Interaction with sildenafil, tadalafil, or vardenafil for erectile dysfunction may cause serious systemic vasodilatation, especially when combined with a nitrate. In stroke, interaction with nimodipine may cause systemic hypotension.

Table 10.20. Some CYP3A4 Substrates and Interactions with Grapefruit Juice (78)

Drug	Interactiona	Drug	Interactiona
Calcium channel blocker		HMG-CoA reductase inhibitors	
Amlodipine	Y	Atorvastatin	Y
Felodipine	Y	Cerivastatin	Y?
Nifedipine	Y	Fluvastatin	N?
Nimodipine	Y	Lovastatin	Y
Nisoldipine	Y	Pravastatin	N?
Nitrendipine	Y	Simvasta	Y
Pranidipine	Y	CNS Drugs	
Antiarrhythmics		Buspirone	Y
Diltiazem	N	Carbamazepine	Y

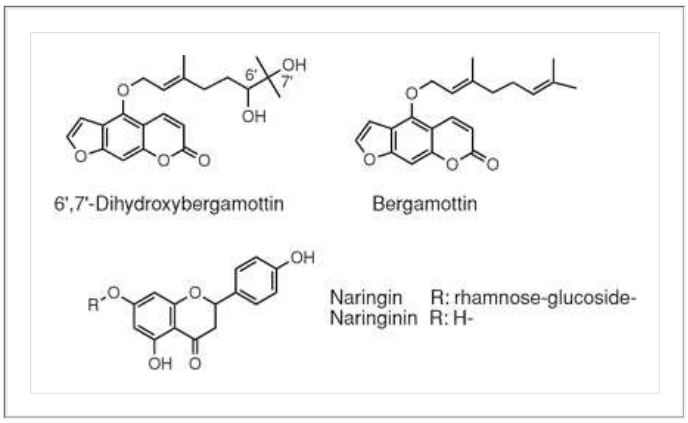
Verapamil	N	Diazepam	Y
Quinidine	N	Midazolam	Y
Antihistamines		Triazolam	Y
Ebastine	Y?	Immunosuppressants	
Loratidine	Y?	Cyclosporine	Y
HIV protease inhibitors		Tacrolimus	Y?
Indinavir	N?	Other	
Nelfinavir	N?	Methadone	Y
Ritonavir	N?	Sildenafil	Y
Saquinavir	Y		
Macrolides			
Clarithromycin	N		

[a]Y (yes) and N (no) indicate published evidence of the presence or absence of an interaction with grapefruit juice. Y? and N? indicate expected findings based on available data. Those drugs with Y or Y? should not be consumed with grapefruit juice in an unsupervised manner.

If a drug has low inherent oral bioavailability from presystemic metabolism by CYP3A4 or efflux transport by P-gp and the potential to produce serious overdose toxicity, avoidance of grapefruit juice entirely during pharmacotherapy appears mandatory. Although altered drug response is variable among individuals, the outcome is difficult to predict, and avoiding the combination will guarantee that toxicity is prevented. The elderly are at particular risk, because they often are prescribed medications and frequently consume grapefruit juice.

The mechanism by which grapefruit juice produces its effect is through inhibition of the enzymatic activity and a decrease in the intestinal expression of CYP3A4. The P-gp efflux pump also transports many CYP3A4 substrates; thus, the presence of inhibitors of P-gp in grapefruit juice (e.g., 6′,7′-dihydroxybergamottin and other furanocoumarins) could be a related factor for drug–grapefruit juice interactions (82). Numerous studies have shown that grapefruit juice acts on intestinal CYP3A4, not at the hepatic level.

Does the quantity of juice matter? The majority of the presystemic CYP3A4 inhibition is obtained following ingestion of one glass of grapefruit juice; however, 24 hours after ingestion of a glass of grapefruit juice, 30% of its effect is still present (78). The reduction in intestinal CYP3A4 concentration is rapid: a 47% decrease occurred in a healthy volunteer within 4 hours after consuming grapefruit juice. Daily ingestion of grapefruit juice results in a loss of CYP3A4 from the small intestinal epithelium. Consumption of very large quantities of grapefruit juice (six to eight glasses/day) may lead to inhibition of hepatic CYP3A4.



The active constituents found in grapefruit juice responsible for its effects on CYP3A4 include flavonoids (e.g., naringenin and naringin) and furanocoumarins (e.g., bergamottin and 6′,7′-dihydroxybergamottin) (82). Of particular interest are the effects of naringin and 6′,7′-dihydroxybergamottin on the activity of intestinal CYP3A4. The majority of studies to date have used either freshly squeezed grapefruit juice, reconstituted frozen juice, commercial grapefruit juice, grapefruit segments, or grapefruit extract; all are capable of causing drug–drug interactions with CYP3A4 substrates (blended grapefruit juices have not yet been investigated). The active constituents in grapefruit juice are present not just in the juice but also in the pulp, peel, and core of the fruit and are responsible for its flavor. Bergamottin and 6′,7′-dihydroxybergamottin are potent mechanism-based inhibitors of CYP3A4, and naringenin isomers are competitive inhibitors of CYP3A4 (82). Higher concentrations of 6′,7′-dihydroxybergamottin

and naringin are present in grapefruit segments. Thus, any therapeutic concern for a drug interaction with grapefruit juice should now be extended to include whole fruit and other products derived from the grapefruit peel. The difference in the in vitro CYP3A4 inhibition between grapefruit juice and orange juice is that orange juice contained no measurable amounts of 6′,7′-dihydroxybergamottin.

If a patient has been taking medication with grapefruit juice for some time without ill effects, is it safe to continue to do so? Much of this unpredictability results from the inconsistency of the juice concentrations and the sporadic manner in which grapefruit juice is consumed, suggesting that this approach may not be entirely safe (106). Given the unpredictability of the effect of grapefruit juice on the oral bioavailability of the drugs in Table 10.20, patients should be advised to avoid this combination, thus preventing the onset of potential adverse effects. Each patient's situation should be considered, and advice should be based on consumption history and the specific medications involved. The benefits of increased and controlled drug bioavailability by grapefruit juice may, in the future, be achieved through either standardizing the constituents or coadministration of the isolated active ingredients. This would then lead to a safe, effective, and cost-saving means to enhance the absorption of many therapeutic agents.

P-glycoprotein–Drug Interactions

From the earlier discussion regarding P-gp, it is obvious that P-gp–mediated transport plays an important role in pharmacokinetic-mediated drug–drug interactions (79). Thus, inhibition of P-gp–mediated transport could dramatically increase the systemic bioavailability of an otherwise poorly absorbed drug. Similar consequences could be expected with a reduction in renal or biliary clearances (e.g., digoxin). Numerous investigations with drugs such as digoxin, etoposide, cyclosporine, vinblastine, taxol, loperamide, domperidone, and ondansteron demonstrate that P-gp has an important role in determining the pharmacokinetics of substrate drugs (79). For example, if drug A is a substrate for both P-gp and *only* for CYP3A4, and if a second drug B is added that is an inhibitor for both P-gp and CYP3A4 (Table 10.16), then the plasma drug concentration for unmetabolized drug A will be elevated, with increased potential for drug–drug interactions as adverse effects or for causing a drug overdose. If drug A is a substrate for multiple CYP450 isoforms, however, then drug A will be metabolized by these other isoforms, with minimal effect on plasma drug concentrations. On the other hand, if the second drug B is only an inhibitor for P-gp, then drug A will be subject to CYP3A4 metabolism, thus decreasing the plasma concentration for drug A to subtherapeutic levels. The effect of P-gp inhibition is to increase the oral bioavailability so that the later actions of CYP3A4 inhibition will be increased. One of the best examples is the interaction between digoxin and quinidine. Quinidine blocks P-gp in the intestinal muscosa and in the proximal renal tubule; thus, digoxin elimination into the intestine and urine is inhibited, increasing the plasma digoxin concentration to toxic levels. Another example is loperamide, which is an opiate antidiarrheal normally kept out of the brain by the P-gp pump; however, inhibition of P-gp allows accumulation of loperamide in the brain, leading to respiratory depression. Increasingly, the relevant clinical data for drug interactions can be found on the World Wide Web.

The components of grapefruit juice reportedly inhibit P-gp, and this may be one of the mechanisms for the increase in bioavailability of drugs that are substrates for P-gp (Table 10.16). Although fexofenadine is a P-gp substrate, rather than a decrease in its plasma levels when it is coadministered with grapefruit juice, the blood levels are increased as a result of fexofenadine being a substrate of the anion transporter (OATP) in the intestine. Studies have shown that apple and other fruit juices are more potent inhibitors of OATP than of P-gp.

Food–Drug Interactions

Drug pharmacokinetics can be altered by the fat content of food through changes in drug solubility as well as the nutritional status of a patient (107). The fact that grapefruit juice can increase the bioavailability of certain drugs by their reducing presystemic intestinal metabolism has led to renewed interest in the area of “food–drug interactions,” with particular interest regarding the effects of grapefruit constituents. Specific naturally occurring chemicals in food have been associated with drug interactions. For example, severe hypertensive reactions have occurred when patients treated with antidepressant MAO inhibitors have ingested cheeses and other foods rich in the biogenic amine tyramine (see Chapter 21).

Drug–Dietary Supplement Interactions

The increasing use of dietary supplements presents a special challenge in health care; thus, there is an increasing need to predict and avoid these potential adverse drug–dietary supplement interactions. The present interest and widespread use of herbal remedies has created the possibility of interaction between them and over-the-counter or prescription drugs if they are used simultaneously. As herbal medicines become more popular, herbal hepatotoxicity is being increasingly recognized. Females appear to be predisposed to hepatotoxicity, and coadministered agents that induce CYP450 enzymes (e.g., St. Johns wort) also may increase individual susceptibility to some dietary supplements. Currently, nearly one in five adults taking prescription medicines also are taking at least one dietary supplement. The mechanisms for drug–dietary supplement interactions are similar to those for drug–drug interactions affecting the pharmacokinetics of the respective drug. Little is known regarding the pharmacokinetic properties of many of the substances in dietary supplements. Therefore, the

potential for drug–dietary supplement interactions has greatly increased. Licorice, when taken with steroids, can reduce their metabolism and elimination.

St. John's Wort

A commonly reported drug–dietary supplement interaction is between St. John's Wort and HIV protease inhibitors, leading to drug resistance and treatment failure. St. John's wort is a popular dietary supplement often used for depression. Of the two substances found in St. John's wort, hypericin and hyperforin, hyperforin appears to be the main constituent, with in vitro selective serotonin reuptake inhibitor (SSRI) activity (see Chapter 21). Hyperforin also appears to be the more potent inducer of CYP3A enzymes based on in vitro and in vivo studies.

The U.S. FDA has issued a statement that "concomitant use of St. John's wort with protease inhibitors or nonnucleoside reverse transcriptase inhibitors is not recommended." St. John's wort appeared to have minimal effects on the CYP3A4 enzymes after acute administration; however, chronic administration (≥2 weeks) of St. John's wort selectively induced CYP3A4, with a greater effect in the small intestine than in the liver. Administration of St. John's wort for 8 weeks decreased the plasma levels of norethindrone, a low-dose oral contraceptive, and reduced the half-life of ethinyl estradiol, consistent with increased CYP3A activity, increase breakthrough bleeding, and reduce contraceptive efficacy. Based on the these in vivo and in vitro studies, the efficacy of drugs that are substrates for the CYP3A family or P-gp may be reduced on coadministration of St. John's wort. St. John's wort should be listed along with other known CYP3A inducers (e.g., rifampin and rifabutin) as possibly decreasing plasma levels of CYP3A substrates. The drug products Kaletra (lopinavir and ritonavir), Mifeprex (mifepristone, RU-486), Nuvaring (etonogestrel/ethinyl estradiol), Gleevec (imatinib), Neoral (cyclosporine), Rapamune (sirolimus), and Prograf (tacrolimus) include information about drug interactions with St. John's wort in their labeling. Thus, patients ingesting St. John's wort products should be advised that St. John's wort can have potentially dangerous interactions with some prescription drugs and to consult a physician before taking St. John's wort if currently taking anticoagulants, oral contraceptives, antidepressants, antiseizure medications, drugs to treat HIV or prevent transplant rejections, or any other prescription drug.

St. John's Wort also decreases the absorption of digoxin and fexofenadine, apparently by inducing P-gp in the intestinal and renal endothelium, increasing their elimination in the intestine and urine, respectively, and their plasma concentrations.

Echinacea

In vitro or in vivo chronic administration studies of Echinacea, an herbal product used for the treatment of colds and viral infections, inhibited hepatic CYP1A2 and intestinal CYP3A activities and induced hepatic CYP3A. Based on these preliminary findings, the effect of Echinacea on various CYP3A substrates may vary depending on the relative contribution to a given drug's overall clearance by intestinal CYP3A versus hepatic CYP3A in the individual substrate's clearance pathway.

Ginkgo Biloba

In vitro studies with Ginkgo biloba, often used for memory improvement, exhibited induction of CYP2C19. The extent of induction appears to be CYP2C19 genotype dependent.

Kava

Reports of hepatotoxicity have been associated with the use of kava, a popular drug in Europe and North America. Hepatotoxicity was not observed when kava was prepared as a water infusion but was with solvent-extracted products available in stores and on the World Wide Web. The three kava lactones (methysticin, desmethoxyyangonin, and yangonin; active principles) are potent inhibitors of CYP1A2, CYP2C9, CYCYP2C19, CYP2E1, and CYP3A4, with methysticin being the most potent enzyme inhibitor as well as the most cytotoxic. The potent inhibition of CYP450 enzymes suggests a high potential for interactions with drugs and other herbs that are metabolized by the same CYP450 enzymes. Long-term use or use in individuals with liver disorders should be avoided, and liver function transaminases need to be checked frequently.

Other Dietary Supplements Exhibiting Drug-Induced Heptatotoxicity

DHEA and androstenedione are testosterone precursors that have been associated with hepatic toxicity and should be avoided in those with hepatic disease or coingestion with other potentially hepatotoxic products or enzyme inducers that might increase the risk of liver damage. Liver enzymes should be monitored once or twice a year. Boldo can cause hepatotoxicity and exacerbate existing liver disease. Because chaparral, comfrey, germander, skullcap, valerian root can cause acute and chronic liver injury, these products should be considered unsafe. Pennyroyal oil can cause acute hepatotoxicity liver injury, which has been attributed to the bioactivation of the terpine, *R* (+) pulegone resulting in depletion of hepatic glutathione. In some cases, unknown adulterants found in these herbal products may be responsible for the hepatotoxicity. Black cohosh, commonly used by women for menopausal symptoms, including hot flashes and sleep disorders, formed quinone metabolites in vitro, but no mercapturate conjugates were detected in urine samples from women who consumed multiple oral doses of up to 256 mg of a standardized black cohosh extract. At moderate doses of black cohosh, the risk of liver injury is minimal.

Silybum marianum (milk thistle) is used in the treatment of chronic or acute liver disease as well as in protecting the liver against toxicity

(109). Silybum is cited as one of the oldest known herbal medicines. The active

P.321

constituents of milk thistle are flavonolignans, which are known collectively as silymarin. The most remarkable use of silymarin is in the treatment of *Amanita* mushroom poisoning. *Amanita* mushrooms possess two extremely powerful hepatotoxins, amanitin and phalloidin (the median lethal dose of amanitin is 0.1 mg/kg body weight). Severe liver damage (and death) is avoided if silymarin is administered within 24 hours following ingestion of *Amanita*. It also is a hepatoprotective on chronic exposure to ethanol and acetaminophen toxicity.

Miscellaneous Drug Interactions

The ability of drugs and other foreign substances to stimulate (induction) metabolism of other drugs has already been discussed. Phenobarbital, for example, stimulates metabolism of a variety of drugs (e.g., phenytoin and coumarin anticoagulants). Stimulation of bishydroxycoumarin metabolism can create a problem in patients undergoing anticoagulant therapy. If phenobarbital administration is stopped, the rate of metabolism of the anticoagulant decreases, resulting in greater plasma concentrations of bishydroxycoumarin and enhanced anticoagulant activity, increasing the possibility of hemorrhage. Serious side effects have resulted from this type of interaction. These observations indicate that combined therapy of a potent drug (e.g., bishydroxycoumarin) and a inducer of drug metabolism (e.g., phenobarbital) can create a hazardous situation if the enzyme inducer is withdrawn and therapy with the potent drug is continued without an appropriate decrease in dose.

Some drugs are competitive inhibitors of nonmicrosomal metabolic pathways. Serious reactions have been reported in patients treated with an MAO inhibitor, such as trancypromine or iproniazid, because they usually are sensitive to a subsequent dose of a sympathomimetic amine (e.g., amphetamine) or a tricyclic antidepressant (e.g., amitriptyline), which is metabolized by MAO.

Allopurinol, a xanthine oxidase inhibitor used for the treatment of gout, inhibits metabolism of 6-mercaptopurine and other drugs metabolized by this enzyme. A serious drug interaction results from the concurrent use of allopurinol for gout and 6-mercaptopurine to block the immune response from a tissue transplant or as antimetabolite in neoplastic diseases. In some cases, however, allopurinol is used in conjunction with 6-mercaptopurine to control the increase in uric acid elimination from 6-mercaptopurine metabolism. The patient should be supervised closely, because when given in large doses, allopurinol, an inhibitor of purine metabolism, may have serious effects on bone marrow.

Gender Differences in Drug Metabolism

The role of gender as a contributor to variability in xenobiotic metabolism and IDRs, which are more common in women than in men, is not clear, but increasing numbers of reports show differences in metabolism between men and women, raising the intriguing possibility that endogenous sex hormones, hydrocortisone, or their synthetic equivalents may influence the activity of inducible CYP3A. For example, N-demethylation of erythromycin was significantly higher in females than males. Nevertheless, the N-demethylation was persistent throughout adulthood. In contrast, males exhibited unchanged N-demethylation values.

Gender-dependent differences of metabolic rates have been detected for some drugs. Side-chain oxidation of propranolol was 50% faster in males than in females, but no differences between genders were noted in aromatic ring hydroxylation. N-demethylation of meperidine was depressed during pregnancy and for women taking oral contraceptives. Other examples of drugs cleared by oxidative drug metabolism more rapidly in men than in women included chlordiazepoxide and lidocaine. Diazepam, prednisolone, caffeine, and acetaminophen are metabolized slightly faster by women than by men. No gender differences have been observed in the clearance of phenytoin, nitrazepam, and trazodone, which interestingly are not substrates for the CYP3A subfamily. Gender differences in the rate of glucuronidation have been noted.

More investigation is warranted, and future pharmacokinetic studies examining the alteration in drug metabolism in one gender need to be reexamined with respect to the other gender. Even in postmenopausal women, CYP3A function may be altered and influenced by the lack of estrogen or the presence of androgens.

Major Pathways of Metabolism

Table 10.10 contains an extensive list of commonly used drugs and the CYP450 isoforms that catalyze their metabolism. In addition, Phase 1 and Phase 2 metabolic pathways for some common drugs are listed in Table 10.21.

P.322

P.323

P.324

Drug	Pathway
Amphetamines 	Deamination (followed by oxidation and reduction of the ketone formed) N-oxidation N-dealkylation Hydroxylation of the aromatic ring Hydroxylation of the β-carbon atom Conjugation with glucuronic acid of the acid and alcohol products from the ketone formed by deamination
Phenothiazines 	N-dealkylation in the N^{10} side chain N-oxidation in the N^{10} side chain Oxidation of the heterocyclic S atom to sulfoxide or sulfone Hydroxylation of one or both aromatic rings Conjugation of phenolic metabolites with glucuronic acid or sulfate Scission of the N^{10} side chain
Phenytoin 	Hydroxylation of one aromatic ring Conjugation of phenolic products with glucuronic acid or sulfate Hydrolytic scission of the hydantoin ring at the bond between carbons 3 and 4 to give 5,5-diphenylhydantoic acid
Pentazocine 	Hydroxylation of terminal methyl groups of the alkenyl side chain to give cis and trans (major) alcohols Oxidation of hydroxymethyl product of the alkenyl side chain to carboxylic acids Reduction of alkenyl side chain and oxidation of terminal methyl group
Phenmetrazine 	Oxidation to lactam Aromatic hydroxylation N-oxidation Conjugation of phenolic products
Propranolol 	Aromatic hydroxylation at C-4' N-dealkylation Oxidative deamination Oxidation of deaminated product to naphthoxylactic acid Conjugation with glucuronic acid O-dealkylation
Diphenoxylate 	Hydrolysis of ester to acid Hydroxylation of one aromatic ring attached to the N-alkyl side chain
Prostaglandins 	Reduction of double bonds at carbons 5 and 6, and 13 and 14 Oxidation of 15-hydroxyl to ketone β-Oxidation of carbons 3, 5 and 7 ω-Oxidation of carbon 20 to acid
Hydralazine 	N-acetylation with cyclization to a methyl-s-triazolophthalazine N-formylation with cyclization to an s-triazolo-phthalazine Aromatic hydroxylation of benzene ring Oxidative loss of hydrazinyl group to 1-hydroxy Hydroxylation of methyl of methyl-s-triazolophthalazine Conjugation with glucuronic acid
Lidocaine 	N-dealkylation Oxidative cyclization to a 4-imidazolidone N-oxidation of amide N Aromatic hydroxylation ortho to methyl Hydrolysis of amide
Cimetidine 	S-oxidation Hydroxylation of 5-methyl
Piroxicam 	Pyridine 5'-hydroxylation Hydrolysis of amide Decarboxylation
Theophylline 	N^3-demethylation N^1-demethylation C-8 oxidation to uric acids Imidazole ring opened 1-Me xanthine to 1-Me uric acid - xanthine oxidase
Ibuprofen 	CoA thioester and epimerization of R- to S+ enantiomer Methyl hydroxylation to CH_2OH CH_2OH to COOH Acylglucuronide
Lovastatin 	6'-Hydroxylation 3'-Side chain hydroxylation 3'-Hydroxylation β-oxidation of lactone O-glucuronides
Labetalol 	O-sulfate (major)

Drug	Pathway
Barbiturates 	Oxidation and complete removal of substituents at carbon 5 N-dealkylation at N^1 and N^3 Desulfuration at carbon 2 (thiobarbiturates) Scission of the barbiturate ring at the 1-6 bond to give substituted malonylureas
Sulfonamides 	Acetylation at the N^4 amino group Conjugation with glucuronic acid or sulfate at the N^4 amino group Acetylation or conjugation with glucuronic acid at the N^1 amino group
Meperidine 	Hydroxylation and conjugation in the heterocyclic ring,R Hydrolysis of ester to acid N-dealkylation Hydroxylation of aromatic ring N-oxidation Both N-dealkylation and hydrolysis Conjugation of phenolic products
Cocaine 	Hydrolysis of methyl ester Hydrolysis of benzoate ester N-dealkylation Both hydrolysis and N-dealkylation
Ephedrine 	N-dealkylation Oxidative deamination Oxidation of deaminated product to benzoic acid Reduction of deaminated product to 1,2-diol
Indomethacin 	O-demethylation N-deacylation of p-chlorobenzoyl group Both O-dealkylation and N-deacylation Conjugation of phenolic products with glucuronic acid Other conjugation products
Diazepam 	N-dealkylation at N1 Hydroxylation at carbon3 Conjugation with glucuronic acid Both N-dealkylation of N1 and hydroxylation at carbon3
Cyproheptadine 	N-dealkylation 10,11-Epoxide formation Both N-dealkylation and 10,11-epoxidation
Methadone 	Reduction of ketone to hydroxyl Aromatic hydroxylation of one aromatic ring N-dealkylation of alcohol product N-dealkylation with cyclization to pyrrolidine
Imipramine 	N-dealkylation Hydroxylation at C-11 Aromatic hydroxylation (C-2) N-oxidation Both N-dealkylation and hydroxylation
Valproic acid 	CoA thioester Dehydrogenation to (E) 2-ene Dehydrogenation to (E) 2,4-diene Dehydrogenation to 4-ene 3-Hydroxylation
Caffeine 	N^3-demethylation N^1-demethylation N^7-demethylation to theophylline C-8 oxidation to uric acids Imidazole ring opened
Nicotine 	Pyrrolidine 5'-hydroxylation to cotinine Pyrrolidine N-oxidation (FMO) N-demethylation (nornicotine and norcotinine) Pyridine N-methylation 3'-Hydroxylation of cotinine
Tamoxifen 	N-demethylation 4'-Hydroxylation N-oxidation (FMO) 4'-O-sulfate 4'-O-glucuronide
Ciprofloxacin 	Piperazine 3'-hydroxylation N-sulfation
Acetaminophen 	O-glucuronide O-sulfate Oxidation to N-acetyl-p-benzoquinoneimine Conjugation of N-acetyl-p-benzoquinoneimine with glutathione

Table 10.21. Metabolic Pathways of Common Drugs

Cast Study

Victoria F. Roche

S. William Zito

WH-L is a 62-year-old, Beijing-born scientist attending an international scientific meeting in your hometown. While delivering his groundbreaking paper on the neuroprotective action of some unique bicyclic molecules he has synthesized, WH-L experienced a very rapid and irregular heart rate, followed by a tight, gripping pain in his chest. Recognizing that he was having a myocardial infarction (MI), WH-L immediately took an aspirin tablet while his colleagues called an ambulance to take him to a nearby hospital. Fortunately, his quick action has averted a fatality, although the medical staff cannot get his heartbeat to stabilize. His situation is considered dire, and the decision is made to put him on an antiarrhythmic agent until he is well enough to return home to consult with his personal physician. It also is decided that β-adrenergic blocking therapy is in order. WH-L has evidence of coronary artery disease and elevated blood pressure. He is taking rosuvastatin calcium (Crestor' 20 mg q.d.) to keep his serum cholesterol levels in check and flurbiprofen potassium (Ansaid, 50 mg q.i.d.) for mild–moderate arthritis pain.

As the pharmacist-in-charge on the drug therapy decision team, you consult with WH-L and learn that he recently had an oral abscess that resulted in a tooth extraction and used codeine sulfate to treat his significant, but short-term, postsurgical pain. A few years ago, he experienced a deep vein thrombosis that was treated for 12 weeks with standard doses of warfarin sodium (Coumadin). A decision is made to initiate warfarin therapy again post-MI. WH-L does not consume alcohol but loves grapefruit juice, which he always has for breakfast and often once or twice again during the course of the day. He has asked for it routinely while in the hospital. Given this medical history, and keeping the drug metabolism pathways firmly in mind, select one antiarrhythmic agent and one β-blocker that would best suit the needs of this patient. Assume that all drug choices would be therapeutically effective for the disease they are intended to treat.

1. Identify the therapeutic problem(s) for which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough metabolic analysis of all therapeutic alternatives provided in the case.
4. Evaluate the metabolic findings against the patient-specific factors and desired therapeutic outcomes and make a therapeutic decision.
5. Counsel your patient.

Chapter 11
U.S. Drug Regulation: An Overview

Douglas J. Pisano

Introduction

Regulations and laws are central, social constructs that provide guidance for all societies around the globe. Governments create laws in a number of ways and with various intents for a myriad of purposes. In the United States, laws are created by the Congress, a body of officials elected by the citizenry and charged with the governance of the country by representing the common, public good. The Congress proposes and passes laws that are relatively general in nature and intended to address some particular issue in a fashion that can be consistently applied by all who are affected by them. Once passed, laws are remanded to the appropriate government or administrative agency, which then decides how these laws are to be applied. These applications of law are termed “regulations.” Regulations serve as the practical foundation from which citizens adhere to the law as it was originally intended.

In the United States, all food, drugs, cosmetics and medical devices, for both humans and animals, are regulated under the authority of the U.S. Food and Drug Administration (FDA). The U.S. FDA and all its regulations were created by the federal government in response to the pressing need to address the safety of the public with respect to its foods and medicinals. The purpose of this chapter is to describe and explain the nature and extent of these regulations as they apply to drugs in the United States. A historical perspective is offered as a foundation for regulatory context. In addition, the chapter will discuss the U.S. FDA's regulatory oversight and that of other agencies, the drug approval and development process, the mechanisms used to regulate manufacturing and marketing, as well as various violation and enforcement schema.

Brief History of Drug Laws and Regulations

Before 1902, the U.S. government took a hands-off approach to the regulation of drugs. Many of the drugs available were so-called “patent medicines,” which were so named because each had a more or less descriptive or patent name that was protected by a trademark, the contents of which were incompletely disclosed. No laws, regulations, or standards existed to regulate drugs, their purity, and their strength to any noticeable extend, even though the U.S. Pharmacopeia (USP) became a reality in 1820 as the first official compendia of the United States. The USP set standards for drug strength and purity that could be used by physicians and pharmacists who needed centralized guidelines to extract, compound, and otherwise use drug components that existed at the time (1).

Biologics Control Act

In 1848, however, the first U.S. drug law, the Drug Importation Act, was enacted when American troops serving in Mexico became seriously ill from the quinine that was administered to treat malaria. The quinine was subsequently discovered to be adulterated. This law required laboratory inspection, detention, and even

destruction of drugs that did not meet acceptable standards. Later, in 1902, the Virus, Serum, and Toxins Act (Biologics Control Act) was passed in response to tetanus-infected diphtheria antitoxin serum that was manufactured by a small laboratory in St. Louis, Missouri. Ten schoolchildren died as a result of the infected serum. No national standards were as yet in place for establishing purity or potency of medicinal products.

Wiley Act

The Biologics Control Act authorized the U.S. Public Health Service to license and regulate the interstate sale of serum, vaccines, and related biological products used to prevent or treat disease. This Act also spurred Dr. Harvey W. Wiley, Chief Chemist for the Bureau of Chemistry, a branch of the U.S. Department of Agriculture and the forerunner for today's U.S. FDA, to investigate the country's foods and drugs. He established the Hygienic Table, a group of young men who volunteered to serve as human guinea pigs, which would allow Dr. Wiley to feed them a controlled diet laced with a variety of preservatives and artificial colors. More popularly known as the “Poison Squad,” they helped Dr. Wiley gather enough data to prove that many of America's foods and drugs were either “adulterated” and that the products' strength or purity were suspect or “misbranded” with inadequate or inaccurate labeling. Dr. Wiley's efforts, along with publication of Upton Sinclair's *The Jungle* (a book revealing the putrid conditions in America's meat industry), were rewarded when Congress passed America's first food and drug law in 1906, the Pure Food and Drug Act (USPFDA; also known as the Wiley Act). The Wiley Act prohibited interstate commerce of misbranded foods or drugs based on their labeling. This act did not affect unsafe drugs, however, in that its legal authority would only come to bear when a product's ingredients were falsely labeled. Even intentionally false therapeutic claims were not prohibited.

Sherley Amendment

Changes in the labeling of drugs began to occur in 1911 with the enactment of the Sherley Amendment, which was intended to prohibit the labeling of medications with false therapeutic claims that were meant to defraud the purchaser. The Sherley Amendment, however, required the government to find proof of intentional labeling fraud. Later, in 1937, a sentinel event occurred that changed the entire regulatory picture. Sulfa (e.g., sulfanilamide) became the miracle drug of the time and was used to treat many life-threatening infections. It tasted bad and was hard to swallow, which led entrepreneurs to seek a palatable solution. S.E. Massingill Co. of Bristol, Tennessee, developed what they thought was a palatable, raspberry-flavored liquid product. They used diethylene glycol to solubilize the sulfa, however, and six gallons of this dangerous mixture (“Elixir of Sulfanilamide”) killed approximately 107 people, mostly children.

Federal Food, Drug, and Cosmetic Act

The result of these unnecessary deaths from ingestion of diethylene glycol was the passage of one of the most comprehensive statutes in the history of U.S. health law, the Federal Food, Drug, and Cosmetic Act of 1938 (FDCA). The enactment of this act repealed the Sherley Amendment and required that all new drugs be tested by their manufacturers for human safety and that results then be submitted to the government for marketing approval via a New Drug Application. The FDCA also

mandated that drugs be labeled with adequate directions if they were shown to have had harmful effects. In addition, the FDCA authorized the U.S. FDA to conduct unannounced inspections of drug manufacturing facilities. Though amended many times since 1938, the FDCA is still the broad foundation of the statutory authority for the U.S. FDA as it exists today.

A new crisis loomed, however. Throughout the late 1950s, European and Canadian physicians began to encounter a number of infants born with a curious birth defect called phocomeglia, which resulted in limbs that resembled “flippers” similar to those found on seals. These birth defects were traced back to mothers who had been prescribed the drug thalidomide in an effort to relieve morning sickness while pregnant. The manufacturer of this drug applied for U.S. marketing approval as a sleep aid. Because of the efforts of Dr. Frances O. Kelsey, however, who was the U.S. FDA's chief medical officer at the time, the case was made that the drug was not safe for human consumption and, therefore, not effective for release in the U.S. marketplace.

Kefauver-Harris Act

Dr. Kelsey's efforts and decisive work by the Congress resulted in yet another necessary amendment to the FDCA in 1962, the Kefauver-Harris Act. This Act essentially closed many of the loopholes regarding drug safety in U.S. law. These “Drug Efficacy Amendments” now required manufacturers to prove the safety and efficacy of their drug products registered with the U.S. FDA, to be inspected at least every 2 years, to have their prescription drug advertising approved by the U.S. FDA (this authority being transferred from the Federal Trade Commission), to provide and obtain documented “informed consent” from research subjects before human clinical trials, and to have increased controls over drug manufacturing and testing to determine drug effectiveness.

To address these new provisions of the Act, the U.S. FDA contracted the National Academy of Sciences, along with the National Research Council, to examine some 3,400 drug products approved between 1938 and 1962 based on safety alone. Called the Drug Efficacy Study Implementation Review of 1966 (DESI), it charged these organizations with making a determination as to whether post-1938 drug products were “Effective,” “Probably Effective,” “Possibly Effective,” or “Ineffective” for the indications claimed in their labeling. Those products not deemed “Effective” were either removed from the marketplace, reformulated, or sold with a clear warning to prescribers that the product was deemed not to be effective.

Over-The-Counter Product Review

Later, in 1972, the U.S. FDA began to examine over-the-counter (OTC) drug products. Phase II of the Drug Efficacy Amendments required the U.S. FDA to determine the efficacy of OTC drug products. This project was much larger in scope than the analysis of prescription drugs. During the 1970s, American consumers could choose from more than 300,000 OTC drug products. The U.S. FDA soon realized that it did not have the resources to evaluate each and every OTC drug product and, hence, created advisory panels of scientists, medical professionals, and consumers who were charged with evaluating the active ingredients used in OTC products within 80 defined therapeutic categories. After examining both the scientific and medical literature of the day, the advisory panels made decisions regarding active ingredients and their labeling. The result was a “monograph” that described, in detail, acceptable active ingredients and labeling for products within a

therapeutic class. Products that complied with monograph guidelines were deemed “Category I: Safe and Effective, Not Misbranded.” Products not in compliance with monograph guidelines, however, were deemed “Category II: Not Safe and Effective” or “Misbranded.” Category II products were removed from the marketplace or reformulated. Products for which data was insufficient for classification were deemed “Category III” and allowed to continue on the market until substantive data could be established or until they were reformulated and in compliance with the monograph. The OTC Drug Review took approximately 20 years to complete.

Federal Controlled Substances Act

Though numerous other federal laws and regulations were passed throughout the 1970s, many were based on

regulating the professional practice of medical professionals or for the direct protection of consumers. For example, the Federal Controlled Substances Act, part of the Comprehensive Drug Abuse and Prevention Act of 1970, placed drugs with a relatively high potential for abuse into five federal schedules along with a “closed record keeping system” designed to track federally controlled substances via a definite paper trail as they were ordered, prescribed, dispensed, and used throughout the health care system.

Orphan Drug Act

The 1980s also saw significant regulatory change. Biotechnology had begun on a grand scale, and the pharmaceutical industry was on its cutting edge. Many of the medicinal compounds being discovered were shown to be very expensive and to have limited use in the general U.S. population. These compounds could prove life-saving, however, to demographically small patient populations (less than 200,000) who suffered from diseases and conditions considered to be rare. In an effort to encourage these biotech pharmaceutical companies to continue developing these and other products, Congress passed the Orphan Drug Act in 1983. The Act continues to allow manufacturers to gain incentives for research, development, and marketing of drug products used to treat rare diseases or conditions that otherwise would be unprofitable via a system of breaks and deductions in a manufacturer's corporate taxes. Though the success of the Orphan Drug Act provided great medical benefit for a few, a scandal was looming in other parts of the pharmaceutical industry.

Price Competition and Patent Restoration Act (Waxman-Hatch Act)

The generic pharmaceutical industry experienced steady growth as many of the exclusive patents enjoyed by major pharmaceutical companies for brand-named products were beginning to expire. Generic versions of these now freely copied products were appearing much more frequently in the marketplace. These generic copies, however, were required to undergo the same rigorous testing that brand name, pioneer, or innovator products did. This led to a very public scandal in which a few unscrupulous generic pharmaceutical companies took shortcuts in reporting data, submitted fraudulent samples, and offered bribes to U.S. FDA officials to gain easy and rapid market approval of their products. As a result, Congress passed the Price Competition and Patent Restoration Act of 1984. This Act, also called the Waxman-Hatch Act after its sponsors, was designed to level the playing field in the

prescription drug industry with regard to pioneer/innovator/brand name prescription drug products and their generic copies. The Act was composed of two distinct parts, or “Titles.” Title I was for the benefit of the generic pharmaceutical industry and extended the scope of the Abbreviated New Drug Application to cover generic versions of drug products approved after 1962. It required that generic versions of pioneer or innovator drugs have the same relevant properties regarding bioequivalence (rate and extent of absorption of the active drug in the human body) and pharmaceutical equivalence (same dosage form as the pioneer drug to which it is compared). Though somewhat simplified, the Waxman- Hatch Act permitted easier market access to generic copies of pioneer drugs provided they were not significantly different from the pioneer drug in its absorption, action, and dosage form. In addition, Title II was designed to aid and encourage research-based or innovator pharmaceutical companies in continuing their search for new and useful medicinal compounds by extending the patent life of pioneer drug products while in the U.S. FDA “review period.”

Prescription Drug User Fee Act

The patent extension benefit has become somewhat moot, however, because of an overall reduction in U.S. FDA review time as a result of prescription drug user fees. In 1992, Congress passed the Prescription Drug User Fee Act (PDUFA). The Act was intended to help the U.S. FDA generate additional funds to upgrade and modernize its operations and to accelerate drug approval. It authorized the U.S. FDA to charge pharmaceutical manufacturers a “user fee” to accelerate drug review. As a result of the PDUFA legislation, the U.S. FDA has been able to reduce approval time of new pharmaceutical products from more than 30 months to approximately 13 to 15 months. The Act had a “sunset” provision, however, that limited the authority of the U.S. FDA to charge user fees until the year 1997.

U.S. FDA Modernization Act

After reviewing the successes of the PDUFA legislation, Congress extended the user fee provisions during passage of the U.S. FDA Modernization Act (FDAMA) of 1997. The FDAMA reauthorized the fees until the year 2002 in an effort to further reduce prescription drug approval time. The Act, however, not only extended user fee provisions. It also gave the U.S. FDA the authority to conduct “fast-track” product reviews to further speed life-saving drug therapies to market, permitted an additional 6-month patent exclusivity for pediatric prescription drug products, and required the National Institutes of Health to build a publicly accessible database of clinical studies involving investigational drugs or life-threatening diseases.

Summary

American drug law has come quite far since the early 1900s. Today, the U.S. FDA continues to work with Congress and the pharmaceutical industry to regulate and evaluate new and existing drug, biologic, and device products. The overriding regulatory challenge that the U.S. FDA will face will be to keep current, through regulation

and policy, with future technological advances by the science and the industry.

Regulatory Oversight of Pharmaceuticals

The primary responsibility for the regulation and oversight of pharmaceuticals and the pharmaceutical industry lies with U.S. FDA, created in 1931 and one of several branches within the U.S. Department of Health and Human Services. The U.S. FDA's counterparts within that department include agencies such as the Centers for Disease Control and Prevention, the National Institutes of Health, and the Health Care Financing Administration.

U.S. Food and Drug Administration

The U.S. FDA is organized into a number of Offices and Centers headed by a Commissioner who is appointed by the President with consent of the Senate. It is a scientifically based law enforcement agency whose mission is to safeguard the public health and to ensure honesty and fairness between health regulated industries (i.e., pharmaceutical, device, biologic, and the consumer) (2). It licenses and inspects manufacturing facilities, tests products, evaluates claims and prescription drug advertising, monitors research, and creates regulations, guidelines, standards and policies. It does all this through its Office of Operations, which contains component Offices and Centers such as the Center for Drug Evaluation and Research (CDER), Center for Biologics Evaluation and Research, Center for Devices and Radiological Health (CDRH), Center for Food Safety and Applied Nutrition, Center for Veterinary Medicine, Office of Orphan Products Development, Office of Biotechnology, Office of Regulatory Affairs, and National Center for Toxicological Research. Each of these entities has a defined role, but sometimes their authorities overlap. For example, if a pharmaceutical company submits a drug that is contained and delivered to a patient during therapy by a device not comparable to any other, the CDER and CDRH may need to coordinate that product's approval. Most prescription drugs are evaluated by CDER, but any other Center or Office may become involved with its review. One of the most significant resources to industry and consumers is the U.S. FDA's website (http://www.fda.gov) and its FDA approved drug products website (http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm). Easily accessible and navigable, each Center and Office has its own HTML page within the site.

Other Governmental Agencies

The U.S. FDA is not the only agency within the U.S. government with a stake in pharmaceutical issues. The Federal Trade Commission has authority over general business practices in general, such as deceptive and anticompetitive practices (i.e., false advertising). In addition, the Federal Trade Commission regulates the advertising of OTC drugs, medical devices, and cosmetics. To a lesser degree, the Consumer Product Safety Commission regulates hazardous substances and the containers of poisons and other harmful agents, the U.S. Environmental Protection Agency regulates pesticides used in agriculture, the U.S. FDA regulates food products; the Occupational Safety and Health Administration regulates the working environment of employees who may use U.S. FDA–regulated commodities (i.e., syringes, chemotherapy, and chemical reagents); the Health Care Financing Administration regulates the federal Medicaid and Medicare programs, and the Drug Enforcement Administration enforces the Federal Controlled Substances Act and is charged with controlling and monitoring the flow of licit and illicit controlled substances. Additionally, various state and local drug control agencies establish their own regulations and procedures for manufacturing, research, and development of pharmaceuticals.

New Drug Approval and Development

Before any discussion of how pharmaceuticals make their way through the U.S. FDA for market approval, one needs to have an understanding of what constitutes a "drug." A drug is a substance that exerts an action on the structure or function of the body by chemical action or metabolism and is intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease (3). The concept of "new drug" stems from the Kefauver-Harris Amendments to the FDCA. A new drug is defined as one that is not generally recognized as safe and effective for the indications proposed. This definition has much greater reach, however, than simply a "new" chemical entity. The term "new drug" also refers to a drug product already in existence but never approved by U.S. FDA for marketing in the United States, a new therapeutic indication, a new dosage form, a new route of administration, a new dosing schedule, or any other significant clinical differences than those previously approved (4). Therefore, any chemical substance intended for use in humans or animals for medicinal purposes, or any existing chemical substance that has some significant change associated with it, is considered not safe or effective and to be a new drug until proper testing is performed and U.S. FDA approval is granted.

Approval by the U.S. FDA can be a fairly lengthy and expensive process. For a pharmaceutical manufacturer to place a product on the market for human use, a multiphase procedure must be followed. Remember that the mission of U.S. FDA is to protect the public, and they take that charge very seriously. Hence, all drug products must at least follow the stepwise process.

Preclinical Investigation

The testing of new drugs in humans cannot begin until solid evidence exists that the drug product can be used with reasonable safety in humans. This phase is termed

"preclinical investigation." The basic goal of preclinical investigation is to assess the potential therapeutic effects of the substance on living organisms and to gather sufficient data to determine reasonable safety of the substance in humans through laboratory experimentation and animal investigation (5). The U.S. FDA requires no previous approval for investigators or pharmaceutical industry sponsors to begin a preclinical investigation on a potential drug substance. Investigators and sponsors are, however, required to follow Good Laboratory Practices (GLP) regulations (6). The GLPs govern laboratory facilities, personnel, equipment, and operations. Compliance with GLPs requires procedures and documentation of training, study schedules, processes, and status reports, which are submitted to facility management and are included in the final study report to the U.S. FDA. Preclinical investigation usually takes from 1 to 3 years to complete. If at that time enough data are gathered to reach the goal showing a potential therapeutic effect and reasonable safety, the product sponsor must formally notify the U.S. FDA of their wishes to test the potential new drug on humans.

Investigational New Drug Application

Overview

Unlike the preclinical investigation stage, the Investigational New Drug Application (INDA) phase has much more direct U.S. FDA activity throughout. Because a preclinical investigation is designed to gather significant evidence of reasonable

safety and efficacy of the compound in live organisms, the INDA phase is the clinical phase in which all activity is used to gather significant evidence of reasonable safety and efficacy data about the potential drug compound in humans. Clinical trials in humans are carefully scrutinized and regulated by the U.S. FDA to protect the health and safety of human test subjects and to ensure the integrity and usefulness of the clinical study data (7). Numerous meetings between both the agency and sponsor will occur during this time. As a result, the clinical investigation phase may take as many as 12 years to complete. Only one in five compounds tested may actually demonstrate clinical effectiveness and safety and reach the U.S. marketplace.

The sponsor will submit the INDA to the U.S. FDA. The INDA must contain information regarding the compound itself and information about the study. All INDAs must have the same basic components: a detailed cover sheet, a table of contents, an introductory statement and basic investigative plan, an investigators' brochure, comprehensive investigation protocols, the compound's actual or proposed chemistry, manufacturing and controls, any pharmacology and toxicology information, any previous human experience with the compound, and any other pertinent information that the U.S. FDA deems necessary. After submission, the sponsor company must wait 30 days to commence clinical trials. If the U.S. FDA does not object within that period, the trials may begin.

Institutional Review Board

Before the actual commencement of the clinical investigations, however, a few ground rules must be established. For example, a clinical study protocol must be developed, proposed by the sponsor, and reviewed by an Institutional Review Board (IRB). An IRB is required by regulation (8) and is a committee of medical and ethical experts designated by an institution, such as a University Medical Center, in which the clinical trial will take place. The charge of the IRB is to oversee the research to ensure that the rights of human test subjects are protected and that rigorous medical and scientific standards are maintained (9). The IRBs must approve the proposed clinical study and monitor the research as it progresses. It must develop written procedures of its own regarding its study review process and its reporting of any changes to the ongoing study as they occur. In addition, an IRB must review and approve documents for informed consent before commencement of the proposed clinical study. Regulations require that potential patients in a clinical study are informed adequately about the risks, benefits, and treatment alternatives before participating in experimental research (10). The membership of an IRB must be sufficiently diverse to review the study in terms of the specific research issue, community and legal standards, and professional conduct and practice norms. All its activities must be well documented and open to U.S. FDA inspection at any time.

Once the IRB is satisfied that the proposed trial is ethical and proper, the clinical trial phase will begin. The clinical trial phase has three steps or phases. Each phase has a purpose, requires numerous patients, and can take more than 1 year to complete.

Phase I

A Phase I study is relatively small (<100 subjects) and brief (≤1 year). The purpose is to determine toxicology, metabolism, pharmacological actions, and if possible, any early evidence of effectiveness. The results of the Phase I study are used to

develop the next step.

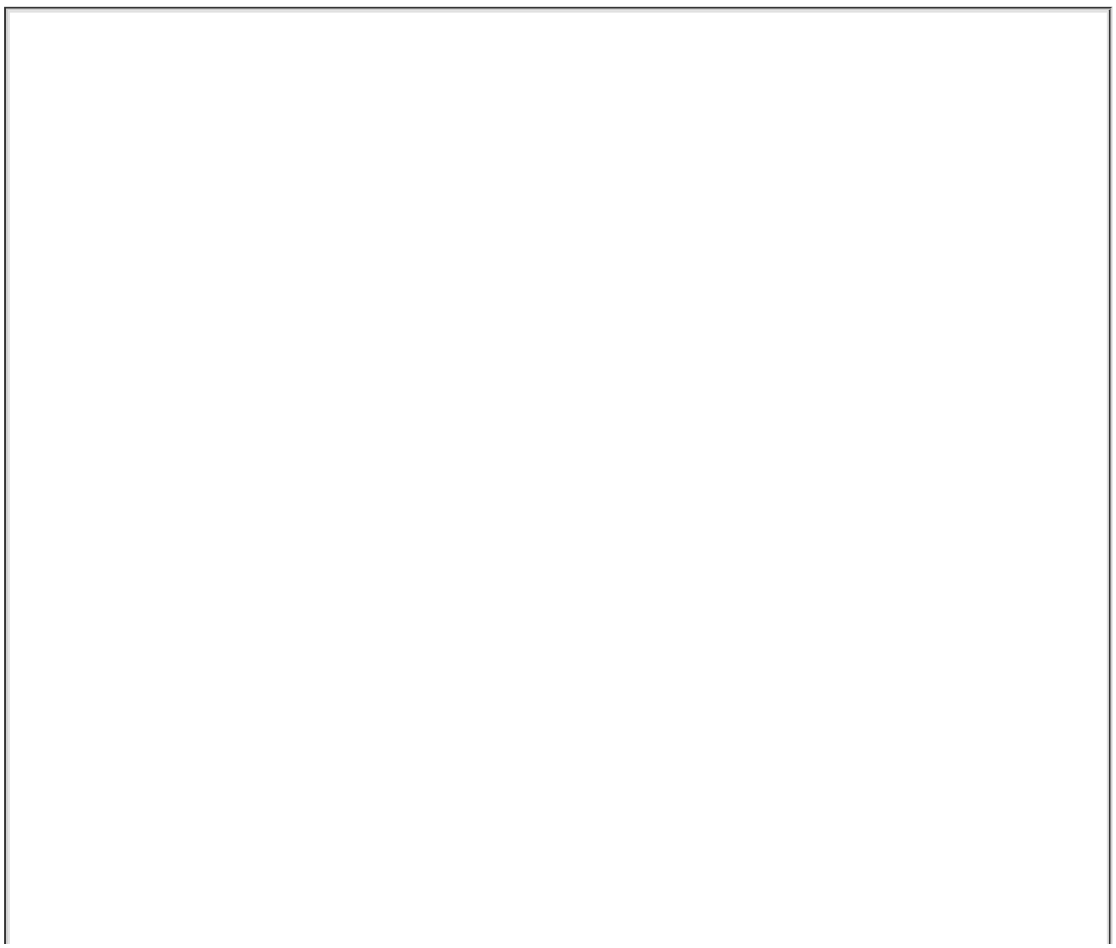
Phase II

Phase II studies are the first controlled clinical trials using several hundred subjects afflicted with the disease or condition being studied. The purpose of Phase II is to determine the compound's possible effectiveness against the targeted disease or condition and its safety in humans. Phase II may be divided into two subparts: Phase IIa, a pilot study that is used to determine initial efficacy, and Phase IIb, which uses controlled studies on several hundred patients. At the end of the Phase II studies, the sponsor and the U.S. FDA usually will confer to discuss the data and plans for Phase III.

Phase III

Phase III studies are considered to be “pivotal” trials that are designed to collect all the necessary data to meet the safety and efficacy standards the U.S. FDA requires to approve the compound for the U.S. marketplace. Phase III studies usually are very large, consisting of several thousand patients in numerous clinical study centers and a large number of investigators who conduct

long-term trials over several months or years. Additionally, Phase III studies establish the final formulation, marketing claims, product stability, packaging, and storage conditions. On completion of Phase III, all clinical studies are complete, all safety and efficacy data have been analyzed, and the sponsor is ready to submit the compound to the U.S. FDA for market approval. This process begins with submission of a New Drug Application.



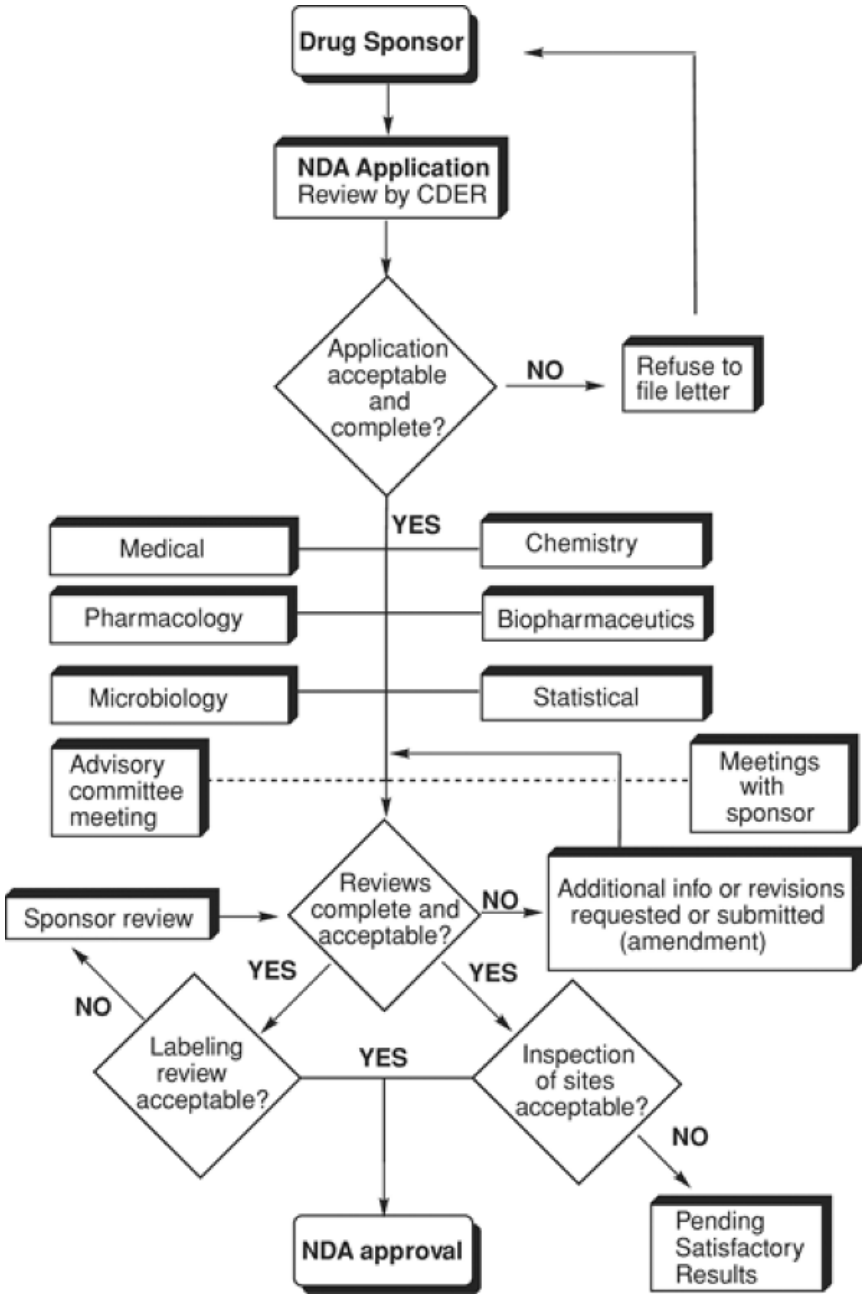


Fig. 11.1. New Drug Application (NDA) review process. (Adapted from http://www.fda.gov/cder/handbook/nda.htm. Accessed March 2007.)

New Drug Application

Overview

A New Drug Application (NDA) is a regulatory mechanism that is designed to give the U.S. FDA sufficient information to make a meaningful evaluation of a new drug (11) (see Fig. 11.1 for an overview of the NDA review process). All NDAs must contain the following information: preclinical laboratory and animal data; human pharmacokinetic and bioavailability data; clinical data; methods of manufacturing, processing, and packaging; a description of the drug product and substance; a list

of relevant patents for the drug; its manufacture or claims; and any proposed labeling. In addition, an NDA must provide a summary of the application's contents and a presentation of the risks and benefits of the new drug (12). Traditionally, NDAs have consisted of hundreds of volumes of information, in triplicate and all cross-referenced. Since 1999, the U.S. FDA has issued final guidance documents that allow sponsors to submit NDAs electronically in a standardized format. These

electronic submissions facilitate ease of review and possible approval (13).

The NDA must be submitted complete, in the proper form, and with all critical data. If “accepted,” the U.S. FDA will then determine the applications completeness. If “complete,” the agency considers the application “filed” and will begin the review process within 60 days (14). The purpose of an NDA from the U.S. FDA's perspective is to ensure that the new drug meets the criteria to be “safe and effective.” Safety and effectiveness are determined through the Phase III pivotal studies based on “substantial evidence” gained from a well-controlled clinical study. Because there are no absolutely safe drugs, the U.S. FDA looks to the new drug's efficacy as a measure of its safety. It weighs the risks versus benefits of approving the drug for use in the U.S. market.

Additionally, the NDA must be very clear about the manufacture and marketing of the proposed drug product. The application must define and describe the manufacturing processes, validate Current Good Manufacturing Practices, and provide evidence of quality, purity, strength, identity, and bioavailability (a preinspection of the manufacturing facility will be conducted by the U.S. FDA). Finally, the U.S. FDA will review all product packaging and labeling for content and clarity. Statements on a product's package label, package insert, media advertising, or professional literature must be reviewed. Of note, “labeling” refers to all of the above and not just the label on the product container.

The U.S. FDA is required to review an application within 180 days of filing. At the end of that time, the agency is required to respond with an “action letter.” There are three kinds of action letters. An “Approval Letter” signifies that all substantive requirements for approval are met and that the sponsor company can begin marketing the drug as of the date on the letter. An “Approvable Letter” signifies that the application substantially complies with the requirements but has some minor deficiencies that must be addressed before an approval letter is sent. Generally, these deficiencies are minor in nature, and the product sponsor must respond within 10 days of receipt. At this point, the sponsor may amend the application and address the agency's concerns, request a hearing with the agency, or withdraw the application entirely. A “Non-Approvable Letter” signifies that the U.S. FDA has major concerns with the application and will not approve the proposed drug product for marketing as submitted. The remedies that a sponsor can take for this type of action letter are similar to those for the “Approvable Letter.”

Effects of PDUFA and FDAMA

The NDA review has been significantly affected by both the PDUFA and FDAMA legislation. The PDUFA allows the U.S. FDA to collect fees from sponsor companies who submit applications for review. The fees are used to update facilities and to hire and train reviewers. The fees only apply to NDA drug submissions, biological drug submissions, and any supplement thereto. The fees do not apply to generic drugs or medical devices. The results of the PDUFA legislation were significant: Approval rates have increased from approximately 50 to nearly 80%, and review

times have decreased to under 15 months for most applications (15).

Later, in 1997, the FDAMA reauthorized the PDUFA until the year 2002. It waives the user fee to small companies who have fewer than 500 employees, are submitting their first application, allows payment of the fee in stages, and permits a certain percentage of refund if the application is refused. Additionally, it exempts applications for drugs used in rare conditions (i.e., orphan drugs), supplemental applications for pediatric indications, and applications for biologicals used as precursors for other biologics manufacture. The FDMA also permits a “fast-track” approval of compounds that demonstrate significant benefit to critically ill patients, such as those who suffer from AIDS (16).

Biologics

Biologics are defined as substances derived from or made with the aid of living organisms and include vaccines, antitoxins, serums, blood, blood products, therapeutic protein drugs derived from natural sources (i.e., antithrombin III), biotechnology (i.e., recombinantly derived proteins), and gene or somatic cell therapies (17). As with the more traditionally derived drug products, biologics follow virtually the same regulatory and clinical testing schema with regard to safety and efficacy. A Biologics License Application is used rather than an NDA, although the official U.S. FDA Form is designated “356h” and is one and the same. The sponsor merely indicated in a check box if the application is for a drug or a biologic. Compounds characterized as biologics are reviewed by the Center for Biologics Evaluation and Research (18).

Orphan Drugs

Orphan drugs are approved using many of the same processes as any other application; however, there are several significant differences. An orphan drug, as defined under the Orphan Drug Act of 1993, is a drug used to treat a “rare disease” that normally would not be of interest to commercial manufactures during the ordinary course of business. A “rare disease” is defined in the law as any disease that affects fewer than 200,000 persons in the United States or one for which a manufacturer has no reasonable expectation of recovering the cost of its development and availability in the United States. The Act creates a series of financial incentives for these manufacturers. For example, the Act permits grant assistance for clinical research, tax credits for research and development, and a 7-year market exclusivity to the first applicant who obtains market approval for a drug designated as an orphan. This means that if a sponsor gains approval for an orphan drug, the U.S. FDA will not approve any

application by any other sponsor for the same drug for the same disease or condition for 7 years from the date of the first applicant's approval provided that certain conditions are met, such as an assurance of sufficient availability of drug to those in need or a revocation of the drug's orphan status (19,20).

Abbreviated New Drug Applications

Abbreviated New Drug Applications (ANDAs) are used when a patent has expired for a drug product that has been on the U.S. market and another pharmaceutical company wishes to market a generic copy. In the United States, a drug patent is good for 20 years. After that time, a manufacturer is able to submit an abbreviated application for the pioneer product provided the manufacturer certifies that the

product patent in question has already expired, is invalid, or will not be infringed.

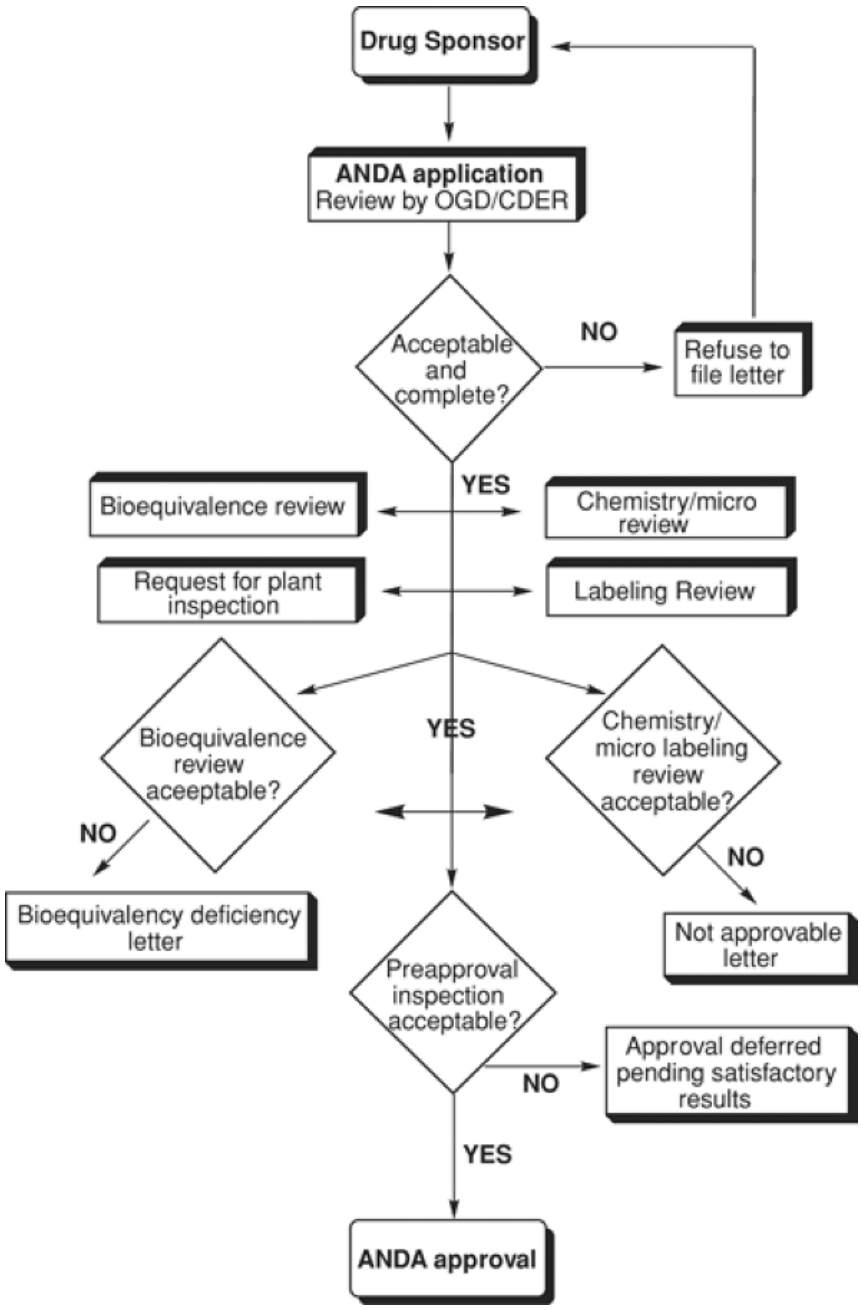

Fig. 11.2. Generic Abbreviated New Drug Application (ANDA) review process. (Adapted from http://www.fda.gov/cder/handbook/generic.htm. Accessed March 2007.)

The generic copy must meet certain other criteria as well. The drug's active ingredient must already have been approved for the conditions of use proposed in the ANDA, and nothing must have changed to call into question the basis for approval of the original drug's NDA (21). Sponsors of ANDAs are required to prove that their version meets with standards of bioequivalency and pharmaceutical equivalence. This is accomplished using an abbreviated clinical study that serves to validate, within reasonable parameters, that the generic copy acts in a therapeutic

way similar to the action of the original product. This abbreviated study may use several hundred patients or less and may be completed in 1 to 3 years. Once bioequivalency and pharmaceutical equivalency are established, the sponsor company may then submit the ANDA to the U.S. FDA for approval (see Fig. 11.2 for an overview of the ANDA generic drug review process).

P.335

The U.S. FDA publishes a list of all approved drugs called “Approved Drug Products with Therapeutic Equivalence Evaluations,” which is also called the “Orange Book” because of its orange-colored cover. It lists marketed drug products that are considered by the U.S. FDA to be safe and effective, and it provides monthly information about therapeutic equivalence evaluations for approved multisource prescription drug products (22). The Orange Book rates drugs based on their therapeutic equivalence. For a product to be considered therapeutically equivalent, it must be both pharmaceutically equivalent (i.e., same dose, dosage form, strength, etc.) and bioequivalent (i.e., rate and extent of its absorption not significantly different from the rate and extent of absorption of the drug with which it is to be interchanged) (Fig. 11.2)

Realizing that there may be some degree of variability in patients, the U.S. FDA allows pharmaceuticals to be considered bioequivalent using either of two methods. The first method studies the rate and extent of absorption of a test drug that may or may not be a generic variation and a reference or brand-name drug under similar experimental conditions and in similar dosing schedules where the test results do not show significant differences. The second approach uses the same method. The results, however, determine that there is a difference in the test drug's rate and extent of absorption, except the difference is considered to be medically insignificant for the proper clinical outcome of that drug. In other words,

> bioequivalence of different formulations of the same drug substance involves equivalence with respect to the rate and extent of drug absorption. Two formulations whose rate and extent of absorption differ by 20% or less are generally considered bioequivalent. The use of the 20% rule is based on a medical decision that, for most drugs, a 20% difference in the concentration of the active ingredient in blood will not be clinically significant. (23)

The U.S. FDA's Orange Book uses a two-letter coding system that is helpful in determining which drug products are considered to be therapeutically equivalent. The first letter, either an A or a B, indicates a drug product's therapeutic equivalence rating. The second letter describes the dose forms and can be any one of a number of different letters.

The “A” codes are described in the “Orange Book” as follows:

> Drug products that FDA considers to be therapeutically equivalent to other pharmaceutically equivalent products, i.e., drug products for which:

1. There are no known or suspected bioequivalence problems. These are designated **AA, AN, AO, AP**, or **AT**, depending on the dose form; or

2. Actual or potential bioequivalence problems have been resolved with adequate in vivo and/or in vitro evidence supporting bioequivalence. These are designated **AB.** (24)

The B codes are a much less desirable rating when compared to the A codes. Products that are rated with a B code may still be commercially marketed; however, they may not be considered therapeutically equivalent. The Orange Book describes B codes as follows:

> Drug products that FDA at this time does not consider to be therapeutically equivalent to other pharmaceutically equivalent products, i.e., drug products for which actual or potential bioequivalence problems have not been resolved by adequate evidence of bioequivalence. Often the problem is with specific dosage forms rather than with the active ingredients. These are designated BC, BD, BE, BN, BP, BR, BS, BT, or BX. (25)

The U.S. FDA has adopted an additional subcategory of B codes. The designation, B* is assigned to former A-rated drugs “if [the] FDA receives new information that raises a significant question regarding therapeutic equivalence” (26). Not all drugs are listed in the Orange Book. Drugs obtainable only from a single manufacturing source, DESI drugs, or drugs manufactured before 1938 are not included. Those that do appear in the Orange Book are listed by generic name.

Phase IV, Postmarketing Surveillance, and Supplemental NDAs

Pharmaceutical companies that successfully gain marketing approval for their products are NOT exempt from further regulatory requirements. Many products are approved for market on the basis of a continued submission of clinical research data to the U.S. FDA. This data may be required to further validate efficacy or safety, to detect new uses or abuses for the product, or to determine the effectiveness of labeled indications under conditions of widespread usage (27). Additionally, the U.S. FDA may require a Phase IV study for drugs approved under the “fast-track” provisions of the FDAMA.

Any changes to the approved product's indications, active ingredients, manufacture, or labeling require the manufacturer to submit a Supplemental NDA (SNDA) for agency approval. Additionally, “adverse drug reports” are required to be reported to the agency. All reports must be reviewed by the manufacturer promptly, and if found to be serious, life-threatening, or unexpected (i.e., not listed in the product's labeling), the manufacturer is required to submit an “alert report” within 15 working days of receiving the information. All adverse reactions thought not to be serious or unexpected must be reported quarterly for 3 years after the application is approved and annually thereafter (28).

Over-The-Counter Regulations (1951 Durham-Humphrey Amendments)

The 1951 Durham-Humphrey Amendments of the FDCA specified three criteria to justify prescription-only status. If the compound is shown to be habit forming, requires a prescriber's supervision, or has a NDA prescription-only limitation, it will

require a prescription. The principles used to establish OTC status (no prescription required) are a wide margin of safety, method of use, benefit-to-risk

ratio, and adequacy of labeling for self-medication. For example, injectable drugs may not be used OTC with certain exceptions (e.g., insulin). Entry into the OTC market is less restrictive than that into the prescription market and does not require premarket clearance. They pose many fewer safety hazards than prescription drugs, because they are designed to alleviate symptoms rather than disease. Easier access to OTC drugs far outweighs the risks of side effects that can be adequately addressed through proper labeling.

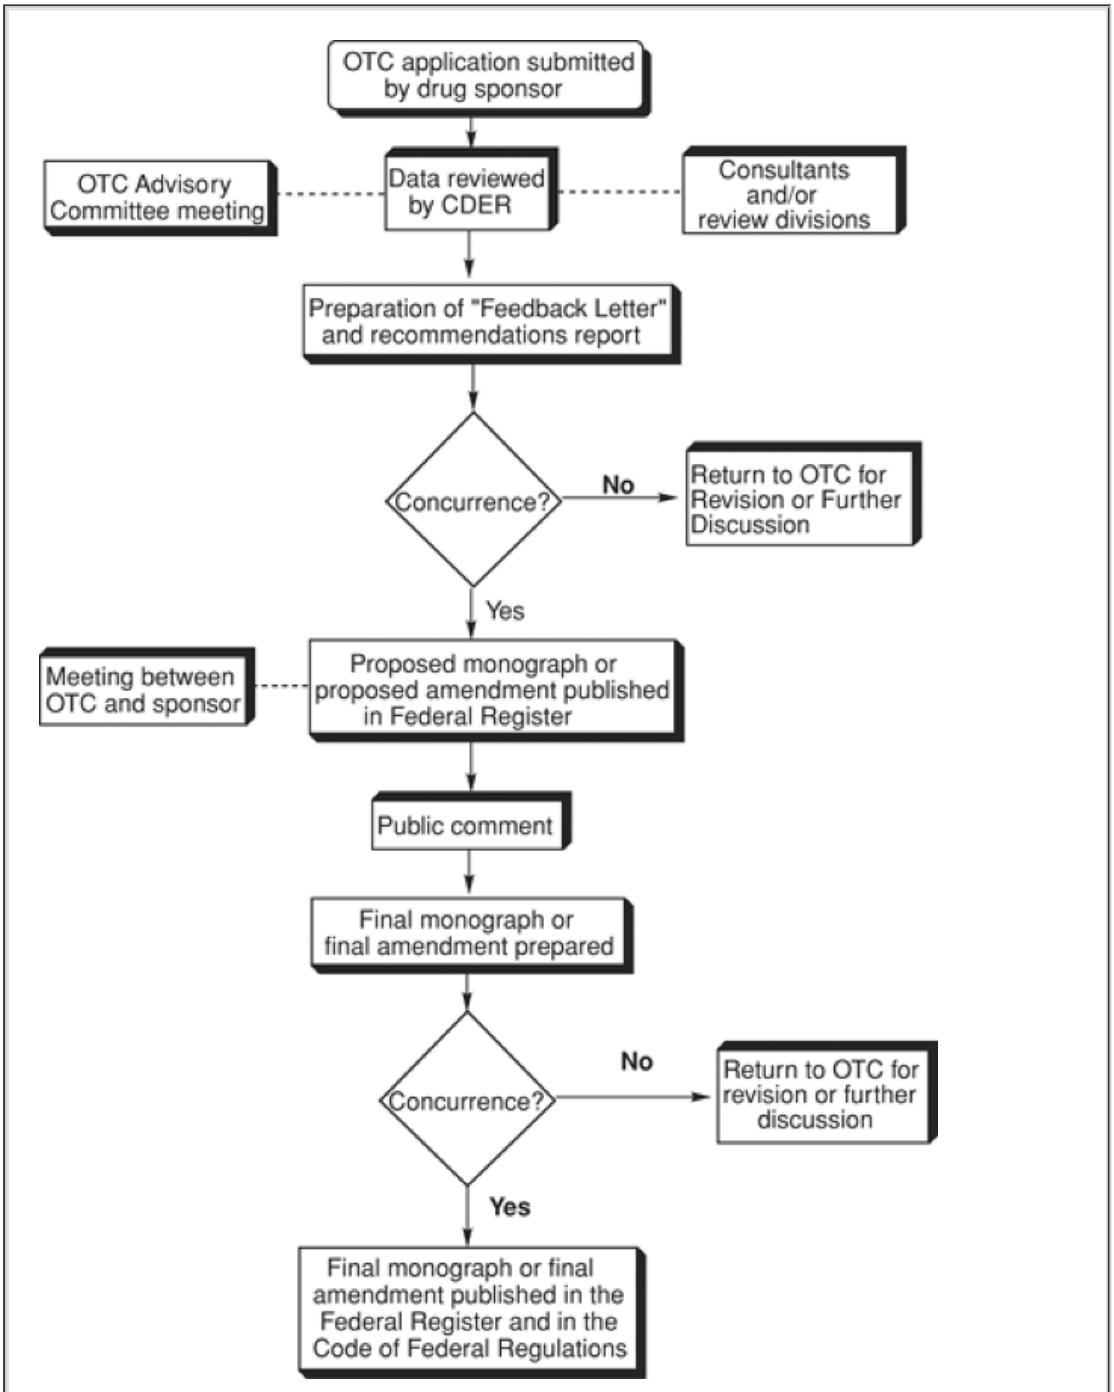

Fig. 11.3. Over-the-counter (OTC) drug monograph review process. (Adapted from http://www.fda.gov/cder/handbook/otc.htm. Accessed

March 2007.)

As previously discussed, OTC products underwent an efficacy review in 1972. Though reviewing the therapeutic efficacy of the more than 30,000 OTC drug products in existence at the time would have been virtually impossible, the U.S. FDA created OTC Advisory Panels to review data based on some 26 therapeutic categories. The OTC drugs would only be examined by active ingredient within a therapeutic category. Inactive ingredients would only be examined provided they were shown to be safe and suitable for the product and not to interfere with effectiveness and quality.

This review of active ingredients would result in the promulgation of a regulation or a “monograph,” which is a “recipe” or set of guidelines applicable to all OTC products within a therapeutic category (see Fig. 11.3 for an overview of the OTC application review process). The OTC monographs are general and require that OTC products be shown to have “general recognition of the safety and effectiveness of the active ingredient.” The OTC products do not fall under prescription status if

their active ingredients (or combinations) are deemed by the U.S. FDA to be “Generally Recognized as Safe and Effective” (GRASE). The monograph system is a public system with a public comment component included after each phase of the process. Any products for which a final monograph has not been established may remain on the market until one is determined.

The OTC monograph system has four phases. In Phase I, an expert panel is selected to review data for each active ingredient in each therapeutic category for safety, efficacy, and labeling. Their recommendations are made in the *Federal Register*. A public comment period of 30 to 60 days is permitted, and supporting or contesting data are accepted for review. Then, the panel reevaluates the data and publishes a “proposed monograph” in the *Federal Register* that publicly announces the conditions for which the panel believed OTC products in a particular therapeutic class are GRASE and not misbranded. A “Tentative Final Monograph,” the U.S. FDA's position on safety and efficacy of a particular ingredient within a therapeutic category and acceptable labeling for indications, warnings, and directions for use, is then developed and published. Active ingredients are deemed as follows: Category I, GRASE for claimed therapeutic indications and not misbranded; Category II, Not-GRASE and or misbranded; and Category III, insufficient data for determination.

After public comment, the final monograph is established and published with the U.S. FDA's final criteria for which all drug products in a therapeutic class become GRASE and not misbranded. Following the effective date of the final monograph, all covered drug products that fail to conform to its requirements are considered to be misbranded and an unapproved new drug (29).

Because the monograph panels are no longer convened, however, many current products are switched from prescription to OTC status. A company that wishes to make this switch and offer an OTC product to the U.S. marketplace can submit an amendment to a monograph to the U.S. FDA, which will act as the sole reviewer. The company also may file an SNDA provided that they have 3 years of marketing experience as a prescription product, can demonstrate a relatively high use during

that period, and can validate that the product has a mild profile of adverse reactions. The last method involves a “Citizens Petition,” which rarely is used (30).

Regulating Marketing

The U.S. FDA has jurisdiction over prescription drug advertising and promotion. The basis for these regulations lies within the 1962 Kefauver-Harris Amendments. Essentially, any promotional information in any form must be truthful, balanced, and fully disclosed. The U.S. FDA views this information as either “advertising” or “labeling.” Advertising includes all traditional outlets in which a company places an ad. Labeling includes everything else, including brochures, booklets, lectures, slide kits, letters to physicians, company-sponsored magazine articles, and so on. All information must be truthful and not misleading. All material facts must be disclosed in a manner that is balanced and accurate. If any of these requirements are violated, the product is considered to be “misbranded” regarding the indications for which it was approved under its NDA. Additionally, the U.S. FDA also is sensitive to the promotion of a product for “off-label use,” which occurs when a product is in some way presented in a manner that does not agree with or is not addressed in its approved labeling. Also, provisions of the Prescription Drug Marketing Act of 1987 apply. The Act prohibits company representatives from directly distributing or reselling prescription drug samples. Companies are required to establish a closed system of record keeping that will be able to track a sample from their control to that of a prescriber to prevent diversion. Prescribers are required to receive these samples and to record and store them appropriately (31).

Violations and Enforcement

The U.S. FDA has the power to enforce the regulations for any product as defined under the FDCA. It has the jurisdiction to inspect a manufacturer's premises and their records. After a facilities inspection, an agency inspector will issue a U.S. FDA Form 483s, which describes observable violations. Response to the finding as described on this form must be made promptly. A “Warning Letter” may be used when the agency determines that one or more of a company's practices, products, or procedures are in violation of the FDCA. The U.S. FDA district office has 15 days to issue a warning letter after an inspection. The company has 15 days in which to respond to this warning letter. If the company response is satisfactory to the U.S. FDA, no other action is warranted. If the response is not, the U.S. FDA may request a “recall” of the violated products. However, the U.S. FDA has no authority to force a company to recall a product but may force removal of a product through the initiation of a seizure.

Recalls

Recalls can fall into one of three classes. A Class I recall exists when a reasonable possibility exists that the use of a product will cause either serious adverse effects on health or death. A Class II recall exists when the use of a product may cause temporary or medically reversible adverse effects on health or when the probability of serious adverse effects on health is remote. A Class III recall exists when the use of a product is not likely to cause adverse health consequences. Recalls also are categorized as consumer level, where the product is requested to be recalled from the consumers' homes or control; retail level, where the products are to be removed from retail shelves or control; and wholesale level, where the product is to be removed from wholesale distribution. Companies that conduct a recall of their

products are required to conduct “Effectiveness Checks” to determine the effectiveness of recalling the product from the marketplace.

An Injunction

If a company refuses to recall the product, the U.S. FDA will seek an injunction against the company (32). An injunction is recommended by the U.S. FDA to the U.S. Department of Justice, which takes the request to federal court and issues the order that forbids a company from carrying out a particular illegal act, such as marketing a product that the U.S. FDA considers a violation of the FDCA. Companies can either comply with the order and sign a “consent agreement,” which will specify changes required by the U.S. FDA for the company to continue operations, or litigate.

Seizure of Products

The U.S. FDA also may initiate a seizure of violative products (33). A seizure is ordered by the federal court in the district that the products are located. The seizure order specifies products, their batch numbers, and any records determined by the U.S. FDA as violative. The U.S. Marshals carry out this action. The U.S. FDA institutes a seizure to prevent a company from selling, distributing, moving, or otherwise tampering with the product.

Additionally, the U.S. FDA may debar individuals or firms from assisting or submitting an ANDA or from directly providing services to any firm with an existing or pending drug product application. Debarment may last for up to 10 years (34).

One of the more powerful deterrents that the U.S. FDA uses is adverse publicity. The U.S. FDA has no authority to require a company to advertise adverse publicity, but it does publish administrative actions against a company in any number of federal publications, such as the *Federal Register, FDA Enforcement Report, FDA Medical Bulletin*, and *FDA Consumer* (35).

Summary

The laws and regulations that govern the U.S. pharmaceutical industry are both vast and complicated. Interpretation of the FDCA is in a constant state of flux. The U.S. FDA is charged with this interpretation based on the rapid technological changes that are occurring each day within the industry. Many may suggest that more rapid drug approval places the citizenry in greater danger of adverse events. Others may reply that technology offers newer and more effective therapies for deadly diseases.

Historically, Congress has passed laws governing our medication based on a reaction to a crises. The USPFDA, the FDCA, and the Price Competition and Patent Restoration Act are just a few. One hopes that this method of regulation will not continue as the norm. We can be proud of proactive legislation, such as the Kefauver-Harris Act, the Orphan Drug Act, the PDUFA, and FDAMA. These Acts have paved the way for meaningful change within the drug investigation process as we continue in our battle against disease. The U.S. system of investigating new drugs is one that continues to have merit by allowing enough time to investigate benefit versus risk. The American public can look forward to great advances from the industry and should be comfortable that the U.S. FDA is watching.

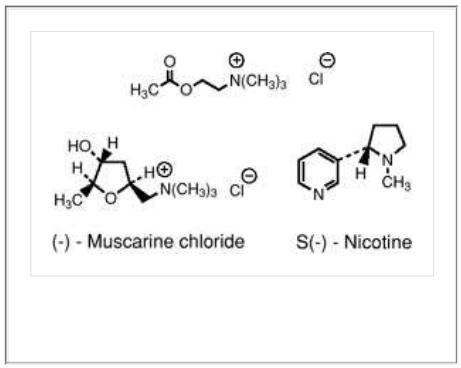
Chapter 12

Drugs Affecting Cholinergic Neurotransmission

E. Kim Fifer

Introduction

It is likely that no other mammalian system or chemical neurotransmitter has been studied as exhaustively as the parasympathetic nervous system and acetylcholine. Acetylcholine functions as the neurotransmitter for many different neurons (Fig. 12.1) (1). In the autonomic nervous system, it is released by pre- and postganglionic fibers of the parasympathetic division, preganglionic fibers of the sympathetic division, and a few postganglionic fibers of the sympathetic division (e.g., sweat and salivary glands). It also is released by neurons of the somatic (voluntary) nervous system and by some neurons in the central nervous system (CNS). Neurons that release acetylcholine are referred to as cholinergic, as are the receptors on which these neurons synapse. These receptors are further classified as either muscarinic or nicotinic, depending on their ability to bind the naturally occurring alkaloid muscarine or nicotine, respectively. Parasympathetic nerve impulses stimulate contraction of smooth muscle in the gastrointestinal tract and urinary tract, contraction of the ciliary muscle of the eye, relaxation of smooth muscle of the blood vessels, and decreased heart contractility and rate.



Chemical compounds that cause stimulation of the parasympathetic nervous system are called cholinomimetic or, more specifically, parasympathomimetic agents. Cholinomimetic agents might be agonists that act directly on cholinergic receptors or function as inhibitors of acetylcholinesterase (AChE), the enzyme responsible for hydrolysis of acetylcholine. Those compounds that possess affinity for cholinergic receptors but exhibit no intrinsic activity are called cholinergic antagonists, cholinolytic, or parasympatholytic agents. This chapter is devoted to the discussion of cholinergic agonists and antagonists and to the biochemistry of cholinergic neurotransmission.

Studies of the parasympathetic nervous system and cholinergic agents led to the concept of neurochemical transmission and were instrumental in the development of early drug receptor hypotheses and our understanding of the stereochemical influence on drug action. An excellent summary of this history is presented by Holmstedt (2).

In 1914, Dale defined two subdivisions of the parasympathetic nervous system when he observed that ethers and esters (including acetylcholine) of choline produced effects similar to those of muscarine (muscarinic effects) or nicotine (nicotinic effects) (2). The initial experiments were performed using an ergot extract contaminated with acetylcholine, although Dale was unaware of this contamination. Ewins, a chemist who collaborated with Dale, isolated acetylcholine from the ergot extract and subsequently synthesized acetylcholine, thus allowing Dale to show that the unexpected muscarinic effects observed with the ergot preparation were the result of acetylcholine. He proposed the term "parasympathomimetic" to describe

the ability of acetylcholine to produce the same effects as electrical stimulation of parasympathetic nerves, and he suggested that acetylcholine was a chemical neurotransmitter in the parasympathetic nervous system. Dale also observed that the action of acetylcholine was short-lived, and he proposed that tissues contained an esterase that hydrolyzed acetylcholine. In 1921, Loewi (3) demonstrated that a chemical compound mediated impulses between nerves; he referred to the chemical substance in his preparation as *vagusstoff*. In 1926, Loewi and Navratil (4) provided experimental evidence suggesting that vagusstoff was acetylcholine.

Clinical Significance

Agents affecting cholinergic neurotransmission are some of the most widely studied agents to date. It also is one of the most intriguing classes of study in that the clinical utility of these compounds runs the gamut from the life-saving potential of atropine given to patients undergoing cardiac life support to the life-threatening capacity of chemical warfare agents, such as sarin. Advancements in our understanding of muscarinic and nicotinic receptor activity and compounds that modulate these effects have led to decreased morbidity and mortality and increased quality of life for millions of individuals throughout the world. Additionally, those agents employed as insecticides or pesticides have had tremendous economic impact as well. Agents affecting cholinergic neurotransmission are used to treat a variety of clinical conditions, including impaired or excessive gastric motility/secretion, glaucoma, bradycardia, Alzheimer's disease, Parkinson's disease, and myasthenia gravis. Nicotinic antagonists are used to facilitate surgical procedures by reducing the amount of anesthetic or sedative agent required, thus reducing risk to the patient.

A thorough understanding of the structure–activity relationships of these compounds has led to an ability to enhance their desired pharmacodynamic effects while minimizing unwanted or harmful adverse effects. The impact of the application of this knowledge is multifaceted for the clinician. Examples include the synthesis of newer chemical compounds used to treat Alzheimer's disease that provide greater affinity for acetylcholinesterase in the brain than in the periphery, decrease the frequency of dosing required, and alleviate the risk

of hepatotoxicity that was associated with the first Alzheimer's agent, tacrine. These advances have increased the utility of these agents and given hope to countless individuals and families affected by this devastating disease. Modifications to the neuromuscular blocking agents have resulted in differences in onset and length of activity, reduction in adverse effects (e.g., hypotension), and alternate routes of elimination, which increase their utility for patients with certain comorbid conditions (e.g., cardiac disease or renal dysfunction). Finally, it also is important for the clinician to recognize the capacity of certain chemical configurations to be allergenic or more prone to producing adverse effects so that the best agent for a particular patient can be selected.

Kathryn Neill, Pharm.D.

Assistant Professor

Critical Care Specialist

Department of Pharmacy Practice

College of Pharmacy

University of Arkansas for Medical Sciences

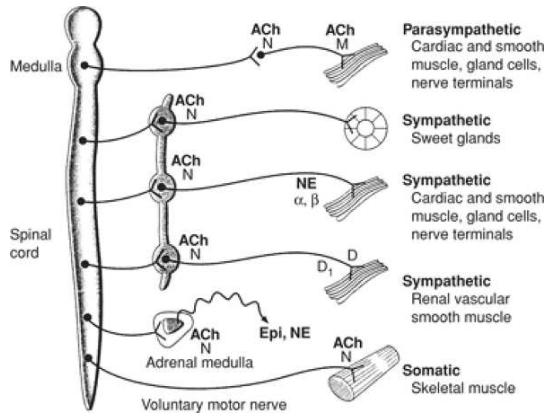


Fig. 12.1. Schematic representation of autonomic and somatic motor nerves. The sites of action of acetylcholine (ACh), norepinephrine (NE), epinephrine (Epi), and dopamine (D) are indicated. Cholinergic receptors are designated as nicotinic (N) or muscarinic (M). (From Katzung BG. Introduction to autonomic pharmacology. In: Katzung BG, ed. Basic and Clinical Pharmacology, 9th Ed. New York: McGraw-Hill, 2004, pp. 75–93; with permission.)

These classic studies are the foundation of our current understanding about the role of acetylcholine in cholinergic nerve transmission and our recognition of muscarinic and nicotinic cholinergic receptors. They provided the stimulus for subsequent studies of acetylcholine biochemistry, synthesis of new organic compounds (e.g., cholinergic and anticholinergic drugs), and purification of cholinergic receptors.

The concept that muscarinic and nicotinic receptors may explain the different physiologic responses produced by acetylcholine was derived from this early research of Dale and Loewi. Although it currently is recognized that there are multiple subclasses of both muscarinic and nicotinic receptors, the general classification of these two types of cholinergic receptors continues to

effectively explain the different physiologic responses produced by acetylcholine.

Because of the important role of acetylcholine as a chemical neurotransmitter in the autonomic nervous system, an imbalance in parasympathetic tone can lead to serious consequences. Conceptually, deficiencies in acetylcholine could be treated by administering the neurotransmitter itself, but acetylcholine is a poor therapeutic agent. Its actions are nonselective, producing effects at all cholinergic receptor sites, which could result in serious consequences for the patient. Because acetylcholine is a quaternary ammonium salt, it is poorly absorbed across biological membranes, resulting in poor bioavailability regardless of the route of administration. Furthermore, its ester functional group is rapidly hydrolyzed in the acidic conditions of the gastrointestinal tract and by esterases in plasma.

Muscarinic cholinergic agents are used postsurgically to reestablish smooth muscle tone of the gastrointestinal and urinary tracts to relieve abdominal distention and urinary retention. They also are used to treat some forms of glaucoma by enhancing the outflow of aqueous humor, thereby reducing intraocular pressure. Cholinomimetic compounds with CNS activity are being evaluated for the treatment of cognitive disorders (e.g., Alzheimer's disease). Those that exhibit nicotinic effects are commonly used to treat myasthenia gravis.

Cholinergic muscarinic antagonists (anticholinergic drugs) are sometimes referred to as antispasmodics because of their ability to reduce smooth muscle spasms resulting from overstimulation of the gastrointestinal smooth muscles. Newer drugs in this class have found use in the treatment of overactive bladder.

Many synthetic cholinergic agonists have been designed using structure–activity relationships (SARs) based on the structure of acetylcholine. To design cholinergic agents that are selective for specific cholinergic receptors, it is necessary to have a thorough understanding of acetylcholine neurochemistry as well as the chemical nature and role of cholinergic receptors.

Cholinergic Receptors

History

Much effort has gone into understanding how cholinergic receptors carry out the two primary functions of all receptors—molecular recognition

and signal transduction. A thorough understanding of these phenomena is essential to achieving rational, efficient, and selective drug therapy.

Knowledge regarding the structure and function of cholinergic receptors has increased substantially since the concept of distinct muscarinic and nicotinic receptors was first postulated. Early efforts to describe these receptors were hindered in that receptors were only a concept. Indeed, their existence was not established until 1973, when Pert and Snyder (5) provided demonstrable evidence for the existence of opiate receptors.

Early attempts to characterize cholinergic receptors were based on SAR and stereochemical studies of cholinergic agonists and antagonists. This led to synthesis of agonists and antagonists with exceptionally high affinity and selectivity for cholinergic receptors as well as to synthesis of radiolabeled cholinergic ligands with high specific radioactivity. These advances were paralleled by advances in biochemistry, molecular pharmacology, and molecular biology that made possible the purification and sequencing of small quantities of protein, the measurement of ligand binding to cell membranes and subcellular components, and the cloning and sequencing of genes. This led to isolation, purification, and amino acid sequencing of one of the nicotinic cholinergic receptors—the first acetylcholine receptor and the first neurotransmitter receptor to be fully characterized (6,7). Subsequently, muscarinic receptors were isolated, purified, and sequenced using these techniques.

Current pharmacological and molecular biological research indicates that multiple muscarinic and nicotinic acetylcholine receptor subtypes exist (8,9). The traditional classification of muscarinic and nicotinic receptors, however, adequately describes the actions of most cholinergic medicinal agents and is used throughout this chapter. Furthermore, most of the current therapeutic agents acting at muscarinic receptors exhibit little selectivity for the receptor subtypes, with the exception of a few recently introduced anticholinergic agents for treatment of overactive bladder.

Muscarinic Receptors

The SAR regarding the affinity and efficacy of cholinergic agonists provided the basis for early models of muscarinic receptor structure. An early model of the muscarinic receptor, depicted in Fig. 12.2, illustrates the importance of muscarinic agonists having an ester functional group and a quaternary ammonium group separated by two carbons. This model depicts ionic bonding between the positively charged quaternary nitrogen of acetylcholine and a negative charge at the anionic site of the receptor. The negative charge was suggested to result from a carboxylate ion from the free carboxyl group of a dicarboxylic amino acid (e.g., aspartate or glutamate) at the binding site of the receptor protein. This model also involved a hydrogen bond between the ester oxygen of acetylcholine and a hydroxyl group contributed by the esteratic site of the receptor.

Although this early muscarinic receptor model accounted for two important SAR requirements for muscarinic agonists, it failed to explain the following: 1) At least two of the alkyl groups bonded to the quaternary nitrogen must be methyl groups, 2) the known stereochemical

requirements for agonist binding to the receptor, and 3) the fact that all potent cholinergic agonists have only five atoms between the quaternary nitrogen and the terminal hydrogen atom. This last point is known as Ing's “Rule of Five” (10).

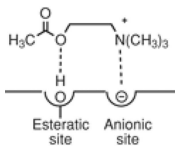

Fig. 12.2. Original representation of the muscarinic receptor.

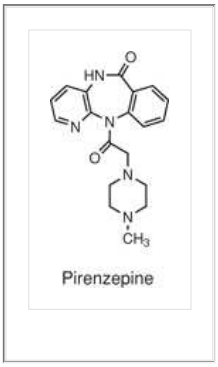
Subsequent models of the cholinergic muscarinic receptor depicted the receptor as a binding site on a protein molecule and explained more completely the structural and stereochemical requirements for cholinergic agonist activity. Some scientists proposed that the muscarinic receptor and AChE were the same entity, but this proposal was dispelled by experiments demonstrating that interaction of cholinergic ligands with the muscarinic receptor did not lead to hydrolysis of the ligand. None of these models, however, completely explained the diverse pharmacological effects produced by all muscarinic agonists and antagonists.

Subsequent developments suggested that the effects of muscarinic receptor stimulation are mediated by second messengers that are biosynthesized by at least two important events: 1) inhibition of adenylyl cyclase*, and 2) activation of phospholipase C. Both involve a guanosine triphosphate (GTP)–dependent mechanism. Two other important developments were the synthesis of radiolabeled muscarinic ligands and the utilization of molecular biology techniques in the study of muscarinic receptors.

Heterogeneity in the muscarinic receptor population was first suggested in the late 1970s during pharmacological studies using the muscarinic antagonist pirenzepine. At the time, pirenzepine was the only muscarinic antagonist to block gastric acid secretion at concentrations that did not block the effects of muscarinic agonists. This observation initiated research that ultimately led to discovery of muscarinic receptor subtypes, designated as M_1, M_2, and M_3 based on their pharmacological responses to various ligands. Rapid advances in molecular biology led to the cloning of cDNAs that encoded for five muscarinic receptors, designated as m1 through m5; m1, m2, and m3 correspond to the respective M_1 through M_3 receptors identified by their pharmacological specificity. The International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification has recommended that the uppercase nomenclature M_1 through M_5 be used to designate both pharmacological as well as molecular subtypes (8).



Pirenzepine

All the muscarinic receptor subtypes (M_1–M_5) are found in the CNS, and other tissues may contain more than one subtype. These receptors are summarized in Table 12.1 (11). As more muscarinic receptor subtypes have been discovered, it has become apparent that there is a lack of known antagonists exhibiting "very high subtype selectivity" and that there "are no muscarinic agonists with high selectivity" (8). Thus, proof for involvement of any one receptor subtype in a given system currently requires use of more than one antagonist. Additionally, if the selectivity of a novel muscarinic antagonist or putative agonist is to be assessed, it should be through the use of recombinant muscarinic receptors expressed in cell lines rather than with native receptors.

Cloning and sequencing of genes encoding muscarinic receptors have led to major advances in understanding of their chemical nature and function (8,12,13,14). These experiments demonstrated that muscarinic receptors belong to a group of receptors that are coupled to guanine nucleotide–binding proteins and are referred to as G protein–coupled receptors (GPCR) (8,15,16). The guanine nucleotide regulatory protein to which the receptors are coupled has three subunits (α, β, and γ), which link the receptor to effectors that produce second messenger molecules within the cell. Binding of muscarinic agonists to GPCRs leads to a variety of effector responses (see below). The ultimate observable response is a function of the tissue where the receptor is located.

The amino acid sequences (primary structures) of muscarinic receptor proteins expressed by cloned genes for the GPCRs have been deduced from the base sequence of the respective genes. These GPCRs are components of the cell membrane and consist of seven hydrophobic transmembrane helical domains as well as hydrophilic extracellular and intracellular domains (17). The N-terminus of the GPCR protein is extracellular, and the C-terminus is intracellular. This proposed arrangement for the human type 1 muscarinic receptor, including its deduced amino acid sequence, is illustrated in Fig. 12.3 (12). Computer-assisted molecular modeling also has made it possible to obtain three-dimensional models of the muscarinic receptor (17); a proposed top-view model of the M_1 muscarinic receptor is shown in Fig. 12.4 (18). It is interesting to observe that this model suggests that the quaternary nitrogen of acetylcholine participates in an ionic bond with the free carboxylate group of an aspartate residue (D105)—one of the receptor functional groups that was hypothesized to be involved in receptor binding of acetylcholine almost 60 years ago using only SAR data and the powers of deduction.

The current model for muscarinic receptors is much more descriptive than earlier models, and it better describes ligand binding (molecular recognition) and its effect (signal transduction) (Fig. 12.5) (14). In this model, acetylcholine binds to the muscarinic receptor located in the cell membrane, and this ligand–receptor interaction is translated, presumably by a conformational perturbation, through the receptor protein to

the receptor-coupled guanine nucleotide regulatory protein (G protein). A relationship between the guanine nucleotide regulatory protein and the effector is illustrated in Fig. 12.6. In this scheme, the G protein is in the inactive state, with guanosine diphosphate (GDP) bound to its α subunit. On interaction of an agonist with the muscarinic receptor, the α subunit releases GDP and binds GTP. The α subunit–GTP complex then dissociates from the βγ subunits. Both the α subunit–GTP complex and the βγ subunits interact with membrane-bound effectors (phospholipase C or adenylate cyclase) or ion channels (K^+ and Ca^{2+}), either independently or in a parallel manner. The α subunit possesses GTPase activity and quickly hydrolyzes the GTP to GDP to terminate signal transmission, at which time the α, β, and γ subunits reassociate and migrate back to the receptor protein. Characteristics of the α subunit determine the classification of the particular G protein:

Table 12.1. Muscarinic Acetylcholine Receptor Subtypes[a]

Receptor	G Protein	Tissue Location	Cellular Response	Function
M_1	$G_{q/11}$	CNS, gastric and salivary glands, autonomic ganglia, enteric nerves	PLC activation (↑IP_3 & ↑DAG → ↑Ca^{2+} & PKC); depolarization and excitation (↑sEPSP); PLA_2 and PLD_2 activation; ↑AA	↑ Cognitive function ↑Seizure activity ↑Secretions ↑ Autonomic ganglia depolarization ↓ DA release and locomotion
M_3	$G_{q/11}$	CNS (< other mAChRs), smooth muscle, glands, heart	Same as M_1	↑ Smooth muscle contraction (e.g., bladder) ↑ Salivary gland secretion ↑ Food intake, body fat deposits Inhibits dopamine

				release Synthesis of nitric oxide
M_5	$G_{q/11}$	Low levels in CNS & periphery; predominate mAChRs in dopaminergic neurons of substantia nigra & ventral tegmentum area	Same as M_1	Mediates dilation of cerebral arteries Facilitates dopamine release Augments drug seeking behavior and reward
M_2	G_i/G_o	Autonomic nerve terminals; CNS; heart; smooth muscle	Inhibition of adenylyl cyclase (↓cAMP) & voltage gated Ca^{2+} channels; activation of inwardly rectifying K^+ channels	↓ Heart rate ↑ Smooth muscle contraction Neural inhibition in periphery via autoreceptors and heteroreceptor ↓ Ganglionic transmission Neural inhibition in CNS ↑ Tremors hypothermia & analgesia
M_4	G_i/G_o	CNS	Same as M_2	Inhibition of autoreceptor- and heteroreceptor-mediated transmitter release in CNS Analgesia Cataleptic activity; Facilitates dopamine release

[a]CNS, central nervous system; PLC, phospholipase C; IP_3, inositol-1, 4, 5-triphosphate; DAG, diacylglycerol; PLD_2, phospholipase D; AA, arachidonic acid; PKC, protein kinase C; sEPSP, slow excitatory postsynaptic potential; mAChRs, muscarinic acetylcholine receptor subtypes; PLA, phospholipase A; cAMP, cyclic adenosine monophosphate; VTA, ventral tegmentum area.

Gs	increases adenylyl cyclase activity and increases Ca21 currents
G_i	decreases adenylyl cyclase activity and increases K^+ currents
G_o	decreases Ca^{2+} currents
G_q	increases phospholipase C activity

The βγ subunits are involved with receptor-operated K^+ currents and with activity of adenylyl cyclase and phospholipase C.

Signal transduction at the stimulatory "odd-numbered" muscarinic receptors (i.e., M_1, M_3, and M_5) is via coupling with a $G_{q/11}$ protein that is involved with mobilization of intracellular calcium. Agonist binding to these receptors results in activation of phospholipase C, with subsequent production of the second messengers, diacylglycerol and inositol-1,4,5-triphosphate (IP_3). Stimulation of IP_3 ion channel receptors leads to the release of intracellular calcium from the endoplasmic reticulum. The diacylglycerol produced, along with calcium, activates protein kinase C, which phosphorylates proteins to afford various physiological responses. The M_1, M_3, and M_5 receptors also stimulate phospholipase A_2 and

phospholipase D. Activation of phospholipase A_2 results in release of arachidonic acid, with subsequent synthesis of eicosanoids (C_{20} fatty acids).

The "even-numbered" muscarinic receptor subtypes (i.e., M_2 and M_4) are coupled to G_i/G_o proteins, the activation of which results in inhibition of adenylyl cyclase.

P.366

This results in a decrease in cyclic adenosine monophosphate, inhibition of voltage-gated calcium channels, and activation of inwardly rectifying potassium channels (19). The result is hyperpolarization and inhibition of these excitable membranes.

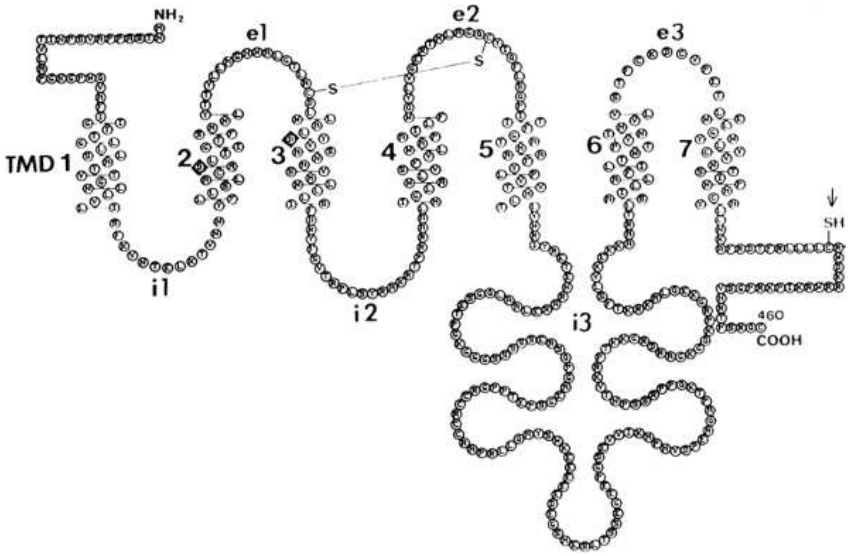

Fig. 12.3. Deduced amino acid sequence of human muscarinic acetylcholine receptor M_1 and putative arrangement of the seven transmembrane domains, three intracellular domains (i_1–i_3), and three extracellular domains (e_1–e_3). (From Lameh J, Cone RI, Maeda S, et al. Structure and function of G protein coupled receptors. Pharm Res 1990;7:1213–1221; with permission.)

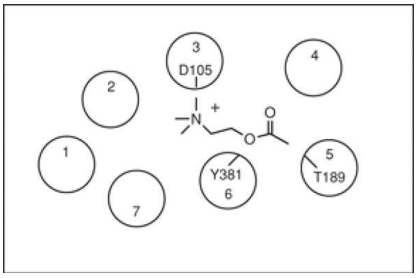

Fig. 12.4. Model of acetylcholine interaction with muscarinic M_1 receptor. Circles represent seven transmembrane domains; D105, T189, and Y381 are aspartate, threonine, and tyrosine residues, respectively.

The M_1 receptors sometimes are termed "neural" because of their abundance in the cerebral cortex, hippocampus, and striatum. The M_1 receptors have been implicated in Alzheimer's disease and are thought to be involved with such functions as memory and learning. Early studies suggested that the agonist McN-A-343 was selective for the M_1 receptor, but more recent evidence indicates otherwise. It may show moderate selectivity for

P.367

M_4 receptors. Additionally, M_1 receptors are found at autonomic ganglia, enteric nerves, and salivary and gastric glands. Agonists at M_1 receptors show the greatest promise for treatment of the cholinergic deficit associated with Alzheimer's disease.

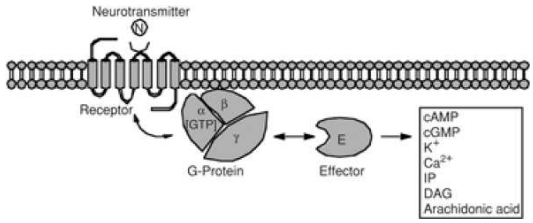

Fig. 12.5. Model of signal transduction by a G protein–coupled receptor. This illustrates a proposed relationship between receptor, G protein, effector, and various second messengers.

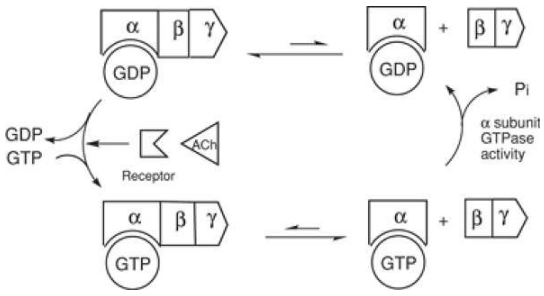

Fig. 12.6. Diagram of a GTPase cycle and subunit association/dissociation proposed to control signal transduction between muscarinic G protein–coupled receptors and the effector. The ACh–receptor interaction facilitates GTP binding and activates the α subunit. The α subunit–GTP complex then dissociates from the βγ subunit, and each is free to activate effector proteins. The duration of separation is determined by the rate of α subunit–mediated GTP hydrolysis.

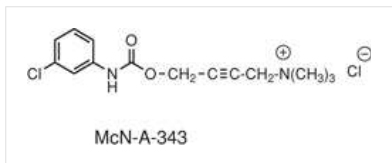

The M_2 receptors are found in abundance in the heart, where their activation exerts both negative chronotropic and inotropic actions. In smooth muscle, they stimulate contraction. Activation of M_2 autoreceptors located on nerve terminals affords neural inhibition by decreasing acetylcholine release.

The M_3 receptors are found in abundance in smooth muscle and glands, where their stimulation leads to contraction and secretion, respectively. Knowledge of this effect on smooth muscle of the bladder has led to the development and subsequent approval of several M_3 receptor antagonists for the treatment of overactive bladder (see below). Although widely distributed in the CNS, their concentration there is lower than those of other muscarinic receptors. They function to decrease neurotransmitter release.

The M_4 receptors are found in the striatum and basal forebrain, where they decrease transmitter release in both the CNS and periphery. Their activation in smooth muscle and secretary glands leads to inhibition of potassium and calcium channels.

The M_5 receptors are the least characterized of the muscarinic receptors. There is evidence for their existence in the CNS and the periphery, and they may regulate dopamine release in the CNS.

Nicotinic Receptors

Nicotinic acetylcholine receptors are found at the skeletal neuromuscular junction, adrenal medulla, and autonomic ganglia. They have been the

focus of intensive research interest, even though the majority of clinically effective cholinergic medicinal agents are either muscarinic agonists or antagonists (20). This interest in nicotinic receptors is the result of both the availability of the receptor protein from the electric organs of the electric eel *(Electrophorus electricus)* and the marine ray *(Torpedo californica)* and the important role they play in myasthenia gravis, an autoimmune disease.

The concept of multiple nicotinic receptors is based on the different structural requirements for agonists and antagonists acting at the autonomic ganglia and the skeletal neuromuscular junction. This multiplicity of nicotinic receptors also is supported by molecular biology research (20).

Both neuronal and muscular nicotinic receptors are classified as ligand-gated ion channel receptors, and they are structurally and functionally related to other ligand-gated ion channel receptors, such as γ-aminobutyric acid receptors, 5-hydroxytryptamine receptors, and glycine receptors (21). The receptor creates a transmembrane ion channel (the gate), and acetylcholine (the ligand) serves as a gatekeeper by binding with the receptor to modulate passage of ions, principally K^+ and Na^+, through the channel.

A nicotinic receptor was the first neurotransmitter receptor to be isolated and purified in the active form using the same molecular biological techniques described above for isolation and purification of muscarinic receptors. The primary sequence of nicotinic receptors has been deduced from cloning and sequencing of genes that encode their receptor proteins (22,23). Nicotinic receptors are pentameric transmembrane proteins made up of α, β, δ, and/or γ subunits (24).

The nicotinic receptor of muscle tissue is a transmembrane glycoprotein consisting of four types of subunits—α, β, γ(or ε), and δ. Only the α_1 subtype of the α subunit is present in muscle. In a mature muscle end plate, the γ subunit is replaced by an ε subunit. This change in gene expression encoding the γ and ε subunits affects ligand selectivity along with receptor turnover and/or tissue location.

One class of neuronal nicotinic receptors exists as a heteromeric pentamer composed of α (α_2–α_6) and β (β_2–β_4) subunits (25,26,27)—for example, $\alpha_4\beta_3$ with a stoichiometry of two α_4 and three β_3 subunits. Another class of functional homomeric nicotinic receptors is composed of α_7 through α_{10} subunits. The diversity of the subunits and the pentameric structure suggest that a large number of nicotinic receptor subtypes may exist.

The five subunits of each receptor protein in muscle tissue are arranged around a central pore that serves as

the ion channel. Based on molecular modeling of the deduced primary structure of the individual subunits, it has been proposed that each subunit (α, β, γ, δ, or ε) possesses a hydrophilic extracellular N-terminus, a hydrophilic intracellular C-terminus, and four α helical hydrophobic transmembrane domains (M_1–M_4) (Fig. 12.7) (26,28). A pentameric arrangement of these five amphipathic subunits makes up the walls of the ion channel. Two acetylcholine binding sites exist on the extracellular domain of each receptor molecule. In Figure 12.7, one binding site is located on each α subunit at the αγ and αδ interfaces (28). The binding sites show a positive cooperativity, even though the two binding sites are not adjacent to each other in the pentameric receptor. Some central and peripheral nicotinic receptor subtypes are summarized in Table 12.2 (11).

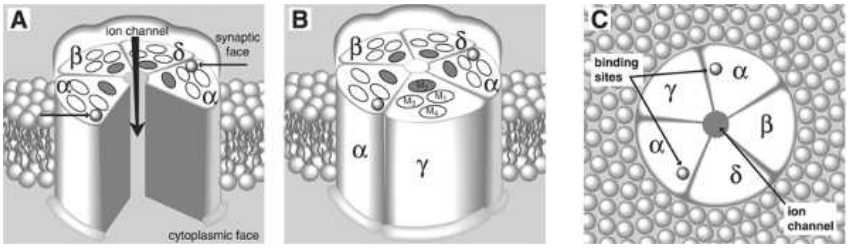

Fig. 12.7. Nicotinic cholinergic receptor. (A) Longitudinal view (γ subunit removed) showing the internal ion channel. Acetylcholine binding sites on the α subunits are indicated by the arrows. These are located at the αγ and αδ interfaces. (B) Each of the five transmembrane subunits (α, α, β, δ, and γ) are composed of four hydrophobic membrane spanning segments (M_1–M_4). (C) Top view of the nicotinic receptor showing the subunits surrounding the ion channel.

Our knowledge and understanding of the muscarinic and nicotinic receptors have advanced tremendously from the time when these receptors were only ethereal concepts. This understanding provides the basis for the rational design of new selective therapeutic agents to treat diseases associated with cholinergic neurons.

Table 12.2 Nicotinic Acetylcholine Receptor Subtypes

Receptor	Location	Membrane Response	Molecular Mechanism	Agonists	Antagonists
Skeletal muscle (N_M) $(\alpha_1)_2\beta_1$ εδ $(\alpha_1)_2\beta_1$ γδ	Skeletal neuromuscular junction (postjunctional)	Excitatory; end plate depolarization; contraction (skeletal **m**uscle)	Increased Na^+ & K^+ permeability	ACh; nicotine; succinylcholine	Atracurium; vecuronium; *d*-tubocurarine; pancuronium; α-conotoxin; α-bungarotoxin

Peripheral neuronal (N_N) $(\alpha_3)_2(\beta_4)_3$	Autonomic ganglia; adrenal medulla	Excitatory; depolarization firing of postganglionic neuron; depolarization & secretion of catecholamines	Increased Na^+ & K^+ permeability	ACh; nicotine; epibatidine; dimethylphenyl-piperazinium	Trimethaphan; mecamylamine; dihydro-β erythrodine; erysodine lophotoxin
Central neuronal (CNS) $(\alpha_4)_2(\beta_4)_3$ (α-bungarotoxin insensitive)	CNS; pre- & postjunctional	Pre- & postsynaptic excitation; prejunctinal control of transmitter release	Increased Na^+ & K^+ permeability	Cytisine; epibatidine; Anatoxin A	
$(\alpha_7)_5$ (α-bungarotoxin sensitive)	CNS; pre- and postsynaptic	Same as central neuronal	Increased CA^{2+} permeability	Anatoxin A	Methyllycaconities; α-conotoxin; α-bungarotoxin

Drugs Affecting Cholinergic Neurotransmission

Acetylcholine Neurochemistry

The neurochemistry of acetylcholine includes its biosynthesis, storage, release, and metabolism. These are illustrated in Figure 12.8.

Biosynthesis

Acetylcholine is biosynthesized in cholinergic neurons by the enzyme-catalyzed transfer of the acetyl group from acetyl coenzyme A (acetyl-S-CoA) to choline, a quaternary ammonium alcohol (29). The enzyme catalyzing this reaction, choline acetyltransferase, is also biosynthesized in the cholinergic neuron. Some choline is biosynthesized from the amino acid serine (Fig. 12.9), but most of the choline used to form acetylcholine is recycled following AChE-catalyzed hydrolysis of acetylcholine in the synaptic space. Extracellular choline is actively transported into the presynaptic nerve terminal by both high-affinity and low-affinity uptake sites. The high-affinity sites are responsible for the uptake of most of the choline recycled from the synapse. Uptake is considered to be the rate-determining step in biosynthesis of acetylcholine. This uptake is inhibited by hemicholinium.

Efforts to Modulate Acetylcholine Biosynthesis

Efforts to develop therapeutic agents based on regulation of acetylcholine biosynthesis have not been successful. Dexpanthenol, the dextrorotatory enantiomer of the alcohol derived from pantothenic acid (a vitamin), was once used as a cholinomimetic agent to help reestablish normal smooth muscle tone in the gastrointestinal tract following surgery. Pantothenic acid is essential for the biosynthesis of coenzyme A (CoA). The apparent rationale for the therapeutic use of dexpanthenol was that it would be biotransformed to pantothenic acid, which would be incorporated into CoA. This would lead to increased intracellular levels of acetyl CoA, which would facilitate increased biosynthesis of acetylcholine. The limited therapeutic success of dexpanthenol, difficulty with administration, and effectiveness of synthetic cholinergic agonists led to its discontinuation. The quaternary pyridinium salt, *trans*-N-methyl-4-(1-naphthylvinyl)pyridinium iodide, is an effective inhibitor of choline acetyltransferase in vitro, but it has proven to be a poor inhibitor in whole animal experiments.

Although efforts have been made to design cholinergic agents based on the mechanism of biosynthesis of acetylcholine, such agents would be expected to have nonselective effects, because it currently is thought that acetylcholine is biosynthesized by the same mechanism in all cholinergic neurons.

Storage

Most newly biosynthesized acetylcholine is actively transported into cytosolic storage vesicles located in presynaptic

nerve endings, where it is maintained with ATP (10:1 ratio) along with calcium and magnesium ions until it is released. Some acetylcholine remains in the cytosol and eventually is hydrolyzed. Only the stored form of acetylcholine serves as the functional neurotransmitter.

Release

Release of acetylcholine from the storage vesicles is initiated by an action potential that has traveled down the axon to the presynaptic nerve membrane. This action potential leads to opening of voltage-dependent calcium channels, affording an influx of Ca^{2+} and exocytotic release of acetylcholine into the synapse. The increase in intracellular Ca^{2+} may induce fusion of acetylcholine storage vesicles with the presynaptic membrane before release of the neurotransmitter. Each synaptic vesicle contains a quantum of acetylcholine; one quantum represents between 12,000 and 60,000 molecules of acetylcholine. A single action potential causes the release of several hundred quanta of acetylcholine into the synapse.

Metabolism

Acetylcholine in the synapse can bind with cholinergic receptors on the postsynaptic or presynaptic membranes to produce a response. Free acetylcholine that is not bound to a receptor is hydrolyzed by AChE. This hydrolysis is the physiologic mechanism for terminating the action of acetylcholine. Enough AChE is present in the synapse to hydrolyze approximately 3×10^8 molecules of acetylcholine in 1 millisecond; thus, adequate enzyme activity exists to hydrolyze all the acetylcholine (~3×10^6 molecules) released by one action potential. A number of useful therapeutic cholinomimetic agents have been developed based on the ability of the compounds to inhibit AChE; these agents are addressed later in this chapter.

Stereochemistry

One shortcoming of early models for cholinergic receptors was that they did not account for the observed stereoselectivity of the receptors for agonist and antagonist ligands. Even though acetylcholine is achiral, many synthetic and naturally occurring agonists and antagonists possess chirality; usually, one enantiomer is many times more active than the other. It was apparent to early receptor investigators that the stereochemistry of cholinergic ligands was important for receptor binding. In this regard, the stereochemical–activity relationships of cholinergic ligands have been studied extensively to provide a rational basis for design of cholinergic drugs as well as to describe the properties and functions of cholinergic receptors.

The stereochemistry of acetylcholine resides in the different arrangements in space of its atoms by virtue of rotation about σ bonds (i.e., conformational isomerism). Because of relatively unrestricted rotation about these single covalent bonds, acetylcholine can exist in an infinite number of conformations. Most studies of the conformational isomerism of acetylcholine have focused on torsion angles between the ester oxygen atom and the quaternary nitrogen resulting from rotation about the Cα-Cβ bond. Four of these conformations are illustrated by Newman projections in Fig. 12.10.

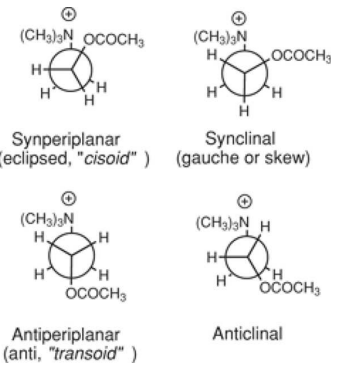

Fig. 12.10. Conformational isomers of acetylcholine.

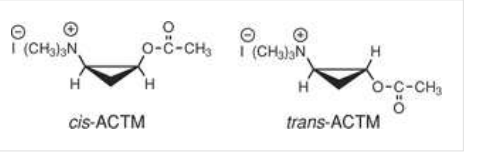
Nuclear magnetic resonance (NMR) studies in aqueous solution revealed that the preferred conformation between the ester oxygen and the quaternary nitrogen of acetylcholine was synclinal (gauche or skew). Using x-ray data, the synclinal conformation was observed for acetylcholine in the solid crystalline state as well. The same conclusion was also obtained for the preferred conformation of acetylcholine using molecular orbital calculations. These experimental and theoretical determinations of the acetylcholine conformation differ from the antiperiplanar conformation that might be expected when using molecular models to visualize minimum steric interactions. The synclinal conformation would be stabilized by intramolecular electrostatic interactions between the quaternary nitrogen and the carbonyl oxygen.

It must be emphasized that the experimentally determined synclinal conformation of acetylcholine is only that measured in aqueous solution (NMR) or the crystalline state (x-ray). This may not be the conformation preferred by the receptors. Indeed, the conformation of receptor-bound acetylcholine could be much different and might not be a thermodynamically preferred conformation.

In recognition of this possibility, conformationally restricted acetylcholine analogues have been synthesized and pharmacologically evaluated in an effort to determine the conformation of acetylcholine when it binds to cholinergic receptors. The most significant study in this regard is that of Armstrong et al. (30). They synthesized and evaluated the muscarinic and nicotinic activity of *cis*- and *trans*-isomers of a conformationally rigid model

P.371

of acetylcholine, *cis*- and *trans*-2-acetoxycyclopropyl-1-trimethylammonium iodide. Because this model is based on the cyclopropane ring, the ester and quaternary ammonium functional groups cannot change their relative positions by bond rotation. The *cis*- and *trans*-isomers are rigidly constrained to the conformations shown. The *cis*-isomer is similar to the synperiplanar conformation of acetylcholine, and the *trans*-isomer approximates the anticlinal conformation. The (+)-*trans*-enantiomer was observed to be equally as or more potent, depending on the pharmacological test used, than acetylcholine at muscarinic receptors; it was much more potent than the (–)-*trans*-enantiomer. The racemic *cis*-compound had almost no activity in the same muscarinic receptor test system, and all compounds were very weak nicotinic agonists.



The important conclusion drawn from this study (30) was that acetylcholine would most probably interact with muscarinic receptors in its less favored anticlinal conformation. The most active isomer, the (+)-*trans*-enantiomer, of these cyclopropane analogues was found to have a torsion angle of 137° (anticlinal) between the ester oxygen and the quaternary nitrogen. This is significantly different from the 60° torsion angle in the synclinal conformation found by NMR and x-ray determinations to be the preferred conformation.

Stereochemistry of cholinergic ligands and stereoselectivity of receptors has played an important role in design of cholinergic ligands as therapeutic agents. This role becomes apparent in subsequent sections.

Acetylcholine Mimetics—Muscarinic Agonists

Interaction of cholinergic agonists with muscarinic receptors leads to well-defined pharmacological responses depending on the tissue or organ in which the receptor is located. These responses include contractions of smooth muscle, vasodilation, increased secretion from exocrine glands, miosis, and decreased heart rate and force of contraction.

Acetylcholine

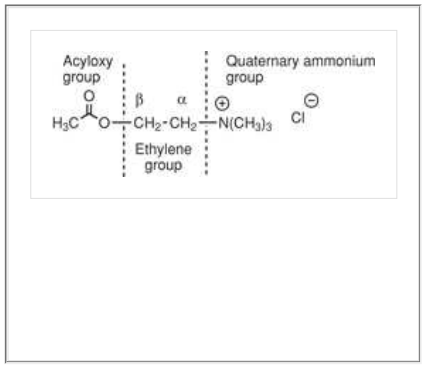
Acetylcholine is the prototypical muscarinic (and nicotinic) agonist, because it is the physiologic chemical neurotransmitter. It is a poor

therapeutic agent, however, both because of its lack of nicotinic or muscarinic receptor specificity and because of the chemical and physicochemical properties associated with its ester and quater- nary ammonium salt functional groups. It is quite stable in the solid crystalline form but undergoes rapid hydrolysis in aqueous solution. This hydrolysis is accelerated in the presence of catalytic amounts of either acid or base. For this reason, acetylcholine cannot be administered orally because of rapid hydrolysis in the gastrointestinal tract. Even when administered parenterally, its pharmacological action is fleeting as a result of hydrolysis by butyrylcholinesterase (pseudocholinesterase) in serum. The quaternary ammonium functional group of acetylcholine imparts excellent water solubility, but quaternary ammonium salts are poorly absorbed across lipid membranes because of their high hydrophilic and ionic character. Thus, even if acetylcholine were stable enough to be administered orally, it would be poorly absorbed. When used during ocular surgery to produce complete miosis within seconds, acetylcholine must be directly instilled into the anterior chamber. It cannot be administered topically, because it is not lipophilic enough to penetrate the cornea. It requires aqueous reconstitution immediately before instillation because of its chemical hydrolytic lability.

Structure–Activity Relationship

The necessity to design compounds that would serve as therapeutic alternatives to acetylcholine and as probes to study the role of acetylcholine in neurotransmission led to an exhaustive study of the structural features required for the action of acetylcholine. Structure–activity relationships that developed from these studies have provided the basis for the design of all muscarinic agonists currently used as therapeutic agents.

To review the SAR, it is logical to divide the structure of acetylcholine into the three components shown below to examine the effects of chemical modification of each group:



Modification of the quaternary ammonium group

Analogues of acetylcholine in which the nitrogen atom was replaced by arsenic, phosphorus, or sulfur have been synthesized (10,31). Although they exhibited some of the activity of acetylcholine, these compounds are less active and are not used clinically. It was concluded that only compounds possessing a positive charge on the atom in the position of the nitrogen had appreciable muscarinic activity.

Compounds in which all three methyl groups on the nitrogen are replaced by larger alkyl groups are inactive as agonists. When the methyl groups are replaced by three ethyl groups, the resulting compound is a cholinergic antagonist. Replacement of only one methyl group by an ethyl or propyl group affords a compound that is

active, but much less so than acetylcholine (32). Furthermore, successive replacement of one, two, or three of the methyl groups with hydrogen atoms to afford a tertiary, secondary, or primary amine, respectively, leads to successively diminishing muscarinic activity (33,34).

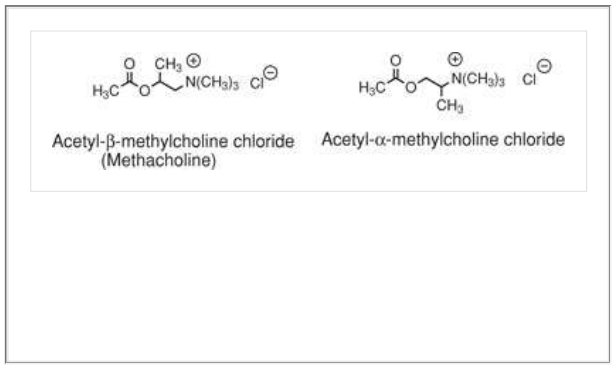
Modification of the ethylene bridge

Synthesis of acetic acid esters of quaternary ammonium alcohols of greater length than choline led to a series of compounds with activity that was rapidly reduced as the chain length increased. This observation led Ing (10) to postulate his Rule of Five. This rule suggests that there should be no more than five atoms between the nitrogen and the terminal hydrogen atom for maximal muscarinic potency. Present concepts suggest that the muscarinic receptor cannot successfully accommodate molecules larger than acetylcholine and still produce its physiologic effect. Although larger molecules may bind to the receptor, they lack efficacy and demonstrate antagonist properties.

Replacement of the hydrogen atoms of the ethylene bridge by alkyl groups larger than methyl affords compounds that are much less active than acetylcholine. Introduction of a methyl group on the carbon β to the quaternary nitrogen affords acetyl-β-methylcholine (methacholine), which has muscarinic potency almost equivalent to that of acetylcholine and much greater muscarinic than nicotinic selectivity.

A methyl group on the carbon α to the quaternary nitrogen affords acetyl-α-methylcholine. Although activity relative to acetylcholine is reduced at both muscarinic and nicotinic receptors, it exhibits greater nicotinic than muscarinic potency. This compound is not currently used as a therapeutic agent.

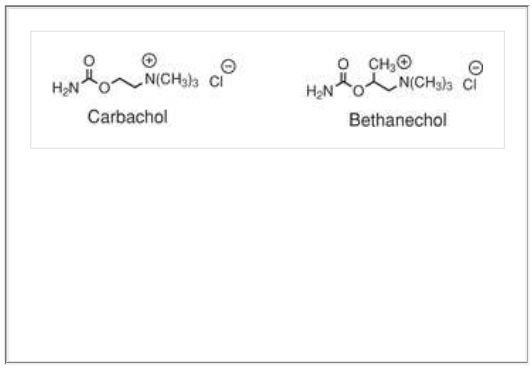
Addition of methyl groups to either one or both of the ethylene carbons results in chiral molecules. Muscarinic receptors (see below) display stereoselectivity for the enantiomers of methacholine. The S-(+)-enantiomer is equipotent with acetylcholine, and the R-(–)-enantiomer is approximately 20-fold less potent. Acetylcholinesterase hydrolyzes the S-(+)-isomer much slower (approximately half the rate) than acetylcholine. The R-(–)-isomer is not hydrolyzed by AChE and even acts as a weak competitive inhibitor of the enzyme. This stability toward AChE hydrolysis as well as the AChE inhibitory effect of the R-(–)-enantiomer may explain why racemic methacholine produces a longer duration of action than acetylcholine. The nicotinic receptor and AChE exhibit little stereoselectivity for the optical isomers of acetyl-α-methylcholine.



Modification of the acyloxy group

As would be predicted by the Rule of Five (10), when the acetyl group is replaced by higher homologues (i.e., the propionyl or butyryl groups), the resulting esters are less potent than acetylcholine. Choline esters of aromatic or higher-molecular-weight acids possess cholinergic antagonist activity.

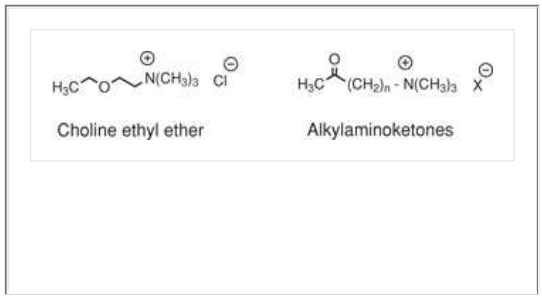
Because the fleeting pharmacological action and chemical instability of acetylcholine result from its rapid hydrolysis, a logical approach to the development of better muscarinic therapeutic agents was to replace the acetyloxy functional group with a functional group more resistant to hydrolysis. This led to synthesis of the carbamic acid ester of choline (carbachol), a potent cholinergic agonist possessing both muscarinic and nicotinic activity. Esters derived from carbamic acid are referred to as carbamates, and because their carbonyl carbon is less electrophilic, they are more stable than carboxylate esters to hydrolysis. Carbachol is less readily hydrolyzed by gastric acid, AChE, or butyrylcholinesterase than acetylcholine is, and it can be administered orally.



This same chemical logic was extended to methacholine and led to synthesis of its carbamate ester, bethanechol, an orally effective potent muscarinic agonist with almost no nicotinic activity at therapeutic doses. Muscarinic receptors exhibit stereoselectivity for the two optical isomers of bethanechol, and similar to methacholine, the S-(+)-enantiomer exhibits greater binding affinity at muscarinic receptors than the R-(–)-enantiomer in isolated receptor preparations.

The profound muscarinic activity of the alkaloid muscarine provided substantial rationale for synthesizing ethers of choline. Muscarine, which is obtained from the red variety of mushroom (*Amanita muscaria*) and other mushrooms is one of the oldest known cholinergic agonists and is the compound for which muscarinic receptors were named. It was used in many pharmacological experiments during the latter 19th century and the early part of the 20th century, and its use preceded the discovery and chemical characterization of acetylcholine (2). The chemical structure of muscarine (see above), however, was not completely characterized until 1957. Muscarine possesses three chiral centers (C2, C3, and C5). Thus, eight optical isomers (four enantiomeric pairs) are possible. Of these, only the naturally occurring alkaloid, (2S,3R,5S)-(+)-muscarine (also called L-(+)-muscarine), is correctly referred to as muscarine. The C5 carbon of (+)-muscarine has the same absolute configuration as the analogous chiral β carbon in S-(+)-methacholine.

Other choline ethers as well as alkylaminoketones have been synthesized and evaluated for muscarinic activity. Choline ethyl ether exhibits significant muscarinic activity and is chemically stable, but it has not been used clinically. The most potent ketone derivatives possess the carbonyl on the carbon δ to the quaternary nitrogen; this is the same relative position as the carbonyl in acetylcholine. This suggests that these carbonyl groups bind by either a hydrogen bond or other dipole–dipole interaction with an appropriate group on the muscarinic receptor. Furthermore, the activity of these ethers and ketones demonstrates that neither the ester functional group nor a carbonyl is required for muscarinic agonist activity.



The classic SAR for muscarinic agonist activity can be summarized as follows:

1. The molecule must possess a nitrogen atom capable of bearing a positive charge, preferably a quaternary ammonium salt.
2. For maximum potency, the size of the alkyl groups substituted on the nitrogen should not exceed the size of a methyl group.
3. The molecule should have an oxygen atom, preferably an ester-like oxygen, capable of participating in a hydrogen bond.
4. There should be a two-carbon unit between the oxygen atom and the nitrogen atom.

It is important to note that this SAR was based on in vitro and in vivo pharmacological evaluations performed over a 60-year period. Scientists conducting this research did not have the luxury of modern, highly refined biological testing systems (i.e., protein-binding assays, cell membrane–binding assays, and single-cell models) that are considered to be state-of-the-art today for pharmacological evaluation of new medicinal agents. This is why some classic muscarinic agonists and many of the more modern agents do not adhere to this SAR. Indeed, SAR rules are not static; they should change as new experimental data refine the structural and stereochemical requirements for muscarinic agonist activity.

Specific Muscarinic Agonists

Methacholine chloride (Provocholine)

Methacholine, acetyl β-methylcholine, (see previous structure and SAR discussion) is marketed as the racemic mixture. It is a selective muscarinic agonist with very little activity at nicotinic receptors. Although methacholine chloride is marketed as the racemic mixture, the S-(+)-enantiomer is 240-fold more potent than the R-(–)-isomer at muscarinic receptors. In addition, AChE hydrolyzes S-(+)–methacholine at approximately 54% the rate of acetylcholine, whereas the R-(–)–enantiomer is a weak inhibitor. Methacholine chloride is used via inhalation for the diagnosis of asthma. The resulting bronchospasm may be relieved with bronchodilators. Methacholine chloride is available as a powder that is reconstituted for inhalation.

Carbachol chloride (Isopto Carbachol)

Carbachol (see structure above), the carbamate analogue of acetylcholine, shows no selectivity for muscarinic or nicotinic receptors. Because it is a carbamate ester, carbachol is more resistant toward acid-, base-, or enzyme (AChE)-catalyzed hydrolysis than acetylcholine. It also is reported to exhibit weak anticholinesterase activity. Both of these actions work to prolong the duration of action of carbachol. Because of erratic absorption and its actions at nicotinic receptors, use of carbachol has been limited to the treatment of glaucoma and for the induction of miosis in ocular surgery. Carbachol is available as an intraocular solution and an ophthalmic solution.

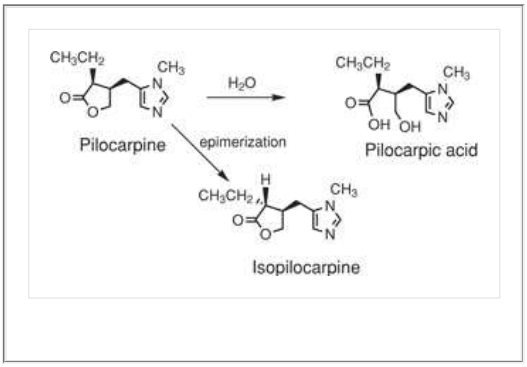
Bethanechol chloride (Urecholine)

Bethanechol (see structure above), the carbamate analogue of methacholine, is selective for muscarinic receptors and exhibits almost no activity at nicotinic receptors. It is used to treat postsurgical and postpartum urinary retention and abdominal distention. Bethanechol is administered orally, because there is danger of a cholinergic crisis if it is given by intravenous or intramuscular injection.

Pilocarpine hydrochloride (Isopto Carpine)

Pilocarpine, the salt of an alkaloid obtained from *Pilocarpus jaborandi*, is an example of a muscarinic agonist that does not adhere to the traditional SAR. In 1876, Langley reported that extracts containing the alkaloid stimulated the end organs of parasympathetic neurons. The structure of pilocarpine was reported in 1901.

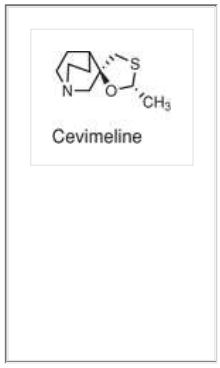
Pilocarpine is marketed as tablets (Salogen), an ophthalmic solution, and gel. It penetrates the eye well and is the miotic of choice for open-angle glaucoma and to terminate acute angle closure attacks. It also is used for the treatment of xerostomia (dryness of the mouth) caused by radiation therapy of the head and neck, Sjogren's syndrome, or as a side effect of some psychotropic drugs.



Because pilocarpine is a lactone, its solutions are subject to hydrolysis to afford the pharmacologically inactive pilocarpic acid and to base-catalyzed epimerization at C3 in the lactone to give isopilocarpine, an inactive stereoisomer of pilocarpine. Epimerization is not believed to be a serious problem if the drug is properly stored. Its solutions can be stored at room temperature, but the gel should be refrigerated and labeled with a 2-week expiration date when dispensed.

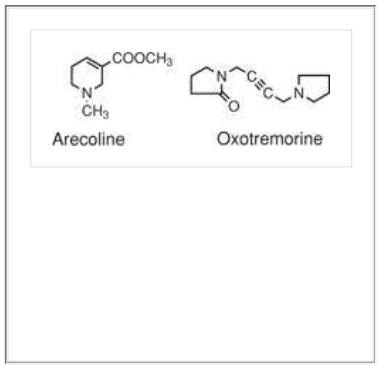
Cevimeline hydrochloride (Evoxac)

Cevimeline is a nonclassical muscarinic agonist. It is a quinuclidine derivative that exhibits partial direct M_1 receptor agonist activity in the CNS and affinity for M_3 receptors in epithelial tissue of lacrimal and salivary glands. Its elimination half-life is 3 to 5 hours. It is metabolized by CYP2D6, CYP3A3, and CYP3A4 to inactive metabolites, the *cis*- and *trans*-sulfoxide, N-oxide, and glucuronide. Cevimeline hydrochloride is available as an oral capsule for the treatment of xerostomia (dry mouth) associated with Sjogren's syndrome. Before its approval, pilocarpine was the only drug for this condition.

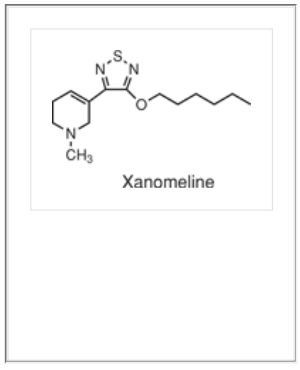


Future Muscarinic Agonists

Current research interest in the design and synthesis of new muscarinic agonists is focused on discovering agents that might be effective in the treatment of Alzheimer's disease and other cognitive disorders. Investigators are searching actively for muscarinic agonists that exhibit selectivity for muscarinic receptors in the brain. Among these compounds are analogues of arecoline, oxotremorine, and McN-A-343 as well as many other novel chemical structures possessing muscarinic agonist activity.

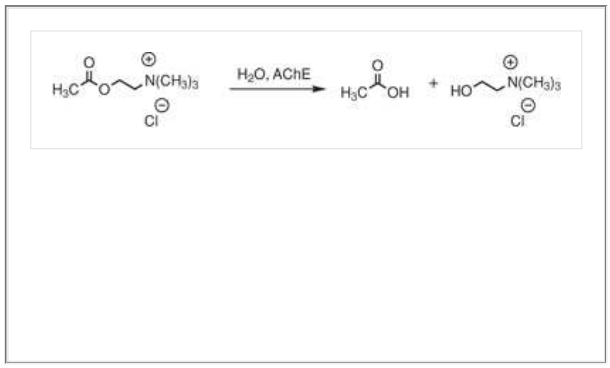


Arecoline is of historical interest, because its structure, like those of many other early medicinal agents, was determined and confirmed by a 19th-century German pharmacist, E. Jahns (2). Xanomeline may be viewed as a nonclassical bio-isostere of the ester moiety of arecoline. It is a muscarinic M_1/M_4 agonist that is showing promise in clinical trials for the treatment of Alzheimer's disease (35). Although it is not tolerated at orally effective doses, transdermal delivery systems are showing promise.



Acetylcholinesterase Inhibitors

Another means of producing a cholinergic response is to interfere with the mechanism by which the action of acetylcholine is terminated. Thus, inhibition of its rapid hydrolysis by AChE increases the concentration of acetylcholine in the synapse and results in production of both muscarinic and nicotinic effects.



Therapeutic Application

Acetylcholinesterase inhibitors (AChEIs), sometimes referred to as anticholinesterases, are classified as indirect cholinomimetics, because their principle mechanism of action does not involve binding to cholinergic receptors. These agents are used therapeutically to improve muscle strength in myasthenia gravis. They also are used in open-angle glaucoma to decrease intraocular pressure by stimulating contraction of the ciliary muscle and sphincter of the iris. This facilitates outflow of aqueous humor via the canal of Schlemm. Recently, AChEIs have found use in the treatment of symptoms of Alzheimer's disease and similar cognitive disorders (36,37), which are conditions characterized by a cholinergic deficiency in the cortex and basal forebrain. They are used extensively as insecticides and are in military arsenals for use as chemical warfare agents.

Mechanism of Acetylcholinesterase Hydrolysis

Extensive studies of AChE have resulted in the purification and amino acid sequencing of the enzyme from several sources as well as the description of its quaternary structure from x-ray crystallographic and molecular modeling studies (38). To understand the mode of action of AChEIs, it is necessary to examine the mechanism by which AChE catalyzes hydrolysis of acetylcholine. This enzymatically controlled hydrolysis parallels the two chemical mechanisms for hydrolysis of esters. The first mechanism is acid-catalyzed hydrolysis, in which the initial step involves protonation of the carbonyl oxygen. The transition state is formed by the attack of a molecule of water at the electrophilic carbonyl carbon atom. Collapse of the transition state affords the carboxylic acid and the alcohol (Fig. 12.11). The second mechanism, base-catalyzed hydrolysis, involves the nucleophilic attack

of hydroxide anion on the electrophilic carbonyl carbon (Fig. 12.12).

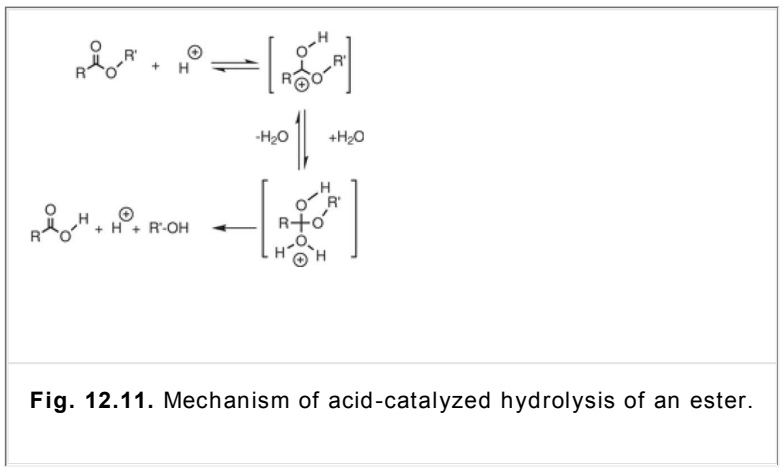


Fig. 12.11. Mechanism of acid-catalyzed hydrolysis of an ester.

Both mechanisms for ester hydrolysis are proposed to be involved in the mechanism for AChE-catalyzed hydrolysis of acetylcholine. Fig. 12.13 is a schematic illustration of the binding of acetylcholine to the catalytic (active) site of AChE, which consists of an ester-binding site and an "anionic-binding site." This figure reflects binding of the quaternary nitrogen of acetylcholine to an area that has been described as an "anionic site" on the enzyme. Originally, this "anionic site" was proposed to be contributed by the free carboxylate group of a glutamate residue. Current evidence using selective mutagenesis, however, suggests that rather than ionic bonding between the quaternary nitrogen and an anionic site, there is a cation–pi interaction between the quaternary nitrogen and the aromatic rings of tryptophan and phenylalanine of the enzyme (39). In Fig. 12.13, there is a concerted protonation of the carbonyl oxygen by an imidazole proton from a histidine residue and nucleophilic attack on the partial positive carbon of the carbonyl group by the hydroxyl group of a serine residue. The remainder of the hydrolysis mechanism is described in Fig. 12.14: Transition state B is unstable and collapses to form choline and acetylated AChE (C); this form of the enzyme is referred to as the acetylated enzyme. As long as the enzyme is acetylated, it cannot bind another molecule of acetylcholine; the enzyme is in an inactive state. The acetylated enzyme undergoes rapid hydrolysis to regenerate the original, active form of AChE and a molecule of acetic acid.

The latter step in the mechanism—the regeneration of the active enzyme—is important in the development of AChEIs. If the enzyme becomes acylated by a functional group (i.e., carbamyl or phosphate) that is more stable to hydrolysis than a carboxylate ester, the enzyme remains inactive for a longer period of time. Application of this chemical principle regarding rates of hydrolysis led to discovery and design of two classes of AChEIs, the reversible inhibitors and the irreversible inhibitors.

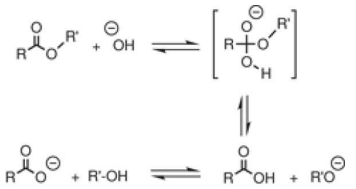

Fig. 12.12. Mechanism of base-catalyzed hydrolysis of an ester.

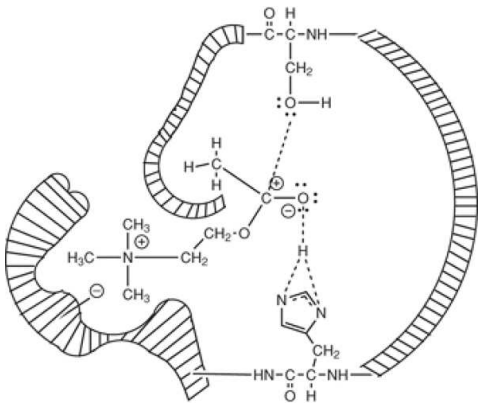

Fig. 12.13. Binding of acetylcholine to catalytic site of acetylcholinesterase; role of serine and histidine residues is illustrated.

Reversible Inhibitors of Acetylcholinesterase

Mechanism of action

Reversible AChEIs are those compounds that are substrates for and react with AChE to form an acylated enzyme, which is more stable than the acetylated enzyme but still capable of undergoing hydrolytic regeneration, or that bind to AChE with greater affinity than acetylcholine but do not react with the enzyme as a substrate. Inhibitors of both types have found clinical application. Those that acylate AChE include the aryl carbamates, such as esters of carbamic acid and phenols (e.g., physostigmine). Alkyl carbamates (esters of carbamic acid and alcohols), such as carbachol and bethanechol, both of which are structurally related to acetylcholine, also are substrates for and competitively inhibit AChE, because they are hydrolyzed very slowly by AChE. For reasons previously discussed, carbachol and

bethanechol are more resistant than acetylcholine to AChE-catalyzed hydrolysis.

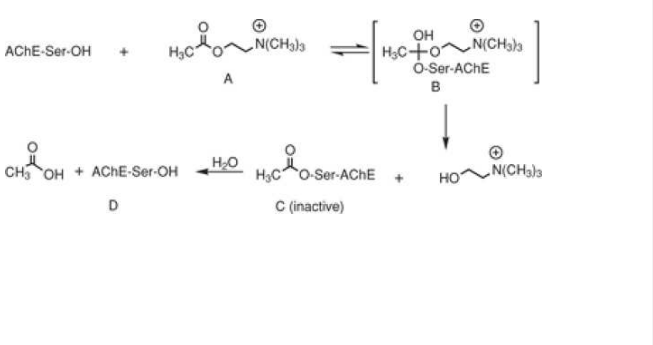

Fig. 12.14. Mechanistic steps in the hydrolysis of ACh.

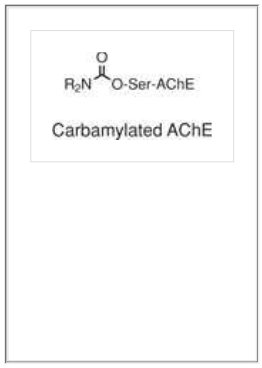
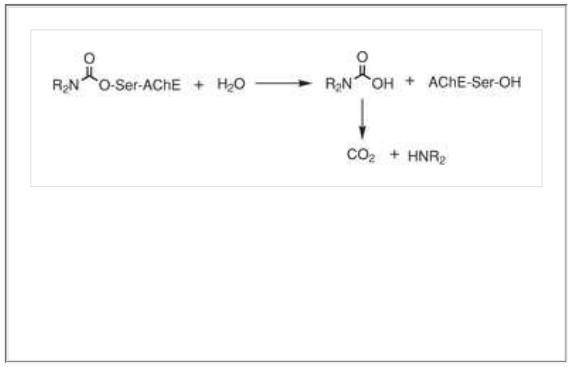
When aryl carbamate AChEIs, such as physostigmine and its analogues, bind to the catalytic site of AChE, hydrolysis of the carbamate occurs. This transesterifies the serine residue with carbamic acid, forming what is termed a "carbamylated enzyme." The rate of carbamylation follows the order of carbamic acid esters > methylcarbamic acid esters > dimethylcarbamic acid esters (40).



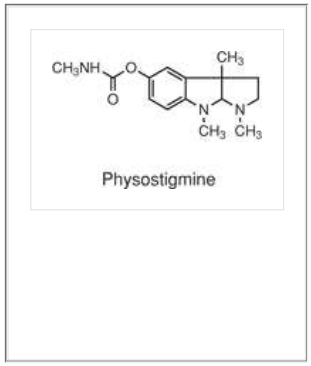
Regeneration of active AChE by hydrolysis of the carbamylated enzyme is much slower than hydrolysis of the acetylated enzyme. The rate for hydrolytic regeneration of the carbamylated AChE is measured in minutes (e.g., the half-life for methyl carbamylated enzyme is ~15 minutes); the rate of hydrolytic regeneration of acetylated AChE is measured in milliseconds (e.g., the half-life for acetylated enzyme is ~0.2 milliseconds). Despite the longer time required to regenerate the carbamylated enzyme, the active form of AChE eventually is regenerated. Therefore, these inhibitors are considered to be reversible.



Aryl carbamates are superior to alkyl carbamates as AChEIs, because they have better affinity for AChE and, therefore, carbamylate AChE more efficiently. Physostigmine and other aryl carbamates exhibit inhibition constants (K_i) on the order of 10^{-9} to 10^{-8} M and are three to four orders of magnitude more effective than alkyl carbamates, such as carbachol (K_i ~ 10^{-5} M). This is to be expected, because phenoxide anions are more stable than and, hence, are better leaving groups than alkoxide anions. Phenoxide anions are stabilized through resonance with the aromatic ring. Thus, the therapeutically effective carbamate inhibitors of AChE are derived from phenols.

Specific Agents

Reversible acetylcholinesterase inhibitors



Physostigmine

The classic AChEI, physostigmine, is an alkaloid obtained from seeds of the Calabar bean (*Physostigma venenosum*) (37). Its parasympathomimetic effects were recognized long before its structure was elucidated in 1923. In 1929, Stedman found that the mechanism of the parasympathomimetic effects of physostigmine was inhibition of AChE; it inhibits AChE by acting as a substrate and carbamylating the enzyme. Acetylcholinesterase is carbamylated at a slow rate, but physostigmine has exceptionally high affinity (K_i ~ 10^{-9} M) for the catalytic site of the enzyme. By comparison, the K_s for acetylcholine is on the order of 10^{-4} M. Thus, physostigmine is classified as a reversible AChEI that carbamylates the enzyme at a slow rate; the carbamylated AChE also is regenerated quite slowly. Because physostigmine is a tertiary amine with a pK_a of 8.2 ($^{+}$BH) rather than a quaternary ammonium salt, it is more lipophilic than many other AChEIs and can diffuse across the blood-brain

barrier. The tertiary amine also imparts pH dependence to its ability to inhibit AChE, because its affinity for AChE is greater when the amine is protonated. Physostigmine is metabolized in vivo by esterases to the phenol and has an elimination half-life of 1 to 2 hours. Its aqueous solutions are subject to hydrolytic decomposition to form eseroline, which undergoes light-catalyzed oxidation to form rubreserine, a red-colored compound (Fig. 12.15). Both degradation products are inactive as AChEIs.

Physostigmine has been used for many years in ophthalmology for the treatment of glaucoma. More recently, the salicylate salt has been used in hospital emergency rooms to treat overdoses of compounds possessing significant anticholinergic CNS effects (for example, antidepressants), such as atropine and tricyclic antidepressants. Physostigmine's ability to cross the

blood-brain barrier has led to renewed interest in this molecule, and it also is one of a number of centrally active AChEIs being investigated as indirect cholinomimetics for use in the treatment of Alzheimer's disease and other cognitive disorders.

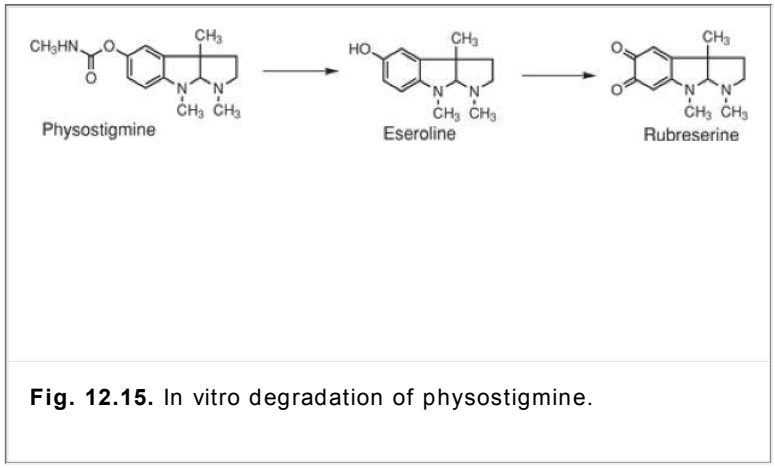


Fig. 12.15. In vitro degradation of physostigmine.

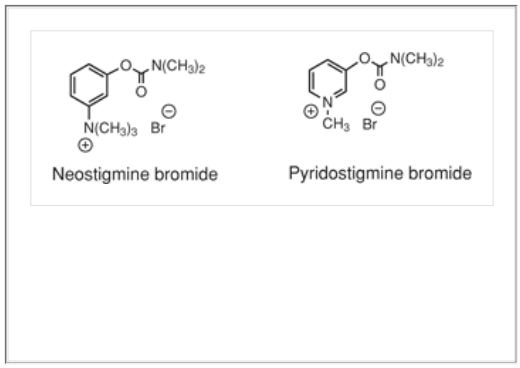
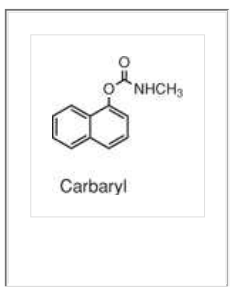


Neostigmine (Prostigmin)

The discovery that physostigmine and other aryl carbamates inhibit AChE reversibly led to research to find other AChEIs possessing this activity. Most of this research involved incorporation of the required structural features of both physostigmine and acetylcholine into the new molecules. This led to synthesis of neostigmine, a compound resembling physostigmine but having a much simpler structure. Neostigmine retains the substituted carbamate group, the benzene ring, and the nitrogen atom of the first heterocyclic ring of physostigmine. The distance between the ester and the quaternary ammonium group is approximately the same as that found in acetylcholine and physostigmine. Because of its quaternary ammonium group, it lacks central activity. Neostigmine is metabolized to 3-hydroxyphenyltrimethylammonium, 3-hydroxyphenyldimethylamine, and its glucuronide conjugate, and it has an elimination half-life of 15 to 90 minutes. Neostigmine is indicated for prophylaxis of postoperative abdominal distension and urinary retention, myasthenia gravis, reversal of neuromuscular blockade.

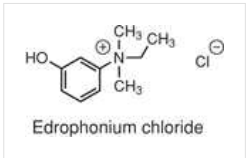
Pyridostigmine (Mestinon)

Pyridostigmine, a closely related structure to neostigmine that incorporates the charged nitrogen into a pyridine ring, acts by the same mechanism as physostigmine, but it lacks CNS activity. It is orally effective and, compared to neostigmine, has a longer duration of action and a lower incidence of side effects. Thus, it is a better choice for oral therapy of myasthenia gravis. It is approved for U.S. military use as an adjunct for prophylaxis of soman nerve gas exposure. It is also administered parenterally to reverse the effects of nondepolarizing neuromuscular blocking agents. Its elimination half-life is 1 to 2 hours.



Carbaryl

Carbaryl is a reversible, carbamate-derived AChEI that has tremendous economic impact as an insecticide for use on houseplants and vegetables as well as for control of fleas and ticks on pets. Its structural relationship to physostigmine and neostigmine is readily apparent. A number of other carbamate AChEIs also are commercially available for this use.



Edrophonium chloride

Edrophonium chloride (Enlon, Reversol)

Edrophonium is a quaternary ammonium-substituted phenol. Because it is a phenol derivative rather than a carbamate ester of a phenol, it does not carbamylate AChE. It does, however, inhibit AChE in a reversible manner, and it also exhibits a direct cholinomimetic effect at skeletal muscle. Edrophonium is used intravenously for the diagnosis of myasthenia gravis, where it acts rapidly to increase muscle strength. It also is administered intramuscularly to rapidly reverse the effects of nondepolarizing neuromuscular blocking agents like *d*-tubocurarine and gallamine. It is not effective, however, at reversing the effects of the depolarizing blockers such as succinylcholine and decamethonium. Its elimination half-life 1.3 to 2.4 hours.

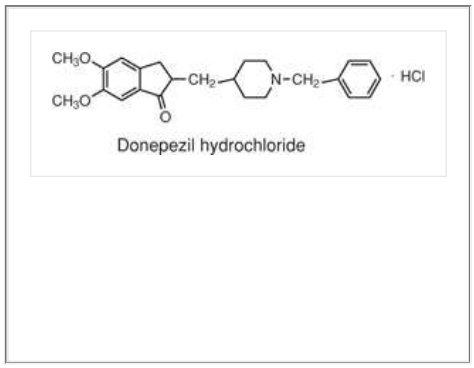
Reversible acetylcholinesterase inhibitors for treatment of Alzheimer's disease

Of all the age-related disorders in which dementia is a component, Alzheimer's disease (AD) is probably the best known. Much effort has been expended to discover the cause of AD. Autopsy examination of the brains of patients who had AD has revealed microscopic structural changes characteristic of the disease. In addition, neurotransmitter dysfunction involving reduction in acetylcholine, serotonin, norepinephrine, dopamine, and glutamate levels have been reported. For a review of AD and the search for therapies, see Rzeszotarski (41). It is known that in AD patients, there is widespread atrophy in the primary motor and sensory cortices and cerebellum. There is a disruption in cholinergic innervation in these areas of the brain, along with decreases in choline acetyltransferase, high-affinity nicotinic acetylcholine receptor binding, and choline transporter sites (42,43,44,45). Impairment of short-term memory is the first observable symptom of the disease, and progressive memory impairment, severe mood changes, and depression coupled with loss of judgment and reasoning ability follow. The U.S. Food and Drug Administration has approved four AChEIs for the treatment of AD: tacrine, donepezil, rivastigmine, and galantamine. Although these four AChEIs are not without problems, they do provide some benefit in early to mild AD. Their clinical effectiveness in advanced AD is yet to be shown.

Tacrine

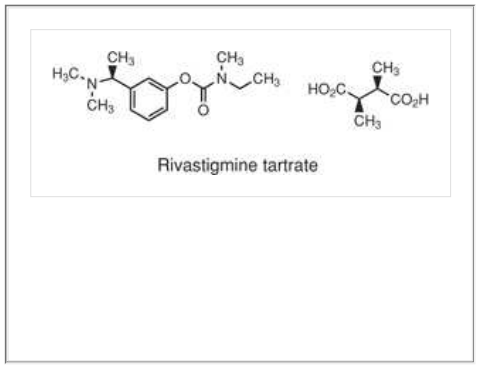
Tacrine hydrochloride (Cognex)

Tacrine, an aminoacridine synthesized in the 1930s, is a nonclassic cholinesterase inhibitor that binds to both AChE or butyrylcholinesterase (46). It was approved in 1993 for the treatment of AD. Approximately 20% of tacrine-treated patients may show improvement, but its use has been limited because of hepatotoxicity. Use of tacrine has greatly decreased because of the recent development of safer AChEIs. Tacrine is extensively metabolized by CYP450 to at least three metabolites. The major metabolite, 1-hydroxy-tacrine, is active. Its elimination half-life is between 1.5 and 4 hours, with metabolites being are excreted via the urine.



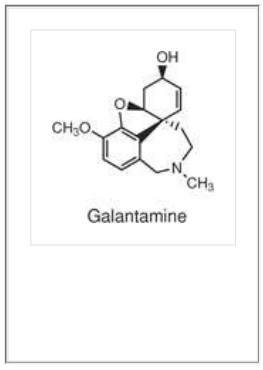
Donepezil (Aricept)

Donepezil is another "nonclassic," centrally acting, reversible, noncompetitive AChEI that was approved in 1997 for treatment of mild-to-moderate AD and dementia. Its selectivity for AChE is 570- to 1,250-fold that for butyrylcholinesterase, and it also exhibits greater affinity for brain AChE than for AChE in the periphery (47). When compared to tacrine, donepezil exhibits greater CNS AChE selectivity, longer elimination half-life (70–104 hours in subjects older than 55 years) and little or no potential for hepatotoxicity. Donepezil is metabolized by CYP2D6 and CYP3A4 via demethylation, debenzylation, hydroxylation, oxidation to the *cis*-N-oxide, and glucuronidation. The 6-O-desmethyl metabolite accounts for 11% of a dose, and it exhibits AChE inhibitory activity comparable to that of the parent compound.



Rivastigmine (Exelon)

Rivastigmine is a centrally selective, arylcarbamate AChEI that was approved in 2000 for oral administration in the treatment of AD. It has an elimination half-life of 1.4 to 1.7 hours but is able to inhibit AChE for up to 10 hours. Because of the slow dissociation of the carbamylated enzyme, it has been referred to as a pseudo-irreversible AChEI (47). Like donepezil, rivastigmine exhibits a low level of hepatotoxicity. It is rapidly and extensively hydrolyzed in the CNS by cholinesterase with minimal involvement of CYP450. The phenolic metabolite is excreted primarily via the kidneys.



Galantamine hydrobromide (Razadyne)

Galantamine, which was introduced in 2001, is an alkaloid found in plants of the family Amaryllidaceae, which includes the daffodil (*Narcissus pseudonarcissus*) and snowflake (*Leucojum aestivum*). It is a reversible inhibitor of AChE, but it does not appear to inhibit butyrylcholinesterase. Because it is a tertiary amine and can cross the blood-brain barrier, it is indicated for treatment of mild-to-moderate AD and dementia. It has been used outside the U.S. for more than 30 years as an anticurare agent in anesthesia. Galantamine differs from other cholinesterase inhibitors, because it allosterically binds to nicotinic receptors, giving it a dual cholinergic action. It is metabolized (75%) by CYP2D6 and CYP3A4 to afford the normethyl, O-desmethyl, and O-desmethylnormethyl metabolites, along with some other minor metabolites. Unlike tacrine, galantamine is not associated with hepatotoxicity. Its elimination half-life is 5.7 hours.

Irreversible Inhibitors of Acetylcholinesterase

Mechanism of action

The chemical logic involved in the development of effective AChEIs was to synthesize compounds that would be substrates for AChE and result in an acylated enzyme more stable to hydrolysis than a carboxylate ester. Phosphate esters are very stable to hydrolysis, being even more stable than many amides. Application of this chemical property to the design of AChEI compounds led to derivatives of phosphoric, pyrophosphoric, and phosphonic acids that are effective inhibitors of AChE. These act as inhibitors by the same mechanism as the carbamate inhibitors, except that they leave the enzyme esterified as phosphate esters. The rate of hydrolytic regeneration of the phosphorylated enzyme is much slower than that of the carbamylated enzyme, and its rate is measured in hours (e.g., the half-lives for diethyl phosphates are ~8 hours). Because the duration of action of these compounds is much longer than that of carbamate esters, they are referred to as irreversible inhibitors of AChE.

An important difference between irreversible phosphoester-derived AChEIs and reversible AChEIs is that the phosphorylated AChE can undergo a process known as aging (Fig. 12.16). The aging process plays an

important role in the toxicity of these irreversible AChEIs. Aging is the result of cleavage of one or more of the phosphoester bonds while the AChE is phosphorylated. This reaction affords an anionic phosphate that possesses a phosphorus atom that is much less electrophilic and, therefore, much less likely to undergo hydrolytic regeneration than the original phosphoester. Thus, the aged phosphorylated enzyme does not undergo nucleophilic attack and regeneration by antidotes (see next section) for phosphate ester AChEIs. This aging process occurs over a period of time, which depends on the rate of the P-O bond cleavage reaction; during this time, the antidotes to phosphate ester poisoning may be effective.

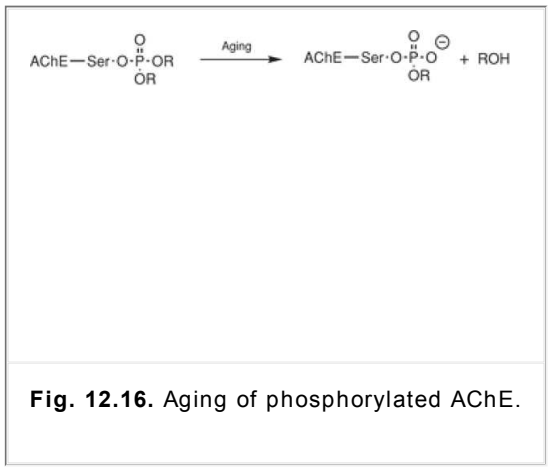


Fig. 12.16. Aging of phosphorylated AChE.

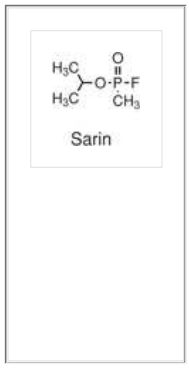
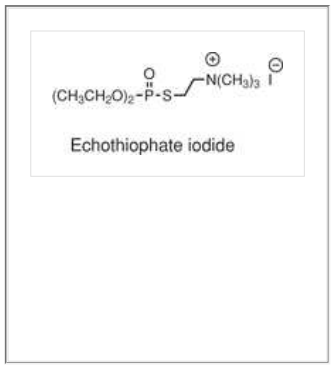
Only those phosphorus-derived AChEIs that have at least one phosphoester group undergo the aging process. Knowledge of the chemical mechanisms associated with irreversible inhibition of AChE and the aging process led to the development of deadly phosphorus-derived chemical warfare agents, one of which is sarin (GB is the two letter NATO designation for this nerve agent). When this compound phosphorylates AChE, only one aging reaction takes place, and then the enzyme becomes refractory to regeneration by the currently available antidotal agents.



Specific agents



Echothiophate iodide (Phospholine Iodide)

Echothiophate iodide has found therapeutic application for the treatment of glaucoma and strabismus. Echothiophate is applied topically as a solution and is the only irreversible AChEI for the treatment of glaucoma. The decrease in intraocular pressure observed can last up to 4 weeks. Phosphoester AChEIs exhibit cataractogenic properties; thus, their use should be reserved for patients who are refractory to other forms of treatment (i.e., short-acting miotics, β-blockers, epinephrine, and possibly, carbonic anhydrase inhibitors). Because of its toxicity, echothiophate is not used for its systemic action. Selectivity of echothiophate for the AChE catalytic site was enhanced by incorporation in the molecule of a quaternary ammonium salt functional group two carbons removed from the phosphoryl group.

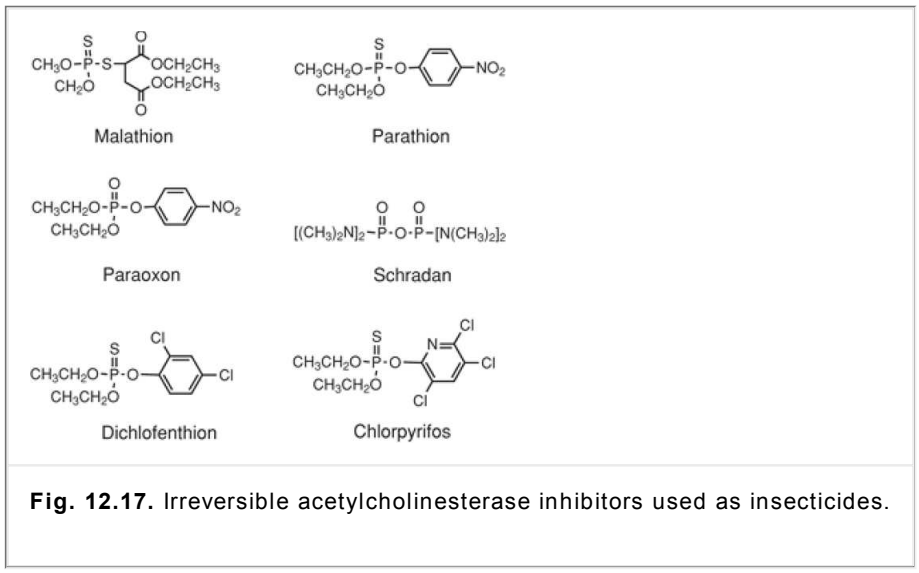


Fig. 12.17. Irreversible acetylcholinesterase inhibitors used as insecticides.

Insecticidal AChEIs

A number of lipophilic derivatives of phosphoester AChEIs have been designed as insecticides; the structures of some of these are shown in Fig. 12.17. This group of irreversible AChEI insecticides is beneficial to agricultural production throughout the world. In addition to being extremely lipophilic, another physicochemical property common to these compounds is a high vapor pressure. This combination of physicochemical properties makes it imperative that these compounds be used with extreme caution in the presence of humans and other mammals to prevent inhalation of the vapors and their absorption through the skin. Both routes of exposure cause a number of poisoning accidents every year, some of which are fatal.

Some of these irreversible AChEI insecticides have a sulfur atom bonded to the phosphorus atom with a coordinate-covalent bond. These compounds exhibit little AChEI activity, but they are rapidly bioactivated via desulfurization by microsomal oxidation in insects to afford the corresponding oxo derivatives (phosphate esters), which are quite potent. A good example of this bioactivation phenomenon is illustrated by the commercially available insecticide parathion and its bioactivation to a toxic metabolite paraoxon.

Malathion (Ovide)

Malathion (Fig. 12.17) is a dithiophosphate ester that has found use both as an aerial insecticide and clinically as a mitocide for topical treatment of lice infestations of the hair and scalp. It will kill

both hatched lice and their eggs (nits) within 3 seconds after application. Compared to other organophosphate AChEIs, malathion exhibits lower transdermal absorption. On intact skin, less than 10% of a topical dose is systemically absorbed. Similar to parathion, malathion is bioactivated in insects to its toxic phosphate ester metabolite. It is much less toxic in humans, mammals, and birds than in insects. Selective toxicity with malathion is achieved because plasma esterases hydrolyze the carboxylate esters to less toxic carboxylic acid metabolites that are rapidly eliminated in urine as carboxylate anions in humans but not in insects. Acute toxicity with malathion is rare and usually occurs only after oral ingestion. The lethal dose in mammals is approximately 1 g/kg.

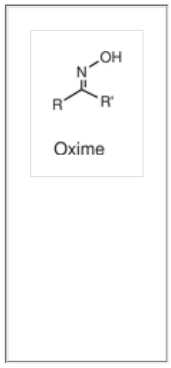
Antidotes for Irreversible AChEIs

Background

The marked toxicity of the phosphate ester irreversible AChEIs, their widespread use as insecticides, and their proliferation as chemical warfare agents posed serious problems that stimulated research to develop antidotes for these agents. This required rational use of reaction kinetics, organic reaction mechanisms, and synthetic organic chemistry. Water is a nucleophile capable of rapidly hydrolyzing acetylated AChE and regenerating the active enzyme. Phosphorylated AChE (irreversibly inhibited), however, was known to involve a phosphate ester of serine. It is well established from reaction kinetic studies that the rate of hydrolysis is much slower for organic phosphate esters than for carboxylate esters and that a significantly stronger nucleophile than water would be required for efficient hydrolysis of phosphate esters. The problem required the design of reagents capable of efficiently catalyzing phosphate ester cleavage to regenerate active AChE while being safe enough for use as therapeutic agents. The resolution of this problem is an elegant example of the application of chemical principles to the solution of a therapeutic problem (48,49,50).

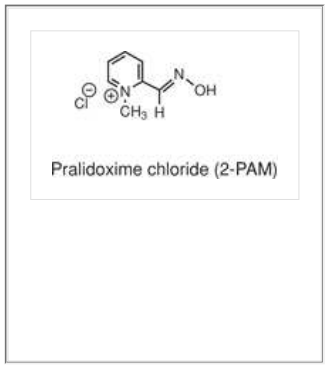
Hydroxylamine (NH_2OH) is a strong nucleophilic compound that efficiently cleaves phosphate esters. It significantly increases the rate of hydrolysis of phosphorylated AChE, but only at toxic concentrations (51). This prompted the development of a number of structurally related compounds in the hope of eliminating toxicity. The toxicity inherent in hydroxylamine would most probably be present in any structurally related compound, but this toxicity might be minimized if sufficiently small doses could be used. It would be logical to design a compound that would have a high degree of selectivity and strong binding affinity for AChE and also carry a hydroxylamine-like nucleophile into close proximity to the phosphorylated serine residue. This was achieved by synthesis of hydroxylamine derivatives of organic compounds possessing a functional group bearing a positive charge.

Reaction of hydroxylamine with aldehydes or ketones affords oximes, which possess the desired nucleophilic oxygen atom. A pyridine ring was considered an attractive carrier for the oxime function, because such groups are common in a number of biochemical systems (e.g., NAD and NADP), indicating a possible low order of toxicity. Furthermore, three readily available positional isomers of pyridine aldehyde can be converted easily to oximes. Finally, the nitrogen atom of the pyridine ring can be converted to a quaternary ammonium salt by treatment with methyl iodide. This cationic charge would be expected to increase affinity of the compound for the anionic-binding site of the phosphorylated AChE.



Oxime

The three isomeric pyridine aldoxime methiodides were synthesized and biologically evaluated. Of these, the most effective is the isomer derived from 2-pyridinylaldehyde. This compound, known as pralidoxime chloride (2-PAM, or 2-pyridine aldoxime methyl chloride) currently is the only available agent proven to be clinically effective as an antidote for poisoning by phosphate ester AChEIs. The proposed mechanism for regeneration of AChE by 2-PAM is illustrated in Fig. 12.18. The initial step involves binding of the quaternary ammonium nitrogen of 2-PAM to the anionic-binding site of phosphorylated AChE. This places the nucleophilic oxygen of 2-PAM in close proximity to the electrophilic phosphorus atom. Nucleophilic attack of the oxime oxygen results in breaking of the ester bond between the serine oxygen atom and the phosphorus atom. The final products of the reaction are the regenerated active form of AChE and phosphorylated 2-PAM.



Pralidoxime chloride (2-PAM)

Pralidoxime is administered subcutaneously, intramuscularly, or intravenously, and it must be given within a short

period of time after enzyme phosphorylation, generally a few hours after exposure, for it to be effective because of the aging process of the phosphorylated enzyme. Little reactivation is likely if given 36 hours after exposure. If the phosphorylated AChE has aged, 2-PAM will not regenerate the enzyme. For this reason, as well as because new phosphate ester AChEIs capable of aging rapidly are being developed as insecticides and chemical warfare agents, there is a continuing effort to discover new and better substitutes for 2-PAM. This research is focused on finding substitutes for 2-PAM that are better nucleophiles and, therefore, more effective generators of active AChE as well as compounds that cross the blood-brain barrier to regenerate phosphorylated AChE in the brain.

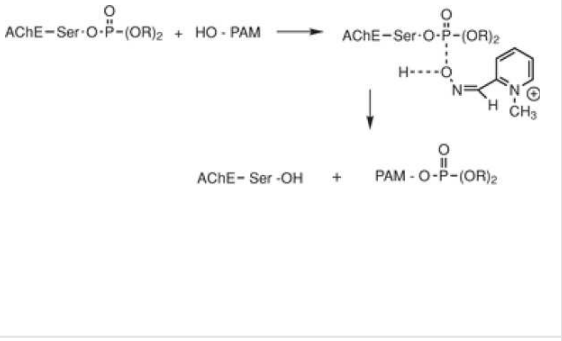


Fig. 12.18. Reactivation of AChE with 2-PAM.

Acetylcholine Antagonists—Muscarinic Antagonists

Muscarinic antagonists are compounds that have high binding affinity for muscarinic receptors but have no intrinsic activity. When the antagonist binds to the receptor, it is proposed that the receptor protein undergoes a conformational perturbation that is different from that produced by an agonist. Therefore, antagonist binding to the receptor produces no response. Muscarinic antagonists commonly are referred to as anticholinergics, antimuscarinics, cholinergic blockers, antispasmodics, or parasympatholytics. The term "anticholinergic" refers, in a pure sense, to medicinal agents that are antagonists at both muscarinic and nicotinic receptors. Common usage of the term, however, has become synonymous with muscarinic antagonist, and it is used as such in this section.

Therapeutic Application

Muscarinic antagonists frequently are employed as both prescription drugs and over-the-counter medications. Because they act as competitive (reversible) antagonists of acetylcholine, these compounds have pharmacological effects that are opposite those of muscarinic agonists. Responses of muscarinic antagonists include decreased contractions of smooth muscle of the gastrointestinal and urinary tracts, dilation of the pupils, and reduced gastric, mucociliary, and salivary secretions. It follows that these compounds have therapeutic value in treating smooth muscle spasms associated with increased tone of the gastrointestinal tract or with overactive bladder, in ophthalmologic examinations, and in treatment of gastric ulcers. Compounds possessing muscarinic antagonist activity are common components of cold and flu remedies that act to reduce nasal and upper respiratory tract secretions.

In addition to reducing gastric motility, anticholinergic agents decrease gastric acid secretion and were once widely used to manage peptic ulcers. Histamine H_2 antagonists and, more recently, the proton pump inhibitors have largely replaced them for this use. When used systemically, they tend to produce undesirable side effects, such as blurred vision, photophobia, dry mouth, and difficulty in urination. These side effects tend to reduce patient compliance.

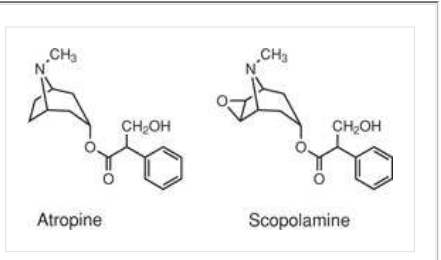
Anticholinergic agents exhibit a mydriatic action and, thus, must be used with caution because of their effect on intraocular pressure. Drainage of the canal of Schlemm is restricted by the iris when the pupil is dilated, and this can cause an increase in intraocular pressure. Hence, muscarinic antagonists are contraindicated in patients with glaucoma.

The aforementioned side effect of causing difficulty in urination has been used to advantage with the recent approval of several anticholinergic agents—darifenacin trospium, solifenacin, tolterodine, and oxybutynin—for the treatment of overactive bladder.

Centrally acting belladonna alkaloids, such as scopolamine, have been used in transdermal delivery systems for the prevention of motion sickness. They are most effective when used prophylactically; they have less effect when used after nausea and vomiting have begun. Several of the synthetic muscarinic antagonists have been used to treat parkinsonism and to block the extrapyramidal effects of antipsychotic agents. The anticholinergic alkaloid atropine is used for treatment of central and peripheral symptoms associated with poisoning by organophosphorus anticholinesterase agents.

Specific Agents—Solanaceous Alkaloids

The earliest known anticholinergic agents were alkaloids found in the family Solanaceae, a large family of plants that includes potatoes. *Atropa belladonna* (deadly nightshade), *Hyoscyamus niger* (black henbane), and *Datura stramonium* (jimsonweed, thorn apple) are plants that have significant historical importance to our understanding of the parasympathetic nervous system. Pharmacological effects of extracts from these plants have been recognized since the Middle Ages, although these effects were not associated with the autonomic nervous system until the latter part of the 19th century. (–)-Hyoscyamine, isolated as atropine, and scopolamine are the two alkaloids that have found the widespread clinical applications.



Atropine

Atropine is the tropic acid ester of tropine and is marketed as the sulfate salt. The naturally occurring alkaloid, (–)-hyoscyamine, undergoes base-catalyzed racemization during isolation from plants of the Solanaceae to give (±)-hyoscyamine or atropine. It was the first compound shown to block the effects of electrical

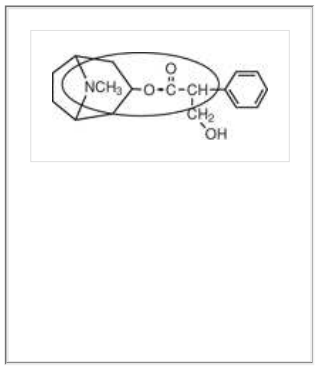
stimulation and muscarine on the parasympathetic nervous system. Atropine sulfate has a number of clinical uses; two of the most common are treatment of bradycardia and as a preoperative agent to reduce secretions before surgery. Its use for management of parkinsonism has been supplanted by newer agents with fewer peripheral side effects. It has been used in ophthalmology as a cycloplegic agent to paralyze the iris and ciliary muscle in the treatment of iritis and uveitis and as a cycloplegic/mydriatic agent. Atropine is contraindicated in glaucoma because of its ability to increase intraocular pressure during mydriasis. Its prolonged duration of mydriasis makes other drugs more attractive for this purpose. In poisoning by organophosphate nerve agents and insecticides, atropine is used to decrease the muscarinic cholinergic actions (e.g., lacrimation, salivation, sweating, bradycardia, and breathing problems) associated with this poisoning. It only treats the symptoms and does not reverse the underlying AChE inhibition. Atropine undergoes nonenzymatic ester hydrolysis in vivo and has an elimination half-life of 4 hours in adults and 6.5 hours in children.

Scopolamine

Scopolamine, another Solanaceous alkaloid, is chemically and pharmacologically similar to atropine. Scopolamine is the generic name given to (–)-hyoscine, the naturally occurring alkaloid. The racemic compound, isolated during extraction of the alkaloid from plants, is atroscine. Scopolamine is marketed as the hydrobromide salt, because it is less deliquescent than some of its other salts. Scopolamine is a CNS depressant at usual therapeutic doses, whereas atropine and other antimuscarinic agents are CNS stimulants. It has been used for the treatment of uveitis, iritis, and parkinsonism, but its most widespread use is for the treatment of motion sickness. For this indication, scopolamine is used in a transdermal patch applied behind the ear. It is almost completely metabolized in the liver and is excreted via the kidneys. Its elimination half-life is approximately 8 hours.

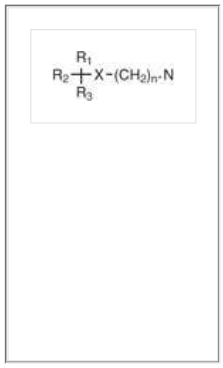
Structure–activity relationship

Atropine, the prototype anticholinergic agent, provided the structural model that guided the design of synthetic muscarinic antagonists for almost 70 years. The circled portion of the atropine molecule depicts the segment resembling acetylcholine.



Although the amine functional group is separated from the ester oxygen by more than two carbons, the conformation assumed by the tropine ring orients these two atoms such that the intervening distance is similar to that in acetylcholine. One important structural difference between atropine and acetylcholine, both of which are esters of amino alcohols, is the size of the acyl portion of the molecules. Based on the assumption that size was a major factor in blocking action, many substituted acetic acid esters of amino alcohols were prepared and evaluated for biological activity.

It became apparent that the most potent compounds were those that possessed two lipophilic ring substituents on the carbon α to the carbonyl of the ester moiety. This is the first of the classic SARs for muscarinic antagonist activity, and this SAR became defined more precisely as research on these antagonists continued. The SAR for muscarinic antagonists can be summarized as follows:



1. Substituents R_1 and R_2 should be carbocyclic or heterocyclic rings for maximal antagonist potency. The rings may be identical, but the

more potent compounds have different rings. Generally, one ring is aromatic and the other saturated or possessing only one olefinic bond. Substituents R_1 and R_2, however, may be combined into a fused aromatic tricyclic ring system, such as that found in propantheline (Table 12.1). The size of these substituents is limited. For example, substitution of naphthalene rings for R_1 and R_2 affords compounds that are inactive, apparently because of steric hindrance of the binding of these compounds to the muscarinic receptor.

2. The R_3 substituent may be a hydrogen atom, a hydroxyl group, a hydroxymethyl group, or a carboxamide, or it may be a component of one of the R_1 and R_2 ring systems. When this substituent is either a hydroxyl group or a hydroxymethyl group, the antagonist usually is more potent than the same compound without this group. The hydroxyl group presumably increases binding strength by participating in a hydrogen bond interaction at the receptor.
3. The X substituent in the most potent anticholinergic agents is an ester, but an ester functional group is not an absolute necessity for muscarinic antagonist activity. This substituent may be an ether oxygen, or it may be absent completely.
4. The N substituent is a quaternary ammonium salt in the most potent anticholinergic agents. This is not a requirement, however, because tertiary amines also possess antagonist activity, presumably by binding to the receptor in the cationic (conjugate acid) form. The alkyl substituents usually are methyl, ethyl, propyl, or isopropyl.
5. The distance between the ring-substituted carbon and the amine nitrogen apparently is not critical; the length of the alkyl chain connecting these may

be from two to four carbons. The most potent anticholinergic agents have two methylene units in this chain.

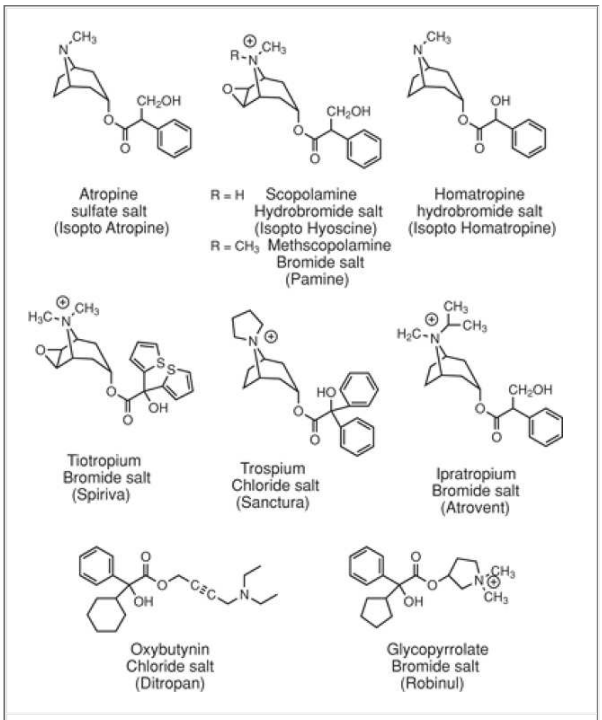


Fig. 12.19. Anticholinergic aminoalcohol esters.

Muscarinic antagonists must compete with agonists for a common receptor. Their ability to do this effectively is because the large groups R_1 and R_2 enhance binding to the receptor. Because antagonists are larger than agonists, this suggests that groups R_1 and R_2 bind outside the binding site of acetylcholine. It has been suggested that the area surrounding the binding site of acetylcholine is hydrophobic in nature (52). This accounts for the fact that in potent cholinergic antagonists, groups R_1 and R_2 must be hydrophobic (usually phenyl, cyclohexyl, or cyclopentyl). This concept also is supported by the current models for muscarinic receptors.

Figures 12.19 and 12.20 and Table 12.3 include structures and pharmacological properties of some of the anticholinergic agents that have found clinical application. These compounds reflect the SAR features that have been described. All these compounds are effective when administered orally or parenterally. Anticholinergic agents possessing a quaternary ammonium functional group generally are not well absorbed from the gastrointestinal tract because of their ionic character. These drugs are useful primarily in the treatment of ulcers or other conditions for which a reduction in gastric secretions and reduced motility of the gastrointestinal tract are desired. Those antagonists having a tertiary nitrogen are much better absorbed and distributed following all routes of administration and are especially useful when systemic distribution is desired. The tertiary amino-derived anticholinergic agents readily cross the blood-brain barrier. These have proven to be particularly beneficial in the treatment of Parkinson's disease and other diseases requiring a central anticholinergic effect.

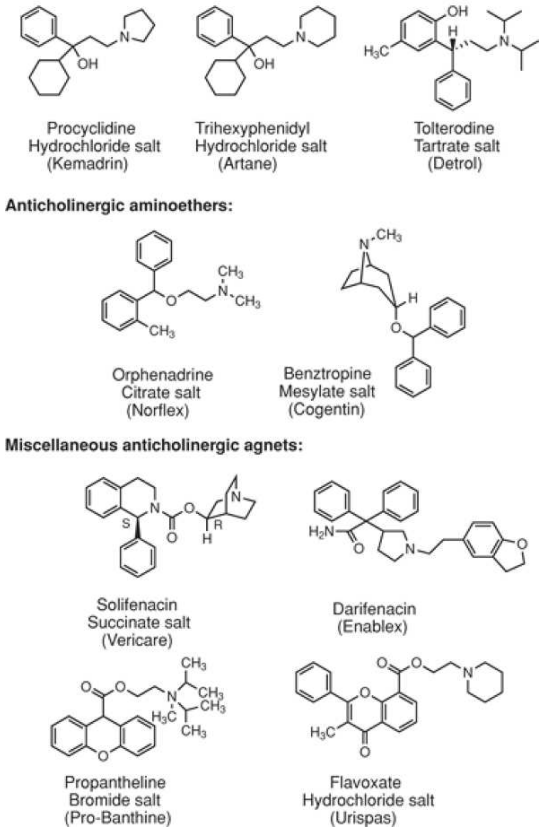

Fig. 12.20. Aminoalcohol, aminoether, and miscellaneous anticholinergic agents.

All these drugs display pronounced selectivity for muscarinic receptors; however, some of those possessing the quaternary ammonium functional group exhibit nicotinic antagonist activity at high doses. With the exception of the M_3 antagonists, solifenacin and darifenacin, these agents display no marked selectivity for muscarinic receptor subtypes.

Recent muscarinic antagonists

More recently discovered muscarinic antagonists display a higher affinity for

P.384

P.385

the receptors compared with the older agents, as exemplified by quinuclidinylbenzilate (QNB), which has structural features common to the classic anticholinergic agents. Radiolabeled QNB was instrumental in the development of muscarinic receptor labeling techniques as well as the discovery of subtypes of muscarinic receptors. This latter research also depended on the M_1-selective antagonist pirenzepine, a compound having a novel structure for muscarinic antagonist activity. A number of compounds structurally related to pirenzepine have demonstrated a similar M_1 selectivity; among these is telenzepine (53). Because of their selectivity for muscarinic M_1 receptors, pirenzepine and telenzepine have been evaluated in clinical trials for the treatment of duodenal ulcers. It is of interest to note that AFDX-116, structurally similar to pirenzepine, is a muscarinic antagonist exhibiting selectivity for cardiac M_2 receptors.

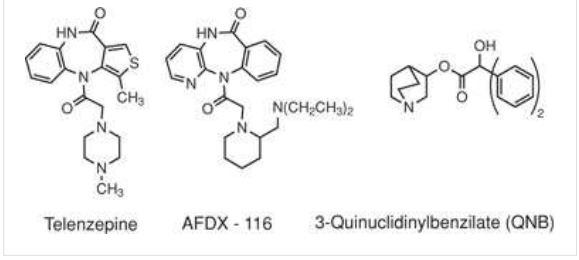
Table 12.3. Anticholinergic Agents

Name	Calculateda Log P Log D (pH 7)	Half-life	Metabolism	Indications	Comments
Atropine	1.53–1.21	3.5 ± 1.5 hours	Hydrolysis; N-dealkylation; N-oxide	Bradycardia; parkinsonism; cycloplegic/mydriatic	Nonselective muscarinic antagonist; stimulates the CNS
Scopolamine	0.76 0.29	8 hours	Almost completely metabolized (liver)	Uveitis; iritis; parkinsonism; motion	Nonselective muscarinic

				sickness	antagonist; CNS depressant
Homatropine (Isopto Homatropine)	1.57 –1.17	—	—	Cycloplegic/mydriatic	Nonselective muscarinic antagonist; less potent an shorter duration than atropine
Ipratropium bromide (Atrovent)	—	2 hours	Hydrolysis	Bronchodilator (oral inhalation); seasonal rhinitis (nasal spray)	Nonselective muscarinic antagonist; slow onset after inhalation
Tiotropium bromide (Spiriva)	—	5–6 days	CYP2D6 and CYP3A4 Hydrolysis; N-dealkylation; glucuronide conjugation	Chronic obstructive pulmonary disease (oral inhalation)	Equal affinity for M_1, M_2 and M_3 receptors
Trospium Chloride (Sanctura)	—	20 hours	Hydrolysis; conjugation	Urinary and gastrointestinal antispasmodic	High affinity for M_1 and M_3 receptors, lesser affinity for M_2.
Oxybutynin	5.19				
(Oral: Ditropan and Ditropan XL) Oxybutynin (transdermal: Oxytrol)	3.93	2–5 hours	CYP3A4 Hydrolysis; N-dealkylation	Overactive bladder	Nonselective muscarinic antagonist
Solifenacin (Vesicare)	3.70 1.70	55 hours	4 R-Hydroxy (active); N-glucuronide; N-oxide; 4R-hydroxy-N-oxide	Overactive bladder	Selective M_3 antagonist
Tolterodine (Detrol)	5.77 2.79	2–4 hours (extensive metabolizers) 9.6 (poor metabolizers)	Primary pathway: CYP2D6 (primary); 7% of Caucasians & 2% of African Americans lack CYP2D6; CYP3A4 is the primary pathway in the latter. Metabolites: 5-hydroxymethyl (active), 5-carboxylic acid, N-dealkylated-5-carboxylic acid	Overactive bladder	Nonselective muscarinic antagonist

Darifenacin	4.50 2.25	—	CYP2D6 (primary; see tolterodine above); hydroxylation of the dihydrobenzofuran; ring opening (dihydrobenzofurna); N-dealkylation	Overactive bladder	Selective M_3 antagonist

[a]Values calculated using ACD Lab Solarius, Chemical Abstracts Service, 2006, Columbus, OH (values for quaternary compounds are not listed).

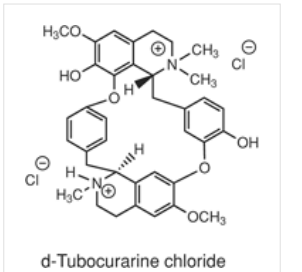


Nicotinic Antagonists—Neuromuscular Blocking Agents

Nicotinic antagonists are chemical compounds that bind to cholinergic nicotinic receptors but have no efficacy. All therapeutically useful nicotinic antagonists are competitive antagonists; in other words, the effects are reversible with acetylcholine. There are two subclasses of nicotinic antagonists—skeletal neuromuscular blocking agents and ganglionic blocking agents—classified according to the two populations of nicotinic receptors. This section emphasizes nicotinic antagonists used clinically as neuromuscular blocking agents. These medicinal agents should not be confused with those skeletal muscle relaxant compounds that produce their effects through the CNS.

History

In terms of the historical perspective, tubocurarine, the first known neuromuscular blocking drug, was as important to the understanding of nicotinic antagonists as atropine was to that of muscarinic antagonists. The neuromuscular blocking effects of extracts of curare were first reported as early as 1510, when explorers of the Amazon River region of South America found natives using these plant extracts as arrow poisons. Early research with these crude plant extracts indicated that the active components caused muscle paralysis by effects on either the nerve or the muscle (remember that the concept of neurochemical transmission was not introduced until the late 19th century). In 1856, however, Bernard (54) described the results of his experiments, which demonstrated unequivocally that curare extracts prevented skeletal muscle contractions by an effect at the neuromuscular junction, rather than the nerve innervating the muscle or the muscle itself.



Much of the early literature concerning the effects of curare is confusing and difficult to interpret. This is not at all surprising considering that this research was performed using crude extracts, many of which came from different plants. It was not until the late 1800s that scientists recognized that curare extracts contained quaternary ammonium salts. This knowledge prompted the use of other quaternary ammonium compounds to explore the neuromuscular junction. In the meantime, curare extracts continued to be used to block the effects of nicotine and acetylcholine at skeletal neuromuscular junctions and to explore the nicotinic receptors.

In 1935, King (55) isolated a pure alkaloid, which he named *d*-tubocurarine, from a tube curare of unknown botanical origin. The word “tube” refers to the container in which the South American natives transported their plant extract. It was almost 10 years later that the botanical source for *d*-tubocurarine was clearly identified as *Chondodendron tomentosum.* The structure that King assigned to tubocurarine possessed two nitrogen atoms, both of which were quaternary ammonium salts (e.g., a *bis*-quaternary ammonium compound). It was not until 1970 that the

correct structure was reported by Everett et al. (56). The correct structure, shown here, has only one quaternary ammonium nitrogen; the other nitrogen is a tertiary amine salt. Nevertheless, the incorrect structure of tubocurarine served as the model for the synthesis of all the neuromuscular blocking agents in use today. These compounds have been of immense therapeutic value for surgical and orthopedic procedures and have been essential to research that led to the isolation and purification of nicotinic receptors.

The potential therapeutic benefits of the neuromuscular blocking effects of tubocurarine as well as the difficulty in obtaining pure samples of the alkaloid encouraged medicinal chemists to design structurally related compounds possessing nicotinic antagonist activity. Using the incorrectly assigned *bis*-quaternary ammonium structure of tubocurarine (as reported by King) as

a guide, a large number of compounds were synthesized and evaluated. It became apparent that a *bis*-quaternary ammonium compound having two quaternary ammonium salts separated by 10 to 12 carbon atoms (similar to the distance between the nitrogen atoms in tubocurarine) was a requirement for neuromuscular blocking activity. The rationale for this structural requirement was that in contrast to muscarinic receptors, nicotinic receptors possessed two anionic-binding sites, both of which had to be occupied for a neuromuscular blocking effect. It is important to observe that the current transmembrane model for the nicotinic receptor protein has two anionic sites in the extracellular domain.

Some of the new *bis*-quaternary ammonium agents produced depolarization of the postjunctional membrane at the neuromuscular junction before causing blockade; other compounds, such as tubocurarine, did not produce this depolarization. Thus, the structural features of the remainder of the molecule determined whether the nicotinic antagonist was a depolarizing or a nondepolarizing neuromuscular blocker.

Therapeutic Application

Neuromuscular blocking agents are used primarily as an adjunct to general anesthesia. They produce skeletal muscle relaxation that facilitates operative procedures such as abdominal surgery. Furthermore, they reduce the depth requirement for general anesthetics; this decreases the overall risk of a surgical procedure and shortens the postanesthetic recovery time. Muscles producing rapid movements are the first to be affected by neuromuscular blocking agents. These include muscles of the face, eyes, and neck. Muscles of the limbs, chest, and abdomen are affected next, with the diaphragm (respiration) being affected last. Recovery generally is in the reverse order.

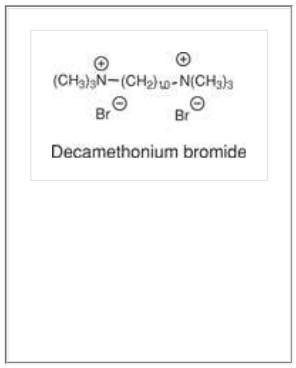
Neuromuscular blocking agents also have been used in the correction of dislocations and the realignment of fractures. Short-acting neuromuscular blocking agents, such as succinylcholine, are routinely used to assist in tracheal intubation. When choosing a neuromuscular blocking agent, four questions must be considered:

1. Will the compound produce the desired neuromuscular blockade?
2. What is its duration of action?
3. What are its adverse effects?
4. What is its relative cost?

Side Effects

Adverse reactions to most, but not all, of the neuromuscular blocking agents may include hypotension, bronchospasm, and cardiac disturbances. The depolarizing agents also cause an initial muscle fasciculation before relaxation. Many of these agents cause release of histamine and subsequent cutaneous (flushing, erythema, urticaria, and pruritus), pulmonary (bronchospasm and wheezing), and cardiovascular (hypotension) effects.

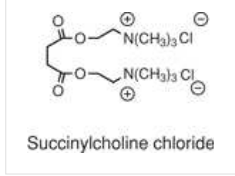
Specific Depolarizing Neuromuscular Blocking Agents



Decamethonium bromide

Decamethonium bromide

Decamethonium was one of the first neuromuscular blocking agents to be synthesized. An SAR study on a series of *bis*-quaternary ammonium compounds with varying numbers of methylene groups separating the nitrogen atoms demonstrated that maximal neuromuscular blockade occurred with 10 to 12 unsubstituted methylene groups. Activity diminished as the number of carbons was either decreased or increased. The compound with six methylene groups, hexamethonium, is a nicotinic antagonist at autonomic ganglia (ganglionic blocking agent). All the compounds in this series that possessed neuromuscular blocking activity also caused depolarization of the postjunctional membrane.



Succinylcholine chloride

Succinylcholine chloride (Anectine)

Succinylcholine is a depolarizing neuromuscular blocking agent that represents a dimer of acetylcholine bonded through their α carbons. The molecule can exist in an extended conformation (antiperiplanar), as shown in the Newman projection. This would account for the appropriate separation of the quaternary nitrogens. Succinylcholine is rapidly hydrolyzed and rendered inactive both in aqueous solution and by plasma esterases; this chemical instability must be considered when preparing solutions for parenteral administration. This same chemical property, however, gives the compound a brief duration of action. As a result, succinylcholine is frequently used for the rapid induction of neuromuscular blockade and when blockade of short duration is desired (Table 12.4). As such, it is used primarily to produce muscle relaxation during endotracheal intubation or endoscopic procedures. The depolarizing property is undesirable in neuromuscular blockers, so most research efforts have been directed toward the design of nondepolarizing agents.

Specific Nondepolarizing Neuromuscular Blocking Agents

Compounds in this class have one or two quaternary ammonium groups. Those with only one quaternary ammonium group, however, exist as *bis*-cations in vivo because of the second positive charge being on a protonated tertiary amine. The various structures of these compounds serve primarily as a “scaffold” to position two

positive charges in the correct three-dimensional orientation for interaction with the transmembrane nicotinic receptors.

Table 12.4. Properties of Clinically Useful Neuromuscular Blocking Agents

Agent	Time of Onset (min)	Duration of Action (min)	Half-life (min)	Mode of Elimination
Succinylcholine	1–1.5	6–8	<1	Hydrolysis by plasma cholinesterases
d-Tubocurarine	4–6	80–120	173	Renal elimination, liver clearance
Vecuronium	2–4	30–40	65–80	Liver metabolism and clearance, renal elimination
Pancuronium	4–6	120–180	89–140	Renal elimination, liver metabolism and clearance
Pipecuronium	2–4	80–100	137–161	Renal elimination, liver metabolism and clearance
Rocuronium	1–2	30–40	84–131	Liver metabolism and clearance
Atracurium	2–4	30–40	16–20	Hofmann degradation, hydrolysis by plasma cholinesterases
Mivacurium	2–4	12–18	1.8–2.0	Hydrolysis by plasma cholinesterases
Doxacurium	4–6	90–120	72–96	Renal elimination, liver metabolism and clearance

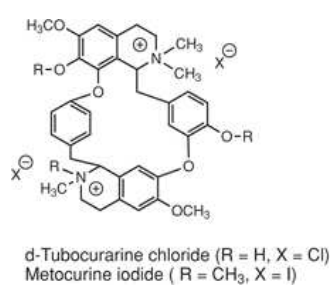
Brunton LL, Lazo JS, Parker KL, eds., Goodman and Gilman's The Pharmacological Basis of Therapeutics, 11th Ed. New York: McGraw-Hill, 2006, pp. 217–236; with permission.



d-Tubocurarine and metocurine (Metubine Iodide)

The prototype of this class is *d*-tubocurarine. It is administered intravenously and has a relatively long duration of action. Only approximately 1% of a dose is demethylated in the liver, and it is excreted primarily as unchanged drug in the urine and bile. *d*-Tubocurarine preparations contain bisulfites and, thus, may potentiate allergic reactions in patients with bisulfate allergy. It is the most potent inducer of histamine release of all the nondepolarizing neuromuscular blockers.

Reaction of *d*-tubocurarine with methyl iodide affords metocurine iodide (see above), in which the two phenolic hydroxyl groups of *d*-tubocurarine are changed to the methyl ethers and the tertiary amine becomes quaternary. This agent is approximately fourfold more potent than *d*-tubocurarine in neuromuscular blocking activity. Like *d*-tubocurarine, it has a long duration of action and is eliminated (predominantly unchanged) via the kidney.

Steroid-based neuromuscular blocking agents

An ideal neuromuscular blocking agent would be a nondepolarizing compound that is metabolically inactivated and rapidly eliminated. Efforts to design such a neuromuscular blocker have resulted in the development of several synthetic neuromuscular agents. Those that have found clinical use are either aminosteroids derived from (+)-malouetine (an aminosteroid found in the rain forest of central Africa) (Fig. 12.21) or tetrahydroisoquinoline derivatives (Fig. 12.22).

Pancuronium bromide (Pavulon)

Pancuronium, a long-acting agent, is more active than tubocurarine. It may cause increases in heart rate and blood pressure and should not be used in patients with coronary artery disease. Pancuronium undergoes hydrolysis in the liver to the active 3-hydroxy metabolite and the inactive 17-hydroxy and 3,17-dihydroxy metabolites; it is excreted primarily in the urine, with small amounts in the bile.

Vecuronium bromide (Norcuron)

Removal of the methyl group from the quaternary piperidinium group at position 3 of pancuronium affords vecuronium, an intermediate-acting agent. Vecuronium has the advantage of not inducing histamine release at normal doses and of not exhibiting significant cardiovascular effects. One-third of an administered dose of vecuronium is hydrolyzed to the 3-hydroxy, 17-hydroxy, and 3,17-dihydroxy metabolites, all of which are active. Accumulation of the 3,17-dihydroxy metabolite is responsible for prolonged neuromuscular blockade in patients receiving long-term therapy with vecuronium.

Pipecuronium bromide (Arduan)

Pipecuronium bromide, a long-acting neuromuscular blocking agent, exhibits minimal cardiovascular effects. Like pancuronium and vecuronium, pipecuronium undergoes some hydrolysis but is excreted primarily unchanged in the urine with very small amounts in the bile. Pipecuronium may be used in patients with coronary artery disease, but neuromuscular blockade is prolonged in patients with renal failure.

Rocuronium bromide (Zemuron)

Rocuronium bromide is an intermediate-acting agent with a duration of action similar to vecuronium and atracurium but with a more rapid onset. It does not appear to cause significant histamine release.

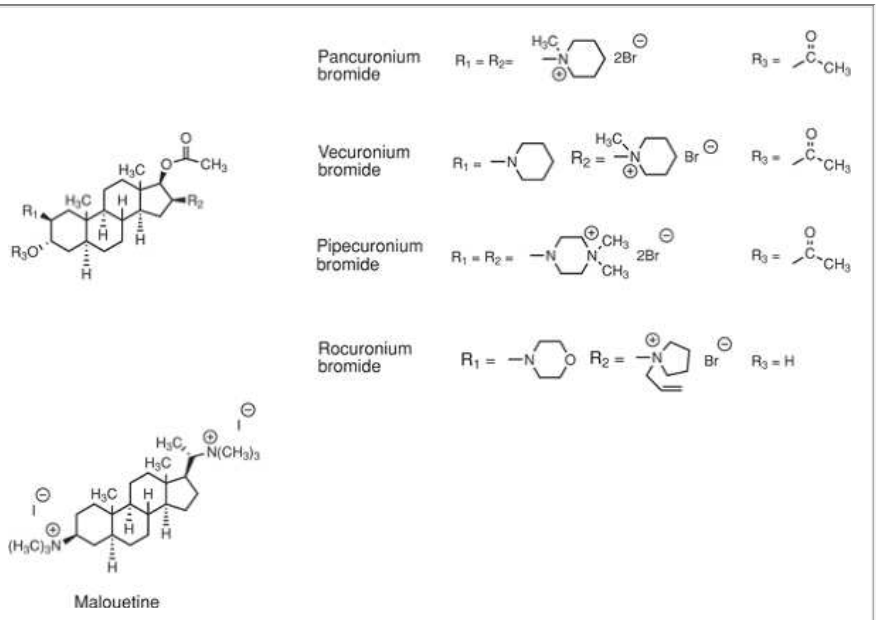


Fig. 12.21. Amino steroid–based neuromuscular blocking agents.

Tetrahydroisoquinoline-based neuromuscular blocking agents

Atracurium besylate (Tracrium)

Atracurium besylate is a nondepolarizing neuromuscular blocker in which the quaternary ammonium groups are located in two substituted tetrahydroisoquinoline rings separated by an aliphatic diester. It has a duration of action slightly longer than that of succinylcholine. Atracurium is not metabolized in the liver; rather, it undergoes hydrolysis of the ester functional groups that connect the two quaternary nitrogens. It also undergoes Hofmann elimination, a nonenzymatic, base-catalyzed decomposition, to yield laudanosine, which is inactive (Fig. 12.23) (57,58). Thus, termination of the effects of atracurium are independent of renal elimination. Because of this unusual metabolic profile, it is useful in patients with hepatic or renal disease.

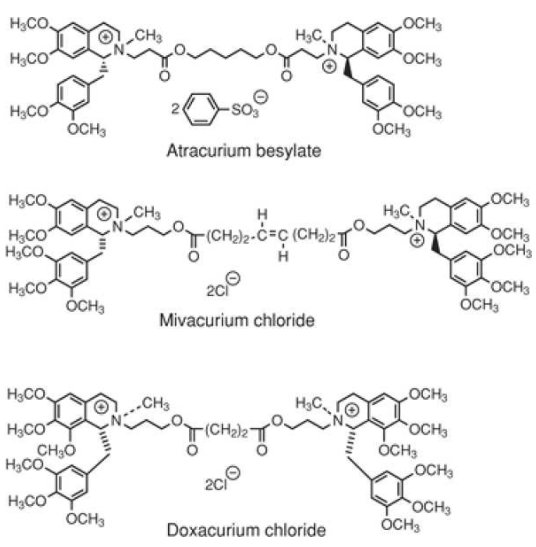

Fig. 12.22. Tetrahydroisoquinoline-based neuromuscular blocking agents.

Mivacurium chloride (Mivacron)

Mivacurium chloride is a mixture of three stereoisomers, with the *trans-trans* (92–96%) and the *cis-trans* diesters being equipotent. The *cis-cis* diester produces only minimal (<5%) neuromuscular blockade. It is hydrophilic, has a small volume of distribution, and is distributed primarily to extracellular fluids. Mivacurium is short acting (Table 12.4), with mean elimination half-lives for the *trans-trans* and *cis-trans* stereoisomers of 2.0 and 1.8 minutes, respectively, in adults receiving opioid/nitrous oxide/oxygen anesthesia. It is rapidly hydrolyzed and does not undergo

Hofmann elimination like atracurium.

Doxacurium chloride (Nuromax)

Doxacurium is a mixture of three *trans*, *trans*-stereoisomers, a *dl* pair [(1R,1′R,2S,2′S) and (1S,1′S,2R,2′R)] and a meso form (1R,1′S,2S,2′R). Doxacurium is hydrophilic, has a small volume of distribution, and is distributed primarily to extracellular fluids. It is not metabolized by plasma cholinesterase or hepatic enzymes and does not undergo Hofmann elimination.

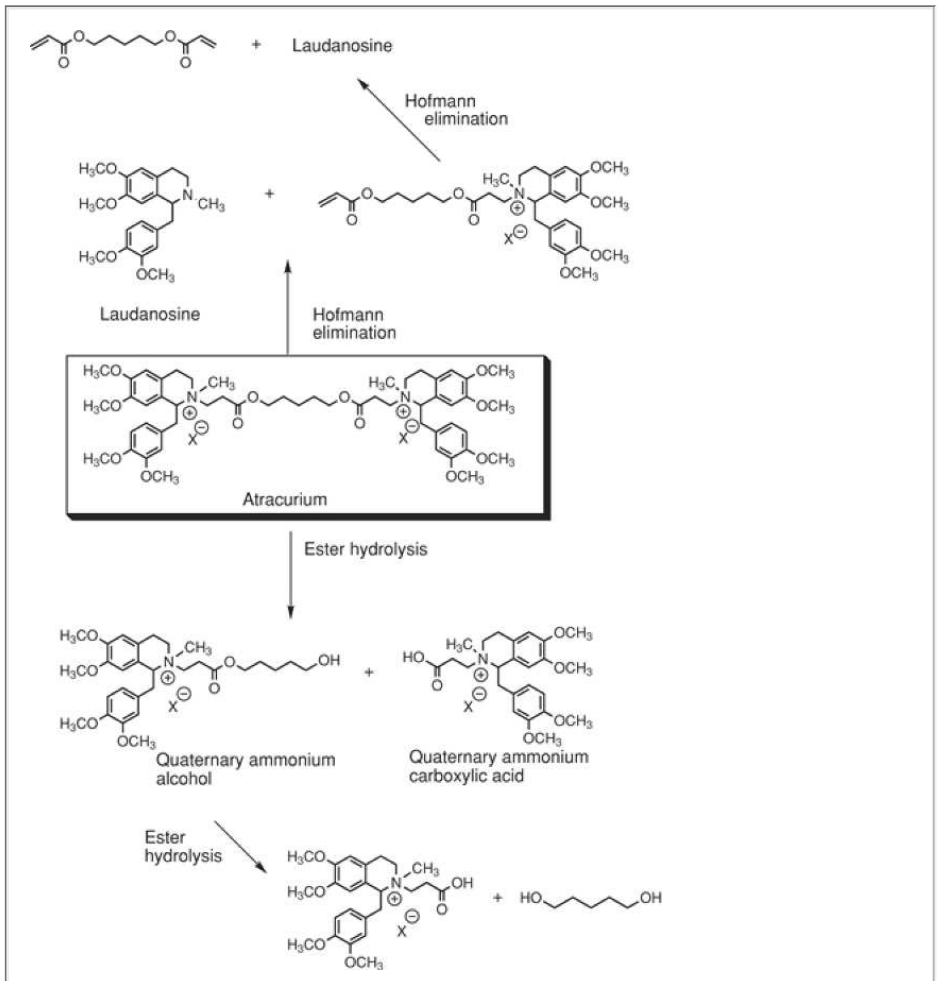

Fig. 12.23. Inactivation of atracurium by Hofmann elimination and hydrolysis.

Case Study

Victoria F. Roche

S. William Zito

PJ was brought to the emergency department where you work by his fellow housemates. PJ is a 29-year-old graduate student at the local university who has been studying for his Ph.D. in anthropology for the past 7 years. His housemates say he is a devotee of "natural highs" and is known to consume 6 to 12 beers per day and for his stash of natural substances, including marijuana. In the emergency department, he is extremely agitated, confused, and combative. His friends say he became that way soon after he ingested a handful of brown, kidney-shaped seeds. On examination, PJ's vital signs showed a temperature of 102°F, with tachycardia, hypertension, and unresponsive, dilated pupils. Urine was collected for routine drug screening and serum for liver function tests. Test results determined that he had elevated aspartate aminotransferase and lactate dehydrogenase, a prolongation of his prothrombin time, and atropine and scopolamine (structures 1 and 2, respectively) in the urine. A diagnosis of anticholinergic overdose was made, and PJ was administered gastric lavage with 2.5 L of normal saline followed by activated charcoal. The physician wants to administer a cholinergic agonist to counter the effects of the anticholinergic overdose. Evaluate structures 3 to 5 for possible use in this case.

1. Identify the therapeutic problem(s) where the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented SAR analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 13

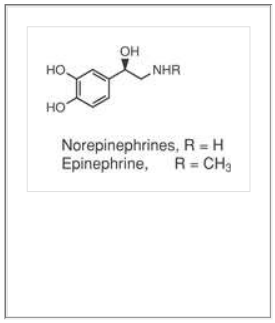
Adrenergic Receptors and Drugs Affecting Adrenergic Neurotransmission

Robert K. Griffith

Introduction

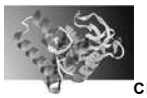
Adrenergic drugs are a broad class of agents employed in the treatment of disorders of widely varying severity. Adrenergic drugs include popular prescription drugs, such as albuterol for asthma and atenolol for hypertension (Table 13.1), as well as many common over-the-counter cold remedies, such as the nasal decongestant pseudoephedrine.

Adrenergic drugs act on effector cells through adrenoceptors that normally are activated by the neurotransmitter norepinephrine (noradrenaline), or they may act on the neurons that release the neurotransmitter. The term "adrenergic" stems from the discovery early in the twentieth century that administration of the hormone adrenaline (epinephrine) had specific effects on selected organs and tissues similar to the effects produced by stimulation of the sympathetic (adrenergic) nervous system. For a number of years, adrenaline was thought to be the neurotransmitter in the sympathetic nervous system, but it also was recognized that the effects of administered epinephrine were not quite identical to those of sympathetic stimulation. Finally, in the 1940s, norepinephrine was identified as the true neurotransmitter at the terminus of the sympathetic nervous system (1,2). Adrenoceptors are widely located in various organs and tissues as well as on neurons of both the peripheral nervous system (PNS) and central nervous system (CNS).



Norepinephrine and epinephrine are members of a class of pharmacologically active substances known as catecholamines, because they contain within their structures both an amine and ortho-dihydroxybenzene, which is known by the common chemical name of catechol. Many adrenergic drugs also are catecholamines, and their structure-activity-relationships (SARs) will be discussed.

Neurons at the terminus of an adrenergic neuron fiber release norepinephrine to influence the target tissue through binding to receptors on cells of the tissue or organ. The cells bearing the receptors are called effector cells, because they produce the effect seen by adrenergic stimulation.



Clinical Significance

Through the years, an increased understanding of adrenergic receptors and compounds that modulate their activity has led to decreased morbidity and mortality as well as increased quality of life for millions of patients worldwide with multiple drugs in this category on the Top 200 list of prescriptions dispensed. Agents affecting adrenergic neurotransmission are used to treat a variety of clinical conditions, including hypertension, hypotension, angina, heart failure, arrhythmias, and asthma. In fact, our understanding of structure-activity relationships led to an ability to alter the pharmacodynamic effects of various agents even before the specific receptor types were identified.

A thorough understanding of the structure-activity relationships of these compounds and application of the principles of medicinal chemistry to alter their pharmacodynamic effects has enhanced the desired properties and diminished the incidence and/or severity of associated unwanted adverse effects. Furthermore, therapeutic utility and patient compliance has been improved with the advent of orally active agents with longer elimination times and decreased frequency of dosing. For clinicians, a thorough understanding of the resultant pharmacodynamic properties of these agents is necessary to substantiate therapeutic decision making for an individual patient. For example, a patient with hypotension resulting in shock is treated with an adrenergic agonist that will increase blood pressure. If the patient's hypotension results from distributive shock, an agent with α_1-stimulant properties is necessary. If the hypotension results from cardiogenic shock, however, a β_1-agonist drug would be most effective, and in actuality, an α_1-stimulant agent may cause the patient to further decompensate by increasing cardiac workload without lending support to the failing heart. Manipulation of three sites on the basic phenylethanolamine structure alter these receptor specificities, which allows a clinician to tailor drug selection for an individual patient based on the specific desired pharmacological effects of each compound. A second example would be selection of a β_1-selective receptor blocking agent like metoprolol as opposed to a nonspecific β-antagonist like propranolol to treat a patient with asthma who has experienced a myocardial infarction. This allows the patient to benefit from the potential mortality reduction associated with the β-blocking agent while minimizing the risk of decreasing β_2-agonist utility for bronchospasm. These are only a couple of simple illustrations of altering the structure-activity relationship of adrenergic compounds to increase their utility for specific disease processes and outlining the importance of understanding the pharmacodynamic impact of these alterations.

Table 13.1. Adrenergic Prescription Drugs in the Top 200 for 2005

Drug	Application
Albuterol (Ventolin)	Bronchodilator

Atenolol (Tenormin)	Antihypertensive
Metoprolol (Lopressor)	Antihypertensive
Clonidine (Catapress)	Antihypertensive
Doxazosin (Cardura)	Antihypertensive, benign prostatic hyperplasia
Bisoprolol (Zebeta)	Antihypertensive
Propranolol (Inderal)	Antihypertensive
Terazosin (Hytrin)	Antihypertensive, benign prostatic hyperplasia
Labetolol (Normodyne)	Antihypertensive
Nadolol (Corgard)	Antihypertensive
Timolol (Timoptic)	Glaucoma therapy
Sotalol (Betapace)	Antiarrhythmic

In general, stimulation of the sympathetic nervous system causes what is known as “fight-or-flight” responses. These effects include an increased rate and force of heart contraction, a rise in blood pressure, a shift of blood flow to skeletal muscles, dilation of bronchioles and pupils, and an increase in blood glucose levels through gluconeogenesis and glycogenolysis. These responses are what one might predict in a mammal that is enraged and preparing to fight or in one that is frightened and preparing to flee. Drugs can influence adrenergic responses through a variety of mechanisms, and an understanding of these mechanisms requires knowledge regarding the details of norepinephrine biosynthesis, storage, release, and fate following release.

Biosynthesis, Storage, and Release of Norepinephrine

Biosynthesis of norepinephrine takes place within adrenergic neurons near the terminus of the axon and junction with the effector cell. The biosynthetic pathway (Fig. 13.1) begins with the active transport of the amino acid L-tyrosine into the adrenergic neuron cell (1). In the first step within the cytoplasm, the enzyme tyrosine hydroxylase (tyrosine-3-monooxygenase) oxidizes the 3′ position of tyrosine to form the catechol amino acid L-dopa. This is the rate-limiting step in norepinephrine biosynthesis, and the activity of tyrosine hydroxylase is carefully controlled (3). The enzyme is under feedback inhibition control by product catecholamines and is controlled through a complex pattern of phosphorylation/

dephosphorylation, in which phosphorylation by protein kinases activates the enzyme and dephosphorylation by phosphatases decreases activity.

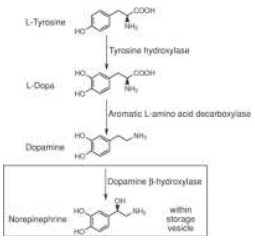

Fig. 13.1. Biosynthesis of norepinephrine.

In the second step, L-dopa is decarboxylated to dopamine by aromatic L-amino acid decarboxylase, another cytoplasmic enzyme. Aromatic L-amino acid decarboxylase was discovered in the 1930s and originally named dopa decarboxylase. Researchers subsequently discovered that dopa decarboxylase is not specific for dopa and decarboxylates other aromatic amino acids having the L (or S) absolute configuration, such as 5-hydroxytryptophan, tryptophan, and tyrosine. Nevertheless, the enzyme often still is referred to by the older name.

The dopamine formed in the cytoplasm by decarboxylation of L-dopa is then taken up by active transport into storage vesicles or granules located near the terminus of the adrenergic neuron. Within these vesicles, the enzyme dopamine β-hydroxylase stereospecifically introduces a hydroxyl group in the R absolute configuration on the carbon atom β to the amino group to generate the neurotransmitter norepinephrine. Norepinephrine is stored in the vesicles in a 4:1 complex with ATP in such quantities that each vesicle in a peripheral adrenergic neuron contains between 6,000 and 15,000 molecules of norepinephrine (4). The norepinephrine remains in the vesicles until released into the synapse during signal transduction. When a wave of depolarization reaches the terminus of an adrenergic neuron, it triggers the transient opening of voltage-dependent calcium channels, causing an influx of calcium ions. This influx of calcium ions triggers fusion of the storage vesicles with the neuronal cell membrane, spilling the norepinephrine and other contents of the vesicles into the synapse through exocytosis (Fig. 13.2). The pathway for epinephrine biosynthesis in the adrenal medulla is the same as for norepinephrine with the additional step of conversion of norepinephrine to epinephrine by the enzyme phenylethanolamine-N-methyltransferase.

Reuptake and Metabolism of Norepinephrine Following Release

Following its release, norepinephrine diffuses through the intercellular space to bind reversibly to adrenoceptors (α or β) on the effector cell, inducing a conformational change in the receptor. This conformational change triggers a biochemical cascade that results in a physiologic response by the effector cell. In addition to the receptors on effector cells are adrenoreceptors that respond to norepinephrine (α_2-receptors) on the presynaptic neuron,

which, when stimulated by norepinephrine, act to inhibit the release of additional norepinephrine into the synapse. Once it has been released and is stimulating its

various receptors, there must be mechanisms for removing the norepinephrine from the synapse and terminating the adrenergic impulse. By far the most important of these mechanisms for removing the norepinephrine is transmitter recycling through active transport uptake into the presynaptic neuron. This process, called uptake-1, is efficient, and in some tissues, up to 95% of released norepinephrine likely is removed from the synapse by this mechanism (5). Part of the norepinephrine taken into the presynaptic neuron by uptake-1 is metabolized to 3,4-dihydroxyphenylglycolaldehyde (DOPGAL) by mitochondrial monoamine oxidase (MAO) (Fig. 13.3), and part of it is sequestered in the storage vesicles to be used again as neurotransmitter. A less efficient uptake process, called uptake-2, operates in a variety of other cell types but only in the presence of high concentrations of norepinephrine. That portion of released norepinephrine that escapes uptake-1 diffuses out of the synapse and is metabolized in extraneuronal sites by catechol-O-methyltransferase (COMT), which methylates the meta hydroxyl group. Norepinephrine also is metabolized to DOPGAL by MAO at extraneuronal sites, principally the liver and blood platelets. Both DOPGAL and normetanephrine are subject to further metabolism, as outlined in Figure 13.3 (6). These pathways also are important to drugs that are structural analogues of norepinephrine. In particular, drugs that are catechols (a 1,2-diphenolic moiety) are subject to metabolism by COMT, and drugs with unsubstituted aliphatic amino groups often are substrates for MAO.

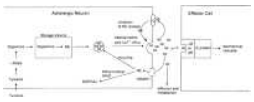

Fig. 13.2. Neurotransmission events in an adrenergic neuron and effector cell. NE, norepinephrine; αR, α adrenoceptor; βR, β adrenoceptor; MAO, monoamine oxidase; DOPGAL, 3,4-dihydroxyphenylglycolaldehyde.

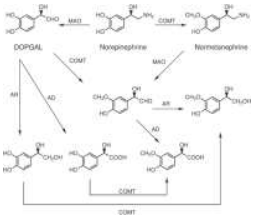

Fig. 13.3. Metabolism of norepinephrine. MAO, monoamine oxidase; COMT, catechol-O-methyltransferase; AR, aldehyde reductase; AD, aldehyde dehydrogenase.

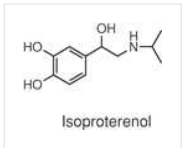
In summary (Fig. 13.3), following biosynthesis and storage in a vesicle, norepinephrine release into the synapse is triggered by depolarization-induced calcium influx. The norepinephrine in the synapse interacts with postsynaptic G protein–linked α- or β-receptors on the effector cell, triggering effector cell response, or with presynaptic α_2-receptors on the neuron, which inhibit release of more norepinephrine. Most of the synaptic neurotransmitter is taken back into the presynaptic neuron by uptake-1 active transport. Some of the norepinephrine is metabolized by MAO, and the remainder is stored in a vesicle to be used again. That portion of norepinephrine not captured by uptake-1 diffuses out of the synapse and is metabolized by COMT and MAO.

Characterization of Adrenergic Receptor Subtypes

The discovery of subclasses of adrenergic receptors and the ability of relatively small molecule drugs to stimulate differentially or block these receptors represented a major advance in several areas of pharmacotherapeutics. Adrenergic receptors were subclassified by Ahlquist (7) in 1948 into α- and β-adrenoreceptor classes according to their responses to different adrenergic receptor agonists, principally norepinephrine, epinephrine, and isoproterenol. These catecholamines are able to stimulate α-adrenoceptors in the following descending order of potency: epinephrine > norepinephrine > isoproterenol.

P.396

In contrast, β-adrenoceptors are stimulated in the following descending order of potency: isoproterenol > epinephrine > norepinephrine.



In the years since Ahlquist's original classification, additional small molecule agonists and antagonists have been used to allow further subclassification of α- and β-receptors into α_1 and α_2 subtypes of α-receptors and the β_1, β_2, and β_3 subtypes of β-adrenoceptors. The powerful tools of molecular biology have been used to clone, sequence, and identify even more subtypes of alpha receptors for a total of six. Currently, three types of α_1-adrenoceptor, called α_{1A}, α_{1B}, and α_{1D}, are known. (There is no α_{1C}, because identification of a supposed α_{1C} was found to be incorrect.) Currently, three subtypes of α_2, known as α_{2A}, α_{2B}, and α_{2C}, also are known (8). The data derived from molecular biology provides a wealth of information on the structures and biochemical properties of both α- and β-receptors. Intensive research continues in this area, and the coming years may provide evidence of additional subtypes of both α- and β-receptors. At this time, however, only the α_1-, α_2-, β_1-, and β_2-receptor subtypes are sufficiently well differentiated by their small molecule binding characteristics to be clinically significant in pharmacotherapeutics, although therapeutic agents acting selectively on β_3-adrenoceptors to induce fat catabolism may become available in the near future (9).

The adrenoceptors, both α and β, are members of a receptor superfamily of membrane-spanning proteins, including muscarinic, serotonin, and dopamine receptors, which are coupled to intracellular GTP-binding proteins (G proteins), which determine the cellular response to receptor activation (10). All these receptors exhibit a common motif of a single polypeptide chain that is looped back and forth through the cell membrane seven times with an extracellular N-terminus and intracellular C-terminus. The human β_2-adrenoceptor was one of the first to be cloned and thoroughly studied (Fig. 13.4) (11). The seven transmembrane domains, TMD1 through

P.397

TMD7, are composed primarily of lipophilic amino acids arranged in α-helices connected by regions of hydrophilic amino acids. The hydrophilic regions form loops on

the intracellular and extracellular faces of the membrane. In all the adrenoceptors, the agonist/antagonist recognition site is located within the membrane-bound portion of the receptor. This binding site is within a pocket formed by the membrane-spanning regions of the peptide, as illustrated in Figure 13.5 for epinephrine bound to the human β_2-receptor. All the adrenoceptors are coupled to their effector systems through a G protein, which is linked through reversible binding interactions with the third intracellular loop of the receptor protein.

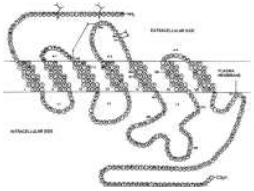


Fig. 13.4. Human β_2-adrenergic receptor: amino acid sequence of the human β_2-receptor showing the seven transmembrane domains (I–VII), the connecting intracellular and extracellular loops, extracellular glycosylation sites at asparagines 6 and 15, and intrachain disulfide bonds between cysteines 106–184 and 190–191. Also indicated are the amino acids identified as participating in neurotransmitter binding—aspartate 113 in transmembrane domain III, which binds the positively charged amine of the neurotransmitter, and serines 204 and 207 of transmembrane domain V, which form hydrogen-bonds with the catechol hydroxyls. Phenylalanine 290 may participate in agonist binding as well. Amino acids 222–229 and 258–270 of the third intracellular loop are critical for G protein–coupling, and palmitoylated cysteine 341 is critical for proper adenylyl cyclase activation. (From Ostrowski J, Kjelsberg MA, Caron MG, et al. Mutagenesis of the β_2-adrenergic receptor: how structure elucidates function. Annu Rev Pharmacol Toxicol 1992;32:167–183; with permission.)

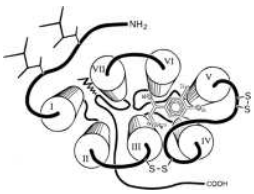

Fig. 13.5. Proposed arrangement for the transmembrane helices of the β_2-adrenergic receptor depicting the binding site for epinephrine as viewed from the extracellular side. (From Ostrowski J, Kjelsberg MA, Caron MG, et al. Mutagenesis of the β_2-adrenergic receptor: how structure elucidates function. Annu Rev Pharmacol Toxicol 1992;32:167–183; with permission.)

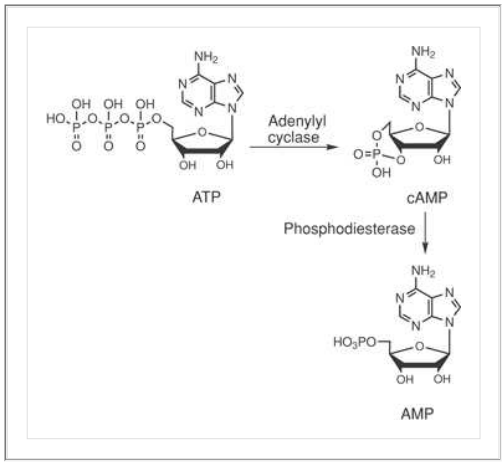
Salient features of the extensively studied β_2-adrenoreceptor are indicated in Figure 13.4. Binding studies with selectively mutated β_2-receptors have provided strong evidence for binding interactions between agonist functional groups and specific residues in the transmembrane domains of adrenoceptors. Such studies indicate that Asp113 in transmembrane domain 3 (TMD3) of the β_2-receptor is the acidic residue that forms a bond, presumably ionic or a salt bridge, with the positively charged amino group of catecholamine agonists. An aspartic acid residue also is found in a comparable position in all the other adrenoceptors as well as other known G protein–coupled receptors that bind substrates having positively charged nitrogens in their structures. Elegant studies with mutated receptors and analogues of isoproterenol demonstrated that Ser204 and Ser207 of TMD5 are the residues that form hydrogen bonds with the catechol hydroxyls of β_2-agonists (12). Furthermore, the evidence indicates that Ser204 interacts with the meta hydroxyl group of the ligand, whereas Ser207 interacts specifically with the para hydroxyl group. Serine residues are found in corresponding positions in TMD5 of the other known adrenoceptors. Evidence indicates that the phenylalanine residue of TMD6 also is involved in ligand-receptor bonding with the catechol ring. Studies such as these and others that indicated the presence of specific disulfide bridges between cysteine residues of the β_2-receptor led to the binding scheme shown in Figure 13.5.

Structural differences exist among the various adrenoceptors with regard to their primary structure, including the actual peptide sequence and length. Each of the adrenoceptors is encoded on a distinct gene, and this information was crucial to the proof that each adrenoreceptor is, indeed, distinct although related. The amino acids that make up the seven transmembrane regions are highly conserved among the various adrenoreceptors, but the hydrophilic portions are quite variable. The largest differences occur in the third intracellular loop connecting TMD5 and TMD6, which is the site of linkage between the receptor and its associated G protein. Compare the diagram of the β_2-receptor in Figure 13.4 with that of the α_2-receptor in Figure 13.6 (13).

Effector Mechanisms of Adrenergic Receptors



Each adrenoceptor is coupled through a G protein to an effector mechanism. Effector mechanisms are proteins that are able to translate the conformational change caused by activation of the receptor into a biochemical event within the cell. All the β-adrenoceptors are coupled via specific G proteins (G_s) to the activation of adenylyl cyclase* (14). Thus, when the receptor is stimulated by an agonist, adenylyl cyclase is activated to catalyze the formation of cyclic AMP (cAMP) from ATP. Called a second

messenger for the β-adrenoceptors, cAMP is known to function as a second messenger for a number of other receptor types. cAMP is considered to be a messenger, because it can diffuse through the cell for at least short distances to modulate biochemical events remote from the synaptic cleft. Modulation of biochemical events by cAMP includes a phosphorylation cascade of other proteins. Additionally, cAMP is rapidly deactivated by hydrolysis of the phosphodiester bond by the enzyme phosphodiesterase. The α_2-receptor may use more than one effector system depending on the location of the receptor. To date, however, the best-understood effector

system of the α_2-receptor appears to be similar to that of the β-receptors, except that linkage via a G protein (G_i) leads to inhibition of adenylyl cyclase instead of activation.

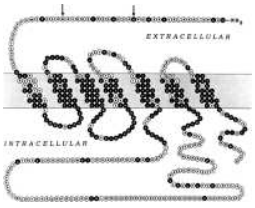


Fig. 13.6. Human kidney α_2-adrenergic receptor: amino acid sequence of the human kidney α_2-receptor showing the seven transmembrane domains and the connecting intracellular and extracellular loops. Note particularly the large third intracellular loop, which is the G protein–binding site. The arrows point to the sites of glycosylation. Amino acids in black circles are those identical to the amino acids in the human platelet α_2-receptor. (From Regan JW, Kobilka TS, Yang-Feng TL, et al. Cloning and expression of a human kidney cDNA for an α_2-adrenergic receptor subtype. Proc Natl Acad Sci U S A 1988;85:6301–6305; with permission.)

The α_1-adrenoreceptor is linked through yet another G protein to a complex series of events involving hydrolysis of polyphosphatidylinositol (15). The first event set in motion by activation of the α_1-receptor is activation of the enzyme phospholipase C. Phospholipase C catalyzes the hydrolysis of phosphatidylinositol-4,5-biphosphate. This hydrolysis yields two products, each of which has biological activity as second messengers of the α_1-receptor (see Chapter 4). These two products are 1,2-diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP_3). The latter, IP_3, causes the release of calcium ions from intracellular storage sites in the endoplasmic reticulum, resulting in an increase in free intracellular calcium levels. Increased free intracellular calcium is correlated with smooth muscle contraction. The other product, DAG, is thought to activate cytosolic protein kinase C, which may induce slowly developing contractions of vascular smooth muscle. The end result of a complex series of protein interactions triggered by agonist binding to the α_1-receptor includes increased intracellular free calcium, which leads to smooth muscle contraction. When the smooth muscle innervated by α_1-receptors is in vascular walls, stimulation leads to vascular constriction.

Receptor Localization

The generalization made in the past about synaptic locations of adrenoreceptor subtypes was that all α_1-, β_1-, β_2-, and β_3-receptors are postsynaptic receptors that are linked to stimulation of biochemical processes in the postsynaptic cell. Presynaptic β-receptors, however, are

known to occur, although their function is unclear. Traditionally, the α_2-receptor has been viewed as a presynaptic receptor that resides on the outer membrane of the nerve terminus or presynaptic cell and reacts with released neurotransmitter. The α_2-receptor serves as a sensor and modulator of the quantity of neurotransmitter present in the synapse at any given moment. Thus, during periods of rapid nerve firing and neurotransmitter release, the α_2-receptor is stimulated and causes an inhibition of further release of neurotransmitter. This is a well-characterized mechanism for modulation of neurotransmission. Not all α_2-receptors are presynaptic, but the physiologic significance of postsynaptic α_2-receptors is less well understood (16).

Therapeutic Relevance of Adrenergic Receptor Subtypes

The clinical utility of receptor-selective drugs becomes obvious when one considers the adrenoreceptor subtypes and effector responses of only a few organs and tissues innervated by the sympathetic nervous system. The major adrenoceptor subtypes are listed in Table 13.2. For example, the predominant response to adrenergic stimulation of smooth muscle of the peripheral vasculature is constriction causing a rise in blood pressure. Because this response is mediated through α_1-receptors, an α_1-antagonist would be expected to cause relaxation of the blood vessels and a drop in blood pressure with clear implications for treating hypertension. In addition, the presence of α_1-adrenoceptors in the prostate gland leads to the use of α_1-antagonists in treating benign prostatic hyperplasia. The principal therapeutic uses of adrenergic agonists and antagonists are shown in Table 13.3. A smaller number of β_2-receptors on vascular smooth muscle mediate arterial dilation, particularly to skeletal muscle, and a few antihypertensives act through stimulation of these β_2-receptors. (Adrenergic antihypertensives are discussed more thoroughly in Chapter 29.) Adrenergic stimulation of the lungs causes smooth muscle relaxation and bronchodilation mediated through β_2-receptors. Drugs acting as β_2-agonists are useful for alleviating respiratory distress in persons with asthma or other obstructive pulmonary diseases (see Chapter 44). Activation of β_2-receptors in the uterus also causes muscle relaxation, and so some β_2-agonists are used to inhibit uterine contractions in premature labor. Adrenergic stimulation of the heart causes an increase in rate and force of contraction, which is mediated primarily by β_1-receptors. Drugs with β_1-blocking activity slow the heart rate and decrease the force of contraction. These drugs have utility in treating hypertension, angina, and certain cardiac arrhythmias (see Chapters 26 and 29).

Table 13.2. Selected Tissue Responses to Stimulation of Adrenoceptor Subtypes

Organ or Tissue	Type Receptor Major	Response
Arterioles, vascular bed to skeletal muscle	α_1, α_2 β_2	Constriction Dilation
Eye (radial muscle)	α_1	Contraction (papillary dilation)
Heart	β_1	Increased rate and force
Lungs	β_2	Relaxation (bronchodilation)
Liver	α_1, β_2	Increased gluconeogenesis and glycogenolysis
Fat cells	α_1, β_3	Lipolysis
Uterus (pregnant)	α_1 β_2	Contraction Relaxation
Intestine	α_1, β_2	Decreased motility

From the preceding discussions of the biosynthesis, storage, release, and fate of norepinephrine, one can readily conceive of a number of possible sites of drug action for adrenergic drugs. As mentioned, there are drugs that act

directly on the receptors as agonists and antagonists, drugs that affect storage and release from vesicles, drugs that affect neurotransmitter biosynthesis, and drugs that affect uptake and catabolism of norepinephrine and epinephrine. These categories are discussed in turn. Most adrenergic drugs fit into well-defined classes with readily defined SARs, but a few adrenergic drugs do not permit such straightforward structural definition of their activity. We begin with a discussion of phenylethanolamine (or phenethanolamine) agonists, which do have reasonably clear SARs. Although many of these drugs directly stimulate adrenoceptors, others exhibit what is termed "indirect activity." Indirect agonists do not directly bind to and activate adrenergic receptors; rather, they are taken up into the presynaptic neuron, where they cause the release of norepinephrine, which can diffuse into the receptor causing the observed response. Mixed-acting drugs have both a direct and an indirect component to their action, and the relative amount of direct versus indirect activity for a given drug varies considerably with its chemical structure, the tissue preparation examined, and the experimental animal species.

Table 13.3. Principal Therapeutic Uses of Adrenergic Agonists and Antagonists

Adrenoceptor	Drug Action	Therapeutic Uses
α_1	Agonists	Shock, hypotension (to raise blood pressure) Hasal decongestants
	Antagonists	Antihypertensives Benign prostatic hyperplasia (BPH)
α_2	Agonists	Antihypertensives Glaucoma Analgesia Sedatives
β_1	Antagonists	Antihypertensives Antiarrythmics
β_2	Agonists	Bronchodilators (asthma and COPD) Glaucoma
β_3	Agonists	Weight loss (investigational drugs)

Structure-Activity Relationships of Adrenergic Agonists

Phenylethanolamine Agonists

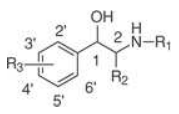
The structures of many clinically useful phenylethanolamine-type adrenergic agonists are summarized in Table 13.4. Agents of this type have been extensively studied over the years since discovery of the naturally occurring prototypes, epinephrine and norepinephrine, and the structural requirements and tolerances for substitutions at each of the indicated positions have been established (2). In general, a primary or secondary aliphatic amine separated by two carbons from a substituted benzene ring is minimally required for high agonist activity in this class. Because of the basic amino groups (pK_a range, ~8.5–10), all these agents are highly positively charged at physiologic pH. By definition, agents in this class have a hydroxyl group on C1 of the side chain, β to the amine, as in epinephrine and norepinephrine. This hydroxyl-substituted carbon must be in the R absolute configuration for maximal direct activity as in the natural neurotransmitter, although most drugs currently are sold as mixtures of both (R) and (S) stereoisomers at this position (racemates). Given these features in common, the nature of the other substituents determines receptor selectivity and duration of action. In the following discussions, keep in mind that saying a drug is selective for a given receptor does not mean it has no activity at other receptors and that the clinically observed degree of selectivity is frequently dose-dependent.

R^1, Substitution on the Amino Nitrogen

We have already seen that as R^1 is increased in size from hydrogen in norepinephrine to methyl in epinephrine to isopropyl in isoproterenol, that activity at α-receptors decreases, and that activity at β-receptors increases. These

compounds were used to define α- and β-activity long before receptor proteins could be isolated and characterized. The activity at both α- and β-receptors is maximal when R^1 is methyl as in epinephrine, but α-agonist activity is dramatically decreased when R^1 is larger than methyl and is negligible when R^1 is isopropyl, as in isoproterenol, leaving only β-activity. In fact, the β-activity of isoproterenol actually is enhanced over norepinephrine and epinephrine. Presumably, the β-receptor has a large lipophilic binding pocket adjacent to the amine-binding aspartic acid residue, which is absent in the α-receptor. As R^1 becomes larger than *t*-butyl into aryl-α-methylalkyl groups, affinity for α_1-receptors, but not intrinsic activity, returns, which means large lipophilic groups can afford compounds with α_1-blocking activity (e.g., labetalol, a mixed α/β-antagonist). In addition, the N-substituent also can provide selectivity for different β-receptors, with a *t*-butyl group affording selectivity for β_2-receptors. For example, with all other features of the molecules being constant, colterol is a selective β_2-agonist, whereas isoproterenol is a nonselective β-agonist. When considering use as a bronchodilator, a nonselective β-agonist, such as isoproterenol, has undesirable cardiac stimulatory properties because of its β_1-activity, which is greatly diminished in a selective β_2-agonist, such as albuterol. Also, an arylalkyl group (where the alkyl chain ranges from 2–11 carbon/oxygen atoms) can provide β-selectivity with increased lipophilicity and cell penetration for longer duration of action.

Table 13.4. Phenylethanolamine Adrenergic Agonists

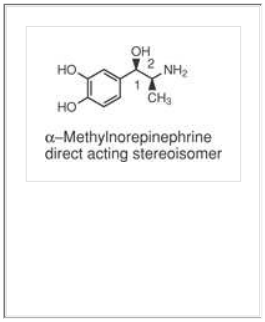


Drug	R_1	R_2	R_3	Receptor Activity
Norepinephrine	H	H	3′,4′-diOH	α + β
Epinephrine	CH_3	H	3′,4′-diOH	β ≥ α

α-Methylnorepinephrine	H	CH_3	3′,4′-diOH	α + β
Ethylnorepinephrine	H	CH_2CH_3	3′,4′-diOH	β > α
Isoproterenol	$CH(CH_3)_2$	H	3′,4′-diOH	General β
Isoetharine	$CH(CH_3)_2$	CH_2CH_3	3′,4′-diOH	Selective β_2
Colterol	$C(CH_3)_3$	H	3′,4′-diOH	Selective β_2
Metaproterenol	$CH(CH_3)_2$	H	3′,5′-diOH	Selective β_2
Terbutaline	$C(CH_3)_3$	H	3′,5′-diOH	Selective β_2
Albuterol	$C(CH_3)_3$	H	3′-CH_2OH, 4′-OH	Selective β_2
Phenylephrine	CH_3	H	3′-OH	α
Metaraminol	H	CH_3	3′-OH	α
Methoxamine	H	CH_3	2′,5′-diOCH_3	α
Ephedrine, pseudoephedrine	CH_3	CH_3	H	α + β
Phenylpropanolamine	H	CH_3	H	α + β
Salmeterol	-$(CH_2)_6$-O-$(CH_2)_4$-C_6H_5	H	3′-CH_2OH, 4′-OH	$\beta_2 > \beta_1$
Formoterol	-$CH(CH_3)CH_2$-C_6H_4-4-OCH_3	H	3′-NH-COH, 4′-OH	$\beta_2 > \beta_1$

R^2, Substitution α to the Basic Nitrogen, Carbon-2

Small alkyl groups, methyl or ethyl, may be present on the carbon adjacent to the amino nitrogen, carbon-2 in Table 13.4. Such substitution slows metabolism by MAO but has little overall effect on duration of action in catecholamines, because they remain substrates for COMT. Resistance to MAO activity is more important in noncatechol, indirect-acting phenylethylamines. An ethyl group in this position diminishes α-activity far more than β-activity, affording compounds with β-selectivity, such as ethylnorepinephrine. Substitution on this carbon also introduces another asymmetric center into these molecules producing pairs of diastereomers, which can have significantly different biological and chemical properties. For example, maximal direct activity in the stereoisomers of α-methylnorepinephrine resides with the erythro stereoisomer with the 1R,2S absolute configuration (17). The configuration of C2 has a great influence on receptor binding, because the 1R,2R diastereomer of α-methylnorepinephrine has primarily indirect activity, even though the absolute configuration of the hydroxyl-bearing C1 is the same as in norepinephrine. In addition, with respect to α-activity, this additional methyl group makes the direct-acting 1R,2S stereoisomer of α-methylnorepinephrine more selective for α_2-adrenoceptors than for α_1-adrenoceptors. This has important consequences in the antihypertensive activity of α-methyldopa, which is discussed later and in Chapter 29. The same stereochemical relationships hold for metaraminol and other phenyletha-nolamines, in which stereochemical properties have been investigated.

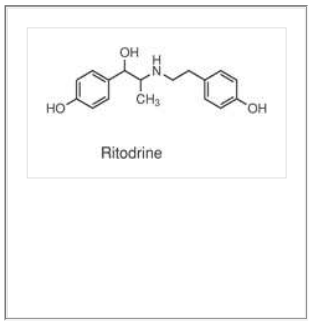


α–Methylnorepinephrine
direct acting stereoisomer

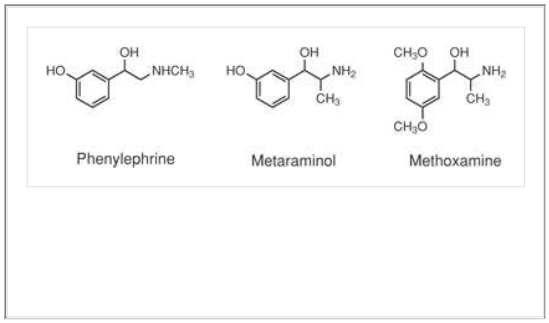
R^3, Substitution on the Aromatic Ring

The natural 3′,4′-dihydroxy–substituted benzene ring in norepinephrine provides excellent receptor activity for both α- and β-sites. Such catechol-containing compounds have poor oral activity, however, because they are rapidly metabolized by COMT. Alternative substitutions have been found that retain good activity but are more resistant to COMT metabolism. In particular, 3′,5′-dihydroxy compounds are not good substrates for COMT and, in addition, provide selectivity for β_2-receptors. Thus, because of its ring substitution pattern, metaproterenol is an orally active bronchodilator with little of the β_1 cardiac stimulatory properties possessed by isoproterenol.

Other substitutions are possible that enhance oral activity and provide selective β_2-activity, such as the 3′-hydroxymethyl and 4′-hydroxy substitution pattern of albuterol, the 3′-amino or 3′-formylamino, which also are resistant to COMT. At least one of the groups must be capable of forming hydrogen bonds, and if there is only one, it should be at the 4′ position to retain β-activity. For example, ritodrine has only a 4′-OH for R3 yet retains good β-activity, with the large substituent on the nitrogen making it β_2 selective. Ritodrine has been administered to pregnant women to prevent premature labor, consistent with β_2-adrenoceptor stimulation relaxing the uterus.

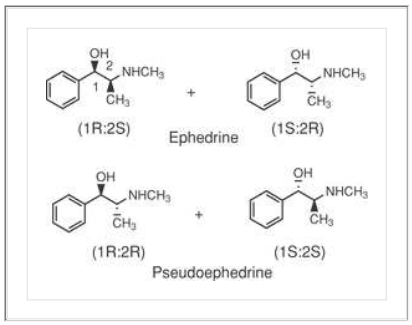


If R3 is only a 3′-OH or 3′-sulfonamide, however, activity is reduced at α sites but almost eliminated at β sites, thus affording selective α-agonists, such as phenylephrine and metaraminol. Further indication that α sites have a wider range of substituent tolerance for agonist activity is shown by the 2′,5′-dimethoxy substitution of methoxamine, which is a selective α-agonist that also has β-blocking activity at high concentrations. In keeping with the presence of α-adrenoceptors in the peripheral vasculature, all three of these agents cause vasoconstriction.



When the phenyl ring has no phenolic substituents (i.e., R3 = H), these phenylethanolamines may have both direct and indirect activity. Direct activity (i.e., agonist) is the stimulation of an adrenoceptor by the drug itself; indirect activity is the result of displacement of norepinephrine from its storage granules or reuptake inhibition, resulting in nonselective stimulation of the adrenoceptors by the displaced norepinephrine. Because norepinephrine stimulates both α- and β-adrenoceptors, indirect activity cannot be selective. Stereochemistry of the various substituents also may play a role in determining the extent of direct/indirect activity.

For example, ephedrine and pseudoephedrine have the same substitution pattern, but substitution of both carbons 1 and 2 means four stereoisomers are possible. Racemic (±)-ephedrine is a mixture of the erythro enantiomers 1R,2S and 1S,2R, whereas the threo pair of enantiomers, 1R,2R and 1S,2S, are known as racemic pseudoephedrine (±)-ephedrine). As discussed for α-methylnorepinephrine, (–)-ephedrine is the naturally occurring stereoisomer and has the 1R,2S absolute configuration with a mixed direct activity on both α- and β-receptors and some indirect activity. Its 1S,2R-(+)-enantiomer exhibits primarily indirect activity. 1S,2S-(+)-Pseudoephedrine has virtually no direct receptor activity and is mostly indirect acting.



Norepinephrine and Epinephrine

Norepinephrine has limited clinical application because of the nonselective nature of its action, which causes both vasoconstriction and cardiac stimulation. In addition, it must be given intravenously, because it has no oral activity (poor oral bioavailability) as a result of its rapid metabolism by intestinal and liver COMT and MAO, 3′-O-glucuronidation/sulfation in the intestine, and low lipophilicity. Rapid metabolism by MAO and COMT limits its duration of action to only 1 or 2 minutes, even when given by infusion. The drug is used to counteract various hypotensive crises, because its α-activity raises blood pressure and as an adjunct treatment in cardiac arrest, where its β-activity stimulates the heart.

Epinephrine is far more widely used clinically than norepinephrine, although it also lacks oral activity for the same reasons as norepinephrine. Epinephrine, similar to norepinephrine, is used to treat hypotensive crises and, because of its greater β-activity, to stimulate the heart in cardiac arrest. The β_2-activity of epinephrine leads to its administration intravenously and in inhalers to relieve bronchoconstriction in asthma and to application in inhibiting uterine contractions. Because it has significant α-activity, epinephrine has been used in nasal decongestants. Constriction of dilated blood vessels in mucous membranes shrinks the membranes and reduces nasal congestion, although significant aftercongestion may limit its utility.

Selective α-Adrenergic Agonists

α_1-Agonist Phenylethanolamines: Metaraminol, Methoxamine, and Phenylephrine

Metaraminol, methoxamine, and phenylephrine are selective for α_1-receptors and have minimal cardiac stimulatory properties. Because they are not substrates for COMT, their duration of action is significantly longer than that of norepinephrine. Their α_1-agonist activity makes them strong vasoconstrictors, however, and their primary systemic use is limited to treating hypotension during surgery or severe hypotension accompanying shock. Methoxamine is bioactivated by O-demethylation to an active m-phenolic metabolite. The β-blocking activity of methoxamine, which is seen at high concentrations, affords some use in treating tachycardia. Phenylephrine, which also is a selective α_1-agonist, is used similarly to metaraminol and methoxamine for hypotension. It also has widespread use as a nonprescription nasal decongestant in both oral and topical preparations. Its oral bioavailability is less than 10% because of its hydrophilic properties and intestinal

3′-O-glucuronidation/sulfation. Phenylephrine preparations applied topically to the eye constrict the dilated blood vessels of bloodshot eyes and, in higher concentrations, are used to dilate the pupil during eye surgery.

2-Arylimidazoline α_1-Agonists

In addition to phenylethanolamine derivatives, α-adrenoceptors accommodate a diverse assortment of structures. The imidazoline derivatives in Figure 13.7 also are selective α_1-agonists and, therefore, are called vasoconstrictors/vasopressors. They all contain a one-carbon bridge between C2 of the imidazoline ring (pK_a range, 10–11) and a phenyl substituent; therefore, the general skeleton of a phenylethylamine is contained within the structures. Lipophilic substitution on the phenyl ring *ortho* to the methylene bridge appears to be required for agonist activity at α_1- and α_2-receptors (15). Presumably, the bulky lipophilic groups attached to the phenyl ring at the meta or para positions provide selectivity for the α_1-receptor by

diminishing affinity for α_2-receptors. These highly ionic compounds are widely used only in topical preparations as nasal decongestants and eye drops (Table 13.5). Systemically, they are potent vasoconstrictors.

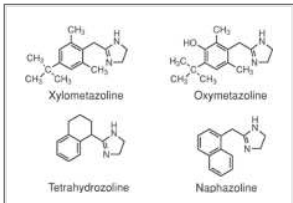


Fig. 13.7. Imidazoline α_1-adrenergic agonists.

α_2-Adrenergic Agonists: 2-Aminoimidazolines and Other α_2-Agonists

Three subtypes of α_2-adrenoceptors, α_{2A}, α_{2B}, and α_{2C}, are recognized. Each plays a role in the different clinical applications of α_2-agonists, which include use as antihypertensives (see Chapter 29), antiglaucoma drugs, and analgesics. The first of these drugs, clonidine, was introduced as an antihypertensive, an effect attributed to central α_{2A}-adrenoceptors in cardiovascular control areas of the brain (18).

Clonidine (Catapres)

Closely related structurally to the imidazoline nasal decongestants is clonidine and other developed analogues (Fig. 13.8). Clonidine was originally synthesized as a vasoconstricting nasal decongestant but, in early clinical trials, was found to have dramatic hypotensive effects—in contrast to all expectations for a vasoconstrictor (19). Subsequent pharmacological investigations showed that clonidine not only has some α_1-agonist (vasoconstrictive) properties in the periphery but also that it is a powerful α_2-adrenergic agonist and exhibits specific binding to nonadrenergic imidazoline binding sites in the CNS (mainly in the medulla oblongata) causing inhibition of sympathetic output (sympathoinhibition) (see Chapter 29). Because of its peripheral activity on extraneuronal vascular postsynaptic α_{2B}-receptors (18), initial doses of clonidine may produce a transient vasoconstriction and an increase in blood pressure that is soon overcome by vasodilation as clonidine penetrates the blood-brain barrier and interacts with CNS α_{2A}-receptors.

Table 13.5 Imidazoline α_1-Agonists in Over-the-Counter Vasoconstrictors

Drug	Nasal Decongestant	Eye drops
Xylometazoline	Otrivin, Inspire	—
Oxymetazoline	Afrin, Duration, Neo-Synephrine, Vicks Sinex	Visine L.R. Ocu Clear
Tetrahydrozoline	—	Murine, Visine, Soothe
Naphazoline	4-Way Fast Acting, Privine	Naphcon, Clear Eyes

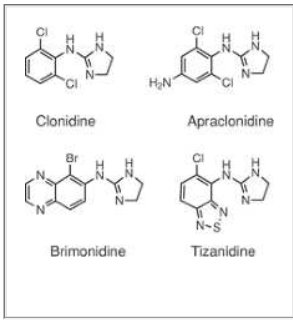

Fig. 13.8. Imidazoline α_2-adrenergic agonists.

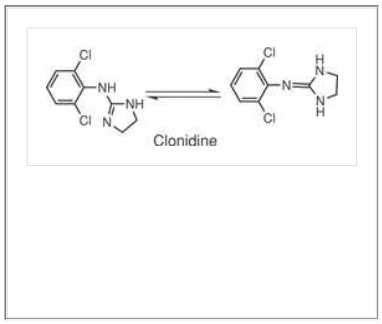
Similar to the imidazoline α_1-agonists, clonidine has lipophilic *ortho*-dichloro substituents on the phenyl ring, but the most readily apparent difference between clonidine and the α_1-agonists in Figure 13.7 is the replacement of the CH_2 bridge on C1 of the imidazoline by an amine NH. This makes the imidazoline ring part of a guanidino group, and the uncharged form of clonidine exists as a pair of tautomers as shown.



Clonidine has a pK_a of 8.3 and is approximately 80% ionized at physiologic pH. Its experimental log P is 1.6 (log D at pH 7.4 is 0.8). The positive charge is shared through resonance by all three nitrogens of the guanidino group. Steric crowding by the bulky *ortho*-chlorine groups does not permit a coplanar conformation of the two rings, as illustrated in Figure 13.9.

The o,o′-dichloro-substituents in clonidine can be replaced by a methyl group without losing any potency or selectivity. A methyl group is approximately similar in size (volume) as a chlorine atom; thus, it will exhibit similar steric interactions to force the phenyl ring to assume proper conformation for binding to the α_2-receptors similar to Figure 13.9. Thus, replacement of the o-dichlorines by bulky groups in clonidine will retain its agonist potency. The aromatic methyl group, however, will be readily

metabolized by the cytochrome P450 enzyme to the corresponding hydroxymethyl and then to the carboxylic acid group, both of which are inactive at the α_2-receptors. Thus, the methyl analogue will have a shorter duration of action.

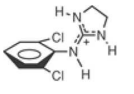


Fig. 13.9. Protonated clonidine.

In addition to its use as an antihypertensive, clonidine has been proven useful in a wide variety of conditions. Clonidine has sedative properties and has been used to treat attention-deficit hyperactivity disorder, nicotine and opiate withdrawal, and glaucoma among other uses. Epidural anesthesia has been found to be enhanced by α_2-agonists (20), and clonidine is available in an injectable form for epidural administration.

Tizanidine

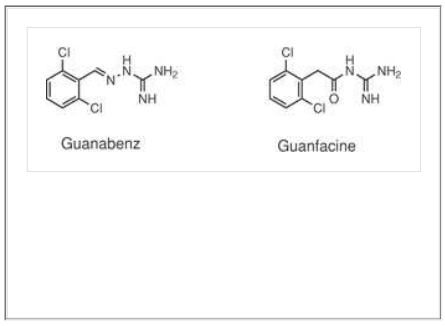
Tizanidine (Fig. 13.8) is a centrally active muscle relaxant analogue of clonidine that is approved for use in reducing spasticity associated with cerebral or spinal cord injury. Its mechanism of action for reducing spasticity suggests presynaptic inhibition of motor neurons at the α_2-adrenergic receptor sites, reducing the release of excitatory amino acids and inhibiting facilitatory ceruleospinal pathways, thus resulting in a reduction in spasticity. Tizanidine only has a small fraction of the antihypertensive action of clonidine, presumably because of action at a selective subgroup of α_{2C}-adrenoceptors, which appear to be responsible for the analgesic and antispasmodic activity of imidazoline α_2-agonists(20).

Apraclonidine (Iopidine) and brimonidine (Alphagan)

The other imidazoline α_2-agonists in Figure 13.8 that are clinically used for treatment of glaucoma are apraclonidine (pK_a = 9.22, log P = 1.53) and brimonidine (pK_a = 7.4, log P = 0.78). Stimulation of α_2-receptors in the eye reduces production of aqueous humor and enhances outflow of aqueous humor, thus reducing intraocular pressure, and also has a neuroprotective effect apparently through α_{2A}-receptors located in the retina (21,22). Animal and human studies suggest that apraclonidine's primary mechanism of action may be related to a reduction of aqueous formation, whereas brimonidine lowers intraocular pressure by reducing aqueous humor production and increasing uveoscleral outflow. Brimonidine is approximately 1,000-fold more selective for α_2-receptors than are clonidine or apraclonidine and is a first-line agent for treating glaucoma. It exhibited minimal effect on blood pressure and heart rate. Although both are applied topically to the eye, measurable quantities of these drugs are detectable in plasma, so caution must be employed when cardiovascular agents also are being coadministered to the patient. Plasma brimonidine levels peaked within 1 to 4 hours and declined with a systemic half-life of approximately 3 hours. Brimonidine has been reported to enter the brain and can potentially cause fatigue and/or drowsiness in some patients. Brimonidine is primarily metabolized by aldehyde oxidase.

Guanfacine (Tenex) and guanabenz (Wytensin)

Following the discovery of clonidine, extensive research into the SAR of central α_2-agonists showed that the imidazoline ring was not necessary for activity in this class but that the phenyl ring required at least one ortho chlorine or methyl group. Two clinically useful antihypertensive agents resulting from this effort are guanfacine and guanabenz (see Chapter 29). These are ring-opened analogues of clonidine, and their mechanism of action is the same as that of clonidine.



Methyldopa (Aldomet)

Although structurally unrelated to the aminoimidazolines or the guanidines, the pro-drug L-α-methyldopa (methyldopa) is an α_2-agonist acting in the CNS via its active metabolite, α-methylnorepinephrine (Fig. 13.10). Methyldopa is transported across the blood-brain barrier, where it is decarboxylated by aromatic L-amino acid decarboxylase in the brain to α-methyldopamine, which is then stereospecifically hydroxylated to 1R,2S-α-methylnorepinephrine. This stereoisomer is a selective α_2-agonist and acts as an antihypertensive agent much like clonidine to inhibit sympathetic neural output from the CNS, thus lowering blood pressure. α-Methylnorepinephrine and α-methyldopamine do not cross the blood-brain barrier because of their hydrophilicity. Originally synthesized as a norepinephrine biosynthesis inhibitor, methyldopa was thought to act through a combination of inhibition of norepinephrine biosynthesis through dopa decarboxylase inhibition and metabolic decarboxylation to generate α-methylnorepinephrine. The latter was thought to replace norepinephrine in the nerve terminal and, when released, to have less intrinsic activity than the natural neurotransmitter. This latter mechanism is an example of the concept of a false neurotransmitter. (The antihypertensive properties for methyldopa are further described in Chapter 29.)

β-Adrenergic Agonists

β_2-Agonist Phenylethanolamines

Most of the β_2-selective adrenergic agonists listed in Table 13.4 are used primarily as bronchodilators in

asthma and other constrictive pulmonary conditions. Their pharmacological and pharmacokinetic properties are described in Table 13.6. Isoproterenol is a nonselective β-agonist ($\beta_2/\beta_1 = 1$), and the cardiac stimulation caused by its β_1-activity and its lack of oral activity have led to its diminished use in favor of more selective β_2-agonists.

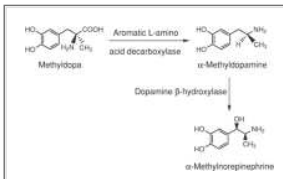


Fig. 13.10. Methyldopa bioactivation.

Table 13.6. Pharmacologic Effects and Pharmacokinetic Properties of Sympathomimetic Bronchodilators

Sympathomimetic	Adrenergic Receptor Activity	β_2-potency	Route of Administratio Onset (min)	Duration (hr)
Salmetero2 (Serevent)	β1<<β2	0.5 Inh	within 20	12
Albuterol2 (Ventolid, Airet, Proventil)	β1<<β2	2 PO Inh3	within 30 within 5	4–8 3–6
Levalbuterol R-albuterol (Xopenex)	β1<<<β2	3–4 Inh3	within 5	3–6

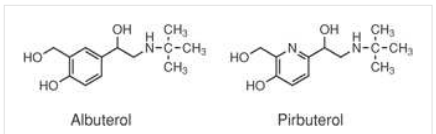
Epinephrine	αβ1 β2	SC	5–10	4–6

[1]Relative molar potency: 1= potent.

[2]These agents all have minor β activity.
[3]May be administered via aerosol or bulb nebulizer or IPPB administration. Table modified from Drug Facts and Comparisons 2000.

Short-Acting β_2-Adrenergic Agonists



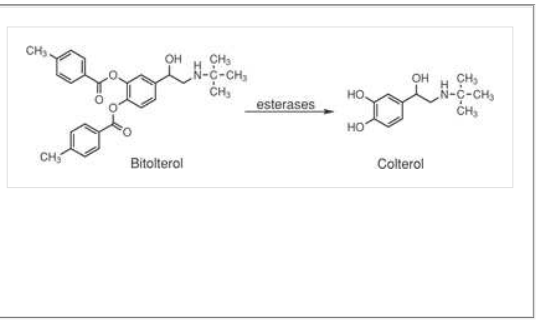
Albuterol, pirbuterol, terbutaline

The noncatechol selective β_2-agonists, such as racemic albuterol (β_2/β_1 = 60), metaproterenol, and terbutaline, are available in oral dosage forms as well as in inhalers. All have similar activities and durations of action. Pirbuterol is an interesting analogue of albuterol in which the benzene ring has been replaced by a pyridine ring, altering its pharmacokinetic properties. Similar to albuterol, pirbuterol is a selective β_2-agonist currently available only for administration by inhalation.

Studies with the R/S enantiomers of albuterol have shown that the (S)-enantiomer may be proinflammatory, exacerbating airway reactivity to a variety of spasmogens and, thereby, enhancing bronchial muscle contraction, thus opposing the bronchodilation effects of the (R)-enantiomer levoalbuterol. Moreover, racemic albuterol exhibits enantioselective presystemic metabolism. Levalbuterol undergoes more rapid metabolism (sulfation) than the (S)-(+)-isomer, resulting in a lower oral bioavailability and rapid elimination. Because of its slower metabolism, (S)-albuterol thus has a higher and prolonged tissue concentrations than levalbuterol, increasing airway reactivity. These adverse effects of (S)-albuterol are completely avoided by using the (R)-enantiomer, levalbuterol (Xopenex®). Thus, the removal of (S)-albuterol from racemic albuterol increases the clinical potency of levalbuterol, such that bronchodilator efficacy is achieved at one-fourth the dose of racemic albuterol along with a marked reduction in side effects.

Bitolterol

Bitolterol is a pro-drug form of colterol in which the catechol hydroxyl groups have been converted to 4-methylbenzoic (p-toloyl) acid esters, providing increased lipid solubility and prolonged duration of action. Bitolterol is administered by inhalation, and the ester groups are hydrolyzed by esterases to liberate the active drug, colterol. Colterol is then subject to metabolism by COMT, but the duration of action of a single dose of the pro-drug bitolterol, up to 8 hours, is twice that of a single dose of colterol, permitting less frequent administration and greater convenience to the patient.



Ritodrine

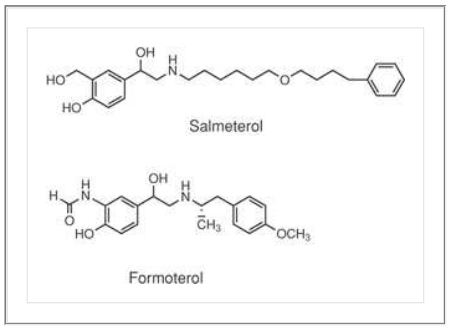
The previously mentioned ritodrine is a selective β_2-agonist that is used exclusively for relaxing uterine muscle and inhibiting the contractions of premature labor. Terbutaline, in addition to its use as a bronchodilator, also has been used for halting the contractions of premature labor.

Long-Acting β_2-Adrenergic Agonists

The mechanisms behind the long duration of the bronchodilating effect of the β_2-adrenoceptor agonists formoterol and salmeterol are only partially understood. The long duration of action for formoterol and salmeterol is attributed to their higher lipophilicity and greater receptor affinity compared to those of the short-acting agonists at the β_2-adrenoceptor. Lipophilicity determines the amount of drug entering into the cell membrane of the β_2-adrenoceptor and how much β_2-adrenoceptor agonist must remain at the receptor for maximal sustained activity.

Salmeterol (Serevent)

A β_2-agonist with a slow onset and extended duration of action is salmeterol. Salmeterol has the same phenyl ring substitution R^3 as albuterol but also an unusually long and lipophilic group R^1 on the nitrogen. The octanol–water partition coefficient, log P, for salmeterol is 3.88, compared with 0.66 for albuterol. Salmeterol is approximately 50-fold more selective than albuterol for the β_2-receptor. Substantial evidence indicates that its long duration of action results from a specific binding interaction ("anchoring") of the phenyl group at the end of the extended lipophilic side chain with a specific region of the β_2-receptor, affording salmeterol a unique binding mechanism (Fig. 13.11).



Salmeterol usually is prescribed for severe persistent asthma following previous treatment with a short-acting β-agonist, such as albuterol. The noticeable differences between salmeterol and albuterol are the onset of action and their duration of action (Table 13.6). When used regularly every day as prescribed, inhaled albuterol decreases the number and severity of asthma attacks. It is not used, however, for relieving an asthma attack that has already started.

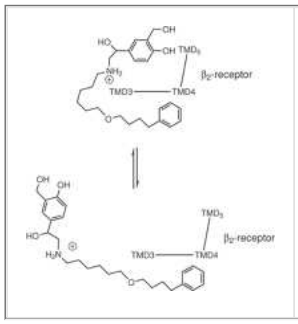


Fig. 13.11. Mechanism of action for salmeterol.

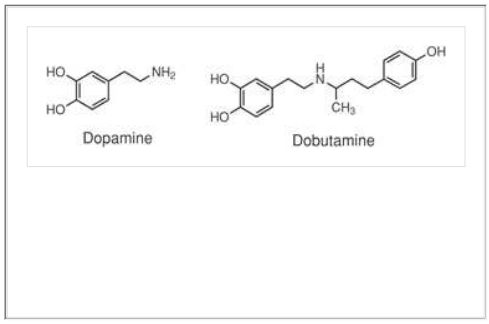
Formoterol (Foradil)

Formoterol has 3′-formylamino and 4′-hydroxy ring R^3 substitution pattern but also an alkoxyphenylethyl lipophilic group R^1 on the nitrogen, similar to ritodrine. Although it is less lipophilic (log P = 1.6) than salmeterol, it has a 12-hour duration of action similar to that for salmeterol. It is administered as an inhaled dry powder, because it is unstable to heat and moisture. It is a mixture of (R,R)-(–)- and (S,S)-(+)-stereoisomers, with the (R,R)-isomer having approximately 1,000-fold more affinity for the β_2-receptor than the (S,S)-isomer. Because of its high potency and low dose, however, there is no clinical advantage for using (R,R)-formoterol as bronchodilator compared to the racemate. Unlike salmeterol, formoterol has a faster onset of action as a result of its lower lipophilicity. It is also more potent; a 12-μg dose of formoterol has been demonstrated to be equivalent to a 50-μg dose of salmeterol.

β_1-Adrenergic Agonists



Dopamine

Although not strictly an adrenergic drug, dopamine is a catecholamine with properties related to the cardiovascular activities of the other agents in this chapter. Dopamine acts on specific dopamine receptors to dilate renal vessels, increasing renal blood flow.

Dopamine also stimulates cardiac β_1-receptors through both direct and indirect mechanisms. It is used to correct hemodynamic imbalances induced by conditions such as shock, myocardial infarction, trauma, or congestive heart failure. As a catechol and primary amine, dopamine is rapidly metabolized by COMT and MAO and, similar to dobutamine, has a short duration of action with no oral activity. It is administered as an intravenous infusion.

Dobutamine (Dobutrex)

Not all the adrenergic agonists with direct activity have an aliphatic β-hydroxyl group such as the agents discussed so far. One of these is the catechol dobutamine. Dobutamine is a dopamine analogue with a bulky arylalkyl group on the nitrogen and one chiral (asymmetric) center. Racemic (±)-dobutamine has direct activity on both α_1- and β_1-receptors, but because of some unusual properties of its two enantiomers, the overall pharmacological response looks similar to that of a selective β_1-agonist. The (S)-(–)-enantiomer of dobutamine exhibits β_1-agonist activity and also is a powerful α_1-agonist and vasopressor. The (R)-(+)-isomer is an α_1-antagonist; thus, when the racemate is used clinically, the α-effects of the enantiomers cancel each other, leaving primarily the β_1-effects. The stereochemistry of the methyl substituent does not affect the ability of the drug to bind to the α_1-receptor but does affect the ability of the molecule to activate the receptor. That is, the stereochemistry of the methyl group affects intrinsic activity but not affinity. Because both stereoisomers are β_1-agonists with the (–)-isomer approximately one-tenth the potency of the (+)-isomer, the net effect is β_1 stimulation. Dobutamine is used as a cardiac stimulant after surgery or congestive heart failure. As a catechol, dobutamine is readily metabolized by COMT and has a short duration of action with no oral activity.

Mixed-Acting Sympathomimetics

Phenylpropanolamines

(–)-Ephedrine

As discussed earlier, ephedrine is a natural product isolated from several species of ephedra plants, which have been used for centuries in folk medicines in a variety of cultures worldwide (23). Its occurrence in ephedra is approximately 80 to 90%. Other substances also found include (+)-pseudoephedrine (10–15%) and N-methylephedrine (2–5%). Pure ephedrine was first isolated and crystallized in 1887 from a Chinese herbal medicine called Ma Huang. Its sympathomimetic activity was not recognized until 1917, and the pure drug was used clinically even before epinephrine and norepinephrine were isolated and characterized. Ephedrine does not have any phenolic substituents on the phenyl ring, giving it a mixed-acting response and good oral activity, because it is not a substrate for COMT. Lacking hydrogen-bonding phenolic substituents, ephedrine is less polar than the other compounds discussed thus far and crosses the blood-brain barrier far better than the catechols do. Because of its ability to penetrate the CNS, ephedrine has been used as a stimulant and exhibits side effects related to its action in the brain. Ephedrine is widely used for many of the same indications as epinephrine, including use as a bronchodilator, vasopressor, cardiac stimulant, and nasal decongestant.

(+)-Pseudoephedrine

Pseudoephedrine, as previously discussed, is the threo diastereomer of ephedrine, with virtually no direct activity and fewer CNS side effects than ephedrine. (+)-Pseudoephedrine is widely used as a nasal decongestant.

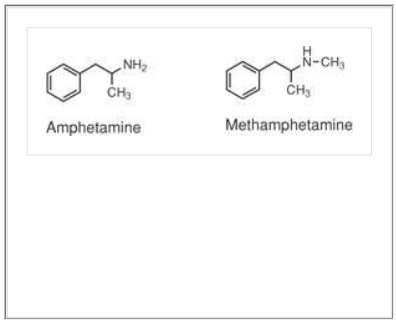
(+)-Phenylpropanolamine

Phenylpropanolamine (Table 13.4) is the N-desmethyl analogue of ephedrine that has many of the same properties. Lacking the N-methyl group, however, phenylpropanolamine has none of the β_2-agonist activity of ephedrine, is slightly less lipophilic, and therefore, does not enter the CNS as well as ephedrine. Phenylpropanolamine, similar to ephedrine, is a mixture of erythro enantiomers with mixed direct and mostly indirect activity. The drug had been the active ingredient of a number of nasal decongestants and used as a nonprescription appetite suppressant (anorexiant) until its U.S. Food and Drug Administration (FDA)–mandated recall in 2000 because of cerebral hemorrhages in women.

Phenylisopropylamines

Amphetamine and methamphetamine

Other methyl-substituted phenylethylamines (phenylisopropylamines), such as (S)-(+)-amphetamine and (S)-(+)-methamphetamine, which lack both ring substituents and a side-chain hydroxyl, are sufficiently lipophilic to cross the blood-brain barrier readily and cause dramatic CNS stimulation, which gives them serious abuse potential. The clinical utility of (S)-(+)-amphetamine and its derivatives is entirely based on CNS stimulant and central appetite suppressant effects. The only amphetamine product available that is used for the treatment of attention-deficit disorder combines the sulfate, saccharate, and aspartate salts of dextroamphetamine and amphetamine (total amphetamine base, 3.1 mg; Adderall®). (These agents as well as the methoxylated amphetamines are discussed in Chapter 23.)



Structure–Activity Relationships of Adrenergic Antagonists

Nonselective α-Antagonists

Phenoxybenzamine

Because α-agonists cause vasoconstriction and raise blood pressure, one would expect α-antagonists to be therapeutically used as antihypertensive agents. An old

but powerful drug in this class is phenoxybenzamine (dibenzyline), a β-haloalkylamine that alkylates α-receptors. β-haloalkylamines are present in nitrogen mustard anticancer agents and are highly reactive alkylating agents. The acid salt of phenoxybenzamine is stable, but at physiologic pH, equilibrium exists between the protonated drug and free base. The unshared electrons of the unprotonated amino group are nucleophilic and displace the β-chlorine atom in an intramolecular reaction to form a highly reactive aziridinium ion (Fig. 13.12). If this occurs in the vicinity of an α-receptor, a nucleophile group X on the receptor can open the aziridinium ion in a nucleophilic reaction to form a covalent bond between the receptor and the drug. The substituents attached to the haloalkylamine provide selectivity for binding to α-adrenoceptors so that the nucleophile generally is part of the target receptor. The nucleophile X is presumably part of an amino acid side chain, such as a cysteine thiol, serine hydroxyl, or lysine amino group, but the specific site of covalent attachment to the α-receptor has not been determined. Because the reaction in which phenoxybenzamine forms covalent bonds with the receptors is irreversible, new receptors must be synthesized before the effects can be overcome. Therefore, the α-blockade is long-lasting.

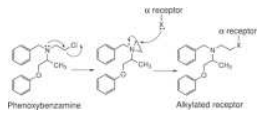


Fig. 13.12. Phenoxybenzamine alkylation of α-adrenoceptors. X is a nucleophile, such as S, N, or O.

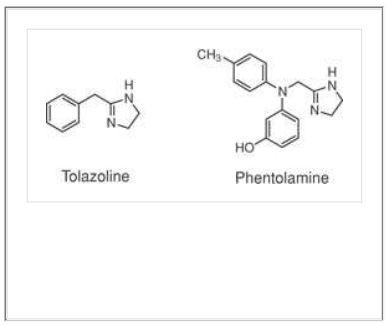
Unfortunately, other biomolecules besides the target α-receptor also are alkylated. Because of its receptor nonselectivity and toxicity, the use of phenoxybenzamine largely is limited to alleviating the sympathetic effects of pheochromocytoma. This tumor of chromaffin cells of the adrenal medulla produces large amounts of epinephrine and norepinephrine, which are released into the bloodstream, producing hypertension and generalized sympathetic stimulation.

Tolazoline and Phentolamine



Tolazoline and phentolamine are two imidazoline α-antagonists that also have antihypertensive activity, although they have been replaced in general clinical use by far better agents. Tolazoline has clear structural similarities to the imidazoline α_1-agonists, such as naphazoline and xylometazoline (Fig. 13.7), but does not have the lipophilic substituents required for agonist activity. The resemblance of phentolamine is not as readily apparent, but extensive molecular modeling studies have provided a topologic scheme for α_1-antagonist SAR (19). This pattern, however, cannot be readily visualized without computer graphics and is beyond the scope of this chapter.

Both phentolamine and tolazoline are potent but rather nonspecific α-antagonists. Both drugs stimulate gastrointestinal smooth muscle, an action blocked by atropine, which would indicate cholinergic activity, and they both stimulate gastric secretion, possibly through release of histamine. Because of these and other side effects, the clinical applications of tolazoline and phentolamine also are limited to treating the symptoms of pheochromocytoma.

Selective α_1-Antagonists

Prazosin, Doxazosin, Terazosin, Tamsulosin, and Alfuzosin

Prazosin, the first known selective α_1-blocker, was discovered in the late 1960s (24) and is now one of a small group of selective α_1-antagonists that includes three other quinoxaline antihypertensives terazosin, doxazosin, and alfuzosin and the nonquinazoline benzensulfonamide tamsulosin (Fig. 13.13). Prazosin, doxazosin, and terazosin contain a 4-amino-6,7-dimethoxyquinazoline ring system attached to a piperazine ring except for alfuzosin, which has a rotatable propylenediamine group (an open piperazine ring). The other structural differences are the heterocyclic acyl groups attached to the second nitrogen of the piperazine or the propyl chain. The differences in these groups afford dramatic differences in some of the pharmacokinetic properties of these agents (Table 13.7). For example, reduction of the furan ring for prazosin to the tetrahydrofuran ring of terazosin increases its duration of action by altering its rate of metabolism. Some of the important clinical parameters of the quinazolines are shown in Table 13.6. Perhaps most significant are the long half-lives and durations of action for terazosin, doxazosin, and tamsulsin, which permit once-a-day dosing and generally lead to increased patient compliance.

Prazosin is an antihypertensive agent, as are terazosin and doxazosin. The latter two were subsequently discovered to block α_1-receptors in the prostate gland and alleviate the symptoms of benign prostatic hyperplasia (BPH) (see Chapter 45). The more recently developed tamsulosin and alfuzosin are more selective for the subtype of α_1-adrenoceptor found in the prostate gland, α_{1A}, over those found in vascular tissue. Thus, tamsulosin and alfuzosin are first-line drugs for the treatment of BPH and have no utility in treating hypertension. They have fewer cardiovascular side effects than terazosin and doxazosin

in treating BPH. (Details on the use and pharmacokinetics of α_1-antagonists in treating hypertension and BPH are provided in Chapters 29 and 45, respectively.)

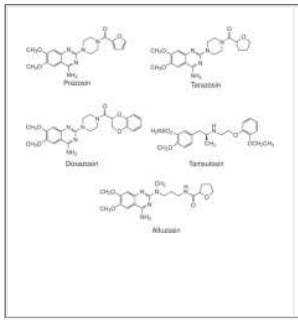


Fig. 13.13. Selective α_1-adrenergic antagonists.

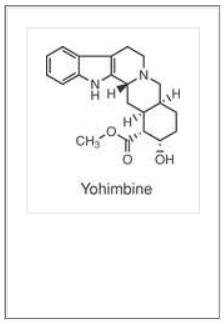
Selective α_2-Adrenergic Antagonists



Yohimbine

Yohimbine, an indole alkaloid isolated from *Pausinystlia yohimbe* bark and *Rauwolfia* roots is an α_2-antagonist with greater selectivity for α_2- than for α_1-adrenoceptors, but it also is a serotonin antagonist. It has actions both in the CNS and in the periphery, inducing hypertension and increases in heart rate. Yohimbine has no indications sanctioned by the U.S. FDA, but it has been used to treat male impotence and postural hypotension. Yohimbine also has been used in research to induce anxiety. As was the case with ephedrine and the herbal Ma Huang, the purified chemical yohimbine is regulated by the U.S. FDA. Herbal remedies

and dietary supplements containing yohimbe bark are not regulated,

however, even though the active ingredient is the same chemical entity.

Table 13.7. Selected Clinical Parameters of α_1-Adrenergic Antagonists

Drug	Trade Name	cLogP/LogDa (pH 7)	Half-life (hours)	Duration of Action (hours)	Bioavailability (%)
Prazosin	Minipres	-1.1/-1.3	2–3	4–6	45–65
Terazosin	Hytrin	-1.0/-1.0	12	>18	90
Doxazosin	Cardura	0.7/0.5	22	18–36	65
Tamsulosin	Flomax	2.2/0.5	14–15	>24	<50 with food 50–90 fasting
Aflusosin	Uroxatral	-1.0/-2.7	3–5	>48	65

β-Adrenergic Antagonists

In the 1950s, dichloroisoproterenol (DCI), a derivative of isoproterenol in which the catechol hydroxyls had been replaced by chlorines, was discovered to be a β-antagonist that blocked the effects of sympathomimetic amines on bronchodilation, uterine relaxation, and heart stimulation (25). Although DCI had no clinical utility, replacement of the 3,4-dichloro substituents with a carbon bridge to form a naphthylethanolamine derivative did afford a clinical candidate, pronethalol, which was introduced in 1962 only to be withdrawn in 1963 because of tumor induction in animal tests.

Structure–Activity Relationships

Shortly thereafter, a major innovation in drug development for the β-adrenergic antagonists was introduced when it was discovered that an oxymethylene bridge, OCH_2, could be inserted into the arylethanolamine structure of pronethalol to afford propranolol, an aryloxypropanolamine and the first clinically successful β-blocker. Note that along with the introduction of the oxymethylene bridge, the side chain has been moved from C2 of the naphthyl group to the C1 position. In general, the aryloxypropanolamines are more potent β-blockers than the corresponding arylethanolamines, and most of the β-blockers currently being used clinically are aryloxypropanolamines. β-Blockers have found wide use in treating hypertension (Chapter 29) and certain types of glaucoma. Several β-blockers are in the Top 200 prescription drugs in the United States (Table 13.1).

Initially, it might appear that lengthening the side chain would prevent appropriate binding of the required functional groups to the same receptor site. Molecular models, however, show that the side chains of aryloxypropanolamines can adopt a conformation that places the hydroxyl and amine groups into approximately the same position in space (Fig. 13.14). Although the simple two-dimensional drawing in Figure 13.14 exaggerates the true degree of overlap, elaborate molecular modeling studies confirm that the aryloxypropanolamine side chain can adopt a low-energy conformation that permits close overlap with the arylethanolamine side chain (26).

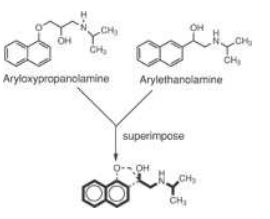

Fig. 13.14. Overlap of aryloxypropanolamines and arylethanolamines. The structures of prototype β-antagonists propranolol and pronethalol may be superimposed so the critical functional groups occupy the same approximate regions in space, as indicated by the bold lines in the superimposed drawings. The dotted lines are those parts that do not overlap but are not necessary to receptor binding.

Propranolol

Propranolol was initially introduced for the treatment of angina pectoris and later underwent trials as an antiarrhythmic. During clinical trials as an antianginal, propranolol was discovered to have antihypertensive properties, and it has been widely employed for that purpose for decades (27). Propranolol rapidly became widely used for a variety of cardiac arrhythmias as well. In addition, because of its high lipophilicity and ability to penetrate the CNS, propranolol has found use in treating

disorders of the CNS, such as anxiety.

At approximately this same time, a new series of 4-substituted phenyloxypropanololamines emerged that selectively inhibited sympathetic cardiac stimulation. These observations led to the recognition that not all β-receptors were the same, which in turn led to the introduction of β_1 and β_2 nomenclature to differentiate cardiac β_1-receptors from others. Development of β-blockers proceeded rapidly, and today, a large number of additional drugs, both nonselective β-antagonists and selective β_1-antagonists, are available on the world market. (Clinical use of β-blockers as antihypertensives are covered in Chapter 29.) Of those antagonists that are selective for the cardiac β_1-receptor, most also have some β_2-antagonist properties at the higher levels of therapeutic dosing (dose dependent). With the exception of sotalol, all the drugs shown in Figures 13.15 and 13.16 are aryloxypropanolamines. Metipranolol (Fig. 13.15) is an exception to the general rule that 4-substituted aryloxypropanolamines are selective β_1-blockers.

Other than β_1-selectivity of 4-substituted aryloxypropanolamines, little obvious structural pattern relates

P.411

β-blockers to specific clinical applications, with the exception of esmolol. Esmolol is the methyl ester of the carboxylic metabolite of metoprolol, which makes it is susceptible to hydrolysis by serum esterases. The acid metabolite generated by hydrolysis is essentially inactive and readily excreted as its zwitterion. For this reason, esmolol has a half-life of only approximately 8 minutes and is used to control supraventricular tachycardia during surgery when a short-acting β_1-adrenergic antagonist is desirable.

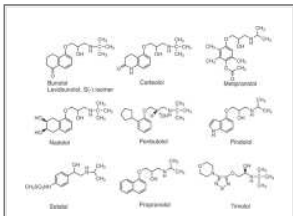

Fig. 13.15. Nonselective β-adrenergic antagonists.

Another physicochemical parameter with some clinical correlation is the relative lipophilicity of different agents. Propranolol is by far the most lipophilic of the available β-blockers, and it enters the CNS far better than the less lipophilic agents, such as atenolol or nadolol. Lipophilicity as measured by octanol–water partitioning also correlates with the primary site of clearance, as seen in Table 13.8. The more lipophilic drugs are primarily cleared by the liver, whereas the more hydrophilic agents are cleared by the kidney. This could influence the choice of agents in cases of renal failure or liver disease. Several of the β-blockers must be dose adjusted in patients with impaired renal function, as indicated in Table 13.7.

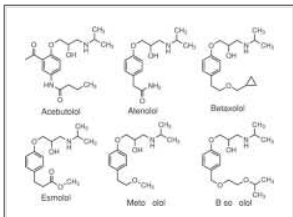

Fig. 13.16. Selective β_1-adrenergic antagonists.

β-Blockers also have found extensive use in treating glaucoma, although the mechanism of action in treating glaucoma is more difficult to explain. The β-blockers lower intraocular pressure by decreasing the amount of aqueous humor fluid produced in the eye by the ciliary body, and β_2-receptors have been found in that tissue. Observations have shown, however, that the ciliary body has no adrenergic innervation, that the effect is not stereoselective, and that a correlation of activity exists with decreased ciliary blood flow and decreased dopamine levels, indicating that the mechanism of action of β-blockers in treating glaucoma is unusual (28).

Mixed α/β-Adrenergic Antagonists

Labetalol and carvedilol are antihypertensives with α_1-, β_1-, and β_2-blocking activity (Fig. 13.17) (see Chapter 29). In terms of SAR, recall from the earlier discussion of phenylethanolamine agonists that the type of N-substituents, such as N-isopropyl and N-t-butyl, eliminated α-receptor activity; however, arylalkyl groups with α-methyl substituent returned α_1-affinity but not intrinsic activity (c.f., dobutamine). Thus, these two drugs have

P.412

P.413

structural features that permit binding to the α_1-receptor and nonselectively to both β-receptors. The β-blocking activity of labetalol is approximately 1.5-fold that of its α-blocking activity. Carvedilol has an estimated β-blocking activity 10- to 100-fold its α-blocking activity.

Table 13.8. Pharmacologic/Pharmacokinetic Properties of β-Adrenergic Blocking Agents

Drug	Adrenergic Receptor Blocking Activity	Membrane Stabilizing Activity	Intrinsic Sympathomimetic Activity	cLog P a/Log D (pH 7)	Extent of Absorption (%)	Absolute Oral Bioavailability (%)	Half-life (hours)	Protein binding (%)	Metabolism/Excretion
Acebutolol (Sectral)	$\beta_1$1	+	+	2.67/0.52	90	20–60	3–4	26	Hepatic; renal excretion, 30–40%; nonrenal excretion, 50–60% (bile)
Atenolol (Tenormin)	$\beta_1$1	0	0	0.1/–2.0	50	50–60	6–9	16–16	~50% excreted unchanged in feces

Betaxolol (Kerlone, Betoptic)	$\beta_1$1	+	0	2.7/0.6	~100	89	14–22	~50	Hepatic; >80% recovered in urine, 15% unchanged
Bisoprolol (Zebeta)	$\beta_1$1	0	0	2.2/0.1	≥90	80	9–12	~30	~50% excreted unchanged in urine, remainder as inactive metabolites; <2% excreted in feces.
Esmolol (Brevibloc)	$\beta_1$1	0	0	1.9/–0.22	na5	na5	0.15	55	Rapid metabolism by esterases in cytosol of red blood cells
Metoprolol (Lopressor) Metoprolol, LA	$\beta_1$1	02	0	1.8/–0.34	95	40–50 77	3–7	12	Hepatic; renal excretion, <5% unchanged
Carteolol (Cartrol, Ocupress)	β_1 β_2	0	++	1.7/–0.4	80	85	6	23–30	50–70% excreted unchanged in urine
Nadolol (Corgard)	β_1 β_2	0	0	1.3/0.84	30	30–50	20–24	30	Urine, unchanged
Penbutolol (Levatol)	β_1 β_2	0	+	4.2/2.1	~100	~100	5	80–98	Hepatic (conjugation, oxidation); renal excretion of metabolites (17% as conjugate)
Pindolol (Visken)	β_1 β_2	+	+++	1.97/–0.2	95	~100	3–43	40	Urinary excretion of metabolites (60–65%) and unchanged drug (35–40%)
Propranolol (Inderal) Propranolol, LA	β_1 β_2	++	0	3.1/1	90	30 9–18	3–5 8–11	90	Hepatic; <1% excreted unchanged in urine
Sotalol (Betapace)	β_1 β_2	0	0	0.3/–1.8	nd6	90–100	12	0	Not metabolized; excreted unchanged in urine
Timolol (Blocadren, Timoptic)	β_1 β_2	0	0	–4.3/–2	90	75	4	10	Hepatic; urinary excretion of metabolites and unchanged drug
Labetalol4 (Normodyne)	β_1 β_2 α_1	0	0	2.9/0.99	100	30–40	5.5–8	50	55–60% excreted in urine as conjugates or unchanged drug
Carvedilol (Coreg)	β_1 β_2 α_1	0	0	4.2/3.2	>90	25–35	7–10	98

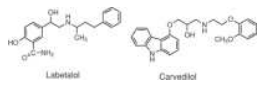

Fig. 13.17. Mixed α/β-adrenergic antagonists.

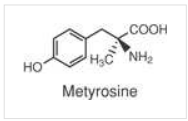
Stereochemistry of the β-Adrenergic Antagonists

A factor that sometimes causes confusion when comparing the structures of arylethanolamines with aryloxypropanolamines is the stereochemical nomenclature of the side-chain carbon bearing the hydroxyl group. For maximum effectiveness in receptor binding, the hydroxy group must occupy the same region in space as it does for the phenylethanolamine agonists in the R absolute configuration. Because of the insertion of an oxygen atom in the side chain of the aryloxypropanolamines, the Cahn-Ingold-Prelog priority of the substituents around the asymmetric carbon changes, and the isomer with the required special arrangement now has the S absolute configuration. This is an effect of the nomenclature rules; the groups still have the same spatial arrangements (Fig. 13.18).

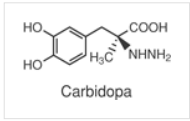
Drugs Affecting Norepinephrine/Epinephrine Biosynthesis

Hypothetically, inhibitors of any of the three enzymes involved in the conversion of L-tyrosine to norepinephrine could be used as drugs to moderate adrenergic transmission. Inhibitors of the rate-limiting enzyme tyrosine hydroxylase would be the most logical choice. One inhibitor of tyrosine hydroxylase, metyrosine or α-methyl-L-tyrosine, is in limited clinical use to help control hypertensive episodes and other symptoms of catecholamine overproduction in patients with the rare adrenal tumor pheochromocytoma (29). Metyrosine, a competitive inhibitor of tyrosine hydroxylase, inhibits the production of catecholamines by the tumor. Although metyrosine is useful in treating hypertension caused by excess catecholamine biosynthesis in pheochromocytoma tumors, it is not useful for treating essential hypertension. The drug metyrosine is the (S)-stereoisomer of α-methyltyrosine. The enantiomer, (R)-α-methyltyrosine, does not bind to the active site of tyrosine hydroxylase and, thus, has no useful pharmacological activity.

Fig. 13.18. Stereochemical nomenclature for arylethanolamines versus aryloxypropanolamines. The relative positions in space of the four functional groups are the same in the two structures; however, one is designated (R) and the other (S). This is because the introduction of an oxygen atom into the side chain of the aryloxypropanolamine changes the priority of two of the groups used in the nomenclature assignment.



Powerful inhibitors of the next enzyme in the pathway, aromatic L-amino acid decarboxylase (e.g., carbidopa), have proven clinically useful, but not as modulators of peripheral adrenergic transmission. Rather, these agents are used to inhibit the metabolism of exogenous L-dopa administered in the treatment of Parkinson's disease (see Chapter 25).



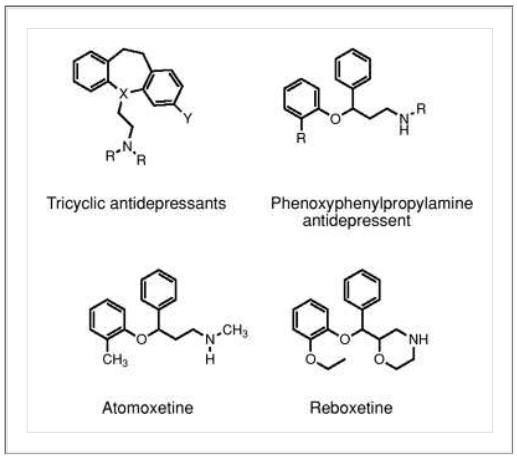
The next enzyme in the biosynthetic pathway to norepinephrine and epinephrine, dopamine β-hydroxylase, has been the subject of extensive research into its chemical mechanism and the subject of many enzyme inhibition studies. The inhibitors known to date, however, are primarily of basic biochemical research interest and have no therapeutic relevance. The same is true of phenylethanolamine-N-methyltransferase, the last enzyme in the biosynthesis of epinephrine in the adrenal medulla.

Drugs Affecting Norepinephrine Release, Reuptake, and Metabolism

Two drugs that act by inhibiting the release of norepinephrine from the nerve terminal and depleting stored norepinephrine are guanethidine and guanadrel, which have been used as antihypertensives but have largely been replaced by more effective agents and discontinued in the United States.

Drugs that selectively block the reuptake of norepinephrine can exert an acute and powerful sympathomimetic effect by prolonging the amount of time that released norepinephrine remains in the synaptic cleft. Cocaine is a powerful inhibitor of catecholamine reuptake (see Chapter 23). The tricyclic secondary amines, such as the antidepressants desipramine, nortriptyline,

or the phenoxypropylamines roboxetine and atomoxetine, block the reuptake of norepinephrine into the presynaptic terminals, whereas the tricyclic tertiary amine antidepressants amitriptyline, doxepin, and imipramine block both norepinephrine and serotonin reuptake in their respective presynpatic terminals (see Chapter 21). The tertiary tricyclic antidepressants are promiscuous antagonists at muscarinic, α-adrenergic, and H_1-histaminic receptors. (Clinical application of these and other antidepressant drugs is discussed in more detail in Chapter 21.)



Inhibitors of the enzymes that degrade norepinephrine, MAO and COMT, have application as antidepressants and anti-Parkinson's agents, respectively. These drugs are covered in Chapters 21 and 25.

Ergot Alkaloids

The ergot alkaloids have been recognized for more than 2,000 years, but their effects are varied and complex. Because of their structural similarities with the neurotransmitters, the ergot alkaloids exhibit affinity for α-adrenergic, dopaminergic, and serotonergic receptor systems. They also block the release of vasoactive neuropeptides, such as substance P. In general, their pharmacological effects result from their action as partial agonists and antagonists on these biogenic amine receptors. Their spectrum of effects varies with their structural features. Thus, the ergot alkaloids have been largely displaced by other more selective and effective drugs, except for methysergide, which remains the gold standard for the treatment of migraine headaches. They are discussed in this chapter because of their effects on the adrenergic nervous system.

The ergot alkaloids are a large group of indole alkaloids isolated from the ergot fungus, *Claviceps purpurea*, which is a plant parasite principally infecting rye. Eating grain contaminated with ergot caused a severely debilitating and painful disease during the Middle Ages called St. Anthony's Fire (ergotism), but in small doses, ergot was known to midwives for centuries for its ability to stimulate uterine contraction. Gangrene with burning pain in the extremities was one of two common presentations of ergot poisoning, which also could produce convulsions, hallucinations, severe psychosis, and death. St. Anthony was the patron saint of those who were stricken, and the Order of St. Anthony provided care for these patients. Outbreaks of "dancing mania," which occurred between the thirteenth and sixteenth centuries, sometimes have been attributed to ergotism, and one appealing—if unprovable—theory proposes that the women accused of witchcraft in the Salem trials of 1692 were suffering from ergot-induced psychosis and convulsions. The pharmacology of the various ergot alkaloids is complex, involving actions on the adrenergic nervous system as well as a number of others. The structures of several ergot alkaloids are shown in Figure 13.19.

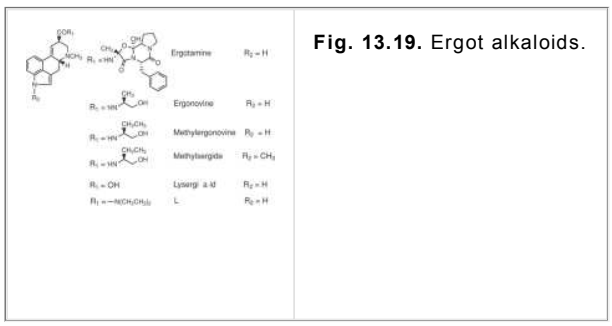


Fig. 13.19. Ergot alkaloids.

Ergotamine and dihydroergotamine are structurally related to biogenic amines and, because of this structural relationship, exert a broad range of pharmacological effects mediated by the adrenergic, the dopaminergic, and particularly, the serotonergic receptor systems. These are the serotonin (5-HT) 1A, 1B, 1D, and 1F receptor agonists, and they also block the release of two important vasoactive neuropeptides currently thought to be involved in migraine, substance P and calcitonin gene-related peptide. They exhibit mixed agonist/antagonist effects at the adrenergic and dopaminergic receptors. Ergotamine is a potent vasoconstrictor but also can produce vasodilatory effects depending on the degree of resistance of the vasculature. When preexisting resistance is low, vasoconstriction occurs, resulting in increased arterial blood pressure. When there is increased resistance of the vascular bed, vasodilation may occur, whereas ergotamine binding to serotonin receptors

result in vasoconstrictor effects. In migraine headache, ergotamine most likely relieves cranial vascular pressure by selective vasoconstriction of arterial cranial vessel beds, thus reducing carotid blood flow, as well as by depression of central serotonergic neurons, thus mediating pain transmission. The uterine stimulant properties (oxytocic) of

ergotamine result from its strong induction of contractions in the pregnant uterus, which appears to be partially an α-adrenergic effect, because it is blocked by phentolamine. Ergotamine is more potent than dihydroergotamine as a uterine stimulant. It also is used to contract the postpartum uterus to prevent excessive bleeding. The bioavailability of ergotamine following oral, sublingual, inhalation, and rectal administration is less than 5%., but oral bioavailability is improved when ergotamine is coadministered with caffeine Its elimination half-life is 1.5 to 2.5 hours. These medications may cause nausea and vomiting via direct stimulation of the chemoreceptor trigger zone.

Dihydroergotamine mesylate (Migranal) is a 5-HT_{1D} receptor agonist used to treat migraine headache with or without aura. Its clinical efficacy in treatment of migraine is thought to be related to the activation of 5-HT_{1D} receptors in the intracranial blood vessel bed, resulting in vasoconstriction. Dihydroergotamine also inhibits the release of pro-inflammatory neuropeptides, such as substance P release caused by the activation of the 5-HT_{1D} receptors found on sensory nerve endings. The oral bioavailability is less than 1%, whereas with an intranasal spray, the bioavailability is 32%. It also is administered intramuscularly, subcutaneously and intravenously.

Ergonovine (Ergotrate) and methylergonovine (Methergen) produce arterial vasoconstriction by stimulating the α-adrenergic and serotonin receptors and inhibiting the release of endothelial-derived relaxation factor. As vasoconstrictors, they are less potent than ergotamine. Ergonovine causes vasoconstriction of coronary arteries. In the CNS, it exhibits weak dopaminergic antagonist actions in certain blood vessels and partial agonist actions at serotonin receptors in umbilical and placental blood vessels, but it does not possess significant α-adrenergic blocking activity. Its duration of action as uterine stimulant is approximately 3 hours. Ergonovine is a strong inducer of uterine contractions and, because of its better oral absorption, has largely replaced ergotamine for this purpose. Methylergonovine is rapidly and completely absorbed following oral or intramuscular administration, with an oral bioavailability of 60%, even though it undergoes extensive first-pass metabolism to ergonovine.

Methysergide (Sansert), which is structurally identical to methylergonovine except for the addition of a methyl group to the indole nitrogen, has far less of the uterine stimulatory properties of the other agents and, instead, is used exclusively for treatment of migraine headache as a serotonin antagonist at 5-HT_1/5-HT_2 receptors. Methysergide is a potent peripheral inhibitor of 5-HT receptors in the blood vessel, which inhibits vessel-wall permeability. Methysergide also inhibits the release of histamine from mast cells and stabilizes platelets against the release of 5-HT, which may be responsible for the onset of the migraine attack. In contrast to its peripheral effects, methysergide appears to be a central 5-HT_1 agonist, resulting in alleviation of the central hyperalgesia effect that occurs in patients with migraine. Its oral bioavailability of less than 13% suggests extensive first-pass N-demethylation to its primary metabolite, methylergonovine, which has a longer elimination half-life than methysergide. The fact that the metabolite has a higher concentration and a longer half-life than the parent drug may be relevant to the treatment of migraine if methylergonovine contributes to the antimigraine effect of methysergide.

All these ergot alkaloids are amide derivatives of lysergic acid, but only the diethylamide LSD produces the profound hallucinatory effects for which it is so well-known.

Case Study

Victoria F. Roche

S. William Zito

CB is a 57-year-old female independent real estate agent with mild persistent asthma who recently moved to your community after the traumatic breakup of her 25-year marriage and the death of her beloved mother. She and her mother grew very close during the last years of her stormy marriage, and while she felt the need for this new start, she is feeling quite lost and alone. She is currently taking the antidepressant duloxetine hydrochloride (Cymbalta, 20 mg b.i.d.) to assist in managing her emotional stress and has initiated psychotherapy with a qualified counselor. She is in the process of finding a realty company with which to affiliate to ease her way into the market, but thus far, she has not had a firm offer of employment. She has a modest inheritance from her mother that will tide her over for a time, but she is definitely anxious about her situation and wonders whether she did the right thing in leaving her old hometown. She claims to have lost 20 pounds over the past several months because of the stress and still is not able to eat very well.

CB's asthma is currently being treated with a low-dose of the inhaled corticosteroid beclomethasone dipropionate (QVAR, 40 μg b.i.d.). She is in your pharmacy now with prescriptions for both chronic medications written by her new provider. After taking her medical history and reviewing her psychosocial situation, you recognize that she has many risk factors for “near-fatal asthma” and believe she should have ready access to rescue therapy in case she experiences an acute episode of severe bronchoconstriction. Consider the structures of the adrenergic agents drawn below, and prepare to make a therapeutic recommendation to CB's new physician.

1. Identify the therapeutic problems in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 14

Serotonin Receptors and Drugs Affecting Serotonergic Neurotransmission

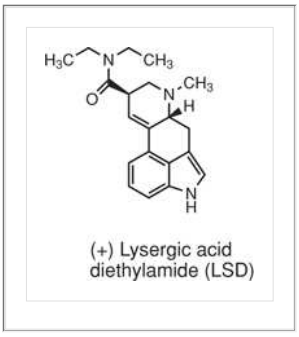
Richard A. Glennon

Malgorzata Dukat

Serotonin

Serotonin is the "baby boomer" of neurotransmitters: It was identified in the late 1940s, its adolescence was troubled and turbulent, it made the drug scene in the 1960s, and it nearly died of an overdose in the early 1970s. At one point, the remark was made that "serotonin doesn't do anything" (1). On reaching its middle years, serotonin has matured and become an important topic of study, a household name, and more complicated than ever. Serotonin has been associated with, among other things, anxiety, depression, schizophrenia, drug abuse, sleep, dreaming, hallucinogenic activity, headache, cardiovascular disorders, and appetite control, and it is now dabbling in acupuncture and transcendental meditation. This has prompted the comment that "it almost appears that serotonin is involved in everything" (1). A review of the patent literature provides an indication of some of the claims being made for novel serotonergic agents (Table 14.1). Tens of thousands of papers have been published on serotonin. Much is known—but an incredible amount remains to be learned.

Historical Perspectives



Serotonin was independently identified in the late 1940s by two groups of investigators: In the United States, it was called serotonin, whereas in Italy, it was called enteramine. Its total synthesis in the early 1950s confirmed that both substances were 5-hydroxytryptamine (5-HT). Serotonin (5-HT) was detected in numerous plant and animal species and, in the mid-1950s, was identified in the central nervous system (CNS) of animals. A neurotransmitter role was subsequently proposed for this substance. Later, 5-HT was implicated in a variety of central and peripheral physiologic actions. It seemed to be involved in vasoconstriction and vasodilation, regulation of body temperature, sleep, and hormonal regulation, and evidence suggested that it might be involved in depression. The structural similarity between 5-HT and the then recently discovered hallucinogenic agent (+)-lysergic acid diethylamide (LSD) intrigued investigators. This observation led to speculation that 5-HT might be involved in the mechanism of action of psychoactive substances and that it might play a seminal role in various mental disorders. The hallucinogenic agent LSD was shown to behave as a potent 5-HT agonist in some peripheral assays and as a potent antagonist in others. The late 1960s and early 1970s, however, witnessed a decline in 5-HT research as the result of three factors: 1) sophisticated techniques were still lacking for the investigation of the central actions of 5-HT: 2) apart from ergolines (LSD-related agents), only a few potent 5-HT agonists or antagonists had been developed: and 3) it was becoming increasingly difficult to understand how a single putative neurotransmitter substance could be involved in so many different central and peripheral actions. The development of histochemical fluorescence techniques and radioligand binding methodology led to the mapping of serotonergic pathways, to identifying binding sites in the brain, and to measuring the affinity (i.e., K_i values) of serotonergic agents for their respective serotonergic receptors. Much of the earlier work on serotonin and on most of the more established serotonergic agents has been reviewed (2); the interested reader is urged to consult this review for references to the primary literature.

Clinical Significance

Discovery of the different types of serotonin receptors during the past few years has created the potential to target these receptors. Altering the chemical structures may improve tolerability, reduce the risk for side effects, improve efficacy, enhance compliance, or simply provide an alternative drug should another in the class fail to provide relief for a given patient.

The clinical effects of serotonin receptors are multifaceted. At this time, only a few of the identified receptors have drugs that are currently marketed for use in humans. Buspirone stimulates the 5-HT_{1A} receptor to cause antianxiety effects. The 5-HT_{1D} agonists, or the "triptans," vary by side chains on essentially the same core structure to create compounds with different affinities for the 5-HT_{1D} receptors and, likely, for other serotonin receptors as well. The varying affinities of each triptan for receptors change the profiles of their effectiveness and adverse or complimentary effects. As a rule, the triptans work to treat migraine headaches by causing vasoconstriction. Unfortunately, they also may cause coronary vasoconstriction, making them contraindicated in patients with underlying coronary artery disease. Antagonists of the 5-HT_3 receptor, ondansetron and granisetron, work to lessen emesis in chemotherapy-induced and

radiation-associated emesis as well as postoperative nausea and vomiting. A variety of drugs work to inhibit selective serotonin reuptake without acting on any specific serotonin receptor. Drugs such as fluoxetine, paroxetine, sertraline, fluvoxamine, and others have been effective in the treatment of depression, obsessive-compulsive disorder, and panic disorder with varying degrees of side effects like weight gain, weight loss, and drowsiness.

College of Pharmacy

University of Arkansas for Medical Sciences

Table 14.1. Some Indications and Treatment Claims for Novel Serotonergic Agents in Recent Patent Literature

Aggression disorders	Esophagitis	Obsessive-compulsive
Alcoholism	Gastric motility	Pain
Alzheimer's disease	Head injury	Panic disorders
Amnesia	Headache	Parkinson's disease
Anorexia	Hypertension	Psychosis
Bulimia	Impotence	Raynaud's disease
Cardiac failure	Irritable bowel syndrome	Schizophrenia
Cardiovascular disorders	Ischemia	Sedation
Cerebrovascular disorders	Migraine	Sexual dysfunction
Cognition	Movement disorders	Sleep disorders
Depression	Nausea	Substance abuse
Drug abuse	Neurodegenerative disease	Substance dependence
Emesis	Obesity	Thromobembolism

Radioligands

Radioligand binding techniques measure the affinity of agonists and antagonists for their respective receptors (i.e., K_i values). Radioligands are receptor agonists or antagonists to which a radioactive atom (label) is covalently attached.

Serotonin Biosynthesis, Catabolism, and Function as Targets for Drug Manipulation

Serotonin, or 5-HT, is biosynthesized (3) from its dietary precursor L-tryptophan (Fig. 14.1). Serotonergic neurons contain tryptophan hydroxylase (L-tryptophan-5-monooxygenase) that converts tryptophan to 5-hydroxytryptophan (5-HTP) in what is the rate-limiting step in 5-HT biosynthesis and aromatic L-amino acid decarboxylase (previously called 5-HTP decarboxylase) that decarboxylates 5-HTP to 5-HT. This latter enzyme also is responsible for the conversion of L-DOPA to dopamine (see Chapter 12). The major route of metabolism for 5-HT is oxidative deamination by monoamine oxidase (MAO-A) to the unstable 5-hydroxyindole-3-acetaldehyde, which is either reduced to 5-hydroxytryptophol (~15%) or oxidized to 5-hydroxyindole-3-acetic acid (~85%). In the pineal gland, 5-HT is acetylated by 5-HT N-acetyltransferase to N-acetylserotonin, which undergoes O-methylation by 5-hydroxyindole-O-methyltransferase to melatonin.

Each of the steps in 5-HT biosynthesis, metabolism, and function is a theoretical target for drug manipulation (Fig. 14.2). Tryptophan depletion, by reducing or eliminating dietary tryptophan, can result in decreased 5-HT biosynthesis. Conversely, tryptophan "loading," by increasing dietary tryptophan, can result in the overproduction of 5-HT. This latter effect also can occur in nonserotonergic neurons, such as dopaminergic neurons, because of the nonselective nature of aromatic amino acid decarboxylase. Inhibitors of tryptophan hydroxylase, such as *para*-chlorophenylalanine, are used as pharmacological tools; they are not used therapeutically.

Therapeutically exploited serotonergic targets include the postsynaptic receptors, reuptake mechanisms, and metabolism. The monoamine oxidase (MAO) inhibitors effectively interfere with the oxidative deamination of 5-HT to increase synaptic concentrations of 5-HT. The

MAO inhibitor tranylcypromine, for example, has been used since the 1960s as an antidepressant. A problem associated with many MAO inhibitors is that they are notoriously nonselective and can interfere with the metabolism of other neurotransmitters, amines found in certain foods, and exogenously administered amine-containing therapeutic agents.

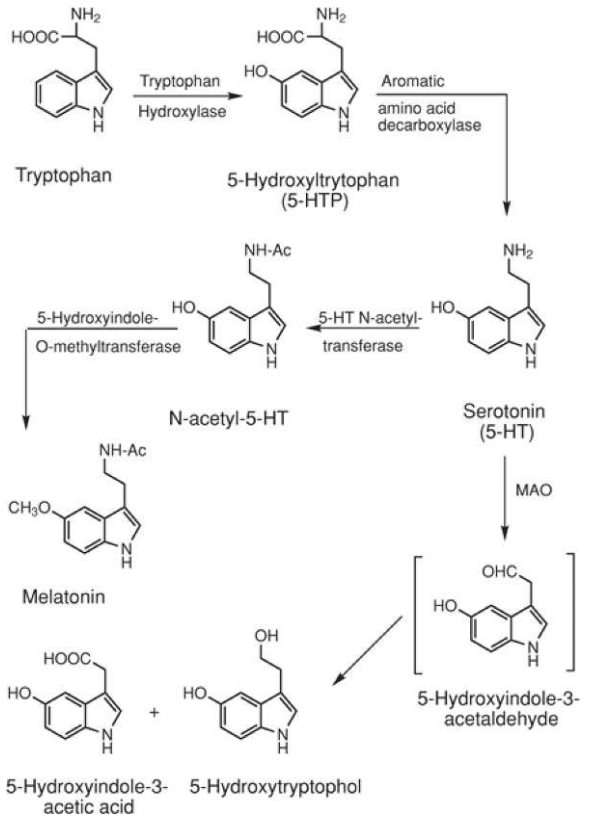

Fig. 14.1. Biosynthesis and catabolism of serotonin. In the pineal, serotonin is converted to melatonin. Ac = acetyl.

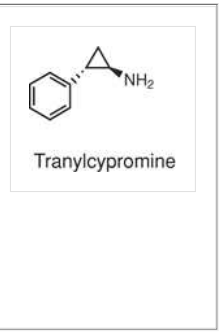

Serotonin Receptors

Seven families or populations of serotonergic receptors have been identified, 5-HT_1 through 5-HT_7, and several are divided into distinct subpopulations (Table 14.2). The discovery of the individual populations and subpopulations of 5-HT receptors follows the approximate order of their numbering, and as a consequence, more is known about 5-HT_1 and 5-HT_2 receptors than about 5-HT_6 and 5-HT_7 receptors. Other factors contributing to our current lack of knowledge about certain receptor populations (i.e., 5-HT_{1E} or 5-HT_5 receptors) is the absence of agonists/antagonists with selectivity for these receptors.

Fig. 14.2. Steps involved in serotonergic neurotransmission. The serotonin precursor tryptophan is taken up into the neuron (A) and converted to 5-HT (B). Synthesized 5-HT is stored in synaptic vesicles (C). Under the appropriate conditions, the synaptic vesicles migrate to and fuse with the cell membrane, releasing their store of 5-HT (D). Released neurotransmitter interacts with postsynaptic receptors (E) and, in the case of G protein–coupled receptors, activates second messenger systems (F). The action of 5-HT is terminated (G) either by diffusion of 5-HT away from the synapse, with subsequent metabolism, or by the 5-HT being taken back up by a 5-HT transporter into the presynaptic neuron (i.e., reuptake), where it can be stored or metabolized.

History

Tritiated LSD ([^{3}H]LSD) was the first radioligand used to identify a brain 5-HT binding site, suggesting it to be a "hallucinogen receptor." Tritiated 5-HT ([^{3}H]5-HT)–labeled serotonergic sites displayed high affinity for LSD. Thus, not only did 5-HT and LSD share structural similarity, there was now evidence that these agents might be acting via a common receptor type. According to the interconvertible receptor conformation hypothesis that was popular at the time, 5-HT (known to be an agonist) interacted with the agonist conformation of the receptor, whereas [^{3}H]LSD (LSD being known to be a partial agonist) labeled both the agonist and antagonist conformations. A search was initiated for 5-HT antagonists that could be used as radioligands for studying serotonergic receptors. Following the serendipitous discovery that a tritiated version of the dopamine antagonist spiperone not only labeled dopaminergic receptors but also labeled nondopaminergic receptors in other brain regions, it was shown that 5-HT displayed modest affinity for these sites

and that they might represent 5-HT receptors. Spiperone also was shown to antagonize some of the pharmacological effects of 5-HT. These data, coupled with the additional observation that 5-HT agonists, tended to display higher affinity for [^{3}H]5-HT–labeled sites, whereas 5-HT antagonists displayed higher affinity for [^{3}H]spiperone-labeled sites, led to the conclusion that [^{3}H]5-HT and [^{3}H]spiperone labeled two distinct populations of sites, termed 5-HT$_1$ and 5-HT$_2$ receptors, respectively (5). Soon thereafter, 5-HT$_1$ receptors were found to consist of 5-HT$_{1A}$ and 5-HT$_{1B}$ subpopulations. During the 1950s, Gaddum and Picarelli had demonstrated the existence of two populations of serotonergic receptors in isolated guinea pig ileum and called these receptors 5-HT-D (because the phenoxybenzamine dibenzyline blocked 5-HT at this receptor) and 5-HT-M (because morphine and cocaine blocked the actions of 5-HT at the second population). Later, 5-HT-D receptors were found to be identical with 5-HT$_2$ receptors, and 5-HT-M receptors were eventually renamed 5-HT$_3$ receptors. By the early 1980s, 5-HT$_{1A}$, 5-HT$_{1B}$, 5-HT$_2$, and 5-HT$_3$ receptors had been identified, and interest in 5-HT research exploded. Molecular biology intervened in the late 1980s and early 1990s, which allowed new populations of serotonergic receptors to be cloned and expressed. This led to attempts to develop selective agonists and antagonists for each subpopulation (2,6).

Table 14.2. Classification and Nomenclature for the Various Populations of 5-HT Receptors

Populations and Subpopulations	Second Messenger Systema	Currently Accepted Nameb	Comments
5-HT$_1$			
5-HT$_{1A}$	AC(–)	5-HT$_{1A}$	Cloned and pharmacological 5-HT$_{1A}$ receptors
5-HT$_{1B}$	AC(–)	5-HT$_{1B}$	Rodent homologue of 5-HT$_{1B}$ receptors
5-HT$_{1B\beta}$			A mouse homologue of h5-HT$_{1B}$ receptors
5-HT$_{1D}$			Sites identified in binding studies using human and calf brain homogenates
5-HT$_{1D\alpha}$	AC(–)	h5-HT$_{1D}$	A cloned human 5-HT$_{1D}$ subpopulation
5-HT$_{1D\beta}$	AC(–)	h5-HT$_{1B}$	A second cloned human 5-HT$_{1D}$ subpopulation; human counterpart of rat 5-HT$_{1B}$

5-HT_{1E}	AC(–)	5-HT_{1E}	Sites identified in binding studies using brain homogenates and cloned receptors
5-$HT_{1E\alpha}$			An alternate name that has been used for cloned human 5-HT_{1e} receptors
5-$HT_{1E\beta}$	AC(–)	5-ht_{1F}	A cloned mouse homologue of 5-HT_{1F} receptors
5-HT_{1F}			A cloned human 5-HT_1 receptor population
5-HT_2			
5-HT_2	PI	5-HT_{2A}	Original "5-HT_2" (sometimes called 5-$HT_{2\alpha}$) receptors
5-HT_{2F}	PI	5-HT_{2B}	5-HT_2-like receptors originally found in rat fundus
5-HT_{1C}	PI	5-HT_{2C}	Originally described as 5-HT_{1C} (5-$HT_{2\beta}$) receptors
5-HT_3			
5-HT_3	Ion channel	5-HT_3	An ion channel receptor
5-HT_4	AC(+)	5-HT_4	5-HT_4 population originally described in functional studies
5-HT_{4S}			Short form of cloned 5-HT_4 receptors
5-HT_{4L}			Long form of cloned 5-HT_4 receptors
5-$HT_{4(b)–4(d)}$			Recently identified human 5-HT_4 receptor isoforms
5-HT_5			
5-HT_{5A}	?	5-HT_{5A}	Cloned mouse, rat and human 5-HT_5 receptors
5-HT_{5B}	?	5-HT_{5A}	Cloned mouse and rat 5-HT_{5A}-like receptor
5-HT_6			
5-HT_6	AC(+)	5-HT_6	Cloned rat and human 5-HT receptor
5-HT_7			
5-HT_7	AC(+)	5-HT_7	Cloned rat, mouse, guinea pig and human 5-HT receptors

[a]AC = adenylate cyclase; (–) = negatively coupled; (+) = positively coupled; PI = phospholipase coupled.
[b]Currently accepted names are taken from Hoyer et al. (8).

Table 14.2 lists the receptor classification and nomenclatures that have been employed for serotonergic receptors. Other 5-HT orphan receptors that have not yet been cloned include the 5-HT_{1P} receptors, which are found only in the gastrointestinal tract. Care should be used when reading the older primary literature, because 5-HT receptor nomenclature has changed so dramatically and often can be confusing and very frustrating to comprehend.

All of the seven serotonergic receptor populations have been cloned and, together with the cloning of other neurotransmitter receptors, has led to generalizations regarding amino acid sequence homology (7). Any two receptors with amino acid sequences that are approximately 70 to 80% identical in their transmembrane-spanning segments are called the intermediate-homology

group. This group of receptors may be members of the same subfamily and have highly similar to nearly indistinguishable pharmacological profiles or second messenger systems. A low-homology group (~35–55% transmembrane homology) consists of distantly related receptor subtypes from the same neurotransmitter family, and a high-homology group (~95–99% transmembrane homology) consists of species homologues from the same gene in different species (7). Species homologues of the same gene reveal high sequence conservation in regions outside the transmembrane domains, whereas intraspecies receptor subtypes usually are quite different (7). Current 5-HT receptor classification and nomenclature require that several criteria be met before a receptor population can be adequately characterized. Receptor populations must be identified on the basis of drug binding characteristics (operational or recognitory criteria), receptor–effector coupling (transductional criteria), and gene and receptor structure sequences for the nucleotide and amino acid components, respectively (structural criteria) (6,7,8).

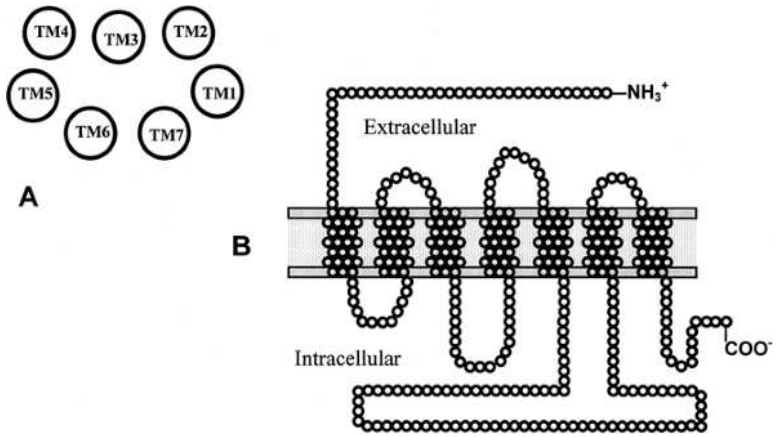

Fig. 14.3. Top (A) and side (B) views of a schematic representation of a typical G protein–coupled receptor. In B, the transmembrane-spanning helical portions are numbered, from left to right, as TM1 to TM7. The seven helices are connected by extracellular and intracellular loops. The large intracellular loop between TM5 and TM6 is believed to be associated with coupling to a second messenger system. The helices are arranged in such a manner that TM1 is adjacent to TM7, as shown in A. Molecular graphics studies suggest that agonists might bind in a manner that utilizes an aspartate residue in TM3 (common to all G protein–coupled 5-HT receptors) and residues in the TM4, TM5, and TM6 regions (Site 1), whereas antagonists likely utilize the aspartate moiety but residues in the TM6, TM7, and TM1 regions (Site 2).

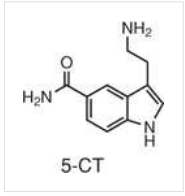
5-HT$_1$ Family

The 5-HT$_1$ receptors were one of the first two populations of 5-HT receptors to be identified (5), and 5-HT$_{1A}$, 5-HT$_{1B}$, 5-HT$_{1C}$ (later renamed 5-HT$_{2C}$), 5-HT$_{1D}$, 5-HT$_{1E}$, and 5-HT$_{1F}$ receptor subfamilies have been subsequently defined and cloned. With the exception of 5-HT$_{1E}$ receptors, all 5-HT$_1$ receptors exhibit high affinity for 5-carboxamidotryptamine (5-CT).



5-HT$_{1A}$ Receptors and Agents

The 5-HT$_{1A}$ receptors are G protein–coupled receptors that consist of seven transmembrane-spanning helices connected by intracellular and extracellular loops (see Fig. 14.3 for a schematic representation of a generalized G-protein receptor structure). The receptors are negatively coupled to an adenylate cyclase* second messenger system, and the 5-HT$_{1A}$ receptors located in the raphe nuclei correspond to somatodendritic autoreceptors (Fig. 14.4). The 5-HT$_{1A}$ receptors differ significantly in structure from most other 5-HT receptors and exhibit a substantial similarity to adrenergic receptors, which probably explains why a number of adrenergic agents bind at 5-HT$_{1A}$ receptors with high affinity. Cloned 5-HT$_{1A}$ receptors and 5-HT$_{1A}$ ligands have been extensively reviewed (8,9,10,11,12,13,14,15,16,17,18).

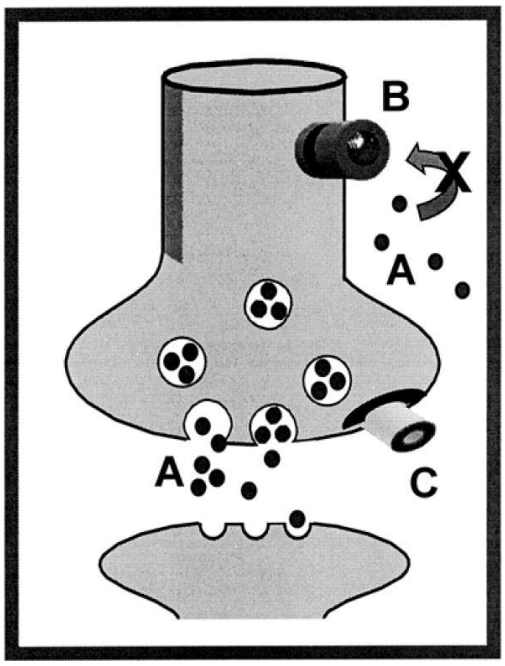


Fig. 14.4. Typical nerve ending showing the cell body (i.e., somatodendritic) autoreceptors (B) and the terminal autoreceptors (C). Neurotransmitter molecules also are shown (A). Neurotransmitters can interact with cell body autoreceptors (B) to regulate synthesis and with terminal autoreceptors (C) to regulate release. Shown above is a drug molecule blocking the cell body autoreceptor and preventing an interaction with the neurotransmitter.

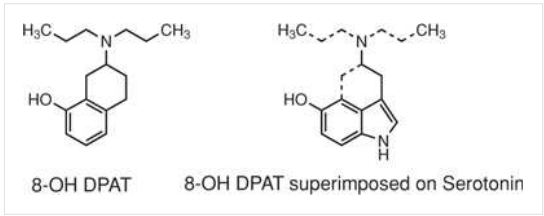
Structure–activity relationship of 5-HT$_{1A}$ agonists

Overview

Numerous tryptamines bind with high affinity at 5-HT$_{1A}$ receptors, but most are notoriously nonselective. One of the most selective 5-HT$_{1A}$ receptor agonists is the aminotetralin derivative 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH DPAT), and its early discovery was significant in advancing an understanding of 5-HT$_{1A}$ receptors. Furthermore, because the structure of 8-OH DPAT is similar to that of 5-HT (8-OH DPAT/serotonin), its activity indicated that an intact indole nucleus was not required for 5-HT$_{1A}$ actions. Although numerous 8-OH DPAT derivatives have been reported, none is used therapeutically because of low oral bioavailability. This has led to efforts to develop novel aminotetralins with greater oral availability.



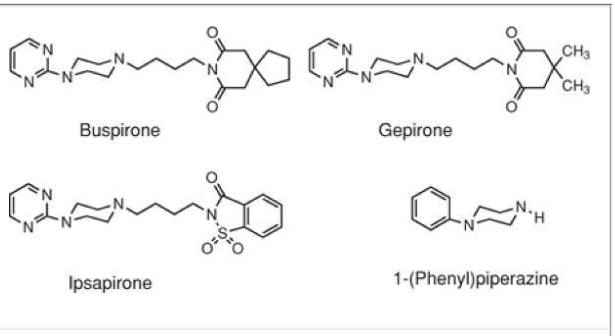


Fig. 14.5. 5-HT_{1A} agonists (arylpiperazines).

Long-chain arylpiperazines

Simple arylpiperazines (i.e., those bearing no N_4-substituent or only a small N_4-substituent), such as 1-(phenyl)piperazine (Fig. 14.5), bind with modest to reasonably high affinity at a multitude of receptor types and are nonselective agents. Long-chain arylpiperazines (LCAPs), which are those piperazines possessing an elaborated N_4 substituent, probably represent the largest class of 5-HT_{1A} ligands (13). Buspirone (Fig. 14.5), the first arylpiperazine approved for clinical use as an anxiolytic agent, and the structurally related gepirone and ipsapirone bind at 5-HT_{1A} receptors and behave as agonists or partial agonists. Structure–activity relationships (SARs) and structure–affinity relationships have been formulated, and this has led to LCAPs with enhanced affinity and selectivity for 5-HT_{1A} receptors (12,13,14). With the LCAPs, there seems to be substantial structural latitude for 5-HT_{1A} binding (14).

The aryl portion of these agents (Fig. 14-6) typically is a phenyl, substituted phenyl, or a heteroaryl group, such as 2-pyrimidinyl. The intact piperazine ring seems to be optimal for binding to 5-HT_{1A} receptors. A spacer or linker separates the N_4-nitrogen atom of the piperazine and the terminus. There has been controversy as to whether the spacer actively participates in binding to the receptor or whether it acts simply as a connector; in any event, a chain of two to five atoms is common. The terminus typically is an amide or imide, but it has been shown that neither is required for binding. Alternatively, it may be a phenyl or some other aryl or heteroaryl substituent (14). With respect to spacer length, when the spacer is -$(CH_2)_n$–, two to four methylene groups appear optimal. Chain length (*n*) can influence affinity and selectivity. When the terminus contains a heteroarylamide, *n* = 4 seems to be optimal, whereas when the terminus is an alkylamide, optimal affinity is associated with *n* = 2. A region of bulk tolerance is associated with the terminus, or at least a portion thereof, and very bulky groups have been introduced into this part of the molecule (12,13,14). Some LCAPs are nonselective and may

variously bind at other populations of 5-HT receptors, dopamine receptors, or adrenergic receptors.

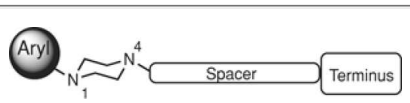

Fig. 14.6. General structure of long-chain arylpiperazines.

Structure–activity relationship of 5-HT_{1A} antagonists

Many 5-HT_{1A} antagonists possess a 2-methoxyphenyl group with structural similarity to buspirone. BMY 7378 and NAN-190 were among the first agents shown to be very-low-efficacy partial agonists at 5-HT_{1A} receptors and were used as antagonists (Fig. 14.7). Certain aminotetralins (e.g., S(–)UH-301) and arylpiperazines (e.g., WAY 100135 and WAY 100635) represent new classes of 5-HT_{1A} antagonists that are termed "silent antagonists," because they are without any 5-HT_{1A} agonist action. The alkylpiperidine spiperone is a 5-HT_{1A} antagonist, but it displays even greater affinity for D_2-dopamine receptors and 5-HT_{2A} receptors.

Molecular graphics studies suggest (15,16) that 5-HT and 5-HT_{1A} agonists typically interact with amino acid residues associated with helices 4, 5 and 6 (Site 1), whereas 5-HT_{1A} antagonists likely interact with amino acid residues in helices 1, 2, 7 and perhaps, 6 (Site 2). The basic primary amine for both types of agents are thought to bind at a common aspartate residue found in TM helix (TM) 3 (Fig. 14.3). The 5-hydroxy group of 5-HT forms a hydrogen bond with threonine residue in TM5 (15,16).

5-HT_{1A} receptor agonists: clinical significance

In preclinical studies, 5-HT_{1A} agonists have demonstrated antianxiety, antidepressant, antiaggressive, and perhaps, anticraving, anticataleptic, antiemetic, and neuroprotective properties (17). Evidence also exists that indicates 5-HT_{1A} receptors might be involved in sleep, impulsivity, alcoholism, sexual behavior, appetite control, thermoregulation, and cardiovascular function (17,19,20,21). The main focus of drug development for 5-HT_{1A} receptors is their therapeutic potential for the treatment of anxiety and depression (19). Buspirone (Buspar) was the first LCAP to become clinically available as an anxiolytic agent, and a number of structurally related agents hold promise as novel anxiolytics (11,12,22). Additionally, 5-HT_{1A} agents might be useful in the treatment of depression, and there may be a relationship between 5-HT metabolism, depression, and violent behavior. The antianxiety actions of 5-HT_{1A} (partial) agonists may involve primarily presynaptic somatodendritic 5-HT_{1A} receptors, whereas the antidepressant actions of 5-HT_{1A} agents may primarily involve postsynaptic 5-HT_{1A} receptors (17). Gepirone produced marked improvement in depressed patients, and buspirone was effective in the treatment of mixed anxious-depressive patients. The 5-HT_1 and, possibly, 5-HT_{1A} receptors have been implicated in obsessive-compulsive disorders.

5-HT$_{1A}$ receptor antagonists: clinical significance

A new direction in 5-HT$_{1A}$ research targets the development of 5-HT$_{1A}$ antagonists (23). Agents such as the dopaminergic antagonist spiperone and the β-adrenergic antagonist propranolol were among the first to see application as 5-HT$_{1A}$ antagonists. These agents are obviously nonselective, however, and bind at other populations of neurotransmitter receptors with higher affinities than they display at 5-HT$_{1A}$ receptors. The next generation of 5-HT$_{1A}$ antagonists, the LCAPs BMY 7378 and NAN-190, possessed postsynaptic antagonist character but also some presynaptic agonist action (14,23) (Fig. 14.7). A third generation of agents—the "silent" 5-HT$_{1A}$ antagonists—has been developed and includes WAY 100635, WAY 100135 (a structural relative of BMY 7378 and NAN-190), and S(–)UH-301 (a derivative of the 5-HT$_{1A}$ agonist 8-OH DPAT); these are both presynaptic and postsynaptic 5-HT$_{1A}$ antagonists (23,24). The silent 5-HT$_{1A}$ antagonists, such as WAY 100135 and S(–)UH-301, are not intrinsically inactive and can indirectly produce non-5-HT$_{1A}$ serotonin-mediated actions (25,26). These antagonists presumably block presynaptic 5-HT$_{1A}$ autoreceptors, increasing the synaptic concentration of 5-HT, which results in the activation of other serotonergic receptor populations. Human evaluation of silent and selective 5-HT$_{1A}$ antagonists should prove interesting and could open new vistas in 5-HT$_{1A}$ research and therapeutics. For example, pretreatment of patients with 5-HT$_{1A}$ antagonists could accelerate the effects of selective 5-HT reuptake inhibitors (SSRIs) and enhance their clinical efficacy as antidepressants (27). The 5-HT$_{1A}$ antagonist WAY 100635 enhances the anorectic effect of citalopram in animals (28) and, thus, may be of benefit in weight reduction. Combination therapy using an SSRI plus a 5-HT$_{1A}$ antagonist, including the β-blocker pindolol, which binds at 5-HT$_{1A}$ receptors, has been reported (29). A new

LCAP, LY426965, is more metabolically stable than WAY 100635 and is orally available. In combination with fluoxetine, LY426965 has been shown to increase extracellular levels of 5-HT beyond that achievable by fluoxetine alone, and it is being examined for the treatment of depression and as a smoking cessation agent (30). The therapeutic potential of 5-HT$_{1A}$ antagonists is quite intriguing.

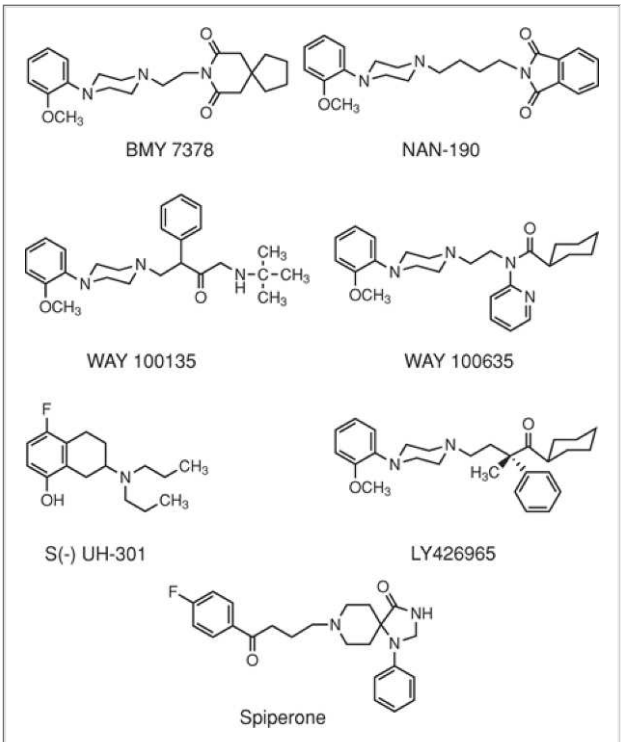

Fig. 14.7. 5-HT$_{1A}$ antagonists.

5-HT$_{1B}$ Receptors and Agents

Overview

Early studies identified 5-HT$_{1B}$ receptors in rodent brain using radioligand binding techniques but failed to find them in human brain. The 5-HT$_{1B}$ receptors are located both presynaptically, where they regulate the release of 5-HT (Fig. 14.4), and postsynaptically (31). Like 5-HT$_{1A}$ receptors, they are negatively coupled to adenylate cyclase. (See 5-HT1D Receptors for further related discussion.)

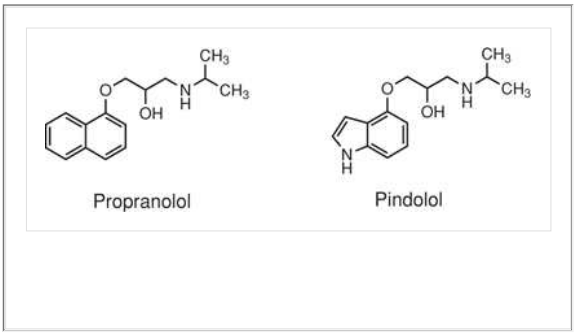
5-HT$_{1B}$ receptors: clinical significance

Rodent 5-HT$_{1B}$ receptors have been implicated as playing roles in thermoregulation, respiration, appetite control, sexual behavior, aggression, locomotor activity, sleep regulation, sensorimotor inhibition, and anxiety (32).

5-HT$_{1D}$ Receptors

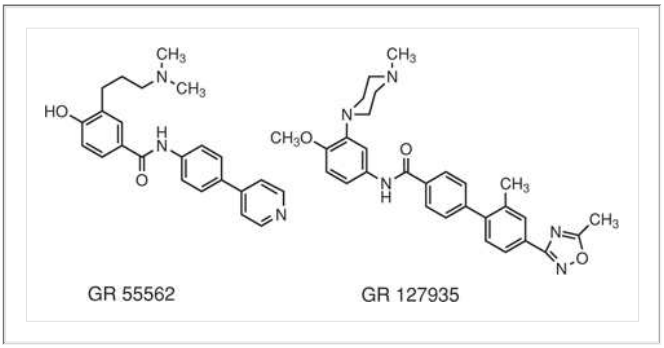
The 5-HT$_{1D}$ receptors were first identified by radioligand binding techniques, and they are widely distributed throughout the CNS (33). They are G protein–linked and are coupled to inhibition of adenylate cyclase. Two human subpopulations of 5-HT$_{1D}$ receptors, 5-HT$_{1D\alpha}$ and 5-HT$_{1D\beta}$ receptors, display approximately 77% sequence homology, and their pharmacological properties are nearly indistinguishable. Because of the high degree of species homology with rat and mouse 5-HT$_{1B}$ receptors, human 5-HT$_{1D\beta}$ receptors have been renamed h5-HT$_{1B}$ receptors. Human 5-HT$_{1D\alpha}$ receptors have been renamed h5-HT$_{1D}$. Most agents that bind at 5-HT$_{1B}$ receptors typically bind at 5-HT$_{1D}$ receptors. Curious exceptions have been observed with certain aryloxyalkylamines, however, such as the β-blockers, propranolol, and pindolol, which exhibit very low affinity (K_i > 5,000 nM) for h5-HT$_{1D}$ receptors (34,35). The major functional difference between rat 5-HT$_{1B}$ receptors and human h5-HT$_{1B}$ receptors has been attributed to both the presence of a threonine residue at position 355 (i.e., Thr 355) in TM7 of the latter and the presence of an asparagine residue at the corresponding position in 5-HT$_{1B}$ receptors; site-directed mutagenesis studies have demonstrated that conversion of Thr 355 to an asparagine (i.e., a T355N mutant) accounts for the binding differences of certain ligands (e.g., aryloxyalkylamines such as propranolol). Combined ligand SAR, site-directed mutagenesis, and molecular modeling studies have led to the conclusion that although most typical

serotonergic agonists bind in the central cavity formed by TM3, TM4, TM5, and TM6 (Site 1) (Fig. 14.3), propranolol most likely occupies the region defined by TM1, TM2, TM3, and TM7 (Site 2). The higher affinity of propranolol for the T355N mutant 5-HT_{1B} receptors relative to the wild-type receptors was specifically attributed to the formation of two hydrogen bonds between the receptor asparagine and the ether and hydroxyl oxygen atoms of propranolol (35).



5-HT_{1D} agonists and antagonists

There are few 5-HT_{1D}-selective agonists, but one agent commonly referred to as a prototypical 5-HT_{1D} agonist is sumatriptan (Imitrex). Sumatriptan, however, exhibits only 2- to 20-fold greater selectivity for the 5-HT_{1D} receptors than for certain other populations of 5-HT_1 receptors, binds at h5-HT_{1D} and h5-HT_{1B} receptors with nearly identical affinity, and also binds at 5-HT_{1F} receptors (36). Structure–activity relationships for 5-HT_{1D} agonists have been reported for many indolealkylamines or tryptamine derivatives, which bind with high affinity but with little selectivity. New agents displaying high affinity and reasonable selectivity for h5-HT_{1D}/h5-HT_{1B} receptors over other populations of 5-HT receptors (37) include, for example, zolmitriptan (Zomig), naratriptan (Amerge), rizatriptan (Maxalt), and alniditan. Of these, all are tryptamine derivatives or sumatriptan-related structures except for the benzopyran alniditan. Many of these are commercially available or currently undergoing clinical trials. Other investigational agonists are shown in Figure 14.8.



Several 5-HT_{1D} receptor antagonists have been developed, including GR127935 (high affinity for h5-HT_{1D}/h5-HT_{1B} receptors but possibly a low-efficacy partial agonist) and GR55562. Both of these agents antagonize many of the effects of sumatriptan.

5-HT_{1D} receptors: clinical significance

The clinical significance of 5-HT_{1D} receptors remains largely unknown. These receptors are speculated to be involved in anxiety, depression, and other neuropsychiatric disorders, but this remains to be substantiated. Recent studies show, however, that 5-HT_{1D} receptors are the dominant species

in human cerebral blood vessels. Sumatriptan and several closely related agents are clinically effective in the treatment of migraine, and logical extrapolation implies a role for 5-HT_{1D} receptors in this disorder. Agents with 5-HT_{1D} agonist activity that have found application in the treatment of migraine are, as a group, termed “triptans,” because the first agent introduced was sumatriptan. As efficacious as the triptans may be, however, it is unknown if their activity involves action only in the periphery or in the CNS as well (38). Sumatriptan is a h5-HT_{1B} and h5-HT_{1D} agonist. It also is an agonist at 5-HT_{1F} receptors. Most triptans share a similar binding profile. The vasoconstrictor properties of sumatriptan probably are mediated by its action on arterial smooth muscle. The triptans also are believed to inhibit the activation of peripheral nociceptors (38), and this might be related to the localization of 5-HT_{1D} receptors on peptide nociceptors.

Relatively little sumatriptan normally penetrates the blood-brain barrier. Although it has been speculated that transient changes in blood-brain barrier permeability might occur during migraine attacks, agents with greater lipophilicity (and, hence, enhanced ability to penetrate the blood-brain barrier) have been introduced, including zolmitriptan and rizatriptan (Table 14.3), Their greater lipophilicity, however, does not seem to correlate with significantly improved clinical efficacy over sumatriptan (38). Other triptans (Fig. 14.8) currently being examined include eletriptan, almotriptan, donatriptan, and frovatriptan (37).

In general, the newer triptans (e.g. zolmitriptan, rizatriptan, and naratriptan) have a higher oral bioavailability and longer plasma half-life than sumatriptan (39,40) (Table 14.3). Additionally, most triptans bind at 5-HT_{1F} receptors, and 5-HT_{1F} receptor agonists have demonstrated efficacy in the treatment of migraine (41). At this time, it is not known whether 5-HT_{1D} (i.e., h5-HT_{1B} and h5-HT_{1D}), 5-HT_{1F}, or a combination of 5-$HT_{1D/1F}$ actions are most important for the treatment of migraine. The 5-HT receptor binding characteristics of various triptans have been compared (37).

The safety of the triptans has been established, with more than 8 million patients treating greater than 340 million attacks with sumatriptan alone. All triptans narrow coronary arteries by 10 to 20% at clinical doses and should not be administered to patients with coronary or cerebrovascular disease. Triptans having the potential for significant drug–drug interactions include sumatriptan, naratriptan, rizatriptan, almotriptan, and MAO inhibitors; rizatriptan and propanolol; zolmitriptan and cimetidine; and zolmitriptan, naratriptan, and eletriptan and CYP3A4-metabolized drugs and P-glycoprotein pump inhibitors.

The rational employment of triptans should be governed by the use of these medications for patients with disability associated with migraine. Patients with greater than 10 days of at least 50% disability during 3 months have benefited from treatment with triptans as their first-line treatment for acute attacks. When the decision has been made to treat with a triptan, the patient should be instructed to treat early in the attack, when the pain is at a mild phase. This approach increases the likelihood of achieving a pain-free response, with fewer adverse events and lower likelihood of the headache recurring.

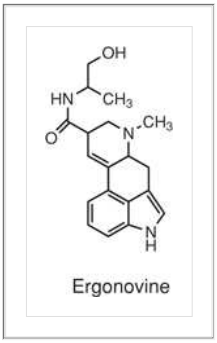
5-HT$_{1E}$ Receptors and Agents

The masking of brain 5-HT$_{1A}$ and 5-HT$_{1B}$ receptors in radioligand binding studies using [^{3}H]5-HT as radioligand resulted in biphasic competition curves, providing evidence for additional 5-HT$_1$-like receptor populations. One of these was the 5-HT$_{1D}$ receptors, and the other was termed 5-HT$_{1E}$. The low affinity of 5-CT and ergotamine for 5-HT$_{1E}$ receptors allowed their differentiation from 5-HT$_{1D}$ receptors. Simple O-methylation of 5-HT reduces the affinity of 5-HT for this receptor by approximately 100- to 300-fold (42,43). The receptors have been cloned, and typically, ergolines, such as ergonovine and methylergonovine, bind to 5-HT$_{1E}$ receptors with K_i values in the 100 nM range. Studies indicate that these receptors are negatively coupled to adenylate cyclase. No 5-HT$_{1E}$-selective agonists or antagonists have been reported.



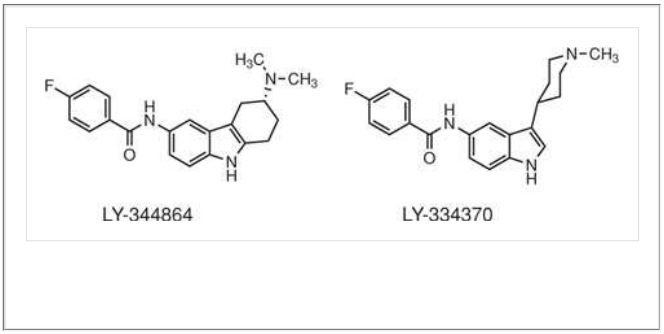
Ergonovine

5-HT$_{1F}$ Receptors

Overview

The newest 5-HT$_1$ receptor subpopulation to be cloned is the human 5-HT$_{1F}$ receptor (44), which exhibits intermediate (~50–70%) amino acid sequence homology with other 5-HT$_1$ receptor subpopulations. The receptors are coupled to inhibition of adenylate cyclase. Detection of these receptors in the uterus and mesentery suggest a possible role in vascular contraction. Although their distribution in the brain appears to be limited, distributional similarities with h5-HT$_{1B}$ receptors are observed. A 4-(3-indolyl)piperidine, LY-334370, and an aminocarbazole, LY-344864, have been identified as the first 5-HT$_{1F}$-selective agonists

(45). The nonselective 5-HT_1 antagonist methiothepin also has been shown to act as a 5-HT_{1F} antagonist.

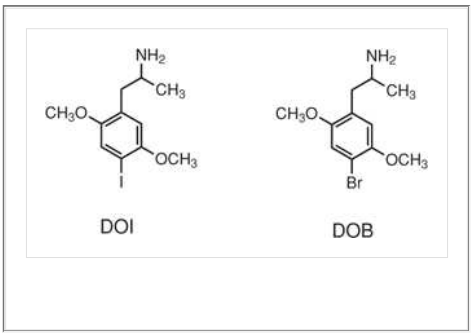


5-HT_{1F} receptors: clinical significance

The clinical significance of 5-HT_{1F} receptors is unknown at this time. The binding of sumatriptan to this receptor population suggests a relationship between 5-HT_{1F} receptor binding and antimigraine activity. Other antimigraine agents, including naratriptan, rizatriptan, and zolmitriptan, also bind at 5-HT_{1F} receptors (37). Recent studies show that 5-HT_{1D} receptors are the dominant species in human cerebral blood vessels and that 5-HT_{1F} receptors also are expressed in both neural and vascular tissue; however, 5-HT_{1F} agents might play a role in migraine as well (41).

5-HT_2 Family

Serotonin receptors were first divided into 5-HT_1 and 5-HT_2 receptor families in 1979 (5), and the latter was subsequently divided into the subfamilies 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} (formerly 5-HT_{1C}) receptors. The term "5-HT_2" now refers to a receptor family, not to an individual population of receptors. Ketanserin was identified early as a 5-HT_2 antagonist with no affinity for 5-HT_1 receptors, and [^{3}H]ketanserin was introduced as a radioligand to label 5-HT_2 receptors. 1-(2,5-Dimethoxy-4X-phenyl)-2-aminopropane, where X = -Br and -I (DOB and DOI, respectively) were introduced as 5-HT_2 agonists. A significant amount of pharmacology was published, and structure–activity studies led to the development of many novel agents (46). Many of the original agents thought to be 5-HT_2-selective, including standard antagonists such as ketanserin and the agonists DOB and DOI, were later shown to bind nonselectively both to 5-HT_{2A} and 5-HT_{2C} receptors. Consequently, pharmacological actions originally thought to be 5-HT_2-mediated might actually involve 5-HT_{2A} receptors, 5-HT_{2C} receptors, or a combination of 5-HT_{2A} and 5-HT_{2C} receptors. The structures of the three 5-HT_2 receptor subpopulations were found to be consistent with those of transmembrane-spanning G protein–coupled receptors, and the receptors all utilize a phospholipase C second messenger system. Approximately 70 to 80% sequence homology is found among the three receptor subtypes. Only very recently have novel agents with subpopulation selectivity been reported.



5-HT_{2A} Receptors

The 5-HT_{2A} receptors, formerly called the 5-HT_2 receptors, have been extensively reviewed (10,46,47,48,49,50). The 5-HT_{2A} receptors have been cloned from various species, including human, and exhibit a high degree (>90%) of species homology. Significant (78%) amino acid sequence homology is found between the transmembrane portions of 5-HT_{2A} receptors and cloned 5-HT_{2C} receptors, which may explain the observed similarities in

the binding of various ligands at the two receptor populations. Evidence was provided that 5-HT_{2A} receptors exist in a high-affinity state and a low-affinity state (sometimes referred to as the 5-HT_{2H} and 5-HT_{2L} state, respectively). Under normal conditions, the low-affinity state predominates. The tritiated antagonist [^{3}H]ketanserin has comparable affinity for both states, whereas agonists display higher affinity for the high-affinity state (e.g., when a tritiated agonist is employed as radioligand).

5-HT_{2A} agonists

The SARs for 5-HT_{2A} binding have been reviewed (8,13,46,50). Most indolealkylamines are nonselective 5-HT_{2A} ligands, and they typically bind with higher affinity at the tritiated agonist–labeled high-affinity state. Recent investigations suggest that all indolealkylamines may not bind in the same manner at 5-HT_{2A} receptors (51). Phenylalkylamines, such as DOB and DOI, act as 5-HT_{2A} agonists or high-efficacy partial agonists (see Chapter 23) and are significantly more selective than the indolealkylamines because of their low affinity for non-5-HT_{2A} sites, but they do not differentiate between 5-HT_2 subpopulations.

5-HT_{2A} antagonists

One of the largest and more selective classes of 5-HT_{2A} antagonists are the N-alkylpiperidines. The best-known examples are ketanserin and ritanserin. Although numerous ketanserin-related derivatives have been reported, their SARs still have not been well defined. Nevertheless, far less than the entire structure of ketanserin is required for high affinity. Spiperone (Fig. 14.7) has been employed as a 5-HT_{2A} antagonist with 1,000-fold selectivity for 5-HT_{2A} versus 5-HT_{2C} receptors, but it also is a dopamine antagonist, a 5-HT_{1A} antagonist, and a 5-HT_7 antagonist. Other structurally-related agents, such as the piperazine derivative irindalone, also act as 5-HT_{2A} antagonists. Many 5-HT_{2A} antagonists, although fairly selective for 5-$HT_{2A/2C}$ receptors versus most other populations of 5-HT receptors, bind with modest to high affinity at dopaminergic, histaminergic, or adrenergic neurotransmitter receptors. The tricyclic antipsychotics, atypical antipsychotics (risperidone, clozapine, and olanzapine) (Fig. 14.9), and tricyclic antidepressants also bind at 5-HT_{2A} receptors. Current research is focused on 5-HT_2 subtype-selective antagonists, and the most popular 5-HT_{2A}-selective antagonist is MDL 100,907 (also called M100907).

5-HT_{2A} receptors: clinical implications

Overview

The potential therapeutic roles of 5-HT_{2A} ligands and the possible involvement of 5-HT_{2A} receptors in modulating normal physiologic functions and various pathologic and psychopathologic conditions have been extensively reviewed (10,20,21). The 5-HT_{2A} receptors appear to play a role in thermoregulation and sleep, and they might be involved in appetite control, learning, and along with various other serotonergic receptor populations, cardiovascular function and muscle contraction. Many of the clinical implications of 5-HT_{2A} receptors actually may involve 5-HT_{2C} receptors or a combination of 5-HT_{2A} and 5-HT_{2C} receptors, both because of the high homology between the two populations and because the investigations were conducted before the discovery of subpopulations of 5-HT_2 receptors. With the recent development of subpopulation-selective agents, this is currently an important area of research.

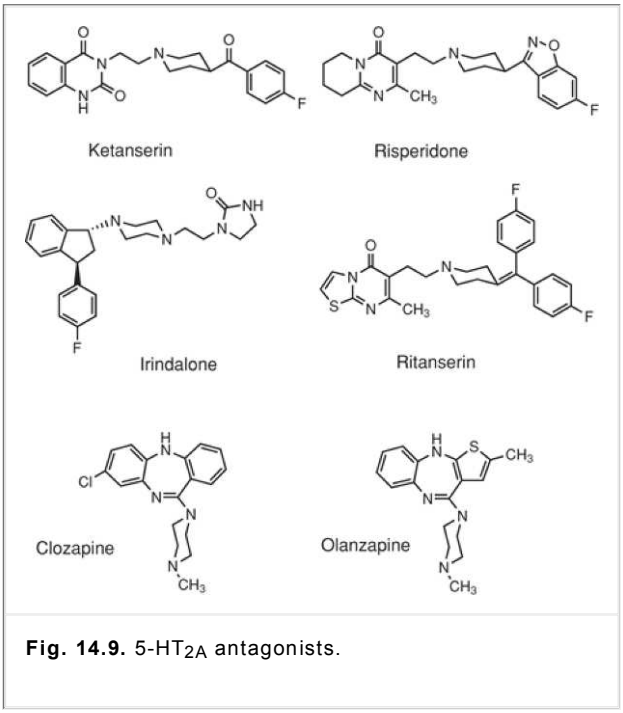


Fig. 14.9. 5-HT_{2A} antagonists.

Antipsychotic agents and antidepressants

Various typical and atypical antipsychotic agents (see Chapter 22) and antidepressants (see Chapter 21) bind with relatively high affinity at 5-HT_{2A} receptors as antagonists (52,53). Although no direct correlation exists between their receptor affinities and clinically effective doses, strong evidence suggests that these disorders involve, at least to some extent, 5-HT_{2A} receptors. For example, chronic administration of 5-HT_{2A} antagonists results in a paradoxical downregulation of 5-HT_{2A} receptors. Such a downregulation would be of benefit in the treatment of depression. Several 5-HT_{2A} antagonists, such as risperidone, seem to possess antipsychotic activity. Many 5-HT_{2A} antagonists also bind at dopamine receptors. Although this may obfuscate the role of 5-HT_{2A} antagonism versus dopamine antagonism as being the more important for antipsychotic activity, it has been suggested that certain types of schizophrenia might actually be more responsive to the combined effect. That is, D_2-dopaminergic antagonists seem to be more effective for treating the positive symptoms of schizophrenia, whereas the 5-HT_{2A} antagonists might be more effective in treating the negative symptoms. Certain atypical antipsychotic agents (e.g., clozapine, olanzepine quetiapine, risperidone, and ziprasidone) bind both to dopamine and to 5-HT_{2A} receptors, suggesting an atypicality theory of psychosis (52,54). This theory suggests that the 5-HT_{2A} component of binding may be related to the decrease in extrapyramidal

side effects associated with these types of agents. Those drugs that display a D_2/5-HT_{2A} ratio of greater than one seem to produce fewer extrapyramidal effects than those with ratios of less than one. The atypical antipsychotic agent clozapine, for example, has a D_2/5-HT_{2A} ratio of 10 to 20. From preclinical studies, there are indications that 5-HT_{2A} antagonists possess anxiolytic properties; for example, ritanserin (Fig. 14.9) has been demonstrated to produce both antipsychotic and antianxiety effects in humans. The role of 5-HT receptors in anxiety has been reviewed elsewhere (22).

The 5-HT_{2A} receptors may be involved in the actions of the classical hallucinogens (55) (see Chapter 23). Although indolealkylamine (e.g., 5-methoxy-N,N-dimethyltryptamine [5-OMe DMT]) and ergot-related (e.g., LSD) classical hallucinogens are fairly nonselective ligands that bind to multiple populations of serotonergic receptors, the phenylalkylamine hallucinogens (e.g., DOB, and DOI) are much more 5-HT_2-selective agonists. Furthermore, a significant correlation exists between the human hallucinogenic potencies of classical hallucinogens and their 5-HT_{2A} receptor affinities (55). Interestingly, phenylalkylamine hallucinogens also bind at 5-HT_{2B} and 5-HT_{2C} receptors, and here, too, a significant correlation is found between human potency and receptor affinity for 17 different agents (56). Recent studies suggest that 5-HT_{2A} receptors may play a more prominent role than 5-HT_{2B} or 5-HT_{2C} receptors for the behavioral actions of hallucinogens (56), and differences may exist in the manner in which hallucinogens activate the different receptor populations (57,58).

5-HT_{2B} Receptors

The rat fundus preparation is a peripheral tissue assay that has been used as a functional assay for serotonergic action for approximately 50 years. Long-standing questions concerning the pharmacological similarity of serotonergic fundus receptors (now called 5-HT_{2B} receptors) to the 5-HT_2 family of receptors were answered once they were cloned (59). The 5-HT_{2B} receptors exhibit approximately 70% homology to 5-HT_{2A} and 5-HT_{2C} receptors, and like 5-HT_{2A} receptors, they appear to couple functionally to phosphoinositol hydrolysis. Nevertheless, rat and human 5-HT_{2B} receptors display more than 90% transmembrane sequence homology. Therefore, most agents that bind at rat 5-HT_{2B} receptors also bind with similar affinity at human 5-HT_{2B} receptors. There are, however, some exceptions (60). The standard 5-HT_{2A} antagonist ketanserin and the 5-HT_{2A} agonists DOI and DOB display higher affinity for 5-HT_{2A} and 5-HT_{2C} receptors than for 5-HT_{2B} receptors (56). Nevertheless, a number of DOI-related hallucinogens have been shown to bind at 5-HT_{2B} receptors with modest affinity (56). Evidence suggests that human 5-HT_{2B} receptors, like human 5-HT_{2A} receptors, also exist in high-affinity and low-affinity states (60). The 5-HT_{2B} receptors are found on cardiovascular tissue. Activation of such receptors by agents with a 5-HT_{2B} agonist character might result in cardiac valvulopathy; valvular heart disease associated with the anorectic agent fenfluramine might involve its metabolism to norfenfluramine—a high affinity 5-HT_{2B} agonist (61). The designer drug MDMA (Ecstasy) and its N-desmethyl analogue MDA also show a 5-HT_{2B} agonist character (62).

5-HT_{2C} Receptors

The 5-HT_{2C} receptors, formerly called 5-HT_{1C} receptors, originally were identified in various regions of the brain using autoradiographic and radioligand binding

techniques. Cloned human 5-HT_{2C} receptors display a high amino acid sequence homology with 5-HT_{2A} receptors, and like 5-HT_{2A} receptors, they are coupled to phosphoinositol hydrolysis. As previously mentioned, some pharmacological functions once attributed to 5-HT_{2A} receptors actually might involve a 5-HT_{2C} mechanism. For example, the hyperthermic activity of a series of phenylisopropylamines is significantly correlated not only with 5-HT_{2A} but also with their 5-HT_{2C} receptor affinity. Numerous atypical antipsychotic agents bind at 5-HT_{2C} receptors as well as at 5-HT_{2A} receptors; however, no significant correlation exists between their atypical properties and binding affinity. The 5-HT_{2C} receptors may play a greater role than 5-HT_{2A} receptors in migraine. Other preclinical studies also suggest that 5-HT_{2C} receptors might be involved in anxiolytic activity (63) or be targeted for the treatment of obesity (64). The 5-HT_{2C} agonist 1-(3-chlorophenyl)piperazine (*m*CPP) produces an appetite suppressant effect in rodents.

Newer 5-HT_2 Subpopulation-Selective Agents

Although numerous SARs for overall 5-HT_2 binding and pharmacology have been published, very few agents at present can discriminate between subpopulations of 5-HT_2 receptors. In fact, relatively few agents have even been examined in all three 5-HT_2 subpopulations. Spiperone, MDL 100,907, and AMI-193 are among the most 5-HT_{2A}-selective antagonists available (65) (Fig. 14.10). Spiperone and AMI-193 bind at 5-HT_{2A} receptors with 1,000- to 3,000-fold selectivity relative to 5-HT_{2C} receptors but display higher affinity for 5-HT_{1A} and D_2 dopamine receptors. A newer member of this series, KML-010, is a spiperone-related derivative that lacks affinity for 5-HT_{2C} and 5-HT_{1A} receptors and binds at D_2-dopamine receptors with low affinity (65). MDL 11,939 displays more than 300-fold selectivity for 5-HT_{2A} versus 5-HT_{2C} receptors, and its affinity and selectivity are primarily associated with its R-(–)-enantiomer, MDL 100,907 (66). The latter agent is one of the best-investigated 5-HT_{2A}-selective antagonists, and it has been examined as a novel antipsychotic agent in humans. A series of 1-substituted β-carbolines (e.g., LY-23728, LY-287375, and LY-266097) has been reported to be the first 5-HT_{2B}-selective antagonists. SB-221284 shows 100-fold selectivity for 5-HT_{2C} versus 5-$HT_{2A/2B}$ receptors and is probably the most 5-HT_{2C}-selective antagonist to date.

Much less work has been done with 5-HT_2 subpopulation-selective agonists. Mounting evidence suggests that many of the behavioral properties of DOB-like

phenylisopropylamines are mediated by 5-HT_{2A} receptors. A series of isotryptamine derivatives, including Ro 60-0175 (ORG-35030), has been shown to display up to 1,000-fold selectivity for 5-HT_{2C} versus 5-HT_{2A} receptors and to possess 5-HT agonist activity; structurally related tricyclic analogues, such as Ro 60-0332 (ORG-35035), also have been examined and display more than 100-fold selectivity (67). 10-Methoxy-9-methylpyrazino[1,2-a]indole, Ro 60-0175, and Ro 60-0332 all were active in animal models predictive of therapeutic utility for obsessive-compulsive disorders, panic disorders, and depression (67).

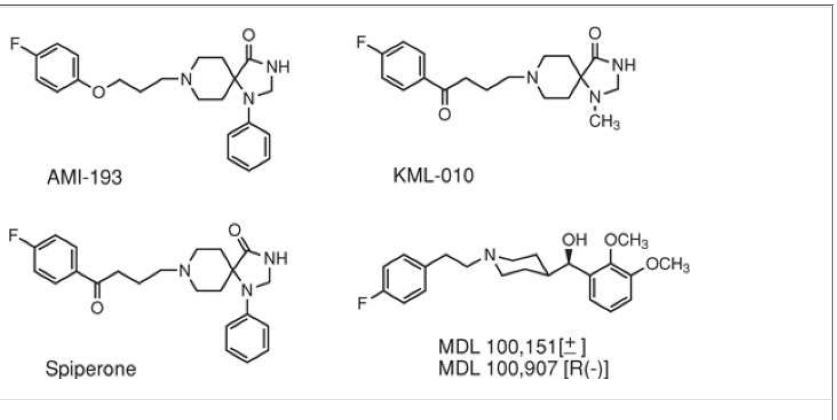

Fig. 14.10. Typical examples of newer 5-HT_2 subpopulation selective agents.

It is still not known with confidence specifically what pharmacological effects are related to what 5-HT_2 subpopulation. Nevertheless, results with the newer agents indicate that 5-HT_{2A} receptors might be involved in psychosis, depression, and hallucinogenic activity and that 5-HT_{2C} receptors may play a role in obsessive-compulsive disorders, panic, anxiety, depression, and eating disorders. In the periphery, 5-HT_{2B} receptors seem to be involved in muscle contraction; however, their function in the CNS is still a matter of speculation. On the basis of some preliminary studies and considering their central distribution in brain, 5-HT_{2B} receptors might be involved in anxiety, cognition, food intake, neuroendocrine regulation, locomotor coordination, and balance (68). Several novel approaches may assist in further elucidating the roles of these subpopulations and in the development of site-selective agents. For example, site-directed mutagenesis and synthesis of chimeric receptors, coupled with the use of molecular graphics modeling studies, are beginning to identify what portions of the receptors are important for ligand binding (49).

5-HT_3 Receptors

Unlike most 5-HT receptor populations, early 5-HT_3 pharmacology relied almost exclusively on functional assays. It took a number of years before radioligands were available to identify 5-HT_3 receptors in brain. The 5-HT_3 receptors are unique among the families of serotonergic receptors in that they are nonselective Na^+/K^1 ion channel receptors (Fig. 14.11). They are found in the periphery and in the CNS, and they bear greater structural and functional similarity to nicotinic acetylcholinergic receptors than to other members of the 5-HT receptor family (69,70). Evidence indicates that 5-HT_3 receptors modulate release of other neurotransmitters, including dopamine, acetylcholine, GABA, and serotonin (71).

Structure–Activity Relationships of 5-HT_3 Agonists

Only a few 5-HT_3 agonists have been identified, and the topic has been comprehensively reviewed (72). Many
